A The logprob-to-go for HMMs

As noted in §2.1, the logprob-to-go H_t can be computed by the backward algorithm. By the definition of H_t in equation (10),

$$\exp H_t = \sum_{\mathbf{y}_{t:}} \exp\left(G_T - G_t\right) \tag{35}$$

$$= \sum_{\mathbf{y}_{t:}} \exp \sum_{j=t+1}^{T} g_\theta(\mathbf{s}_{j-1}, x_j, y_j) \tag{36}$$

$$= \sum_{\mathbf{y}_{t:}} \prod_{j=t+1}^{T} p_\theta(y_j \mid y_{j-1}) \cdot p_\theta(x_j \mid y_j)$$

$$= (\boldsymbol{\beta}_t)_{y_t} \text{ (backward prob of } y_t \text{ at time } t)$$

where the vector $\boldsymbol{\beta}_t$ is defined by base case $(\boldsymbol{\beta}_T)_y = 1$ and for $0 \leq t < T$ by the recurrence

$$(\beta_t)_y \stackrel{\text{def}}{=} \sum_{\mathbf{y}_{t:}} p_\theta(\mathbf{x}_{t:}, \mathbf{y}_{t:} \mid y_t = y) \tag{37}$$

$$= \sum_{y'} p_\theta(y' \mid y) \cdot p_\theta(x_{t+1} \mid y') \cdot (\boldsymbol{\beta}_{t+1})_{y'}$$

The backward algorithm (20) for OOHMMs in §2.2 is a variant of this.

B Gradients for Training the Proposal Distribution

For a given $\mathbf{x}$, both forms of KL divergence achieve their minimum of 0 when $(\forall \mathbf{y})\ q_\phi(\mathbf{y} \mid \mathbf{x}) = p(\mathbf{y} \mid \mathbf{x})$. However, we are unlikely to be able to find such a ϕ; the two metrics penalize q_ϕ differently for mismatches. We simplify the notation below by writing $q_\phi(\mathbf{y})$ and $p(\mathbf{y})$, suppressing the conditioning on $\mathbf{x}$.

Inclusive KL Divergence The inclusive KL divergence has that name because it is finite only when $\text{support}(q_\phi) \supseteq \text{support}(p)$, i.e., when q_ϕ is capable of proposing any string $\mathbf{y}$ that has positive probability under p. This is required for q_ϕ to be a valid proposal distribution for importance sampling.

$$\begin{aligned} &\text{KL}\left(p||q_\phi\right) \\ &\quad = \mathbb{E}_{\mathbf{y}\sim p}\left[\log p\left(\mathbf{y}\right) - \log q_\phi(\mathbf{y})\right] \\ &\quad = \mathbb{E}_{\mathbf{y}\sim p}\left[\log p\left(\mathbf{y}\right)\right] \\ &\qquad - \mathbb{E}_{\mathbf{y}\sim p}\left[\log q_\phi\left(\mathbf{y}\right)\right] \end{aligned} \tag{38}$$

The first term $\mathbb{E}_{\mathbf{y}\sim p}\left[\log p\left(\mathbf{y}\right)\right]$ is a constant with regard to ϕ. As a result, the gradient of the above is just the gradient of the second term:

$$\nabla_\phi \text{KL}(p||q_\phi) = \nabla_\phi \underbrace{\mathbb{E}_{\mathbf{y}\sim p}\left[-\log q_\phi\left(\mathbf{y}\right)\right]}_{\text{the cross-entropy } H(p,q_\phi)}$$

We cannot directly sample from p. However, our weighted mixture $\hat{p}$ from equation (28) (obtained by sequential importance sampling) could be a good approximation:

$$\begin{aligned} \nabla_\phi \text{KL}(p||q_\phi) &\approx \nabla_\phi \mathbb{E}_{\mathbf{y}\sim\hat{p}}\left[-\log q_\phi\left(\mathbf{y}\right)\right] \\ &= \sum_{t=1}^{T} \mathbb{E}_{\hat{p}}\left[-\nabla_\phi \log q_\phi(y_t \mid y_{:t-1}, \mathbf{x})\right] \end{aligned} \tag{39}$$

Following this approximate gradient downhill has an intuitive interpretation: if a particular y_t value ends up with high relative weight in the final ensemble $\hat{p}$, then we will try to adjust q_ϕ so that it would have had a high probability of proposing that y_t value at step t in the first place.

Exclusive KL Divergence The exclusive divergence has that name because it is finite only when $\text{support}(q_\phi) \subseteq \text{support}(p)$. It is defined by

$$\begin{aligned} \text{KL}(q_\phi||p) &= \mathbb{E}_{\mathbf{y}\sim q_\phi}\left[\log q_\phi(\mathbf{y}) - \log p(\mathbf{y})\right] \\ &= \mathbb{E}_{\mathbf{y}\sim q_\phi}\left[\log q_\phi(\mathbf{y}) - \log \tilde{p}(\mathbf{y})\right] + \log Z \\ &= \sum_{\mathbf{y}} q_\phi(\mathbf{y}) \underbrace{\left[\log q_\phi(\mathbf{y}) - \log \tilde{p}(\mathbf{y})\right]}_{\text{call this } d_\phi(\mathbf{y})} + \log Z \end{aligned} \tag{40}$$

where $p(\mathbf{y}) = \frac{1}{Z}\tilde{p}(\mathbf{y})$ for $\tilde{p}(\mathbf{y}) = \exp G_T$ and $Z = \sum_{\mathbf{y}} \tilde{p}(\mathbf{y})$. With some rearrangement, we can write its gradient as an expectation that can be estimated by sampling from q_ϕ.[17] Observing that Z is constant with respect to ϕ, first write

$$\nabla_\phi \text{KL}(q_\phi||p) \tag{41}$$

$$= \sum_{\mathbf{y}} \nabla_\phi \left(q_\phi(\mathbf{y})\, d_\phi(\mathbf{y})\right) \tag{42}$$

$$\begin{aligned} &= \sum_{\mathbf{y}} \left(\nabla_\phi q_\phi(\mathbf{y})\right)\, d_\phi(\mathbf{y}) \\ &\qquad + \sum_{\mathbf{y}} \underbrace{q_\phi(\mathbf{y}) \nabla_\phi \log q_\phi(\mathbf{y})}_{=\nabla_\phi q_\phi(\mathbf{y})} \\ &= \sum_{\mathbf{y}} \left(\nabla_\phi q_\phi(\mathbf{y})\right)\, d_\phi(\mathbf{y}) \end{aligned}$$

where the last step uses the fact that $\sum_{\mathbf{y}} \nabla_\phi q_\phi(\mathbf{y}) = \nabla_\phi \sum_{\mathbf{y}} q_\phi(\mathbf{y}) = \nabla_\phi 1 = 0$. We can turn this into an expectation with a second use of Glynn (1990)'s observation that

[17] This is an extension of the REINFORCE trick (Williams, 1992), which estimates the gradient of $\mathbb{E}_{\mathbf{y}\sim q_\phi}\left[\text{reward}(\mathbf{y})\right]$ when the reward is independent of ϕ. In our case, the expectation is over a quantity that does depend on ϕ.

$\nabla_\phi q_\phi(\mathbf{y}) = q_\phi(\mathbf{y}) \nabla_\phi \log q_\phi(\mathbf{y})$ (the "likelihood ratio trick"):

$$\begin{aligned}
&\nabla_\phi \mathrm{KL}(q_\phi || p) \\
&\quad = \sum_{\mathbf{y}} q_\phi(\mathbf{y}) d_\phi(\mathbf{y}) \nabla_\phi \log q_\phi(\mathbf{y}) \\
&\quad = \mathbb{E}_{\mathbf{y} \sim q_\phi} \left[d_\phi(\mathbf{y}) \nabla_\phi \log q_\phi(\mathbf{y}) \right] \qquad (43)
\end{aligned}$$

which can, if desired, be further rewritten as

$$\begin{aligned}
&= \mathbb{E}_{\mathbf{y} \sim q_\phi} \left[d_\phi(\mathbf{y}) \nabla_\phi d_\phi(\mathbf{y}) \right] \\
&= \mathbb{E}_{\mathbf{y} \sim q_\phi} \left[\nabla_\phi \left(\tfrac{1}{2} d_\phi(\mathbf{y})^2 \right) \right] \qquad (44)
\end{aligned}$$

If we regard $d_\phi(\mathbf{y})$ as a signed error (in the log domain) in trying to fit q_ϕ to $\tilde{p}$, then the above gradient of KL can be interpreted as the gradient of the mean squared error (divided by 2).[18]

We would get the same gradient for any rescaled version of the unnormalized distribution $\tilde{p}$, but the formula for obtaining that gradient would be different. In particular, if we rewrite the above derivation but add a constant b to both $\log \tilde{p}(\mathbf{y})$ and $\log Z$ throughout (equivalent to adding b to G_T), we will get the slightly generalized expectation formulas

$$\mathbb{E}_{\mathbf{y} \sim q_\phi} \left[(d_\phi(\mathbf{y}) - b) \nabla_\phi \log q_\phi(\mathbf{y}) \right] \qquad (45)$$

$$\mathbb{E}_{\mathbf{y} \sim q_\phi} \left[\nabla_\phi \left(\tfrac{1}{2} \left(d_\phi(\mathbf{y}) - b \right)^2 \right) \right] \qquad (46)$$

in place of equations (43) and (44). By choosing an appropriate "baseline" b, we can reduce the variance of the sampling-based estimate of these expectations. This is similar to the use of a baseline in the REINFORCE algorithm (Williams, 1992). In this work we choose b using an exponential moving average of past $\mathbb{E}\left[d_\phi(\mathbf{y})\right]$ values: at the end of each training minibatch, we update $b \leftarrow 0.1 \cdot b + 0.9 \cdot \bar{d}$, where $\bar{d}$ is the mean of the estimated $\mathbb{E}_{\mathbf{y} \sim q_\phi(\cdot|\mathbf{x})}\left[d_\phi(\mathbf{y})\right]$ values for all examples $\mathbf{x}$ in the minibatch.

C Implementation Details

We implement all RNNs in this paper as GRU networks (Cho et al., 2014) with $d = 32$ hidden units (state space $\mathbb{R}^{32}$). Each of our models (§6) always specifies the logprob-so-far in equations (2) and (3) using a 1-layer left-to-right GRU,[19] while the corresponding proposal distribution (§3.3) always specifies the state $\bar{\mathbf{s}}_t$ in (6) using a 2-layer right-to-left GRU, and specifies the compatibility function C_t in (23) using a 4-layer feedforward ReLU network.[20] For the Chinese social media NER task (§6.1), we use the Chinese character embeddings provided by Peng and Dredze (2015), while for the source separation tasks (§6.2), we use the 50-dimensional GloVe word embeddings (Pennington et al., 2014). In other cases, we train embeddings along with the rest of the network. We optimize with the Adam optimizer using the default parameters (Kingma and Ba, 2015) and L_2 regularization coefficient of 10^{-5}.

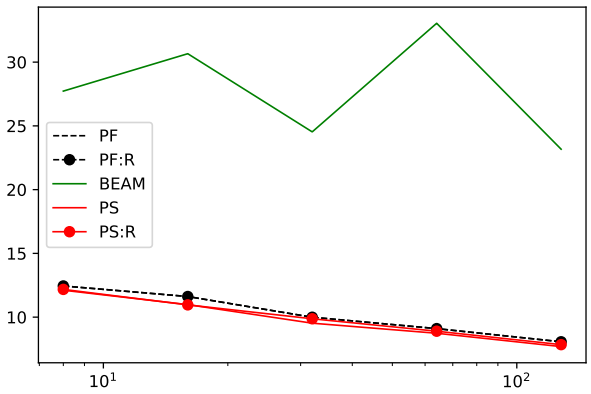

Figure 3: Offset KL divergence for the source separation task on phoneme sequences.

D Training Procedures

In all our experiments, we train the incremental scoring models (the tagging and source separation models described in §6.1 and §6.2, respectively) on the training dataset T. We do early stopping, using perplexity on a held-out development set D_1 to choose the number of epochs to train (maximum of 3).

Having obtained these model parameters θ, we train our proposal distributions $q_{\theta,\phi}$ on T, keeping θ fixed and only tuning ϕ. Again we use early stopping, using the KL divergence from §7.1 on a separate development set D_2 to choose the number of epochs to train (maximum of 20 for the two tagging tasks and source separation on the PTB dataset, and maximum of 50 for source separation on the phoneme sequence dataset). We then evaluate q_{θ^*,ϕ^*} on the test dataset E.

[Appendices E–G appear in the supplementary material file.]

[18] We thank Hongyuan Mei, Tim Vieira, and Sanjeev Khudanpur for insightful discussions on this derivation.

[19] For the tagging task described in §6.1, $g_\theta(\mathbf{s}_{t-1}, x_t, y_t) \stackrel{\text{def}}{=} \log p_\theta(x_t, y_t \mid \mathbf{s}_{t-1})$, where the GRU state $\mathbf{s}_{t-1}$ is used to define a softmax distribution over possible (x_t, y_t) pairs in the same manner as an RNN language model (Mikolov et al., 2010). Likewise, for the source separation task (§6.2), the source language models described in Appendix G are GRU-based RNN language models.

[20] As input to C_t, we actually provide not only $\mathbf{s}_t, \bar{\mathbf{s}}_t$ but also the states $f_\theta(\mathbf{s}_{t-1}, x_t, y)$ (including $\mathbf{s}_t$) that could have been reached for *each* possible value y of y_t. We have to compute these anyway while constructing the proposal distribution, and we find that it helps performance to include them.

Neural Syntactic Generative Models with Exact Marginalization

Abstract

We present neural syntactic generative models with exact marginalization that support both dependency parsing and language modeling. Exact marginalization is made tractable through dynamic programming over shift-reduce parsing and minimal RNN-based feature sets. Our algorithms complement previous approaches by supporting batched training and enabling online computation of next word probabilities. For supervised dependency parsing, our model achieves a state-of-the-art result among generative approaches. We also report empirical results on unsupervised syntactic models and their role in language modeling. We find that our model formulation of latent dependencies with exact marginalization do not lead to better intrinsic language modeling performance than vanilla RNNs, and that parsing accuracy is not correlated with language modeling perplexity in stack-based models.

1 Introduction

We investigate the feasibility of neural syntactic generative models with structured latent variables in which exact inference is tractable. Recent models have added structure to recurrent neural networks at the cost of giving up exact inference, or through using soft structure instead of latent variables (Dyer et al., 2016; Yogatama et al., 2016; Grefenstette et al., 2015). We propose generative models in which syntactic structure is modelled with a discrete stack which can be marginalized as a latent variable through dynamic programming. This enables us to investigate the trade-off between model expressivity and exact marginalization in probabilistic models based on recurrent neural networks (RNNs).

While Long Short-term Memory (Hochreiter and Schmidhuber, 1997) (LSTM) RNNs have driven strong improvements in intrinsic language modelling performance, they fail at capturing certain long-distance dependencies, such as those required for modelling subject-verb agreement (Linzen et al., 2016) or performing synthetic transduction tasks based on context-free grammars (Grefenstette et al., 2015). We propose generative models, based on transition-based dependency parsing (Nivre, 2008), a widely used framework for incremental syntactic parsing, that are able to capture desirable dependencies.

Our generative approach to dependency parsing encodes sentences with an RNN and estimate transition and next word probability distributions by conditioning on a small number of features represented by RNN encoder vectors. In contrast to previous syntactic language models such as RNNG (Dyer et al., 2016), marginal word probabilities can be computed both online and exactly. A GPU implementation which exploits parallelization enables unsupervised learning and fast training and decoding. The price of exact inference is that our models are less expressive than RNNG, as the recurrence is not syntax-dependent.

Our generative models are based on the arc-eager and arc-hybrid transition systems, with $O(n^3)$ dynamic programs based on Kuhlmann et al. (2011). Previous work on dynamic programming for transition-based parsing either required approximate inference due to a too high polynomial order run-time complexity (Huang and Sagae, 2010), or had too restrictive feature spaces to be used as accurate models (Kuhlmann et al., 2011; Cohen et al., 2011). Recent work showed that bidirectional RNNs enable accurate graph-based and transition-based dependency parsing using minimal feature spaces (Kiperwasser and Goldberg, 2016; Cross and Huang, 2016; Dozat and Manning, 2017). Shi et al. (2017) further showed that under this approach exact decoding

and globally-normalized discriminative training is tractable with dynamic programming.

While discriminative neural network-based models obtain state-of-the-art parsing accuracies (Dozat and Manning, 2017), generative models for structured prediction have a number of advantages: They do not suffer from label bias or explaining away effects (Yu et al., 2017), have lower sample complexity (Yogatama et al., 2017), are amenable to unsupervised learning and can model uncertainty and incorporate prior knowledge through latent variables.

As a supervised parser our model obtains state of the art performance in transition-based generative dependency parsing. While its intrinsic language modelling performance is worse than that of a well-tuned vanilla RNN, we see that the formulation of the generative model has a large impact on both the informedness of the syntactic structure and the parsing accuracy of the model. Furthermore, there is a discrepancy between the model structure most suitable for parsing and for language modeling. Our analysis shows that there exist informative syntactically-motivated dependencies which LSTMs are not capturing, even though our syntactic models are not able to predict them accurately enough during online processing to improve language modelling performance. Our implementation is available at `https://github.com/janmbuys/ndp-parser`.

2 Generative shift-reduce parsing

We start by defining a shift-reduce transition system which does not predict dependency arcs, but simply processes the words in a sentence left to right through shifting words onto a stack and reducing (popping) them from the stack. We define a generative model for this transition system and a dynamic program to perform inference over all possible shift-reduce transitions to process a given sentence. An example dependency tree is given in Figure 1, along with the dependencies our generative model is capturing when making word predictions. The arc-hybrid transition sequence for the example is given in Table 1.

Let sentence $\mathbf{w}_{0:n}$ be a sequence of words, where w_0 is always the designated root symbol `ROOT` and w_n the end-of-sentence symbol `EOS`. The state variables of the transition system are the stack σ, consisting of word indexes, and a current word index β, also referred to as the buffer. The first and second elements on the stack are referred to as σ_0 and σ_1, respectively. We use the notation $\sigma|j$ to indicate that j is on top of the stack. The initial state (σ, β) is $([0], 1)$ and the final state is $([], n)$. There are two transition actions, *shift* and *reduce*. Shift updates the transition state from (σ, j) to $(\sigma|j, j+1)$. Reduce changes the state from $(\sigma|i, j)$ to (σ, j).

2.1 Generative model

The generative model for this transition system is defined by a probability distribution over $\mathbf{w}$,

$$p(\mathbf{w}) = \sum_{\mathbf{t}} p(\mathbf{w}_{0:n}, \mathbf{t}_{0:2n}), \qquad (1)$$

where $\mathbf{t}_{0:2n}$ is a transition sequence that processes the sentence. Shift actions predict (assign probability to) the next word in the sentence. The end-

of-sentence symbol is generated implicitly when ROOT is reduced from the stack.

The sentence is encoded left-to-right by an LSTM RNN taking the word embedding of the last predicted word as input at each time step, independent of $\mathbf{t}$. The RNN hidden states $\boldsymbol{h}_{0:n}$ represent each sentence position in its linear context. The probability of a shift action and the word that it predicts is

$$p_{\text{tr}}(\text{sh}|h_{\sigma_0}, h_{\beta-1})p_{\text{gen}}(w|h_{\sigma_0}, h_{\beta-1}).$$

Reduce is predicted with probability $p_{\text{tr}}(\text{re}|h_{\sigma_0}, h_{\beta-1}) = 1 - p_{\text{tr}}(\text{sh}|h_{\sigma_0}, h_{\beta-1})$.

The transition and word probability distributions are estimated by non-linear output layers that take the context-depending RNN representations of positions in the transition system as input,

$$p_{\text{tr}} = \text{sigmoid}(r^T \text{relu}(W_{ts}h_{\sigma_0} + W_{tb}h_{\beta-1})) \quad (2)$$

$$p_{\text{gen}} = \text{softmax}(R^T \tanh(W_{gs}h_{\sigma_0} + W_{tb}h_{\beta-1})), \quad (3)$$

where R and the W's are neural network parameter matrices and r is a parameter vector.

The model has two ways of representing context: The RNN encoding, which has a recency bias, and the stack, which can represent long range dependencies and has a syntactic distance bias. The choice of RNN states (corresponding to stack elements) to condition on is restricted by our goal of making the dynamic programming tractable.

We propose two formulations of the generative model: In the first, referred to as *stack-next*, shift generates the word pushed on the stack, which is currently at position β, as in the equations above. In the second formulation, referred to as *buffer-next*, shift generates the word at position $\beta+1$, i.e., the next word on the buffer. The first formulation has a more intuitive generative story as the generation of a word is conditioned on the top of the stack when it is generated (see Table 1), but the second formulation has the advantage that transition predictions are conditioned on the current word at position β, which is more informative for parsing predictions. Models are defined using *stack-next* unless stated otherwise.

2.2 Dynamic program

We now define a dynamic program for this model, based on the algorithms proposed by Kuhlmann et al. (2011) and their application to generative dependency parsing (Cohen et al., 2011).

The key to the dynamic program is the decomposition of the transition sequence into *push computations*. Each push computation is a sequence of transitions which results in a single node having been pushed to the stack. The simplest push computation is a single shift operation. Push computations can be composed recursively: combining two consecutive push computations followed by a reduce transition yields a new push operation. Therefore the derivation of a sentence under the transition system can be seen as a composition of push computations.

Items in the deduction system (Shieber et al., 1995) of the dynamic program have the form $[i, j]$, which has the interpretation that there exists a push computation between actions a_k and a_l such that $\beta = i$ at time step k and $\sigma_0 = i$ and $\beta = j$ at time step l. In the deduction system $[0, 1]$ is an axiom, $[0, n]$ is the goal and the deduction rules corresponding to the transitions are

$$[i, j-1] \rightarrow [j-1, j] \qquad \text{(shift)}$$
$$[i, k][k, j] \rightarrow [i, j] \qquad \text{(reduce)}.$$

The marginal probability distribution is computed by defining the inside score $I(i, j) = p(\mathbf{w}_{i:j-1})$ for every deduction system item. Computing the sentence probability corresponds to computing the inside score of the goal, $I(0, n) = p(\mathbf{w}_{0:n-1})$, followed by computing the final reduce probability.

Reduce probabilities are computed conditioned on positions k and j, which are accessible through the dynamic program deduction rule. However the shift probabilities cannot be computed at the *shift* rule for deducing $[j-1, j]$, as it does not have access there to the top of the stack. One solution is to extend the deduction system to a three-tuple that can track the value of an additional position, leading to a $O(n^4)$ dynamic program. Instead Shi et al. (2017) showed that the computation can be performed in the $O(n^3)$ algorithm by computing the shift probability of word k during the *reduce* deduction, as it was generated when i was on top of the stack. The inside algorithm is given in Algorithm 1.

To train the model without supervised transition sequences, we can optimize the negative log likelihood of $p(w_{0:n})$ directly with gradient-based optimization using automatic differentiation, which

Algorithm 1 Inside algorithm for the shift-reduce transition-based generative model.

1: $I(0,1) \leftarrow 1$
2: **for** $j = 2, \ldots, n$ **do**
3: $\quad I(j-1,j) \leftarrow 1$
4: $\quad$ **for** $i = j-2, \ldots, 0$ **do**
5: $\quad\quad$ **for** $k = i+1, \ldots, j-1$ **do**
6: $\quad\quad\quad T(k) \leftarrow p_{\text{tr}}(\text{sh}|h_i, h_{k-1}) p_{\text{gen}}(w_k|h_i, h_{k-1})$
7: $\quad\quad$ **end for**
8: $\quad\quad I(i,j) \leftarrow \sum_{k=i+1}^{j-1} I(i,k) I(k,j) p_{tr}(\text{re}|h_k, h_{j-1}) T(k)$
9: $\quad$ **end for**
10: **end for**
11: **return** $I(0,n) + p_{tr}(\text{re}|h_0, h_{n-1})$

is equivalent to computing the gradients with the outside algorithm (Eisner, 2016). For decoding we perform Viterbi search over the dynamic program by maximizing rather than summing over different split positions (values of k when reducing).

The *buffer-next* generative formulation, where shift generates the next word β, can also be computed with the dynamic program. Here w_1 is predicted at the initial state in $I(0,1)$, while the end-of-sentence token is generated explicitly when a shift action results in buffer being set to position n, regardless of the state of the stack.

3 Transition-based dependency parsing

The arc-eager (Nivre, 2008) and arc-hybrid (Kuhlmann et al., 2011) transition systems for projective dependency parsing use the same shift-reduce operations but predict left- and right-arcs at different time steps. We propose generative models for these transition systems based on the dynamic program for shift-reduce parsing proposed above, again following Kuhlmann et al. (2011). For supervised training we optimize the joint probability distribution $p(\mathbf{w}, \mathbf{t})$, where an oracle is used to derive transition sequence $\mathbf{t}$ from the training examples. In cases of spurious ambiguity arcs are added as soon as possible.

3.1 Arc-hybrid parser

The arc-hybrid transition system has three actions: Shift, left-arc and right-arc (see Table 2 for definitions). *Left-arc* and *right-arc* are both reduce actions, but they add arcs between different word pairs. Arc label predictions are conditioned on the same context as transition predictions. Right-arc adds a dependency of which σ_1 is the head, but the dynamic program does not allow conditioning on it when making transition decisions. However, we found that this does not actually decrease performance.

The dynamic program for the arc-hybrid parser has the same structure as the shift-reduce model. The marginal probability is independent of arc directionality, as it does not influence future decisions. Consequently unsupervised training based on this model cannot learn to predict arc directions. Exact decoding is performed with the Viterbi algorithm: At every item $[i,j]$ the highest scoring arc direction is recorded. After the most likely transition sequence is extracted, arc labels are predicted greedily.

3.2 Arc-eager parser

The arc-eager parser has four transitions, as defined in Table 2. *Shift* and *right-arc* are shift actions, while *left-arc* and *reduce* are reduce actions. However the two reduce actions, reduce and left-arc, are always mutually exclusive; the former is only valid if the stack top has already been assigned a head (through a previous right-arc) and the latter only if the stack top is not headed. To keep track of which actions are valid, the state configuration and the dynamic program are augmented to record whether elements on the stack are headed. As with arc-hybrid, we decompose the transition probability into deciding between shifting and reducing, and then predicting directionality. In this case, the shift decision decomposes into *shift* and *right-arc* transitions, where *shift* is implicitly deciding that the shifted word will be reduced through a left-arc. Consequently the only real difference between the arc-hybrid and arc-eager transition systems under dynamic programming is the information conditioned on when arc directionality is predicted.

A different deduction system is defined for arc-eager, although it follows the same structure as the shift-reduce one. Items have the form $[i^c, j]$, where c is a binary variable indicating whether node i is headed. The axiom and goal are $[0^0, n]$ and $[0^0, 1]$, respectively. The deduction rules are

$$[i^c, j] \rightarrow [j^0, j+1] \quad \text{(shift)}$$
$$[i^c, j] \rightarrow [j^1, j+1] \quad \text{(right-arc)}$$
$$[i^c, k][k^0, j] \rightarrow [i^c, j] \quad \text{(left-arc)}$$
$$[i^c, k][k^1, j] \rightarrow [i^c, j] \quad \text{(reduce)}$$

The inside algorithm for arc-eager parsing is given in Algorithm 2. The algorithm is structured such that the inner loop computations (lines $8-22$) can be vectorized, which is crucial for efficient

Action	State before	State after	Arc added	Probability
Shift	$(\sigma\|i,j)$	$(\sigma\|i\|j,j+1)$	-	$p_{tr}(\text{sh}\|h_i,h_{j-1})p_{gen}(w_j\|h_i,h_{j-1})$

GPU implementation. At $\beta = n$, the dynamic program is restricted to allow only reduce transitions, requiring the remaining stack elements (apart from ROOT) to be headed. The Viterbi algorithm again follows the same structure as the inside algorithm: For every item $[i^c, j]$ the highest scoring splitting item k^b is recorded, where k is the splitting point and b indicates whether word k is headed or not, which corresponds to whether a reduce or left-arc is performed.

4 Experiments

We follow the standard setup for English dependency parsing, training on sections 2-21 of the Penn Treebank (PTB) Wall Street Journal corpus, using section 22 for development and section 23 for testing. Dependency trees follow the Stanford dependency (SD) representation (version 3.3.0) used in recent parsing research (Chen and Manning, 2014; Dyer et al., 2015). We also report some results using the older representation of Yamada and Matsumoto (2003) (YM). We follow Buys and Blunsom (2015b) and Dyer et al. (2016) in replacing training singletons and unknown words in the test set with unknown word class tokens based to their surface forms, following the rules implemented in the Berkeley parser.[1]

Our models are implemented in PyTorch, which constructs computation graphs dynamically.[2] During training, sentences are shuffled at each epoch, and minibatches are constructed of sentences of the same length. We base the hyperparameters of our models primarily on the language models of Zaremba et al. (2014). Models are based on two-layer LSTMs with embedding and hidden state size 650 with dropout of 0.5 on the RNN inputs and outputs. For all models weights are initialized randomly from the uniform distribution over $[-0.05, 0.05]$. Gradient norms are clipped to 5.0. The supervised parsers are trained with batch size 16, with an initial learning rate 1.0, which is decreased by a factor of 1.7 for every epoch after 6 initial epochs. The sequential LSTM baseline is trained with the same parameters, except that the learning rate decay is 1.4. The unsupervised models are trained with an initial learning rate 0.1, which is decreased by a factor of 2.0 for every epoch, with batch size 8.

We train and execute our models on a GPU, obtaining significant speed improvements over CPUs. For supervised training we also perform batch processing: After the sentences are encoded with an RNN, we extract the inputs to the transition, word and relation prediction models across the batch, and then perform the neural network computations in parallel. The supervised models' training speed is about 3 minutes per epoch.

Arc-hybrid	**91.01/88.54**	**90.71/88.68**

Table 4: PTB test set parsing results with supervised generative models, on the Stanford (SD) and Yamada and Matsumoto (2003) (YM) dependencies. The models from Buys and Blunsom (2015b) and Titov and Henderson (2007) were retrained to make results directly comparable.

4.1 Parsing

In order to benchmark parsing performance, we train discriminative baselines using the same feature space as the generative models. Unidirectional or bidirectional RNNs can be used; we see that the bidirectional encoder is crucial for accuracy (Table 3). The performance of our implementation is on par with than that of the arc-hybrid transition-based parser of Kiperwasser and Goldberg (2016), which obtains 93.2/91.2 UAS/LAS on the test set against 93.29/90.83 for our arc-hybrid model. State of the art parsing performance is 95.7%/94.1 UAS/LAS (Dozat and Manning, 2017).

Exact decoding is only marginally more accurate than greedy decoding, giving further evidence of the label bias problem. Andor et al. (2016) similarly showed that a locally normalised model without lookahead features cannot obtain good performance even with beam-search (81.35% UAS), while their globally normalised model can reach close to optimal performance without look-ahead. Shi et al. (2017) showed that globally normalised training improves the accuracy of these discriminative models.

Exact decoding is crucial to the performance of the generative models (Table 3). They are much more accurate than the unidirectional discriminative models, which shows that the word prediction model benefits parsing accuracy. The arc-hybrid model is more accurate than arc-eager, as was the case for the unidirectional discriminative models. This can be explained by arc-eager making attachment decisions earlier in the transition sequence than arc-hybrid, which means that it has access to less context to condition these predictions on.

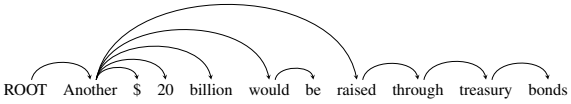

Figure 2: Sentence with dependencies induced by the unsupervised model.

Our best generative model outperforms a previous incremental generative dependency parser based on feed-forward neural networks and approximate inference (Buys and Blunsom, 2015b) (Table 4). It is competitive with a previous RNN-based generative parser with a much more complex architecture than our model, including recurrent connections based on parsing decision (Titov and Henderson, 2007). Our exact decoding algorithm is also actually faster than the beam-search approaches for previous models, as it is implemented on GPU. Our arc-hybrid model parses 7.4 sentences per second, against 4 sentences per second for Buys and Blunsom (2015b) and approximately 1 sentence per second for Titov and Henderson (2007).

We also train the model as an unsupervised parser by directly optimizing the marginal sentence probability. The limitation of our approach is that our models cannot learn arc directionality without supervision, so we interpret shift as adding a (right-arc) dependency between top of the stack and the word being generated. In our experiments the model did not succeed in learning informative, non-trivial tree structures – in most cases it learns to attach words either to the immediate previous word or to the root. However, unsupervised dependency parsers usually require elaborate initialization schemes or biases to produce non-trivial trees (Klein and Manning, 2004; Spitkovsky et al., 2010; Bisk and Hockenmaier, 2015). An example dependency tree predicted by the unsupervised model is given in Figure 2.

Model	Perplexity
Interpolated Kneser-Ney 5-gram	170.09
Sequential LSTM (unbatched)	118.69
Sequential LSTM (batched)	**100.67**
Buys and Blunsom (2015b)	138.62
RNNG (Kuncoro et al., 2017)	**101.2**
Supervised (SD) shift-reduce buffer-next	111.53
Supervised (SD) shift-reduce stack-next	**107.61**
Unsupervised shift-reduce stack-next	125.20

Table 5: Language modelling perplexity results on the PTB parsing test set.

4.2 Language modelling

We apply our model to language modelling with both supervised and unsupervised training. The supervised models are trained as arc-hybrid parsers; the performance of arc-eager is almost identical as arc labels and directionality are not predicted. The unsupervised model is trained with only shift and reduce transitions as latent.

We evaluate language models with a sentence i.i.d. assumption. In contrast, the standard evaluation setup for RNN language models treats the entire corpus as single sequence. To evaluate the consequence of the sentence independence assumption, we trained a model on the most widely used PTB language modelling setup (Chelba and Jelinek, 2000; Mikolov et al., 2011), which uses a different training/testing split and preprocessing which limits the vocabulary to 10k. Our baseline LSTM obtains 92.71 test perplexity on this setup, against 78.4 of Zaremba et al. (2014), which uses the same hyperparameters without a sentence i.i.d. assumption. The syntactic neural language model of Emami and Jelinek (2005) obtained 131.3.

Results are reported in Table 5. Perplexity is obtained by exponentiating the negative log likelihood per token; end of sentence symbols are predicted but excluded from the token counts. As baselines without syntactic structure we use the interpolated Kneser-Ney n-gram model (Kneser and Ney, 1995) and vanilla LSTMs, trained with or without batching.

The LSTM baselines already outperform the syntactic feed-forward neural model of Buys and Blunsom (2015b). We see that there is a significant difference between training with or without mini-batching for the baseline; similarly our model's perplexities also improve when trained with batching. The batched baseline performs slightly better than Recurrent Neural Network Grammars (RNNG) (Dyer et al., 2016; Kuncoro et al., 2017), a constituency syntax-based RNN language model trained without batching.[3]

The results show that our syntactic language models perform slightly worse than the LSTM baseline. We experimented with different dependency representations on the development set, including SD, YM and Universal Dependencies (Nivre et al., 2016). We found little difference in language modelling performance between the dependency representations. Unsupervised training does not lead to better perplexity than the supervised models; however, due to much longer training times we did less hyperparameter tuning for the unsupervised model.

4.3 Analysis

We further analyze the probability distribution that our model is learning by calculating some perplexity-related quantities. We compare the perplexity of the marginal distribution $p(\mathbf{w})$ to the perplexity based only on the most likely transition sequence $\mathbf{a} = \text{argmax}\ p(\mathbf{w}, \mathbf{a})$, based on either the joint distribution $p(\mathbf{w}, \mathbf{a})$ or the conditional distribution $p(\mathbf{w}|\mathbf{a})$. Note that while the former is a bound on the marginal perplexity, the latter is not a true perplexity but simply helps us to quantify the contribution of the syntactic structure to reducing the uncertainty in the prediction.

The results (Table 6) show that the difference between the joint and marginal perplexities are relatively small for the supervised models, indicating that the distribution is very peaked around the most likely parse trees. However the conditional quantity shows that the syntactic structure encoded by the *stack-next* model is much more informative than that of the *buffer-next* model, although the only difference between them is the choice of elements to condition on when predicting the next word. Although the *stack-next* model has a better marginal perplexity, the disadvantage is that it has more uncertainty in the syntactic structure it is predicting (as can be seen by lower parsing accuracy) even though that structure is more informative.

The strength of RNNG over our approach is that it computes a compositional representation of

[3]Our experimental setup is the same as Dyer et al. (2016), except for a minor implementation difference in unknown word clustering; Dyer et al. (2016) reports 169.31 perplexity on the same IKN model.

Model	Marginal ppl	Argmax parse joint ppl	Argmax parse conditional ppl
RNNG (Dyer et al., 2016)	104.10	107.58	41.60
Supervised (SD) shift-reduce buffer-next	111.53	120.09	102.28
Supervised (SD) shift-reduce stack-next	107.61	119.20	71.27
Unsupervised shift-reduce stack-next	125.20	350.01	169.87

Table 6: Language modelling perplexity analysis on the PTB test set.

the stack and the partially constructed parse tree, while our model can only make use of the position on top of the stack and otherwise has to rely on the sequentially computed RNN representations. The disadvantage of RNNG is that inference can only be performed over entire sentences, as the proposal distribution for their importance sampling method is a discriminative parser. Exact inference allows our models to estimate next word probabilities from partially observed sequences.

5 Related work

5.1 Syntactic generative models

Chelba and Jelinek (2000) and Emami and Jelinek (2005) proposed incremental syntactic language models that predict binarized constituency trees with a shift-reduce model, parameterized by interpolated n-gram smoothing and feed-forward neural networks, respectively. Language modelling probabilities were approximated incrementally using beam-search. Rastrow et al. (2012) applied a transition-based dependency n-gram language model to speech recognition. These models obtained perplexity improvements primarily when interpolated with standard n-gram models, and were not employed as parsers.

Henderson (2004) proposed an incremental constituency parser based on recurrent neural networks that have additional connections to previous recurrent states based on the parser configuration at each time step. The generative version of this model was more accurate than the discriminative one. Titov and Henderson (2007) applied a similar approach to dependency parsing. Buys and Blunsom (2015a) and Buys and Blunsom (2015b) proposed generative syntactic models that are applied to both dependency parsing and language modelling, using Bayesian and feed-forward neural networks, respectively. Recurrent Neural Network Grammar (RNNG) (Dyer et al., 2016) is a generative transition-based constituency parser based on stack LSTMs (Dyer et al., 2015), that was also applied as a language model.

Recently, Shen et al. (2017) proposed an RNN-based language model that uses a soft gating mechanism to learn structure that can be interpreted as constituency trees, reporting strong language modelling performance. There has also been work on non-incremental syntactic language modelling: Mirowski and Vlachos (2015) proposed a dependency neural language model where each word is conditioned on its ancestors in the dependency tree, and showed that this model achieves strong performance on a sentence completion task.

5.2 Neural models with latent structure

There have been a number of recent proposals for neural abstract machines that augment RNNs with external memory, including stacks and other data structures that are operated on with differentiable operations to enable end-to-end learning. Neural Turing machines (Graves et al., 2014) have read-write memory that is updated at each timestep. Grefenstette et al. (2015) proposed a neural stack that is operated on with differentiable push and pop computations.

Another strand of recent work which our models are related to has proposed neural models with structured latent variables: Rastogi et al. (2016) incorporated neural context into weighted finite-state transducers with a bidirectional RNN, while Tran et al. (2016) proposed a neural hidden Markov model for Part-of-Speech (POS) induction. Yu et al. (2016) proposed a neural transduction model with polynomial-time inference where the alignment is a latent variable. Kim et al. (2017) proposed structured attention mechanisms that compute features by taking expectations over latent structure. They define a tree-structured model with a latent variable for head selection,

along with projectivity constraints. The soft head selection learned by the model is used as features in an attention-based decoder.

Reinforcement learning has been proposed to learn compositional tree-based representations in the context of an end task (Andreas et al., 2016; Yogatama et al., 2016), but this approach has high variance and provide no guarantees of finding optimal trees.

6 Conclusion

We proposed a new framework for generative models of syntactic structure based on recurrent neural networks. We presented efficient algorithms for training these models with or without supervision, and to apply them to make online predictions for language modelling through exact marginalization. Results show that the model obtains state-of-the-art performance on supervised generative dependency parsing, but does not obtain better intrinsic language modelling performance than a standard RNN.

Noise-Robust Morphological Disambiguation for Dialectal Arabic

Nasser Zalmout, Alexander Erdmann, Nizar Habash
Computational Approaches to Modeling Language Lab
New York University Abu Dhabi
United Arab Emirates
{nasser.zalmout,ae1541,nizar.habash}@nyu.edu

Abstract

User-generated text tends to be noisy with many lexical and orthographic inconsistencies, making natural language processing (NLP) tasks more challenging. The challenging nature of noisy text processing is exacerbated for dialectal content, where in addition to spelling and lexical differences, dialectal text is characterized with morpho-syntactic and phonetic variations. These issues increase sparsity in NLP models and reduce accuracy. We present a neural morphological tagging and disambiguation model for Egyptian Arabic, with various extensions to handle noisy and inconsistent content. Our models achieve about 5% relative error reduction (1.1% absolute improvement) for full morphological analysis, and around 22% relative error reduction (1.8% absolute improvement) for part-of-speech tagging, over a state-of-the-art baseline.

1 Introduction

There has been a growing interest in noise-robust NLP tools recently, motivated by the sheer magnitude of user-generated content in social media platforms. The noisy nature of user-generated content makes its processing very challenging for NLP tools. Noisy content is non-canonical in nature, with lexical, orthographic, and phonetic variations that increase the perplexity and sparsity of NLP models. Several contributions show considerable drop in performance for a number of tasks, where simply retraining existing models with social media data does not provide substantial improvement (Gimpel et al., 2011; Ritter et al., 2011; Habash et al., 2013a).

Morphological disambiguation for noisy content is further complicated for dialectal content, with additional morpho-syntactic variations. Morphological disambiguation is also more challenging for morphologically rich and ambiguous languages, like Arabic and Dialectal Arabic (DA). Arabic is morphologically rich, having more fully inflected words (types) than morphologically poorer languages. It is also ambiguous, with short vowels (diacritic marks) often dropped and disambiguated in context. These issues result in more morpho-syntactic variations for DA in written text compared to other dialectal content, and increase the number of potential analyses.

We present several morphological disambiguation models for Egyptian Arabic (EGY), based on previous models for EGY and Modern Standard Arabic (MSA). We use a bidirectional long short term memory (Bi-LSTM) architecture and various noise reduction techniques, including character embedding and embedding space mapping. We also experiment with the width of the embedding window in the pre-trained embeddings. Character embeddings allow access to subword units, while the embedding space mapping normalizes non-canonical forms to canonical neighbors. The narrow/wide embedding window in the pre-trained embeddings allows for more of syntactic/semantic modeling, respectively.

The goal of the various models is to achieve noise-robust analysis, rather than explicit noise normalization. We therefore use the normalization techniques on the vector-level only, instead of replacing the raw forms, which allows for less aggressive lexical normalization. The separation of raw forms and vector normalization also allows for independent word and character level normalization, eliminating any propagation of error.

Our system achieves a 5% relative error reduction (1.1% absolute accuracy boost) over a state-of-the-art baseline, using a strict metric. Our noise-robust system also matches the performance of a version of the system trained and tested on a manually orthography-normalized copy of the data. This indicates that the system performs as well as could be expected without orthographic in-

Proceedings of NAACL-HLT 2018, pages 953–964
New Orleans, Louisiana, June 1 - 6, 2018.

consistency. We also present an error analysis of the system and identify areas of improvement.

The rest of the paper is structured as follows. We present common challenges to DA processing in Section 2. This is followed by background and related work in Section 3. We introduce the approach and various models in Section 4, and discuss the experimental setup and results in Section 5. We conclude and provide some directions for future work in Section 6.

2 Linguistic Issues

Dialectal Arabic, including EGY among other dialects, is the primarily spoken language used by native Arabic speakers in daily exchanges. The outbreak of social media platforms expanded the use of DA as a written language. The lack of a standard orthography (Habash et al., 2012a), combined with the fact that user-generated content in social media is prone to noise, increase sparsity and reduce performance.

EGY, similar to MSA, is also a morphologically complex language, having a number of morphological features, e.g., gender, number, person, mood, and attachable clitics. Moreover, the diacritization-optional orthography for Arabic (both DA and MSA) results in orthographic ambiguity, leading to several interpretations of the same surface forms. Richness of form increases model sparsity, and ambiguity makes disambiguation harder. One approach to model complexity, richness, and ambiguity uses *morphological analyzers*, also known as morphological dictionaries. Morphological analyzers are usually used to encode all potential word inflections in the language. A good morphological dictionary should return all the possible analyses of a surface word (ambiguity), and cover all the inflected forms of a word lemma (richness), covering all related features. The best analysis is then chosen through *morphological disambiguation*.

The set of morphological features that we model for EGY morphological disambiguation includes:

- Lexicalized features: lemma, diacritization.
- Non-lexicalized features: aspect, case, gender, person, part-of-speech (POS), number, mood, state, voice.
- Clitics: enclitics, like pronominal enclitics, negative particle enclitics; proclitics, like article proclitic, preposition proclitics, conjunction proclitics, question proclitics.

Despite the similarities, EGY and MSA have many differences that prevent MSA tools from being effectively utilized for EGY text. These include lexical, phonological, and morphological inconsistencies. Lexical differences can be numerous, beyond simple cognates, like the word ازاي *AzAy*[1] 'how' in EGY corresponds to the word كيف *kyf* in MSA. There are also many morphological differences, for example the MSA future proclitic /sa/+ (spelled +سـ s+) appears in EGY as either /ha/+ (+هـ) or /Ha/+ (+حـ). There are also many phonological variations between EGY and MSA that have direct implications on orthography as well. These include the consonant ث /θ/ in MSA, which can be mapped to either ت /t/ or س /s/ in EGY. These variations make the written EGY content more susceptible to noise and inconsistency. Table 1 shows an EGY sentence example, along with the set of potential analyses for a given word.

3 Background and Related Work

Explicit handling of noisy content in NLP has recently gained momentum with the increasing use of social media outlets. Notable contributions for POS tagging include the ARK tagger (Owoputi et al., 2013), which is targeted for online conversational text. ARK tagger uses conditional random fields with word clusters as features, obtained via Brown clustering (Brown et al., 1992), along with various lexical features. Gimpel et al. (2011) also use conditional random fields for POS tagging, trained on annotated Twitter content. Derczynski et al. (2013) use manually curated lists to map low frequency and out of vocabulary terms to more frequent terms. Noisy content has also been addressed for named entity recognition (Liu et al., 2011; Ritter et al., 2011; Aguilar et al., 2017), and syntactic parsing (Foster et al., 2011; Petrov and McDonald, 2012).

Most relevant to our work is the paper by van der Goot et al. (2017), where they use Word2vec (Mikolov et al., 2013) to find potential normalization candidates for non-canonical words on the lexical level, and rank them using a classifier. They experiment with various normalization and embedding settings, and they find that both normalization and pre-trained embeddings are helpful for the task of POS tagging.

[1] Arabic transliterations are in the Habash-Soudi-Buckwalter transliteration scheme (Habash et al., 2007).

Table 1: An example highlighting the effect of non-standard and ambiguous orthography, along with rich morphology, on EGY morphological disambiguation. The word برضك *barDak* 'still' is provided in the example with the non-standard (non-CODA compliant) orthography بردك *bardak*, which can lead to different morphological analyses than the one intended in context.

The issue of noisy text processing is exacerbated for dialectal content. Most contributions focus on spelling/lexical variations, whereas dialectal content is further characterized with morpho-syntactic and phonetic variations that make automatic processing more challenging (Jørgensen et al., 2015). In addition to the issues of morphological complexity, ambiguity, and lack of standard orthography for MSA and DA. There has been several contributions covering various NLP tasks including morphological analysis, disambiguation, POS tagging, tokenization, lemmatization and diacritization, addressing both MSA and DA (Al-Sabbagh and Girju, 2010; Mohamed et al., 2012; Habash et al., 2012b, 2013a; Abdelali et al., 2016; Khalifa et al., 2016b). Notable contributions for both MSA and EGY include MADAMIRA (Pasha et al., 2014), a morphological disambiguation tool that uses morphological analyzers to handle complexity and ambiguity. MADAMIRA can automatically correct common spelling errors as a side effect of disambiguation, but does not include explicit processing steps for noisy content. A neural version of MADAMIRA for MSA is presented by Zalmout and Habash (2017), who use Bi-LSTMs and morphological tag embeddings. Their system shows significant improvement over MADAMIRA, but does not use any explicit character embeddings nor noise reduction techniques.

To address the lack of standardized orthography for DA, Habash et al. (2012a) proposed CODA, a Conventional Orthography for Dialectal Arabic. CODA presents a detailed description of orthographic guidelines, mainly for the purpose of developing DA computational models, applied to EGY, and later extended to several other Arabic dialects (Zribi et al., 2014; Saadane and Habash, 2015; Turki et al., 2016; Khalifa et al., 2016a; Jarrar et al., 2016; Habash et al., 2018). CODA-treated DA content should be less sparse and less noisy. Eskander et al. (2013) presented a tool to normalize raw texts into a CODA compliant version using the K-nearest neighbor algorithm. Scaling this tool to other dialects, however, is challenging due to the lack of training data.

Our morphological tagging architecture is similar to the work of Inoue et al. (2017) and Zalmout and Habash (2017), but we further experiment with CNN-based character embeddings, and pre-train the word embeddings. The architecture is also similar to the work of Heigold et al. (2017) and Plank et al. (2016) in terms of the character embeddings, both LSTM and CNN-based systems. Our architecture, however, uses neural language models for modeling lemmas and diacritized forms, and utilizes the word-level embeddings in various configurations to combat noise, as explained throughout the rest of the paper.

4 Approach

We present a morphological disambiguation model for EGY. We use an LSTM-based architecture for morphological tagging and language modeling for the various morphological features in EGY. We also experiment with several embedding models for words and characters, and present several approaches for noise-robust modeling on the raw form and vector levels.

We present the overall tagging and disambiguation architecture, in addition to the character embedding model, in 4.1. We then present the noise handling approaches in 4.2 and 4.3.

4.1 Morphological Tagging and Disambiguation Architecture

We use a similar disambiguation approach as in previous contributions for MSA and EGY (Habash and Rambow, 2005; Habash et al., 2009, 2013b).

The morphological disambiguation task is intended to choose the correct morphological analysis from the set of potential analyses, obtained from the morphological analyzer. The analyzer provides a set of morphological features for each given word. These features can be grouped into non-lexical features, where a tagger is used to predict the relevant morphological tag, handled through *morphological feature tagging*, and lexical features that need a language model (Roth et al., 2008), handled through *lexicalized feature language models*. The inflectional, clitic, and part-of-speech features are handled with a tagger, while the lexical features are handled with a language model.

4.1.1 Morphological Feature Tagging

Overall Architecture We use Bi-LSTM-based taggers for the morphological feature tagging tasks. Given a sentence of length L words $\{w_1, w_2, ..., w_L\}$, every word w_i is converted into vector v_i:

$$v_i = [v_{w_i}; v_{c_i}; v_{t_i}]$$

composed of the word embedding vector v_{w_i}, word-level characters embedding vector v_{c_i}, and the candidate morphological tag embedding vector v_{t_i}. This separation of word and character embedding vectors enables further noise handling on the word embedding level alone, with the character embeddings learnt from the raw forms without any modification. We pre-train the word embeddings using Word2vec (Mikolov et al., 2013).

We use two LSTM layers to model the relevant context for both directions of the target word, where the input is represented by the v_i vectors mentioned above:

$$\overrightarrow{h}_i = g(v_i, \overrightarrow{h}_{i-1})$$

$$\overleftarrow{h}_i = g(v_i, \overleftarrow{h}_{i+1})$$

where h_i is the context vector from the LSTM for each direction. We join both sides, apply a non-linearity function, and softmax to get a probability distribution. Figure 1 shows the architecture.

Character Embedding We use convolutional neural networks (CNN) and LSTM-based architectures for the character embedding vectors v_{c_i}, both applied to the character sequence within each word separately. LSTM-based architectures have been shown to outperform CNN-based character

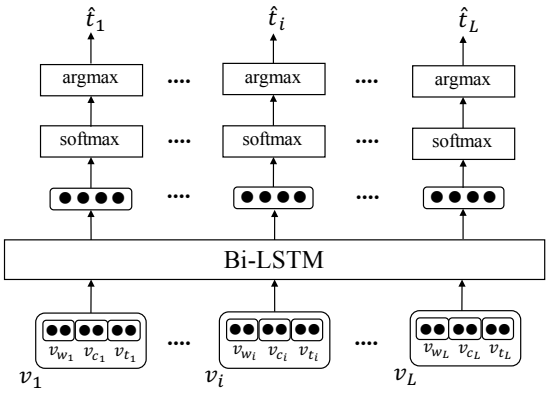

Figure 1: The overall tagging architecture, with the input vector as the concatenation of the word, characters, and candidate tag embeddings.

embedding in POS tagging (Heigold et al., 2017), but we experiment with both architectures to report their performance in noisy EGY content. We use various filter widths and max pooling for the CNN system, with the output fed to a dense connection layer. The resulting vector is used as the character embedding vector for the given word. For the LSTM-based architecture we use the last state vector as the embedding representation of the word's characters. Both architectures are outlined at figure 2.

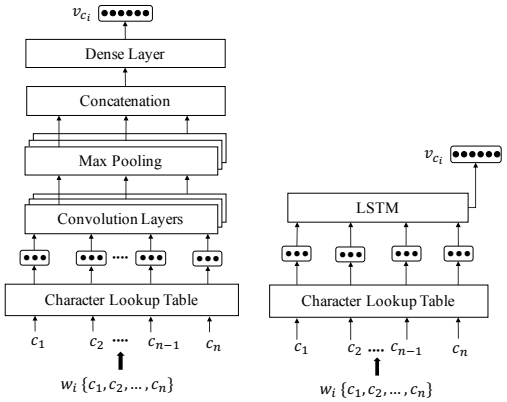

Figure 2: CNN-based (left) and LSTM-based (right) architectures for word-level character embedding. Similar to the architecture by Heigold et al. (2017).

Morphological Tag Embedding The morphological features vector v_{t_i} embeds the candidate tags for each feature. The tags include the collection of morphological features. We use the morphological analyzer to obtain all possible tag values of the word to be analyzed. We use a lookup table to map the tags to their trainable vector representation, then sum all the resulting vectors to

get v_{t_i}, since these tags are alternatives and do not constitute a sequence of any sort. Figure 3 outlines the tag embedding model.

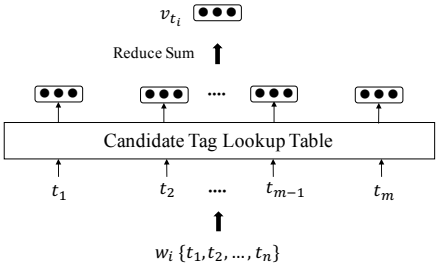

Figure 3: Candidate tag embedding, through summing the vectors of the individual tags.

Embedding the morphological tags using the analyzer does not constitute a hard constraint in the system, and the v_{t_i} vector can be discarded or substituted with less resource-demanding options for other languages or dialects.

4.1.2 Lexicalized Feature Language Models

We use LSTM-based neural language models (Enarvi and Kurimo, 2016) for the lexical features (lemma and diacritization). Lemmas and diacritized forms are lexical and cannot be modeled directly using a classifier (Habash and Rambow, 2007), since the target space is big (around 13K for lemmas, and 33K for the diacritized forms, in Train). We therefore use a language model to choose among the candidate lemmas and diacritized forms obtained from the analyzer. We encode the runtime dataset in the HTK Standard Lattice Format (SLF), with a word mesh representation for the various options of each word.

4.2 Embedding Window Width

Several contributions show that the window size (i.e. amount of context) in word embeddings affects the type of linguistic information that gets modeled. Goldberg (2016) and Trask et al. (2015) explain that larger windows tend to create more semantic and topical embeddings, whereas smaller windows capture syntactic similarities. Tu et al. (2017) also find that a window of one (one word before the target word and one word after) is optimal for syntactic tasks.

We experiment with both wide and narrow window embeddings, and evaluate their effects on tagging accuracy. These experiments show the role of topical or semantic vs syntactic embeddings in the morphological disambiguation model.

We then experiment with embedding vector extension, by combining both wide and narrow embeddings through concatenation. This technique is expected to handle noisy and unstandardized spellings, since spelling variants are not just semantically related, but must share the same syntactic valency.

Figure 4 shows the updated architecture, with the narrow window embedding $v_{w_i}^{narrow}$ concatenated to the v_i vector, along with the existing wide window embedding $v_{w_i}^{wide}$.

4.3 Embedding Space Mapping

The embedding space mapping approach is based on the hypothesis that non-standard words are likely to have similar contexts as their canonical equivalents. We define the canonical equivalent here as the most frequent semantically and syntactically equivalent word to the target word. We use this definition since the operation is unsupervised, and for the lack of a standard canonical forms. Variants of this approach have been used in several spelling error correction tasks (Sridhar, 2015). Dasigi and Diab (2011) also use a similar approach to identify variants in DA. We use the Word2vec framework (Mikolov et al., 2013) in the Gensim implementation (Řehůřek and Sojka, 2010) to generate the embedding spaces. We use these embeddings to learn and score normalization candidates based on their cosine distance as a semantic score, and edit distance as a lexical score. In this scope, we first learn a weighted distance function for the individual insertion, deletion, and substitution operations, then use these weights to score the candidates.

Edit Distance Weights The spelling variants are first identified based on narrow window and wide window embeddings, to capture both semantic and syntactic based relationships. For each word in each embedding space we get the nearest *N* neighbors, and intersect them with the *N* nearest neighbors of the word in the other embedding space. We get these neighbors to obtain the weights first, and then use them again for the actual normalization in the next step. We discard candidates that have an edit distance above two, and obtain the individual edit operation weights through their normalized frequencies in the remaining candidates.

Word Mapping We use the learnt edit distance weights to score the normalization candidates mentioned above from the wide and nar-

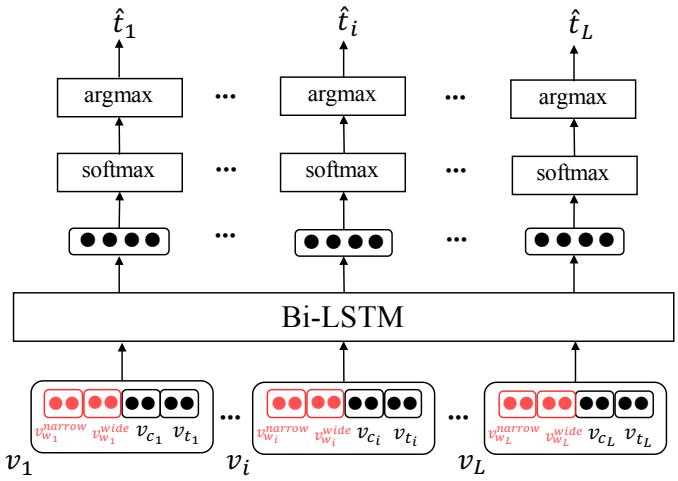

Figure 4: The tagging architecture with the extended (wide and narrow) window embeddings.

row window embedding spaces, and further prune them based on their weighted edit distance. We select the candidate with the highest frequency in the text as the canonical equivalent.

Low Frequency Words Word2vec has a minimum count threshold for the words to be embedded. This value is tunable based on the used corpus. For the words below this threshold Word2vec does not guarantee a good vector representation, and discards them in the embedding model, so we can not use this normalization approach in this case. Instead, we use the weighted edit distances to score and map these words to more frequent cognates, on the character level only.[2]

Normalized Embeddings The pipeline so far results in a more consistent version of the text, which we use to learn the final embeddings upon. These embeddings are used as the pre-trained embeddings in the tagging architecture. This results in normalization at the embedding space level only, where the raw forms are still unmodified. The raw forms can be used for character-level noise reduction later in the tagging pipeline.

5 Experiments

5.1 Data

We use the "ARZ" (Maamouri et al., 2012) manually annotated EGY Arabic corpus, from the Linguistic Data Consortium (LDC), parts 1, 2, 3, 4 and 5. The corpus is based on the POS guidelines used by the LDC for Egyptian Arabic, and consists of about 160K words (excluding numbers and punctuations, 175K overall). The set of analyses for a given raw word includes the correct CODA orthography, in addition to the full morphological and POS annotations.

We use the splits suggested by Diab et al. (2013), comprised of a training set (Train) of about 134K words, a development set (Dev) of 20K words, and a blind testing set (Blind Test) of 21K words. The Dev set is used during the system development to assess design choices. The Blind Test set is used at the end to present the results.

The morphological analyzer we use in this paper is similar to the one used by Habash et al. (2013b). It is based on the SAMA (Graff et al., 2009), CALIMA (Habash et al., 2012b), and ADAM (Salloum and Habash, 2014) databases. EGY content, as in DA in general, contains many MSA cognates. The decision therefore to use all three analyzers was to maximize the recall of the overall analyzer.

We also use an in-house EGY monolingual corpus of about 410 million words, collected from online commentaries of blogs and social media platforms, to pre-train the word embeddings.

To better assess the notions of noise and ambiguity in the EGY dataset, we compare it to the Penn Arabic Treebank (PATB parts 1, 2 and 3) (Maamouri et al., 2004), which is commonly used for morphological disambiguation systems in MSA. MSA is also morphologically rich with high ambiguity levels, so it should provide a suitable reference for EGY. We sample an MSA data of size similar to the EGY dataset size, to be able to

[2] Instead of searching through the entire word space for each word to be normalized, which is computationally expensive, we pruned the search space by only looking at words sharing at least two consonants (in the same order) with it.

draw comparable comparison. Table 2 provides some statistics regarding both datasets. The average number of unique types per lemma (different types mapped to the same lemma encountered in the corpus) is relatively higher for the raw EGY content compared to MSA, at 2.7 vs 2.4. The average for the CODA-based EGY, however, is similar to MSA. This indicates that the normalized version of EGY has a similar sparsity as that for MSA, which is inherently less noisy. The difference in the ratio between raw and CODA EGY is a good indicator of the noise and inconsistency in the EGY dataset.

	EGY Raw	EGY CODA	MSA
Tokens	133,751	133,751	133,763
Inflected types	32,927	30,272	22,022
Lemmas	13,242	13,242	9,522
Avg types/lemma	2.7	2.4	2.4

Table 2: Dataset statistics showing tokens, types, and lemmas count in EGY and an MSA subset. Both from the Train set. The average inflections per lemma is calculated by counting the average unique types that map to the same lemma.

Regarding ambiguity, we calculated the average number of different analyses from the morphological analyzer for a given word in EGY at about 24 analyses per word (about 15 MSA, 6.5 DA, and 2.5 "no-analysis" analyses[3]), whereas for MSA it is around 12. This reflects the severe ambiguity of the EGY dataset compared with MSA in this context. Both noise and ambiguity issues make morphological tagging and disambiguation systems for EGY a very challenging task.

5.2 Experimental Setup

For the Bi-LSTM tagging architecture we use two hidden layers of size 800. Each layer is composed of two LSTM layers for each direction, and a dropout wrapper with keep probability of 0.8, and peephole connections. We use Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.002, and cross-entropy cost function. We use Tensorflow as the development environment.

The LSTM character embedding architecture uses two LSTM layers of size 100, and embedding size 50. The CNN architecture also uses embedding size 50, with filter widths ranging from one to six and max pooling strides of 50.

[3] The morphological analyzer has a backoff mode of "no-analysis" that provides a "proper noun" analysis to all word. The "proper noun" analysis can sometimes be cliticized, so some words might have multiple backoff analyses.

As for the neural language models for lemmatization and diacritization, we use two hidden layers of size 400 for lemmatization, and 600 for diacritization. We also use an input layer of size 300. We use Adam optimizer (Kingma and Ba, 2014) as the optimization algorithm, with learning rate of 0.002. We use TheanoLM (Enarvi and Kurimo, 2016) to develop the models.

The pre-trained word embeddings are of size 250, for both narrow and wide window embeddings. The wide window is set to five, whereas the narrow window is set to two (we experimented with a window of one but it performed slightly lower than a window of two). The number of nearest neighbors in the embedding space mapping experiment is 10 neighbors.

Metrics We use the following evaluation metrics for all systems:

- POS Accuracy (POS): The accuracy over the POS tag set comprised of 36 tags (Habash et al., 2013b).
- Morph Tags Accuracy (Morph Tags): The analysis and disambiguation accuracy over the 14 morphological features we work with, excluding lemmas and diacritized forms.
- Lemmatization Accuracy (Lemma): The accuracy of the lemma form of the words.
- Diacritization Accuracy (Diac): The accuracy of the diacritized form of the words.
- Full Analysis Accuracy (Full): The evaluation accuracy over the entire analysis, including the morphological features, lemma, and diacritized form.

5.3 Results

Table 3 shows the results of all systems for Dev, and Table 4 shows the results for the Blind Test set. We use the MADAMIRA results as the baseline.

Narrow embeddings seem to consistently outperform wide embeddings across all experiments. Regarding character embeddings, using both CNN and LSTM-based character embeddings improve the overall performance for both wide and narrow word embeddings, but LSTMs show consistent improvement over CNNs, which is in line with the conclusions of Heigold et al. (2017).

Embedding extension, through combining the wide and narrow window word embeddings, with

Table 4: Results of the various systems over the Blind Test dataset.

the LSTM-based character embeddings, significantly enhances the performance beyond the character embeddings alone for the wide embeddings. This is not the case though for narrow window embeddings. This highlights the significance of narrow embeddings for syntactic and morphological modeling, since the extension approach merely adds narrow window embedding capability to the wide window embeddings.

We observe the same pattern for the embedding space mapping approach for noise reduction against the narrow window embeddings. However, combining the extension with the embedding space mapping methods, along with the LSTM-based character embeddings, results in the best performing system. Both approaches seem to complement each other, as the accuracy exceeds any of the methods alone.

The result of the narrow window embeddings is particularly interesting, as it shows that to achieve a relatively good noise-robust morphological disambiguation accuracy, using narrow window embeddings should go a long way. Using more sophisticated, and computationally expensive, noise handling approaches, like embedding extension with embedding space mapping, should achieve even better results.

5.4 System Analysis

Oracle Conventional Orthography Experiment The availability of the manually annotated CODA equivalent of the EGY dataset allows for a deeper analysis of the noise effects on morphological disambiguation. We trained and tested the system using the CODA version of the data, as an oracle experiment of noise-reduced content. CODA-based content is not guaranteed to be noise-free, or be optimal for such syntactic and morphological tasks, but it should provide a good reference in terms of orthography-normalized content.

We train the model on the CODA-EGY training, and test it with the CODA-EGY Dev set. We use the same word pre-training dataset as before. We use LSTM-based character embeddings, and experiment with both wide and narrow embedding window. Table 5 shows the results for the CODA based modeling for Dev. The results are very similar to the best performing model in our earlier ex-

Model	Lemma	Diac	POS	Morph Tags	Full

Table 5: Results of training and testing the system using the CODA-based Dev data, compared to the results of our system (taken from Table 3). All systems use LSTM-based character embeddings.

periments. These results indicate that our model is very close to the upper performance limit in terms of noise and inconsistency, and achieves noise-robust tagging and disambiguation.

The results for wide and narrow window contexts are also consistent with our earlier experiments, with narrow windowed contexts performing better across all evaluation metrics.

Manual Error Analysis

POS analysis We first analyze the overall error distribution in the POS tagging results. The most common POS error type is mistagging a nominal tag (Noun, Adjective, etc) with a different nominal tag, at 74% of the errors. Nominals include many very frequent tags, such as nouns and adjectives. The next most common error category is mistagging particles with other particles, at around 15%. Mistagging nominals with verbs is at around 4%. Several other low frequency errors cover the remaining 7%. To better understand the nature of the errors we manually checked a sample of 100 POS tagging errors. Almost 48% of them are gold errors, out of which our system gets 74% correct.

Lemma analysis We also manually checked a sample of 100 lemmatization errors. We observe that 30% of them are gold errors, 23% are the result of a wrong POS tag, 15% are acceptable MSA lemmas, 12% are due to minor and normally acceptable spelling issues, mainly the Hamza letter (glottal stops), and 6% are due to inconsistent diacritization. The MSA-related errors are due to the many MSA cognates in DA content. So providing an MSA-based analysis instead of an equivalent DA analysis can be acceptable for the purpose of this analysis. Hamza spelling variations, especially at the beginning of the word, are common in both DA and MSA written content.

Diacritization analysis We checked a sample of 100 diacritization errors. We observed more errors attributed to error propagation, as wrong POS tags and lemmas lead to many diacritization errors. The percentage of gold errors is only 17%, whereas MSA-cognate related errors are about 32%, POS related errors cover 13%, Hamza errors 11%, lemmatization errors include 7%, and the rest are mostly due to wrong case, gender, person tags, and other unidentified issues.

6 Conclusion and Future Work

We presented several neural morphological disambiguation models for EGY, and used several approaches for noise-robust processing. Our system outperforms a state-of-the-art system for EGY. We observed that character embeddings, combined with pre-trained word embeddings, provide a significant performance boost over the baseline. We showed that LSTM-based character embeddings outperform CNN-based models for EGY. We also showed that narrow window embeddings significantly outperform wide window embeddings for tagging. We also experimented with a normalization model on the word-level vectors, mapping non-canonical words to canonical neighbors through embedding space mapping. The results showed an additional improvement over the narrow window embeddings.

Future directions include exploring additional deep learning architectures for morphological modeling and disambiguation, especially joint and multitasking architectures. We also plan to explore knowledge transfer and adaptation models for more dialects with limited resources.

Abstract

We study the problem of analyzing tweets with Universal Dependencies (UD; Nivre et al., 2016). We extend the UD guidelines to cover special constructions in tweets that affect tokenization, part-of-speech tagging, and labeled dependencies. Using the extended guidelines, we create a new tweet treebank for English (TWEEBANK V2) that is four times larger than the (unlabeled) TWEEBANK V1 introduced by Kong et al. (2014). We characterize the disagreements between our annotators and show that it is challenging to deliver consistent annotation due to ambiguity in understanding and explaining tweets. Nonetheless, using the new treebank, we build a pipeline system to parse raw tweets into UD. To overcome annotation noise without sacrificing computational efficiency, we propose a new method to distill an ensemble of 20 transition-based parsers into a single one. Our parser achieves an improvement of 2.2 in LAS over the un-ensembled baseline and outperforms parsers that are state-of-the-art on other treebanks in both accuracy and speed.

1 Introduction

NLP for social media messages is challenging, requiring domain adaptation and annotated datasets (e.g., treebanks) for training and evaluation. Pioneering work by Foster et al. (2011) annotated 7,630 tokens' worth of tweets according to the phrase-structure conventions of the Penn Treebank (PTB; Marcus et al., 1993), enabling conversion to Stanford Dependencies. Kong et al. (2014) further studied the challenges in annotating tweets and presented a tweet treebank (TWEEBANK), consisting of 12,149 tokens and largely following conventions suggested by Schneider et al. (2013), fairly close to Yamada and Matsumoto (2003) dependencies (without labels). Both annotation efforts were highly influenced by the PTB, whose guidelines have good grammatical coverage on newswire. However, when it comes to informal, unedited, user-generated text, the guidelines may leave many annotation decisions unspecified.

Universal Dependencies (Nivre et al., 2016, UD) were introduced to enable consistent annotation across different languages. To allow such consistency, UD was designed to be adaptable to different genres (Wang et al., 2017) and languages (Guo et al., 2015; Ammar et al., 2016). We propose that analyzing the syntax of tweets can benefit from such adaptability. In this paper, we introduce a new English tweet treebank of 55,607 tokens that follows the UD guidelines, but also contends with social media-specific challenges that were not covered by UD guidelines.[1] Our annotation includes tokenization, part-of-speech (POS) tags, and (labeled) Universal Dependencies. We characterize the disagreements among our annotators and find that consistent annotation is still challenging to deliver even with the extended guidelines.

Based on these annotations, we nonetheless designed a pipeline to parse raw tweets into Universal Dependencies. Our pipeline includes: a bidirectional LSTM (bi-LSTM) tokenizer, a word cluster–enhanced POS tagger (following Owoputi et al., 2013), and a stack LSTM parser with character-based word representations (Ballesteros et al., 2015), which we refer to as our "baseline" parser. To overcome the noise in our annotated

[1] We developed our treebank independently of a similar effort for Italian tweets (Sanguinetti et al., 2017). See §2.5 for a comparison.

Proceedings of NAACL-HLT 2018, pages 965–975
New Orleans, Louisiana, June 1 - 6, 2018.

data and achieve better performance without sacrificing computational efficiency, we distill a 20-parser ensemble into a single greedy parser (Hinton et al., 2015). We show further that learning directly from the exploration of the ensemble parser is more beneficial than learning from the gold standard "oracle" transition sequence. Experimental results show that an improvement of more than 2.2 points in LAS over the baseline parser can be achieved with our distillation method. It outperforms other state-of-the-art parsers in both accuracy and speed.

The contributions of this paper include:

- We study the challenges of annotating tweets in UD (§2) and create a new tweet treebank (TWEEBANK V2), which includes tokenization, part-of-speech tagging, and labeled Universal Dependencies. We also characterize the difficulties of creating such annotation.
- We introduce and evaluate a pipeline system to parse the raw tweet text into Universal Dependencies (§3). Experimental results show that it performs better than a pipeline of the state-of-the-art alternatives.
- We propose a new distillation method for training a greedy parser, leading to better performance than existing methods and without efficiency sacrifices.

Our dataset and system are publicly available at `https://github.com/Oneplus/Tweebank` and `https://github.com/Oneplus/twpipe`.

2 Annotation

We first review TWEEBANK V1 of Kong et al. (2014), the previous largest Twitter dependency annotation effort (§2.1). Then we introduce the differences in our tokenization (§2.2) and part-of-speech (§2.3) (re)annotation with O'Connor et al. (2010) and Gimpel et al. (2011), respectively, on which TWEEBANK V1 was built. We describe our effort of adapting the UD conventions to cover tweet-specific constructions (§2.4). Finally, we present our process of creating a new tweet treebank, TWEEBANK V2, and characterize the difficulties in reaching consistent annotations (§2.6).

2.1 Background: TWEEBANK

The annotation effort we describe stands in contrast to the previous work by Kong et al. (2014). Their aim was the rapid development of a dependency parser for tweets, and to that end they contributed a new annotated corpus, TWEEBANK, consisting of 12,149 tokens. Their annotations added unlabeled dependencies to a portion of the data annotated with POS tags by Gimpel et al. (2011) and Owoputi et al. (2013) after rule-based tokenization (O'Connor et al., 2010). Kong et al. also contributed a system for parsing; we defer the discussion of their parser to §3.

Kong et al.'s rapid, small-scale annotation effort was heavily constrained. It was carried out by annotators with only cursory training, no clear annotation guidelines, and no effort to achieve consensus on controversial cases. Annotators were allowed to underspecify their analyses. Most of the work was done in a very short amount of time (a day). Driven both by the style of the text they sought to annotate and by exigency, some of their annotation conventions included:

- Allowing an annotator to exclude tokens from the dependency tree. A clear criterion for exclusion was not given, but many tokens were excluded because they were deemed "non-syntactic."
- Allowing an annotator to merge a multiword expression into a single node in the dependency tree, with no internal structure. Annotators were allowed to take the same step with noun phrases.
- Allowing multiple roots, since a single tweet might contain more than one sentence.

These conventions were justified on the grounds of making the annotation easier for non-experts, but they must be revisited in our effort to apply UD to tweets.

2.2 Tokenization

Our tokenization strategy lies between the strategy of O'Connor et al. (2010) and that of UD. There is a tradeoff between preservation of original tweet content and respecting the UD guidelines.

The regex-based tokenizer of O'Connor et al. (2010)—which was originally designed for an exploratory search interface called TweetMotif, not for NLP—preserves most whitespace-delimited tokens, including hashtags, at-mentions, emoticons, and unicode glyphs. They also treat contractions and acronyms as whole tokens and do not

split them. UD tokenization,[2] in order to better serve dependency annotation, treats each syntactic word as a token. They therefore more aggressively split clitics from contractions (e.g., *gonna* is tokenized as *gon* and *na*; *its* is tokenized as *it* and *s* when *s* is a copula). But acronyms are not touched in the UD tokenization guidelines. Thus, we follow the UD tokenization for contractions and leave acronyms like *idc* ("I don't care") as a single token.

In the different direction of splitting tokens, UD guidelines also suggest to merge *multi-token words* (e.g., *20 000*) into one single token in some special cases. We witnessed a small number of tweets that contain multi-token words (e.g., *Y O*, and *R E T W E E T*) but didn't combine them for simplicity. Such tokens only account for 0.07% and we use the UD *goeswith* relation to resolve these cases in the dependency annotations.

2.3 Part-of-Speech Annotation

Before turning to UD annotations, we (re)annotated the data with POS tags, for consistency with other UD efforts, which adopt the universal POS tagset.[3] In some cases, non-corresponding tag conflicts arose between the UD English Web Treebank treebank conventions (UD_English-EWT; de Marneffe et al., 2014)[4] and the conventions of Gimpel et al. (2011). In these cases, we always conformed to UD, enabling consistency (e.g., when we exploit the existing UD_English-EWT treebank in our parser for tweets, §3). For example, the nominal URL in Figure 2 is tagged as *other* (`X`) and + is tagged as *symbol* (`SYM`) rather than *conjunction* (`CCONJ`).

Tokens that do not have a syntactic function (see Figure 1, discussed at greater length in the next section) were usually annotated as *other* (`X`), except for emoticons, which are tagged as *symbol* (`SYM`), following UD_English-EWT.

Tokens that abbreviate multiple words (such as *idc*) are resolved to the POS of the syntactic head of the expression, following UD conventions (in this example, the head *care* is a verb, so *idc* is tagged as a verb). When the token is not phrasal, we use the POS of the left-most sub-phrase. For example, *mfw* ("my face when") is tagged as a noun (for *face*).

Compared to the effort of Gimpel et al. (2011), our approach simplifies some matters. For example, if a token is not considered syntactic by UD conventions, it gets an *other* (`X`) tag (Gimpel et al. had more extensive conventions). Other phenomena, like abbreviations, are more complicated for us, as discussed above; Gimpel et al. used a single part of speech for such expressions.

Another important difference follows from the difference in tokenization. As discussed in §2.2, UD calls for more aggressive tokenization than that of O'Connor et al. (2010) which opted out of splitting contractions and possessives. As a consequence of adopting O'Connor et al.'s (2010) tokenization, Gimpel et al. introduced new parts of speech for these cases instead.[5] For us, these tokens must be split, but universal parts of speech can be applied.

2.4 Universal Dependencies Applied to Tweets

We adopt UD version 2 guidelines to annotate the syntax of tweets. In applying UD annotation conventions to tweets, the choices of Kong et al. (2014) must be revisited. We consider the key questions that arose in our annotation effort, and how we resolved them.

Acronym abbreviations. We follow Kong et al. (2014) and annotate the syntax of an acronym as a single word without normalization. Their syntactic functions are decided according to their context. Eisenstein (2013) studied the necessity of normalization in social media text and argued that such normalization is problematic. Our solution to the syntax of abbreviations follows the spirit of his argument. Because abbreviations which clearly carry syntactic functions only constitute 0.06% of the tokens in our dataset, we believe that normalization for acronyms is an unnecessarily complicated step.

Non-syntactic tokens. The major characteristic that distinguishes tweets from standard texts is that a large proportion of tokens don't carry any syntactic function. In our annotation, there are five types of non-syntactic tokens commonly seen in tweets: sentiment emoticons, retweet markers and

[2] http://universaldependencies.org/u/overview/tokenization.html

[3] A revised and extended version of Petrov et al. (2012) with 17 tags.

[4] https://github.com/UniversalDependencies/UD_English-EWT

[5] These tags only account for 2.7% of tokens, leading to concerns about data sparseness in tagging and all downstream analyses.

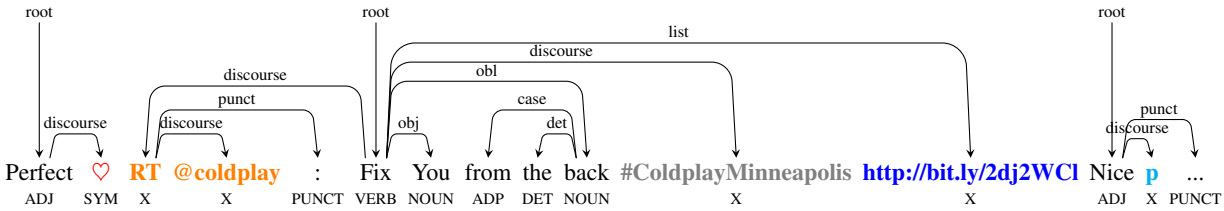

Figure 1: An example to illustrate non-syntactic tokens: sentiment emoticon, retweet marker and its following at-mention, topical hashtag, referential URL, and truncated word. This is a concatenation of three real tweets.

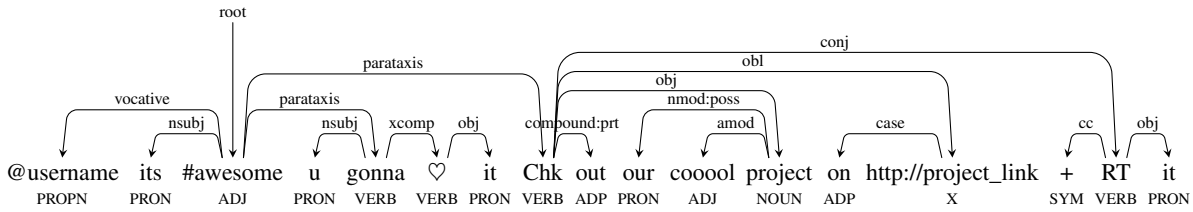

Figure 2: An example to illustrate informal but syntactic tokens. This is a contrived example inspired by several tweets.

	syntactic (%)	non-syntactic (%)
emoticons	0.25	0.95
RT	0.14	2.49
hashtag	1.02	1.24
URL	0.67	2.38
truncated words	0.00	0.49
total	2.08	7.55

Table 1: Proportions of non-syntactic tokens in our annotation. These statistics are obtained on 140 character–limited tweets.

their following at-mentions, topical hashtags, referential URLs, and truncated words.[6] Figure 1 illustrates examples of these non-syntactic tokens. As discussed above, these are generally tagged with the *other* (X) part of speech, except emoticons, which are tagged as *symbol* (SYM). In our annotation, 7.55% of all tokens are belong to one of the five types; detailed statistics can be found in Table 1.

It is important to note that these types may, in some contexts, have syntactic functions. For example, besides being a discourse marker, *RT* can abbreviate the verb *retweet*; emoticons and hashtags may be used as content words within a sentence; and at-mentions can be normal vocative proper nouns: see Figure 2. Therefore, the criteria for annotating a token as non-syntactic must be context-dependent.

Inspired by the way UD deals with *punctuation* (which is canonically non-syntactic), we adopt the following conventions:

- If a non-syntactic token is within a sentence that has a clear predicate, it will be attached to this predicate. The retweet construction is a special case and we will discuss its treatment in the following paragraph.
- If the whole sentence is a sequence of non-syntactic tokens, we attach all these tokens to the first one.
- Non-syntactic tokens are mostly labeled as *discourse*, but URLs are always labeled as *list*, following the UD_English-EWT dataset.

Kong et al. (2014) proposed an additional preprocessing step, *token selection*, in their annotation process. They required the annotators to first select the non-syntactic tokens and exclude them from the final dependency annotation. In order to keep our annotation conventions in line with UD norms and preserve the original tweets as much as possible, we include non-syntactic tokens in our annotation following the conventions above. Compared with Kong et al. (2014), we also gave a clear definition of non-syntactic tokens, which helped us avoid confusion during annotation.

[6]The tweets we analyze have at most 140 characters. Although Twitter has doubled the tweet length limit to 280 characters since our analysis, we believe this type of token will still remain.

Retweet construction. Figure 1 shows an example of the retweet construction (*RT @coldplay :*). This might be treated as a verb phrase, with *RT* as a verb and the at-mention as an argument. This solution would lead to an uninformative root word and, since this expression is idiomatic to Twitter, might create unnecessary confusion for downstream applications aiming to identify the main predicate(s) of a tweet. We therefore treat the whole expression as non-syntactic, including assigning the *other* (X) part of speech to both *RT* and *@coldplay*, attaching the at-mention to *RT* with the *discourse* label and the colon to *RT* with the *punct*(uation) label, and attaching *RT* to the predicate of the following sentence.

Constructions handled by UD. A number of constructions that are especially common in tweets are handled by UD conventions: ellipsis, irregular word orders, and paratactic phrases and sentences not explicitly delineated by punctuation.

Vocative at-mentions. Another idiomatic construction on Twitter is a vocative at-mention (sometimes a signal that a tweet is a reply to a tweet by the mentioned user). We treat these at-mentions as vocative expressions, labeling them with POS tag *proper noun* (PROPN) and attaching them to the main predicate of the sentence it is within with the label *vocative* as in UD guidelines (see Figure 2 for an example).

2.5 Comparison to PoSTWITA-UD

The first Twitter treebank annotated with Universal Dependencies was the *PosTWITA-UD* corpus for Italian (Sanguinetti et al., 2017), which consists of 6,738 tweets (119,726 tokens). In their convention, tokenization tends to preserve the original tweet content but two special cases, *articulated prepositions* (e.g., *nella* as *in la*) and *clitic clusters* (e.g. *guardandosi* as *guardando si*), are tokenized. Their lemmas include spelling normalization, whereas our lemmas only normalize casing and inflectional morphology. The current UD guidelines on lemmas are flexible, so variation between treebanks is expected.[7]

With respect to tweet-specific constructions, Sanguinetti et al.'s (2017) and our interpretations of headedness are the same, but we differ in the relation label. For topical hashtags, we use *discourse* while they used *parataxis*. In referential URLs, we use *list* (following the precedent of UD_English-EWT) while they used *dep*. Our choice of *discourse* for sentiment emoticons is inspired by the observation that emoticons are annotated as *discourse* by UD_English-EWT; Sanguinetti et al. (2017) used the same relation for the emoticons. Retweet constructions and truncated words were not explicitly touched by Sanguinetti et al. (2017). Judging from the released treebank[8], the *RT* marker, at-mention, and colon in the retweet construction are all attached to the predicate of the following sentence with *dep*, *vocative:mention* and *punct*. We expect that the official UD guidelines will eventually adopt standards for these constructions so the treebanks can be harmonized.

2.6 TWEEBANK V2

Following the guidelines presented above, we create a new Twitter dependency treebank, which we call TWEEBANK V2.

2.6.1 Data Collection

TWEEBANK V2 is built on the original data of TWEEBANK V1 (840 unique tweets, 639/201 for training/test), along with an additional 210 tweets sampled from the POS-tagged dataset of Gimpel et al. (2011) and 2,500 tweets sampled from the Twitter stream from February 2016 to July 2016.[9] The latter data source consists of 147.4M English tweets after being filtered by the *lang* attribute in the tweet JSON and *langid.py*.[10] As done by Kong et al. (2014), the annotation unit is always the tweet in its entirety—which may consist of multiple sentences—not the sentence alone. Before annotation, we use a simple regular expression to anonymize usernames and URLs.

2.6.2 Annotation Process

Our annotation process was conducted in two stages. In the first stage, 18 researchers worked on the TWEEBANK V1 portion and the additional 210 tweets and created the initial annotations in one day. Before annotating, they were given a tutorial overview of the general UD annotation conventions and our guidelines specifically for annotating tweets. Both the guidelines and annotations

split	TWEEBANK V1 tweets	TWEEBANK V1 tokens	TWEEBANK V2 tweets	TWEEBANK V2 tokens
train	639	9,310	1,639	24,753
dev.	–	–	710	11,742
test	201	2,839	1,201	19,112
total	840	12,149	3,550	55,607

Table 2: Statistics of TWEEBANK V2 and comparison with TWEEBANK V1.

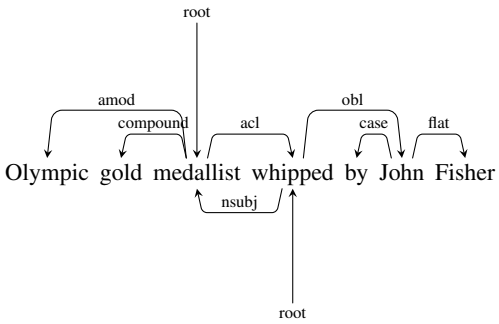

Figure 3: An example of disagreement; one annotator's parse is shown above, disagreeing arcs from the other annotator are shown below. This is a real example in our annotation.

were further refined by the authors of this paper to increase the coverage of our guidelines and solve inconsistencies between different annotators during this exercise. In the second stage, a tokenizer, a POS tagger, and a parser were trained on the annotated data from the first stage (1,050 tweets in total), and used to automatically analyze the sampled 2,500 tweets. Authors of this paper manually corrected the parsed data and finally achieved 3,550 labeled tweets.[11] Newly created annotations are split into train, development, and test sets and appended to the original splits of TWEEBANK V1. Statistics of our annotations and data splits are shown in Table 2.

We report the inter-annotator agreement between the annotators in the second stage. There is very little disagreement on the tokenization annotation. The agreement rate is 96.6% on POS, 88.8% on unlabeled dependencies, and 84.3% on labeled dependencies. Further analysis shows the major disagreements on POS involve entity names (30.6%) and topical hashtags (18.1%). Taking the example in Figure 1, "Fix you" can be understood as a verbal phrase but also as the name of the Coldplay's single and tagged as proper noun. An example of a disagreement on dependencies is shown in Figure 3. Depending on whether this is an example of a zero copula construction, or a clause-modified noun, either annotation is plausible.

[11] Manual annotation was done with Arborator (Gerdes, 2013), a web platform for drawing dependency trees.

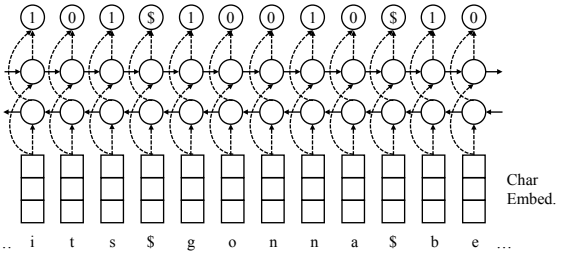

Figure 4: The bi-LSTM tokenizer that segments '*its gonna be*' into '*it s gon na be*'.

3 Parsing Pipeline

We present a pipeline system to parse tweets into Universal Dependencies. We evaluate each component individually, and the system as a whole.

3.1 Tokenizer

Tokenization, as the initial step of many NLP tasks, is non-trivial for informal tweets, which include hashtags, at-mentions, and emoticons (O'Connor et al., 2010). Context is often required for tokenization decisions; for example, the asterisk in *4*3* is a separate token signifying multiplication, but the asterisk in *sh*t* works as a mask to evoke censorship and should not be segmented.

We introduce a new character-level bidirectional LSTM (bi-LSTM) sequence-labeling model (Huang et al., 2015; Ma and Hovy, 2016) for tokenization. Our model takes the raw sentence and tags each character in this sentence as whether it is the beginning of a word (1 as the beginning and 0 otherwise). Figure 4 shows the architecture of our tokenization model. Space is treated as an input but deterministically assigned a special tag $.

Experimental results. Our preliminary results showed that our model trained on the combination of UD_English-EWT and TWEEBANK V2 outperformed the one trained only on the UD_English-EWT or TWEEBANK V2, consistent with previous work on dialect treebank parsing (Wang et al., 2017). So we trained our tokenizer on the training portion of TWEEBANK V2 combined with the UD_English-EWT training set and tested on the TWEEBANK V2 test set. We report F_1 scores, combining precision and recall for token identification. Table 3 shows the tokenization results,

System	F_1
Stanford CoreNLP	97.3

Owoputi et al., 2013 (CRF)	94.6
Ma and Hovy, 2016	92.5

Table 4: POS tagger comparison on gold-standard tokens in the TWEEBANK V2 test set.

Tokenization System	F_1
Stanford CoreNLP	92.3
our bi-LSTM tokenizer (§3.1)	93.3

Table 5: Owoputi et al. (2013) POS tagging performance with automatic tokenization on the TWEEBANK V2 test set.

compared to other available tokenizers. Stanford CoreNLP (Manning et al., 2014) and Twokenizer (O'Connor et al., 2010)[12] are rule-based systems and were not adapted to the UD tokenization scheme. The UDPipe v1.2 (Straka and Straková, 2017) model was re-trained on the same data as our system. Compared with UDPipe, we use an LSTM instead of a GRU in our model and we also use a larger size for hidden units (64 vs. 20), which has stronger representational power. Our bi-LSTM tokenizer achieves the best accuracy among all these tokenizers. These results speak to the value of statistical modeling in tokenization for informal texts.

3.2 Part-of-Speech Tagger

Part-of-speech tagging for tweets has been extensively studied (Ritter et al., 2011; Gimpel et al., 2011; Derczynski et al., 2013; Owoputi et al., 2013; Gui et al., 2017). We therefore consider existing POS taggers for tweets instead of developing our own. On the annotation scheme designed in §2.3, based on UD and adapted for Twitter, we compared several existing systems: the Stanford CoreNLP tagger, Owoputi et al.'s (2013) word cluster–enhanced tagger (both greedy and CRF variants), and Ma and Hovy's (2016) neural network tagger which achieves the state-of-the-art performance on PTB. Gui et al. (2017) presented a state-of-the-art neural tagger for Twitter, but their implementation works only with the PTB tagset, so we exclude it. All compared systems were re-trained on the combination of the UD_English-EWT and TWEEBANK V2 training sets. We use Twitter-specific GloVe embeddings released by Pennington et al. (2014) in all neural taggers and parsers.[13]

Experimental results. We tested the POS taggers on the TWEEBANK V2 test set. Results with gold-standard tokenization are shown in Table 4. Careful feature engineering and Brown et al. (1992) clusters help Owoputi et al.'s (2013) feature-based POS taggers to outperform Ma and Hovy's (2016) neural network model.

Results of the Owoputi et al. (2013) tagger with non-greedy inference on automatically tokenized data are shown in Table 5. We see that errors in tokenization do propagate, but tagging performance is above 93% with our tokenizer.

3.3 Parser

Social media applications typically require processing large volumes of data, making speed an important consideration. We therefore begin with the neural greedy stack LSTM parser introduced by Ballesteros et al. (2015), which can parse a sentence in linear time and harnesses character representations to construct word vectors, which should help mitigate the challenge of spelling variation. We encourage the reader to refer their paper for more details about the model.

In our initial experiments, we train our parser on the combination of UD_English-EWT and TWEEBANK V2 training sets. Gold-standard tokenization and automatic POS tags are used. Automatic POS tags are assigned with 5-fold jackknifing. Hyperparameters are tuned on the TWEEBANK V2 development set. Unlabeled attachment score and labeled attachment score (including punctuation) are reported. All the experiments were run on a Xeon E5-2670 2.6 GHz machine.

Reimers and Gurevych (2017) and others have

[12] We use the updated version of Twokenizer from Owoputi et al. (2013).

[13] http://nlp.stanford.edu/data/glove.twitter.27B.zip

System	UAS	LAS	Kt/s
Kong et al. (2014)	81.4	76.9	0.3
Dozat et al. (2017)	81.8	77.7	1.7
Ballesteros et al. (2015)	80.2	75.7	2.3
Ensemble (20)	83.4	79.4	0.2
Distillation ($\alpha = 1.0$)	81.8	77.6	2.3
Distillation ($\alpha = 0.9$)	82.0	77.8	2.3
Distillation w/ exploration	82.1	77.9	2.3

Table 6: Dependency parser comparison on TWEEBANK V2 test set, with automatic POS tags. We use Ballesteros et al. (2015) as our baseline and build the ensemble and distilling model over it. The "Kt/s" column shows the parsing speed evaluated by thousands of tokens the model processed per second.

pointed out that neural network training is nondeterministic and depends on the seed for the random number generator. Our preliminary experiments confirm this finding, with a gap of 1.4 LAS on development data between the best (76.2) and worst (74.8) runs. To control for this effect, we report the average of five differently-seeded runs, for each of our models and the compared ones.

Initial results. The first section of Table 6 compares the stack LSTM with TWEEBOPARSER (the system of Kong et al., 2014) and the state-of-the-art parser in the CoNLL 2017 evaluations, due to Dozat et al. (2017). Kong et al.'s (2014) parser is a graph-based parser with lexical features and word cluster and it uses dual decomposition for decoding. The parser in Dozat et al. (2017) is also a graph-based parser but includes character-based word representations and uses a biaffine classifier to predict whether an attachment exists between two words. Both of the compared systems require superlinear runtime due to graph-based parsing. They are re-trained on the same data as our system. Our baseline lags behind by nearly two LAS points but runs faster than both of them.

Ensemble. Due to ambiguity in the training data—which most loss functions are not robust to (Frénay and Verleysen, 2014), including the log loss we use, following Ballesteros et al. (2015)—and due to the instability of neural network training, we follow Dietterich (2000) and consider an ensemble of twenty parsers trained using different random initialization. To parse at test time, the transition probabilities of the twenty members of the ensemble are averaged. The result achieves LAS of 79.4, outperforming all three systems above (Table 6).

Distillation. The shortcoming of the 20-parser ensemble is, of course, that it requires twenty times the runtime of a single greedy parser, making it the slowest system in our comparison. Kuncoro et al. (2016) proposed the distillation of 20 greedy transition-based parser into a single *graph-based* parser; they transformed the votes of the ensemble into a structured loss function. However, as Kuncoro et al. pointed out, it is not straightforward to use a structured loss in a *transition-based* parsing algorithm. Because fast runtime is so important for NLP on social media, we introduce a new way to distill our greedy ensemble into a single transition-based parser (the first such attempt, to our knowledge).

Our approach applies techniques from Hinton et al. (2015) and Kim and Rush (2016) to parsing. Note that training a transition-based parser typically involves the transformation of the training data into a sequence of "oracle" state-action pairs. Let $q(a \mid s)$ denote the distilled model's probability of an action a given parser state s; let $p(a \mid s)$ be the probability under the ensemble (i.e., the average of the 20 separately-trained ensemble members). To train the distilled model, we minimize the interpolation between their distillation loss and the conventional log loss:

$$\begin{aligned}\operatorname{argmin}_q \quad & \alpha \sum_i \underbrace{\sum_a -p(a \mid s_i) \cdot \log q(a \mid s_i)}_{\text{distillation loss}} \\ & + (1-\alpha) \sum_i \underbrace{-\log q(a_i \mid s_i)}_{\text{log loss}}\end{aligned} \tag{1}$$

Distilling from this parser leads to a single greedy transition-based parser with 77.8 LAS—better than past systems but worse than our more expensive ensemble. The effect of α is illustrated in Figure 5; generally paying closer attention to the ensemble, rather than the conventional log loss objective, leads to better performance.

Learning from exploration. When we set $\alpha = 1$, we eliminate the oracle from the estimation procedure (for the distilled model). This presents an opportunity to learn with *exploration*, by randomly sampling transitions from the ensemble, found useful in recent methods for training greedy models that use dynamic oracles (Goldberg and Nivre, 2012, 2013; Kiperwasser and Goldberg,

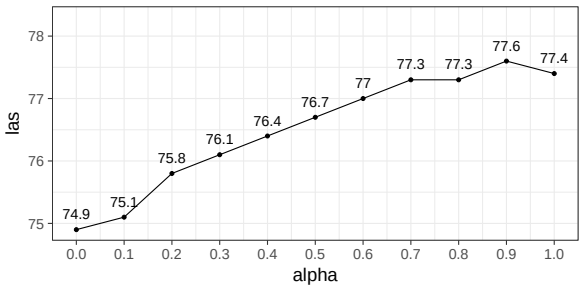

Figure 5: The effect of α on distillation.

Pipeline stage	Score	Ours	SOTA
Tokenization	F_1	98.3	97.3
POS tagging	F_1	93.3	92.2
UD parsing	*LAS* F_1	74.0	71.4

Table 7: Evaluating our pipeline against a state-of-the-art pipeline.

2016; Ballesteros et al., 2016). We find that this approach outperforms the conventional distillation model, coming in 1.5 points behind the ensemble (last line of Table 6).

Pipeline evaluation. Finally, we report our full pipeline's performance in Table 7. We also compare our model with a pipeline of the state-of-the-art systems (labeled "SOTA"): Stanford CoreNLP tokenizer,[14] Owoputi et al.'s (2013) tagger, and Dozat et al.'s (2017) parser. Our system differs from the state-of-the-art pipeline in the tokenization and parser components. From Table 7, our pipeline outperforms the state of the art when evaluated in pipeline manner. The results also emphasize the importance of tokenization: without gold tokenization UD parsing performance drops by about four points.

4 Conclusion

We study the problem of parsing tweets into Universal Dependencies. We adapt the UD guidelines to cover special constructions in tweets and create the TWEEBANK V2, which has 55,607 tokens. We characterize the disagreements among our annotators and argue that inherent ambiguity in this genre makes consistent annotation a challenge. Using this new treebank, we build a pipeline system to parse tweets into UD. We also propose a new method to distill an ensemble of 20 greedy parsers into a single one to overcome annotation noise without sacrificing efficiency. Our parser achieves an improvement of 2.2 in LAS over a strong baseline and outperforms other state-of-the-art parsers in both accuracy and speed.

[14] We choose the Stanford CoreNLP tokenizer in the spirit of comparing rule-based and statistical methods.

Robust Multilingual Part-of-Speech Tagging via Adversarial Training

Michihiro Yasunaga **Jungo Kasai** **Dragomir Radev**
Department of Computer Science, Yale University
{michihiro.yasunaga,jungo.kasai,dragomir.radev}@yale.edu

Abstract

Adversarial training (AT)[1] is a powerful regularization method for neural networks, aiming to achieve robustness to input perturbations. Yet, the specific effects of the robustness obtained from AT are still unclear in the context of natural language processing. In this paper, we propose and analyze a neural POS tagging model that exploits AT. In our experiments on the Penn Treebank WSJ corpus and the Universal Dependencies (UD) dataset (27 languages), we find that AT not only improves the overall tagging accuracy, but also 1) prevents over-fitting well in low resource languages and 2) boosts tagging accuracy for rare / unseen words. We also demonstrate that 3) the improved tagging performance by AT contributes to the downstream task of dependency parsing, and that 4) AT helps the model to learn cleaner word representations. 5) The proposed AT model is generally effective in different sequence labeling tasks. These positive results motivate further use of AT for natural language tasks.

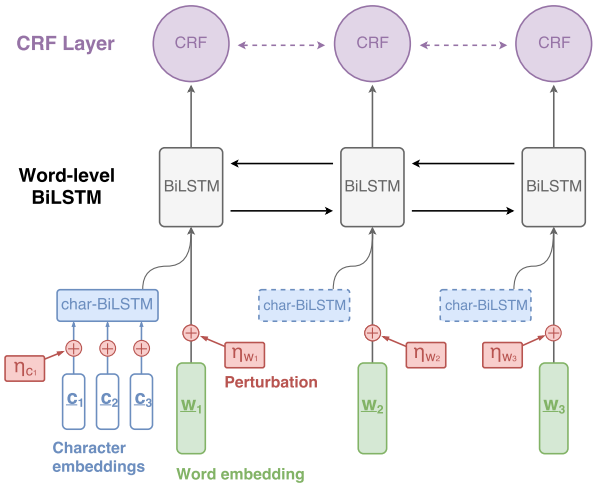

Figure 1: Illustration of our architecture for adversarial POS tagging. Given a sentence, we input the normalized word embeddings ($\underline{\boldsymbol{w}}_1, \underline{\boldsymbol{w}}_2, \underline{\boldsymbol{w}}_3$) and character embeddings (showing $\underline{\boldsymbol{c}}_1, \underline{\boldsymbol{c}}_2, \underline{\boldsymbol{c}}_3$ for w_1). Each word is represented by concatenating its word embedding and its character-level BiLSTM output. They are fed into the main BiLSTM-CRF network for POS tagging. In adversarial training, we compute and add the worst-case perturbation η to all the input embeddings for regularization.

1 Introduction

Recently, neural network-based approaches have become popular in many natural language processing (NLP) tasks including tagging, parsing, and translation (Chen and Manning, 2014; Bahdanau et al., 2015; Ma and Hovy, 2016). However, it has been shown that neural networks tend to be locally unstable and even tiny perturbations to the original inputs can mislead the models (Szegedy et al., 2014). Such maliciously perturbed inputs are called *adversarial examples*. *Adversarial training* (Goodfellow et al., 2015) aims to improve the robustness of a model to input perturbations by training on both unmodified examples and adversarial examples. Previous work (Goodfellow et al., 2015; Shaham et al., 2015) on image recognition has demonstrated the enhanced robustness of their models to unseen images via adversarial training and has provided theoretical explanations of the regularization effects.

Despite its potential as a powerful regularizer, adversarial training (AT) has yet to be explored extensively in natural language tasks. Recently, Miyato et al. (2017) applied AT on text classification, achieving state-of-the-art accuracy. Yet, the specific effects of the robustness obtained from AT are still unclear in the context of NLP. For example, research studies have yet to answer questions such as 1) how can we interpret perturbations or robustness on natural language inputs? 2) how are they related to linguistic factors like vocabulary statis-

[1]We distinguish AT from Generative Adversarial Networks (GANs).

Proceedings of NAACL-HLT 2018, pages 976–986
New Orleans, Louisiana, June 1 - 6, 2018.

tics? 3) are the effects of AT language-dependent? Answering such questions is crucial to understand and motivate the application of adversarial training on natural language tasks.

In this paper, spotlighting a well-studied core problem of NLP, we propose and carefully analyze a neural part-of-speech (POS) tagging model that exploits adversarial training. With a BiLSTM-CRF model (Huang et al., 2015; Ma and Hovy, 2016) as our baseline POS tagger, we apply adversarial training by considering perturbations to input word/character embeddings. In order to demystify the effects of adversarial training in the context of NLP, we conduct POS tagging experiments on multiple languages using the Penn Treebank WSJ corpus (Englsih) and the Universal Dependencies dataset (27 languages), with thorough analyses of the following points:

- Effects on different target languages
- Vocabulary statistics and tagging accuracy
- Influence on downstream tasks
- Representation learning of words

In our experiments, we find that our adversarial training model consistently outperforms the baseline POS tagger, and even achieves state-of-the-art results on 22 languages. Furthermore, our analyses reveal the following insights into adversarial training in the context of NLP:

- The regularization effects of adversarial training (AT) are general across different languages. AT can prevent overfitting especially well when training examples are scarce, providing an effective tool to process low resource languages.
- AT can boost the tagging performance for rare/unseen words and increase the sentence-level accuracy. This positively affects the performance of down-stream tasks such as dependency parsing, where low sentence-level POS accuracy can be a bottleneck (Manning, 2011).
- AT helps the network learn cleaner word embeddings, showing stronger correlations with their POS tags.

We argue that the effects of AT can be interpreted from the perspective of natural language. Finally, we demonstrate that the proposed AT model is generally effective across different sequence labeling tasks. This work therefore provides a strong motivation and basis for utilizing adversarial training in NLP tasks.

2 Related Work

2.1 POS Tagging

Part-of-speech (POS) tagging is a fundamental NLP task that facilitates downstream tasks such as syntactic parsing. While current state-of-the-art POS taggers (Ling et al., 2015; Ma and Hovy, 2016) yield accuracy over 97.5% on PTB-WSJ, there still remain issues. The per token accuracy metric is easy since taggers can easily assign correct POS tags to highly unambiguous tokens, such as punctuation (Manning, 2011). Sentence-level accuracy serves as a more realistic metric for POS taggers but it still remains low. Another problem with current POS taggers is that their accuracy deteriorates drastically on low resource languages and rare words (Plank et al., 2016). In this work, we demonstrate that adversarial training (AT) can mitigate these issues.

It is empirically shown that POS tagging performance can greatly affect downstream tasks such as dependency parsing (Dozat et al., 2017). In this work, we also demonstrate that the improvements obtained from our AT POS tagger actually contribute to dependency parsing. Nonetheless, parsing with gold POS tags still yields better results, bolstering the view that POS tagging is an essential task in NLP that needs further development.

2.2 Adversarial Training

The concept of adversarial training (Szegedy et al., 2014; Goodfellow et al., 2015) was originally introduced in the context of image classification to improve the robustness of a model by training on input images with malicious perturbations. Previous work (Goodfellow et al., 2015; Shaham et al., 2015; Wang et al., 2017) has provided a theoretical framework to understand adversarial examples and the regularization effects of adversarial training (AT) in image recognition.

Recently, Miyato et al. (2017) applied AT to a natural language task (text classification) by extending the concept of adversarial perturbations to word embeddings. Wu et al. (2017) further explored the possibility of AT in relation extraction. Both report improved performance on their tasks via AT, but the specific effects of AT have yet to be analyzed. In our work, we aim to address this issue by providing detailed analyses on the effects of AT from the perspective of NLP, such as different languages, vocabulary statistics, word embedding distribution, and aim to motivate future research

that exploits AT in NLP tasks.

AT is related to other regularization methods that add noise to data such as dropout (Srivastava et al., 2014) and its variant for NLP tasks, word dropout (Iyyer et al., 2015). Xie et al. (2017) discuss various data noising techniques for language modeling. While these methods produce random noise, AT generates perturbations that the current model is particularly vulnerable to, and thus is claimed to be effective (Goodfellow et al., 2015).

It should be noted that while related in name, adversarial training (AT) differs from Generative Adversarial Networks (GANs) (Goodfellow et al., 2014). GANs have already been applied to NLP tasks such as dialogue generation (Li et al., 2017) and transfer learning (Kim et al., 2017; Gui et al., 2017). Adversarial training also differs from adversarial *evaluation*, recently proposed for reading comprehension tasks (Jia and Liang, 2017).

3 Method

In this section, we introduce our baseline POS tagging model and explain how we implement adversarial training on top.

3.1 Baseline POS Tagging Model

Following the recent top-performing models for sequence labeling tasks (Plank et al., 2016; Lample et al., 2016; Ma and Hovy, 2016), we employ a Bi-directional LSTM-CRF model as our baseline (see Figure 1 for an illustration).

Character-level BiLSTM. Prior work has shown that incorporating character-level representations of words can boost POS tagging accuracy by capturing morphological information present in each language. Major neural character-level models include the character-level CNN (Ma and Hovy, 2016) and (Bi)LSTM (Dozat et al., 2017). A Bi-directional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) processes each sequence both forward and backward to capture sequential information, while preventing the vanishing / exploding gradient problem. We observed that the character-level BiLSTM outperformed the CNN by 0.1% on the PTB-WSJ development set, and hence in all of our experiments we use the character-level BiLSTM. Specifically, we generate a character-level representation for each word by feeding its character embeddings into the BiLSTM and obtaining the concatenated final states.

Word-level BiLSTM. Each word in a sentence is represented by concatenating its word embedding and its character-level representation. They are fed into another level of BiLSTM (word-level BiLSTM) to process the entire sentence.

CRF. In sequence labeling tasks it is beneficial to consider the correlations between neighboring labels and jointly decode the best chain of labels for a given sentence. With this motivation, we apply a conditional random field (CRF) (Lafferty et al., 2001) on top of the word-level BiLSTM to perform POS tag inference with global normalization, addressing the "label bias" problem. Specifically, given an input sentence, we pass the output sequence of the word-level BiLSTM to a first-order chain CRF to compute the conditional probability of the target label sequence:

$$p(\boldsymbol{y} \mid \boldsymbol{s}; \boldsymbol{\theta})$$

where $\boldsymbol{\theta}$ represents all of the model parameters (in the BiLSTMs and CRF), $\boldsymbol{s}$ and $\boldsymbol{y}$ denote the input embeddings and the target POS tag sequence, respectively, for the given sentence.

For training, we minimize the negative log-likelihood (loss function)

$$L(\boldsymbol{\theta}; \boldsymbol{s}, \boldsymbol{y}) = -\log p(\boldsymbol{y} \mid \boldsymbol{s}; \boldsymbol{\theta}) \quad (1)$$

with respect to the model parameters. Decoding searches for the POS tag sequence $\boldsymbol{y}^*$ with the highest conditional probability using the Viterbi algorithm. For more detail about the BiLSTM-CRF formulation, refer to Ma and Hovy (2016).

3.2 Adversarial Training

Adversarial training (Goodfellow et al., 2015) is a powerful regularization method, primarily explored in image recognition to improve the robustness of classifiers to input perturbations. Given a classifier, we first generate input examples that are very close to original inputs (so should yield the same labels) yet are likely to be misclassified by the current model. Specifically, these *adversarial examples* are generated by adding small perturbations to the inputs in the direction that significantly increases the loss function of the classifier (*worst-case* perturbations). Then, the classifier is trained on the mixture of clean examples and adversarial examples to improve the stability to input perturbations. In this work, we incorporate adversarial training into our baseline POS tagger, aiming to achieve better regularization effects and to provide their interpretations in the context of NLP.

Generating adversarial examples. Adversarial training (AT) considers continuous perturbations to inputs, so we define perturbations at the level of dense word / character embeddings rather than one-hot vector representations, similarly to Miyato et al. (2017). Specifically, given an input sentence, we consider the concatenation of all the word/character embeddings in the sentence: $\boldsymbol{s} = [\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{c}_1, \boldsymbol{c}_2, \ldots]$. To prepare an adversarial example, we aim to generate the worst-case perturbation of a small bounded norm ϵ that maximizes the loss function L of the current model:

$$\boldsymbol{\eta} = \underset{\boldsymbol{\eta}': \|\boldsymbol{\eta}'\|_2 \leq \epsilon}{\arg\max}\ L(\hat{\boldsymbol{\theta}}; \boldsymbol{s} + \boldsymbol{\eta}', \boldsymbol{y})$$

where $\hat{\boldsymbol{\theta}}$ is the current value of the model parameters, treated as a constant, and $\boldsymbol{y}$ denotes the target labels. Since the exact computation of such $\boldsymbol{\eta}$ is intractable in complex neural networks, we employ the Fast Gradient Method (Liu et al., 2017; Miyato et al., 2017) i.e. first order approximation to obtain an approximate worst-case perturbation of norm ϵ, by a single gradient computation:

$$\boldsymbol{\eta} = \epsilon\, \boldsymbol{g}/\|\boldsymbol{g}\|_2, \text{ where } \boldsymbol{g} = \nabla_{\boldsymbol{s}} L(\hat{\boldsymbol{\theta}}; \boldsymbol{s}, \boldsymbol{y}) \quad (2)$$

ϵ is a hyperparameter to be determined in the development dataset. Note that the perturbation $\boldsymbol{\eta}$ is generated in the direction that significantly increases the loss L. We find such $\boldsymbol{\eta}$ against the current model parameterized by $\hat{\boldsymbol{\theta}}$, at each training step, and construct an adversarial example by

$$\boldsymbol{s}_{\text{adv}} = \boldsymbol{s} + \boldsymbol{\eta}$$

However, if we do not restrict the norm of word / character embeddings, the model could trivially learn embeddings of large norms to make the perturbations insignificant. To prevent this issue, we normalize word/character embeddings so that they have mean 0 and variance 1 for every entry, as in Miyato et al. (2017). The normalization is performed every time we feed input embeddings into the LSTMs and generate adversarial examples. To ensure a fair comparison, we also normalize input embeddings in our baseline model.

While Miyato et al. (2017) set the norm of a perturbation ϵ (Eq 2) to be a fixed value for all input sentences, to generate adversarial examples for an entire sentence of a variable length and to include character embeddings besides word embeddings, we make the perturbation size ϵ adaptive to the dimension of the concatenated input embedding $\boldsymbol{s} \in \mathbb{R}^D$. We set ϵ to be $\alpha\sqrt{D}$ (i.e., proportional to $\sqrt{D}$), as the expected squared norm of $\boldsymbol{s}$ after the embedding normalization is D. The scaling factor α is selected from $\{0.001, 0.005, 0.01, 0.05, 0.1\}$ based on the development performance in each treebank. We used 0.01 for PTB-WSJ and UD-Spanish, and 0.05 for the rest. Note that $\alpha = 0$ would generate no noise (identical to the baseline); if $\alpha = 1$, the generated adversarial perturbation would have a norm comparable to the original embedding, which could change the semantics of the input sentence (Wu et al., 2017). Hence, the optimal perturbation scale α should lie in between and be small enough to preserve the semantics of the original input.

Adversarial training. At each training step, we generate adversarial examples against the current model, and train on the mixture of clean examples and adversarial examples to achieve robustness to input perturbations. To this end, we define the loss function for adversarial training as:

$$\tilde{L} = \gamma L(\boldsymbol{\theta}; \boldsymbol{s}, \boldsymbol{y}) + (1 - \gamma) L(\boldsymbol{\theta}; \boldsymbol{s}_{\text{adv}}, \boldsymbol{y})$$

where $L(\boldsymbol{\theta}; \boldsymbol{s}, \boldsymbol{y})$, $L(\boldsymbol{\theta}; \boldsymbol{s}_{\text{adv}}, \boldsymbol{y})$ represent the loss from a clean example and the loss from its adversarial example, respectively, and γ determines the weighting between them. We used $\gamma = 0.5$ in all our experiments. This objective function can be optimized with respect to the model parameters $\boldsymbol{\theta}$, in the same manner as the baseline model.

4 Experiments

To fully analyze the effects of adversarial training, we train and evaluate our baseline/adversarial POS tagging models on both a standard English dataset and a multilingual dataset.

4.1 Datasets

As a standard English dataset, we use the Wall Street Journal (WSJ) portion of the Penn Treebank (PTB) (Marcus et al., 1993), containing 45 different POS tags. We adopt the standard split: sections 0-18 for training, 19-21 for development and 22-24 for testing (Collins, 2002; Manning, 2011).

For multilingual POS tagging experiments, to compare with prior work, we use treebanks from Universal Dependencies (UD) v1.2 (Nivre et al., 2015) (17 POS) with the given data splits. We experiment on languages for which pre-trained Polyglot word embeddings (Al-Rfou et al., 2013) are available, resulting in 27 languages listed in Table 2. We regard languages with less than 60k tokens of training data as low-resource (Table 2, bottom), as in Plank et al. (2016).

Model	Accuracy
Toutanova et al. (2003)	97.27
Manning (2011)	97.28

Ours – Adversarial	97.58

Table 1: POS tagging accuracy on the PTB-WSJ test set, with other top-performing systems.

4.2 Training & Evaluation Details

Model settings. We initialize word embeddings with 100-dimensional GloVe (Pennington et al., 2014) for English, and with 64-dimensional Polyglot (Al-Rfou et al., 2013) for other languages. We use 30-dimensional character embeddings, and set the state sizes of character/word-level BiLSTM to be 50, 200 for English, 50, 100 for low resource languages, and 50, 150 for other languages. The model parameters and character embeddings are randomly initialized, as in Ma and Hovy (2016). We apply dropout (Srivastava et al., 2014) to input embeddings and BiLSTM outputs for both baseline and adversarial training, with dropout rate 0.5.

Optimization. We train the model parameters and word/character embeddings by the mini-batch stochastic gradient descent (SGD) with batch size 10, momentum 0.9, initial learning rate 0.01 and decay rate 0.05. We also use a gradient clipping of 5.0 (Pascanu et al., 2012). The models are trained with early stopping (Caruana et al., 2001) based on the development performance.

Evaluation. We evaluate per token tagging accuracy on test sets. We repeat the experiment three times and report the statistical significance.

4.3 Results

PTB-WSJ dataset. Table 1 shows the POS tagging results. As expected, our baseline (BiLSTM-CRF) model (accuracy 97.54%) performs on par with other state-of-the-art systems. Built upon this baseline, our adversarial training (AT) model reaches accuracy 97.58% thanks to its regularization power, outperforming recent POS taggers except Ling et al. (2015). The improvement over the baseline is statistically significant, with p-value $<$ 0.05 on the t-test. We provide additional analysis on this result in later sections.

Table 2: POS tagging accuracy (test) for 27 UD v1.2 treebanks, with other recent works, Plank et al. (2016), Berend (2017) and Nguyen et al. (2017). For Plank et al. (2016), we include the traditional baselines TNT and CRF, and their state-of-the-art model that employs a multi-task BiLSTM. Languages with • are morphologically rich, and those at the bottom ('el' to 'ta') are low-resource, containing less than 60k tokens in their training sets.

Multilingual dataset (UD). Experimental results are summarized in Table 2. Our AT model shows clear advantages over the baseline in all of the 27 languages (average improvement ∼0.25%; see the two shaded columns). Considering that our baseline (BiLSTM-CRF) is already a top performing model for POS tagging, these improvements made by AT are substantial. The improvements are also statistically significant for all the languages, with p-value $<$ 0.05 on the t-test, suggesting that the regularization by AT is generally effective across different languages. Moreover, our AT model achieves state-of-the-art on nearly all of the languages, except the five where Plank et al. (2016)'s multi-task BiLSTM yielded better results. Among the five, most languages are morphologically rich (•).[2] We suspect that their joint training of word rarity may be of particular help in processing morphologically complex words.

[2]We followed the criteria of morphological richness used in Nguyen et al. (2017).

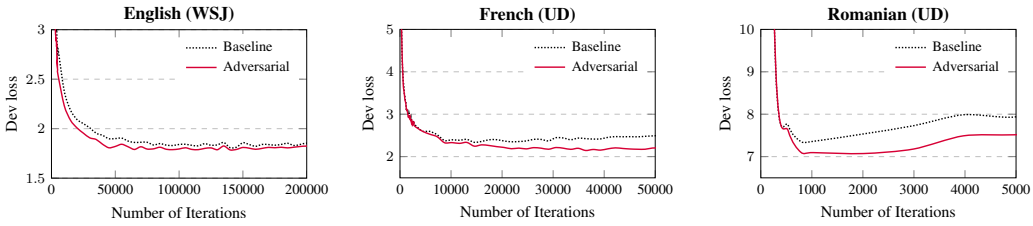

Figure 2: Learning curves for three representative languages (Romanian is low-resource). We show the transition of loss (defined in Eq 1) on the development sets.

Table 4: POS tagging accuracy (test) on *neighboring* words. We cluster all words in the test set in the same way as Table 3 and consider the tagging performance on the neighbors (left and right) of these words in the test text.

Additionally, we see that our AT model achieves notably large improvements over the baseline in resource-poor languages (the bottom of Table 2), with average improvement 0.35%, as compared to that for resource-rich languages, 0.20%. To further visualize the regularization effects, we present the learning curves for three representative languages, English (WSJ), French (UD-fr) and Romanian (UD-ro, low-resource), based on the development loss (see Figure 2). For all the three languages, we can observe that the AT model (red solid line) prevents overfitting better than the baseline (black dotted line), and this advantage is more significant in low resource languages. For example, in Romanian, the baseline model starts to increase development loss after 1,000 iterations even with dropout, whereas the AT model keeps improving until 2,500 iterations, achieving notably lower development loss (0.4 down). These results illustrate that AT can prevent overfitting especially well on small datasets and can augment the regularization power beyond dropout. AT can also be viewed as an effective means of data augmentation, where we generate and train with new examples the current model is particularly vulnerable to at every time step, enhancing the robustness of the model. AT can therefore be a promising tool to process low resource languages.

5 Analysis

In the previous sections, we demonstrated the regularization power of adversarial training (AT) on different languages, based on the overall POS tagging performance and learning curves. In this section, we conduct further analyses on the robustness of AT from NLP specific aspects such as word statistics, sequence modeling, downstream tasks, and word representation learning.

We find that AT can boost tagging accuracy on rare words and neighbors of unseen words (§5.1). Furthermore, this robustness against rare / unseen words leads to better sentence-level accuracy and downstream dependency parsing (§5.2). We illustrate these findings using two major languages, English (WSJ) and French (UD), which have substantially large training and testing data to discuss vocabulary statistics and sentence-level performance. Finally, we study the effects of AT on word representation learning (§5.3), and the applicability of AT to different sequential tasks (§5.4).

5.1 Word-level Analysis

Poor tagging accuracy on rare/unseen words is one of the bottlenecks in current POS taggers (Manning, 2011; Plank et al., 2016). Aiming to reveal

English (WSJ)

Table 5: Sentence-level accuracy and downstream dependency parsing performance by our baseline/adversarial POS taggers.

the effects of AT on rare/unseen words, we analyze tagging performance at the word level, considering vocabulary statistics.

Word frequency. To define rare/unseen words, we consider each word's frequency of occurrence in the training set. We categorize all words in the test set based on this frequency and study the test tagging accuracy for each group (see Table 3).[3] In both languages, the AT model achieves large improvements over the baseline on rare words (e.g., frequency 1-10 in training), as opposed to more frequent words. This result again corroborates the data augmentation power of AT under small training examples. On the other hand, we did not observe meaningful improvements on unseen words (frequency 0 in training). A possible explanation is that AT can facilitate the learning of words with at least a few occurrences in training (rare words), but is not particularly effective in inferring the POS tags of words for which no training examples are given (unseen words).

Neighboring words. One important characteristic of natural language tasks is the sequential nature of inputs (i.e., sequence of words), where each word influences the function of its neighboring words. Since our model uses BiLSTM-CRF for that reason, we also study the tagging performance on the neighbors of rare/unseen words, and analyze the effects of AT with the sequence model in mind. In Table 4, we cluster all words in the test set based on their frequency in training again, and consider the tagging accuracy on the neighbors (left and right) of these words in the test text. We observe that AT tends to achieve large improvements over the baseline on the neighbors of unseen words (training frequency 0), while the improvements on the neighbors of more frequent words remain moderate. Our AT model thus exhibits strong stability to uncertain neighbors, as compared to the baseline. We suspect that because we generate adversarial examples against entire input sentences, training with adversarial examples makes the model more robust not only to perturbations in each word but also to perturbations in its neighboring words, leading to greater stability to uncertain neighbors.

[3]To conduct the analysis, we picked the median result from the three repeated experiments.

5.2 Sentence-level & Downstream Analysis

In the word-level analysis, we showed that AT can boost tagging accuracy on rare words and the neighbors of unseen words, enhancing overall robustness on rare/unseen words. In this section, we discuss the benefit of our improved POS tagger in a major downstream task, dependency parsing.

Most of the recent state-of-the-art dependency parsers take predicted POS tags as input (e.g. Chen and Manning (2014); Andor et al. (2016); Dozat and Manning (2017)). Dozat et al. (2017) empirically show that their dependency parser gains significant improvements by using POS tags predicted by a Bi-LSTM POS tagger, while POS tags predicted by the UDPipe tagger (Straka et al., 2016) do not contribute to parsing performance as much. This observation illustrates that POS tagging performance has a great influence on dependency parsing, motivating the hypothesis that the POS tagging improvements gained from our adversarial training help dependency parsing.

To test the hypothesis, we consider three settings in dependency parsing of English and French: using POS tags predicted by the baseline model, using POS tags predicted by the AT model, and using gold POS tags. For English (PTB-WSJ), we first convert the treebank into Stanford Dependencies (SD) using Stanford CoreNLP (ver 3.8.0) (Manning et al., 2014), and then apply two well-known dependency parsers: Stanford Parser (ver 3.5.0) (Chen and Manning, 2014) and Parsey McParseface (SyntaxNet) (Andor et al., 2016). For French (UD), we use Parsey Universal from SyntaxNet. The three parsers are all publicly available and pre-trained on corresponding treebanks.

Table 5 shows the results of the experiments. We can observe improvements in both languages by using the POS tags predicted by our AT POS tagger. As Manning (2011) points out, when pre-

English (WSJ)

POS Cluster	NN	VB	JJ	RB	Avg.
1) Initial (GloVe)	0.243	0.426	0.220	0.549	0.359
2) Baseline	0.280	0.431	**0.309**	0.667	0.422
3) Adversarial	**0.281**	**0.436**	0.306	**0.675**	**0.424**

French (UD)

POS Cluster	NOUN	VERB	ADJ	ADV	Avg.
1) Initial (polyglot)	0.215	0.233	0.210	0.540	0.299
2) Baseline	0.258	0.271	0.262	0.701	0.373
3) Adversarial	**0.263**	**0.272**	**0.263**	**0.720**	**0.379**

Table 6: Cluster tightness evaluation for word embeddings, based on the cosine similarity measure. Higher scores indicate better clustering (cleaner word vector distribution). Each row corresponds to word vectors 1) at the beginning, 2) after baseline training, and 3) after adversarial training.

English (WSJ)

Perturbation scale α	0	0.001	0.01	0.05	0.1	0.5
Avg. cluster tightness	0.422	0.423	0.424	0.429	**0.436**	0.429

Table 7: Average cluster tightness for word embeddings trained with varied perturbation scale α (0 indicates baseline training).

dicted POS tags are used for downstream dependency parsing, a single bad mistake in a sentence can greatly damage the usefulness of the POS tagger. The robustness of our AT POS tagger against rare/unseen words helps to mitigate such an issue. This advantage can also be observed from the AT POS tagger's notably higher sentence-level accuracy than the baseline (see Table 5 left). Nonetheless, gold POS tags still yield better parsing results as compared to the baseline/AT POS taggers, supporting the claim that POS tagging needs further improvement for downstream tasks.

5.3 Effects on Representation Learning

Next, we perform an analysis on representation learning of words (word embeddings) for the English (PTB-WSJ) and French (UD) experiments. We hypothesize that adversarial training (AT) helps to learn better word embeddings so that the POS tag prediction of a word cannot be influenced by a small perturbation in the input embedding.

To verify this hypothesis, we cluster all words in the test set based on their correct POS tags[4] and evaluate the tightness of the word vector distribution within each cluster. We compare this clustering quality among the three settings: 1) beginning (initialized with GloVe or Polyglot), 2) after baseline training (50 epochs), and 3) after adversarial training (50 epochs), to study the effects of AT on word representation learning.

For evaluating the tightness of word vector distribution, we employ the cosine similarity metric, which is widely used as a measure of the closeness between two word vectors (e.g., Mikolov et al. (2013); Pennington et al. (2014)). To measure the tightness of each cluster, we compute the cosine similarity for every pair of words within, and then take the average. We also report the average tightness across all the clusters.

The evaluation results are summarized in Table 6. We report the tightness scores for the four major clusters: *noun*, *verb*, *adjective*, and *adverb* (from left to right). As can be seen from the table, for both languages, adversarial training (AT) results in cleaner word embedding distributions than the baseline, with a higher cosine similarity within each POS cluster, and with a clear advantage in the average tightness across all the clusters. In other words, the learned word vectors show stronger correlations with their POS tags. This result confirms that training with adversarial examples can help to learn cleaner word embeddings so that the meaning / grammatical function of a word cannot be altered by a small perturbation in its embedding. This analysis provides a means to interpret the robustness to input perturbations, from the perspective of NLP.

Relation with perturbation size ϵ. We also study how the size of added perturbations influences word representation learning in adversarial training. Recall that we set the norm of a perturbation ϵ to be $\alpha\sqrt{D}$, where D is the dimension of the concatenated input embeddings (see §3.2). For instance, $\alpha = 0$ would produce no noise; $\alpha = 1$ would generate a perturbation of a norm equivalent to the original word embeddings. We hypothesize that AT facilitates word representation learning when α is small enough to preserve the semantics of input words, but can hinder the learning when α is too large. To test the hypothesis, we repeat the clustering evaluation for word embeddings trained with varied perturbation scale α: 0, 0.001, 0.01, 0.05, 0.1, 0.5 (see Table 7). We observe that the quality of learned word embedding distribution keeps improving as α goes up from 0 to 0.1, but starts to drop around $\alpha = 0.5$. We also find that this optimal α in word embedding learning (i.e., 0.1) is larger than the α which

[4] We excluded words with multiple tags in the test text.

yielded the best tagging performance on development sets (i.e., 0.01 or 0.05). A possible explanation is that while word embeddings can adapt to relatively large α (e.g., 0.1) during training, as adversarial perturbations are generated at the embedding level, such α could change the semantics of the input from the current tagging model's perspective and hinder the training of *tagging*.

5.4 Other Sequence Labeling Tasks

Finally, to further confirm the applicability of AT, we experiment with our BiLSTM-CRF AT model in different sequence labeling tasks: chunking and named entity recognition (NER).

Chunking can be performed as a sequence labeling task that assigns a chunking tag (B-NP, I-VP, etc.) to each word. We conduct experiments on the CoNLL 2000 shared task with the standard data split: PTB-WSJ Sections 15-18 for training and 20 for testing. We use Section 19 as the development set and employ the IOBES tagging scheme, following Hashimoto et al. (2017).

NER aims to assign an entity type to each word, such as *person*, *location*, *organization*, and *misc*. We conduct experiments on the CoNLL-2003 (English) shared task (Tjong Kim Sang and De Meulder, 2003), adopting the IOBES tagging scheme as in (Lample et al., 2016; Ma and Hovy, 2016).

The results are summarized in Table 8 and 9. AT enhanced F1 score from the baseline BiLSTM-CRF model's 95.18 to 95.25 for chunking, and from 91.22 to 91.56 for NER, also significantly outperforming Ma and Hovy (2016). These improvements made by AT are bigger than that for English POS tagging, most likely due to the larger room for improvement in chunking and NER. The improvements are again statistically significant, with p-value < 0.05 on the t-test. The experimental results suggest that the proposed adversarial training scheme is generally effective across different sequence labeling tasks.

Our BiLSTM-CRF AT model did not reach the performance by Hashimoto et al. (2017)'s multi-task model and Peters et al. (2017)'s state-of-the-art system that incorporates pretrained language models. It would be interesting future work to combine the strengths of these joint models (e.g., syntactic and semantic aids) and adversarial training (e.g., robustness).

6 Conclusion

We proposed and carefully analyzed a POS tagging model that exploits adversarial training (AT). In our multilingual experiments, we find that AT achieves substantial improvements on all the languages tested, especially on low resource ones. AT also enhances the robustness to rare/unseen words and sentence-level accuracy, alleviating the major issues of current POS taggers, and contributing to the downstream task, dependency parsing. Furthermore, our analyses on different languages, word/neighbor statistics and word representation learning reveal the effects of AT from the perspective of NLP. The proposed AT model is applicable to general sequence labeling tasks. This work therefore provides a strong basis and motivation for utilizing AT in natural language tasks.

Abstract

Code-switching is a phenomenon of mixing grammatical structures of two or more languages under varied social constraints. The code-switching data differ so radically from the benchmark corpora used in NLP community that the application of standard technologies to these data degrades their performance sharply. Unlike standard corpora, these data often need to go through additional processes such as language identification, normalization and/or back-transliteration for their efficient processing. In this paper, we investigate these indispensable processes and other problems associated with syntactic parsing of code-switching data and propose methods to mitigate their effects. In particular, we study dependency parsing of code-switching data of Hindi and English multilingual speakers from Twitter. We present a treebank of Hindi-English code-switching tweets under Universal Dependencies scheme and propose a neural stacking model for parsing that efficiently leverages part-of-speech tag and syntactic tree annotations in the code-switching treebank and the preexisting Hindi and English treebanks. We also present normalization and back-transliteration models with a decoding process tailored for code-switching data. Results show that our neural stacking parser is 1.5% LAS points better than the augmented parsing model and our decoding process improves results by 3.8% LAS points over the first-best normalization and/or back-transliteration.

1 Introduction

Code-switching[1] (henceforth CS) is the juxtaposition, within the same speech utterance, of grammatical units such as words, phrases, and clauses belonging to two or more different languages (Gumperz, 1982). The phenomenon is prevalent in multilingual societies where speakers share more than one language and is often prompted by multiple social factors (Myers-Scotton, 1995). Moreover, code-switching is mostly prominent in colloquial language use in daily conversations, both online and offline.

Most of the benchmark corpora used in NLP for training and evaluation are based on edited monolingual texts which strictly adhere to the norms of a language related, for example, to orthography, morphology, and syntax. Social media data in general and CS data, in particular, deviate from these norms implicitly set forth by the choice of corpora used in the community. This is the reason why the current technologies often perform miserably on social media data, be it monolingual or mixed language data (Solorio and Liu, 2008b; Vyas et al., 2014; Çetinoğlu et al., 2016; Gimpel et al., 2011; Owoputi et al., 2013; Kong et al., 2014). CS data offers additional challenges over the monolingual social media data as the phenomenon of code-switching transforms the data in many ways, for example, by creating new lexical forms and syntactic structures by mixing morphology and syntax of two languages making it much more diverse than any monolingual corpora (Çetinoğlu et al., 2016). As the current computational models fail to cater to the complexities of CS data, there is often a need for dedicated techniques tailored to its specific characteristics.

Given the peculiar nature of CS data, it has been widely studied in linguistics literature (Poplack, 1980; Gumperz, 1982; Myers-Scotton, 1995), and more recently, there has been a surge in studies concerning CS data in NLP as well (Solorio and Liu, 2008a,a; Vyas et al., 2014; Sharma et al., 2016; Rudra et al., 2016; Joshi et al., 2016; Bhat et al., 2017; Chandu et al., 2017; Rijhwani et al.,

[1] Code-mixing is another term in the linguistics literature used interchangeably with code-switching. Both terms are often used to refer to the same or similar phenomenon of mixed language use.

Proceedings of NAACL-HLT 2018, pages 987–998
New Orleans, Louisiana, June 1 - 6, 2018.

2017; Guzmán et al., 2017, and others). Besides the individual computational works, a series of shared-tasks and workshops on preprocessing and shallow syntactic analysis of CS data have also been conducted at multiple venues such as Empirical Methods in NLP (EMNLP 2014 and 2016), International Conference on NLP (ICON 2015 and 2016) and Forum for Information Retrieval Evaluation (FIRE 2015 and 2016). Most of these works have attempted to address preliminary tasks such as language identification, normalization and/or back-transliteration as these data often need to go through these additional processes for their efficient processing. In this paper, we investigate these indispensable processes and other problems associated with syntactic parsing of code-switching data and propose methods to mitigate their effects. In particular, we study dependency parsing of Hindi-English code-switching data of multilingual Indian speakers from Twitter. Hindi-English code-switching presents an interesting scenario for the parsing community. Mixing among typologically diverse languages will intensify structural variations which will make parsing more challenging. For example, there will be many sentences containing: (1) both SOV and SVO word orders[2], (2) both head-initial and head-final genitives, (3) both prepositional and postpositional phrases, etc. More importantly, none among the Hindi and English treebanks would provide any training instance for these mixed structures within individual sentences. In this paper, we present the first code-switching treebank that provides syntactic annotations required for parsing mixed-grammar syntactic structures. Moreover, we present a parsing pipeline designed explicitly for Hindi-English CS data. The pipeline comprises of several modules such as a language identification system, a back-transliteration system, and a dependency parser. The gist of these modules and our overall research contributions are listed as follows:

- back-transliteration and normalization models based on encoder-decoder frameworks with sentence decoding tailored for code-switching data;
- a dependency treebank of Hindi-English code-switching tweets under Universal Dependencies scheme; and
- a neural parsing model which learns POS tagging and parsing jointly and also incorporates knowledge from the monolingual treebanks using neural stacking.

[2]Order of Subject, Object and Verb in transitive sentences.

2 Preliminary Tasks

As preliminary steps before parsing of CS data, we need to identify the language of tokens and normalize and/or back-transliterate them to enhance the parsing performance. These steps are indispensable for processing CS data and without them the performance drops drastically as we will see in Results Section. We need normalization of non-standard word forms and back-transliteration of Romanized Hindi words for addressing out-of-vocabulary problem, and lexical and syntactic ambiguity introduced due to contracted word forms. As we will train separate normalization and back-transliteration models for Hindi and English, we need language identification for selecting which model to use for inference for each word form separately. Moreover, we also need language information for decoding best word sequences.

2.1 Language Identification

For language identification task, we train a multilayer perceptron (MLP) stacked on top of a recurrent bidirectional LSTM (Bi-LSTM) network as shown in Figure 1.

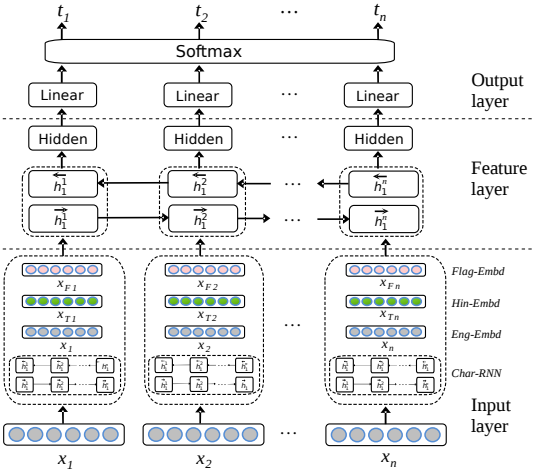

Figure 1: Language identification network

We represent each token by a concatenated vector of its English embedding, back-transliterated Hindi embedding, character Bi-LSTM embedding and flag embedding (English dictionary flag and word length flag with length bins of 0-3, 4-6, 7-10, and 10-all). These concatenated vectors are passed to a Bi-LSTM network to generate a sequence of

hidden representations which encode the contextual information spread across the sentence. Finally, output layer uses the feed-forward neural network with a softmax function for a probability distribution over the language tags. We train the network on our CS training set concatenated with the data set provided in ICON 2015[3] shared task (728 Facebook comments) on language identification and evaluate it on the datasets from Bhat et al. (2017). We achieved the state-of-the-art performance on both development and test sets (Bhat et al., 2017). The results are shown in Table 1.

Label	Precision	Recall	F1-Score	count
hi	97.76	98.09	97.92	1465

(Bhat et al., 2017)	-	96.10	-	-

Table 1: Language Identification results on CS test set.

2.2 Normalization and Back-transliteration

We learn two separate but similar character-level models for normalization-cum-transliteration of noisy Romanized Hindi words and normalization of noisy English words. We treat both normalization and back-transliteration problems as a general sequence to sequence learning problem. In general, our goal is to learn a mapping for non-standard English and Romanized Hindi word forms to standard forms in their respective scripts. In case of Hindi, we address the problem of normalization and back-transliteration of Romanized Hindi words using a single model. We use the attention-based encoder-decoder model of Luong (Luong et al., 2015) with global attention for learning. For Hindi, we train the model on the transliteration pairs (87,520) from the Libindic transliteration project[4] and Brahmi-Net (Kunchukuttan et al., 2015) which are further augmented with noisy transliteration pairs (1,75,668) for normalization. Similarly, for normalization of noisy English words, we train the model on noisy word forms (4,29,715) synthetically generated from the English vocabulary. We use simple rules such as dropping non-initial vowels and replacing consonants based on their phonological proximity to generate synthetic data for normalization. Figure 2 shows some of the noisy forms generated from standard word forms using simple and finite rules which include vowel elision (`please` → `pls`), interchanging similar consonants and vowels (`cousin` → `couzin`), replacing consonant or vowel clusters with a single letter (`Twitter` → `Twiter`), etc. From here onwards, we will refer to both normalization and back-transliteration as normalization.

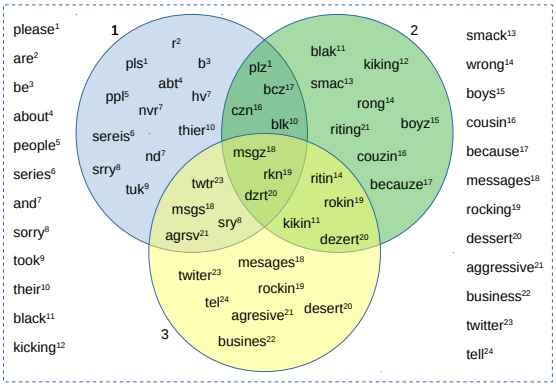

Figure 2: Synthetic normalization pairs generated for a sample of English words using hand crafted rules.

At inference time, our normalization models will predict the most likely word form for each input word. However, the single-best output from the model may not always be the best option considering an overall sentential context. Contracted word forms in social media content are quite often ambiguous and can represent different standard word forms. For example, noisy form '`pt`' can expand to different standard word forms such as '`put`', '`pit`', '`pat`', '`pot`' and '`pet`'. The choice of word selection will solely depend on the sentential context. To select contextually relevant forms, we use exact search over n-best normalizations from the respective models extracted using beam-search decoding. The best word sequence is selected using the Viterbi decoding over b^n word sequences scored by a trigram language model. b is the size of beam-width and n is the sentence length. The language models are trained on the monolingual data of Hindi and English using KenLM toolkit (Heafield et al., 2013). For each word, we extract five best normalizations (b=5). Decoding the best word sequence is a non-trivial problem for CS data due to lack of normalized and back-transliterated CS data for training a language model. One obvious solution is to apply decoding on individual language fragments in a CS sentence (Dutta et al., 2015). One major prob-

[4] https://github.com/libindic/indic-trans

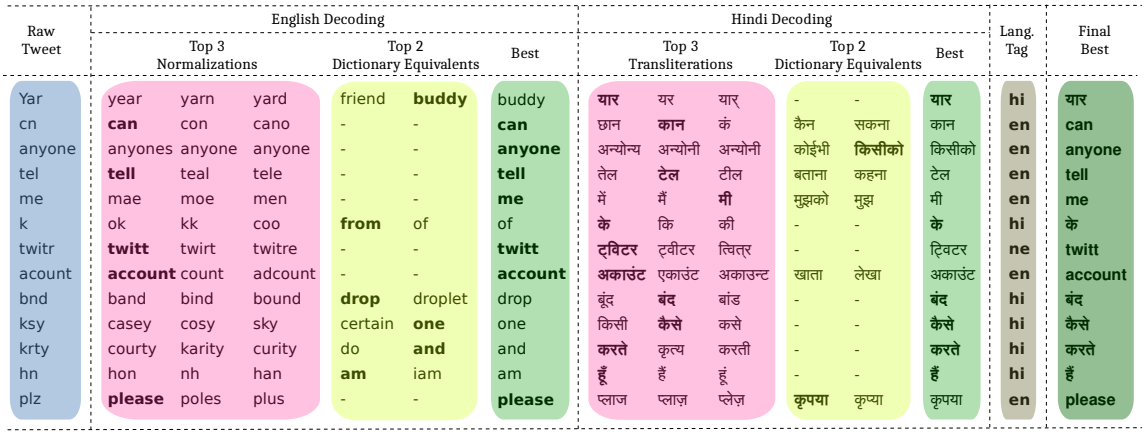

Figure 3: The figure shows a 3-step decoding process for the sentence *"Yar cn anyone tel me k twitr account bnd ksy krty hn plz" (Friend can anyone tell me how to close twitter account please).*

lem with this approach is that the language models used for scoring are trained on complete sentences but are applied on sentence fragments. Scoring individual CS fragments might often lead to wrong word selection due to incomplete context, particularly at fragment peripheries. We solve this problem by using a 3-step decoding process that works on two separate versions of a CS sentence, one in Hindi, and one in English. In the first step, we replace first-best back-transliterated forms of Hindi words by their translation equivalents using a Hindi-English bilingual lexicon.[5] An exact search is used over the top '5' normalizations of English words, the translation equivalents of Hindi words and the actual word itself. In the second step, we decode best word sequence over Hindi version of the sentence by replacing best English word forms decoded from the first step by their translation equivalents. An exact search is used over the top '5' normalizations of Hindi words, the dictionary equivalents of decoded English words and the original words. In the final step, English and Hindi words are selected from their respective decoded sequences using the predicted language tags from the language identification system. Note that the bilingual mappings are only used to aid the decoding process by making the CS sentences lexically monolingual so that the monolingual language models could be used for scoring. They are not used in the final decoded output. The overall decoding process is shown in Figure 3.

Both of our normalization and back-transliteration systems are evaluated on the evaluation set of Bhat et al. (2017). Results of our systems are reported in Table 3 with a comparison of accuracies based on the nature of decoding used. The results clearly show the significance of our 3-step decoding over first-best and fragment-wise decoding.

Data-set	Hindi				English			
	Tokens	FB	FW	3-step	Tokens	FB	FW	3-step
Dev	1549	82.82	87.28	**90.01**	34	82.35	**88.23**	**88.23**
Test	1465	83.54	88.19	**90.64**	28	71.42	75.21	**81.71**

3 Universal Dependencies for Hindi-English

Recently Bhat et al. (2017) provided a CS dataset for the evaluation of their parsing models which they trained on the Hindi and English Universal Dependency (UD) treebanks. We extend this dataset by annotating 1,448 more sentences. Following Bhat et al. (2017) we first sampled CS data from a large set of tweets of Indian language users that we crawled from Twitter using Tweepy[6]–a Twitter API wrapper. We then used a language identification system trained on ICON dataset (see Section 2) to filter Hindi-English CS tweets from the crawled Twitter data. Only those tweets were selected that satisfied a minimum ratio of 30:70(%) code-switching. From this dataset, we manually selected 1,448 tweets for annotation. The selected tweets are thoroughly checked for code-switching ratio. For POS tagging and dependency annotation, we used Version 2 of Universal dependency guidelines (De Marneffe et al., 2014),

[5] An off-the-shelf MT system would have been appropriate for this task, however, we would first need to adapt it to CS data which in itself is a non-trivial task.

[6] http://www.tweepy.org/

while language tags are assigned based on the tag set defined in (Solorio et al., 2014; Jamatia et al., 2015). The dataset was annotated by two expert annotators who have been associated with annotation projects involving syntactic annotations for around 10 years. Nonetheless, we also ensured the quality of the manual annotations by carrying an inter-annotator agreement analysis. We randomly selected a dataset of 150 tweets which were annotated by both annotators for both POS tagging and dependency structures. The inter-annotator agreement has a 96.20% accuracy for POS tagging and a 95.94% UAS and a 92.65% LAS for dependency parsing.

We use our dataset for training while the development and evaluation sets from Bhat et al. (2017) are used for tuning and evaluation of our models. Since the annotations in these datasets follow version 1.4 of the UD guidelines, we converted them to version 2 by using carefully designed rules. The statistics about the data are given in Table 3.

Data-set	Sentences	Tokens	Hi	En	Ne	Univ	Acro
Train	1,448	20,203	8,363	8,270	698	2,730	142
Dev	225	3,411	1,549	1,300	151	379	32
Test	225	3,295	1,465	1,283	168	349	30

Table 3: Data Statistics. Dev set is used for tuning model parameters, while Test set is used for evaluation.

4 Dependency Parsing

We adapt Kiperwasser and Goldberg (2016) transition-based parser as our base model and incorporate POS tag and monolingual parse tree information into the model using neural stacking, as shown in Figures 4 and 6.

4.1 Parsing Algorithm

Our parsing models are based on an arc-eager transition system (Nivre, 2003). The arc-eager system defines a set of configurations for a sentence $w_1, \ldots, w_n$, where each configuration $c = (S, B, A)$ consists of a stack S, a buffer B, and a set of dependency arcs A. For each sentence, the parser starts with an initial configuration where $S = [ROOT]$, $B = [w_1, \ldots, w_n]$ and $A = \emptyset$ and terminates with a configuration c if the buffer is empty and the stack contains the ROOT. The parse trees derived from transition sequences are given by A. To derive the parse tree, the arc-eager system defines four types of transitions (t): Shift, Left-Arc, Right-Arc, and Reduce.

We use the training by exploration method of Goldberg and Nivre (2012) for decoding a transition sequence which helps in mitigating error propagation at evaluation time. We also use pseudo-projective transformations of Nivre and Nilsson (2005) to handle a higher percentage of non-projective arcs in the CS data (∼2%). We use the most informative scheme of head+path to store the transformation information.

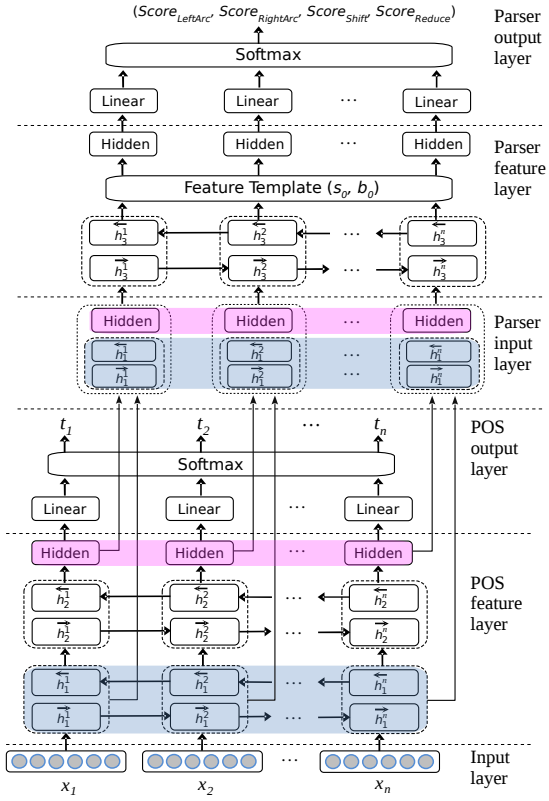

Figure 4: POS tagging and parsing network based on stack-propagation model proposed in (Zhang and Weiss, 2016).

4.2 Base Models

Our base model is a stack of a tagger network and a parser network inspired by stack-propagation model of Zhang and Weiss (2016). The parameters of the tagger network are shared and act as a regularization on the parsing model. The model is trained by minimizing a joint negative log-likelihood loss for both tasks. Unlike Zhang and Weiss (2016), we compute the gradients of the log-loss function simultaneously for each training instance. While the parser network is updated given the parsing loss only, the tagger network is updated with respect to both tagging and parsing losses. Both tagger and parser networks comprise of an input layer, a feature layer, and an output layer as shown in Figure 4. Following Zhang and Weiss (2016), we refer to this model as stack-prop.

Tagger network: The input layer of the tagger encodes each input word in a sentence by concatenating a pre-trained word embedding with its character embedding given by a character Bi-LSTM. In the feature layer, the concatenated word and character representations are passed through two stacked Bi-LSTMs to generate a sequence of hidden representations which encode the contextual information spread across the sentence. The first Bi-LSTM is shared with the parser network while the other is specific to the tagger. Finally, output layer uses the feed-forward neural network with a softmax function for a probability distribution over the Universal POS tags. We only use the forward and backward hidden representations of the focus word for classification.

Parser Network: Similar to the tagger network, the input layer encodes the input sentence using word and character embeddings which are then passed to the shared Bi-LSTM. The hidden representations from the shared Bi-LSTM are then concatenated with the dense representations from the feed-forward network of the tagger and passed through the Bi-LSTM specific to the parser. This ensures that the tagging network is penalized for the parsing error caused by error propagation by back-propagating the gradients to the shared tagger parameters (Zhang and Weiss, 2016). Finally, we use a non-linear feed-forward network to predict the labeled transitions for the parser configurations. From each parser configuration, we extract the top node in the stack and the first node in the buffer and use their hidden representations from the parser specific Bi-LSTM for classification.

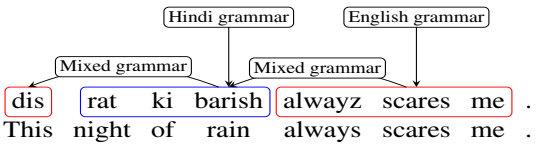

Figure 5: Code-switching tweet showing grammatical fragments from Hindi and English.

4.3 Stacking Models

It seems reasonable that limited CS data would complement large monolingual data in parsing CS data and a parsing model which leverages both data would significantly improve parsing performance. While a parsing model trained on our limited CS data might not be enough to accurately parse the individual grammatical fragments of Hindi and English, the preexisting Hindi and English treebanks are large enough to provide sufficient annotations to capture their structure. Similarly, parsing model(s) trained on the Hindi and English data may not be able to properly connect the divergent fragments of the two languages as the model lacks evidence for such mixed structures in the monolingual data. This will happen quite often as Hindi and English are typologicalls very diverse (see Figure 5).

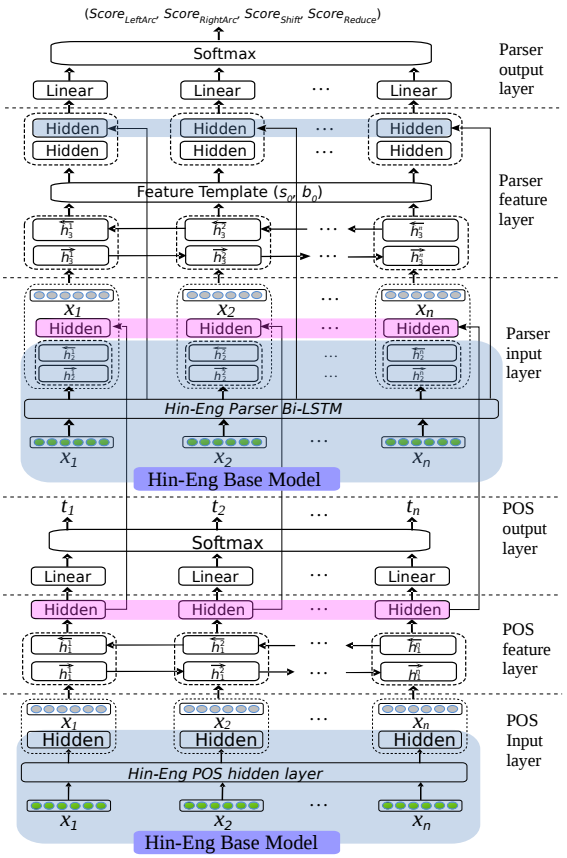

Figure 6: Neural Stacking-based parsing architecture for incorporating monolingual syntactic knowledge.

As we discussed above, we adapted feature-level neural stacking (Zhang and Weiss, 2016; Chen et al., 2016) for joint learning of POS tagging and parsing. Similarly, we also adapt this stacking approach for incorporating the monolingual syntactic knowledge into the base CS model. Recently, Wang et al. (2017) used neural stacking for injecting syntactic knowledge of English into a graph-based Singlish parser which lead to significant improvements in parsing performance. Unlike Wang et al. (2017), our base stacked models will allow us to transfer the POS tagging knowledge as well along the parse tree knowledge.

As shown in Figure 6, we transfer both POS tagging and parsing information from the source

model trained on augmented Hindi and English data. For tagging, we augment the input layer of the CS tagger with the MLP layer of the source tagger. For transferring parsing knowledge, hidden representations from the parser specific Bi-LSTM of the source parser are augmented with the input layer of the CS parser which already includes the hidden layer of the CS tagger, word and character embeddings. In addition, we also add the MLP layer of the source parser to the MLP layer of the CS parser. The MLP layers of the source parser are generated using raw features from CS parser configurations. Apart from the addition of these learned representations from the source model, the overall CS model remains similar to the base model shown in Figure 4. The tagging and parsing losses are back-propagated by traversing back the forward paths to all trainable parameters in the entire network for training and the whole network is used collectively for inference.

5 Experiments

We train all of our POS tagging and parsing models on training sets of the Hindi and English UD-v2 treebanks and our Hindi-English CS treebank. For tuning and evaluation, we use the development and evaluation sets from Bhat et al. (2017). We conduct multiple experiments in gold and predicted settings to measure the effectiveness of the sub-modules of our parsing pipeline. In predicted settings, we use the POS taggers separately trained on the Hindi, English and CS training sets. All of our models use word embeddings from transformed Hindi and English embedding spaces to address the problem of lexical differences prevalent in CS sentences.

5.1 Hyperparameters

Word Representations For language identification, POS tagging and parsing models, we include the lexical features in the input layer of our neural networks using 64-dimension pre-trained word embeddings, while we use randomly initialized embeddings within a range of $[-0.1, +0.1]$ for non-lexical units such as POS tags and dictionary flags. We use 32-dimensional character embeddings for all the three models and 32-dimensional POS tag embeddings for pipelined parsing models. The distributed representation of Hindi and English vocabulary are learned separately from the Hindi and English monolingual corpora. The English monolingual data contains around 280M sentences, while the Hindi data is comparatively smaller and contains around 40M sentences. The word representations are learned using Skip-gram model with negative sampling which is implemented in `word2vec` toolkit (Mikolov et al., 2013). We use the projection algorithm of Artetxe et al. (2016) to transform the Hindi and English monolingual embeddings into same semantic space using a bilingual lexicon ($\sim$63,000 entries). The bilingual lexicon is extracted from ILCI and Bojar Hindi-English parallel corpora (Jha, 2010; Bojar et al., 2014). For normalization models, we use 32-dimensional character embeddings uniformly initialized within a range of $[-0.1, +0.1]$.

Hidden dimensions The POS tagger specific Bi-LSTMs have 128 cells while the parser specific Bi-LSTMs have 256 cells. The Bi-LSTM in the language identification model has 64 cells. The character Bi-LSTMs have 32 cells for all three models. The hidden layer of MLP has 64 nodes for the language identification network, 128 nodes for the POS tagger and 256 nodes for the parser. We use hyperbolic tangent as an activation function in all tasks. In the normalization models, we use single layered Bi-LSTMs with 512 cells for both encoding and decoding of character sequences.

Learning For language identification, POS tagging and parsing networks, we use momentum SGD for learning with a minibatch size of 1. The LSTM weights are initialized with random orthonormal matrices as described in (Saxe et al., 2013). We set the dropout rate to 30% for POS tagger and parser Bi-LSTM and MLP hidden states while for language identification network we set the dropout to 50%. All three models are trained for up to 100 epochs, with early stopping based on the development set.

In case of normalization, we train our encoder-decoder models for 25 epochs using vanilla SGD. We start with a learning rate of 1.0 and after 8 epochs reduce it to half for every epoch. We use a mini-batch size of 128, and the normalized gradient is rescaled whenever its norm exceeds 5. We use a dropout rate of 30% for the Bi-LSTM.

Language identification, POS tagging and parsing code is implemented in DyNet (Neubig et al., 2017) and for normalization without decoding, we use Open-NMT toolkit for neural machine translation (Klein et al., 2017). All

the code is available at https://github.com/irshadbhat/nsdp-cs and the data is available at https://github.com/CodeMixedUniversalDependencies/UD_Hindi_English.

6 Results

In Table 4, we present the results of our main model that uses neural stacking for learning POS tagging and parsing and also for knowledge transfer from the Bilingual model. Transferring POS tagging and syntactic knowledge using neural stacking gives 1.5% LAS[7] improvement over a naive approach of data augmentation. The Bilingual model which is trained on the union of Hindi and English data sets is least accurate of all our parsing models. However, it achieves better or near state-of-the-art results on the Hindi and English evaluation sets (see Table 5). As compared to the best system in CoNLL 2017 Shared Task on Universal Dependencies (Zeman et al., 2017; Dozat et al., 2017), our results for English are around 3% better in LAS, while for Hindi only 0.5% LAS points worse. The CS model trained only on the CS training data is slightly more accurate than the Bilingual model. Augmenting the CS data to Hindi-English data complements their syntactic structures relevant for parsing mixed grammar structures which are otherwise missing in the individual datasets. The average improvements of around ∼5% LAS clearly show their complementary nature.

Model	Gold (LID+TRN)		Auto (LID+TRN)	
	UAS	LAS	UAS	LAS
Bilingual	75.26	65.41	73.29	63.18
CS	76.69	66.90	75.84	64.94
Augmented	80.39	71.27	78.95	69.51
Neural Stacking	**81.50**	**72.44**	**80.23**	**71.03**
(Bhat et al., 2017)	74.16	64.11	66.18	54.40

Table 4: Accuracy of different parsing models on the evaluation set. POS tags are jointly predicted with parsing. LID = Language tag, TRN = Transliteration/normalization.

Table 6 summarizes the POS tagging results on the CS evaluation set. The tagger trained on the CS training data is 2.5% better than the Bilingual tagger. Adding CS training data to Hindi and English train sets further improves the accuracy by 1%. However, our stack-prop tagger achieves the highest accuracy of 90.53% by leveraging POS information from Bilingual tagger using neural stacking.

[7]The improvements discussed in the running text are for the models that are evaluated in auto settings.

Data-set	Pipeline					Stack-prop		
	Gold POS		Auto POS					
	UAS	LAS	POS	UAS	LAS	POS	UAS	LAS
Hindi	95.66	93.08	97.52	94.08	90.69	**97.65**	**94.36**	**91.02**
English	89.95	87.96	95.75	87.71	84.59	**95.80**	**88.30**	**85.30**

Table 5: POS and parsing results for Hindi and English monolingual test sets using pipeline and stack-prop models.

Model	Gold (LID+TRN)		Auto (LID+TRN)	
	Pipeline	SP	Pipeline	SP
Bilingual	88.36	88.12	86.71	86.27
CS	90.32	90.38	89.12	89.19
Augmented	91.20	91.50	90.02	90.20
Neural Stacking	**91.76**	**91.90**	**90.36**	**90.53**
(Bhat et al., 2017)	86.00		85.30	

Table 6: POS tagging accuracies of different models on CS evaluation set. SP = stack-prop.

Pipeline vs Stack-prop Table 7 summarizes the parsing results of our pipeline models which use predicted POS tags as input features. As compared to our stack-prop models (Table 4), pipeline models are less accurate (average 1% LAS improvement across models) which clearly emphasizes the significance of back-propagating the parsing loss to tagging parameters as well.

Model	Gold (LID+TRN+POS)		Auto (LID+TRN+POS)	
	UAS	LAS	UAS	LAS
Bilingual	82.29	73.79	72.09	61.18
CS	82.73	73.38	75.20	64.64
Augmented	85.66	77.75	77.98	69.16
Neural Stacking	**86.87**	**78.57**	**78.90**	**69.45**

Table 7: Accuracy of different parsing models on the test set using predicted language tags, normalized/back-transliterated words and predicted POS tags. POS tags are predicted separately before parsing. In Neural Stacking model, only parsing knowledge from the Bilingual model is transferred.

Significance of normalization We also conducted experiments to evaluate the impact of normalization on both POS tagging and parsing. The results are shown in Table 8. As expected, tagging and parsing models that use normalization without decoding achieve an average of 1% improvement over the models that do not use normalization at all. However, our 3-step decoding leads to higher gains in tagging as well as parsing accuracies. We achieved around 2.8% improvements in tagging and around 4.6% in parsing over the models that use first-best word forms from the normalization models. More importantly, there is a mod-

erate drop in accuracy (1.4% LAS points) caused due to normalization errors (see results in Table 4 for gold vs auto normalization).

System	POS	UAS	LAS
No Normalization	86.98	76.25	66.02
First Best	87.74	78.26	67.22
3-step Decoding	**90.53**	**80.23**	**71.03**

Table 8: Impact of normalization and back-transliteration on POS tagging and parsing models.

Monolingual vs Cross-lingual Embeddings We also conducted experiments with monolingual and cross-lingual embeddings to evaluate the need for transforming the monolingual embeddings into a same semantic space for processing of CS data. Results are shown in Table 9. Cross-lingual embeddings have brought around ∼0.5% improvements in both tagging and parsing. Cross-lingual embeddings are essential for removing lexical differences which is one of the problems encountered in CS data. Addressing the lexical differences will help in better learning by exposing syntactic similarities between languages.

Embedding	POS	UAS	LAS
Monolingual	90.07	79.46	70.53
Crosslingual	**90.53**	**80.23**	**71.03**

Table 9: Impact of monolingual and cross-lingual embeddings on stacking model performance.

7 Conclusion

In this paper, we have presented a dependency parser designed explicitly for Hindi-English CS data. The parser uses neural stacking architecture of Zhang and Weiss (2016) and Chen et al. (2016) for learning POS tagging and parsing and for knowledge transfer from Bilingual models trained on Hindi and English UD treebanks. We have also presented normalization and back-transliteration models with a decoding process tailored for CS data. Our neural stacking parser is 1.5% LAS points better than the augmented parsing model and 3.8% LAS points better than the one which uses first-best normalizations.

What's Going On in Neural Constituency Parsers? An Analysis

David Gaddy, Mitchell Stern, and Dan Klein

Abstract

A number of differences have emerged between modern and classic approaches to constituency parsing in recent years, with structural components like grammars and feature-rich lexicons becoming less central while recurrent neural network representations rise in popularity. The goal of this work is to analyze the extent to which information provided directly by the model structure in classical systems is still being captured by neural methods. To this end, we propose a high-performance neural model (92.08 F1 on PTB) that is representative of recent work and perform a series of investigative experiments. We find that our model implicitly learns to encode much of the same information that was explicitly provided by grammars and lexicons in the past, indicating that this scaffolding can largely be subsumed by powerful general-purpose neural machinery.

1 Introduction

In the past several years, many aspects of constituency parsing and natural language processing in general have changed. Grammars, which were once the central component of many parsers, have played a continually decreasing role. Rich lexicons and handcrafted lexical features have become less common as well. On the other hand, recurrent neural networks have gained traction as a powerful and general purpose tool for representation. So far, not much has been shown about how neural networks are able to compensate for the removal of the structures used in past models. To gain insight, we introduce a parser that is representative of recent trends and analyze its learned representations to determine what information it captures and what is important for its strong performance.

Our parser is a natural extension of recent work in constituency parsing. We combine a common span representation based on recurrent neural networks with a novel, simplified scoring model. In addition, we replace the externally predicted part-of-speech tags used in some recent systems with character-level word representations. Our parser achieves a test F1 score of 92.08 on section 23 of the Penn Treebank, exceeding the performance of many other state-of-the-art models evaluated under comparable conditions. Section 2 describes our model in detail.

The remainder of the paper is focused on analysis. In Section 3, we look at the decline of grammars and output correlations. Past work in constituency parsing used context-free grammars with production rules governing adjacent labels (or more generally production-factored scores) to propagate information and capture correlations between output decisions (Collins, 1997; Charniak and Johnson, 2005; Petrov and Klein, 2007; Hall et al., 2014). Many recent parsers no longer have explicit grammar production rules, but still use information about other predictions, allowing them to capture output correlations (Dyer et al., 2016; Choe and Charniak, 2016). Beyond this, there are some parsers that use no context for bracket scoring and only include mild output correlations in the form of tree constraints (Cross and Huang, 2016b; Stern et al., 2017). In our experiments, we find that we can accurately predict parents from the representation given to a child. Since a simple classifier can predict the information provided by parent-child relations, this explains why the information no longer needs to be specified explicitly. We also show that we can completely remove output correlations from our model with a variant of our parser that makes independent span label decisions without any tree constraints while maintaining high F1 scores and mostly producing trees.

In Section 4, we look at lexical representations. In the past, parsers used a variety of cus-

Proceedings of NAACL-HLT 2018, pages 999–1010
New Orleans, Louisiana, June 1 - 6, 2018.

tom lexical representations, such as word shape features, prefixes, suffixes, and special tokens for categories like numerals (Klein and Manning, 2003; Petrov and Klein, 2007; Finkel et al., 2008). Character-level models have shown promise in parsing and other NLP tasks as a way to remove the complexity of these lexical features (Ballesteros et al., 2015; Ling et al., 2015b; Kim et al., 2016; Coavoux and Crabbé, 2017; Liu and Zhang, 2017). We compare the performance of character-level representations and externally predicted part-of-speech tags and show that these two sources of information seem to fill a similar role. We also perform experiments showing that the representations learned with character-level models contain information that was hand-specified in some other models.

Finally, in Section 5 we look at the surface context captured by recurrent neural networks. Many recent parsers use LSTMs, a popular type of recurrent neural network, to combine and summarize context for making decisions (Choe and Charniak, 2016; Cross and Huang, 2016a; Dyer et al., 2016; Stern et al., 2017). Before LSTMs became common in parsing, systems that included surface features used a fixed-size window around the fenceposts at each end of a span (Charniak and Johnson, 2005; Finkel et al., 2008; Hall et al., 2014; Durrett and Klein, 2015), and the inference procedure handled most of the propagation of information from the rest of the sentence. We perform experiments showing that LSTMs capture far-away surface context and that this information is important for our parser's performance. We also provide evidence that word order of the far-away context is important and that the amount of context alone does not account for all of the gains seen with LSTMs.

Overall, we find that the same sources of information that were effective for grammar-driven parsers are also captured by parsers based on recurrent neural networks.

2 Parsing Model

In this section, we propose a span-based parsing model that combines components from several recent neural architectures for constituency parsing and other natural language tasks. While this system is primarily introduced for the purpose of our analysis, it also performs well as a parser in its own right, exhibiting some gains over comparable work. Our model is in many respects similar to the chart parser of Stern et al. (2017), but features a number of simplifications and improvements.

2.1 Overview

Abstractly, our model consists of a single scoring function $s(i, j, \ell)$ that assigns a real-valued score to every label ℓ for each span (i, j) in an input sentence. We take the set of available labels to be the collection of all nonterminals and unary chains observed in the training data, treating the latter as atomic units. The score of a tree T is defined as a sum over internal nodes of labeled span scores:

$$s(T) = \sum_{(i,j,\ell) \in T} s(i, j, \ell).$$

We note that, in contrast with many other chart parsers, our model can directly score n-ary trees without the need for binarization or other tree transformations. Under this setup, the parsing problem is to find the tree with the highest score:

$$\hat{T} = \operatorname*{argmax}_{T} s(T).$$

Our concrete implementation of $s(i, j, \ell)$ can be broken down into three pieces: word representation, span representation, and label scoring. We discuss each of these in turn.

2.2 Word Representation

One popular way to represent words is the use of word embeddings. We have a separate embedding for each word type in the training vocabulary and map all unknown words at test time to a single `<UNK>` token. In addition to word embeddings, character-level representations have also been gaining traction in recent years, with common choices including recurrent, convolutional, or bag-of-n-gram representations. These alleviate the unknown word problem by working with smaller, more frequent units, and readily capture morphological information not directly accessible through word embeddings. Character LSTMs in particular have proved useful in constituency parsing (Coavoux and Crabbé, 2017), dependency parsing (Ballesteros et al., 2015), part-of-speech tagging (Ling et al., 2015a), named entity recognition (Lample et al., 2016), and machine translation (Ling et al., 2015b), making them a natural choice for our system. We obtain a character-level representation for a word by running it through a bidirectional character LSTM and concatenating the final forward and backward outputs.

The complete representation of a given word is the concatenation of its word embedding and its character LSTM representation. While past work has also used sparse indicator features (Finkel et al., 2008) or part-of-speech tags predicted by an external system (Cross and Huang, 2016b) for additional word-level information, we find these to be unnecessary in the presence of a robust character-level representation.

2.3 Span Representation

To build up to spans, we first run a bidirectional LSTM over the sequence of word representations for an input sentence to obtain context-sensitive forward and backward representations $\mathbf{f}_i$ and $\mathbf{b}_i$ for each fencepost i. We then follow past work in dependency parsing (Wang and Chang, 2016) and constituency parsing (Cross and Huang, 2016b; Stern et al., 2017) in representing the span (i, j) by the concatenation of the corresponding forward and backward span differences:

$$\mathbf{r}_{ij} = [\mathbf{f}_j - \mathbf{f}_i, \mathbf{b}_i - \mathbf{b}_j].$$

See Figure 1 for an illustration.

2.4 Label Scoring

Finally, we implement the label scoring function by feeding the span representation through a one-layer feedforward network whose output dimensionality equals the number of possible labels. The score of a specific label ℓ is the corresponding component of the output vector:

$$s(i, j, \ell) = [\mathbf{W}_2\, g(\mathbf{W}_1 \mathbf{r}_{ij} + \mathbf{z}_1) + \mathbf{z}_2]_\ell\,,$$

where g is an elementwise ReLU nonlinearity.

2.5 Inference

Even though our model operates on n-ary trees, we can still employ a CKY-style algorithm for efficient globally optimal inference by introducing an auxiliary empty label $\varnothing$ with $s(i, j, \varnothing) = 0$ for all (i, j) to handle spans that are not constituents. Under this scheme, every binarization of a tree with empty labels at intermediate dummy nodes will have the same score, so an arbitrary binarization can be selected at training time with no effect on learning. We contrast this with the chart parser of Stern et al. (2017), which assigns different scores to different binarizations of the same underlying tree and in theory may exhibit varying performance depending on the method chosen for conversion.

With this change in place, let $s_{\text{best}}(i, j)$ denote the score of the best subtree spanning (i, j). For spans of length one, we need only consider the choice of label:

$$s_{\text{best}}(i, i+1) = \max_\ell s(i, i+1, \ell).$$

For general spans (i, j), we have the following recursion:

$$s_{\text{best}}(i, j) = \max_\ell s(i, j, \ell) + \max_k \left[s_{\text{best}}(i, k) + s_{\text{best}}(k, j) \right].$$

That is, we can independently select the best label for the current span and the best split point, where the score of a split is the sum of the best scores for the corresponding subtrees.

To parse the full sentence, we compute $s_{\text{best}}(0, n)$ using a bottom-up chart decoder, then traverse backpointers to recover the tree achieving that score. Nodes assigned the empty label are omitted during the reconstruction process to obtain the full n-ary tree. The overall complexity of this approach is $\mathcal{O}(n^3 + Ln^2)$, where n is the number of words and L is the total number of labels. We note that because our system does not use a grammar, there is no constant for the number of grammar rules multiplying the $\mathcal{O}(n^3)$ term as in traditional CKY parsing. In practice, the $\mathcal{O}(n^2)$ evaluations of the span scoring function corresponding to the $\mathcal{O}(Ln^2)$ term dominate runtime.

2.6 Training

As is common for structured prediction problems (Taskar et al., 2005), we use margin-based training to learn a model that satisfies the constraints

$$s(T^*) \geq s(T) + \Delta(T, T^*)$$

for each training example, where T^* denotes the gold output, T ranges over all valid trees, and Δ is the Hamming loss on labeled spans. Our training objective is the hinge loss:

$$\max\left(0,\, \max_T \left[s(T) + \Delta(T, T^*) \right] - s(T^*)\right).$$

This is equal to 0 when all constraints are satisfied, or the magnitude of the largest margin violation otherwise.

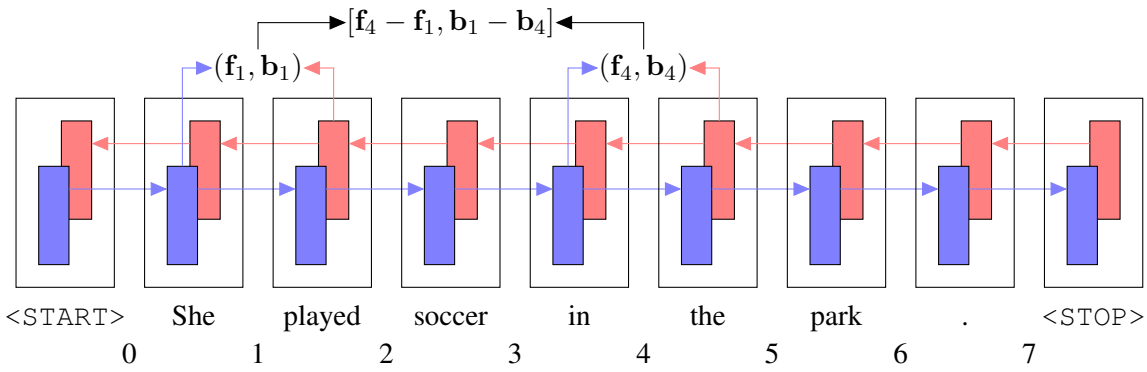

Figure 1: Span representations are computed by running a bidirectional LSTM over the input sentence and taking differences of the output vectors at the two endpoints. Here we illustrate the process for the span $(1, 4)$ corresponding to "played soccer in" in the example sentence.

Since Δ decomposes over spans, the inner loss-augmented decode $\max_T [s(T) + \Delta(T, T^*)]$ can be performed efficiently using a slight modification of the dynamic program used for inference. In particular, we replace $s(i, j, \ell)$ with $s(i, j, \ell) + 1[\ell \neq \ell^*_{ij}]$, where ℓ^*_{ij} is the label of span (i, j) in the gold tree T^*.

2.7 Results

We use the Penn Treebank (Marcus et al., 1993) for our experiments with the standard splits of sections 2-21 for training, section 22 for development, and section 23 for testing. Details about our model hyperparameters and training prodecure can be found in Appendix A.

Across 10 trials, our model achieves an average development F1 score of 92.22 on section 22 of the Penn Treebank. We use this as our primary point of comparison in all subsequent analysis. The model with the best score on the development set achieves a test F1 score of 92.08 on section 23 of the Penn Treebank, exceeding the performance of other recent state-of-the-art discriminative models which do not use external data or ensembling.[1]

3 Output Correlations

Output correlations are information about compatibility between outputs in a structured prediction model. Since outputs are all a function of the input, output correlations are not necessary for prediction when a model has access to the entire input. In practice, however, many models throughout NLP have found them useful (Collins, 1997; Lafferty et al., 2001; Koo and Collins, 2010), and Liang et al. (2008) provides theoretical results suggesting they may be useful for learning efficiently. In constituency parsing, there are two primary forms of output correlation typically captured by models. The first is correlations between label decisions, which often are captured by either production scores or the history in an incremental tree-creation procedure. The second, more subtle correlation comes from the enforcement of tree constraints, since the inclusion of one bracket can affect whether or not another bracket can be present. We explore these two classes of output correlations in Sections 3.1 and 3.2 below.

3.1 Parent Classification

The base parser introduced in Section 2 scores labeled brackets independently then uses a dynamic program to select a set of brackets that forms the highest-scoring tree. This independent labeling is an interesting departure from classical parsing work where correlations between predicted labels played a central role. It is natural to wonder why modeling label correlations isn't as important as it once was. Is there something about the neural representation that allows us to function without it? One possible explanation is that the neural machinery, in particular the LSTM, is handling much of the reconciliation between labels that was previously handled by an inference procedure. In other words, instead of using local information to suggest several brackets and letting the grammar handle interactions between them, the LSTM may be making decisions about brackets already in its latent state, allowing it to use the result of these decisions to inform other bracketings.

One way to explore this hypothesis would be

[1] Code for our parser is available at https://github.com/dgaddy/parser-analysis.

to evaluate whether the parser's learned representations could be used to predict parent labels of nodes in the tree. If the label of a node's parent can be predicted with high accuracy from the representation of its span, then little of the information about parent-child relations provided explicitly by a grammar has been lost. For this experiment, we freeze the input and LSTM parameters of our base model and train a new label scoring network to predict the label of a span's parent rather than the label of the span itself. We only predict parent labels for spans that have a bracket in the gold tree, so that all but the top level spans will have non-empty labels. The new network is trained with a margin loss.

After training on the standard training sections of the treebank, the network was able to correctly predict 92.3% of parent labels on the development set. This is fairly accurate, which supports the hypothesis that the representation knows a substantial amount about surrounding context in the output tree. For comparison, given only a span's label, the best you can do for predicting the parent is 43.3% with the majority class conditioned on the current label.

3.2 Independent Span Decisions

Like other recent parsers that do not capture correlations between output labels (Cross and Huang, 2016b; Stern et al., 2017), our base parser still does have some output correlations captured by the enforcement of tree constraints. In this section, we set out to determine the importance of these output correlations by making a version of the parser where they are removed. Although parsers are typically designed to form trees, the bracketing F1 measure used to evaluate parsers is still defined on non-tree outputs. To remove all output correlations from our parser, we can simply remove the tree constraint and independently make decisions about whether to include a bracketed span. The architecture is identical to the one described in Section 2, producing a vector of label scores for each span. We choose the label with the maximum score as the label for a span. As before, we fix the score of the empty label at zero, so if all other label scores are negative, the span will be left out of the set of predicted brackets. We train with independent margin losses for each span.

Ignoring tree well-formedness, the development F1 score of this independent span selection parser is 92.20, effectively matching the performance of the tree-constrained parser. In addition, we find that 94.5% of predicted bracketings for development set examples form valid trees, even though we did not explicitly encourage this. This high performance shows that our parser can function well even without modeling any output correlations.

4 Lexical Representation

In this section, we investigate several common choices for lexical representations of words and their role in neural parsing.

4.1 Alternate Word Representations

We compare the performance of our base model, which uses word embeddings and a character LSTM, with otherwise identical parsers that use other combinations of lexical representations. The results of these experiments are summarized in Table 1. First, we remove the character-level representations from our model, leaving only the word embeddings. We find that development performance drops from 92.22 F1 to 91.44 F1, showing that word embeddings alone do not capture sufficient information for state-of-the-art performance. Then, we replace the character-level representations with embeddings of part-of-speech tags predicted by the Stanford tagger (Toutanova et al., 2003). This model achieves a comparable development F1 score of 92.09, but unlike our base model relies on outputs from an external system. Next, we train a model which includes all three lexical representations: word embeddings, character LSTM representations, and part-of-speech tag embeddings. We find that development performance is nearly identical to the base model at 92.24 F1, suggesting that character representations and predicted part-of-speech tags provide much of the same information. Finally, we remove word embeddings and rely completely on character-level embeddings. After retuning the character LSTM size, we find that a slightly larger character LSTM can make up for the loss in word-level embeddings, giving a development F1 of 92.24.

4.2 Predicting Word Features

Past work in constituency parsing has demonstrated that indicator features on word shapes, suffixes, and similar attributes provide useful infor-

Word and Character LSTM	92.22
Word Only	91.44
Word and Tag	92.09
Word, Tag, and Character LSTM	92.24
Character Only	92.24

Table 1: Development F1 scores on section 22 of the Penn Treebank for different lexical representations.

mation beyond the identity of a word itself, especially for rare and unknown tokens (Finkel et al., 2008; Hall et al., 2014). We hypothesize that the character-level LSTM in our model learns similar information without the need for manual supervision. To test this, we take the word representations induced by the character LSTM in our parser as fixed word encodings, and train a small feed-forward network to predict binary word features defined in the Berkeley Parser (Petrov and Klein, 2007). We randomly split the vocabulary of the Penn Treebank into two subsets, using 80% of the word types for training and 20% for testing.

We find that the character LSTM representations allow for previously handcrafted indicator features to be predicted with accuracies of 99.7% or higher in all cases. The fact that this simple classifier performs so well indicates that the information contained in these features is readily available from our model's character-level encodings. A detailed breakdown of accuracy by feature can be found in Appendix B.

5 Context in the Sentence LSTM

In this section, we analyze where the information in the sentence-level LSTM hidden vectors comes from. Since the LSTM representations we use to make parsing decisions come from the fenceposts on each side of a span, we would like to understand whether they only capture information from the immediate vicinity of the fenceposts or if they also contain more distant information. Although an LSTM is theoretically capable of incorporating an arbitrarily large amount of context, it is unclear how much context it actually captures and whether this context is important for parsing accuracy.

5.1 Derivative Analysis

First, we would like to know if the LSTM features capture distant information. For this experiment, we use derivatives as a measure of sensitivity to changes in an input. If the derivative of a value with respect to a particular input is high, then that input has a large impact on the final value. For a particular component of an LSTM output vector, we compute its gradient with respect to each LSTM input vector, calculate the ℓ_2-norms of the gradients, and bucket the results according to distance from the output position. This process is repeated for every output position of each sentence in the development set, and the results are averaged within each bucket. Due to the scale of the required computation, we only use a subset of the output vector components to compute the average, sampling one at random per output vector.

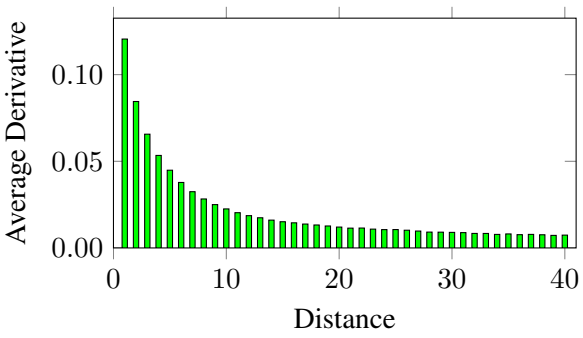

Figure 2: Average derivative of the LSTM output with respect to its input as a function of distance. The output is most sensitive to the closest words, but the tail of the distribution is fairly heavy, indicating that far-away words also have substantial impact.

Figure 2 illustrates how the average gradient norm is affected by the distance between the LSTM input and output. As would be expected, the closest input vectors have the largest effect on the hidden state. However, the tail of values is fairly heavy, with substantial gradient norms even for inputs 40 words away. This shows that far-away inputs do have an effect on the LSTM representation.

5.2 Truncation Analysis

Next, we investigate whether information in the LSTM representation about far-away inputs is actually important for parsing performance. To do so, we remove distant context information from our span encoding, representing spans by features obtained from LSTMs that are run on fixed-sized windows of size k around each fencepost. Figure 3 illustrates this truncated representation. Since the truncated representation also removes information about the size and position of the span in addition to the context words, we learn a position-dependent cell state initialization for each of the

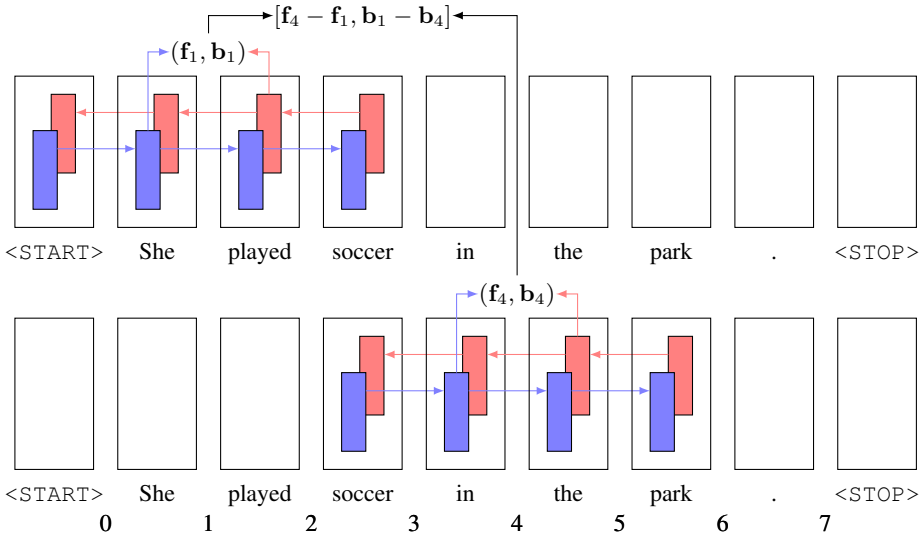

Figure 3: An example of creating a truncated span representation for the span "played soccer in" with context size $k = 2$. This representation is used to investigate the importance of information far away from the fenceposts of a span.

two LSTM directions to give a more fair comparison to the full LSTM. The use of a fixed-sized context window is reminiscent of prior work by Hall et al. (2014) and Durrett and Klein (2015), but here we use an LSTM instead of sparse features. We train parsers with different values of k and observe how their performance varies. All other architecture details and hyperparameters are the same as for the original model.

The blue points in Figure 4 show how the context size k affects parser performance for $k \in \{2, 3, 5, 10, 20, 30\}$. As with the derivative analysis, although most of the weight is carried by the nearby inputs, a nontrivial fraction of performance is due to context more than 10 words away.

5.3 Word Order

Now that we have established that long-distance information is important for parsing performance, we would like to know whether the order of the far-away words is important. Is the LSTM capturing far-away structure, or is the information more like a bag-of-words representation summarizing the words that appear?

To test the importance of order, we train a parser where information about the order of far-away words is destroyed. As illustrated in Figure 5, we run a separate LSTM over the entire sentence for each fencepost, shuffling the input depending on the particular fencepost being represented. We randomly shuffle words outside a context window

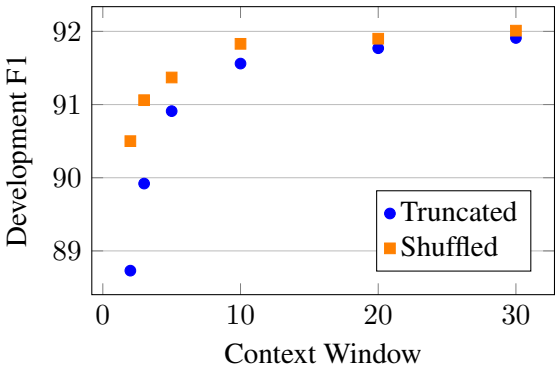

Figure 4: Development F1 as the amount of context given to the sentence-level LSTM varies. The blue points represent parser performance when the LSTM is truncated to a window around the fenceposts, showing that far-away context is important. The orange points represent performance when the full context is available but words outside a window around the fenceposts are shuffled, showing that the order of far-away context is also important.

of size k around the fencepost of interest, keeping words on the left and the right separate so that directional information is preserved but exact positions are lost.

The orange points in Figure 4 show the performance of this experiment with different context sizes k. We observe that including shuffled distant words is substantially better than truncating them completely. On the other hand, shuffling does cause performance to degrade relative to the base parser even when the unshuffled win-

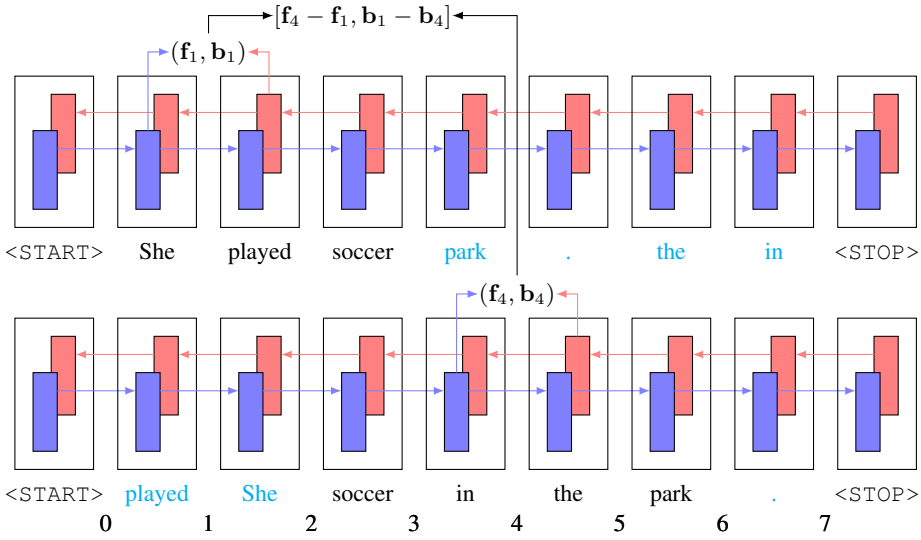

Figure 5: An example of creating a shuffled span representation for the span "played soccer in" with context size $k = 2$. The light blue words are outside the context window and are shuffled randomly. Shuffled representations are used to explore whether the order of far-away words is important.

dow is moderately large, indicating that the LSTM is propagating information that depends on the order of words in far-away positions.

5.4 LSTMs vs. Feedforward

Finally, we investigate whether the LSTM architecture itself is important for reasons other than just the amount of context it can capture. Like any architecture, the LSTM introduces particular inductive biases that affect what gets learned, and these could be important for parser performance. We run a version of the truncation experiment from Section 5.2 where we use a feedforward network in place of a sentence-level LSTM to process the surrounding context of each fencepost. The input to the network is the concatenation of the word representations that would be used as inputs for the truncated LSTM, and the output is a vector of the same size as the LSTM-based representation. As in Section 5.2, we wish to give our representation information about span size and position, so we also include a learned fencepost position embedding in the concatenated inputs to the network. We focus on context window size $k = 3$ for this experiment. We search among networks with one, two, or three hidden layers that are one, two, or four times the size of the LSTM hidden state.

Of all the feedforward networks tried, the maximum development performance was 83.39 F1, compared to 89.92 F1 for the LSTM-based truncation. This suggests that some property of the LSTM makes it better suited for the task of summarizing context than a flat feedforward network.

6 Related Analysis Work

Here we review other works that have performed similar analyses to ours in parsing and other areas of NLP. See Section 2 for a description of how our parser is related to other parsers.

Similar to our independent span prediction in Section 3.2, several works have found that their models still produce valid outputs for the majority of inputs even after relaxing well-formedness constraints. In dependency parsing, Zhang et al. (2017) and Chorowski et al. (2016) found that selecting dependency heads independently often resulted in valid trees for their parsers (95% and 99.5% of outputs form trees, respectively). In constituency parsing, the parser of Vinyals et al. (2015), which produced linearized parses token by token, was able to output valid constituency trees for the majority of sentences (98.5%) even though it was not constrained to do so.

Several other works have investigated what information is being captured within LSTM representations. Chawla et al. (2017) performed analysis of bidirectional LSTM representations in the context of named entity recognition. Although they were primarily interested in finding specific word types that were important for making decisions, they also analyzed how distance affected a word's impact. Shi et al. (2016) and Linzen et al.

(2016) perform analysis of LSTM representations in machine translation and language modeling respectively to determine whether syntactic information is present. Some of their techniques involve classification of features from LSTM hidden states, similar to our analysis in Sections 3.1 and 4.2.

In Section 5.4, we found that replacing an LSTM with a feedforward network hurt performance. Previously, Chelba et al. (2017) had similar findings in language modeling, where using LSTMs truncated to a particular distance improved performance over feedforward networks that were given the same context.

7 Conclusion

In this paper, we investigated the extent to which information provided directly by model structure in classical constituency parsers is still being captured by neural methods. Because neural models function in a substantially different way than classical systems, it could be that they rely on different information when making their decisions. Our findings suggest that, to the contrary, the neural systems are learning to capture many of the same knowledge sources that were previously provided, including the parent-child relations encoded in grammars and the word features induced by lexicons.

A Model Hyperparameters and Training Details

Component	Dimensions	Layers
Word Embeddings	100	
Character Embeddings	50	
Character LSTM	100	1
Sentence LSTM	250	2
Label Feedforward Network	250	1

Table 2: The sizes of the components used in our model.

Our model hyperparameters are summarized in Table 2. We train using the Adam optimizer (Kingma and Ba, 2014) with its default hyperparameters for 40 epochs. We evaluate on the development set 4 times per epoch, selecting the model with the highest overall development performance as our final model. When performing a word embedding lookup during training, we randomly replace words by the `<UNK>` token with probability $1/(1 + \text{freq}(w))$, where $\text{freq}(w)$ is the frequency of a word w in the training set. We apply dropout with probability 0.4 before and inside each layer of each LSTM. Our system is implemented in Python using DyNet (Neubig et al., 2017).

B Character LSTM Word Feature Classification

Binary Feature	Majority Class	Char-LSTM Classifier	Binary Feature	Majority Class	Char-LSTM Classifier
all-letters	77.22%	99.77%	suffix = “s”	82.65%	99.99%
has-letter	89.18%	99.97%	suffix = “ed”	92.52%	99.98%
all-lowercase	56.95%	99.95%	suffix = “ing”	93.26%	99.95%
has-lowercase	85.85%	99.90%	suffix = “ion”	97.75%	99.93%
all-uppercase	96.68%	99.90%	suffix = “er”	96.42%	99.97%
has-uppercase	67.77%	99.97%	suffix = “est”	99.63%	99.98%
all-digits	98.38%	99.99%	suffix = “ly”	97.56%	99.99%

has-period	92.55%	99.95%	suffix = “e”	89.57%	99.99%
has-comma	98.02%	99.97%			

Table 3: Classification accuracy for various binary word features using the character LSTM representations for words induced by a pre-trained parser. Performance substantially exceeds that of a majority class classifier in all cases, reaching 99.7% or higher for all features. The majority class is `True` for the first four features in the left column and `False` for the rest.

Deep Generative Model for Joint Alignment and Word Representation

Abstract

This work exploits translation data as a source of semantically relevant learning signal for models of word representation. In particular, we exploit equivalence through translation as a form of distributional context and jointly learn how to embed and align with a deep generative model. Our EMBEDALIGN model embeds words in their complete observed context and learns by marginalisation of latent lexical alignments. Besides, it embeds words as posterior probability densities, rather than point estimates, which allows us to compare words in context using a measure of overlap between distributions (e.g. KL divergence). We investigate our model's performance on a range of lexical semantics tasks achieving competitive results on several standard benchmarks including natural language inference, paraphrasing, and text similarity.

1 Introduction

Natural language processing applications often count on the availability of word representations trained on large textual data as a means to alleviate problems such as data sparsity and lack of linguistic resources (Collobert et al., 2011; Socher et al., 2011; Tu et al., 2017; Bowman et al., 2015).

Traditional approaches to inducing word representations circumvent the need for explicit semantic annotation by capitalising on some form of indirect semantic supervision. A typical example is to fit a binary classifier to detect whether or not a target word is likely to co-occur with neighbouring words (Mikolov et al., 2013). If the binary classifier represents a word as a continuous vector, that vector will be trained to be discriminative of the contexts it co-occurs with, and thus words in similar contexts will have similar representations.

The underlying assumption is that context (e.g. neighbouring words) stands for the meaning of the target word (Harris, 1954; Firth, 1957). The success of this *distributional hypothesis* hinges on the definition of context and different models are based on different definitions. Importantly, the nature of the context determines the range of linguistic properties the representations may capture (Levy and Goldberg, 2014b). For example, Levy and Goldberg (2014a) propose to use syntactic context derived from dependency parses. They show that their representations are much more discriminative of syntactic function than models based on immediate neighbourhood (Mikolov et al., 2013).

In this work, we take lexical translation as indirect semantic supervision (Diab and Resnik, 2002). Effectively we make two assumptions. First, that every word has a foreign equivalent that stands for its meaning. Second, that we can find this equivalent in translation data through lexical alignments.[1] For that we induce both a latent mapping between words in a bilingual sentence pair and distributions over latent word representations.

To summarise our contributions:

- we model a joint distribution over sentence pairs that generates data from latent word representations and latent lexical alignments;
- we embed words in context mining positive correlations from translation data;
- we find that foreign observations are necessary for generative training, but test time predictions can be made monolingually;
- we apply our model to a range of semantic natural language processing tasks showing its usefulness.

Code available from https://github.com/uva-slpl/embedalign

MR and WA contributed equally.

[1] These assumptions are not new to the community, but in this work they lead to a novel model which reaches more applications. §4 expands on the relation to other uses of bilingual data for word representation.

Proceedings of NAACL-HLT 2018, pages 1011–1023
New Orleans, Louisiana, June 1 - 6, 2018.

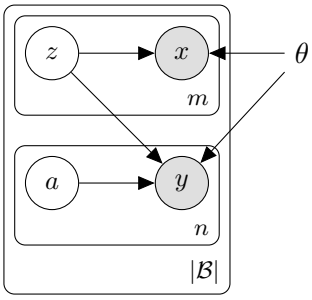

Figure 1: A sequence x_1^m is generated conditioned on a sequence of random embeddings z_1^m; generating the foreign sequence y_1^n further requires latent lexical alignments a_1^n.

2 EMBEDALIGN

In a nutshell, we model a distribution over pairs of sentences expressed in two languages, namely, a language of interest L1, and an auxiliary language L2 which our model uses to mine some learning signal. Our model, EMBEDALIGN, is governed by a simple generative story:

1. sample a length m for a sentence in L1 and a length n for a sentence in L2;
2. generate a sequence $z_1, \ldots, z_m$ of d-dimensional random embeddings by sampling independently from a standard Gaussian prior;
3. generate a word observation x_i in the vocabulary of L1 conditioned on the random embedding z_i;
4. generate a sequence $a_i, \ldots, a_n$ of n random alignments—each maps from a position a_j in x_1^m to a position j in the L2 sentence;
5. finally, generate an observation y_j in the vocabulary of L2 conditioned on the random embedding z_{a_j} that stands for x_{a_j}.

The model is parameterised by neural networks and parameters are estimated to maximise a lower-bound on log-likelihood of joint observations. In the following, we present the model formally (§2.1), discuss efficient training (§2.2), and concrete architectures (§2.3).

2.1 Probabilistic model

Notation We use block capitals (e.g. X) for random variables, lowercase letters (e.g. x) for assignments, and the shorthand X_1^m for a sequence $X_1, \ldots, X_m$. Boldface letters are reserved for deterministic vectors (e.g. $\mathbf{v}$) and matrices (e.g. $\mathbf{W}$). Finally, $\mathbb{E}[f(Z); \alpha]$ denotes the expected value of $f(z)$ under a density $q(z|\alpha)$.

We model a joint distribution over bilingual parallel data, i.e., L1–L2 sentence pairs. An observation is a pair of random sequences $\langle X_1^m, Y_1^n \rangle$, where a random variable X (Y) takes on values in the vocabulary of L1 (L2). For ease of exposition, the length m (n) of each sequence is assumed observed throughout. The L1 sentence is generated one word at a time from a random sequence of latent embeddings Z_1^m, each Z taking on values in $\mathbb{R}^d$. The L2 sentence is generated one word at a time given a random sequence of latent alignments A_1^n, where $A_j \in \{1, \ldots, m\}$ is the position in the L1 sentence to which y_j aligns.[2]

For $i \in \{1, \ldots, m\}$ and $j \in \{1, \ldots, n\}$ the generative story is

$$Z_i \sim \mathcal{N}(\mathbf{0}, \mathbf{I}) \tag{1a}$$
$$X_i | z_i \sim \text{Cat}(f(z_i; \theta)) \tag{1b}$$
$$A_j | m \sim \mathcal{U}(1/m) \tag{1c}$$
$$Y_j | z_1^m, a_j \sim \text{Cat}(g(z_{a_j}; \theta)) \tag{1d}$$

and Figure 1 is a graphical depiction of our model. We map from latent embeddings to categorical distributions over either vocabulary using a neural network whose parameters are deterministic and collectively denote by θ (the *generative parameters*). The marginal likelihood of a sentence pair is shown in Equation (2).

$$P_\theta(x_1^m, y_1^n | m, n) = \int p(z_1^m) \prod_{i=1}^{m} P_\theta(x_i | z_i) \times \prod_{j=1}^{n} \sum_{a_j=1}^{m} P(a_j | m) P_\theta(y_j | z_{a_j}) \mathrm{d}z_1^m \tag{2}$$

Due to the conditional independences of our model, it is trivial to marginalise lexical alignments for any given latent embeddings z_1^m, but marginalising the embeddings themselves is intractable. Thus, we employ amortised mean field variational inference using the inference model

$$q_\phi(z_1^m | x_1^m) \triangleq \prod_{i=1}^{m} \mathcal{N}(z_i | \mathbf{u}_i, \text{diag}(\mathbf{s}_i \odot \mathbf{s}_i)) \tag{3}$$

where each factor is a diagonal Gaussian. We map from x_1^m to a sequence $\mathbf{u}_1^m$ of independent posterior

[2] We pad L1 sentences with NULL to account for untranslatable L2 words (Brown et al., 1993). Instead, Schulz et al. (2016) generate untranslatable words from L2 context—an alternative we leave for future work.

mean (or location) vectors, where $\mathbf{u}_i \triangleq \mu(\mathbf{h}_i; \phi)$, as well as a sequence $\mathbf{s}_1^m$ of independent standard deviation (or scale) vectors, where $\mathbf{s}_i \triangleq \sigma(\mathbf{h}_i; \phi)$, and $\mathbf{h}_1^m = \text{enc}(x_1^m; \phi)$ is a deterministic encoding of the L1 sequence (we discuss concrete architectures in §2.3). All mappings are realised by neural networks whose parameters are collectively denoted by ϕ (the *variational parameters*). Note that we choose to approximate the posterior without conditioning on y_1^n. This allows us to use the inference model for *monolingual* prediction in absence of L2 data.

Variational ϕ and generative θ parameters are jointly point-estimated to attain a local optimum of the evidence lowerbound (Jordan et al., 1999):

$$\log P_\theta(x_1^m, y_1^n | m, n) \geq \sum_{i=1}^{m} \mathbb{E}\left[\log P_\theta(x_i|Z_i); \mathbf{u}_i, \mathbf{s}_i\right] + \sum_{j=1}^{n} \mathbb{E}\left[\log \sum_{a_j=1}^{m} P(a_j|m) P_\theta(y_j|Z_{a_j}); \mathbf{u}_1^m, \mathbf{s}_1^m\right] - \sum_{i=1}^{m} \text{KL}\left[\mathcal{N}(\mathbf{u}_i, \text{diag}(\mathbf{s}_i \odot \mathbf{s}_i)) || \mathcal{N}(\mathbf{0}, \mathbf{I})\right] \quad . \tag{4}$$

The variational family is location-scale, thus we can rely on stochastic optimisation (Robbins and Monro, 1951) and automatic differentiation (Baydin et al., 2015) with reparameterised gradient estimates (Kingma and Welling, 2014; Rezende et al., 2014; Titsias and Lázaro-Gredilla, 2014). Moreover, because the Gaussian density is an exponential family, the KL terms in (4) are available in closed-form (Kingma and Welling, 2014, Appendix B).

2.2 Efficient training

The likelihood terms in the ELBO (4) require evaluating two softmax layers over rather large vocabularies. This makes training prohibitively slow and calls for efficient approximation. We employ an approximation proposed by Botev et al. (2017) termed *complementary sum sampling* (CSS), which we review in this section.

Consider the likelihood term $\log P(X = \mathsf{x}|z)$ that scores an observation x given a sampled embedding z—we use serif font x to distinguish a particular observation from an arbitrary event $x \in \mathcal{X}$ in the support. The exact class probability

$$P(X = \mathsf{x}|z) = \frac{\exp(u(z, \mathsf{x}))}{\sum_{x \in \mathcal{X}} \exp(u(z, x))} \tag{5}$$

requires a normalisation over the complete support. CSS works by splitting the support into two sets, a set $\mathcal{C}$ that is explicitly summed over and must include the *positive* class x, and another set $\mathcal{N}$ that is a subset of the complement set $\mathcal{X} \setminus C$. We obtain an estimate for the normaliser

$$\sum_{x \in \mathcal{C}} \exp(u(z, x)) + \sum_{x \in \mathcal{N}} \kappa(x) \exp(u(z, x)) \tag{6}$$

by importance- or Bernoulli-sampling from the support using a proposal distribution $Q(X)$, where $\kappa(x)$ corrects for bias as $\mathcal{N}$ tends to the entire complement set. In this paper, we design $\mathcal{C}$ and $\mathcal{N}$ per training mini-batch: we take $\mathcal{C}$ to consist of all unique words in a mini-batch of training samples and $\mathcal{N}$ to consist of 10^3 negative classes uniformly sampled from the complement set $\mathcal{X} \setminus \mathcal{C}$, in which case $\kappa(x) = 10^{-3}|\mathcal{X} \setminus \mathcal{C}|$.[3]

CSS makes it particularly easy to approximate likelihood terms such as those with respect to L2 in Equation (4). Because those terms depend on a marginalisation over alignments, an approximation must give support to all words in the sequence y_1^n. With CSS this is extremely simple, we just need to make sure all unique words in y_1^n are in the set $\mathcal{C}$—which our mini-batch procedure does guarantee. Botev et al. (2017) show that CSS is rather stable and superior to the most popular softmax approximations. Besides being simple to implement, CSS also addresses a few problems with other approximations. To name a few: unlike importance sampling approximations, CSS converges to the exact softmax with bounded computation (it takes as many samples as there are classes). Unlike hierarchical softmax, CSS only affects training, that is, at test time we simply use the entire support instead of the approximation.

Without a softmax approximation, inference for our model would take time proportional to $O(m \times v_{\mathsf{x}} + m \times v_{\mathsf{y}} + m \times n)$ where v_{x} (v_{y}) corresponds to the size of the vocabulary of L1 (L2). The first term ($m \times v_{\mathsf{x}}$) corresponds to projecting from m latent embeddings to m categorical distributions over the vocabulary of L1. The second term ($m \times v_{\mathsf{y}}$) corresponds to projecting the same m latent embeddings to m categorical distributions over the vocabulary of L2. Finally, the third term ($m \times n$) is due to marginalisation of alignments.

[3] We sample uniformly from the complement set until we have 10^3 unique classes. We realise this operation outside the computation graph providing $\mathcal{C}$ and $\mathcal{N}$ as inputs to each training iteration, but a GPU-based solution is also possible.

Note, however, that with the CSS approximation we drop the dependency on vocabulary sizes (as the combined sizes of $\mathcal{C}$ and $\mathcal{N}$ is an independent constant). Moreover, if inference is performed on GPU, the squared term ($m \times n \approx m^2$) is amortised due to parallelism. Thus, while training our model is somewhat slower than monolingual models of word representation, which typically run in $O(m)$, it is not at all impracticably slower.

2.3 Architectures

Here we present the neural network architectures that parameterise the different generative and variational components of §2.1. Refer to Appendix B for an illustration.

Generative model We have two generative components, namely, a categorical distribution over the vocabulary of L1 and another over the vocabulary of L2. We predict the parameter (event probabilities) of each distribution with an affine transformation of a latent embedding followed by the softmax nonlinearity to ensure normalisation:

$$f(z_i; \theta) = \text{softmax}\left(\mathbf{W}_1 z_i + \mathbf{b}_1\right) \tag{7a}$$

$$g(z_{a_j}; \theta) = \text{softmax}\left(\mathbf{W}_2 z_{a_j} + \mathbf{b}_2\right) \tag{7b}$$

where $\mathbf{W}_1 \in \mathbb{R}^{v_x \times d}$, $\mathbf{b}_1 \in \mathbb{R}^{v_x}$, $\mathbf{W}_2 \in \mathbb{R}^{v_y \times d}$, $\mathbf{b}_2 \in \mathbb{R}^{v_y}$, and v_x (v_y) is the size of the vocabulary of L1 (L2). With the approximation of §2.2, we replace the L1 softmax layer (7a) by $\exp\left(z_i^\top \mathbf{c}_x + b_x\right)$ normalised by the CSS estimate (6) at training, and similarly for the L2 softmax layer (7b). In that case, we have parameters for $\mathbf{c}_x, \mathbf{c}_y \in \mathbb{R}^d$—deterministic embeddings for x and y, respectively—as well as bias terms $b_x, b_y \in \mathbb{R}$.

Inference model We predict approximate posterior parameters using two independent transformations

$$\mathbf{u}_i = \mathbf{M}_1 \mathbf{h}_i + \mathbf{d}_1 \tag{8a}$$

$$\mathbf{s}_i = \text{softplus}(\mathbf{M}_2 \mathbf{h}_i + \mathbf{d}_2) \tag{8b}$$

of a shared representation $\mathbf{h}_i \in \mathbb{R}^{d_x}$ of the ith word in the L1 sequence x_1^m—where $\mathbf{M}_1, \mathbf{M}_2 \in \mathbb{R}^{d \times d_x}$ are projection matrices, $\mathbf{d}_1, \mathbf{d}_2 \in \mathbb{R}^d$ are bias vectors, and the softplus nonlinearity ensures that standard deviations are non-negative. To obtain the deterministic encoding $\mathbf{h}_1^m$, we employ two different architectures: (1) a bag-of-words (BOW) encoder, where $\mathbf{h}_i$ is a deterministic projection of x_i onto $\mathbb{R}^{d_x}$; and (2) a bidirectional (BIRNN) encoder, where $\mathbf{h}_i$ is the element-wise sum of two LSTM hidden states (ith step) that process the sequence in opposite directions. We use 128 units for deterministic embeddings, and 100 units for LSTMs (Hochreiter and Schmidhuber, 1997) and latent representations (i.e. $d = 100$).

3 Experiments

We start the section describing the data used to estimate our model's parameters as well as details about the optimiser. The remainder of the section presents results on various benchmarks.

Training data We train our model on bilingual parallel data. In particular, we use parliament proceedings (Europarl-v7) (Koehn, 2005) from two language pairs: English-French and English-German.[4] We employed very minimal preprocessing, namely, tokenisation and lowercasing using scripts from MOSES (Koehn et al., 2007), and have discarded sentences longer than 50 tokens. Table 1 lists more information about the training data, including the English-French Giga web corpus (Bojar et al., 2014) which we use in §3.4.[5]

Corpus	Sentence pairs	Tokens
Europarl EN-FR	1.7	42.5
Europarl EN-DE	1.7	43.5
Giga EN-FR	18.3	419.6

Table 1: Training data size (in millions).

Optimiser For all architectures, we use the Adam optimiser (Kingma and Ba, 2014) with a learning rate of 10^{-3}. Except where explicitly indicated, we

- train our models for 30 epochs using mini batches of 100 sentence pairs;
- use validation alignment error rate for model selection;
- train every model 10 times with random *Glorot* initialisation (Glorot and Bengio, 2010) and report mean and standard deviation;
- anneal the KL terms using the following schedule: we use a scalar α from 0 to 1 with additive steps of size 10^{-3} every 500 updates.

[4] The proposed model is not limited to these language pairs.

[5] As we investigate various configurations and train every model 10 times to inspect variance in results, we conduct most of the experiments on the more manageable Europarl.

This means that at the beginning of the training, we allow the model to overfit to the likelihood terms, but towards the end we are optimising the true ELBO (Bowman et al., 2016).

It is also important to highlight that we do not employ regularisation techniques (such as batch normalisation, dropout, or L_2 penalty) for they did not seem to yield consistent results.

3.1 Word alignment

Since our model leverages learning signal from parallel data by marginalising latent lexical alignments, we use alignment error rate to double check whether the model learns sensible word correspondences. Intrinsic assessment of word alignment quality requires manual annotation. For English-French, we use the NAACL English-French hand-aligned data (37 sentence pairs for validation and 447 for test) (Mihalcea and Pedersen, 2003). For English-German, we use the data by Padó and Lapata (2006) (98 sentence pairs for validation and 987 for test). Alignment quality is then measured in terms of alignment error rate (AER) (Och and Ney, 2000)—an F-measure over predicted alignment links. For prediction we condition on the posterior means $\mathbb{E}[Z_1^m]$ which is just the predicted variational means $\mathbf{u}_1^m$ and select the `L1` position for which $P(y_j, a_j|\mathbf{u}_1^m)$ is maximum (a form of approximate Viterbi alignment).

Model	`L1` accuracy	`L2` accuracy	↓AER
BoW	95.59 ± 2.22	5.69 ± 2.07	35.41 ± 1.16
BoW$_\alpha$	99.87 ± 0.22	6.16 ± 0.39	30.94 ± 2.49
BiRNN	95.72 ± 1.28	7.31 ± 0.64	34.32 ± 1.08
BiRNN$_\alpha$	99.97 ± 0.09	7.25 ± 0.62	29.18 ± 1.91

Table 2: English-French validation ↑accuracy and ↓AER results.

Model	`L1` accuracy	`L2` accuracy	↓AER
BoW	93.51 ± 0.56	10.09 ± 0.20	53.66 ± 0.36
BoW$_\alpha$	97.72 ± 2.28	9.71 ± 0.63	52.81 ± 1.47
BiRNN	99.78 ± 0.18	8.63 ± 0.35	55.55 ± 0.67
BiRNN$_\alpha$	99.96 ± 0.05	8.32 ± 0.29	52.32 ± 1.77

Table 3: English-German validation ↑accuracy and ↓AER results.

We start by analysing validation results and selecting amongst a few variants of EmbedAlign. We investigate the use of annealing and the use of a bidirectional encoder in the variational approximation. Table 2 (3) lists ↓AER for En-Fr (En-De) as well as accuracy of word prediction. It is clear that both annealing (systems decorated with subscript α) and bidirectional representations improve the results across the board. In the rest of the paper we still investigate whether or not recurrent encoders help, but we always report results based on annealing.

In order to establish baselines for our models we report IBM models 1 and 2 (Brown et al., 1993). In a nutshell, IBM models 1 and 2 both estimate the conditional $P(y_j|x_1^m) = \sum_{a_j=1}^m P(a_j|m)P(y_j|x_{a_j})$ by marginalisation of latent lexical alignments. The only difference between the two models is the prior over alignments, which is uniform for IBM1 and categorical for IBM2. An important difference between IBM models and EmbedAlign concerns the lexical distribution. IBM models are parameterised with independent categorical parameters, while our model instead is parameterised by a neural network. IBM models condition on a single categorical event x_{a_j}, namely, the word aligned to. Our model instead conditions on the latent embedding z_{a_j} that stands for the word aligned to.

In order to establish even stronger conditional alignment models, we embed the conditioning words and replace IBM1's independent parameters by a neural network (single hidden layer MLP). We call this model a *neural IBM1* (or NIBM for short). Note that in an IBM model, the sequence x_1^m is never modelled, therefore we can condition on it without restrictions. For that reason, we also experiment with a bidirectional LSTM encoder and condition lexical distributions on its hidden states.

Model	En-Fr	En-De
IBM1	32.45	46.71
IBM2	22.61	40.11
NIBM$_{\text{BoW}}$	27.35 ± 0.19	46.22 ± 0.07
NIBM$_{\text{BiRNN}}$	25.57 ± 0.40	43.37 ± 0.11
EmbedAlign$_{\text{BoW}}$	30.97 ± 2.53	49.46 ± 1.72
EmbedAlign$_{\text{BiRNN}}$	29.43 ± 1.84	48.09 ± 2.12

Table 4: Test ↓AER.

Table 4 shows AER for test predictions. First observe that neural models outperform classic IBM1 by far, some of them even approach IBM2's performance. Next, observe that bidirectional encodings make NIBM much stronger at inducing good word-

to-word correspondences. EMBEDALIGN cannot catch up with NIBM, but that is not necessarily surprising. Note that NIBM is a conditional model, thus it can use all of its capacity to better explain L2 data. EMBEDALIGN, on the other hand, has to find a compromise between generating both streams of the data. To make that point a bit more obvious, Table 5 (6) lists accuracy of word prediction for EN-FR (EN-DE). Note that, without sacrificing L2 accuracy, and sometimes even improving it, EMBEDALIGN achieves very high L1 accuracy. This still does not imply that induced representations have captured aspects of lexical semantics such as word senses. All this means is that we have induced features that are jointly good at reconstructing both streams of the data one word at time. Of course it is tempting to conclude that our models must be capturing some useful generalisations. For that, the next sections will investigate a range of semantic NLP tasks.

3.2 Lexical substitution task

The English lexical substitution task (LST) consists in selecting a substitute word for a target word *in context* (McCarthy and Navigli, 2009). In the most traditional variant of the task, systems are presented with a list of potential candidates and this list must be sorted by relatedness.

Dataset The LST dataset includes 201 target words present in 10 sentences/contexts each, along with a manually annotated list of potential replacements. The data are split in 300 instances for validation and 1,710 for test. Systems are evaluated by comparing the predicted ranking to the manual one in terms of generalised average precision (GAP) (Melamud et al., 2015).

Model	cos	KL
RANDOM	30.0	-
SKIPGRAM	44.9	-
BSG	-	46.1
EN_{BoW}	29.75 ± 0.55	27.93 ± 0.25
EN_{BiRNN}	21.31 ± 1.05	27.64 ± 0.40
$\text{EN-FR}_{\text{BoW}}$	42.72 ± 0.36	41.90 ± 0.35
$\text{EN-FR}_{\text{BiRNN}}$	42.19 ± 0.57	41.61 ± 0.55
$\text{EN-DE}_{\text{BoW}}$	41.90 ± 0.58	40.63 ± 0.55
$\text{EN-DE}_{\text{BiRNN}}$	42.07 ± 0.47	40.93 ± 0.59

Table 7: English ↑GAP on LST test data.

Prediction We use EMBEDALIGN to encode each candidate (in context) as a posterior Gaussian density. Note that this task dispenses with inferences about L2. Each candidate is compared to the target word in context through a measure of overlap between their inferred densities—we take KL divergence. We then rank candidates using this measure.

Table 7 lists GAP scores for variants of EMBEDALIN (bottom section) as well as some baselines and other established methods (top section). For comparison, we also compute GAP by sorting candidates in terms of cosine similarity, in which case we take the Gaussian mean as a summary of the density. The top section of the table contains systems reported by Melamud et al. (2015) (RANDOM and SKIPGRAM) and by Brazinskas et al. (2017) (BSG). Note that both SKIPGRAM (Mikolov et al., 2013) and BSG were trained on the very large ukWaC English corpus (Ferraresi et al., 2008). SKIPGRAM is known to perform remarkably well regardless of its apparent insensitivity to context (in terms of design). BSG is a close relative of our model which gives SKIPGRAM a Bayesian treatment (also by means of amortised variational inference) and is by design sensitive to context in a manner similar to EMBEDALIGN, that is, through its inferred posteriors.

Our first observation is that cosine seems to outperform KL slightly. Others have shown that KL can be used to predict directional entailment (Vilnis and McCallum, 2014; Brazinskas et al., 2017), since LST is closer to paraphrasing than to entailment directionality may be a distractor, but we

Model	MR	CR	SUBJ	MPQA	SST	TREC	MRPC	SICK-R	SICK-E	SST14

Table 8: English sentence evaluation results: the last four rows correspond to the mean of 10 runs with EMBEDALIGN models. All models, but W2VEC, employ bidirectional encoders.

leave it as a rather speculative point. One additional point worth highlighting: the middle section of Table 7. EN_{BoW} and EN_{BiRNN} show what happens when we do not give EMBEDALIGN `L2` supervision at training. That is, imagine the model of Figure 1 without the bottom plate. In that case, the model representations overfit for `L1` word-by-word prediction. Without the need to predict any notion of context (monolingual or otherwise), the representations drift away from semantic-driven generalisations and fail at lexical substitution.

3.3 Sentence Evaluation

Conneau et al. (2017) developed a framework to evaluate unsupervised sentence level representations trained on large amounts of data on a range of supervised NLP tasks. We assess our induced representations using their framework on the following benchmarks evaluated on classification ↑accuracy (MRPC is further evaluated on ↑F1)

MR classification of positive or negative movie reviews;

SST fined-grained labelling of movie reviews from the Stanford sentiment treebank (SST);

TREC classification of questions into k-classes;

CR classification of positive or negative product reviews;

SUBJ classification of a sentence into subjective or objective;

MPQA classification of opinion polarity;

SICK-E textual entailment classification;

MRPC paraphrase identification in the Microsoft paraphrase corpus;

as well as the following benchmarks evaluated on the indicated correlation metric(s)

SICK-R semantic relatedness between two sentences (↑Pearson);

SST-14 semantic textual similarity (↑Pearson/Spearman).

Prediction We use EMBEDALIGN to annotate every word in the training set of the benchmarks above with the posterior mean embedding in context. We then average embeddings in a sentence and give that as features to a logistic regression classifier trained with 5-fold cross validation.[6]

For comparison, we report a SKIPGRAM model (here indicated as W2VEC) as well as a model that uses the encoder of a neural machine translation system (NMT) trained on English-French Europarl data. In both cases, we report results by Conneau et al. (2017). Table 8 shows the results for all benchmarks.[7] We report EMBEDALIGN trained on either EN-FR or EN-DE. The last line (COMBO) shows what happens if we train logistic regression on the concatenation of embeddings inferred by both EMBEDALIGN models, that is, EN-FR and EN-DE. Note that these two systems perform sometimes better sometimes worse depending on the benchmark. There is no clear pattern, but differences may well come from some qualitative difference in the induced latent space. It is a known fact that different languages realise lexical ambiguities differently, thus representations induced towards different languages are likely to capture different generalisations.[8] As COMBO results show, the representations induced from different corpora are somewhat complementary. That same observation has guided paraphrasing models based on pivoting (Bannard and Callison-Burch, 2005). Once more we report a monolingual variant of EMBEDALIGN (indicated by EN) in an attempt to illustrate how crucial the

[7] In Appendix A we provide bar plots marked with error bars (2 standard deviations).

[8] We also acknowledge that our treatment of German is likely suboptimal due to the lack of subword features, as it can also be seen in AER results.

translation signal is.

3.4 Word similarity

Word similarity benchmarks are composed of word pairs which are manually ranked out of context. For completeness, we also tried evaluating our embeddings in such benchmarks despite our work being focussed on applications where context matters.

Prediction To assign an embedding for a word type, we infer Gaussian posteriors for all training instances of that type in context and aggregate the posterior means through an average (effectively collapsing all instances).

To cover the vocabulary of the typical benchmark, we have to use a much larger bilingual collection than Europarl. Based on the results of §3.1, we decided to proceed with English-French only—recall that models based on that pair performed better in terms of AER. Results in this section are based on EMBEDALIGN (with bidirectional variational encoder) trained on the Giga web corpus (see Table 1 for statistics). Due to the scale of the experiment, we report on a single run.

We trained on Giga with the same hyperparameters that we trained on Europarl, however, for 3 epochs instead of 30 (with this dataset an epoch amounts to $183,000$ updates). Again, we performed model selection on AER. Table 9 shows the results for several datasets using the framework of Faruqui and Dyer (2014a). Note that EMBEDALIGN was designed to make use of context information, thus this evaluation setup is a bit unnatural for our model. Still, it outperforms SKIPGRAM on 5 out of 13 benchmarks, in particular, on SIMLEX-999, whose relevance has been argued by Upadhyay et al. (2016). We also remark that this model achieves 0.25 test AER and 45.16 test GAP on lexical substitution—a considerable improvement compared to models trained on Europarl and reported in Tables 4 (AER) and 7 (GAP).

Dataset	SKIPGRAM	EMBEDALIGN

4 Related work

Our model is inspired by lexical alignment models such as IBM1 (Brown et al., 1993), however, we generate words y_1^n from a latent vector representation z_1^m of x_1^m, rather than directly from the observation x_1^m. IBM1 takes `L1` sequences as conditioning context and does not model their distribution. Instead, we propose a joint model, where `L1` sentences are generated from latent embeddings.

There is a vast literature on exploiting multilingual context to strengthen the notion of synonymy captured by monolingual models. Roughly, the literature splits into two groups, namely, approaches that derive additional features and/or training objectives based on pre-trained alignments (Klementiev et al., 2012; Faruqui and Dyer, 2014b; Luong et al., 2015; Šuster et al., 2016), and approaches that promote a joint embedding space by working with sentence level representations that dispense with explicit alignments (Hermann and Blunsom, 2014; AP et al., 2014; Gouws et al., 2015; Hill et al., 2014).

The work of Kočiský et al. (2014) is closer to ours in that they also learn embeddings by marginalising alignments, however, their model is conditional—much like IBM models—and their embeddings are not part of the probabilistic model, but rather part of the architecture design. The joint formulation allows our latent embeddings to harvest learning signal from `L2` while still being driven by the learning signal from `L1`—in a conditional model the representations can become specific to alignment deviating from the purpose of well representing the original language. In §3 we show substantial evidence that our model performs better when using both learning signals.

Vilnis and McCallum (2014) first propose to map words into Gaussian densities instead of point estimates for better word representation. For example, a distribution can capture asymmetric relations that

a point estimate cannot. Brazinskas et al. (2017) recast the skip-gram model as a conditional variational auto-encoder. They induce a Gaussian density for each occurrence of a word in context, and for that their model is the closest to ours. Additionally, they estimate a Gaussian prior per word type thus representing both types and occurrences. Unlike our model, the Bayesian skip-gram is not trained generatively by reconstructing the data, but rather discriminatively by prediction of overlapping sets of neighbouring words.

5 Discussion

We have presented a generative model of word representation that learns from positive correlations implicitly expressed in translation data. In order to make these correlations surface, we induce and marginalise latent lexical alignments.

Embedding models such as CBOW and skip-gram (Mikolov et al., 2013) are essentially speaking supervised classifiers. This means they depend on somewhat artificial strategies to derive labelled data from monolingual corpora—words far from the central word still have co-occurred with it even though they are taken as negative evidence. Training our proposed model does not require a heuristic notion of negative training data. However, the model is also based on a somewhat artificial assumption: `L1` words do not necessarily need to have an `L2` equivalent and, even when they do, this equivalent need not be realised as a single word.

We have shown with extensive experiments that our model can induce representations useful to several tasks including but not limited to alignment (the task it most obviously relates to). We observed interesting results on semantic natural language processing benchmarks such as natural language inference, lexical substitution, paraphrasing, and sentiment classification.

We are currently expanding the notion of distributional context to multiple auxiliary foreign languages at once. This seems to only require minor changes to the generative story and could increase the model's disambiguation power dramatically. Another direction worth exploring is to extend the model's hierarchy with respect to how parallel sentences are generated. For example, modelling sentence level latent variables may capture global constraints and expose additional correlations to the model.

Abstract

Word embedding is a key component in many downstream applications in processing natural languages. Existing approaches often assume the existence of a large collection of text for learning effective word embedding. However, such a corpus may not be available for some low-resource languages. In this paper, we study how to effectively learn a word embedding model on a corpus with only a few million tokens. In such a situation, the co-occurrence matrix is sparse as the co-occurrences of many word pairs are unobserved. In contrast to existing approaches often only sample a few unobserved word pairs as negative samples, we argue that the zero entries in the co-occurrence matrix also provide valuable information. We then design a Positive-Unlabeled Learning (PU-Learning) approach to factorize the co-occurrence matrix and validate the proposed approaches in four different languages.

1 Introduction

Learning word representations has become a fundamental problem in processing natural languages. These semantic representations, which map a word into a point in a linear space, have been widely applied in downstream applications, including named entity recognition (Guo et al., 2014), document ranking (Nalisnick et al., 2016), sentiment analysis (Irsoy and Cardie, 2014), question answering (Antol et al., 2015), and image captioning (Karpathy and Fei-Fei, 2015).

Over the past few years, various approaches have been proposed to learn word vectors (e.g., (Pennington et al., 2014; Mikolov et al., 2013a; Levy and Goldberg, 2014b; Ji et al., 2015)) based on co-occurrence information between words observed on the training corpus. The intuition behind this is to represent words with similar vectors if they have similar contexts. To learn a good word embedding, most approaches assume a large collection of text is freely available, such that the estimation of word co-occurrences is accurate. For example, the Google Word2Vec model (Mikolov et al., 2013a) is trained on the Google News dataset, which contains around 100 billion tokens, and the GloVe embedding (Pennington et al., 2014) is trained on a crawled corpus that contains 840 billion tokens in total. However, such an assumption may not hold for low-resource languages such as Inuit or Sindhi, which are not spoken by many people or have not been put into a digital format. For those languages, usually, only a limited size corpus is available. Training word vectors under such a setting is a challenging problem.

One key restriction of the existing approaches is that they often mainly rely on the word pairs that are observed to co-occur on the training data. When the size of the text corpus is small, most word pairs are unobserved, resulting in an extremely sparse co-occurrence matrix (i.e., most entries are zero)[1]. For example, the text8[2] corpus has about 17,000,000 tokens and 71,000 distinct words. The corresponding co-occurrence matrix has more than five billion entries, but only about 45,000,000 are non-zeros (observed on the training corpus). Most existing approaches, such as Glove and Skip-gram, cannot handle a vast number of zero terms in the co-occurrence matrix; therefore, they only sub-sample a small subset of zero entries during the training.

In contrast, we argue that the *unobserved* word pairs can provide valuable information for training a word embedding model, especially when the co-occurrence matrix is very sparse. Inspired

[1]Note that the zero term can mean either the pairs of words cannot co-occur or the co-occurrence is not observed in the training corpus.

by the success of Positive-Unlabeled Learning (PU-Learning) in collaborative filtering applications (Pan et al., 2008; Hu et al., 2008; Pan and Scholz, 2009; Qin et al., 2010; Paquet and Koenigstein, 2013; Hsieh et al., 2015), we design an algorithm to effectively learn word embeddings from both positive (observed terms) and unlabeled (unobserved/zero terms) examples. Essentially, by using the square loss to model the unobserved terms and designing an efficient update rule based on linear algebra operations, the proposed PU-Learning framework can be trained efficiently and effectively.

We evaluate the performance of the proposed approach in English[3] and other three resource-scarce languages. We collected unlabeled language corpora from Wikipedia and compared the proposed approach with popular approaches, the Glove and the Skip-gram models, for training word embeddings. The experimental results show that our approach significantly outperforms the baseline models, especially when the size of the training corpus is small.

Our key contributions are summarized below.

- We propose a PU-Learning framework for learning word embedding.
- We tailor the coordinate descent algorithm (Yu et al., 2017b) for solving the corresponding optimization problem.
- Our experimental results show that PU-Learning improves the word embedding training in the low-resource setting.

2 Related work

Learning word vectors. The idea of learning word representations can be traced back to Latent Semantic Analysis (LSA) (Deerwester et al., 1990) and Hyperspace Analogue to Language (HAL) (Lund and Burgess, 1996), where word vectors are generated by factorizing a word-document and word-word co-occurrence matrix, respectively. Similar approaches can also be extended to learn other types of relations between words (Yih et al., 2012; Chang et al., 2013) or entities (Chang et al., 2014). However, due to the limitation of the use of principal component analysis, these approaches are often less flexible. Besides, directly factorizing the co-occurrence matrix may cause the frequent words dominating the training objective.

In the past decade, various approaches have been proposed to improve the training of word embeddings. For example, instead of factorizing the co-occurrence count matrix, Bullinaria and Levy (2007); Levy and Goldberg (2014b) proposed to factorize *point-wise mutual information* (PMI) and *positive PMI* (PPMI) matrices as these metrics scale the co-occurrence counts (Bullinaria and Levy, 2007; Levy and Goldberg, 2014b). Skip-gram model with negative-sampling (SGNS) and Continuous Bag-of-Words models (Mikolov et al., 2013b) were proposed for training word vectors on a large scale without consuming a large amount of memory. GloVe (Pennington et al., 2014) is proposed as an alternative to decompose a weighted log co-occurrence matrix with a bias term added to each word. Very recently, *WordRank* model (Ji et al., 2015) has been proposed to minimize a ranking loss which naturally fits the tasks requiring ranking based evaluation metrics. Stratos et al. (2015) also proposed CCA (canonical correlation analysis)-based word embedding which shows competitive performance. All these approaches focus on the situations where a large text corpus is available.

Positive and Unlabeled (PU) Learning: Positive and Unlabeled (PU) learning (Li and Liu, 2005) is proposed for training a model when the positive instances are partially labeled and the unlabeled instances are mostly negative. Recently, PU learning has been used in many classification and collaborative filtering applications due to the nature of "implicit feedback" in many recommendation systems—users usually only provide positive feedback (e.g., purchases, clicks) and it is very hard to collect negative feedback.

To resolve this problem, a series of PU matrix completion algorithms have been proposed (Pan et al., 2008; Hu et al., 2008; Pan and Scholz, 2009; Qin et al., 2010; Paquet and Koenigstein, 2013; Hsieh et al., 2015; Yu et al., 2017b). The main idea is to assign a small uniform weight to all the missing or zero entries and factorize the corresponding matrix. Among them, Yu et al. (2017b) proposed an efficient algorithm for matrix factorization with PU-learning, such that the weighted matrix is constructed implicitly. In this paper, we

[3] Although English is not a resource-scarce language, we simulate the low-resource setting in an English corpus. In this way, we leverage the existing evaluation methods to evaluate the proposed approach.

design a new approach for training word vectors by leveraging the PU-Learning framework and existing word embedding techniques. To the best of our knowledge, this is the first work to train word embedding models using the PU-learning framework.

3 PU-Learning for Word Embedding

Similar to GloVe and other word embedding learning algorithms, the proposed approach consists of three steps. The first step is to construct a co-occurrence matrix. Follow the literature (Levy and Goldberg, 2014a), we use the PPMI metric to measure the co-occurrence between words. Then, in the second step, a PU-Learning approach is applied to factorize the co-occurrence matrix and generate word vectors and context vectors. Finally, a post-processing step generates the final embedding vector for each word by combining the word vector and the context vector.

We summarize the notations used in this paper in Table 1 and describe the details of each step in the remainder of this section.

3.1 Building the Co-Occurrence Matrix

Various metrics can be used for estimating the co-occurrence between words in a corpus. PPMI metric stems from *point-wise mutual information* (PMI) which has been widely used as a measure of word association in NLP for various tasks (Church and Hanks, 1990). In our case, each entry $PMI(w, c)$ represents the relevant measure between a word w and a context word c by calculating the ratio between their joint probability (the chance they appear together in a local context window) and their marginal probabilities (the chance they appear independently) (Levy and Goldberg, 2014b). More specifically, each entry of PMI matrix can be defined by

$$PMI(w, c) = \log \frac{\hat{P}(w, c)}{\hat{P}(w) \cdot \hat{P}(c)}, \qquad (1)$$

where $\hat{P}(w), \hat{P}(c)$ and $\hat{P}(w, c)$ are the the frequency of word w, word c, and word pairs (w, c), respectively. The PMI matrix can be computed based on the co-occurrence counts of word pairs, and it is an information-theoretic association measure which effectively eliminates the big differences in magnitude among entries in the co-occurrence matrix.

Extending from the PMI metric, the PPMI metric replaces all the negative entries in PMI matrix by 0:

$$PPMI(w, c) = \max(PMI(w, c), 0). \qquad (2)$$

The intuition behind this is that people usually perceive positive associations between words (e.g. "ice" and "snow"). In contrast, the negative association is hard to define (Levy and Goldberg, 2014b). Therefore, it is reasonable to replace the negative entries in the PMI matrix by 0, such that the negative association is treated as "uninformative". Empirically, several existing works (Levy et al., 2015; Bullinaria and Levy, 2007) showed that the PPMI metric achieves good performance on various semantic similarity tasks.

In practice, we follow the pipeline described in Levy et al. (2015) to build the PPMI matrix and apply several useful tricks to improve its quality. First, we apply a context distribution smoothing mechanism to enlarge the probability of sampling a rare context. In particular, all context counts are scaled to the power of α.[4]:

$$PPMI_\alpha(w, c) = \max\left(\log \frac{\hat{P}(w, c)}{\hat{P}(w)\hat{P}_\alpha(c)}, 0\right)$$

$$\hat{P}_\alpha(c) = \frac{\#(c)^\alpha}{\sum_{\bar{c}} \#(\bar{c})^\alpha},$$

where $\#(w)$ denotes the number of times word w appears. This smoothing mechanism effectively

[4]Empirically, $\alpha = 0.75$ works well (Mikolov et al., 2013b).

alleviates PPMI's bias towards rare words (Levy et al., 2015).

Next, previous studies show that words that occur too frequent often dominate the training objective (Levy et al., 2015) and degrade the performance of word embedding. To avoid this issue, we follow Levy et al. (2015) to sub-sample words with frequency more than a threshold t with a probability p defined as:

$$p = 1 - \sqrt{\frac{t}{\hat{P}(w)}}.$$

3.2 PU-Learning for Matrix Factorization

We proposed a matrix factorization based word embedding model which aims to minimize the reconstruction error on the PPMI matrix. The low-rank embeddings are obtained by solving the following optimization problem:

$$\min_{W,H} \sum_{i,j \in \Omega} C_{ij}(A_{ij} - \boldsymbol{w}_i^T \boldsymbol{h}_j - b_i - \hat{b}_j)^2 + \sum_i \lambda_i \|\boldsymbol{w}_i\|^2 + \sum_j \overline{\lambda}_j \|\boldsymbol{h}_j\|^2, \quad (3)$$

where W and H are $m \times k$ and $n \times k$ latent matrices, representing words and context words, respectively. The first term in Eq. (3) aims for minimizing reconstruction error, and the second and third terms are regularization terms. λ_i and $\overline{\lambda}_j$ are weights of regularization term. They are hyper-parameters that need to be tuned.

The zero entries in co-occurrence matrix denote that two words never appear together in the current corpus, which also refers to unobserved terms. The unobserved term can be either real zero (two words shouldn't be co-occurred even when we use very large corpus) or just missing in the small corpus. In contrast to SGNS sub-sampling a small set of zero entries as negative samples, our model will try to use the information from all zeros.

The set Ω includes all the $|\mathcal{W}| \times |\mathcal{C}|$ entries—both positive and zero entries:

$$\Omega = \Omega^+ \cup \Omega^-. \quad (4)$$

Note that we define the positive samples Ω^+ to be all the (w, c) pairs that appear at least one time in the corpus, and negative samples Ω^- are word pairs that never appear in the corpus.

Weighting function. Eq (3) is very similar to the one used in previous matrix factorization approaches such as GloVe, but we propose a new way to set the weights C_{ij}. If we set equal weights for all the entries, then C_{ij} = constant, and the model is very similar to conducting SVD for the PPMI matrix. Previous work has shown that this approach often suffers from poor performance (Pennington et al., 2014). More advanced methods, such as GloVe, set non-uniform weights for observed entries to reflect their confidence. However, the time complexity of their algorithm is proportional to number of nonzero weights ($|(i,j) \mid C_{ij} \neq 0|$), thus they have to set zero weights for all the unobserved entries ($C_{ij} = 0$ for Ω^-), or try to incorporate a small set of unobserved entries by negative sampling.

We propose to set the weights for Ω^+ and Ω^- differently using the following scheme:

$$C_{ij} = \begin{cases} (Q_{ij}/x_{max})^\alpha, & \text{if } Q_{ij} \leq x_{max}, \text{ and } (i,j) \in \Omega^+ \\ 1, & \text{if } Q_{ij} > x_{max}, \text{ and } (i,j) \in \Omega^+ \\ \rho, & (i,j) \in \Omega^- \end{cases} \quad (5)$$

Here x_{max} and α are re-weighting parameters, and ρ is the unified weight for unobserved terms. We will discuss them later.

For entries in Ω^+, we set the non-uniform weights as in GloVe (Pennington et al., 2014), which assigns larger weights to context word that appears more often with the given word, but also avoids overwhelming the other terms. For entries in Ω^-, instead of setting their weights to be 0, we assign a small constant weight ρ. The main idea is from the literature of PU-learning (Hu et al., 2008; Hsieh et al., 2015): although missing entries are highly uncertain, they are still likely to be true 0, so we should incorporate them in the learning process but multiplying with a smaller weight according to the uncertainty. Therefore, ρ in (5) reflects how confident we are to the zero entries.

In our experiments, we set $x_{max} = 10, \alpha = 3/4$ according to (Pennington et al., 2014), and let ρ be a parameter to tune. Experiments show that adding weighting function obviously improves the performance especially on analogy tasks.

Bias term. Unlike previous work on PU matrix completion (Yu et al., 2017b; Hsieh et al., 2015), we add the bias terms for word and context word

vectors. Instead of directly using $\boldsymbol{w}_i^\top \boldsymbol{h}_j$ to approximate A_{ij}, we use

$$A_{ij} \approx \boldsymbol{w}_i^\top \boldsymbol{h}_j + b_i + \hat{b}_j.$$

Yu et al. (2017b) design an efficient column-wise coordinate descent algorithm for solving the PU matrix factorization problem; however, they do not consider the bias term in their implementations. To incorporate the bias term in (3), we propose the following training algorithm based on the coordinate descent approach. Our algorithm does not introduce much overhead compared to that in (Yu et al., 2017b).

We augment each $\boldsymbol{w}_i, \boldsymbol{h}_j \in R^k$ into the following $(k+2)$ dimensional vectors:

$$\boldsymbol{w}'_i = \begin{bmatrix} w_{i1} \\ \vdots \\ w_{ik} \\ 1 \\ b_i \end{bmatrix} \quad \boldsymbol{h}'_j = \begin{bmatrix} h_{j1} \\ \vdots \\ h_{jk} \\ \hat{b}_j \\ 1 \end{bmatrix}$$

Therefore, for each word and context vector, we have the following equality

$$\langle \boldsymbol{w}'_i, \boldsymbol{h}'_j \rangle = \langle \boldsymbol{w}_i, \boldsymbol{h}_j \rangle + b_i + \hat{b}_j,$$

which means the loss function in (3) can be written as

$$\sum_{i,j \in \Omega} C_{ij} (A_{ij} - \boldsymbol{w}_i'^\top \boldsymbol{h}'_j)^2.$$

Also, we denote $W' = [\boldsymbol{w}'_1, \boldsymbol{w}'_2, \ldots, \boldsymbol{w}'_n]^\top$ and $H' = [\boldsymbol{h}'_1, \boldsymbol{h}'_2, \ldots, \boldsymbol{h}'_n]^\top$. In the column-wise coordinate descent method, at each iteration we pick a $t \in \{1, \ldots, (k+2)\}$, and update the t-th column of W' and H'. The updates can be derived for the following two cases:

a. When $t \leq k$, the elements in the t-th column is $w_{1t}, \ldots, w_{nt}$ and we can directly use the update rule derived in Yu et al. (2017b) to update them.

b. When $t = k+1$, we do not update the corresponding column of W' since the elements are all 1, and we use the similar coordinate descent update to update the $k+1$-th column of H' (corresponding to $\hat{b}_1, \ldots, \hat{b}_n$). When $t = k+2$, we do not update the corresponding column of H' (they are all 1) and we update the $k+2$-th column of W' (corresponding to $b_1, \ldots, b_n$) using coordinate descent.

With some further derivations, we can show that the algorithm only requires $O(\text{nnz}(A) + nk)$ time to update each column,[5] so the overall complexity is $O(\text{nnz}(A)k + nk^2)$ time per epoch, which is only proportional to number of nonzero terms in A. Therefore, with the same time complexity as GloVe, we can utilize the information from all the zero entries in A instead of only sub-sampling a small set of zero entries.

3.3 Interpretation of Parameters

In the PU-Learning formulation, ρ represents the unified weight that assigned to the unobserved terms. Intuitively, ρ reflects the confidence on unobserved entries—larger ρ means that we are quite certain about the zeroes, while small ρ indicates the many of unobserved pairs are not truly zero. When $\rho = 0$, the PU-Learning approach reduces to a model similar to GloVe, which discards all the unobserved terms. In practice, ρ is an important parameter to tune, and we find that $\rho = 0.0625$ achieves the best results in general. Regarding the other parameter, λ is the regularization term for preventing the embedding model from overfitting. In practice, we found the performance is not very sensitive to λ as long as it is resonably small. More discussion about the parameter setting can be found in Section 5.

Post-processing of Word/Context Vectors The PU-Learning framework factorizes the PPMI matrix and generates two vectors for each word i, $\boldsymbol{w}_i \in R^k$ and $\boldsymbol{h}_i \in R^k$. The former represents the word when it is the central word and the latter represents the word when it is in context. Levy et al. (2015) shows that averaging these two vectors ($\boldsymbol{u}_i^{\text{avg}} = \boldsymbol{w}_i + \boldsymbol{h}_i$) leads to consistently better performance. The same trick of constructing word vectors is also used in GloVe. Therefore, in the experiments, we evaluate all models with $\boldsymbol{u}^{\text{avg}}$.

4 Experimental Setup

Our goal in this paper is to train word embedding models for low-resource languages. In this section, we describe the experimental designs to evaluate the proposed PU-learning approach. We first describe the data sets and the evaluation metrics. Then, we provide details of parameter tuning.

[5] Here we assume $m = n$ for the sake of simplicity. And, nnz(A) denotes the number of nonzero terms in the matrix A.

4.1 Evaluation tasks

We consider two widely used tasks for evaluating word embeddings, the word similarity task and the word analogy task. In the word similarity task, each question contains a word pairs and an annotated similarity score. The goal is to predict the similarity score between two words based on the inner product between the corresponding word vectors. The performance is then measured by the Spearmans rank correlation coefficient, which estimates the correlation between the model predictions and human annotations. Following the settings in literature, the experiments are conducted on five data sets, *WordSim353* (Finkelstein et al., 2001), *WordSim Similarity* (Zesch et al., 2008), *WordSim Relatedness* (Agirre et al., 2009), *Mechanical Turk* (Radinsky et al., 2011) and *MEN* (Bruni et al., 2012).

In the word analogy task, we aim at solving analogy puzzles like "man is to woman as king is to ?", where the expected answer is "queen." We consider two approaches for generating answers to the puzzles, namely 3CosAdd and 3CosMul (see (Levy and Goldberg, 2014a) for details). We evaluate the performances on *Google analogy* dataset (Mikolov et al., 2013a) which contains 8,860 semantic and 10,675 syntactic questions. For the analogy task, only the answer that exactly matches the annotated answer is counted as correct. As a result, the analogy task is more difficult than the similarity task because the evaluation metric is stricter and it requires algorithms to differentiate words with similar meaning and find the right answer.

To evaluate the performances of models in the low-resource setting, we train word embedding models on Dutch, Danish, Czech and, English data sets collected from Wikipedia. The original Wikipedia corpora in Dutch, Danish, Czech and English contain 216 million, 47 million, 92 million, and 1.8 billion tokens, respectively. To simulate the low-resource setting, we sub-sample the Wikipedia corpora and create a subset of 64 million tokens for Dutch and Czech and a subset of 32 million tokens for English. We will demonstrate how the size of the corpus affects the performance of embedding models in the experiments.

To evaluate the performance of word embeddings in Czech, Danish, and Dutch, we translate the English similarity and analogy test sets to the other languages by using Google Cloud Translation API[6]. However, an English word may be translated to multiple words in another language (e.g., compound nouns). We discard questions containing such words (see Table 3 for details). Because all approaches are compared on the same test set for each language, the comparisons are fair.

4.2 Implementation and Parameter Setting

We compare the proposed approach with two baseline methods, GloVe and SGNS. The imple-

Table 4: Performance of SGNS, GloVe, and the proposed PU-Learning model in four different languages. Results show that the proposed PU-Learning model outperforms SGNS and GloVe in most cases when the size of corpus is relatively small (around 50 million tokens). Star indicates it is significant better than the second best algorithm in the same column according to Wilcoxon signed-rank test. ($p < 0.05$).

mentations of Glove[7] and SGNS[8] and provided by the original authors, and we apply the default settings when appropriate. The proposed PU-Learning framework is implemented based on Yu et al. (2017a). With the implementation of efficient update rules, our model requires less than 500 seconds to perform one iteration over the entire text8 corpus, which consists of 17 million tokens [9]. All the models are implemented in C++.

We follow Levy et al. (2015)[10] to set windows size as 15, minimal count as 5, and dimension of word vectors as 300 in the experiments. Training word embedding models involves selecting several hyper-parameters. However, as the word embeddings are usually evaluated in an unsupervised setting (i.e., the evaluation data sets are not seen during the training), the parameters should not be tuned on each dataset. To conduct a fair comparison, we tune hyper-parameters on the text8 dataset. For GloVe model, we tune the discount parameters x_{max} and find that $x_{max} = 10$ performs the best. SGNS has a natural parameter k which denotes the number of negative samples. Same as Levy et al. (2015), we found that setting k to 5 leads to the best performance. For the PU-learning model, ρ and λ are two important parameters that denote the unified weight of zero entries and the weight of regularization terms, respectively. We tune ρ in a range from 2^{-1} to 2^{-14} and λ in a range from 2^0 to 2^{-10}. We analyze the sensitivity of the model to these hyper-parameters in the experimental result section. The best performance of each model on the text8 dataset is shown in the Table 2. It shows that PU-learning model outperforms two baseline models.

5 Experimental Results

We compared the proposed PU-Learning framework with two popular word embedding models – SGNS (Mikolov et al., 2013b) and Glove (Pennington et al., 2014) on English and three other languages. The experimental results are reported in Table 4. The results show that the proposed PU-Learning framework outperforms the two baseline approaches significantly in most datasets. This re-

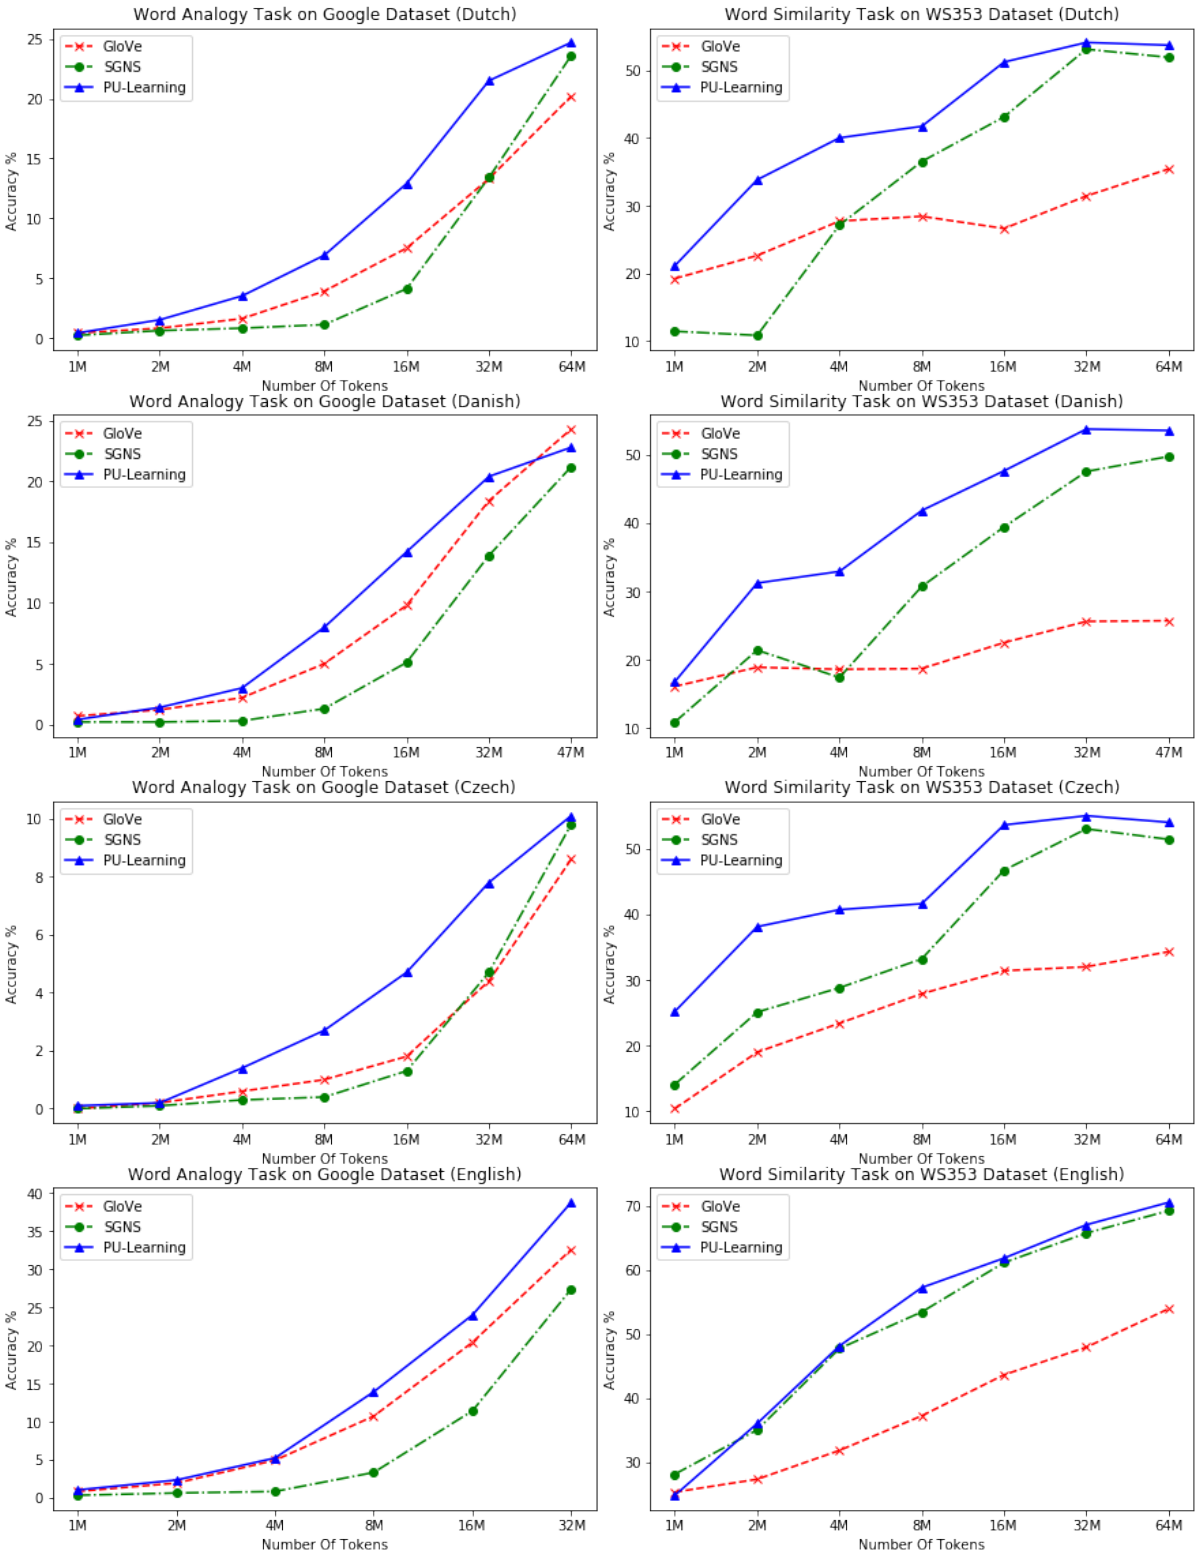

Figure 1: Performance change as the corpus size growing (a) on the Google word analogy task (on the left-hand side) and (b) on the WS353 word similarity task (on the right-hand side). We demonstrate the performance on four languages, Dutch, Danish, Czech and English datasets. Results show that PU-Learning model consistently outperforms SGNS and GloVe when the size of corpus is small.

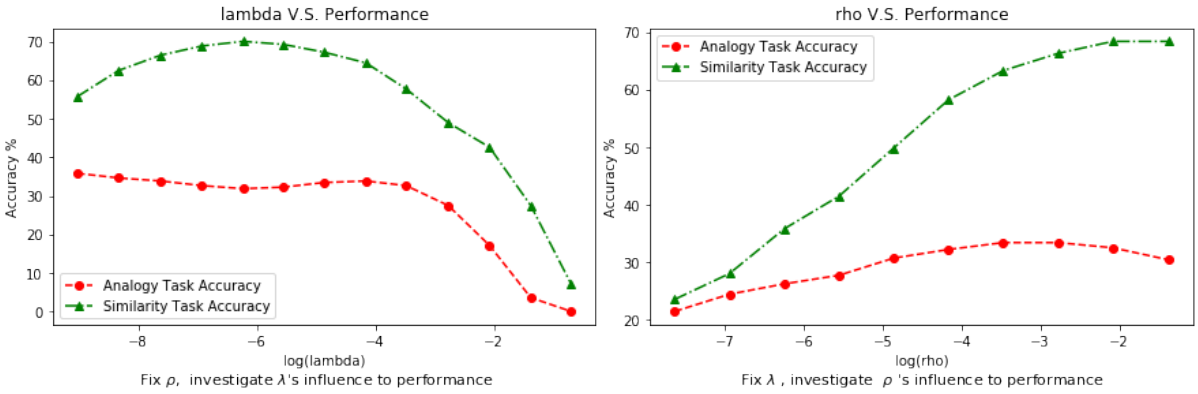

Figure 2: Impact of ρ and λ in the PU-Learning framework.

sults confirm that the unobserved word pairs carry important information and the PU-Learning model leverages such information and achieves better performance. To better understand the model, we conduct detailed analysis as follows.

Performance v.s. Corpus size We investigate the performance of our algorithm with respect to different corpus size, and plot the results in Figure 1. The results in analogy task are obtained by 3CosMul method (Levy and Goldberg, 2014a). As the corpus size grows, the performance of all models improves, and the PU-learning model consistently outperforms other methods in all the tasks. However, with the size of the corpus increases, the difference becomes smaller. This is reasonable as when the corpus size increases the number of non-zero terms becomes smaller and the PU-learning approach is resemblance to Glove.

Impacts of ρ and λ We investigate how sensitive the model is to the hyper-parameters, ρ and λ. Figure 2 shows the performance along with various values of λ and ρ when training on the text8 corpus, respectively. Note that the x-axis is in log scale. When ρ is fixed, a big λ degrades the performance of the model significantly. This is because when λ is too big the model suffers from underfitting. The model is less sensitive when λ is small and in general, $\lambda = 2^{-11}$ achieves consistently good performance.

When λ is fixed, we observe that large ρ (e.g., $\rho \approx 2^{-4}$) leads to better performance. As ρ represents the weight assigned to the unobserved term, this result confirms that the model benefits from using the zero terms in the co-occurrences matrix.

6 Conclusion

In this paper, we presented a PU-Learning framework for learning word embeddings of low-resource languages. We evaluated the proposed approach on English and other three languages and showed that the proposed approach outperforms other baselines by effectively leveraging the information from unobserved word pairs.

In the future, we would like to conduct experiments on other languages where available text corpora are relatively hard to obtain. We are also interested in applying the proposed approach to domains, such as legal documents and clinical notes, where the amount of accessible data is small. Besides, we plan to study how to leverage other information to facilitate the training of word embeddings under the low-resource setting.

Exploring the Role of Prior Beliefs for Argument Persuasion

Esin Durmus

cardie@cs.cornell.edu

Abstract

Public debate forums provide a common platform for exchanging opinions on a topic of interest. While recent studies in natural language processing (NLP) have provided empirical evidence that the language of the debaters and their patterns of interaction play a key role in changing the mind of a reader, research in psychology has shown that prior beliefs can affect our interpretation of an argument and could therefore constitute a competing alternative explanation for resistance to changing one's stance. To study the actual effect of language use vs. prior beliefs on persuasion, we provide a new dataset and propose a controlled setting that takes into consideration two reader-level factors: political and religious ideology. We find that prior beliefs affected by these reader-level factors play a more important role than language use effects and argue that it is important to account for them in NLP studies of persuasion.

1 Introduction

Public debate forums provide to participants a common platform for expressing their point of view on a topic; they also present to participants the different sides of an argument. The latter can be particularly important: awareness of divergent points of view allows one, in theory, to make a fair and informed decision about an issue; and exposure to new points of view can furthermore possibly persuade a reader to change his overall stance on a topic.

Research in natural language processing (NLP) has begun to study persuasive writing and the role of language in persuasion. Tan et al. (2016) and Zhang et al. (2016), for example, have shown that the language of opinion holders or debaters and their patterns of interaction play a key role in changing the mind of a reader. At the same time, research in psychology has shown that prior beliefs can affect our interpretation of an argument even when the argument consists of numbers and empirical studies that would seemingly belie misinterpretation (Lord et al., 1979; Vallone et al., 1985; Chambliss and Garner, 1996).

We hypothesize that studying the actual effect of language on persuasion will require a more controlled experimental setting — one that takes into account any potentially confounding user-level (i.e., reader-level) factors[1] that could cause a person to change, or keep a person from changing, his opinion. In this paper we study one such type of factor: the prior beliefs of the reader as impacted by their political or religious ideology. We adopt this focus since it has been shown that ideologies play an important role for an individual when they form beliefs about controversial topics, and potentially affect how open the individual is to being persuaded (Stout and Buddenbaum, 1996; Goren, 2005; Croucher and Harris, 2012).

We first present a dataset of online debates that enables us to construct the setting described above in which we can study the effect of language on persuasion while taking into account selected user-level factors. In addition to the text of the debates, the dataset contains a multitude of background information on the users of the debate platform. To the best of our knowledge, it is the first publicly available dataset of debates that simultaneously provides such comprehensive information about the debates, the debaters and those voting on the debates.

With the dataset in hand, we then propose the novel task of studying persuasion (1) at the level of individual users, and (2) in a setting that can control for selected user-level factors, in our case, the prior beliefs associated with the political or

[1] Variables that affect both the dependent and independent variables causing misleading associations.

Proceedings of NAACL-HLT 2018, pages 1035–1045
New Orleans, Louisiana, June 1 - 6, 2018.

religious ideology of the debaters and voters. In particular, previous studies focus on predicting the winner of a debate based on the cumulative change in pre-debate vs. post-debate votes for the opposing sides (Zhang et al., 2016; Potash and Rumshisky, 2017). In contrast, we aim to predict which debater an individual user (i.e., reader of the debate) perceives as more successful, given their stated political and religious ideology.

Finally, we identify which features appear to be most important for persuasion, considering the selected user-level factors as well as the more traditional linguistic features associated with the language of the debate itself. We hypothesize that the effect of political and religious ideology will be stronger when the debate topic is *Politics* and *Religion*, respectively. To test this hypothesis, we experiment with debates on only *Politics* or only *Religion* vs. debates from all topics including *Music*, *Health*, *Arts*, etc.

Our main finding is that prior beliefs associated with the selected user-level factors play a larger role than linguistic features when predicting the successful debater in a debate. In addition, the effect of these factors varies according to the topic of the debate topic. The best performance, however, is achieved when we rely on features extracted from user-level factors in conjunction with linguistic features derived from the debate text. Finally, we find that the set of linguistic features that emerges as the most predictive changes when we control for user-level factors (political and religious ideology) vs. when we do not, showing the importance of accounting for these factors when studying the effect of language on persuasion.

In the remainder of the paper, we describe the debate dataset (Section 2) and the prediction task (Section 3) followed by the experimental results and analysis (Section 4), related work (Section 5) and conclusions (Section 6).

2 Dataset

For this study, we collected 67,315 debates from debate.org[2] from 23 different topic categories including *Politics*, *Religion*, *Health*, *Science* and *Music*.[3] In addition to text of the debates, we collected 198,759 votes from the readers of these debates. Votes evaluate different dimensions of the debate.

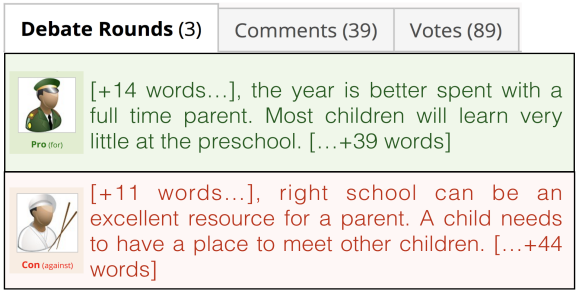

Figure 1: ROUND 1 for the debate claim "PRESCHOOL IS A WASTE OF TIME".

To study the effect of user characteristics, we collected user information for 36,294 different users. Aspects of the dataset most relevant to our task are explained in the following section in more detail.

2.1 Debates

Debate rounds. Each debate consists of a sequence of ROUNDS in which two debaters from opposing sides (one is supportive of the claim (i.e., PRO) and the other is against the claim (i.e., CON)) provide their arguments. Each debater has a single chance in a ROUND to make his points. Figure 1 shows an example ROUND 1 for the debate claim "PRESCHOOL IS A WASTE OF TIME". The number of ROUNDS in debates ranges from 1 to 5 and the majority of debates (61,474 out of 67,315) contain 3 or more ROUNDS.

Votes. All users in the *debate.org* community can vote on debates. As shown in Figure 2, voters share their stances on the debate topic before and after the debate and evaluate the debaters' conduct, their spelling and grammar, the convincingness of their arguments and the reliability of the sources they refer to. For each such dimension, voters have the option to choose one of the debaters as better or indicate a tie. This fine-grained voting system gives a glimpse into the reasoning behind the voters' decisions.

2.1.1 Determining the successful debater

There are two alternate criteria for determining the successful debater in a debate. Our experiments consider both.

Criterion 1: Argument quality. As shown in Figure 2, debaters get points for each dimension of the debate. The most important dimension — in

[2] www.debate.org

[3] The dataset will be made publicly available at http://www.cs.cornell.edu/ esindurmus/.

	Debater 1	Debater 2	Tied	
Agreed with before the debate:	✔	-	-	*0 points*
Agreed with after the debate:	-	✔	-	*0 points*
Who had better conduct:	-	✔	-	*1 point*
Had better spelling and grammar:	-	✔	-	*1 point*
Made more convincing arguments:	-	✔	-	*3 points*
Used the most reliable sources:	-	✔	-	*2 points*
Total points awarded:	**0**	**7**		

Figure 2: An example post-debate vote. Convincingness of arguments contributes to the total points the most.

that it contributes most to the point total — is making convincing arguments. *debate.org* uses Criterion 1 to determine the winner of a debate.

Criterion 2: Convinced voters. Since voters share their stances before and after the debate, the debater who convinces more voters to change their stance is declared as the winner.

2.2 User information

On *debate.org*, each user has the option to share demographic and private state information such as their age, gender, ethnicity, political ideology, religious ideology, income level, education level, the president and the political party they support. Beyond that, we have access to information about their activities on the website such as their overall success rate of winning debates, the debates they participated in as a debater or voter, and their votes. An example of a user profile is shown in Figure 3.

Opinions on the *big issues*. *debate.org* maintains a list of the most controversial debate topics as determined by the editors of the website. These are referred to as *big issues*.[4] Each user shares his stance on each *big issue* on his profile (see Figure 3): either PRO (in favor), CON (against), N/O (no opinion), N/S (not saying) or UND (undecided).

3 Prediction task: which debater will be declared as more successful by an individual voter?

In this section, we first analyze which dimensions of argument quality are the most important for determining the successful debater. Then, we analyze whether there is any connection between selected user-level factors and users' opinions on the

[4] http://www.debate.org/big-issues/

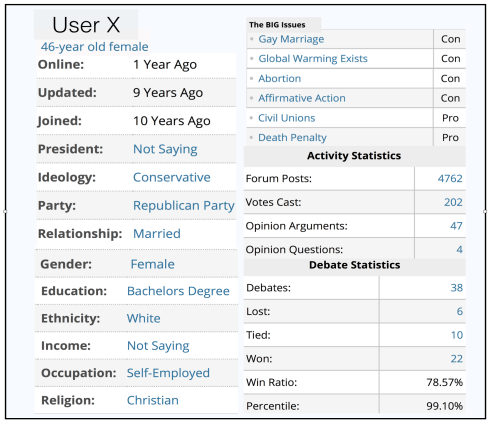

Figure 3: An example of a (partial) user profile. Top right: Some of the *big issues* on which the user shares his opinion are included. The user is against (CON) abortion and gay marriage and in favor of (PRO) the death penalty.

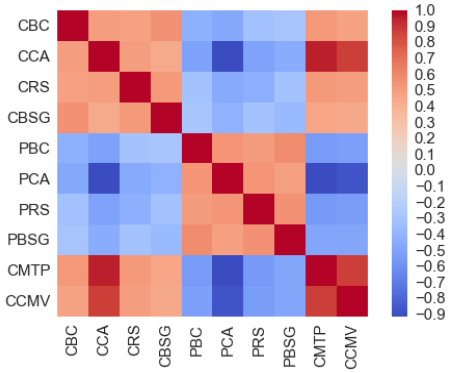

Figure 4: The correlations among argument quality dimensions.

big issues to see if we can infer their opinions from these factors. Finally, using our findings from these analyses, we perform the task of predicting which debater will be perceived as more successful by an individual voter.

3.1 Relationships between argument quality dimensions

Figure 4 shows the correlation between pairs of voting dimensions (in the first 8 rows and columns) and the correlation of each dimension with (1) getting more points (row or column 9) and (2) convincing more people as a debater (final row or column). Abbreviations stand for (on the CON side): has better conduct (CBC), makes more convincing arguments (CCA), uses more reliable sources (CRS), has better spelling and grammar (CBSG), gets more total points (CMTP) and convinces more voters (CCMV). For the PRO side we

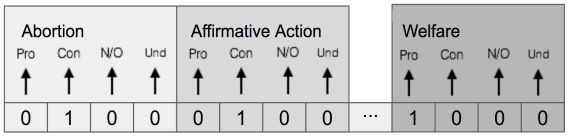

Figure 5: The representation of the BIGISSUES vector derived by this user's decisions on *big issues*. Here, the user is CON for ABORTION and AFFIRMATIVE ACTION issues and PRO for the WELFARE issue.

use PBC, PCA, and so on.

From Figure 4, we can see that making more convincing arguments (CCA) correlates the most with total points (CMTP) and convincing more voters (CCMV). This analysis motivates us to identify the linguistic features that are indicators of more convincing arguments.

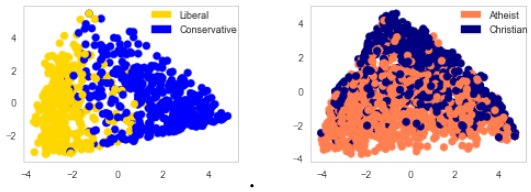
3.2 The relationship between a user's opinions on the *big issues* and their prior beliefs

We disentangle different aspects of a person's prior beliefs to understand how well each correlates with their opinions on the *big issues*. As noted earlier, we focus here only on prior beliefs in the form of self-identified political and religious ideology.

Representing the *big issues*. To represent the opinions of a user on a *big issue*, we use a four-dimensional one-hot encoding where the indices of the vector correspond to PRO, CON, N/O (no opinion), and UND (undecided), consecutively (1 if the user chooses that value for the issue, 0 otherwise). Note that we do not have a representation for N/S since we eliminate users having N/S for at least one *big issue* for this study. We then concatenate the vector for each *big issue* to get a representation for a user's stance on all the *big issues* as shown in Figure 5. We denote this vector by BIGISSUES.

We test the correlation between the individual's opinions on *big issues* and the selected user-level factors in this study using two different approaches: clustering and classification.

Clustering the users' decisions on *big issues*. We apply PCA on the BIGISSUES vectors of users who identified themselves as CONSERVATIVE vs. LIBERAL (740 users). We do the same for the users who identified themselves as ATHEIST vs. CHRISTIAN (1501 users). In Figure 6, we see that there are distinctive clusters of CONSERVATIVE vs. LIBERAL users in the two-dimensional representation



(a) LIBERAL VS. CONSERVATIVE (b) ATHEIST VS. CHRISTIAN.

Figure 6: PCA representation of decisions on *big issues* color-coded with political and religious ideology. We see more distinctive clusters for CONSERVATIVE vs. LIBERAL users suggesting that people's opinions are more correlated with their political ideology.

Prior belief type	Majority	BIGISSUES
Political ideology	57.70%	92.43%
Religious Ideology	52.70%	82.81%

Table 1: Accuracy using majority baseline vs. BIGISSUES vectors as features.

while for ATHEIST VS. CHRISTIAN, the separation is not as distinct. This suggests that people's opinions on the *big issues* identified by *debate.org* correlate more with their political ideology than their religious ideology.

Classification approach. We also treat this as a classification task[5] using the BIGISSUES vectors for each user as features and the user's religious and political ideology as the labels to be predicted. So the classification task is: Given the user's BIGISSUES vector, predict his political and religious ideology. Table 1 shows the accuracy for each case. We see that using the BIGISSUES vectors as features performs significantly better[6] than majority baseline[7].

This analysis shows that there is a clear relationship between people's opinions on the *big issues* and the selected user-level factors. It raises the question of whether it is even possible to persuade someone with prior beliefs relevant to a debate claim to change their stance on the issue. It may be the case that people prefer to agree with the individuals having the same (or similar) beliefs regardless of the quality of the arguments and the

[5]For all the classification tasks described in this paper, we experiment with logistic regression, optimizing the regularizer ($\ell 1$ or $\ell 2$) and the regularization parameter C (between 10^{-5} and 10^{5}).

[6]We performed the McNemar significance test.

[7]The majority class baseline predicts CONSERVATIVE for political and CHRISTIAN for religious ideology for each example, respectively.

particular language used. Therefore, it is important to understand the relative effect of prior beliefs vs. argument strength on persuasion.

3.3 Task descriptions

Some of the previous work in NLP on persuasion focuses on predicting the winner of a debate as determined by the change in the number of people supporting each stance before and after the debate (Zhang et al., 2016; Potash and Rumshisky, 2017). However, we believe that studies of the effect of language on persuasion should take into account other, extra-linguistic, factors that can affect opinion change: in particular, we propose an experimental framework for studying the effect of language on persuasion that aims to control for the prior beliefs of the reader as denoted through their self-identified political and religious ideologies. As a result, we study a more fine-grained prediction task: for an individual voter, predict which side/debater/argument the voter will declare as the winner.

Task 1 : Controlling for religious ideology. In the first task, we control for religious ideology by selecting debates for which each of the two debaters is from a different religious ideology (e.g., debater 1 is ATHEIST, debater 2 is CHRISTIAN). In addition, we consider only voters that (a) self-identify with one of these religious ideologies (e.g., the voter is either ATHEIST or CHRISTIAN) and (b) changed their stance on the debate claim post-debate vs. pre-debate. For each such voter, we want to predict which of the PRO-side debater or the CON-side debater did the convincing. Thus, in this task, we use *Criterion 2* to determine the winner of the debate from the point of view of the voter. Our hypothesis is that the voter will be convinced by the debater that espouses the religious ideology of the voter.

In this setting, we can study the factors that are important for a particular voter to be convinced by a debater. This setting also provides an opportunity to understand how the voters who change their minds perceive arguments from a debater who is expressing the same vs. the opposing prior belief.

To study the effect of the debate topic, we perform this study for two cases — debates belonging to the *Religion* category and then all the categories. The *Religion* category contains debates like "IS THE BIBLE AGAINST WOMEN'S RIGHTS?" and "RELIGIOUS THEORIES SHOULD NOT BE TAUGHT IN SCHOOL". We want to see how strongly a user's religious ideology affects the persuasive effect of language in such a topic as compared to the all topics. We expect to see stronger effects of prior beliefs for debates on *Religion*.

Task 2: Controlling for political ideology. Similar to the setting described above, Task 2 controls for political ideology. In particular, we only use debates where the two debaters are from different political ideologies (CONSERVATIVE vs. LIBERAL). In contrast to Task 1, we consider all voters that self-identify with one of the two debater ideologies (regardless of whether the voter's stance changed post-debate vs. pre-debate). This time, we predict whether the voter gives more total points to the PRO side or the CON side argument. Thus, Task 2 uses *Criterion 1* to determine the winner of the debate from the point of view of the voter. Our hypothesis is that the voter will assign more points to the debater that has the same political ideology as the voter.

For this task too, we perform the study for two cases — debates from the *Politics* category only and debates from all categories. And we expect to see stronger effects of prior beliefs for debates on *Politics*.

3.4 Features

The features we use in our model are shown in Table 2. They can be divided into two groups — features that describe the prior beliefs of the users and linguistic features of the arguments themselves.

User features

We use the cosine similarities between the voter and each of the debaters' *big issue* vectors. These features give a good approximation of the overall similarity of two user's opinions. Second, we use indicator features to encode whether the religious and political beliefs of the voter match those of each of the debaters.

Linguistic features

We extract linguistic features separately for both the PRO and CON side of the debate (combining all the utterances of PRO across different turns and doing the same for CON). Table 2 contains a list of these features. It includes features that carry information about the style of the language (e.g., usage of modal verbs, length, punctuation), represent different semantic aspects of the argu-

User-based features	Description
Opinion similarity.	For $userA$ and $userB$, the cosine similarity of BIGISSUES$_{userA}$ and BIGISSUES$_{userB}$.
Matching features.	For $userA$ and $userB$, 1 if $userA_f$==$userB_f$, 0 otherwise where $f \in$ {political ideology, religious ideology}. We denote these features as *matching political ideology* and *matching religious ideology*.
Linguistic features	**Description**
Length.	Number of tokens.
Tf-idf.	Unigram, bigram and trigram features.
Referring to the opponent.	Whether the debater refers to their opponent using words or phrases like "opponent, my opponent".
Politeness cues.	Whether the text includes any signs of politeness such as "thank" and "welcome".
Showing evidence.	Whether the text has any signs of citing any other sources (e.g., phrases like "according to"), or quotation.
Sentiment.	Average sentiment polarity.
Subjectivity (Wilson et al., 2005).	Number of words with negative strong, negative weak, positive strong, and positive weak subjectivity.
Swear words.	# of swear words.
Connotation score (Feng and Hirst, 2011).	Average # of words with positive, negative and neutral connotation.
Personal pronouns.	Usage of first, second, and third person pronouns.
Modal verbs.	Usage of modal verbs.
Argument lexicon features. (Somasundaran et al., 2007).	# of phrases corresponding to different argumentation styles.
Spelling.	# of spelling errors.
Links.	# of links.
Numbers.	# of numbers.
Exclamation marks.	# of exclamation marks.
Questions.	# of questions.

Table 2: Feature descriptions

ment (e.g., showing evidence, connotation (Feng and Hirst, 2011), subjectivity (Wilson et al., 2005), sentiment, swear word features) as well as features that convey different argumentation styles (argument lexicon features (Somasundaran and Wiebe, 2010). Argument lexicon features include the counts for the phrases that match with the regular expressions of argumentation styles such as assessment, authority, conditioning, contrasting, emphasizing, generalizing, empathy, inconsistency, necessity, possibility, priority, rhetorical questions, desire, and difficulty. We then concatenate these features to get a single feature representation for the entire debate.

4 Results and Analysis

For each of the tasks, prediction accuracy is evaluated using 5-fold cross validation. We pick the model parameters for each split with 3-fold cross validation on the training set. We do ablation for each of user-based and linguistic features. We report the results for the feature sets that perform better than the baseline.

We perform analysis by training logistic regression models using only user-based features, only linguistic features and finally combining user-based and linguistic features for both the tasks.

	Accuracy
Baseline	
Majority	56.10%
User-based Features	
Matching religious ideology	65.37 %
Linguistic features	
Personal pronouns	57.00 %
Connotation	61.26 %
All two features above	65.37 %
User-based+linguistic features	
USER*+ Personal pronouns	65.37%
USER*+ Connotation	66.42%
USER*+ LANGUAGE*	64.37%

Table 3: Results for Task 1 for debates in category *Religion*. USER* represents the best performing combination of user-based features. LANGUAGE* represents the best performing combination of linguistic features. Since using linguistic features only would give the same prediction for all voters in a debate, the maximum accuracy that can be achieved using language features only is 92.86%.

	Accuracy
Baseline	
Majority	57.31%
User-based Features	
Matching religious ideology	62.79 %
Matching religious ideology+ Opinion similarity	62.97%
Linguistic features	
Length [8]	61.01 %
User-based+linguistic features	
USER* + Length	64.56 %
USER*+ Length + Exclamation marks	65.74%

Table 4: Results for Task 1 for debates in all categories. The maximum accuracy that can be achieved using language features only is 95.77%.

Task 1 for debates in category *Religion*. As shown in Table 3, the majority baseline (predicting the winner side of the majority of training examples out of PRO or CON) gets 56.10% accuracy. User features alone perform significantly better than the majority baseline. The most important user-based feature is *matching religious ideology*. This means it is very likely that people change their views in favor of a debater with the same religious ideology. In a linguistic-only features analysis, combination of the *personal pronouns* and *connotation* features emerge as most important and also perform significantly better than the majority baseline at 65.37% accuracy. When we use both user-based and linguistic features to predict, the accuracy improves to 66.42% with *connotation* features. An interesting observation is that including the user-based features along with the linguistic features changes the set of important linguistic features for persuasion removing the *personal pronouns* from the important linguistic features set. This shows the importance of studying potentially confounding user-level factors.

Task 1 for debates in all categories. As shown in Table 4, for the experiments with user-based features only, *matching religious ideology* and *opinion similarity* features are the most important. For this task, *length* is the most predictive linguistic feature and can achieve significant improvement over the baseline (61.01%). When we combine the language features with user-based features, we see that with *exclamation mark* the accuracy improves to (65.74%).

Task 2 for debates in category *Politics*. As shown in Table 5, using user-based features only, the *matching political ideology* feature performs the best (80.40%). Linguistic features (refer to Table 5 for the full list) alone, however, can still obtain significantly better accuracy than the baseline (59.60%). The most important linguistic features include *approval*, *politeness*, *modal verbs*, *punctuation* and *argument lexicon features* such as *rhetorical questions* and *emphasizing*. When combining this linguistic feature set with the *matching political ideology* feature, we see that with the accuracy improves to (81.81%). *Length* feature does not give any improvement when it is combined with the user features.

Task 2 for debates in all categories. As shown in Table 6, when we include all categories, we see that the best performing user-based feature is the *opinion similarity* feature (73.96%). When using language features only, *length* feature (56.88%) is the most important. For this setting, the best accuracy is achieved when we combine user features with *length* and *Tf-idf* features. We see that the set of language features that improve the performance of user-based features do not include some of that perform significantly better than the baseline when used alone (*modal verbs* and *politeness* features).

	Accuracy
Baseline	
Majority	50.91%
User-based Features	
Opinion similarity	80.00 %
Matching political ideology	80.40 %
Linguistic features	
Length	57.37 %
linguistic feature set	59.60 %
User-based+linguistic features	
USER*+ *linguistic feature set*	81.81%

Table 5: Results for Task 2 for debates in category *Politics*. The maximum accuracy that can be achieved using linguistic features only is 75.35%. The *linguistic feature set* includes *rhetorical questions, emphasizing, approval, exclamation mark, questions, politeness, referring to opponent, showing evidence, modals, links,* and *numbers* as features.

	Accuracy
Baseline	
Majority	51.75%
User-based Features	
Opinion similarity	73.96%
Linguistic features	
Length	56.88%
Politeness	55.00%
Modal verbs	52.32%
Tf-idf features	52.89 %
User-based+linguistic features	
USER*+ Length	74.53%
USER*+ Tf-idf	74.13%
USER*+ Length + Tf-idf	75.20%

Table 6: Results for Task 2 for debates in all categories. The maximum accuracy that can be achieved using linguistic features only is 74.53%.

5 Related Work

Below we provide an overview of related work from the multiple disciplines that study persuasion.

Argumentation mining. Although most recent work on argumentation has focused on identifying the structure of arguments and extracting argument components (Persing and Ng, 2015; Palau and Moens, 2009; Biran and Rambow, 2011; Mochales and Moens, 2011; Feng and Hirst, 2011; Stab and Gurevych, 2014; Lippi and Torroni, 2015; Park and Cardie, 2014; Nguyen and Litman, 2015; Peldszus and Stede, 2015; Niculae et al., 2017; Rosenthal and McKeown, 2015), more relevant is research on identifying the characteristics of persuasive text, e.g., what distinguishes persuasive from non-persuasive text (Tan et al., 2016; Zhang et al., 2016; **?**; Habernal and Gurevych, 2016a,b; Fang et al., 2016; Hidey et al., 2017). Similar to these, our work aims to understand the characteristics of persuasive text but also considers the effect of people's prior beliefs.

Persuasion. There has been a tremendous amount of research effort in the social sciences (including computational social science) to understand the characteristics of persuasive text (Kelman, 1961; Burgoon et al., 1975; Chaiken, 1987; Tykocinskl et al., 1994; Chambliss and Garner, 1996; Dillard and Pfau, 2002; Cialdini, 2007; Durik et al., 2008; Tan et al., 2014; Marquart and Naderer, 2016). Most relevant among these is the research of Tan et al. (2016), Habernal and Gurevych (2016a) and Hidey et al. (2017). Tan et al. (2016) focused on the effect of user interaction dynamics and language features looking at the ChangeMyView[9] (an internet forum) community on Reddit and found that user interaction patterns as well as linguistic features are connected to the success of persuasion. In contrast, Habernal and Gurevych (2016a) created a crowd-sourced corpus consisting of argument pairs and, given a pair of arguments, asked annotators which is more convincing. This allowed them to experiment with different features and machine learning techniques for persuasion prediction. Taking motivation from Aristotle's definition for modes of persuasion, Hidey et al. (2017) annotated claims and premises extracted from the ChangeMyView community with their semantic types to study if certain semantic types or different combinations of semantic types appear in persuasive but not in non-persuasive essays. In contrast to the above, our work focuses on persuasion in debates than monologues and forum datasets and accounts for the user-based features.

Persuasion in debates. Debates are another resource for studying the different aspects of persuasive arguments. Different from monologues where the audience is exposed to only one side of the opinions about an issue, debates allow the audience to see both sides of a particular issue via a

[9] https://www.reddit.com/r/changemyview/

controlled discussion. There has been some work on argumentation and persuasion on online debates. Sridhar et al. (2015), Somasundaran and Wiebe (2010) and Hasan and Ng (2014), for example, studied detecting and modeling stance on online debates. Zhang et al. (2016) found that the side that can adapt to their opponents' discussion points over the course of the debate is more likely to be the winner. None of these studies investigated the role of prior beliefs in stance detection or persuasion.

User effects in persuasion. Persuasion is not independent from the characteristics of the people to be persuaded. Research in psychology has shown that people have biases in the ways they interpret the arguments they are exposed to because of their prior beliefs (Lord et al., 1979; Vallone et al., 1985; Chambliss and Garner, 1996). Understanding the effect of persuasion strategies on people, the biases people have and the effect of prior beliefs of people on their opinion change has been an active area of research interest (Correll et al., 2004; Hullett, 2005; Petty et al., 1981). Eagly and Chaiken (1975), for instance, found that the attractiveness of the communicator plays an important role in persuasion. Work in this area could be relevant for the future work on modeling shared characteristics between the user and the debaters. To the best of our knowledge, Lukin et al. (2017) is the most relevant work to ours since they consider features of the audience on persuasion. In particular, they studied the effect of an individual's personality features (open, agreeable, extrovert, neurotic, etc.) on the type of argument (factual vs. emotional) they find more persuasive. Our work differs from this work since we study debates and in our setting the voters can see the debaters' profiles as well as all the interactions between the two sides of the debate rather than only being exposed to a monologue. Finally, we look at different types of user profile information such as a user's religious and ideological beliefs and their opinions on various topics.

6 Conclusion

In this work we provide a new dataset of debates and a more controlled setting to study the effects of prior belief on persuasion. The dataset we provide and the framework we propose open several avenues for future research. One could explore the effect different aspects of people's background (e.g., gender, education level, ethnicity) on persuasion. Furthermore, it would be interesting to study how people's prior beliefs affect their other activities on the website and the language they use while interacting with people with the same and different prior beliefs. Finally, one could also try to understand in what aspects and how the language people with different prior beliefs/backgrounds use is different. These different directions would help people better understand characteristics of persuasive arguments and the effects of prior beliefs in language.

Abstract

We address the detection of abusive words. The task is to identify such words among a set of negative polar expressions. We propose novel features employing information from both corpora and lexical resources. These features are calibrated on a small manually annotated base lexicon which we use to produce a large lexicon. We show that the word-level information we learn cannot be equally derived from a large dataset of annotated microposts. We demonstrate the effectiveness of our (domain-independent) lexicon in the cross-domain detection of abusive microposts.

1 Introduction

Abusive or offensive language is commonly defined as hurtful, derogatory or obscene utterances made by one person to another person.[1] Examples are (1)-(3). In the literature, closely related terms include *hate speech* (Waseem and Hovy, 2016) or *cyber bullying* (Zhong et al., 2016). While there may be nuanced differences in meaning[2], they are all compatible with the general definition above for abusive language.[3]

(1) stop editing this, you **dumbass**.
(2) Just want to slap the **stupid** out of these **bimbos**!!!
(3) Go lick a pig you arab muslim piece of **scum**.

Due to the rise of user-generated web content, in particular on social media networks, the amount of abusive language is also steadily growing. NLP methods are required to focus human review efforts towards the most relevant microposts.

In this paper, we address the task of detecting abusive words (e.g. *dumbass*, *bimbo*, *scum*). Our main assumption is that abusive words form a subset of negative polar expressions. The classification task is to **filter the abusive words from a given set of negative polar expressions**. We proceed as follows. On a base lexicon that is a small subset of negative polar expressions where the abusive words among them have been marked via crowdsourcing (§3), we calibrate a supervised classifier by examining various novel features (§4). A classifier trained on that base lexicon, which contains 551 abusive words, is then applied to a very large list of unlabeled negative polar expressions (from Wiktionary) to extract an expanded lexicon of 2989 abusive words (§5).

We extrinsically evaluate our new lexicon in the novel task of **cross-domain classification** of abusive documents (§6) where we use it as a *high-level* feature. In this work, we consider microposts as documents. While for in-domain classification, supervised classifiers trained on generic features, such as bag of words or word embeddings, usually score very well, on cross-domain classification they perform poorly since they latch on to domain-specific information. In subjectivity, polarity and emotion classification, high-level features based on predictive domain-independent word lists have been proposed to bridge the domain mismatch (Dias et al., 2009; Mohammad, 2012; Wiegand et al., 2013).

New abusive words constantly enter natural language. For example, according to Wiktionary[4] the word *gimboid*, which refers to an incompetent person, was coined in the British television series *Red Dwarf*, possibly from the word *gimp* and the suffix *-oid*. According to Urban Dictionary[5], the word *twunt*, which is a portmanteau of the swearwords *twat* and *cunt*, has been invented

[1] http://thelawdictionary.org/
[2] For example, several research efforts just focus on utterances addressed towards minorities.
[3] The examples in this work are included to illustrate the severity of abusive language. They are taken from actual web data and in no way reflect the opinion of the authors.

New Orleans, Louisiana, June 1 - 6, 2018.

by humourist Chris Morris for the Channel 4 series 'Jam' in 2000. One of the most recent abusive words is *remoaner* which describes someone who complains about or rejects the outcome of the 2016 EU referendum on the UK's membership of the European Union. It is a blend of *moan* and *remainer*. Wiktionary states that this word has a pejorative connotation.

These examples show that the task of creating a lexicon of abusive words cannot be reduced to a one-time manual annotation effort. Recent web corpora and crowdsourced dictionaries (e.g. Wiktionary) should be ideal resources to find evidence of such words.

Our **contribution** is that we present the first work that systematically describes the *automatic* construction of a lexicon of abusive words. We examine novel features derived from various textual resources. We show that the information we learn cannot be equally derived from a large dataset with labeled microposts. The effectiveness of our expanded lexicon is demonstrated on cross-domain detection of abusive microposts. This is also the first work to address this task in general. The supplementary material to this paper[6] includes all resources newly created for our research.

We frame our task as a **binary classification problem**. Each given expression is to be classified as either abusive or not. We study this problem on English. However, many of our features should also be applicable to other languages.

2 Related Work

Lexical knowledge for the detection of abusive language has only received little attention in previous work. Most approaches consider it as one feature among many. Very often existing word lists from the web are employed (Xiang et al., 2012; Burnap and Williams, 2015; Nobata et al., 2016). Their limited effectiveness may be due to the fact that they were not built for the task of abusive language detection. Only the manually-compiled lexicon from Razavi et al. (2010) and the lexicon of *hate verbs* from Gitari et al. (2015) have been compiled for this specific task. Since the latter lexicon is not publicly available we can only consider the former in our evaluation. In both publications, very little is said on the creation of these resources.

Previous work focused on in-domain classification, a setting where generic features (e.g. bag of words) work well and word lists are less important. There have been investigations examining features on various datasets (Nobata et al., 2016; Samghabadi et al., 2017), however, these studies always trained and tested on the *same* domain. We show that a lexicon-based approach is effective in cross-domain classification.

For a more detailed overview on previous work on the detection of abusive language in general, we refer the reader to Schmidt and Wiegand (2017).

3 Data

Base Lexicon. Our base lexicon exclusively comprises negative polar expressions. It is a small set which we have **annotated via crowdsourcing**. We consider abusive words to be a proper subset of negative polar expressions. By just focusing on these types of words, we are more likely to obtain a significant amount of abusive words than just considering a sample of arbitrary words. This lexicon will be used as a gold standard for calibrating features of a classifier. That classifier will be run on a large set of unlabeled negative polar expressions to produce our expanded lexicon (§5).

We sampled 500 negative nouns, verbs and adjectives each from the Subjectivity Lexicon (Wilson et al., 2005). We chose that lexicon since we have extra information available for its entries that we want to examine, namely polar intensity (§4.1.1) and sentiment views (§4.1.2). However, since we noted that the Subjectivity Lexicon misses some prototypical abusive words (e.g. *nigger*, *slut*, *cunt*) we added another 10% (i.e. 150 words) which are abusive words frequently occurring in the word lists mentioned in Schmidt and Wiegand (2017).

Each of the negative polar expressions was judged by 5 annotators from the crowdsourcing platform *ProlificAcademic*.[7] Each annotator had to be a native speaker of English and possess a task approval rate of at least 90%. For our base lexicon (Table 1), we considered a binary word categorization: *abusive* or *non-abusive*. A word was only classified *abusive* if at least 4 out of the 5 raters judged the word to be abusive. This threshold should prevent many ambiguous words from being classified as abusive, a general problem of existing resources (Davidson et al., 2017).

Corpora. In our experiments we employ three

[7] The supplementary material contains more information regarding our annotation set-up (including guidelines).

	adj		noun		verb		all	
class	freq	%	freq	%	freq	%	freq	%
abusive	170	33.8	291	45.3	90	17.8	551	33.4
not abusive	332	66.2	352	54.7	415	82.2	1099	66.6

Table 1: The base lexicon: 1650 entries in total of which 551 are abusive.

		intensity (§4.1.1)		views (§4.1.2)	
class	**all**	weak	strong	actor	speaker
abusive	26.7	14.1	32.0	9.7	32.8
not abusive	73.3	85.9	68.0	90.3	67.2

all numbers only refer to the subset of the base lexicon (Table 1) taken from the Subjectivity Lexicon (i.e. 1500 entries)

Table 3: Percentage of abusive/not abusive instances among (binary) intensity and views.

unlabeled corpora (Table 2). The two larger corpora, the *Amazon Review Corpus – AMZ* (Jindal and Liu, 2008) and the *Web As Corpus – WAC* (Baroni et al., 2009), are used for inducing word embeddings (§4.2). AMZ and the smallest corpus, *rateitall.com – RIA*[8], are used for computing polar word intensity (§4.1.1) from star ratings.

4 Feature Calibration

In the following, we describe the two types of features of our feature-based approach: novel linguistic features and generic word embeddings. They will be examined against some baselines on our base lexicon. As a classifier we use an SVM as implemented in SVM^{light} (Joachims, 1999). We chose that classifier since it is most commonly used for the detection of abusive language (Schmidt and Wiegand, 2017). *For all classifiers in this paper, the supplementary material*[6] *contains information regarding (hyper)parameter settings.*

4.1 Linguistic Features

4.1.1 Polar Intensity (INT)

Intuitively, abusive language should coincide with high polar intensity. We inspect 3 different types.

Binary Intensity (INT$_{bin}$). Our first feature is a simple binary intensity feature we obtain from the Subjectivity Lexicon. In that resource, each entry is categorized as either a *weak* polar expression (e.g. *dirty*) or a *strong* polar expression (e.g. *filthy*). Table 3 (left half), which shows the distribution of intensity on the intersection of our base lexicon and the Subjectivity Lexicon, confirms that abusive words are rarely weak polar expressions and more frequently strong polar expressions.

Fine-grained Intensity (INT$_{fine}$). We also investigate a more fine-grained feature which assigns a real-valued intensity score to polar expressions. It is computed by leveraging the star-rating assigned to the reviews comprising the AMZ corpus (Table 2), a large publicly available review corpus. A review is awarded between 1 and 5 stars where 1 is the most negative score. We infer the polar intensity of a word by the distribution of star-ratings associated with the reviews in which it occurs. We assume negative polar expressions with a very high polar intensity to occur significantly more often in reviews assigned few stars (i.e. 1 or 2). Ruppenhofer et al. (2014) established that the most effective method to derive such polar intensity is by ranking words by their *weighted mean of star ratings* (Rill et al., 2012). All words of our base lexicon are ranked according to that score. As a feature we use the rank of a word.

Intensity Directed towards Persons (INT$_{person}$). Not all negative polar expressions with a high intensity are equally likely to be abusive. The high intensity expressions should also be words typically directed towards persons. Most polar statements in AMZ, however, are directed towards a movie, book or some electronic product. In order to extract negative polar intensity directed towards persons, we replace the AMZ corpus with the RIA corpus (Table 2). RIA contains reviews on arbitrary entities rather than just commercial products as in the case of AMZ. Each review has a category label (e.g. *computer*, *person*, *travel*) that very easily allows us to extract from RIA just those reviews that concern persons.

Table 4 compares a typical 1-star review from AMZ with one from RIA. We consider the RIA-review an abusive comment. It contains many words predictive of abusive language (e.g. *self-absorbed*, *loser*, *arrogant* or *loud-mouthed*).

4.1.2 Sentiment Views (VIEW)

Wiegand et al. (2016b) define sentiment views as the perspective of the opinion holder of polar expressions. They distinguish between expressions conveying the view of the implicit speaker of the utterance typically referred to as *speaker views* (e.g. *cheating* in (4); *ugly* and *stinks* in (5)), and expressions conveying the view of event participants typically referred to as *actor views* (e.g. *disappointed* and *horrified* in (6); *protested* in (7)).

[8]This is a crawl from the review website www.rateitall.com.

corpus	size	properties	purpose
RateItAll (**RIA**)	4.7M	review corpus focused on persons	computation of polar intensity (§4.1.1)
Amazon (**AMZ**)	1.2B	product review corpus	comp. of polar intensity (§4.1.1)/word embeddings (§4.2)
Web as Corpus (**WAC**)	2.3B	large general web corpus	computation of word embeddings (§4.2)

Table 2: Information about unlabeled corpora used (*by size we mean the number of tokens*).

AMZ	*on Halloween 5:* this movie is horrible with a bad plot a disappointment to the halloween series.
RIA	*on Bill Maher:* Self-absorbed loser who tries to pretend to be fair. He is rude, arrogant, loud-mouthed...

Table 4: 1-star reviews in different corpora.

WAC	liar (19), coward (7), name (6), idiot (6), hero (5), horse (5), saint (5), fool (5), snob (4), genius (4)
Twitter	bitch (1534), hoe (432), liar (317), cunt (274), whore (254), pussy (228), nigger (226), loser (217), faggot (217), slut (197)

Table 5: Comparison of the 10 most frequent pattern matches (*numbers in brackets indicate frequency*).

Wiegand et al. (2016b) provided sentiment-view annotations for the entries of the Subjectivity Lexicon.

(4) Peter is always **cheating**$_{speaker\ view}$. *(holder: speaker)*
(5) Mary is an **ugly**$_{speaker\ view}$ girl that **stinks**$_{speaker\ view}$. *(holder: speaker)*
(6) [Peter]$_{holder}$ was **disappointed**$_{actor\ view}$ and **horrified**$_{actor\ view}$ at the same time.
(7) [The public]$_{holder}$ **protested**$_{actor\ view}$ against that law.

Sentiment views have been used for improving the extraction of opinion holders and targets (Deng and Wiebe, 2016; Wiegand et al., 2016a). In this paper we show that they also have relevance for the detection of abusive words. Among actor-view words, there is a much lower proportion of abusive words than among speaker-view words (right half of Table 3). This can be explained by the fact that verbal abuse usually originates from the speaker of an utterance rather than some other discourse entity. We use sentiment-view information as a binary feature.

4.1.3 Emotion Categories (NRC)

We also examine whether knowledge of emotion categories associated with words is helpful. Potentially negative emotions, such as *disgust* or *anger*, should correlate with abusive words. We use the NRC lexicon (Mohammad and Turney, 2013) and employ the categories associated with the words contained in that resource as a feature.

4.1.4 Patterns (PAT)

Noun Pattern (PAT$_{noun}$). We found that the noun pattern (8) can be used to extract abusive nouns. Since this pattern is very sparse even on our largest corpus (i.e. WAC), we also run our pattern as a query on Twitter and extracted all matching tweets coming in a time period of 14 days. (We observed that by then we had reached a saturation point.)

(8) *pattern*: called {me|him|her} a(n) <noun>
(9) *pattern match example*: He called me a **bitch**.

Table 5 compares the most frequent matches for that pattern. Our pattern matches much more frequently on Twitter than on WAC. The quality of the matches on Twitter is also much better than on WAC, where we still find many false positives (e.g. *name* or *saint*). We assume that tweets, in general, are much more negative in tone than arbitrary web documents (as represented by WAC) which could explain the fewer false positives on Twitter. Note that the ranking from Twitter is not restricted to just prototypical abusive words (as Table 5 might suggest). The entire ranking also contains many less common words, such as *weaboo*, *dudebro* or *butterface*. The frequency ranks of the nouns extracted from Twitter are used as a feature.

Adjective Pattern (PAT$_{adj}$). Abusive adjectives often modify an abusive noun as in *brainless idiot*, *smarmy liar* or *gormless twat*. Therefore, we mined Twitter for adjectives modifying mentions of our extracted nouns (PAT$_{noun}$). (We were not able to find a construction identifying abusive verbs, so our output from PAT includes no verbs.)

4.1.5 WordNet (WN) and Wiktionary (WK)

We compare WordNet (Miller et al., 1990) and Wiktionary[4] as two general-purpose lexical resources. Unlike WordNet, Wiktionary is produced collaboratively by volunteers rather than linguistic experts. It contains more abusive words from our base lexicon, i.e. 97% (WK) vs. 87% (WN).

A common way to harness a general-purpose lexicon for induction tasks in sentiment analysis is by using its **glosses** (Choi and Wiebe, 2014; Kang et al., 2014). Assuming that the explanatory texts

of glosses are similar among abusive words, we treat glosses as a bag-of-words feature.

We also exploit information on **word usage**. Many abusive words are marked with tags such as *pejorative*, *derogatory* or *vulgar*. Both WordNet and Wiktionary contain such information. However, in Wiktionary more than 6 times as many of our entries include a tag compared to WordNet.

In order to incorporate a semantic representation more general than individual words, we employ **supersenses**. Supersenses are only contained in WordNet. They represent a set of 45 classes into which entries are categorized. They have been found effective for sentiment analysis (Flekova and Gurevych, 2016). Some categories correlate with abusive words. For example, 76% of the words of our base lexicon that belong to the supersense *person* (e.g. *loser*, *idiot*) are abusive words.

4.1.6 FrameNet (FN)

FrameNet (Baker et al., 1998) is a semantic resource which provides over 1200 semantic frames that comprise words with similar semantic behaviour. We use the frame-memberships of a word as features, expecting that abusive and non-abusive words occur in separate frames.

4.2 Generic Features: Word Embeddings

We induce word embeddings from the two largest corpora, i.e. AMZ and WAC (Table 2) using *Word2Vec* (Mikolov et al., 2013) in default configuration (i.e. 200 dimensions; cbow). The best performance was obtained by concatenating for each word the vectors induced from the two corpora.[9]

4.3 Baselines to Feature-based Approach

In addition to a majority-class classifier we consider the following baselines:

Weak Supervision (WSUP). With this baseline we want to build a lightweight classifier that does not require proper labeled training data. It is inspired by previous induction approaches for sentiment lexicons, such as Hatzivassiloglou and McKeown (1997) or Velikovich et al. (2010) which heuristically label some seed instances and then apply graph-based propagation to label the remaining words of a dataset. On the basis of word embeddings (§4.2), we build a word-similarity graph, where the nodes represent our negative polar expressions and each edge denotes the semantic similarity between two arbitrary words. We compute it by the cosine of their word-embedding vectors. The output of PAT from Twitter (§4.1.4) is considered as positive class seed instances. We chose PAT since it is an effective feature that does not depend on a lexical resource. As negative class seeds, we use the most frequent words in the WAC corpus (Table 2). Our rationale is that high-frequency words are unlikely to be abusive. We chose WAC instead of Twitter since the evidence of PAT (Table 5) suggested less abusive language in that corpus. This word-similarity graph is illustrated in Figure 1. In order to propagate the labels to the unlabeled words from the seeds, we use the Adsorption algorithm (Talukdar et al., 2008).

Using Labeled Microposts (MICR). With our last baseline we examine in how far we can detect abusive words by only using information from labeled microposts rather than labeled words. These experiments are driven by the fact that labeled microposts already exist. We consider two methods using the largest dataset comprising manually labeled microposts, *Wulczyn* (Table 8). The class labels of the microposts and our base lexicon (§3) are the same. Our aim is to produce a ranking of words where the high ranks represent words more likely to be abusive. Since we want to produce a strong baseline, we consider the best possible cut-off rank (*see supplementary material*[6]). Every word higher than this rank is considered abusive and all other words not abusive.

The first method **MICR:pmi** ranks the words of our base lexicon by their Pointwise Mutual Information with the class label *abusive* that is assigned to microposts. To be even more competitive, we introduce a second method **MICR:proj** that learns a projection of embeddings. MICR:proj has the advantage over MICR:pmi that it does not only rank words observed in the labeled microposts but all words represented by embeddings. Since our embeddings (§4.2) are induced on the combination of AMZ and WAC corpora, which together are about 360 times the size of the *Wulczyn* dataset, MICR:proj is likely to cover more abusive words. Let $\mathbf{M} = [\mathbf{w_1}, \ldots, \mathbf{w_n}]$ denote a labeled micropost of n words. Each column $\mathbf{w} \in \{0,1\}^v$ of $\mathbf{M}$ represents a word in a one-hot form. Our aim is learning a one-dimensional projection $\mathbf{S} \cdot \mathbf{E}$ where $\mathbf{E} \in \mathbb{R}^{e \times v}$ represents our unsupervised embeddings of dimensionality e over the vocabulary size v (§4.2) and $\mathbf{S} \in \mathbb{R}^{1 \times e}$ represents the learnt

[9] We also ran experiments with pretrained embeddings from *GoogleNews* but they did not improve classification.

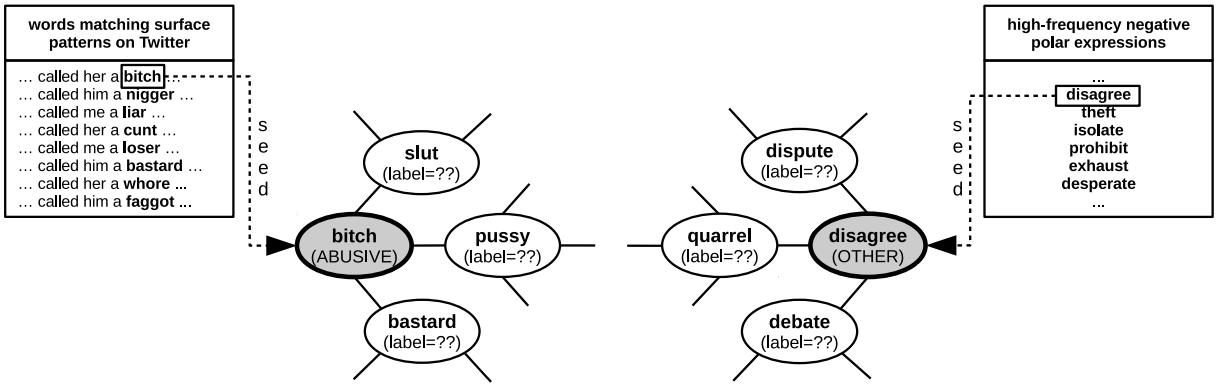

Figure 1: Illustration of word-similarity graph as used for weakly-supervised baseline (WSUP); seeds for abusive words (e.g. *bitch*) are obtained by the output of feature PAT (§4.1.4); seeds for non-abusive words (e.g. *disagree*) are high-frequency negative polar expressions.

Table 6: Different classifiers on base lexicon (Table 1).

projection matrix. We compute a projected micropost $\mathbf{h} = \mathbf{S} \cdot \mathbf{E} \cdot \mathbf{M}$ which is an n-dimensional vector. Each component represents a word from the micropost. The value represents the predictability of the word towards being abusive. We then apply a bag-of-words assumption to use that projected micropost to predict the binary class label y: $p(y|\mathbf{M}) \propto exp(\mathbf{h} \cdot \mathbf{1})$ where $\mathbf{1} \in \{1\}^n$. This model is a feed-forward network trained using Stochastic Gradient Descent (Rumelhart et al., 1986). On the basis of the projected embeddings we rank our negative polar expressions.

4.4 Evaluation of Features on Base Lexicon

We conduct experiments on our base lexicon (Table 1) and report macro-average precision, recall and f-score. SVMs are evaluated on a 10-fold crossvalidation. Table 6 displays the performance of the different classifiers. The least effective information source are labeled microposts (MICR), though, as expected, the projected embeddings (MICR:proj) outperform PMI. The performance of weak supervision (WSUP) outperforms MICR.

Among the SVM configurations, embeddings are already effective. The linguistic features outperform all other methods. The best classifier is an SVM trained on embeddings, linguistic features and the output of WSUP as a further feature.[10]

Table 7 shows the performance of SVMs using different linguistic features (§4.1). Among the three intensity types, the most effective one is the person-based intensity (INT$_{person}$). However, it can be effectively combined with the remaining types. Among the lexical sentiment resources used (i.e. NRC, INT$_{bin}$ and VIEW), VIEW is most effective. Their combination also results in an improvement. The surface patterns (PAT) are surprisingly predictive. Of the general-purpose lexical resources (i.e. WN, WK and FN), WN and WK are both very effective resources. Glosses from WN are the strongest individual feature. Combining WK, WN and FN results in significant improvement. The best feature set combines all features.

Our results also suggest that for languages other than English, there are some very strong features, such as PAT, WK or embeddings, that could be easily adopted since they do not depend on a resource which is only available in English.

5 Expanding the Lexicon

We produce a large **feature-based lexicon** of abusive words by classifying all (unlabeled) negative polar expressions from Wiktionary. We chose Wiktionary since our previous experiments indicated a high coverage of abusive words on that resource (§4.1.5). The negative polar expressions

[10] We did not include MICR among the further features, as they are trained on the labeled microposts that we also use as test data in the extrinsic evaluation (§6).

are identified by applying to the vocabulary of Wiktionary an SVM trained on the words from the Subjectivity Lexicon with their respective polarities. As features, we use word embeddings (§4.2). In order to produce the feature-based lexicon of abusive words another SVM is trained on our base lexicon (Table 1) using the best feature set from Table 6. With 2989 abusive words, our expanded lexicon is 5 times as large as the base lexicon.

In order to measure the impact of our proposed features on the quality of the resulting lexicon, we devised an alternative expansion which just employs word embeddings. For this, we used **SentProp**, the most effective induction method from the *SocialSent* package (Hamilton et al., 2016).[11]

6 Cross-domain Classification

6.1 Motivation and Set Up

We now apply our expanded lexicon (§5) to the classification of abusive microposts, i.e. we classify entire comments rather than words out of context. Table 8 shows the datasets of labeled microposts that we use. The difference between these datasets is the source from which they originate. Consequently, different topics are represented in the different datasets. Still, we find similar types

[11] Since SentProp produces a ranking rather than a classification, we consider 2989 as a cut-off value to separate the instances into 2 classes. This corresponds to the size of abusive words predicted by our feature-based lexicon (Table 9).

dataset	size†	abusive	source
(Warner and Hirschberg, 2012)	3438	14.3%	*diverse*
(Waseem and Hovy, 2016)	16165	35.3%	Twitter
(Razavi et al., 2010)	1525	31.9%	UseNet
(Wulczyn et al., 2017)	115643	11.6%	Wikipedia

†: total number of microposts in the dataset

Table 8: Datasets comprising labeled microposts.

of abusive language (e.g. *racism*, *sexism*). For example, both (10)-(11) from *Waseem* and (12) from *Wulczyn* are sexist comments[12] but (10)-(11) discuss the role of women in sports while (12) addresses women's hygiene in Slavic countries.

(10) *from Waseem dataset:* maybe that's where they should focus? Less **cunts** on *football*.

(11) *from Waseem dataset:* I would rather brush my teeth with sandpaper then watch *football* with a girl!!

(12) *from Wulczyn dataset:* slavic women don't like to wash ... Their **pussy** stinks.

Since our aim is to produce the best possible cross-domain classifier, **all classifiers are trained on one dataset and tested on another**. This is a real-life scenario. Often when a classifier for abusive microposts is needed, sufficient labeled data is only available for other text domains.

Having different topics in training and test data makes cross-domain classification difficult. For example, since a large proportion of sexist comments in *Waseem* relate to sports, traditional supervised classifiers (using bag of words or word embeddings) will learn correlations between words of that domain with the class labels. For instance, the domain-specific word *football* occurs frequently in *Waseem* (i.e. 90 occurrences) with a strong correlation towards abusive language (precision: 95%). Other words, such as *sports* and *commentator*, display a similar behaviour. A supervised classifier will assign a high weight to such words. While such domain-specific words may aid in-domain classification and enable a correct classification of microposts, such as (11), we will show that it has a detrimental effect on cross-domain classification. We claim that the predictive words that abusive comments share across different domains are abusive words, just of the sort that our expanded lexicon contains, e.g. *cunts* in (10) and *pussy* in (12).

Our **proposed classifier** for labeling *microposts* is an SVM trained on features derived from our expanded lexicon (§5). We do not use a binary feature encoding the presence of abusive words. Instead, we rank all abusive words of our lexicon

[12] (12) is also a racist comment.

according to the confidence score of the classifier it produced and use their ranks as features.

As **baseline classifiers** we consider publicly available word lists (Table 9). We include the resource from Razavi et al. (2010), henceforth referred to as ***Ottawa***, the entries of ***Hatebase***[13], which has been used in Nobata et al. (2016) and Davidson et al. (2017), and the derogatory words from Wiktionary (***Derogatory***)[14].[15] Finally, we also include our **base** lexicon (Table 1) in order to evaluate the expansion process of our two expanded lexicons (§5). For all lists, we train on a single feature indicating the frequency of abusive words in a micropost to be classified. *Ottawa* also contains weights assigned to abusive words. We weight the observed frequency with these weights.

We further evaluate 3 classifiers representing the state of the art of in-domain evaluations: ***FastText*** (Joulin et al., 2017), Gated Recurrent Units Recurrent Neural Networks ***RNN***, which have been reported to work best on English microposts (Pavlopoulos et al., 2017), and ***Yahoo***, an SVM trained on the sophisticated feature set proposed by Nobata et al. (2016). Next to character and token n-grams, *Yahoo* includes word and comment embeddings, syntactic features and some linguistic diagnostics.

6.2 Results

In Table 10, we list the performance of the 3 state-of-the-art classifiers along with our proposed classifier using our expanded lexicon on in-domain 10-fold crossvalidation. Due to space limitations, we cannot list the other classifiers. We *only* provide this list to demonstrate the strength of the state-of-the-art classifiers on in-domain evaluation. On this setting, a lexicon-based approach is not competitive since domain-specific information is not included. However, as we show in Table 11, for cross-domain classification, it is exactly that property that ensures that our feature-based lexicon provides best performance. Compared to the in-domain setting, *FastText*, *RNN* and *Yahoo* display a huge drop in performance. They all suffer from overfitting to domain-specific knowledge.

Of all lexicons, our proposed feature-based lexicon performs best. We were surprised by the poor performance of *Hatebase* but attribute this to its small size and the high amount of ambiguous (and debatable) entries, such as *Charlie*, *pancake*, *Pepsi*. Although our feature-based lexicon is the largest of all tested (i.e. 2989 words), our experiments do not support the general rule that larger lexicons always outperform smaller ones. For instance, already our base lexicon with 551 abusive words is much better than the lexicons *Derogatory* or *Ottawa* which are about 3 times larger (Table 9). Each word in our base lexicon was only included if 4 out of 5 raters judged it to be abusive. This ensured a fairly reliable annotation. In contrast, *Derogatory* and *Ottawa* suffer from many ambiguous entries (e.g. *bag*, *Tim*, *yellow*). The high precision of our base lexicon is what ensures that our expanded lexicon does not include much noise.

Another shortcoming of most of the other existing lexicons is that they overwhelmingly focus on nouns. While nouns undoubtedly represent the most frequent abusive terms, there is, however, a substantial number of abusive words that belong to other parts of speech, particularly adjectives (e.g. *vile*, *sneaky*, *slimy*, *moronic*). In our base lexicon, more than 30% of the abusive words are of that part of speech. Our expanded lexicon,

Table 11: Different classifiers on **cross-domain** classification of microposts; best result in **bold**; (*eval.: F1-score*).

which roughly preserves that ratio, includes about 800 adjectives in total. Since abusive adjectives often co-occur with abusive nouns (§4.1.4), they may compensate for abusive nouns that are missing from the lexicon. Such unknown nouns often occur when authors of microposts try to obfuscate their abusive language, e.g. *sneaky assh0le*, *slimy b*st*rd*. Interestingly, the modifying adjectives are not obfuscated, probably because they are considered slightly less offensive in tone.

Given that among the newly created lexicons our feature-based expanded lexicon performs best, we conclude that the expansion is effective (since we improve over the base lexicon), and the features are more effective than a generic induction approach (i.e. *SentProp*).

6.3 Explicitly vs. Implicitly Abusive Microposts

The results in Table 11 also show that the cross-domain performance of our proposed feature-based lexicon is lower on the two datasets *Warner* and *Waseem*. We observed that while on the other two datasets almost all abusive microposts can be considered *explicitly abusive* posts, i.e. they contain abusive words, a large proportion of microposts labeled abusive in *Warner* and *Waseem* are *implicitly abusive* (Waseem et al., 2017), i.e. the abuse is conveyed by other means, such as sarcasm or metaphorical language (11). We asked raters from Prolific Academic to identify explicitly abusive microposts by marking abusive words in those posts. The annotators were not given access to any lexicon of abusive words. We then conducted cross-domain classification on those subsets where the abusive instances were only those rated as explicit. The results are displayed in Table 12. The table shows that our feature-based lexicon is much better on this subset, while the most sophisticated supervised classifier (*Yahoo*) still performs worse. From that we conclude that only *explicitly* abusive microposts can be reliably detected in cross-domain classification.

7 Conclusion

We examined the task of inducing a lexicon of abusive words. We presented novel features including surface patterns, sentiment views, polar intensity and general purpose lexical resources, particularly Wiktionary. The information we thus acquire cannot be learnt all that effectively from labeled microposts, not even with a projection-based classifier. While a lexicon of abusive words can only aid the detection of explicit abuse, its effectiveness was demonstrated on the novel task of cross-domain detection of abusive microposts, where our domain-independent lexicon outperforms previous supervised classifiers which suffer from overfitting to domain-specific features.

Acknowledgements

The authors would like to thank Thomas Kleinbauer, Katja Markert and Ines Rehbein for feedback on earlier drafts of this paper. We are also grateful to William Warner and Diana Inkpen for granting us access to their data on abusive language detection. Special thanks go to Stefan Kazalski for crawling the *rateitall*-website. We also give thanks to John Pavlopoulos for helping us reconstructing the configurations of his RNN. Author Commitment and Social Power: Automatic Belief Tagging to Infer the Social Context of Interactions

Abstract

Understanding how social power structures affect the way we interact with one another is of great interest to social scientists who want to answer fundamental questions about human behavior, as well as to computer scientists who want to build automatic methods to infer the social contexts of interactions. In this paper, we employ advancements in extra-propositional semantics extraction within NLP to study how author commitment reflects the social context of an interactions. Specifically, we investigate whether the level of commitment expressed by individuals in an organizational interaction reflects the hierarchical power structures they are part of. We find that subordinates use significantly more instances of non-commitment than superiors. More importantly, we also find that subordinates attribute propositions to other agents more often than superiors do — an aspect that has not been studied before. Finally, we show that enriching lexical features with commitment labels captures important distinctions in social meanings.

1 Introduction

Social power is a difficult concept to define, but is often manifested in how we interact with one another. Understanding these manifestations is important not only to answer fundamental questions in social sciences about power and social interactions, but also to build computational models that can automatically infer social power structures from interactions. The availability and access to large digital repositories of naturally occurring social interactions and the advancements in natural language processing techniques in recent years have enabled researchers to perform large scale studies on linguistic correlates of power, such as words and phrases (Bramsen et al., 2011; Gilbert, 2012), linguistic coordination (Danescu-Niculescu-Mizil et al., 2012), agenda control (Taylor et al., 2012), and dialog structure (Prabhakaran and Rambow, 2014).

Another area of research that has recently garnered interest within the NLP community is the modeling of author commitment in text. Initial studies in this area were done in processing hedges, uncertainty and lack of commitment, specifically focused on scientific text (Mercer et al., 2004; Di Marco et al., 2006; Farkas et al., 2010). More recently, researchers have also looked into capturing author commitment in non-scientific text, e.g., levels of factuality in newswire (Saurí and Pustejovsky, 2009), types of commitment of beliefs in a variety of genres including conversational text (Diab et al., 2009; Prabhakaran et al., 2015). These approaches are motivated from an information extraction perspective, for instance in aiding tasks such as knowledge base population.[1] However, it has not been studied whether such sophisticated author commitment analysis can go beyond what is expressed in language and reveal the underlying social contexts in which language is exchanged.

In this paper, we bring together these two lines of research; we study how power relations correlate with the levels of commitment authors express in interactions. We use the power analysis framework built by Prabhakaran and Rambow (2014) to perform this study, and measure author commitment using the committed belief tagging framework introduced by (Diab et al., 2009) that distinguishes different types of beliefs expressed in text. Our contributions are two-fold — statistical analysis of author commitment in relation with power, and enrichment of lexical features with commitment labels to aid in computational prediction of power relations. In the first part, we find that au-

[1] The BeSt track of the 2017 TAC-KBP evaluation aimed at detecting the "belief and sentiment of an entity toward another entity, relation, or event" (http://www.cs.columbia.edu/~rambow/best-eval-2017/).

Proceedings of NAACL-HLT 2018, pages 1057–1068
New Orleans, Louisiana, June 1 - 6, 2018.

thor commitment is significantly correlated with the social power relations between their participants — subordinates use more instances of non-commitment, a finding that is in line with sociolinguistics studies in this area. We also find that subordinates use significantly more reported beliefs (i.e., attributing beliefs to other agents) than superiors. This is a new finding; to our knowledge, there has not been any sociolinguistics studies investigating this aspect of interaction in relation with power. In the second part, we present novel ways of incorporating the author commitment information into lexical features that can capture important distinctions in word meanings conveyed through the belief contexts in which they occur; distinctions that are lost in a model that conflates all occurrences of a word into one unit.

We first describe the related work in computational power analysis and computational modeling of cognitive states in Section 2. In Section 3, we describe the power analysis framework we use. Section 4 formally defines the research questions we are investigating, and describes how we obtain the belief information. In Section 5, we present the statistical analysis of author commitment and power. Section 6 presents the utility of enriching lexical features with belief labels in the context of automatic power prediction. Section 7 concludes the paper and summarizes the results.

2 Related Work

The notion of belief that we use in this paper (Diab et al., 2009; Prabhakaran et al., 2015) is closely related to the notion of factuality that is captured in FactBank (Saurí and Pustejovsky, 2009). They capture three levels of factuality, certain (CT), probable (PB), and possible (PS), as well as the underspecified factuality (Uu). They also record the corresponding polarity values, and the source of the factuality assertions to distinguish between factuality assertions by the author and those by the agents/sources introduced by the author. While FactBank offers a finer granularity, they are annotated on newswire text. Hence, we use the corpus of belief annotations (Prabhakaran et al., 2015) that is obtained on online discussion forums, which is closer to our genre.

Automatic hedge/uncertainty detection is a very closely related task to belief detection. The belief tagging framework we use aims to capture the cognitive states of authors, whereas hedges are linguistic expressions that convey one of those cognitive states — non-committed beliefs. Automatic hedge/uncertainty detection has generated active research in recent years within the NLP community. Early work in this area focused on detecting speculative language in scientific text (Mercer et al., 2004; Di Marco et al., 2006; Kilicoglu and Bergler, 2008). The open evaluation as part of the CoNLL shared task in 2010 to detect uncertainty and hedging in biomedical and Wikipedia text (Farkas et al., 2010) triggered further research on this problem in the general domain (Agarwal and Yu, 2010; Morante et al., 2010; Velldal et al., 2012; Choi et al., 2012). Most of this work was aimed at formal scientific text in English. More recent work has tried to extend this work to other genres (Wei et al., 2013; Sanchez and Vogel, 2015) and languages (Velupillai, 2012; Vincze, 2014), as well as building general purpose hedge lexicons (Prokofieva and Hirschberg, 2014). In our work, we use the lexicons from (Prokofieva and Hirschberg, 2014) to capture hedges in text.

Sociolinguists have long studied the association between level of commitment and social contexts (Lakoff, 1973; O'Barr and Atkins, 1980; Hyland, 1998). A majority of this work studies gender differences in the use of hedges, triggered by the influential work by Robin Lakoff (Lakoff, 1973). She argued that women use linguistic strategies such as hedging and hesitations in order to adopt an unassertive communication style, which she terms "women's language". While many studies have found evidence to support Lakoff's theory (e.g., (Crosby and Nyquist, 1977; Preisler, 1986; Carli, 1990)), there have also been contradictory findings (e.g., (O'Barr and Atkins, 1980)) that link the difference in the use of hedges to other social factors (e.g., power). O'Barr and Atkins (1980) argue that the use of hedges is linked more to the social positions rather than gender, suggesting to rename "women's language" to "powerless language". In later work, O'Barr (1982) formalized the notion of powerless language, which formed the basis of many sociolinguistics studies on social power and communication. O'Barr (1982) analyzed courtroom interactions and identified hedges and hesitations as some of the linguistic markers of "powerless" speech. However, there has not been any computational work which has looked into how power relations relate to the level of commitment expressed in text. In this paper, we use com-

putational power analysis to perform a large scale data-oriented study on how author commitment in text reveals the underlying power relations.

There is a large body of literature in the social sciences that studies power as a social construct (e.g., (French and Raven, 1959; Dahl, 1957; Emerson, 1962; Pfeffer, 1981; Wartenberg, 1990)) and how it relates to the ways people use language in social situations (e.g., (Bales et al., 1951; Bales, 1970; O'Barr, 1982; Van Dijk, 1989; Bourdieu and Thompson, 1991; Ng and Bradac, 1993; Fairclough, 2001; Locher, 2004)). Recent years have seen growing interest in computationally analyzing and detecting power and influence from interactions. Early work in computational power analysis used social network analysis based approaches (Diesner and Carley, 2005; Shetty and Adibi, 2005; Creamer et al., 2009) or email traffic patterns (Namata et al., 2007). Using NLP to deduce social relations from online communication is a relatively new area of active research.

Bramsen et al. (2011) and Gilbert (2012) first applied NLP based techniques to predict power relations in Enron emails, approaching this task as a text classification problem using bag of words or ngram features. More recently, our work has used dialog structure features derived from deeper dialog act analysis for the task of power prediction in Enron emails (Prabhakaran and Rambow, 2014; Prabhakaran et al., 2012; Prabhakaran and Rambow, 2013). In this paper, We use the framework of (Prabhakaran and Rambow, 2014), but we analyze a novel aspect of interaction that has not been studied before — what level of commitment do the authors express in language.

There has also been work on analyzing power in other genres of interactions. Strzalkowski et al. (2010) and Taylor et al. (2012) concentrate on lower-level constructs called *Language Uses* such as agenda control to predict power in Wikipedia talk pages. Danescu-Niculescu-Mizil et al. (2012) study how social power and linguistic coordination are correlated in Wikipedia interactions as well as Supreme Court hearings. Bracewell et al. (2012) and Swayamdipta and Rambow (2012) try to identify pursuit of power in discussion forums. Biran et al. (2012) and Rosenthal (2014) study the problem of predicting influence in Wikipedia talk pages, blogs, and other online forums. Prabhakaran et al. (2013) study manifestations of power of confidence in presidential debates.

3 Power in Workplace Email: Data and Analysis Framework

The focus of our study is to investigate whether the level of commitment participants express in their contributions in an interaction is related to the power relations they have with other participants, and how it can help in the problem of predicting social power. In this section, we introduce the power analysis framework as well as the data we use in this study.

3.1 Problem

In order to model manifestations of power relations in interactions, we use our interaction analysis framework from (Prabhakaran and Rambow, 2014), where we introduced the problem of predicting organizational power relations between pairs of participants based on single email threads. The problem is formally defined as follows: given an email thread t, and a related interacting participant pair (p_1, p_2) in the thread, predict whether p_1 is the *superior* or *subordinate* of p_2. In this formulation, a *related interacting participant pair (RIPP)* is a pair of participants of the thread such that there is at least one message exchanged within the thread between them (in either direction) and that they are hierarchically related with a superior/subordinate relation.

3.2 Data

We use the same dataset we used in (Prabhakaran and Rambow, 2014), which is a version of the Enron email corpus in which the thread structure of email messages is reconstructed (Yeh and Harnly, 2006), and enriched by Agarwal et al. (2012) with gold organizational power relations, manually determined using information from Enron organizational charts. The corpus captures dominance relations between 13,724 pairs of Enron employees. As in (Prabhakaran and Rambow, 2014), we use these dominance relation tuples to obtain gold labels for the *superior* or *subordinate* relationships between pairs of participants. We use the same train-test-dev split as in (Prabhakaran and Rambow, 2014). We summarize the number of threads and related interacting participant pairs in each subset of the data in Table 1.

4 Research Hypotheses

Our first objective in this paper is to perform a large scale computational analysis of author com-

Description	Train	Dev	Test
Email threads	18079	8973	9144
# of RIPPs	7510	3578	3920

Table 1: Data Statistics. Row 1: number of threads in subsets of the corpus. Row 2: number of related interacting participant pairs in those subsets. RIPP: Related interacting participant pairs

mitment and power relations. Specifically, we want to investigate whether the commitment authors express towards their contributions in organizational interactions is correlated with the power relations they have with other participants. Sociolinguistics studies have found some evidence to suggest that lack of commitment expressed through hedges and hesitations is associated with lower power status (O'Barr, 1982). However, in our study, we go beyond hedge word lists, and analyze different cognitive belief states expressed by authors using a belief tagging framework that takes into account the syntactic contexts within which propositions are expressed.

4.1 Obtaining Belief Labels

We use the committed belief analysis framework introduced by (Diab et al., 2009; Prabhakaran et al., 2015) to model different levels of beliefs expressed in text. Specifically, in this paper, we use the 4-way belief distinction — COMMITTEDBELIEF, NONCOMMITTEDBELIEF, REPORTEDBELIEF, and NONAPPLICABLE— introduced in (Prabhakaran et al., 2015).[2] (Prabhakaran et al., 2015) presented a corpus of online discussion forums with over 850K words, annotating each propositional head in text with one of the four belief labels. The paper also presented an automatic belief tagger trained on this data, which we use to obtain belief labels in our data. We describe each belief label and our associated hypotheses below.

Committed belief (CB): the writer strongly believes that the proposition is true, and wants the reader/hearer to believe that. E.g.:

(1) a. John will **submit** the report.
b. I know that John is **capable**.

[2]We also performed analysis and experiments using an earlier 3-way belief distinction proposed by (Diab et al., 2009), which also yielded similar findings. We do not report the details of those analyses in this paper.

As discussed earlier, lack of commitment in one's writing/speech is identified as markers of powerless language. We thus hypothesize:

H. 1. *Superiors use more instances of committed belief in their messages than subordinates.*

Non-committed belief (NCB): the writer explicitly identifies the proposition as something which he or she could believe, but he or she happens not to have a strong belief in, for example by using an epistemic modal auxiliary. E.g.:

(2) a. John may **submit** the report.
b. I guess John is **capable**.

This class captures a more semantic notion of non-commitment than hedges, since the belief annotation attempts to model the underlying meaning rather than language uses, and hence captures other linguistic means of expressing non-committedness. Following (O'Barr, 1982), we formulate the below hypothesis:

H. 2. *Subordinates use more instances of non committed belief in their messages than superiors.*

Reported belief (ROB): the writer attributes belief (either committed or non-committed) to another person or group. E.g.:

(3) a. Sara says John will **submit** the report.
b. Sara thinks John may be **capable**.

Note that this label is only applied when the writer's own belief in the proposition is unclear. For instance, if the first example above was *Sara knows John will submit the report on-time*, the writer is expressing commitment toward the proposition that John will submit the report and it will be labeled as committed belief rather than reported belief. Reported belief captures instances where the writer is in effect limiting his/her commitment towards what is stated by attributing the belief to someone else. So, in line with our hypotheses for non-committed beliefs, we formulate the following hypothesis:

H. 3. *Subordinates use more instances of reported beliefs in their messages than superiors.*

Non-belief propositions (NA): – the writer expresses some other cognitive attitude toward the proposition, such as desire or intention (4a), or expressly states that he/she has no belief about the proposition (e.g., asking a question (4b)). E.g.:

(4) a. I need John to **submit** the report.
b. Will John be **capable**?

As per the above definition, requests for information (i.e., questions) and requests for actions are cases where the author is not expressing a belief about the proposition, but rather expressing the desire that some action be done. In the study correlating power with dialog act tags (Prabhakaran and Rambow, 2014), we found that superiors issue significantly more requests than subordinates. Hence, we expect the superiors to have significantly more non belief expressions in their messages, and formulate the following hypothesis:

H. 4. *Superiors use more instances of non beliefs in their messages than subordinates.*

4.2 Testing Belief Tagger Bias

NLP tools are imperfect and may produce errors, which poses a problem when using any NLP tool for sociolinguistic analysis. More than the magnitude of error, we believe that whether the error is correlated with the social variable of interest (i.e., power) is more important; e.g., is the belief-tagger more likely to find ROB false-positives in subordinates text? To test whether this is the case, we performed manual belief annotation on around 500 propositional heads in our corpus. Logistic regression test revealed that the belief-tagger is equally likely to make errors (both false-positives and false-negatives, for all four belief-labels) in sentences written by subordinates as superiors (the null hypothesis accepted at $p > 0.05$ for all eight tests).

5 Statistical Analysis

Now that we have set up the analysis framework and research hypotheses, we present the statistical analysis of how superiors and subordinates differ in their relative use of expressions of commitment.

5.1 Features

For each participant of each pair of related interacting participants in our corpus, we aggregate each of the four belief tags:

- *CBCount*: number of propositional heads tagged as Committed Belief (CB)
- *NCBCount*: number of propositional heads tagged as Non Committed Belief (NCB)
- *ROBCount*: number of propositional heads tagged as Reported Belief (ROB)
- *NACount*: number of propositional heads tagged as Non Belief (NA)

5.2 Hypotheses Testing

Our general hypothesis is that power relations do correlate with the level of commitment people express in their messages; i.e., at least one of H.1 - H.4 is true. In this analysis, each participant of the pair (p_1, p_2) is a data instance. We exclude the instances for which a feature value is undefined.[3]

In order to test whether superiors and subordinates use different types of beliefs, we used a linear regression based analysis. For each feature, we built a linear regression model predicting the feature value using power (i.e., superior vs. subordinate) as the independent variable. Since verbosity of a participant can be highly correlated with each of these feature values (we found it to be highly correlated with subordinates (Prabhakaran and Rambow, 2014)), we added token count as a control variable to the linear regression.

Our linear regression test revealed significant differences in NCB (b=-.095, t(-8.09), p<.001), ROB (b=-.083, t(-7.162), p<.001) and NA (b=.125, t(4.351), p<.001), and no significant difference in CB (b=.007, t(0.227), p=0.821). Figure 1 pictorially demonstrates these results by plotting the difference between the mean values of each commitment feature (here normalized by token count) of superiors vs. subordinates, as a percentage of mean feature value of the corresponding commitment feature for superiors. Dark bars denote statistically significant differences.

5.3 Interpretation of Findings

The results from our statistical analysis validate our original hypothesis that power relations do correlate with the level of commitment people express in their messages. This finding remains statistically significant ($p < 0.001$) even after applying the Bonferroni correction for multiple testing.

The results on NCB confirm our hypothesis that subordinates use more non-committedness in their language. Subordinates' messages contain 48% more instances of non-committed belief than superiors' messages, even after normalizing for the length of messages. This is in line with prior sociolinguistics literature suggesting that people with

[3]These are instances corresponding to participants who did not send any messages in the thread (some of the pairs in the set of related interacting participant pairs only had one-way communication) or whose messages were empty (e.g., forwarding messages).

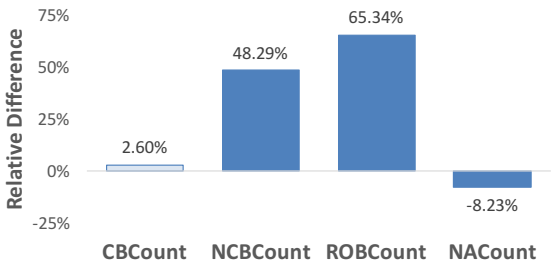

Figure 1: Relative difference (RD) between subordinates and superiors in their use of different types of commitment (counts normalized by word count of contributions). Dark bars: statistical significance at $p < 0.05$. (RD = $\frac{(Mean(Subordinates) - Mean(Superiors)) * 100}{Mean(Superiors)}$).

less power tend to use less commitment, previously measured in terms of hedges. However, in our work, we go beyond hedge dictionaries and use expressions of non-committedness that takes into account the syntactic configurations in which the words appear.

Another important finding is in terms of reported belief (ROB). Our results strongly verify the hypothesis H.3 that subordinates use significantly more reported beliefs than superiors. In fact, it obtained the largest magnitude of relative difference (65.3% more) of all features we analyzed. To our knowledge, ours is the first study that analyzed the manifestation of power in authors attributing beliefs to others. Our results are in line with the finding in (Agarwal et al., 2014) that "if many more people get mentioned to a person then that person is the boss", because as subordinates report other people's beliefs to superiors, they are also likely to mention them.

The finding that superiors use more NAs confirms our hypothesis H.4. As discussed earlier, this is expected since superiors issue more requests (as found by (Prabhakaran and Rambow, 2014)), the propositional heads of which would be tagged as NA by the belief tagger. However, our hypothesis H.1 is proven false. Being a superior or subordinate does not affect how often their messages contain CB, which suggests that power differences are manifested only in terms of lack of commitment.

6 Commitment in Power Prediction

Our next step is to explore whether we can utilize the hedge and belief labels to improve the performance of an automatic power prediction system. For this purpose, we use our POWERPREDICTOR system (Prabhakaran and Rambow, 2014) that predicts the direction of power between a pair of related interacting participants in an email thread. It uses a variety of linguistic and dialog structural features consisting of verbosity features (message count, message ratio, token count, token ratio, and tokens per message), positional features (initiator, first message position, last message position), thread structure features (number of all recipients and those in the *To* and *CC* fields of the email, reply rate, binary features denoting the adding and removing of other participants), dialog act features (request for action, request for information, providing information, and conventional), and overt displays of power, and lexical features (lemma ngrams, part-of-speech ngrams, and mixed ngrams, a version of lemma ngrams with open class words replaced with their part-of-speech tags). The feature sets are summarized in Table 2 ((Prabhakaran and Rambow, 2014) has a detailed description of these features).

Set	Description
VRB	Verbosity (e.g., message count)
PST	Positional (e.g., thread initiator?)
THR	Thread structure (e.g., reply rate)
DIA	Dialog act tagging (e.g., request count)
ODP	Overt displays of power
LEX	Lexical ngrams (lemma, POS, mixed ngrams)

Table 2: POWERPREDICTOR system: Features used

None of the features used in POWERPREDICTOR use information from the parse trees of sentences in the text However, in order to accurately obtain the belief labels, deep dependency parse based features are critical (Prabhakaran et al., 2010). We use the ClearTk wrapper for the Stanford CoreNLP pipeline to obtain the dependency parses of sentences in the email text. To ensure an unified analysis framework, we also use the Stanford CoreNLP for tokenization, part-of-speech tagging, and lemmatization steps, instead of OpenNLP. This change affects our analysis in two ways. First, the source of part-of-speech tags and word lemmas is different from what was presented in the original system, which might affect the performance of the dialog act tagger and overt display of power tagger (DIA and ODP features). Second, we had to exclude 117 threads (0.3%) from the corpus for which the Stanford CoreNLP failed to parse some sentences, resulting in the removal of 11 data points (0.2%), only one of which

was in the test set. On randomly checking, we found that they contained non-parsable text such as dumps of large tables, system logs, or unedited dumps of large legal documents.

In order to better interpret how the commitment features help in power prediction, we use a linear kernel SVM in our experiments. Linear kernel SVMs are significantly faster than higher order SVMs, and our preliminary experiments revealed the performance gain by using a higher order SVM to be only marginal. We use the best performing feature set from (Prabhakaran and Rambow, 2014) as a strong baseline for our experiments. This baseline feature set is the combination of thread structure features (THR) and lexical features (LEX). This baseline system obtained an accuracy of 68.8% in the development set.

6.1 Belief Label Enriched Lexical Features

Adding the belief label counts into the SVM directly as features will not yield much performance improvements, as signal in the aggregate counts would be minimal given the effect sizes of differences we find in Section 5. In this section, we investigate a more sophisticated way of incorporating the belief tags into the power prediction framework. Lexical features are very useful for the task of power prediction. However, it is often hard to capture deeper syntactic/semantic contexts of words and phrases using ngram features. We hypothesize that incorporating belief tags into the ngrams will enrich the representation and will help disambiguate different usages of same words/phrases. For example, let us consider two sentences: *I need the report by tomorrow* vs. *If I need the report, I will let you know*. The former is likely coming from a person who has power, whereas the latter does not give any such indication. Applying the belief tagger to these two sentences will result in *I need(CB) the report ...* and *If I need(NA) the report ....* Capturing the difference between *need(CB)* vs. *need(NA)* will help the machine learning system to make the distinction between these two usages and in turn improve the power prediction performance.

In building the ngram features, whenever we encounter a token that is assigned a belief tag, we append the belief tag to the corresponding lemma or part-of-speech tag in the ngram. We call it the *Append* version of corresponding ngram feature. We summarize the different versions of each type of ngram features below:

- *LN*: the original word lemma ngram; e.g., *i_need_the*.
- LN^{CBApnd}: word lemma ngram with appended belief tags; e.g., *i_need(CB)_the*.
- *PN*: the original part-of-speech ngram; e.g., *PRP_VB_DT*.
- PN^{CBApnd}: part-of-speech ngram with appended belief tags; e.g., *PRP_VB(CB)_DT*.
- *MN*: the original mixed ngram; e.g., *i_VB_the*.
- MN^{CBApnd}: mixed ngram with appended belief tags; e.g., *i_VB(CB)_the*.

Feature Configuration in LEXICAL	Accuracy
LN +PN +MN (*BaseLine*)	68.8
LN^{CBApnd}*+PN +MN*	**69.3**
LN +PN^{CBApnd}*+MN*	68.6
LN +PN +MN^{CBApnd}	69.0
LN^{CBApnd}*+ PN +* MN^{CBApnd}	69.2

Table 3: Power prediction results using different configurations of LEX features. (The full feature set also includes THR.)

In Table 3, we show the results obtained by incorporating the belief tags in this manner to the LEXICAL features of the original baseline feature set. The first row indicates the baseline results and the following rows show the impact of incorporating belief tags using the *Append* method. While the *Append* version of both lemma ngrams and mixed ngrams improved the results, the *Append* version of part of speech ngrams reduced the results. The combination of best performing version of each type of ngram obtained slightly lower result than using the *Append* version of word ngram alone, which posted the overall best performance of 69.3%, a significant improvement ($p<0.05$) over not using any belief information. We use the approximate randomization test (Yeh, 2000) for testing statistical significance of the improvement.

Finally, we verified that our best performing feature sets obtain similar improvements in the unseen test set. The baseline system obtained 70.2% accuracy in the test set. The best performing configuration from Table 3 significantly improved this accuracy to 70.8%. The second best performing configuration of using the *Append* version of both word and mixed ngrams obtained only a small improvement upon the baseline in the test set.

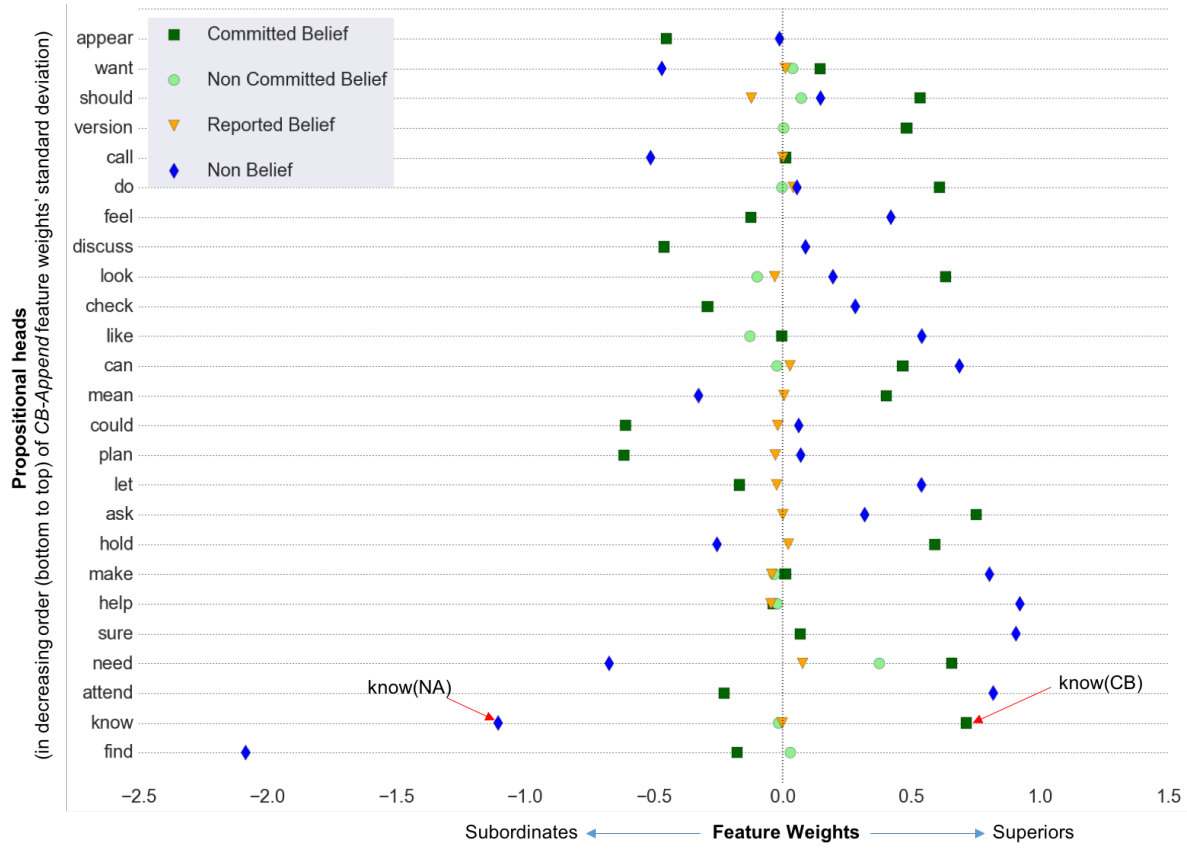

Figure 2: Feature weights of different belief appended versions of 25 propositional heads whose lemma unigrams had the highest standard deviation. Y-axis denotes the propositional heads in decreasing order of standard deviation from bottom to top. X-axis denotes the feature weights.

6.2 Word NGram Feature Analysis

We inspect the feature weights assigned to the LN^{CBApnd} version of lemma ngrams in our best performing model. Each lemma ngram that contains a propositional head (e.g., *need*) has four possible LN^{CBApnd} ngram versions: *need(CB)*, *need(NCB)*, *need(ROB)*, and *need(NA)*. For each lemma ngram, we calculate the standard deviation of weights assigned to different LN^{CBApnd} versions in the learned model as a measure of variation captured by incorporating belief tags into that ngram.[4]

Figure 2 shows the feature weights of different LN^{CBApnd} versions of twenty five propositional heads whose lemma unigrams had the highest standard deviation. The y-axis lists propositional heads arranged in the decreasing order of standard deviation from bottom to top, while the x-axis denotes the feature weights. The markers distinguish the different LN^{CBApnd} versions of each propositional head — square denotes COMMITTEDBELIEF, circle denotes NONCOMMITTEDBELIEF, triangle denotes REPORTEDBELIEF, and diamond denotes NONAPPLICABLE. The feature versions with negative weights are associated more with subordinates' messages, whereas those with positive weights are associated more with superiors' messages. Since NCB and ROB versions are rare, they rarely get high weights in the model.

We find that by incorporating belief labels into lexical features, we capture important distinctions in social meanings expressed through words that are lost in the regular lemma ngram formulation. For example, propositional heads such as *know*, *need*, *hold*, *mean* and *want* are indicators of power when they occur in CB contexts (e.g., *i need ...*), whereas their usages in NA contexts (e.g., *do you need?*, *if i need...*, etc.) are indicators of lack of power. In contrast, the CB version of *attend*, *let*, *plan*, *could*, *check*, *discuss*, and *feel* (e.g., *i will attend/check/plan ...*) are strongly associated with lack of power, while their NA versions (e.g., *can you attend/check/plan?*) are indicators of power.

[4]Not all lemma ngrams have all four versions; we calculated standard deviation using the versions present.

7 Conclusion

In this paper, we made two major contributions. First, we presented a large-scale data oriented analysis of how social power relations between participants of an interaction correlate with different types of author commitment in terms of their relative usage of hedges and different levels of beliefs — committed belief, non-committed belief, reported belief, and non-belief. We found evidence that subordinates use significantly more propositional hedges than superiors, and that superiors and subordinates use significantly different proportions of different types of beliefs in their messages. In particular, subordinates use significantly more non-committed beliefs than superiors. They also report others' beliefs more often than superiors. Second, we investigated different ways of incorporating the belief tag information into the machine learning system that automatically detects the direction of power between pairs of participants in an interaction. We devised a sophisticated way of incorporating this information into the machine learning framework by appending the heads of propositions in lexical features with corresponding belief tags, demonstrating its utility in distinguishing social meanings expressed through the different belief contexts.

This study is based on emails from a single corporation, at the beginning of the 21st century. Our findings on the correlation between author commitment and power may be reflective of the work culture that prevailed in that organization at the time when the emails were exchanged. It is important to replicate this study on emails from multiple organizations in order to assess whether these results generalize across board. It is likely that behavior patterns are affected by factors such as ethnic culture (Cox et al., 1991) of the organization, and the kinds of conversations interactants engage in (for instance, co-operative vs. competitive behavior (Hill et al., 1992)). We intend to explore this line of inquiry in future work.

Comparing Automatic and Human Evaluation of Local Explanations for Text Classification

Dong Nguyen[♠◇]

dnguyen@turing.ac.uk

Abstract

Text classification models are becoming increasingly complex and opaque, however for many applications it is essential that the models are interpretable. Recently, a variety of approaches have been proposed for generating local explanations. While robust evaluations are needed to drive further progress, so far it is unclear which evaluation approaches are suitable. This paper is a first step towards more robust evaluations of local explanations. We evaluate a variety of local explanation approaches using automatic measures based on word deletion. Furthermore, we show that an evaluation using a crowdsourcing experiment correlates moderately with these automatic measures and that a variety of other factors also impact the human judgements.

1 Introduction

While the impact of machine learning is increasing rapidly in society, machine learning systems have also become increasingly complex and opaque. Classification models are usually evaluated based on prediction performance alone (e.g., by measuring the accuracy, recall, and precision) and the interpretability of these models has generally been undervalued. However, the importance of interpretable models is increasingly being recognized (Doshi-Velez and Kim, 2017; Freitas, 2014).

First, higher interpretability could lead to more effective models by revealing incompleteness in the problem formalization (Doshi-Velez and Kim, 2017), by revealing confounding factors that could lead to biased models, and by supporting error analyses or feature discovery (Aubakirova and Bansal, 2016). Second, with the increasing adoption of machine learning approaches for humanities and social science research, there is also an increasing need for systems that support exploratory analyses and theory development.

Various approaches have been explored to increase the interpretability of machine learning models (Lipton, 2016). This paper focuses on *local* explanation, which aims to explain the prediction for an individual instance (e.g., Ribeiro et al. (2016)). A study by Herlocker et al. (2000) found that providing local explanations could help improve the acceptance of movie recommendation systems. Local explanations can come in different forms. For example, Koh and Liang (2017) identify the most influential training documents for a particular prediction. The most common type of local explanation involves identifying the important parts of the input for a prediction, such as the most predictive words in a document for a text classification model.

In this paper we focus on local explanations for text classification. Below is a fragment of a movie review. The words identified by a local explanation method to explain a neural network prediction are in bold. The review is labeled with a negative sentiment, but the classifier incorrectly predicted a positive sentiment. The highlighted words help us understand why.

> steve martin is one of the **funniest** men alive. if you can take that as a **true** statement, then your disappointment at this film will equal mine. martin can be **hilarious**, **creating** some of the best laugh-out-loud **experiences** that have ever taken place in movie theaters. you won't find any of them here. [...]

Words such as *funniest* and *hilarious* were important for the prediction. Besides providing evidence *for* a predicted label, some local explanations can also provide evidence *against* a predicted label. For example, in the above example, the word *disappointment* was one of the highest ranked words against the predicted label.

Proceedings of NAACL-HLT 2018, pages 1069–1078
New Orleans, Louisiana, June 1 - 6, 2018.

Ineffective approaches could generate misleading explanations (Lipton, 2016), but evaluating local explanations is challenging. A variety of approaches has been used, including only visual inspection (Ding et al., 2017; Li et al., 2016a), intrinsic evaluation approaches such as measuring the impact of deleting the identified words on the classifier output (Arras et al., 2016), and user studies (Kulesza et al., 2015).

Contributions To further progress in this area, it is imperative to have a better understanding of how to evaluate local explanations. This paper makes the following contributions:

- *Comparison of local explanation methods for text classification.* We present an in-depth comparison between three local explanation approaches (and a random baseline) using two different automatic evaluation measures on two text classification tasks (Section 4).
- *Automatic versus human evaluation.* Automatic evaluations, such as those based on word deletions, are frequently used since they enable rapid iterations and are easy to reproduce. However, it is unclear to what extent they correspond with human-based evaluations. We show that the automatic measures correlate moderately with human judgements in a task setting and that other factors also impact human judgement. (Section 5).

2 Related Work

Research on interpretable machine learning models has so far mainly focused on computer vision systems (e.g., Simonyan et al. (2013)). Topic modeling is one of the exceptions within NLP where the interpretability of models has been important, since topic models are often valued for their interpretability and are integrated in various user interfaces (Paul, 2016). There has recently been an increasing interest in improving the interpretability of NLP models, perhaps driven by the increasing complexity of NLP models and the rise of deep learning (Manning, 2015).

Global approaches aim to provide a global view of the model. One line of work involves making the machine learning model itself more interpretable, e.g., by enforcing sparsity or imposing monotonicity constraints (Freitas, 2014). However, often there is a trade-off between accuracy and interpretability as adding constraints to the model could reduce the performance. An alternative involves extracting a more interpretable model, such as a decision tree, from a model that is less interpretable, such as a neural network (Craven, 1996). In this case, model performance is not sacrificed but it is essential that the proxy is faithful to the underlying model.

However, often a machine learning model is so complex that interpretable, trustworthy global explanations are difficult to attain. *Local* explanations aim to explain the output for an individual instance. For some models the local explanations are relatively easy to construct, e.g., displaying the word probabilities of a Naive Bayes model with respect to each label (Kulesza et al., 2015) or displaying the path of a decision tree (Lim et al., 2009). However, these models may not be easily interpretable if they make use of many features.

For many machine learning models, extracting local explanations is even less straight-forward. Proposed approaches so far include using the gradients to visualize neural networks (Aubakirova and Bansal, 2016; Li et al., 2016a; Simonyan et al., 2013), measuring the effect of removing individual words (or features) (Li et al., 2016b; Martens and Provost, 2014), decomposition approaches (Arras et al., 2016; Ding et al., 2017), and training an interpretable classifier (e.g., linear model) that approximates the neighborhood around a particular instance (Ribeiro et al., 2016).

Some approaches have only been evaluated using visual inspection (Ding et al., 2017; Li et al., 2016a). Goyal et al. (2016) identified important words for a visual question answering system and informally evaluated their approach by analyzing the distribution among PoS tags (e.g., assuming that nouns are important). However, quantitative evaluations are needed for more robust comparisons. Such evaluations have included measuring the impact of the deletion of words identified by the explanation approaches on the classification output (Arras et al., 2016, 2017), or testing whether the explanation was consistent with an underlying gold model (Ribeiro et al., 2016). These automatic evaluations are fast to carry out but act as a simplistic proxy for explanation quality. While a few user studies have been performed to evaluate explanations (e.g., Ribeiro et al. (2016)), we are not aware of work that analyzes how automatic evaluation measures compare to human-based evaluation.

3 Experimental Setup

This section describes the datasets, the classification models and the local explanation approaches used in our experiments.

3.1 Datasets

We experiment with two datasets (Table 1):

- **Twenty newsgroups (20news).** The Twenty Newsgroups dataset has been used in several studies on ML interpretability (Arras et al., 2016; Kapoor et al., 2010; Ribeiro et al., 2016). Similar to Ribeiro et al. (2016), we only distinguish between *Christianity* and *Atheism*. We use the `20news-bydate` version, and randomly reserve 20% of the training data for development.

- **Movie reviews.** Movie reviews with polarity labels (positive versus negative sentiment) from Pang and Lee (2004). We use the version from Zaidan et al. (2007). The dataset is randomly split into a train (60%), development (20%) and test (20%) set.

	Movie	20news
# training docs	1072	870
# development docs	358	209
# test docs	370	717
label distribution (pos. class)	50.00%	44.49%

Table 1: Dataset statistics

3.2 Text Classification Models

We experiment with two different models. Logistic Regression (**LR**) is implemented using Scikit-learn (Pedregosa et al., 2011) with Ridge regularisation, unigrams and a TF-IDF representation, resulting in a 0.797 accuracy on the movie dataset and a 0.921 accuracy on the 20news dataset. We experiment with a LR model, because the contributions of individual features in a LR model are known. We thus have a ground truth for feature importance to compare against for this model. We also use a feedforward neural network (**MLP**) implemented using Keras (Chollet et al., 2015), with 512 hidden units, ReLU activation, dropout (0.5, not optimized) and Adam optimization, resulting in a 0.832 accuracy on the movie dataset and a 0.939 accuracy on the 20news dataset.

3.3 Local Explanation Methods

In this paper, we focus on local explanation approaches that identify the most influential parts of the input for a particular prediction. In this paper we limit our focus to individual words for explaining the output of text classification models. Other representations, e.g., explanations using phrases or higher-level concepts are left for future work. We experiment with explanations for the *predicted* class, since in real-life settings usually no ground truth labels are available. We experiment with the following local explanation approaches:

- **Random.** A random selection of words in the document.

- **LIME** (Ribeiro et al., 2016) is a model-agnostic approach and involves training an interpretable model (in this paper, a linear model with Ridge regularisation) on samples created around the specific data point by perturbing the data. We experiment with 500–5000 samples and use the implementation provided by the authors.[1]

- **Word omission.** This approach aims to estimate the contribution of individual words by deleting them and measuring the effect, e.g., by the difference in probability (Robnik-Šikonja and Kononenko, 2008). Within NLP, variations have been proposed by Kádár et al. (2016), Li et al. (2016b) and Martens and Provost (2014). It is also similar to occlusion in the context of image classification, which involves occluding regions of the input image (Zeiler and Fergus, 2014). For **LR**, this approach corresponds to ranking words according to the regression weights (and considering the frequency in the text) and is therefore optimal. For **MLP**, we use the difference in probability for the predicted class ($\hat{y}$) when removing word w from input $\boldsymbol{x}$: $p(\hat{y}|\boldsymbol{x}) - p(\hat{y}|\boldsymbol{x}_{\setminus w})$. This approach supports explanations based on interpretable features (e.g., words) even when the underlying representation may be less interpretable. However note that in general, this omission approach might not be optimal, since it estimates the contribution of words independently. This approach is also computationally expensive, especially when many features are used.

[1] https://github.com/marcotcr/lime.

- **First derivative saliency.** This approach computes the gradient of the output with respect to the input (e.g., used in Aubakirova and Bansal (2016), Li et al. (2016a) and Simonyan et al. (2013)). The obtained estimates are often referred to as saliency values. Several variations exist, e.g., Li et al. (2016a) take the absolute value. In this paper, the raw value is taken to identify the words important for and against a certain prediction.

4 Automatic Evaluation

In this section we explore automatic evaluation of local explanations. Local explanations should exhibit high *local fidelity*, i.e. they should match the underlying model in the neighborhood of the instance (Ribeiro et al., 2016). An explanation with low local fidelity could be misleading. Because we generate explanations for the predicted class (rather than the ground truth), explanations with high local fidelity do not necessarily need to match human intuition, for example when the classifier is weak (Samek et al., 2017). Ideally, the evaluation metrics are model agnostic and do not require information that may not always be available such as probability outputs. This paper focuses on local fidelity, but other aspects might also be desired, such as sparsity (Samek et al., 2017; Ribeiro et al., 2016; Martens and Provost, 2014).

4.1 Evaluation Metrics

We measure local fidelity by deleting words in the order of their estimated importance for the prediction. Arras et al. (2016) generated explanations with the correct class as target. By deleting the identified words, accuracy increased for incorrect predictions and decreased for correct predictions. However, their approach assumes knowledge of the ground-truth labels.

We take an alternative, but similar, approach. Words are also deleted according to their estimated importance, e.g. $w_1 ... w_n$ with w_1 the word with the highest importance score, but for the *predicted class* instead. For each document, we measure the number of words that need to be deleted before the prediction switches to another class (the ***switching point***), normalized by the number of words in the document. For example, a value of 0.10 indicates that 10% of the words needed to be deleted before the prediction changed. An advantage of this approach is that ground-truth labels are not needed and that it can be applied to black-box classifiers, we only need to know the predicted class. Furthermore, the approach acts on the raw input. It requires no knowledge of the underlying feature representation (e.g., the actual features might be on the character level). We also experiment with the measure proposed by Samek et al. (2017), referred to as the area over the perturbation curve (***AOPC***):

$$AOPC = \frac{1}{K+1} \langle \sum_{k=1}^{K} f(\boldsymbol{x}) - f(\boldsymbol{x}_{\setminus \mathbf{1..k}}) \rangle_{p(x)}$$

where $f(\boldsymbol{x}_{\setminus \mathbf{1..k}})$ is the probability for the predicted class when words $1..k$ are removed and $\langle \cdot \rangle_{p(x)}$ denotes the average over the documents. This approach is also based on deleting words, but it is more fine-grained since it uses probability values rather than predicted labels. It also enables evaluating negative evidence. A drawback is that AOPC requires access to probability estimates of a classifier. In this paper, K is set to 10.

For **LR**, the exact contribution of individual features to a prediction is known and the words in the document that contributed most to the prediction can be computed directly. For this classifier, the optimal approach corresponds to the omission approach.

4.2 Results

Table 3 reports the results by measuring the effect of word deletions and reporting the average switching point. Lower values indicate that the method was better capable of identifying the words that contributed most towards the predicted class, because on average fewer words needed to be deleted to change a prediction. Table 2 shows the AOPC values with a cut-off at 10. We measure AOPC in two settings: removing positive evidence (higher values indicate a more effective explanation) and negative evidence (lower values indicate a more effective explanation).

Comparison local explanation methods As expected, LIME improves consistently when more samples are used. Furthermore, when comparing the scores of the omission approach for the **LR** model (which corresponds to the ground-truth) we observe that LIME with 5000 samples comes close to the optimal score. We use the two-tailed paired permutation test to test for significance between all methods with both evaluation measures. In al-

saliency	0.812	-0.865

Table 4: Spearman correlation between prediction confidence and AOPC and the switching point (SP) for the **MLP** classifier on the movie dataset.

most all cases, the differences are highly significant ($p < 0.001$), except the difference in average switching point between the omission and salience approach on the movies dataset with the **MLP** classifier (n.s.) and the difference in average switching point between the omission and LIME-5000 approach on 20news with the **MLP** classifier (n.s.). The difference in AOPC scores for evaluating negative evidence was not significant in many cases.

Metric sensitivity First, the results suggest that the values obtained depend strongly on the type of task and classifier. The explanation approaches score better on the sentiment detection task in both Tables 2 and 3. For example, fewer words need to be removed on average to change a prediction in the movie dataset (Table 3). A possible explanation is that for sentiment detection, a few words can provide strong cues for the sentiment (e.g., *terrific*), while for (fine-grained) topic detection (e.g., distinguishing between *Christianity* and *atheism*) the evidence tends to be distributed among more words. Better values are also obtained for the **LR** classifier (a linear model) than for **MLP**.

Second, as shown in Table 2, AOPC enables assessing negative evidence (i.e. the words that provide evidence for the opposite class). The obtained absolute values are much smaller compared to the values obtained for the words identified as positive evidence. This is expected, since the positive evidence in a document for the predicted class should be larger than the negative evidence.

Third, we analyze the relation between the word deletion evaluation measures and the prediction confidence of the classifiers, based on the probability of the output class. Table 4 reports the Spearman correlations for the **MLP** classifier on the movie dataset (similar trends were observed with the **LR** classifier). There is a strong correlation between the prediction confidence and the word deletion evaluation measures. The higher the prediction confidence of a classifier, the more words need to be deleted before a prediction changes (e.g., see the switching points). However, the strength of the correlations is lower for the more robust explanation methods (LIME-5000, omission and saliency).

5 Human-based Evaluation

In the previous section we evaluated the local explanation approaches using automatic measures. However, the explanations are meant to be presented to *humans*. We therefore turn to evaluating the explanations using crowdsourcing. We analyze the usefulness of the generated explanations in a task setting and analyze to what extent the automatic measures correspond to the human-based evaluations. The crowdsourcing experiments are run on CrowdFlower. Only crowdworkers from Australia, Canada, Ireland, United Kingdom and the United States and with quality levels two or three were accepted.

5.1 Forward Prediction Task

One way to evaluate an explanation is by asking humans to guess the output of a model based on the explanation and the input. Doshi-Velez and Kim (2017) refer to this as forward simulation/prediction. As mentioned by Doshi-Velez and Kim (2017), this is a simplified task. Evaluations using more specific application-oriented tasks or tailored towards specific user groups should be explored in future work. We have chosen the forward prediction task as a first step since it is a general setup that could be used to evaluate explanations for a variety of tasks and models.

In this study, crowdworkers are shown the texts (e.g., a movie review), in which the top words identified by the local explanation approaches are highlighted. Crowdworkers are then asked to guess the output of the system (e.g., a positive or negative sentiment). The crowdworkers are also asked to state their confidence on a five-point Likert scale ('*I am confident in my answer*': strongly disagree . . . strongly agree).

Note that the workers need to guess the output of the model regardless of the true label (i.e. the model may be wrong). The crowdworkers are therefore presented with documents with different prediction outcomes (true positive, true negative, false negative, and false positive). We sample up to 50 documents for each prediction outcome. A screenshot is shown in Figure 1. A quiz and test questions are used to ensure the quality of the crowdworkers. Instructions as well as the test questions included cases where the system made an incorrect prediction, so that workers understood that the task was different than standard labeling tasks. See Appendix A for more details.

We experiment with the following parameters: *methods* (random baseline, LIME with 500 and 5000 samples, word omission, saliency) and the *number of words* (10, 20). We experiment with both datasets. Due to space constraints, we only experiment with the **MLP** classifier. We collected the data in August and September 2017. Each HIT (Human Intelligence Task) was carried out by five crowdworkers. We paid $0.03 per judgement. On the 20news dataset, we collected 7,200 judgements from 406 workers (mean nr of. judgements per worker: 17.73, std.: 7.21) and on the movie dataset we collected 8,100 judgements from 445 workers (mean nr of. judgements per worker 18.20, std: 7.24).

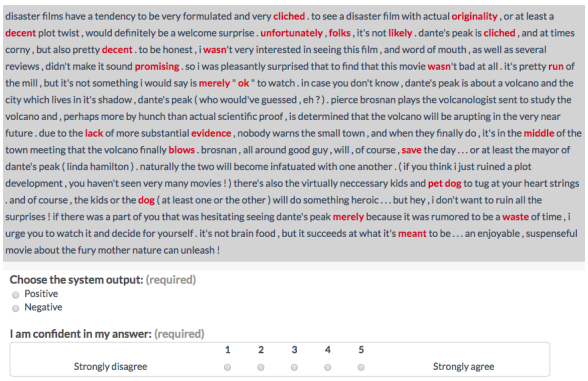

Figure 1: Screenshot of the task

Confidence Most workers chose confidence values of three or four. Table 6 reports the confidence scores by method. On the movie dataset, the trends match the intrinsic evaluations closely. The random method leads to the lowest confidence score, followed by LIME-500 and LIME-5000, and explanations from the omission and saliency approach both lead to the highest confidence scores. On the 20news dataset, the trends are less clear. We observe a small, significant negative correlation between confidence values and time spent (Spearman correlation: ρ=-0.08, p <0.0001 on the movie dataset, ρ=-0.06, p <0.0001 on 20news).

Accuracy Table 6 also reports the fraction of correct guesses per method. Random explanations lead to the lowest accuracies, followed by LIME with 500 samples. The differences between LIME-5000, omission and saliency are small and not consistent across datasets. The crowd had a higher accuracy on the movie data, except when the explanations were randomly generated.

saliency	0.790	0.851	3.691	3.701

Table 6: Confidence and accuracy results

Table 5 separates the results by the different prediction outcomes. The results suggest that false positive and false negative are the most revealing. In these cases, crowdworkers are not able to rely on their intuition and a strong explanation should convince them that the system makes a mistake. Otherwise, crowd workers might choose the label matching the document (and not necessarily the classifier output). This is especially salient in the 20news dataset, where the random approach performs better than expected on the true positives and true negatives. For example, compare the random approach with the omission approach on true positives with ten word explanations.

Our experiments also show that local explanations in the form of the most predictive words are sometimes not enough to simulate the output of a system. For example, the best accuracy on true positive instances in the 20news data is only 0.752. The movie dataset contains difficult instances as well. For example, the omission method identifies the following words in a movie review to explain a false positive prediction: '*believes*', '*become*', '*hair*', '*unhappy*', '*quentin*', '*directed*', '*runs*', '*filled*', '*fiction*', '*clint*'. Due to the composition of the training data, the system has associated words like '*quentin*' and '*clint*' with a positive sentiment. This may have confused the crowdworkers as most of them guessed incorrectly. Expanding the explanation with for example influential documents (Koh and Liang, 2017) or a visualization of the class distributions of the most influential words could make the explanations more informative.

Correlation with automatic evaluation For each explanation, we compute the fraction of workers who correctly predicted the classifier output (the 'crowd accuracy') and correlate these with the automatic measures. We expect a negative correlation with the switching points and a positive correlation with the AOPC. The correlations are moderate (Table 8). The correlations with AOPC on the movie data are the biggest on the false positives and false negatives, when workers are not able to rely on their intuition. The correlations

measured on the true positives in 20news are opposite of what we expect. The 20news data is noisy and the classifier picks up on spurious features, possibly confusing the workers.

An example in the 20news data is an e-mail with the following words highlighted: '*thank*', '*mail*', '*discussions*', '*seminary*', '*before*', '*thanks*', '*question*', '*fill*', '*affected*', '*during*', '*proofs*'. The classifier was confident and the computed switchpoint was low. The e-mail comes from the atheism newsgroup, which becomes clear from reading the text. The highlighted words are all more likely to occur in the christianity newsgroup, but on their own they are not intuitive to lay people. Consequently, workers guessed incorrectly that the predicted label was atheism. Explanations that also show the negative evidence (in this case, words such as '*atheism*' and '*atheists*') and/or the word distributions across classes would likely have led to better crowd accuracy.

Table 10: OLS results with AOPC on the movie data (n = 1,620). *p<0.1; **p<0.05; ***p<0.01. Prediction outcome base level = fn.

As shown in section 4, the automatic measures correlate strongly with the prediction confidence of the classifier. More words need to be removed before a prediction changes (i.e. a higher switching point) when the classifier is more confident. However, we also find that higher classifier confidence leads to higher crowd accuracies (e.g., ρ = 0.236, $p < 0.001$ on the 20news dataset). We therefore fit an Ordinary Least Squares (OLS) model to control for these different factors (Table 9), with crowd accuracy as the dependent variable. A higher switching point significantly leads to a lower accuracy. However, classifier confidence and prediction outcome also significantly impact the accuracy. Similar trends are observed for the AOPC measure (Table 10). We also find that the automatic evaluation measures significantly impact crowd accuracy on the 20news dataset, but the patterns are less strong.

Noise In our final experiment we analyze the effect of noise. We focus on explanations based on saliency scores on the movie dataset. We experiment with introducing noise to the top ten words (Table 7) and we collect additional judgements. A noise level of 0.2 indicates that two out of the top ten words are randomly replaced by other words. The results show that with increasing the noise, as expected, both the performance and average AOPC score decrease.

6 Conclusion

There has been an increasing interest in improving the interpretability of machine learning systems, but evaluating the quality of explanations has been challenging. This paper focused on evaluating local explanations for text classification. Local explanations were generated by identifying important words in a document for a prediction. We compared automatic evaluation approaches, based on measuring the effect of word deletions, with human-based evaluations. Explanations generated using word omissions and first derivatives both performed well. LIME (Ribeiro et al., 2016) performed close to these methods when using enough samples. Our analyses furthermore showed that the evaluation numbers depend on the task/dataset and the confidence of the classifiers.

Next, crowd workers were asked to predict the output of the classifiers based on the generated explanations. We found moderate, but significant, correlations between the automatic measures and crowd accuracy. In addition, the human judgements were impacted by the confidence of the classifier and the type of prediction outcome (e.g., a false negative versus a true positive). Our results also suggest that only highlighting words is sometimes not enough. An explanation can highlight the most important parts of an input and score well on automatic measures, but if the explanation is not intuitive (for example due to biases in the data), humans are still not able to predict the output.

For the classification tasks in this paper (topic classification and sentiment detection) individual words are often predictive. As a result, local explanation approaches that select words independently worked well. However, we expect that for tasks where individual words are not predictive, the current evaluation methods and local explanation approaches may not be sufficient. Furthermore, in future work more fine-grained visualizations (e.g., Handler et al. (2016)) could be explored.

A Appendix: Crowdsourcing

Test questions were manually selected and were cases for which there should be no doubt about the correct answer (e.g., a simple movie review with only words such as '*brilliant*', '*terrific*', etc. highlighted). Thus, these are questions where workers would only fail if they did not pay attention or if they did not understand the task. Explanations were provided for most test questions and were shown after an answer was submitted. The test questions contained instances with different prediction outcomes (e.g. false positives and true positives) to make the task clear. To make sure that the test questions did not overlap with the actual HITs (which were generated to explain the predictions of the **`MLP`**), the test questions were explanations generated for the **`LR`** classifier.

A quiz with test questions was provided to the crowdworkers when starting the task. If the workers performed poorly on the quiz, they were not allowed to continue with the task. Throughout the task, test questions were entered in between the actual HITs (one out of five presented HITs was a test question), to monitor the quality and to flag crowdworkers who performed poorly. We closely monitored the responses to the test questions and in the pilot phase we did remove a few that turned out not be suitable. In the final task, workers performed overall very well on the test questions.

The task was consistently rated positive by the crowdworkers. The task was divided into several batches and the overall rating was consistently above 4.5 (out of 5). The payment rating was consistently above 4. The tasks explicitly mentioned that the results will be used for scientific research ('*By participating you agree that these results will be used for scientific research.*').

Deep Temporal-Recurrent-Replicated-Softmax for Topical Trends over Time

Abstract

Dynamic topic modeling facilitates the identification of topical trends over time in temporal collections of unstructured documents. We introduce a novel unsupervised neural dynamic topic model named as Recurrent Neural Network-Replicated Softmax Model (RNN-RSM), where the discovered topics at each time influence the topic discovery in the subsequent time steps. We account for the temporal ordering of documents by explicitly modeling a joint distribution of latent topical dependencies over time, using distributional estimators with temporal recurrent connections. Applying RNN-RSM to 19 years of articles on NLP research, we demonstrate that compared to state-of-the art topic models, RNN-RSM shows better generalization, topic interpretation, evolution and trends. We also introduce a metric (named as SPAN) to quantify the capability of dynamic topic model to capture word evolution in topics over time.

1 Introduction

Topic Detection and Tracking (Allan et al., 1998) is an important area of natural language processing to find topically related ideas that evolve over time in a sequence of text collections and exhibit temporal relationships. The temporal aspects of these collections can present valuable insight into the topical structure of the collections and can be quantified by modeling the dynamics of the underlying topics discovered over time.

Problem Statement: We aim to generate temporal topical trends or automatic overview timelines of topics for a time sequence collection of documents. This involves the following three tasks in dynamic topic analysis: **(1)** *Topic Structure Detection* (TSD): Identifying main topics in the document collection. **(2)** *Topic Evolution Detection* (TED): Detecting the emergence of a new topic and recognizing how it grows or decays over time (Allan, 2002). **(3)** *Temporal Topic Characterization* (TTC): Identifying the characteristics for each of the main topics in order to track the words' usage (*keyword trends*) for a topic over time i.e. *topical trend analysis for word evolution* (Fig 1, Left).

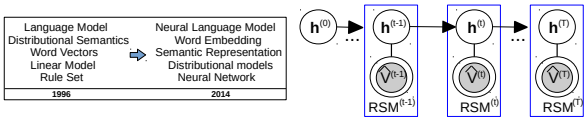

Figure 1: (Left): Word Usage over time for Topic (*Word Representation*) in scholarly articles. (Right): RSM-based dynamic topic model with explicit temporal topic dependence

Probabilistic static topic models, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and its variants (Wang and McCallum, 2006; Hall et al., 2008; Gollapalli and Li, 2015) have been investigated to examine the emergence of topics from historical documents. Another variant known as Replicated Softmax (RSM) (Hinton and Salakhutdinov, 2009) has demonstrated better generalization in log-probability and retrieval, compared to LDA. Prior works (Iwata et al., 2010; Pruteanu-Malinici et al., 2010; Saha and Sindhwani, 2012; Schein et al., 2016) have investigated Bayesian modeling of topics in time-stamped documents. Particularly, Blei and Lafferty (2006) developed a LDA based dynamic topic model (DTM) to capture the evolution of topics in a time sequence collection of documents; however they do not capture explicitly the topic popularity and usage of specific terms over time. We propose a family of probabilistic time series models with distributional estimators to explicitly model the dynamics of the underlying topics, introducing temporal latent topic dependencies (Fig 1, Right).

To model temporal dependencies in high dimen-

Proceedings of NAACL-HLT 2018, pages 1079–1089
New Orleans, Louisiana, June 1 - 6, 2018.

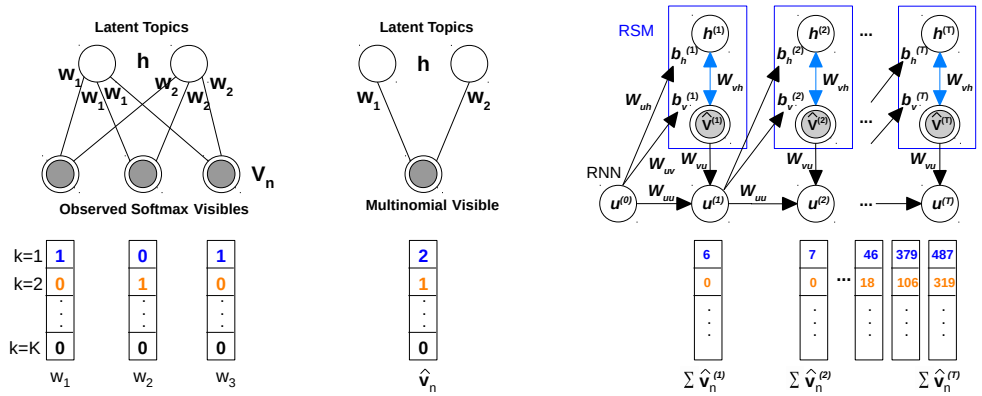

Figure 2: (Left): RSM for a document $\mathbf{V}_n$ of D_n=3 words (w). The bottom layer represents the softmax visible units, that share the same set of weights connected to binary hidden units $\mathbf{h}$. (Middle): Interpretation of RSM in which D_n softmax units with identical weights are replaced by a single multinomial unit, sampled D_n times. (Right): Graphical structure of 2-layered **RNN-RSM**, unfolded in time. Single and double headed arrows represent deterministic and stochastic-symmetric connections, respectively. $\widehat{\mathbf{V}}^{(t)}$ and $\mathbf{h}^{(t)}$ are binary visible and hidden layers of RSM for a document collection at time, t. $\mathbf{u}$ is RNN hidden layer. k: dictionary index for a word w

sional sequences, such as polyphonic music, the temporal stack of RBMs (Smolensky, 1986; Hinton, 2002) has been investigated to model complex distributions. The Temporal RBM (Taylor et al., 2007; Sutskever and Hinton, 2007), Recurrent Temporal RBM (RTRBM) (Sutskever et al., 2009) and RNN-RBM (Boulanger-Lewandowski et al., 2012) show success in modeling the temporal dependencies in such symbolic sequences. In addition, RNNs (Gupta et al., 2015a; Vu et al., 2016a,b; Gupta et al., 2016) have been recognized for sentence modeling in natural language tasks. We aspire to build neural dynamic topic model called RNN-RSM to model document collections over time and learn temporal topic correlations.

We consider RSM for TSD and introduce the explicit latent topical dependencies for TED and TTC tasks. Fig 1 illustrates our *motivation*, where temporal ordering in document collection $\widehat{\mathbf{V}}^{(t)}$ at each time step t, is modeled by conditioning the latent topic $\mathbf{h}^{(t)}$ on the sequence history of latent topics $\mathbf{h}^{(0)}$, ..., $\mathbf{h}^{(t-1)}$, accumulated with temporal lag. Each RSM discovers latent topics, where the introduction of a bias term in each RSM via the time-feedback latent topic dependencies enables to explicitly model topic evolution and specific topic term usage over time. The temporal connections and RSM biases allow to convey topical information and model relation among the words, in order to deeply analyze the dynamics of the underlying topics. We demonstrate the applicability of proposed **RNN-RSM** by analyzing 19 years of scientific articles from NLP research.

The *contributions* in this work are:
(1) Introduce an unsupervised neural dynamic topic model based on recurrent neural network and RSMs, named as RNN-RSM to explicitly model discovered latent topics (evolution) and word relations (topic characterization) over time.
(2) Demonstrate better generalization (log-probability and time stamp prediction), topic interpretation (coherence), evolution and characterization, compared to the state-of-the-art.
(3) It is the first work in dynamic topic modeling using undirected stochastic graphical models and deterministic recurrent neural network to model collections of different-sized documents over time, within the generative and neural network framework. The code and data are available at `https://github.com/pgcool/RNN-RSM`.

2 The RNN-RSM model

RSM (Fig 2, Left) models are a family of different-sized Restricted Boltzmann Machines (RBMs) (Gehler et al., 2006; Xing et al., 2005; Gupta et al., 2015b,c) that models *word counts* by sharing the same parameters with multinomial distribution over the observable i.e. it can be interpreted as a single multinomial unit (Fig 2, Middle) sampled as many times as the document size. This facilitates in dealing with the documents of different lengths.

The proposed RNN-RSM model (Fig 2, Right) is a sequence of conditional RSMs[1] such that at any time step t, the RSM's bias parameters $\mathbf{b_v}^{(t)}$

[1]Notations: $\widehat{\mathbf{U}}$=$\{\mathbf{U}_n\}_{n=1}^{N}$; **U**:2D-Matrix; **l**:vector; **U/l**:Upper/lower-case; Scalars in unbold

and $\mathbf{b_h}^{(t)}$ depend on the output of a deterministic RNN with hidden layer $\mathbf{u}^{(t-1)}$ in the previous time step, $t-1$. Similar to RNN-RBM (Boulanger-Lewandowski et al., 2012), we constrain RNN hidden units ($\mathbf{u}^{(t)}$) to convey temporal information, while RSM hidden units ($\mathbf{h}^{(t)}$) to model conditional distributions. Therefore, parameters ($\mathbf{b_v}^{(t)}$, $\mathbf{b_h}^{(t)}$) are time-dependent on the sequence history at time t (via a series of conditional RSMs) denoted by $\Theta^{(t)} \equiv \{\widehat{\mathbf{V}}^{(\tau)}, \mathbf{u}^{(\tau)} | \tau < t\}$, that captures temporal dependencies. The RNN-RSM is defined by its joint probability distribution:

$$P(\widehat{\mathfrak{V}}, \mathbf{H}) = P(\{\widehat{\mathbf{V}}^{(t)}, \mathbf{h}^{(t)}\}_{t=1}^{T}) = \prod_{t=1}^{T} P(\widehat{\mathbf{V}}^{(t)}, \mathbf{h}^{(t)} | \Theta^{(t)})$$

where $\widehat{\mathfrak{V}} = [\widehat{\mathbf{V}}^{(1)}, ...\widehat{\mathbf{V}}^{(T)}]$ and $\mathbf{H} = [\mathbf{h}^{(1)}, ...\mathbf{h}^{(T)}]$. Each $\mathbf{h}^{(t)} \in \{0,1\}^F$ be a binary stochastic hidden topic vector with size F and $\widehat{\mathbf{V}}^{(t)} = \{\mathbf{V}_n^{(t)}\}_{n=1}^{N^{(t)}}$ be a collection of N documents at time step t. Let $\mathbf{V}_n^{(t)}$ be a $K \times D_n^{(t)}$ observed binary matrix of the n^{th} document in the collection where, $D_n^{(t)}$ is the document size and K is the dictionary size over all the time steps. The conditional distribution (for each unit in hidden or visible) in each RSM at time step, is given by softmax and logistic functions:

$$P(v_{n,i}^{k,(t)} = 1 | \mathbf{h}_n^{(t)}) = \frac{\exp(b_{v,i}{}^{k,(t)} + \sum_{j=1}^{F} h_{n,j}^{(t)} W_{ij}^{k})}{\sum_{q=1}^{K} \exp(b_{v,i}{}^{q,(t)} + \sum_{j=1}^{F} h_{n,j}^{(t)} W_{ij}^{q})}$$

$$P(h_{n,j}^{(t)} = 1 | \mathbf{V}_n^{(t)}) = \sigma(b_{h,j}^{(t)} + \sum_{i=1}^{D_n^{(t)}} \sum_{k=1}^{K} v_{n,i}^{k,(t)} W_{ij}^{k})$$

where $P(v_{n,i}^{k,(t)} = 1 | \mathbf{h}_n^{(t)})$ and $P(h_{n,j}^{(t)} = 1 | \mathbf{V}_n^{(t)})$ are conditional distributions for i^{th} visible $v_{n,i}$ and j^{th} hidden unit $h_{n,j}$ for the n^{th} document at t. W_{ij}^k is a symmetric interaction term between i that takes on value k and j. $v_n^{k,(t)}$ is sampled $D_n^{(t)}$ times with identical weights connected to binary hidden units, resulting in multinomial visibles, therefore the name *Replicated Softmax*. The conditionals across layers are factorized as: $P(\mathbf{V}_n^{(t)} | \mathbf{h}_n^{(t)}) = \prod_{i=1}^{D_n^{(t)}} P(\mathbf{v}_{n,i}^{(t)} | \mathbf{h}_n^{(t)})$; $P(\mathbf{h}_n^{(t)} | \mathbf{V}_n^{(t)}) = \prod_j P(h_{n,j}^{(t)} | \mathbf{V}_n^{(t)})$.

Since biases of RSM depend on the output of RNN at previous time steps, that allows to propagate the estimated gradient at each RSM backward through time (BPTT). The *RSM biases* and RNN hidden state $\mathbf{u}^{(t)}$ at each time step t are given by-

$$\begin{aligned} \mathbf{b_v}^{(t)} &= \mathbf{b_v} + \mathbf{W_{uv}} \mathbf{u}^{(t-1)} \\ \mathbf{b_h}^{(t)} &= \mathbf{b_h} + \mathbf{W_{uh}} \mathbf{u}^{(t-1)} \end{aligned} \quad (1)$$

$$\mathbf{u}^{(t)} = \tanh(\mathbf{b_u} + \mathbf{W_{uu}} \mathbf{u}^{(t-1)} + \mathbf{W_{vu}} \sum_{n=1}^{N^{(t)}} \hat{\mathbf{v}}_n^{(t)}) \quad (2)$$

Algorithm 1 *Training RNN-RSM with BPTT*

Input: *Observed visibles*, $\widehat{\mathfrak{V}} = \{\widehat{\mathbf{V}}^{(0)}, \widehat{\mathbf{V}}^{(1)}, ..., \widehat{\mathbf{V}}^{(t)}, ..., \widehat{\mathbf{V}}^{(T)}\}$
RNN-RSM Parameters: $\theta = \{\mathbf{W_{uh}}, \mathbf{W_{vh}}, \mathbf{W_{uv}}, \mathbf{W_{vu}}, \mathbf{W_{uu}}, \mathbf{b_v}, \mathbf{b_u}, \mathbf{b_h}, \mathbf{b_v}^{(t)}, \mathbf{b_h}^{(t)}, \mathbf{u}^{(0)}\}$

1: Propagate $\mathbf{u}^{(t)}$ in RNN portion of the graph using eq 2.
2: Compute $\mathbf{b_v}^{(t)}$ and $\mathbf{b_h}^{(t)}$ using eq 1.
3: Generate negatives $\mathbf{V}^{(t)*}$ using k-step Gibbs sampling.
4: Estimate the gradient of the cost C w.r.t. parameters of RSM $\mathbf{W_{vh}}$, $\mathbf{b_v}^{(t)}$ and $\mathbf{b_h}^{(t)}$ using eq 5.
5: Compute gradients (eq 6) w.r.t. RNN connections ($\mathbf{W_{uh}}$, $\mathbf{W_{uv}}$, $\mathbf{W_{uu}}$, $\mathbf{W_{vu}}$, $\mathbf{u}^0$) and biases ($\mathbf{b_v}$, $\mathbf{b_h}$, $\mathbf{b_u}$).
6: **Goto** *step 1* until stopping_criteria (early stopping or maximum iterations reached)

where $\mathbf{W_{uv}}$, $\mathbf{W_{uh}}$ and $\mathbf{W_{vu}}$ are weights connecting RNN and RSM portions (Figure 2). $\mathbf{b_u}$ is the bias of $\mathbf{u}$ and $\mathbf{W_{uu}}$ is the weight between RNN hidden units. $\hat{\mathbf{v}}_n^{(t)}$ is a vector of $\hat{v}_n^k$ (denotes the count for the k^{th} word in n^{th} document). $\sum_{n=1}^{N^{(t)}} \hat{\mathbf{v}}_n^{(t)}$ refers to the sum of observed vectors across documents at time step t where each document is represented as-

$$\hat{\mathbf{v}}_n^{(t)} = [\{\hat{v}_n^{k,(t)}\}_{k=1}^{K}] \text{ and } \hat{v}_n^{k,(t)} = \sum_{i=1}^{D_n^{(t)}} v_{n,i}^{k,(t)} \quad (3)$$

where $v_{n,i}^{k,(t)}$=1 if visible unit i takes on k^{th} value.

In each RSM, a separate RBM is created for each document in the collection at time step t with $D_n^{(t)}$ softmax units, where $D_n^{(t)}$ is the count of words in the n^{th} document. Consider a document of $D_n^{(t)}$ words, the *energy* of the state $\{\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)}\}$ at time step, t is given by-

$$\begin{aligned} E(\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)}) = &- \sum_{j=1}^{F} \sum_{k=1}^{K} h_{n,j}^{(t)} W_j^k \hat{v}_n^{k,(t)} \\ &- \sum_{k=1}^{\mathrm{K}} \hat{v}_n^{k,(t)} b_v^k - D_n^{(t)} \sum_{j=1}^{F} b_{h,j} h_{n,j}^{(t)} \end{aligned}$$

Observe that the bias terms on hidden units are scaled up by document length to allow hidden units to stabilize when dealing with different-sized documents. The corresponding energy-probability relation in the energy-based model is-

$$P(\mathbf{V}_n^{(t)}) = \frac{1}{Z_n^{(t)}} \sum_{\mathbf{h}_n^{(t)}} \exp(-E(\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)})) \quad (4)$$

where $Z_n^{(t)} = \sum_{\mathbf{V}_n^{(t)}} \sum_{\mathbf{h}_n^{(t)}} \exp(-E(\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)}))$ is the normalization constant. The lower bound on the log likelihood of the data takes the form:

$$\begin{aligned} \ln P(\mathbf{V}_n^{(t)}) &\geq \sum_{\mathbf{h}^{(t)}} Q(\mathbf{h}_n^{(t)} | \mathbf{V}_n^{(t)}) \ln P(\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)}) + H(Q) \\ &= \ln P(\mathbf{V}_n^{(t)}) - KL[Q(\mathbf{h}_n^{(t)} | \mathbf{V}_n^{(t)}) || P(\mathbf{h}_n^{(t)} | \mathbf{V}_n^{(t)})] \end{aligned}$$

Table 1: Number of papers from ACL and EMNLP conferences over the years

where $H(\cdot)$ is the entropy and Q is the approximating posterior. Similar to Deep Belief Networks (Hinton et al., 2006), adding an extra layer improves lower bound on the log probability of data, we introduce the extra layer via RSM biases that propagates the prior via RNN connections. The dependence analogy follows-

$$E(\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)}) \propto \tfrac{1}{\mathbf{b_v}^{(t)}} \text{ and } E(\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)}) \propto \tfrac{1}{\mathbf{b_h}^{(t)}}$$

$$\ln P(\mathbf{V}_n^{(t)}) \propto \tfrac{1}{E(\mathbf{V}_n^{(t)}, \mathbf{h}_n^{(t)})}; \ln P(\widehat{\mathbf{V}}_n^{(t)}) \propto \ln P(\{\widehat{\mathbf{V}}_n^{\tau}\}_{\tau<t})$$

Observe that the prior is seen as the deterministic hidden representation of latent topics and injected into each hidden state of RSMs, that enables the likelihood of the data to model complex temporal densities i.e. heteroscedasticity in document collections ($\widehat{\mathfrak{V}}$) and temporal topics ($\mathbf{H}$).

Gradient Approximations: The *cost* in RNN-RSM is: $C = \sum_{t=1}^{T} C_t \equiv \sum_{t=1}^{T} -\ln P(\widehat{\mathbf{V}}^{(t)})$

Due to intractable Z, the gradient of cost at time step t w.r.t. (with respect to) RSM parameters are approximated by k-step Contrastive Divergence (CD) (Hinton, 2002). The gradient of the negative log-likelihood of a document collection $\{\mathbf{V}_n^{(t)}\}_{n=1}^{N^{(t)}}$ w.r.t. RSM parameter $\mathbf{W_{vh}}$,

$$\begin{aligned}
&\frac{1}{N^{(t)}} \sum_{n=1}^{N^{(t)}} \frac{\partial(-\ln P(\mathbf{V}_n^{(t)}))}{\partial \mathbf{W_{vh}}} \\
&= \frac{1}{N^{(t)}} \sum_{n=1}^{N^{(t)}} \frac{\partial \mathfrak{F}(\mathbf{V}_n^{(t)})}{\partial \mathbf{W_{vh}}} - \frac{\partial(-\ln Z_n^{(t)})}{\partial \mathbf{W_{vh}}} \\
&= \underbrace{\mathsf{E}_{P_{data}}[\frac{\partial \mathfrak{F}(\mathbf{V}_n^{(t)})}{\partial \mathbf{W_{vh}}}]}_{\text{data-dependent expectation}} - \underbrace{\mathsf{E}_{P_{model}}[\frac{\partial \mathfrak{F}(\mathbf{V}_n^{(t)})}{\partial \mathbf{W_{vh}}}]}_{\text{model's expectation}} \\
&\simeq \frac{1}{N^{(t)}} \sum_{n=1}^{N^{(t)}} \frac{\partial \mathfrak{F}(\mathbf{V}_n^{(t)})}{\partial \mathbf{W_{vh}}} - \frac{\partial \mathfrak{F}(\mathbf{V}_n^{(t)*})}{\partial \mathbf{W_{vh}}}
\end{aligned}$$

The second term is estimated by negative samples $\mathbf{V}_n^{(t)*}$ obtained from k-step Gibbs chain starting at $\mathbf{V}_n^{(t)}$ samples. $P_{data}(\widehat{\mathbf{V}}^{(t)}, \mathbf{h}^{(t)}) = P(\mathbf{h}^{(t)}|\widehat{\mathbf{V}}^{(t)}) P_{data}(\widehat{\mathbf{V}}^{(t)})$ and $P_{data}(\widehat{\mathbf{V}}^{(t)}) = \frac{1}{N^{(t)}} \sum_{n}^{N^{(t)}} \delta(\widehat{\mathbf{V}}^{(t)} - \mathbf{V}_n^{(t)})$ is the empirical distribution on the observable. $P_{model}(\mathbf{V}_n^{(t)*}, \mathbf{h}_n^{(t)})$ is defined in eq. 4. The free energy $\mathfrak{F}(\mathbf{V}_n^{(t)})$ is related to normalized probability of $\mathbf{V}_n^{(t)}$ as $P(\mathbf{V}_n^{(t)}) \equiv \exp^{-\mathfrak{F}(\mathbf{V}_n^{(t)})} / Z_n^{(t)}$ and as follows-

$$\begin{aligned}
\mathfrak{F}(\mathbf{V}_n^{(t)}) = &- \sum_{k=1}^{K} \hat{v}_n^{k,(t)} b_v^k - \sum_{j=1}^{F} \log(1+ \\
&\exp(D_n^{(t)} b_{h,j} + \sum_{k=1}^{K} \hat{v}_n^{k,(t)} W_j^k))
\end{aligned}$$

Gradient approximations w.r.t. RSM parameters,

$$\begin{aligned}
\frac{\partial C_t}{\partial \mathbf{b_v}^{(t)}} &\simeq \sum_{n=1}^{N^{(t)}} \hat{\mathbf{v}}_n^{(t)*} - \hat{\mathbf{v}}_n^{(t)} \\
\frac{\partial C_t}{\partial \mathbf{b_h}^{(t)}} &\simeq \sum_{n=1}^{N^{(t)}} \sigma(\mathbf{W_{vh}} \hat{\mathbf{v}}_n^{(t)*} - D_n^{(t)} \mathbf{b_h}^{(t)}) \\
&\quad - \sigma(\mathbf{W_{vh}} \hat{\mathbf{v}}_n^{(t)} - D_n^{(t)} \mathbf{b_h}^{(t)}) \\
\frac{\partial C_t}{\partial \mathbf{W_{vh}}} &\simeq \sum_{t=1}^{T} \sum_{n=1}^{N^{(t)}} \sigma(\mathbf{W_{vh}} \hat{\mathbf{v}}_n^{(t)*} - D_n^{(t)} \mathbf{b_h}^{(t)}) \\
&\quad \hat{\mathbf{v}}_n^{(t)*T} - \sigma(\mathbf{W_{vh}} \hat{\mathbf{v}}_n^{(t)} - D_n^{(t)} \mathbf{b_h}^{(t)}) \hat{\mathbf{v}}_n^{(t)T}
\end{aligned} \tag{5}$$

The estimated gradients w.r.t. RSM biases are back-propagated via hidden-to-bias parameters (eq 1) to compute gradients w.r.t. RNN connections ($\mathbf{W_{uh}}$, $\mathbf{W_{uv}}$, $\mathbf{W_{vu}}$ and $\mathbf{W_{uu}}$) and biases ($\mathbf{b_h}$, $\mathbf{b_v}$ and $\mathbf{b_u}$).

$$\begin{aligned}
\frac{\partial C}{\partial \mathbf{W_{uh}}} &= \sum_{t=1}^{T} \frac{\partial C_t}{\partial \mathbf{b_h}^{(t)}} \mathbf{u}^{(t-1)T} \\
\frac{\partial C}{\partial \mathbf{W_{uv}}} &= \sum_{t=1}^{T} \frac{\partial C_t}{\partial \mathbf{b_v}^{(t)}} \mathbf{u}^{(t-1)T} \\
\frac{\partial C}{\partial \mathbf{W_{vu}}} &= \sum_{t=1}^{T} \frac{\partial C_t}{\partial \mathbf{u}^{(t)}} \mathbf{u}^{(t)}(1 - \mathbf{u}^{(t)}) \sum_{n=1}^{N^{(t)}} \hat{\mathbf{v}}_n^{(t)T} \\
\frac{\partial C}{\partial \mathbf{b_h}} &= \sum_{t=1}^{T} \frac{\partial C_t}{\partial \mathbf{b_h}^{(t)}} \text{ and } \frac{\partial C}{\partial \mathbf{b_v}} = \sum_{t=1}^{T} \frac{\partial C_t}{\partial \mathbf{b_v}^{(t)}} \\
\frac{\partial C}{\partial \mathbf{b_u}} &= \sum_{t=1}^{T} \frac{\partial C_t}{\partial \mathbf{u}^{(t)}} \mathbf{u}^{(t)}(1 - \mathbf{u}^{(t)}) \\
\frac{\partial C}{\partial \mathbf{W_{uu}}} &= \sum_{t=1}^{T} \frac{\partial C_t}{\partial \mathbf{u}^{(t)}} \mathbf{u}^{(t)}(1 - \mathbf{u}^{(t)}) \mathbf{u}^{(t-1)T}
\end{aligned} \tag{6}$$

Table 3: State-of-the-art Comparison: Generalization (*PPL* and *Err*), Topic Interpretation (*COH*) and Evolution (*TTD*) in DTM and RNN-RSM models

For the single-layer RNN-RSM, the BPTT recurrence relation for $0 \leq t < T$ is given by-

$$\frac{\partial C_t}{\partial \mathbf{u}^{(t)}} = \mathbf{W_{uu}} \frac{\partial C_{t+1}}{\partial \mathbf{u}^{(t+1)}} \mathbf{u}^{(t+1)}(1 - \mathbf{u}^{(t+1)}) + \mathbf{W_{uh}} \frac{\partial C_{t+1}}{\partial \mathbf{b_h}^{(t+1)}} + \mathbf{W_{uv}} \frac{\partial C_{t+1}}{\partial \mathbf{b_v}^{(t+1)}}$$

where $\mathbf{u}^{(0)}$ being a parameter and $\frac{\partial C_T}{\partial \mathbf{u}^{(T)}} = 0$.

See *Training RNN-RSM with BPTT* in Algo 1.

3 Evaluation

3.1 Dataset and Experimental Setup

We use the processed dataset (Gollapalli and Li, 2015), consisting of EMNLP and ACL conference papers from the year 1996 through 2014 (Table 1). We combine papers for each year from the two venues to prepare the document collections over time. We use ExpandRank (Wan and Xiao, 2008) to extract top 100 keyphrases for each paper, including unigrams and bigrams. We split the bigrams to unigrams to create a dictionary of all unigrams and bigrams. The dictionary size (K) and word count are 3390 and 5.19 M, respectively.

We evaluate RNN-RSM against static (RSM, LDA) and dynamic (DTM) topics models for topic and keyword evolution in NLP research over time. Individual 19 different RSM and LDA models are trained for each year, while DTM[2] and RNN-RSM are trained over the years with 19 time steps, where paper collections for a year is input at each time step. RNN-RSM is initialized with RSM ($\mathbf{W_{vh}}$, $\mathbf{b_v}$, $\mathbf{b_h}$) trained for the year 2014.

We use perplexity to choose the number of topics (=30). See Table 2 for hyperparameters.

3.2 Generalization in Dynamic Topic Models

Perplexity: We compute the perplexity on unobserved documents ($\widehat{\mathbf{V}}^{(t)}$) at each time step as

$$\text{PPL}(\widehat{\mathbf{V}}^{(t)}, t) = \exp\left(-\frac{1}{N^{(t)}} \frac{\sum_{n=1}^{N^{(t)}} \log P(\mathbf{V}_n^{(t)})}{\sum_{n=1}^{N^{(t)}} D_n^{(t)}}\right)$$

where t is the time step. $N^{(t)}$ is the number of documents in a collection ($\widehat{\mathbf{V}}^{(t)}$) at time t. Better models have lower perplexity values, suggesting less uncertainties about the documents. For held-out documents, we take 10 documents from each time step i.e. total 190 documents and compute perplexity for 30 topics. Fig 3d shows the comparison of perplexity values for unobserved documents from DTM and RNN-RSM at each time step. The *SumPPL* (Table 3) is the sum of PPL values for the held-out sets of each time step.

Document Time Stamp Prediction: To further assess the dynamic topics models, we split the document collections at each time step into 80-20% train-test, resulting in 1067 held-out documents. We predict the time stamp (dating) of a document by finding the most likely (with the lowest perplexity) location over the time line. See the *mean absolute error* (*Err*) in year for the held-out in Table 3. Note, we do not use the time stamp as observables during training.

3.3 TSD, TED: Topic Evolution over Time

Topic Detection: To extract topics from each RSM, we compute posterior $P(\widehat{\mathbf{V}}^{(t)}|h_j = 1)$ by activating a hidden unit and deactivating the rest in a hidden layer. We extract the top 20 terms for every 30 topic set from 1996-2014, resulting in $|Q|_{max} = 19 \times 30 \times 20$ possible topic terms.

Topic Popularity: To determine topic *popularity*, we selected three popular topics (*Sentiment Analysis*, *Word Vector* and *Dependency Parsing*) in NLP research and create a set[3] of key-terms (including unigrams and bigrams) for each topic. We compute cosine similarity of the key-terms defined for each selected topic and topics discovered by the topic models over the years. We consider the discovered topic that is the most similar to the key-terms in the target topic and plot the similarity values in Figure 3a, 3b and 3b. Observe that RNN-RSM shows better topic evolution for the three emerging topics. LDA and RSM show

Figure 3: (a, b, c): Topic popularity by LDA, RSM, DTM and RNN-RSM over time (d): Perplexity on the unobserved document collections over time (e, f): Mean and Median Topic Coherence (g, h): Topic Evolution (i,j,k,l): Topic focus change over time. Adj- Adjacent; Sim- Similarity

topical locality in Figure 3c attributed to no correlation in topic dynamics over time, while in Figure 3b, DTM does not capture evolution of topic *Word Vector*.

Topic Drift (Focus Change): To compute the topic *focus* change over the years, we first split the time period 1996-2014 into five parts:{1996, 2000, 2005, 2010, 2014}. The cosine similarity scores are computed between the topic sets discovered in a particular year and the years preceding it in the above set, for example the similarity scores between the topic-terms in (1996, 2000), (1996, 2005), (1996, 2010) and (1996, 2014), respectively. Figure 3i, 3j, 3k and 3l demonstrate that RNN-RSM shows higher *convergence* in topic focus over the years, compared to LDA and RSM. In RNN-RSM, the topic similarity is gradually increased over time, however not in DTM. The higher similarities in the topic sets indicate that new/existing topics and words do not appear/disappear over time.

We compute topic-term drift (TTD) to show the changing topics from initial to final year, as

$$TTD = 1.0 - cosineSimilarity(\mathbf{Q}^{(t)}, \mathbf{Q}^{(t')})$$

where $\mathbf{Q}$ is the set of all topic-terms for time step t. Table 3 shows that TTD (where t=1996 and t'=2014) are 0.268 and 0.084 for RNN-RSM and DTM, respectively. It suggests that the higher number of new topic-terms evolved in RNN-RSM, compared to DTM. Qualitatively, the Table 4 shows the topics observed with the highest and lowest cosine drifts in DTM and RNN-RSM.

In Figure 3g and 3h, we also illustrate the temporal *evolution* (drift) in the selected topics by computing cosine similarity on their adjacent topic vectors over time. The topic vectors are selected similarly as in computing topic popularity. We observe better TED in RNN-RSM than DTM for the three emerging topics in NLP research. For instance, for the selected topic *Word Vector*, the red line in DTM (Fig 3h) shows no drift (for x-axis 00-05, 05-10 and 10-14), suggesting the topic-terms in the adjacent years are similar and does not evolve.

Drift	Model (year)	Topic Terms
0.20	**DTM** (1996)	document, retrieval, query, documents, information, search, information retrieval, queries, terms, words, system, results, performance, method, approach
	DTM (2014)	document, query, search, documents, queries, information, retrieval, method, results, information retrieval, research, terms, other, approach, knowledge
0.53	**DTM** (1996)	semantic, lexical, structure, syntactic, argument, frame, example, lexicon, information, approach, source, function, figure, verbs, semantic representation
	DTM (2014)	semantic, argument, frame, sentence, syntactic, semantic parsing, structure, semantic role, example, role labeling, language, learning, logical form, system, lexicon
0.20	**RNN-RSM** (1996)	reordering, statistical machine, translation model, translations, arabic, word align, translation probability, word alignment, translation system, source word, ibm model, source sentence, english translation, target language, word segmentation
	RNN-RSM (2014)	reordering, statistical machine, translation model, translations, arabic, word align, translation probability, word alignment, translation system, source word, reordering model, bleu score, smt system, english translation, target language
0.53	**RNN-RSM** (1996)	input, inference, semantic representation, distributional models, logical forms, space model, clustering algorithm, space models, similar word, frequent word, meaning representation, lexical acquisition, new algorithm, same context, multiple words
	RNN-RSM (2014)	input, inference, word vector, word vectors, vector representation, semantic representation, distributional models, semantic space, space model, semantic parser, vector representations, neural language, logical forms, cosine similarity, clustering algorithm

Table 4: Topics (top 15 words) with the highest and lowest drifts (cosine) observed in DTM and RNN-RSM

3.4 Topic Interpretability

Beyond perplexities, we also compute topic coherence (Chang et al., 2009; Newman et al., 2009; Das et al., 2015) to determine the meaningful topics captured. We use the coherence measure proposed by Aletras and Stevenson (2013) that retrieves co-occurrence counts for the set of topic words using Wikipedia as a reference corpus to identify context features (window=5) for each topic word. Relatedness between topic words and context features is measured using normalized pointwise mutual information (NPMI), resulting in a single vector for every topic word. The coherence (*COH*) score is computed as the arithmetic mean of the cosine similarities between all word pairs. Higher scores imply more coherent topics. We use Palmetto[4] library to estimate coherence.

Quantitative: We compute mean and median coherence scores for each time step using the corresponding topics, as shown in Fig 3e and 3f. Table 3 shows *mean-COH* and *median-COH* scores, computed by mean and median of scores from Fig 3e and 3f, respectively. Observe that RNN-RSM captures topics with higher coherence.

Qualitative: Table 5 shows topics (top-10 words) with the highest and lowest coherence scores.

3.5 TTC: Trending Keywords over time

We demonstrate the capability of RNN-RSM to capture word evolution (usage) in topics over time. We define: *keyword-trend* and SPAN. The *keyword-trend* is the appearance/disappearance of the keyword in topic-terms detected over time, while SPAN is the length of the longest sequence of the keyword appearance in its keyword trend.

COH: 0.268	0.284	0.064	0.071

Table 5: Topics with the highest and lowest coherence

Let $\widehat{\mathbf{Q}}_{model} = \{\mathbf{Q}^{(t)}_{model}\}_{t=1}^{T}$ be a set of sets[5] of topic-terms discovered by the $model$ (LDA, RSM, DTM and RNN-RSM) over different time steps. Let $\mathbf{Q}^{(t)} \in \widehat{\mathbf{Q}}_{model}$ be the topic-terms at time step t. The keyword-trend for a keyword k is a time-ordered sequence of 0s and 1s, as

$$\text{trend}_k(\widehat{\mathbf{Q}}) = [\text{find}(k, \mathbf{Q}^{(t)})]_{t=1}^{T}$$

$$\text{where;} \quad \text{find}(k, \mathbf{Q}^{(t)}) = \begin{cases} 1 & \text{if } k \in \mathbf{Q}^{(t)} \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

And the SPAN (S_k) for the kth keyword is-

$$S_k(\widehat{\mathbf{Q}}) = \text{length}\big(\text{longestOnesSeq}(\text{trend}_k(\widehat{\mathbf{Q}})\big)$$

We compute keyword-trend and SPAN for each term from the set of some popular terms. We define average-SPAN for all the topic-terms appearing in the topics discovered over the years,

$$\text{avg-SPAN}(\widehat{\mathbf{Q}}) = \frac{1}{||\widehat{\mathbf{Q}}||} \sum_{\{k|\mathbf{Q}^{(t)} \in \widehat{\mathbf{Q}} \wedge k \in \mathbf{Q}^{(t)}\}} \frac{S_k(\widehat{\mathbf{Q}})}{\hat{v}^k}$$

$$= \frac{1}{||\widehat{\mathbf{Q}}||} \sum_{\{k|\mathbf{Q}^{(t)} \in \widehat{\mathbf{Q}} \wedge k \in \mathbf{Q}^{(t)}\}} S_k^{dict}(\widehat{\mathbf{Q}})$$

[5] a set by **bold** and set of sets by $\widehat{\textbf{bold}}$

Table 6: SPAN (S_k) for selected terms, avg-SPAN and set $||\widehat{\mathbf{Q}}||$ by LDA, RSM, DTM and RNN-RSM

where $||\widehat{\mathbf{Q}}|| = |\{k|\mathbf{Q}^{(t)} \in \widehat{\mathbf{Q}} \wedge k \in \mathbf{Q}^{(t)}\}|$ is the count of unique topic-terms and $\hat{v^k} = \sum_{t=1}^{T}\sum_{j=1}^{D_t} v_{j,t}^k$ denotes the count of k^{th} keyword.

In Figure 4, the keyword-trends indicate emergence (appearance/disappearance) of the selected popular terms in topics discovered in ACL and EMNLP papers over time. Observe that RNN-RSM captures longer SPANs for popular keywords and better word usage in NLP research. For example: *Word Embedding* is one of the top keywords, appeared locally (Figure 5) in the recent years. RNN-RSM detects it in the topics from 2010 to 2014, however DTM does not. Similarly, for *Neural Language*. However, *Machine Translation* and *Language Model* are globally appeared in the input document collections over time and captured in the topics by RNN-RSM and DTM. We also show keywords (*Rule-set* and *Seed Words*) that disappeared in topics over time.

Higher SPAN suggests that the model is capable in capturing trending keywords. Table 6 shows corresponding comparison of SPANs for the 13 selected keywords. The SPAN S_k for each keyword is computed from Figure 4. Observe that $||\widehat{\mathbf{Q}}||_{DTM} < ||\widehat{\mathbf{Q}}||_{RNN-RSM}$ suggests new topics and words emerged over time in RNN-RSM, while higher SPAN values in RNN-RSM suggest better trends. Figure 6 shows how the word usage, captured by DTM and RNN-RSM for the topic *Word Vector*, changes over 19 years in NLP research. RNN-RSM captures popular terms *Word Embedding* and *Word Representation* emerged in it.

4 Discussion: RNN-RSM vs DTM

Architecture: RNN-RSM treats document's stream as high dimensional sequences over time and models the complex conditional probability distribution i.e. *heteroscedasticity* in document collections and topics over time by a temporal stack of RSMs (undirected graphical model), conditioned on time-feedback connections using RNN (Rumelhart et al., 1985). It has two hidden layers: **h** (stochastic binary) to capture topical information, while **u** (deterministic) to convey temporal information via BPTT that models the topic dependence at a time step t on *all* the previous steps $\tau < t$. In contrast, DTM is built upon

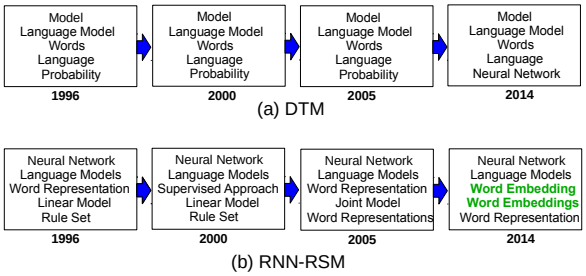

Figure 6: Word usage for emerging topic *Word Vector* over time, captured by DTM and RNN-RSM

LDA (directed model), where Dirichlet distribution on words is not amenable to sequential modeling, therefore its natural parameters (topic and topic proportion distributions) for each topic are chained, instead of latent topics that results in intractable inference in topic detection and chaining.

Topic Dynamics: The introduction of explicit connection in latent topics in RNN-RSM allow new topics and words for the underlying topics to appear or disappear over time by the dynamics of topic correlations. As discussed, the distinction of $\mathbf{h}$ and $\mathbf{u}$ permits the latent topic $\mathbf{h}^{(t)}$ to capture new topics, that may not be captured by $\mathbf{h}^{(t-1)}$.

DTM assumes a fixed number of global topics and models their distribution over time. However, there is no such assumption in RNN-RSM. We fixed the topic count in RNN-RSM at each time step, since $\mathbf{W_{vh}}$ is fixed over time and RSM biases turn off/on terms in each topic. However, this is fundamentally different for DTM. E.g. a unique label be assigned to each of the 30 topics at any time steps t and t'. DTM follows the sets of topic labels: $\{TopicLabels^{(t)}\}_{k=1}^{30} = \{TopicLabels^{(t')}\}_{k=1}^{30}$, due to eq (1) in Blei and Lafferty (2006) (discussed in section 5) that limits DTM to capture new (or local) topics or words appeared over time. It corresponds to the keyword-trends (section 3.5).

Optimization: The RNN-RSM is based on Gibbs sampling and BPTT for inference while DTM employs complex variational methods, since applying Gibbs sampling is difficult due to the nonconjugacy of the Gaussian and multinomial distributions. Thus, easier learning in RNN-RSM.

For all models, approximations are solely used to compute the likelihood, either using variational approaches or contrastive divergence; perplexity was then computed based on the approximated likelihood. More specifically, we use variational approximations to compute the likelihood for DTM (Blei and Lafferty, 2006). For RSM and RNN-RSM, the respective likelihoods are approximated using the standard Contrastive Divergence (CD). While there are substantial differences between variational approaches and CD, and thus in the manner the likelihood for different models is estimated - both approximations work well for the respective family of models in terms of approximating the true likelihood. Consequently, perplexities computed based on these approximated likelihoods are indeed comparable.

5 Conclusion and Future Work

We have proposed a neural temporal topic model which we name as RNN-RSM, based on probabilistic undirected graphical topic model RSM with time-feedback connections via deterministic RNN, to capture temporal relationships in historical documents. The model is the first of its kind that learns topic dynamics in collections of different-sized documents over time, within the generative and neural network framework. The experimental results have demonstrated that RNN-RSM shows better generalization (perplexity and time stamp prediction), topic interpretation (coherence) and evolution (popularity and drift) in scientific articles over time. We also introduced SPAN to illustrate topic characterization.

In future work, we forsee to investigate learning dynamics in variable number of topics over time. It would also be an interesting direction to investigate the effect of the skewness in the distribution of papers over all years. Further, we see a potential application of the proposed model in learning the time-aware i.e. dynamic word embeddings (Aitchison, 2001; Basile et al., 2014; Bamler and Mandt, 2017; Rudolph and Blei, 2018; Yao et al., 2018) in order to capture language evolution over time, instead of document topics.

Acknowledgments

We thank Sujatha Das Gollapalli for providing us with the data sets used in the experiments. We express appreciation for our colleagues Florian Buettner, Mark Buckley, Stefan Langer, Ulli Waltinger and Usama Yaseen, and anonymous reviewers for their in-depth review comments. Abstract

Multilingual topic models enable document analysis across languages through coherent multilingual summaries of the data. However, there is no standard and effective metric to evaluate the quality of multilingual topics. We introduce a new intrinsic evaluation of multilingual topic models that correlates well with human judgments of multilingual topic coherence as well as performance in downstream applications. Importantly, we also study evaluation for low-resource languages. Because standard metrics fail to accurately measure topic quality when robust external resources are unavailable, we propose an adaptation model that improves the accuracy and reliability of these metrics in low-resource settings.

1 Introduction

Topic models provide a high-level view of the main themes of a document collection (Boyd-Graber et al., 2017). Document collections, however, are often not in a single language, driving the development of **multilingual** topic models. These models discover topics that are consistent across languages, providing useful tools for multilingual text analysis (Vulić et al., 2015), such as detecting cultural differences (Gutiérrez et al., 2016) and bilingual dictionary extraction (Liu et al., 2015).

Monolingual topic models can be evaluated through likelihood (Wallach et al., 2009b) or coherence (Newman et al., 2010), but topic model evaluation is not well understood in multilingual settings. Our contributions are two-fold. We introduce an improved intrinsic evaluation metric for multilingual topic models, called Crosslingual Normalized Pointwise Mutual Information (CNPMI, Section 2). We explore the behaviors of CNPMI at both the model and topic levels with six language pairs and varying model specifications. This metric correlates well with human judgments and crosslingual classification results (Sections 5 and 6).

We also focus on evaluation in low-resource languages, which lack large parallel corpora, dictionaries, and other tools that are often used in learning and evaluating topic models. To adapt CNPMI to these settings, we create a coherence estimator (Section 3) that extrapolates statistics derived from antiquated, specialized texts like the Bible: often the only resource available for many languages.

2 Evaluating Multilingual Coherence

A multilingual topic contains one topic for each language. For a multilingual topic to be meaningful to humans (Figure 1), the meanings should be consistent across the languages, in addition to coherent within each language (*i.e.*, all words in a topic are related).

This section describes our approach to evaluating the quality of multilingual topics. After defining the multilingual topic model, we describe topic model evaluation extending standard monolingual approaches to multilingual settings.

2.1 Multilingual Topic Modeling

Probabilistic topic models associate each document in a corpus with a distribution over latent topics, while each topic is associated with a distribution over words in the vocabulary. The most widely used topic model, latent Dirichlet allocation (Blei et al., 2003, LDA), can be extended to connect languages. These extensions require additional knowledge to link languages together.

One common encoding of multilingual knowledge is **document links** (indicators that documents are parallel or comparable), used in polylingual topic models (Mimno et al., 2009; Ni et al., 2009). In these models, each document d indexes a tuple of parallel/comparable language-specific documents,

Proceedings of NAACL-HLT 2018, pages 1090–1100
New Orleans, Louisiana, June 1 - 6, 2018.

$d^{(\ell)}$, and the language-specific "views" of a document share the document-topic distribution θ_d. The generative story for the document-links model is:

for *each topic* k *and each language* ℓ **do**
  Draw a distribution over words $\phi_{\ell k} \sim \text{Dirichlet}(\beta)$;
for *each document tuple* $d = \left(d^{(1)}, \ldots, d^{(L)}\right)$ **do**
  Draw a distribution over topics $\theta_d \sim \text{Dirichlet}(\alpha)$;
  for *each language* $\ell = 1, \ldots, L$ **do**
    for *each token* $t \in d^{(\ell)}$ **do**
      Draw a topic $z_n \sim \theta_d$;
      Draw a word $w_n \sim \phi_{\ell z}$;

Alternatively, word translations (Jagarlamudi and Daumé III, 2010), concept links (Gutiérrez et al., 2016; Yang et al., 2017), and multi-level priors (Krstovski et al., 2016) can also provide multilingual knowledges. Since the polylingual topic model is the most common approach for building multilingual topic models (Vulić et al., 2013, 2015; Liu et al., 2015; Krstovski and Smith, 2016), our study will focus on this model.

2.2 Monolingual Evaluation

Most automatic topic model evaluation metrics use co-occurrence statistics of word pairs from a reference corpus to evaluate topic coherence, assuming that coherent topics contain words that often appear together (Newman et al., 2010). The most successful (Lau et al., 2014) is normalized pointwise mutual information (Bouma, 2009, NPMI). NPMI compares the joint probability of words appearing together $\Pr(w_i, w_j)$ to their probability assuming independence $\Pr(w_i)\Pr(w_j)$, normalized by the joint probability:

$$\text{NPMI}(w_i, w_j) = \frac{\log \frac{\Pr(w_i, w_j)}{\Pr(w_i)\Pr(w_j)}}{\log \Pr(w_i, w_j)}. \quad (1)$$

The word probabilities are calculated from a **reference corpus**, $\mathcal{R}$, typically a large corpus such as Wikipedia that can provide meaningful co-occurrence patterns that are independent of the target dataset.

The quality of topic k is the average NPMI of all word pairs (w_i, w_j) in the topic:

$$\text{NPMI}_k = \frac{-1}{\binom{C}{2}} \sum_{i \in \mathcal{W}(k,C)} \sum_{j \neq i} \text{NPMI}(w_i, w_j), \quad (2)$$

where $\mathcal{W}(k, C)$ are the C most probable words in the topic-word distribution ϕ_k (the number of words is the topic's **cardinality**). Higher NPMI_k means the topic's top words are more coupled.

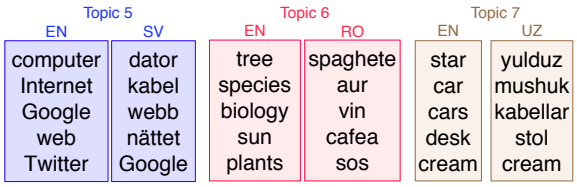

Figure 1: Topic 5 is multilingually coherent: both the English and Swedish topics are about technology. Topic 6 is about biology in English but food in Romanian, so it is low quality although coherent monolingually. Topic 7 is monolingually incoherent, so it is a low quality topic even if it contains word translations.

2.3 Existing Multilingual Evaluations

While automatic evaluation has been well-studied for monolingual topic models, there are no robust evaluations for multilingual topic models. We first consider two straightforward metrics that could be used for multilingual evaluation, both with limitations. We then propose an extension of NPMI that addresses these limitations.

Internal Coherence. A simple adaptation of NPMI is to calculate the monolingual NPMI score for each language independently and take the average. We refer this as internal NPMI (INPMI) as it evaluates coherence *within* a language. However, this metric does not consider whether the topic is coherent *across* languages—that is, whether a language-specific word distribution $\phi_{\ell_1 k}$ is related to the corresponding distribution in another language, $\phi_{\ell_2 k}$.

Crosslingual Consistency. Another straightforward measurement is Matching Translation Accuracy (Boyd-Graber and Blei, 2009, MTA), which counts the number of word translations in a topic between two languages using a bilingual dictionary. This metric can measure whether a topic is well-aligned across languages *literally*, but cannot capture non-literal more holistic similarities across languages.

2.4 New Metric: Crosslingual NPMI

We extend NPMI to multilingual models, with a metric we call crosslingual normalized pointwise mutual information (CNPMI). This metric will be the focus of our experiments.

A multilingually coherent topic means that if w_{i,ℓ_1} in language ℓ_1 and w_{j,ℓ_2} in language ℓ_2 are in the same topic, they should appear in similar contexts in comparable or parallel corpora $\mathcal{R}^{(\ell_1,\ell_2)}$.

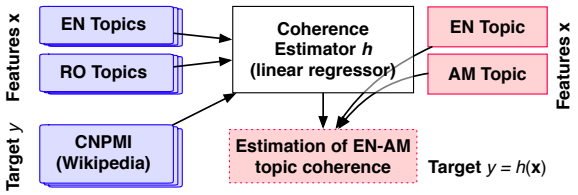

Figure 2: The coherence estimator takes multilingual topics and features from them then outputs an estimated topic coherence.

Our adaptation of NPMI is based on the same principles as the monolingual version, but focuses on the co-occurrences of *bilingual* word pairs. Given a bilingual word pair $(w_{i,\ell_1}, w_{j,\ell_2})$ the co-occurrence of this word pair is the event where word w_{i,ℓ_1} appears in a document in language ℓ_1 and the word w_{j,ℓ_2} appears in a comparable or parallel document in language ℓ_2.

The co-occurrence probability of each bilingual word pair is:

$$\Pr\left(w_{i,\ell_1}, w_{j,\ell_2}\right) \triangleq \frac{\left|\left\{\mathbf{d} : w_{i,\ell_1} \in d^{(\ell_1)}, w_{j,\ell_2} \in d^{(\ell_2)}\right\}\right|}{\left|\mathcal{R}^{(\ell_1,\ell_2)}\right|}, \quad (3)$$

where $\mathbf{d} = \left(d^{(\ell_1)}, d^{(\ell_2)}\right)$ is a pair of parallel/comparable documents in the reference corpus $\mathcal{R}^{(\ell_1,\ell_2)}$. When one or both words in a bilingual pair do not appear in the reference corpus, the co-occurrence score is zero.

Similar to monolingual settings, CNPMI for a bilingual topic k is the average of the NPMI scores of all C^2 bilingual word pairs,

$$\text{CNPMI}(\ell_1, \ell_2, k) = \frac{\sum_{i,j}^{C} \text{NPMI}\left(w_{i,\ell_1}, w_{j,\ell_2}\right)}{C^2}. \quad (4)$$

It is straightforward to generalize CNPMI from a language pair to multiple languages by averaging $\text{CNPMI}(\ell_i, \ell_j, k)$ over all language pairs (ℓ_i, ℓ_j).

3 Adapting to Low-Resource Languages

CNPMI needs a reference corpus for co-occurrence statistics. Wikipedia, which has good coverage of topics and vocabularies is a common choice (Lau and Baldwin, 2016). Unfortunately, Wikipedia is often unavailable or not large enough for low-resource languages. It only covers 282 languages,[1] and only 249 languages have more than 1,000 pages: many of pages are short or unlinked to a high-resource language. Since CNPMI requires comparable documents, the usable reference corpus is defined by *paired* documents.

Another option for a parallel reference corpus is the Bible (Resnik et al., 1999), which is available in most world languages;[2] however, it is small and archaic. It is good at evaluating topics such as family and religion, but not "modern" topics like biology and Internet. Without reference co-occurrence statistics relevant to these topics, CNPMI will fail to judge topic coherence—it must give the ambiguous answer of zero. Such a score could mean a totally incoherent topic where each word pair never appears together (Topics 6 in Figure 1), or an unjudgeable topic (Topic 5).

Our goal is to obtain a reliable estimation of topic coherence for low-resource languages when the Bible is the only reference. We propose a model that can correct the drawbacks of a Bible-derived CNPMI. While we assume bilingual topics paired with English, our approach can be applied to any high-resource/low-resource language pair.

We take Wikipedia's CNPMI from high-resource languages as accurate estimations. We then build a coherence *estimator* on topics from high-resource languages, with the Wikipedia CNPMI as the target output. We use linear regression using the below features. Given a topic in low-resource language, the estimator produces an estimated coherence (Figure 2).

3.1 Estimator Features

The key to the estimator is to find features that capture whether we should trust the Bible. For generality, we focus on features independent of the available resources other than the Bible. This section describes the features, which we split into four groups.

Base Features (BASE) Our base features include information we can collect from the Bible and the topic model: cardinality C, CNPMI and INPMI, MTA, and topic word coverage (TWC), which counts the percentage of topic words in a topic that appear in a reference corpus.

Crosslingual Gap (GAP) A low CNPMI score could indicate a topic pair where each language has a monolingually coherent topic but that are not about the same theme (Topic 6 in Figure 1). Thus, we add two features to capture this information

[1] https://meta.wikimedia.org/wiki/List_of_Wikipedias

[2] The Bible is available in 2,530 languages.

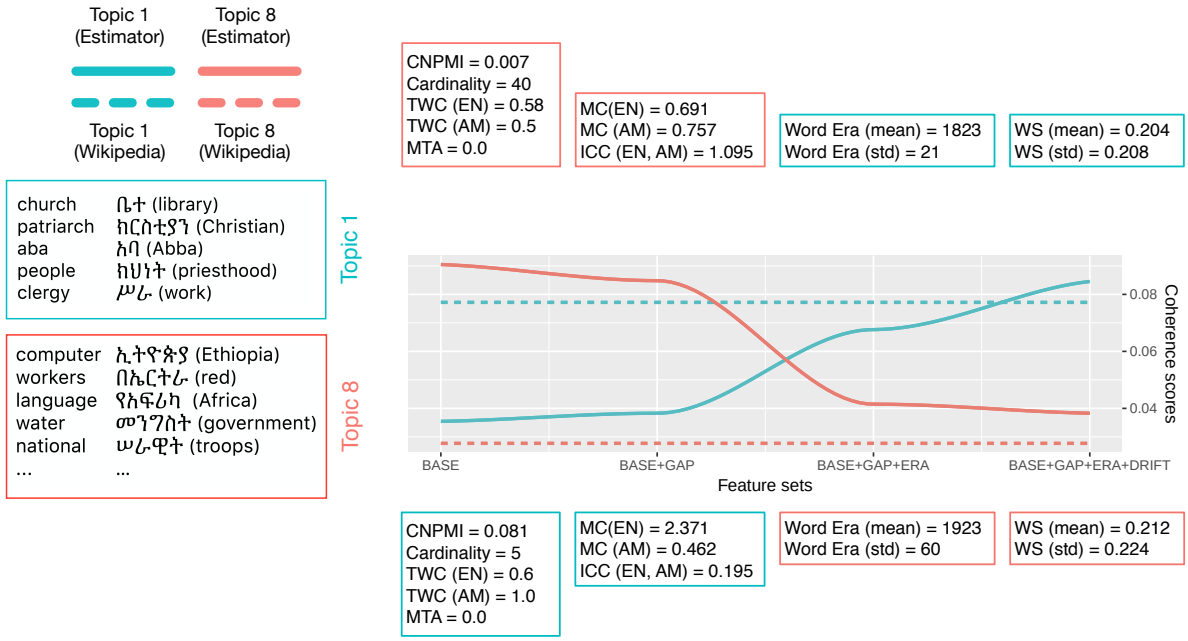

Figure 3: As the estimator adds additional features, the estimated topic coherence scores (solid lines) approach to Wikipedia CNPMI (dashed lines).

using the Bible: mismatch coefficients (MC) and internal comparison coefficients (ICC):

$$\text{MC}(\ell_1; \ell_2, k) = \frac{\text{CNPMI}(\ell_1, \ell_2, k)}{\text{INPMI}(\ell_1, k) + \alpha}, \quad (5)$$

$$\text{ICC}(\ell_1, \ell_2, k) = \frac{\text{INPMI}(\ell_1, k) + \alpha}{\text{INPMI}(\ell_2, k) + \alpha}, \quad (6)$$

where α is a smoothing factor ($\alpha = 0.001$ in our experiments). MC recognizes the gap between crosslingual and monolingual coherence, so a higher MC score indicates a gap between coherence within and across languages. Similarly, ICC compares monolingual coherence to tell if both languages are coherent: the closer to 1 the ICC is, the more comparable internal coherence both languages have.

Word Era (ERA) Because the Bible's vocabulary is unable to evaluate modern topics, we must tell the model what the modern words are. The **word era** features are the earliest usage year [3] for each word in a topic. We use both the mean and standard deviation as features.

Meaning Drift (DRIFT). The meaning of a word can expand and drift over time. For example, in the Bible, "web" appears in Isaiah 59:5:

> They hatch cockatrice' eggs, and weave the spider's **web**.

[3] https://oxforddictionaries.com/

The word "web" could be evaluated correctly in an animal topic. For modern topics, however, Bible fails to capture modern meanings of "web", as in Topic 5 (Figure 1).

To address this **meaning drift**, we use a method similar to Hamilton et al. (2016). For each English word, we calculate the context vector from Bible and from Wikipedia with a window size of five and calculate the cosine similarity between them as **word similarity**. Similar context vectors mean that the usage in the Bible is consistent with Wikipedia. We calculate word similarities for all the English topic words in a topic and use the average and standard deviation as features.

3.2 Example

In Figure 3, Topic 1 is coherent while Topic 8 is not. From left to right, we incrementally add new feature sets, and show how the estimated topic coherence scores (dashed lines) approach the ideal CNPMI (dotted lines). When only using the BASE features, the estimator gives a higher prediction to Topic 8 than to Topic 1. Their low MTA and TWC prevent accurate evaluations. Adding GAP does not help much. However, $\text{ICC}(\text{EN}, \text{AM}, k = 1)$ is much smaller, which might indicate a large gap of internal coherence between the two languages.

Adding ERA makes the estimated scores flip between the two topics. Topic 1 has word era of 1823, much older than Topic 8's word era of 1923, in-

Pair	Training	Reference		
		Wikipedia	The Bible	Wiktionary

EN-TR	874	5,524	1,189	16,853
EN-ZH	874	10,000	1,189	22,946

Table 1: Number of document pairs in the training and reference datasets and number of dictionary entries for each language pair.

dicating that Topic 8 includes modern words the Bible lacks (*e.g.*, "computer"). Using all the features, the estimator gives more accurate topic coherence evaluations.

4 Experiments: Bible to Wikipedia

We experiment on six languages (Table 1) from three corpora: Romanian (RO) and Swedish (SV) from EuroParl as representative of well-studied and rich-resource languages (Koehn, 2005); Amharic (AM) and Tagalog (TL) from collected news, as low-resource languages (Huang et al., 2002a,b); and Chinese (ZH) and Turkish (TR) from TED Talks 2013 (Tiedemann, 2012), adding language variety to our experiments. Each language is paired with English as a bilingual corpus.

Typical preprocessing methods (stemming, stop word removal, *etc.*) are often unavailable for low-resource languages. For a meaningful comparison across languages, we do not apply any stemming or lemmatization strategies, including English, except removing digit numbers and symbols. However, we remove words that appear in more than 30% of documents for each language.

Each language pair is separately trained using the `MALLET` (McCallum, 2002) implementation of the polylingual topic model. Each experiment runs five Gibbs sampling chains with 1,000 iterations per chain with twenty topics. The hyperparameters are set to the default values ($\alpha = 0.1$, $\beta = 0.01$), and are optimized every 50 iterations in `MALLET` using slice sampling (Wallach et al., 2009a).

4.1 Evaluating Multilingual Topics

We use Wikipedia and the Bible as reference corpora for calculating co-occurrence statistics. Different numbers of Wikipedia articles are available for each language pair (Table 1), while the Bible contains a complete set of 1,189 chapters for all of its translations (Christodoulopoulos and Steedman, 2015). We use Wiktionary as the dictionary to calculate MTA.

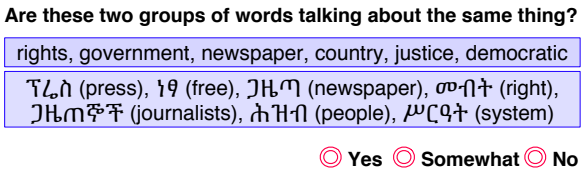

Figure 4: The interface for topic quality judgments. Users read the topic first, and make a judgment on whether the words in this pair are talking about the same thing. The translations are here for illustration; they are not shown to the users.

	Wikipedia		The Bible		MTA
	CNPMI	INPMI	CNPMI	INPMI	
EN-RO	0.490	0.118	−0.096	0.031	**0.592**
EN-SV	**0.453**	−0.295	0.164	−0.351	0.248
EN-AM	0.110	0.019	**0.289**	0.249	0.172
EN-TL	**0.512**	0.277	0.166	0.002	0.289
EN-TR	0.664	0.243	0.209	−0.246	**0.677**
EN-ZH	**0.436**	0.297	0.274	0.157	0.411

Table 2: Pearson correlations between human judgments and CNPMI are higher than INPMI, while MTA correlations are comparable to CNPMI.

4.2 Training the Estimator

In addition to experimenting on Wikipedia-based CNPMI, we also re-evaluate the topics' Bible coherence using our estimator. In the following experiments, we use an AdaBoost regressor with linear regression as the coherence estimator (Friedman, 2002; Collins et al., 2000). The estimator takes a topic and low-quality CNPMI score as input and outputs (hopefully) an improved CNPMI score.

To make our testing scenario more realistic, we treat one language as our estimator's test language and train on multilingual topics from the other languages. We use three-fold cross-validation over languages to select the best hyperparameters, including the learning rate and loss function in `AdaBoost.R2` (Drucker, 1997).

5 Topic-Level Evaluation

We first study CNPMI at the topic level: does a particular topic make sense? An effective evaluation should be consistent with human judgment of the topics (Chang et al., 2009). In this section, we measure gold-standard human interpretability of multilingual topics to establish which automatic measures of topic interpretability work best.

Test	Bible	Train		
		RO+SV	ZH+TR	RO+SV+ZH+TR
AM	−0.015	0.332	0.315	0.333
TL	−0.309	0.767	0.631	0.705
		AM+TL	ZH+TR	AM+TL+ZH+TR
RO	−0.269	0.736	0.681	0.713
SV	0.000	0.787	0.645	0.683
		RO+SV	AM+TL	RO+SV+AM+TL
ZH	0.217	0.751	0.732	0.741
TR	0.113	0.680	0.642	0.666

Table 3: Correlations between the Wikipedia-based CNPMI and the Bible-based CNPMI, before and after using the coherence estimator, at the topic level. Strong correlations indicate that the estimator improves CNPMI estimates.

5.1 Task Design

Following monolingual coherence evaluations (Lau et al., 2014), we present topic pairs to bilingual CrowdFlower users. Each task is a topic pair with the top ten topic words ($C = 10$) for each language. We ask if both languages' top words in a multilingual topic are talking about the same concept (Figure 4), and make a judgment on a three-point scale—coherent (2 points), somewhat coherent (1 point), and incoherent (0 points). To ensure the users have adequate language competency, we insert several topics that are easily identifiable as incoherent as a qualification test.

We randomly select sixty topics from each language pair (360 topics total), and each topic is judged by five users. We take the average of the judgment points and calculate Pearson correlations with the proposed evaluation metrics (Table 2). NPMI-based scores are separately calculated from each reference corpus.

5.2 Agreement with Human Judgments

CNPMI (the extended metric) has higher correlations with human judgments than INPMI (the naive adaptation of monolingual NPMI), while MTA (matching translation accuracy) correlations are comparable to CNPMI.

Unsurprisingly, when using Wikipedia as the reference, the correlations are usually higher than when using the Bible. The Bible's archaic content limits its ability to estimate human judgments in modern corpora (Section 3).

Next, we compare CNPMI to two baselines: INPMI and MTA. As expected, CNPMI outperforms INPMI regardless of reference corpus overall, because INPMI only considers monolingual coherence. MTA has higher correlations than CNPMI scores from the Bible, because the Bible fails to give accurate estimates due to limited topic coverage. MTA, on the other hand, only depends on dictionaries, which are more comprehensive than the Bible. It is also possible that users are judging coherence based on translations across a topic pair, rather than the overall coherence, which would closely correlate with MTA.

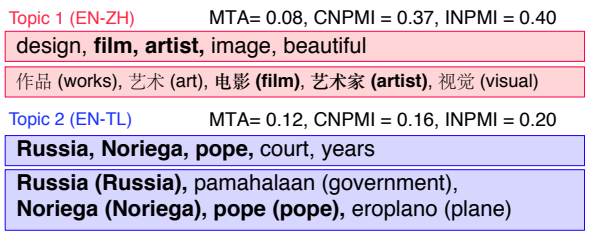

Figure 5: MTA fails to capture semantically related words (Topic 1) and only looks at translation pairs regardless of internal coherence (Topic 2).

5.3 Re-Estimating Topic-Level Coherence

The Bible—by itself—produces CNPMI values that do not correlate well with human judgments (Table 2). After training an estimator (Section 4.2), we calculate Pearson's correlation between Wikipedia's CNPMI and the estimated topic coherence score (Table 3). A higher correlation with Wikipedia's CNPMI means more accurate coherence.

As a baseline, the correlation of Bible-based CNPMI without adaptation has negative and near-zero correlations with Wikipedia;[4] it does not capture coherence. After training the estimator, the correlations become stronger, indicating the estimated scores are closer to Wikipedia's CNPMI.

5.4 When MTA Falls Short

We analyze MTA from two aspects—the inability to capture semantically-related *non-translation* topic words, and insensitivity to cardinality—to show why MTA is not an ideal measurement, even though it correlates well with human judgments.

Semantics We take two examples with EN-ZH (Topic 1) and EN-TL (Topic 2) in Figure 5. Topic 1 has fewer translation pairs than Topic 2, which leads to a lower MTA score for Topic 1. However, all words in Topic 1 talk about art, while it is hard to interpret Topic 2. Wikipedia CNPMI scores reveals

[4]Normally one would not estimate CNPMI on rich-resource languages using low-resource languages. For completeness, however, we also include these situations.

Topic 1 is more coherent. Because our experiments are on datasets with little divergence between the themes discussed across languages, this is uncommon for us but could appear in noisier datasets.

Cardinality Increasing cardinality diminishes a topic's coherence (Lau and Baldwin, 2016). We vary the cardinality of topics from ten to fifty at intervals of ten (Figure 6). As cardinality increases, more low-probability and irrelevant words appear the topic, which lowers CNPMI scores. However, MTA stays stable or increases with increasing cardinality. Thus, MTA fails to fulfill a critical property of topic model evaluation.

Finally, MTA requires a comprehensive multilingual dictionary, which may be unavailable for low-resource languages. Additionally, most languages often only have one dictionary, which makes it problematic to use the same resource (a language's single multilingual dictionary) for training and evaluating models that use a dictionary to build multilingual topics (Hu et al., 2014). Given these concerns, we continue the paper's focus on CNPMI as a data-driven alternative to MTA. However, for many applications MTA may suffice as a simple, adequate evaluation metric.

6 Model-Level Evaluation

While the previous section looked at individual topics, we also care about how well CNPMI characterizes the quality of *models* through an average of a model's constituent topics.

6.1 Training Knowledge

Adding more knowledge to multilingual topic models improves topics (Hu et al., 2014), so an effective evaluation should reflect this improvement as knowlege is added to the model. For polylingual topic models, this knowledge takes the form of the *number* of linked documents.

We start by experimenting with no multilingual knowledge: no document pairs share a topic distribution θ_d (but the documents are in the collection as unlinked documents). We then increase the number of document pairs that share θ_d from 20% of the corpus to 100%. Fixing the topic cardinality at ten, CNPMI captures the improvements in models (Figure 7) through a higher coherence score.

6.2 Agreement with Machines

Topic models are often used as a feature extraction technique for downstream machine learning applications, and topic model evaluations should reflect whether these features are useful (Ramage et al., 2009). For each model, we apply a document classifier trained on the model parameters to test whether CNPMI is consistent with classification accuracy.

Test	Bible	Train		
		RO+SV	ZH+TR	RO+SV+ZH+TR
AM	0.607	0.677	0.707	0.694
TL	0.796	0.875	0.924	0.918
		AM+TL	ZH+TR	AM+TL+ZH+TR
RO	0.631	0.912	0.919	0.931
SV	0.797	0.959	0.848	0.878
		RO+SV	AM+TL	RO+SV+AM+TL
ZH	0.907	0.918	0.951	0.939
TR	0.911	0.862	0.898	0.887

Table 4: At the model level, the estimator improves correlations between CNPMI and downstream classification for all languages except for Turkish.

Specifically, we want our classifier to transfer information from training on one language to testing on another (Smet et al., 2011; Heyman et al., 2016). We train a classifier on one language's documents, where each document's feature vector is the document-topic distribution θ_d. We apply this to TED Talks, where each document is labeled with multiple categories. We choose the most frequent seven categories across the corpus as labels,[5] and only have labeled documents in one side of a bilingual topic model. CNPMI has very strong correlations with classification results, though using the Bible as the reference corpus gives slightly lower correlation—with higher variance—than Wikipedia (Figure 8).

6.3 Re-Estimating Model-Level Coherence

In Section 5.3, we improve Bible-based CNPMI scores for individual topics. Here, we show the estimator also improves model-level coherence. We apply the estimator on the models created in Section 6.2 and calculate the correlation between estimated scores and Wikipedia's CNPMI (Table 4).

The coherence estimator substantially improves scores except for Turkish: the correlation is better *before* applying the estimator (0.911). We suspect a lack of overlap between topics between Turkish and languages other than Chinese is to blame (Figure 9); the features used by the estimator do not generalize well to other kinds of features; training on many languages pairs would hopefully solve this

[5] design, global issues, art, science, technology, business, and culture

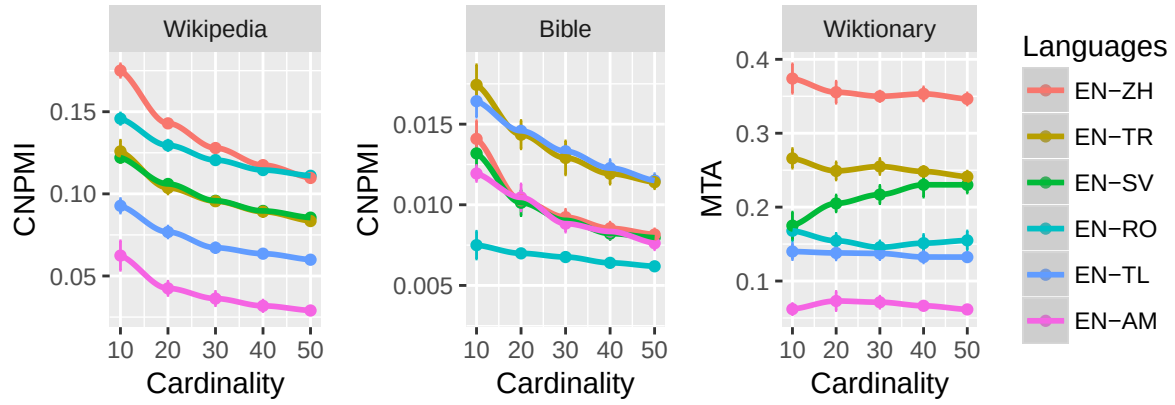

Figure 6: Increasing cardinality of topic pairs makes it harder to judge the coherence. Decreasing CNPMI scores reflect the diminished interpretability of topics, while MTA scores do not.

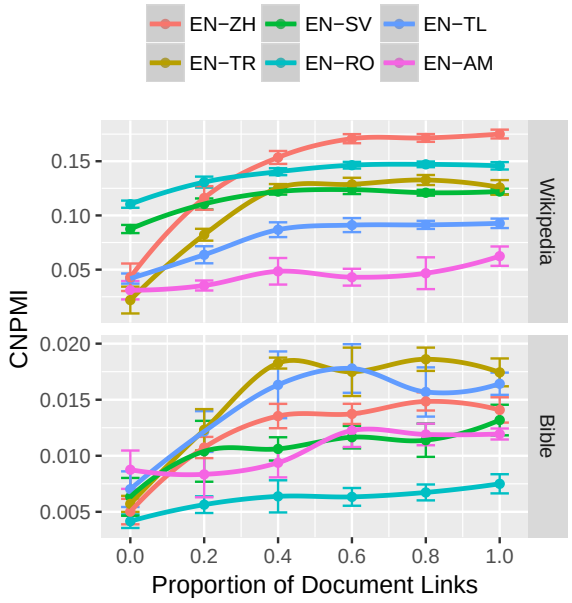

Figure 7: Adding more document links to the model produces more multilingually coherent topics. CNPMI captures this improvement.

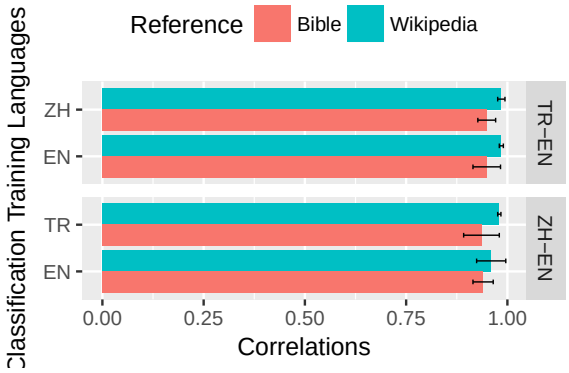

Figure 8: Pearson correlation between classification F1 scores and CNPMI: both CNPMI data sources predict whether a classifier using topic features will work well, but Wikipedia has slightly higher correlation with lower variance.

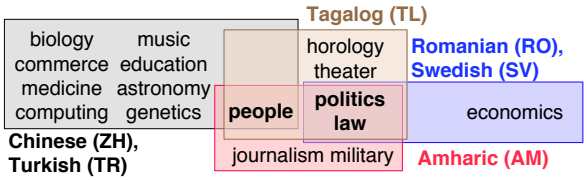

Figure 9: The overlap of topics and domain: only one out of nine Turkish and Chinese topics have domain overlap with Tagalog and Amharic topics. This hinders the Turkish estimator from capturing model-level properties.

issue. Turkish is also morphologically rich, and our preprocessing completely ignores morphology.

6.4 Reference Size

One challenge with low-resource languages is that even if Wikipedia is available, it may have too few documents to accurately calculate coherence. As a final analysis, we examine how the reliability of CNPMI degrades with a smaller reference corpus.

We randomly sample 20% to 100% of document pairs from the reference corpora and evaluate the polylingual topic model with all document links (Figure 10), again fixing the cardinality as 10.

CNPMI is stable across different amounts of reference documents, as long as the number of reference documents is sufficiently large. If there are too few reference documents (for example, 20% of Amharic Wikipedia is only 316 documents), then CNPMI degrades.

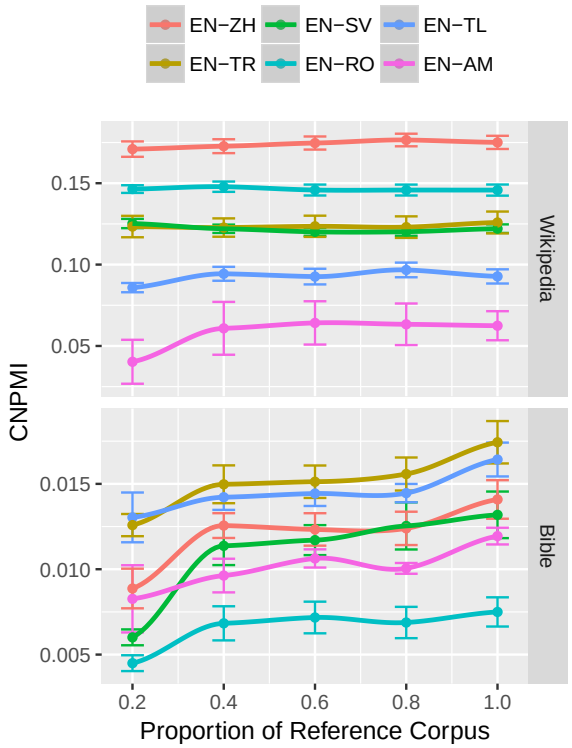

Figure 10: CNPMI is stable once the number of reference documents is large enough (around five thousand documents).

7 Related Work

Topic Coherence Many coherence metrics based on co-occurrence statistics have been proposed besides NPMI. Similar metrics—such as asymmetrical word pair metrics (Mimno et al., 2011) and combinations of existing measurements (Lau et al., 2014; Röder et al., 2015)—correlate well with human judgments. NPMI has been the current gold standard for evaluation and improvements of monolingual topic models (Pecina, 2010; Newman et al., 2011).

External Tasks Another approach is to use a model for predictive tasks: the better the results are on external tasks, the better a topic model is assumed to be. A common task is held-out likelihood (Wallach et al., 2009b; Jagarlamudi and Daumé III, 2010; Fukumasu et al., 2012), but as Chang et al. (2009) show, this does not always reflect human interpretability. Other specific tasks have also been used, such as bilingual dictionary extraction (Liu et al., 2015; Ma and Nasukawa, 2017), cultural difference deteciton (Gutiérrez et al., 2016), and crosslingual document clustering (Vulić et al., 2015).

Representation Learning Topic models are one example of a broad class of techniques of learning representations of documents (Bengio et al., 2013). Other approaches learn respresentations at the word (Klementiev et al., 2012; Vyas and Carpuat, 2016), paragraph (Mogadala and Rettinger, 2016), or corpus level (Søgaard et al., 2015). However, neural representation learning approaches are often data hungry and not adaptable to low-resource languages. The approaches here could help improve the evaluation of all multilingual representation learning algorithms (Schnabel et al., 2015).

8 Conclusion

We have provided a comprehensive analysis of topic model evaluation in multilingual settings, including for low-resource languages. While evaluation is an important area of topic model research, no previous work has studied evaluation of multilingual topic models. Our work provided two primary contributions to this area, including a new intrinsic evaluation metric, CNPMI, as well as a model for adapting this metric to low-resource languages without large reference corpora.

As the first study on evaluation for multilingual topic models, there is still room for improvement and further applications. For example, human judgment is more difficult to measure than in monolingual settings, and it is still an open question on how to design a reliable and accurate survey for multilingual quality judgments. As a measurement of multilingual coherence, we plan to extend CNPMI to high-dimensional representations, *e.g.,* multilingual word embeddings, particularly in low-resource languages (Ruder et al., 2017).

Explainable Prediction of Medical Codes from Clinical Text

James Mullenbach, Sarah Wiegreffe, Jon Duke, Jimeng Sun, Jacob Eisenstein

jsun@cc.gatech.edu, jacobe@gatech.edu

Abstract

Clinical notes are text documents that are created by clinicians for each patient encounter. They are typically accompanied by medical codes, which describe the diagnosis and treatment. Annotating these codes is labor intensive and error prone; furthermore, the connection between the codes and the text is not annotated, obscuring the reasons and details behind specific diagnoses and treatments. We present an attentional convolutional network that predicts medical codes from clinical text. Our method aggregates information across the document using a convolutional neural network, and uses an attention mechanism to select the most relevant segments for each of the thousands of possible codes. The method is accurate, achieving precision@8 of 0.71 and a Micro-F1 of 0.54, which are both better than the prior state of the art. Furthermore, through an interpretability evaluation by a physician, we show that the attention mechanism identifies meaningful explanations for each code assignment.

1 Introduction

Clinical notes are free text narratives generated by clinicians during patient encounters. They are typically accompanied by a set of metadata codes from the International Classification of Diseases (ICD), which present a standardized way of indicating diagnoses and procedures that were performed during the encounter. ICD codes have a variety of uses, ranging from billing to predictive modeling of patient state (Choi et al., 2016; Ranganath et al., 2015; Denny et al., 2010; Avati et al., 2017). Because manual coding is time-consuming and error-prone, automatic coding has been studied since at least the 1990s (de Lima et al., 1998). The task is difficult for two main reasons. First, the label space is very high-dimensional, with over 15,000 codes in the ICD-9 taxonomy, and over 140,000 codes combined in the newer ICD-10-CM and ICD-10-PCS taxonomies (World Health Organization, 2016). Second, clinical text includes irrelevant information, misspellings and non-standard abbreviations, and a large medical vocabulary. These features combine to make the prediction of ICD codes from clinical notes an especially difficult task, for computers and human coders alike (Birman-Deych et al., 2005).

In this application paper, we develop convolutional neural network (CNN)-based methods for automatic ICD code assignment based on text discharge summaries from intensive care unit (ICU) stays. To better adapt to the multi-label setting, we employ a per-label attention mechanism, which allows our model to learn distinct document representations for each label. We call our method **C**onvolutional **A**ttention for **M**ulti-**L**abel classification (CAML). Our model design is motivated by the conjecture that important information correlated with a code's presence may be contained in short snippets of text which could be anywhere in the document, and that these snippets likely differ for different labels. To cope with the large label space, we exploit the textual descriptions of each code to guide our model towards appropriate parameters: in the absence of many labeled examples for a given code, its parameters should be similar to those of codes with similar textual descriptions.

We evaluate our approach on two versions of MIMIC (Johnson et al., 2016), an open dataset of ICU medical records. Each record includes a variety of narrative notes describing a patient's stay, including diagnoses and procedures. Our approach substantially outperforms previous results on medical code prediction on both MIMIC-II and MIMIC-III datasets.

We consider applications of this work in a decision support setting. Interpretability is important for any decision support system, especially in the

medical domain. The system should be able to explain why it predicted each code; even if the codes are manually annotated, it is desirable to explain what parts of the text are most relevant to each code. These considerations further motivate our per-label attention mechanism, which assigns importance values to n-grams in the input document, and which can therefore provide explanations for each code, in the form of extracted snippets of text from the input document. We perform a human evaluation of the quality of the explanations provided by the attention mechanism, asking a physician to rate the informativeness of a set of automatically generated explanations.[1]

2 Method

We treat ICD-9 code prediction as a multilabel text classification problem (McCallum, 1999).[2] Let $\mathcal{L}$ represent the set of ICD-9 codes; the labeling problem for instance i is to determine $y_{i,\ell} \in \{0, 1\}$ for all $\ell \in \mathcal{L}$. We train a neural network which passes text through a convolutional layer to compute a base representation of the text of each document (Kim, 2014), and makes $|\mathcal{L}|$ binary classification decisions. Rather than aggregating across this representation with a pooling operation, we apply an attention mechanism to select the parts of the document that are most relevant for each possible code. These attention weights are then applied to the base representation, and the result is passed through an output layer, using a sigmoid transformation to compute the likelihood of each code. We employ a regularizer to encourage each code's parameters to be similar to those of codes with similar textual descriptions. We now describe each of these elements in more detail.

2.1 Convolutional architecture

At the base layer of the model, we have d_e-dimensional pre-trained embeddings for each word in the document, which are horizontally concatenated into the matrix $\boldsymbol{X} = [\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N]$, where N is the length of the document. Adjacent word embeddings are combined using a convolutional filter $\boldsymbol{W}_c \in \mathbb{R}^{k \times d_e \times d_c}$, where k is the filter width, d_e the size of the input embedding, and d_c the size of the filter output. At each step n, we compute

$$\boldsymbol{h}_n = g(\boldsymbol{W}_c * \boldsymbol{x}_{n:n+k-1} + \boldsymbol{b}_c), \quad (1)$$

where $*$ denotes the convolution operator, g is an element-wise nonlinear transformation, and $\boldsymbol{b}_c \in \mathbb{R}^{d_c}$ is the bias. We additionally pad each side of

[1] Our code, data splits, and pre-trained models are available at github.com/jamesmullenbach/caml-mimic.

[2] We focus on codes from the ICD-9 taxonomy, rather than the more recent ICD-10, for the simple reason that this is the version of ICD used in the MIMIC datasets.

the input with zeros so that the resulting matrix $\boldsymbol{H}$ has dimension $\mathbb{R}^{d_c \times N}$.

2.2 Attention

After convolution, the document is represented by the matrix $\boldsymbol{H} \in \mathbb{R}^{d_c \times N}$. It is typical to reduce this matrix to a vector by applying pooling across the length of document, by selecting the maximum or average value at each row (Kim, 2014). However, our goal is to assign multiple labels (i.e., medical codes) for each document, and different parts of the base representation may be relevant for different labels. For this reason, we apply a per-label attention mechanism. An additional benefit is that it selects the k-grams from the text that are most relevant to each predicted label.

Formally, for each label ℓ, we compute the matrix-vector product, $\boldsymbol{H}^\top \boldsymbol{u}_\ell$, where $\boldsymbol{u}_\ell \in \mathbb{R}^{d_c}$ is a vector parameter for label ℓ. We then pass the resulting vector through a softmax operator, obtaining a distribution over locations in the document,

$$\boldsymbol{\alpha}_\ell = \text{SoftMax}(\boldsymbol{H}^\top \boldsymbol{u}_\ell), \tag{2}$$

where $\text{SoftMax}(\boldsymbol{x}) = \frac{\exp(\boldsymbol{x})}{\sum_i \exp(x_i)}$, and $\exp(\boldsymbol{x})$ is the element-wise exponentiation of the vector $\boldsymbol{x}$. The attention vector $\boldsymbol{\alpha}$ is then used to compute vector representations for each label,

$$\boldsymbol{v}_\ell = \sum_{n=1}^{N} \alpha_{\ell,n} \boldsymbol{h}_n. \tag{3}$$

As a baseline model, we instead use max-pooling to compute a single vector $\boldsymbol{v}$ for all labels,

$$v_j = \max_n h_{n,j}. \tag{4}$$

2.3 Classification

Given the vector document representation $\boldsymbol{v}_\ell$, we compute a probability for label ℓ using another linear layer and a sigmoid transformation:

$$\hat{y}_\ell = \sigma(\boldsymbol{\beta}_\ell^\top \boldsymbol{v}_\ell + b_\ell), \tag{5}$$

where $\boldsymbol{\beta}_\ell \in \mathbb{R}^{d_c}$ is a vector of prediction weights, and b_ℓ is a scalar offset. The overall model is illustrated in Figure 1.

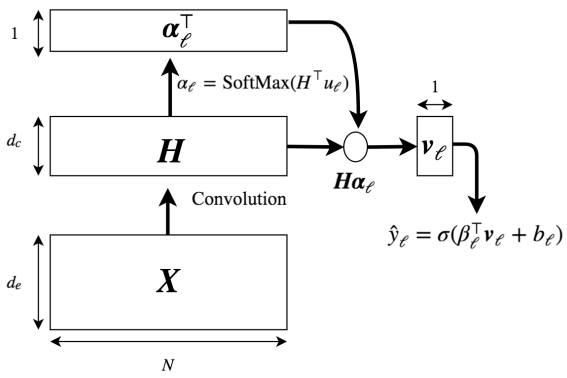

Figure 1: CAML architecture with per-label attention shown for one label. In a max-pooling architecture, $\boldsymbol{H}$ is mapped directly to the vector $\boldsymbol{v}_\ell$ by maximizing over each dimension.

2.4 Training

The training procedure minimizes the binary cross-entropy loss,

$$L_{\text{BCE}}(\boldsymbol{X}, \boldsymbol{y}) = -\sum_{\ell=1}^{\mathcal{L}} y_\ell \log(\hat{y}_\ell) + (1 - y_\ell) \log(1 - \hat{y}_\ell), \tag{6}$$

plus the L2 norm of the model weights, using the Adam optimizer (Kingma and Ba, 2015).

2.5 Embedding label descriptions

Due to the dimensionality of the label space, many codes are rarely observed in the labeled data. To improve performance on these codes, we use text descriptions of each code from the World Health Organization (2016). Examples can be found in Table 1, next to the code numbers. We use these descriptions to build a secondary module in our network that learns to embed them as vectors. These vectors are then used as the target of regularization on the model parameters $\boldsymbol{\beta}_\ell$. If code ℓ is rarely observed in the training data, this regularizer will encourage its parameters to be similar to those of other codes with similar descriptions.

The code embedding module consists of a max-pooling CNN architecture. Let $\boldsymbol{z}_\ell$ be a max-pooled vector, obtained by passing the description for code ℓ into the module. Let n_y be the number of true labels in a training example. We add the following regularizing objective to our loss L,

$$L(\boldsymbol{X}, \boldsymbol{y}) = L_{\text{BCE}} + \lambda \frac{1}{n_y} \sum_{\ell : y_\ell = 1}^{\mathcal{L}} \|\boldsymbol{z}_\ell - \boldsymbol{\beta}_\ell\|_2, \tag{7}$$

where λ is a tradeoff hyperparameter that calibrates the performance of the two objectives. We call this model variant Description Regularized-CAML (DR-CAML).

3 Evaluation of code prediction

This section evaluates the accuracy of code prediction, comparing our models against several competitive baselines.

3.1 Datasets

MIMIC-III (Johnson et al., 2016) is an open-access dataset of text and structured records from a hospital ICU. Following previous work, we focus on discharge summaries, which condense information about a stay into a single document. In MIMIC-III, some admissions have addenda to their summary, which we concatenate to form one document.

Each admission is tagged by human coders with a set of ICD-9 codes, describing both diagnoses and procedures which occurred during the patient's stay. There are 8,921 unique ICD-9 codes present in our datasets, including 6,918 diagnosis codes and 2,003 procedure codes. Some patients have multiple admissions and therefore multiple discharge summaries; we split the data by patient ID, so that no patient appears in both the training and test sets.

In this full-label setting, we use a set of 47,724 discharge summaries from 36,998 patients for training, with 1,632 summaries and 3,372 summaries for validation and testing, respectively.

Secondary evaluations For comparison with prior work, we also follow Shi et al. (2017) and train and evaluate on a label set consisting of the 50 most frequent labels. In this setting, we filter each dataset down to the instances that have at least one of the top 50 most frequent codes, and subset the training data to equal the size of the training set of Shi et al. (2017), resulting in 8,067 summaries for training, 1,574 for validation, and 1,730 for testing.

We also run experiments with the MIMIC-II dataset, to compare with prior work by Baumel et al. (2018) and Perotte et al. (2013). We use the train/test split of Perotte et al. (2013), which consists of 20,533 training examples and 2,282 testing examples. Detailed statistics for the three settings are summarized in Table 2.

Preprocessing We remove tokens that contain no alphabetic characters (e.g., removing "500" but keeping "250mg"), lowercase all tokens, and replace tokens that appear in fewer than three training documents with an 'UNK' token. We pretrain word embeddings of size $d_e = 100$ using the word2vec CBOW method (Mikolov et al., 2013) on the preprocessed text from all discharge summaries. All documents are truncated to a maximum length of 2500 tokens.

3.2 Systems

We compare against the following baselines:

- a single-layer one-dimensional convolutional neural network (Kim, 2014);
- a bag-of-words logistic regression model;
- a bidirectional gated recurrent unit (Bi-GRU).[3]

For the CNN and Bi-GRU, we initialize the embedding weights using the same pretrained word2vec vectors that we use for the CAML models. All neural models are implemented using PyTorch[4]. The logistic regression model consists of $|\mathcal{L}|$ binary one-vs-rest classifiers acting on unigram bag-of-words features for all labels present in the training data. If a label is not present in the training data, the model will never predict it in the held-out data.

Parameter tuning We tune the hyperparameters of the CAML model and the neural baselines using the Spearmint Bayesian optimization package (Snoek et al., 2012; Swersky et al., 2013).[5] We allow Spearmint to sample parameter values for the L2 penalty on the model weights ρ and learning rate η, as well as filter size k, number of filters d_c, and dropout probability q for the convolutional models, and number of hidden layers s of dimension v for the Bi-GRU, using precision@8 on the MIMIC-III full-label validation set as the performance measure. We use these parameters for DR-CAML as well, and port the optimized parameters to the MIMIC-II full-label and MIMIC-III 50-label models, and manually fine-tune the learning rate in these settings. We select λ for DR-CAML based on pilot experiments on the validation sets. Hyperparameter tuning is summarized in Table 3. Convolutional models are trained with dropout after the

[3] Our pilot experiments found that GRU was stronger than long short-term memory (LSTM) for this task.

embedding layer. We use a fixed batch size of 16 for all models and datasets. Models are trained with early stopping on the validation set; training terminates after the precision@8 does not improve for 10 epochs, and the model at the time of the highest precision@8 is used on the test set.

3.3 Evaluation Metrics

To facilitate comparison with both future and prior work, we report a variety of metrics, focusing on the micro-averaged and macro-averaged F1 and area under the ROC curve (AUC). Micro-averaged values are calculated by treating each (text, code) pair as a separate prediction. Macro-averaged values, while less frequently reported in the multi-label classification literature, are calculated by averaging metrics computed per-label. For recall, the metrics are distinguished as follows:

$$\text{Micro-R} = \frac{\sum_{\ell=1}^{|\mathcal{L}|} \text{TP}_\ell}{\sum_{\ell=1}^{|\mathcal{L}|} \text{TP}_\ell + \text{FN}_\ell} \tag{8}$$

$$\text{Macro-R} = \frac{1}{|\mathcal{L}|} \sum_{\ell=1}^{|\mathcal{L}|} \frac{\text{TP}_\ell}{\text{TP}_\ell + \text{FN}_\ell}, \tag{9}$$

where TP denotes true positive examples and FN denotes false negative examples. Precision is computed analogously. The macro-averaged metrics place much more emphasis on rare label prediction.

We also report precision at n (denoted as 'P@n'), which is the fraction of the n highest-scored labels that are present in the ground truth. This is motivated by the potential use case as a decision support application, in which a user is presented with a fixed number of predicted codes to review. In such a case, it is more suitable to select a model with high precision than high recall. We choose $n = 5$ and $n = 8$ to compare with prior work (Vani et al., 2017; Prakash et al., 2017). For the MIMIC-III full label setting, we also compute precision@15, which roughly corresponds to the average number of codes in MIMIC-III discharge summaries (Table 2).

3.4 Results

Our main quantitative evaluation involves predicting the full set of ICD-9 codes based on the text of the MIMIC-III discharge summaries. These results are shown in Table 4. The CAML model gives the strongest results on all metrics. Attention yields substantial improvements over the "vanilla" convolutional neural network (CNN). The recurrent Bi-GRU architecture is comparable to the vanilla CNN, and the logistic regression baseline is substantially worse than all neural architectures. The best-performing CNN model has 9.86M tunable parameters, compared with 6.14M tunable parameters for CAML. This is due to the hyperparameter search preferring a larger number of filters for the CNN. Finally, we observe that the DR-CAML performs worse on most metrics than CAML, with a tuned regularization coefficient of $\lambda = 0.01$.

Among prior work, only Scheurwegs et al. (2017) evaluate on the full ICD-9 code set for MIMIC-III. Their reported results distinguished between diagnosis codes and procedure codes. The CAML models are stronger on both sets. Additionally, our method does not make use of any external information or structured data, while

	AUC		F1				P@n	
Model	Macro	Micro	Macro	Micro	Diag	Proc	8	15
Scheurwegs et. al (2017)	–	–	–	–	0.428	0.555	–	–
Logistic Regression	0.561	0.937	0.011	0.272	0.242	0.398	0.542	0.411
CNN	0.806	0.969	0.042	0.419	0.402	0.491	0.581	0.443
Bi-GRU	0.822	0.971	0.038	0.417	0.393	0.514	0.585	0.445
CAML	0.895	**0.986***	**0.088**	**0.539***	**0.524***	**0.609***	**0.709***	**0.561***
DR-CAML	**0.897**	0.985	0.086	0.529	0.515	0.595	0.690	0.548

Table 4: Results on MIMIC-III full, 8922 labels. Here, "Diag" denotes Micro-F1 performance on diagnosis codes only, and "Proc" denotes Micro-F1 performance on procedure codes only. Here and in all tables, (*) by the bold (best) result indicates significantly improved results compared to the next best result, $p < 0.001$.

Scheurwegs et al. use structured data and various medical ontologies in their text representation.

We feel that precision@8 is the most informative of the metrics, as it measures the ability of the system to return a small high-confidence subset of codes. Even with a space of thousands of labels, our models achieve relatively high precision: of the eight most confident predictions, on average 5.5 are correct. It is also apparent how difficult it is to achieve high Macro-F1 scores, due to the metric's emphasis on rare-label performance. To put these results in context, a hypothetical system that performs perfectly on the 500 most common labels, and ignores all others, would achieve a Macro-F1 of 0.052 and a Micro-F1 of 0.842.

Secondary evaluations To compare with prior published work, we also evaluate on the 50 most common codes in MIMIC-III (Table 5), and on MIMIC-II (Table 6). We report DR-CAML results on the 50-label setting of MIMIC-III with $\lambda = 10$, and on MIMIC-II with $\lambda = 0.1$, which were determined by grid search on a validation set. The other hyperparameters were left at the settings for the main MIMIC-III evaluation, as described in Table 3. In the 50-label setting of MIMIC-III, we see strong improvement over prior work in all reported metrics, as well as against the baselines, with the exception of precision@5, on which the CNN baseline performs best. We hypothesize that this is because the relatively large value of $k = 10$ for CAML leads to a larger network that is more suited to larger datasets; tuning CAML's hyperparameters on this dataset would be expected to improve performance on all metrics. Baumel et al. (2018) additionally report a micro-F1 score of 0.407 by training on MIMIC-III, and evaluating on MIMIC-II. Our model achieves better performance using only the (smaller) MIMIC-II training set, leaving this alternative training protocol for future work.

4 Evaluation of Interpretability

We now evaluate the explanations generated by CAML's attention mechanism, in comparison with three alternative heuristics. A physician was presented with explanations from four methods, using a random sample of 100 predicted codes from the MIMIC-III full-label test set. The most important k-gram from each method was extracted, along with a window of five words on either side for context. We select $k = 4$ in this setting to emulate a span of attention over words likely to be given by a human reader. Examples can be found in Table 1. Observe that the snippets may overlap in multiple words. We prompted the evaluator to select all text snippets which he felt adequately explained the presence of a given code, provided the code and its description, with the option to distinguish snippets as "highly informative" should they be found particularly informative over others.

4.1 Extracting informative text snippets

CAML The attention mechanism allows us to extract k-grams from the text that are most influential in the prediction of each label, by taking the argmax of the SoftMax output $\boldsymbol{\alpha}_\ell$.

Max-pooling CNN We select the k-grams that provide the maximum value selected by max-pooling at least once and weighting by the final layer weights. Defining an argmax vector $\boldsymbol{a}$ which

Model	AUC Macro	AUC Micro	F1 Macro	F1 Micro	P@5

CAML	0.875	0.909	0.532	0.614	0.609
DR-CAML	**0.884***	**0.916**	**0.576***	**0.633**	0.618

Table 5: Results on MIMIC-III, 50 labels.

results from the max-pooling step as

$$\boldsymbol{a}_i = \underset{j \in \{1,\ldots,m-k+1\}}{\arg\max} (\boldsymbol{H}_{ij}), \tag{10}$$

we can compute the importance of position i for label ℓ,

$$\alpha_{i\ell} = \sum_{j:\boldsymbol{a}_j=i}^{d_c} \beta_{\ell,j}. \tag{11}$$

We then select the most important k-gram for a given label as $\arg\max_i \alpha_{i\ell}$.

Logistic regression The informativeness of each k-gram with respect to label ℓ is scored by the sum of the coefficients of the weight matrix for ℓ, over the words in the k-gram. The top-scoring k-gram is then returned as the explanation.

Code descriptions Finally, we calculate a word similarity metric between each stemmed k-gram and the stemmed ICD-9 code description. We compute the idf-weighted cosine similarity, with idf weights calculated on the corpus consisting of all notes and relevant code descriptions. We then select the argmax over k-grams in the document, breaking ties by selecting the first occurrence. We remove those note-label pairs for which no k-gram has a score greater than 0, which gives an "unfair" advantage to this baseline.

4.2 Results

The results of the interpretability evaluation are presented in Table 7. Our model selects the greatest number of "highly informative" explanations, and selects more "informative" explanations than both the CNN baseline and the logistic regression model. While the cosine similarity metric also performs well, the examples in Table 1 demonstrate the strengths of CAML in extracting text snippets in line with more intuitive explanations for the presence of a code. As noted above, there exist some cases, which we exclude, where the cosine similarity method is unable to provide any explanation, because no k-grams in a note have a nonzero similarity for a given label description. This occurs for about 12% of all note-label pairs in the test set.

5 Related Work

Attentional Convolution for NLP CNNs have been successfully applied to tasks such as sentiment classification (Kim, 2014) and language modeling (Dauphin et al., 2017). Our work combines convolution with attention (Bahdanau et al., 2015; Yang et al., 2016) to select the most relevant parts of the discharge summary. Other recent work has combined convolution and attention (e.g., Allamanis et al., 2016; Yin et al., 2016; dos Santos et al., 2016; Yin and Schütze, 2017). Our attention mechanism is most similar to those of Yang et al. (2016) and Allamanis et al. (2016), in that we use context vectors to compute attention over specific locations in the text. Our work differs in that we compute separate attention weights for each label in our label space, which is better tuned to our goal of selecting locations in a document which are most important for predicting specific labels.

Automatic ICD coding ICD coding is a long-standing task in the medical informatics community, which has been approached with machine learning and handcrafted methods (Scheurwegs et al., 2015). Many recent approaches, like ours, use unstructured text data as the only source of information (e.g., Kavuluru et al., 2015; Subotin and Davis, 2014), though some incorporates struc-

tured data as well (e.g., Scheurwegs et al., 2017; Wang et al., 2016). Most previous methods have either evaluated only on a strict subset of the full ICD label space (Wang et al., 2016), relied on datasets that focus on a subset of medical scenarios (Zhang et al., 2017), or evaluated on data that are not publicly available, making direct comparison difficult (Subotin and Davis, 2016). A recent shared task for ICD-10 coding focused on coding of death certificates in English and French (Névéol et al., 2017). This dataset also contains shorter documents than those we consider, with an average of 18 tokens per certificate in the French corpus. We use the open-access MIMIC datasets containing de-identified, general-purpose records of intensive care unit stays at a single hospital.

Perotte et al. (2013) use "flat" and "hierarchical" SVMs; the former treats each code as an individual prediction, while the latter trains on child codes only if the parent code is present, and predicts on child codes only if the parent code was positively predicted. Scheurwegs et al. (2017) use a feature selection approach to ICD-9 and ICD-10 classification, incorporating structured and unstructured text information from EHRs. They evaluate over various medical specialties and on the MIMIC-III dataset. We compare directly to their results on the full label set of MIMIC-III.

Other recent approaches have employed neural network architectures. Baumel et al. (2018) apply recurrent networks with hierarchical sentence and word attention (the HA-GRU) to classify ICD9 diagnosis codes while providing insights into the model decision process. Similarly, Shi et al. (2017) applied character-aware LSTMs to generate sentence representations from specific subsections of discharge summaries, and apply attention to form a soft matching between the representations and the top 50 codes. Prakash et al. (2017) use memory networks that draw from discharge summaries as well as Wikipedia, to predict top-50 and top-100 codes. Another recent neural architecture is the Grounded Recurrent Neural Network (Vani et al., 2017), which employs a modified GRU with dimensions dedicated to predicting the presence of individual labels. We compare directly with published results from all of these papers, except Vani et al. (2017), who evaluate on only a 5000 code subset of ICD-9. Empirically, the CAML architecture proposed in this paper yields stronger results across all experimental conditions. We attribute these improvements to the attention mechanism, which focuses on the most critical features for each code, rather than applying a uniform pooling operation for all codes. We also observed that convolution-based models are at least as effective, and significantly more computationally efficient, than recurrent neural networks such as the Bi-GRU.

Explainable text classification A goal of this work is that the code predictions be explainable from features of the text. Prior work has also em-

phasized explainability. Lei et al. (2016) model "rationales" through a latent variable, which tags each word as relevant to the document label. Li et al. (2016) compute the salience of individual words by the derivative of the label score with respect to the word embedding. Ribeiro et al. (2016) use submodular optimization to select a subset of features that closely approximate a specific classification decision (this work is also notable for extensive human evaluations). In comparison to these approaches, we employ a relatively simple attentional architecture; this simplicity is motivated by the challenge of scaling to multi-label classification with thousands of possible labels. Other prior work has emphasized the use of attention for highlighting salient features of the text (e.g., Rush et al., 2015; Rocktäschel et al., 2016), although these papers did not perform human evaluations of the interpretability of the features selected by the attention mechanism.

6 Conclusions and Future Work

We present CAML, a convolutional neural network for multi-label document classification, which employs an attention mechanism to adaptively pool the convolution output for each label, learning to identify highly-predictive locations for each label. CAML yields strong improvements over previous metrics on several formulations of the ICD-9 code prediction task, while providing satisfactory explanations for its predictions. Although we focus on a clinical setting, CAML is extensible without modification to other multi-label document tagging tasks, including ICD-10 coding. We see a number of directions for future work. From the linguistic side, we plan to integrate the document structure of discharge summaries in MIMIC-III, and to better handle non-standard writing and other sources of out-of-vocabulary tokens. From the application perspective, we plan to build models that leverage hierarchy of ICD codes (Choi et al., 2016), and to attempt the more difficult task of predicting diagnosis and treatment codes for *future* visits from discharge summaries.

Acknowledgments Helpful feedback was provided by the anonymous reviewers, and by the members of the Georgia Tech Computational Linguistics lab. The project was partially supported by project HDTRA1-15-1-0019 from the Defense Threat Reduction Agency, by the National Science Foundation under awards IIS-1418511 and CCF-1533768, by the National Institutes of Health under awards 1R01MD011682-01 and R56HL138415, by Children's Healthcare of Atlanta, and by UCB.

Abstract

This paper introduces the Multi-Genre Natural Language Inference (MultiNLI) corpus, a dataset designed for use in the development and evaluation of machine learning models for sentence understanding. At 433k examples, this resource is one of the largest corpora available for natural language inference (a.k.a. *recognizing textual entailment*), improving upon available resources in both its coverage and difficulty. MultiNLI accomplishes this by offering data from ten distinct genres of written and spoken English, making it possible to evaluate systems on nearly the full complexity of the language, while supplying an explicit setting for evaluating cross-genre domain adaptation. In addition, an evaluation using existing machine learning models designed for the Stanford NLI corpus shows that it represents a substantially more difficult task than does that corpus, despite the two showing similar levels of inter-annotator agreement.

1 Introduction

Many of the most actively studied problems in NLP, including question answering, translation, and dialog, depend in large part on natural language understanding (NLU) for success. While there has been a great deal of work that uses representation learning techniques to pursue progress on these applied NLU problems directly, in order for a representation learning model to fully succeed at one of these problems, it must simultaneously succeed both at NLU, and at one or more additional hard machine learning problems like structured prediction or memory access. This makes it difficult to accurately judge the degree to which current models extract reasonable representations of language meaning in these settings.

The task of natural language inference (NLI) is well positioned to serve as a benchmark task for research on NLU. In this task, also known as *recognizing textual entailment* (Cooper et al., 1996; Fyodorov et al., 2000; Condoravdi et al., 2003; Bos and Markert, 2005; Dagan et al., 2006; MacCartney and Manning, 2009), a model is presented with a pair of sentences—like one of those in Figure 1—and asked to judge the relationship between their meanings by picking a label from a small set: typically ENTAILMENT, NEUTRAL, and CONTRADICTION. Succeeding at NLI does not require a system to solve any difficult machine learning problems except, crucially, that of extracting effective and thorough representations for the meanings of sentences (i.e., their lexical and compositional semantics). In particular, a model must handle phenomena like lexical entailment, quantification, coreference, tense, belief, modality, and lexical and syntactic ambiguity.

As the only large human-annotated corpus for NLI currently available, the Stanford NLI Corpus (SNLI; Bowman et al., 2015) has enabled a good deal of progress on NLU, serving as a major benchmark for machine learning work on sentence understanding and spurring work on core representation learning techniques for NLU, such as attention (Wang and Jiang, 2016; Parikh et al., 2016), memory (Munkhdalai and Yu, 2017), and the use of parse structure (Mou et al., 2016b; Bowman et al., 2016; Chen et al., 2017). However, SNLI falls short of providing a sufficient testing ground for machine learning models in two ways.

Proceedings of NAACL-HLT 2018, pages 1112–1122
New Orleans, Louisiana, June 1 - 6, 2018.

Met my first girlfriend that way.	FACE-TO-FACE **contradiction** C C N C	I didn't meet my first girlfriend until later.

someone else noticed it and i said well i guess that's true and it was somewhat melodious in other words it wasn't just you know it was really funny	TELEPHONE **contradiction** C C C C	No one noticed and it wasn't funny at all.

Table 1: Randomly chosen examples from the development set of our new corpus, shown with their genre labels, their selected gold labels, and the validation labels (abbreviated E, N, C) assigned by individual annotators.

First, the sentences in SNLI are derived from only a single text genre—image captions—and are thus limited to descriptions of concrete visual scenes, rendering the hypothesis sentences used to describe these scenes short and simple, and rendering many important phenomena—like temporal reasoning (e.g., *yesterday*), belief (e.g., *know*), and modality (e.g., *should*)—rare enough to be irrelevant to task performance. Second, because of these issues, SNLI is not sufficiently demanding to serve as an effective benchmark for NLU, with the best current model performance falling within a few percentage points of human accuracy and limited room left for fine-grained comparisons between strong models.

This paper introduces a new challenge dataset, the Multi-Genre NLI Corpus (MultiNLI), whose chief purpose is to remedy these limitations by making it possible to run large-scale NLI evaluations that capture more of the complexity of modern English. While its size (433k pairs) and mode of collection are modeled closely on SNLI, unlike that corpus, MultiNLI represents both written and spoken speech in a wide range of styles, degrees of formality, and topics.

Our chief motivation in creating this corpus is to provide a benchmark for ambitious machine learning research on the core problems of NLU, but we are additionally interested in constructing a corpus that facilitates work on domain adaptation and cross-domain transfer learning. These techniques—which use labeled training data for a source domain, and aim to train a model that performs well on test data from a target domain with a different distribution—have resulted in gains across many tasks (Daume III and Marcu, 2006; Ben-David et al., 2007), including sequence and part-of-speech tagging (Blitzer et al., 2006; Peng and Dredze, 2017). Moreover, in application areas outside NLU, artificial neural network techniques have made it possible to train general-purpose feature extractors that, with no or minimal retraining, can extract useful features for a variety of styles of data (Krizhevsky et al., 2012; Zeiler and Fergus, 2014; Donahue et al., 2014). However, attempts to bring this kind of general purpose representation learning to NLU have seen only very limited success (see, for example, Mou et al., 2016a). Nearly all successful applications of representation learning to NLU have involved models that are trained on data closely resembling the target evaluation data in both task and style. This fact limits the usefulness of these tools for problems involving styles of language not represented in large annotated training sets.

With this in mind, we construct MultiNLI so as to make it possible to explicitly evaluate models both on the quality of their sentence representations within the training domain and on their ability to derive reasonable representations in unfamiliar domains. The corpus is derived from ten different genres of written and spoken English, which are collectively meant to approximate the full diversity of ways in which modern standard

This task will involve reading a line from a non-fiction article and writing three sentences that relate to it. The line will describe a situation or event. Using only this description and what you know about the world:

- Write one sentence that is definitely correct about the situation or event in the line.
- Write one sentence that might be correct about the situation or event in the line.
- Write one sentence that is definitely incorrect about the situation or event in the line.

Figure 1: The main text of a prompt (truncated) that was presented to our annotators. This version is used for the written non-fiction genres.

American English is used. All of the genres appear in the test and development sets, but only five are included in the training set. Models thus can be evaluated on both the *matched* test examples, which are derived from the same sources as those in the training set, and on the *mismatched* examples, which do not closely resemble any of those seen at training time.

2 The Corpus

2.1 Data Collection

The data collection methodology for MultiNLI is similar to that of SNLI: We create each sentence pair by selecting a premise sentence from a preexisting text source and asking a human annotator to compose a novel sentence to pair with it as a hypothesis. This section discusses the sources of our premise sentences, our collection method for hypotheses, and our validation (relabeling) strategy.

Premise Text Sources The MultiNLI premise sentences are derived from ten sources of freely available text which are meant to be maximally diverse and roughly represent the full range of American English. We selected nine sources from the second release of the Open American National Corpus (OANC; Fillmore et al., 1998; Macleod et al., 2000; Ide and Macleod, 2001; Ide and Suderman, 2006, downloaded 12/2016[1]), balancing the volume of source text roughly evenly across genres, and avoiding genres with content that would be too difficult for untrained annotators.

OANC data constitutes the following nine genres: transcriptions from the Charlotte Narrative and Conversation Collection of two-sided, in-person conversations that took place in the early 2000s (FACE-TO-FACE); reports, speeches, letters, and press releases from public domain government websites (GOVERNMENT); letters from the Indiana Center for Intercultural Communication of Philanthropic Fundraising Discourse written in the late 1990s–early 2000s (LETTERS); the public report from the National Commission on Terrorist Attacks Upon the United States released on July 22, 2004[2] (9/11); five non-fiction works on the textile industry and child development published by the Oxford University Press (OUP); popular culture articles from the archives of Slate Magazine (SLATE) written between 1996–2000; transcriptions from University of Pennsylvania's Linguistic Data Consortium Switchboard corpus of two-sided, telephone conversations that took place in 1990 or 1991 (TELEPHONE); travel guides published by Berlitz Publishing in the early 2000s (TRAVEL); and short posts about linguistics for non-specialists from the Verbatim archives written between 1990 and 1996 (VERBATIM).

For our tenth genre, FICTION, we compile several freely available works of contemporary fiction written between 1912 and 2010, spanning various genres, including mystery (*The Mysterious Affair at Styles*,[3] Christie, 1921; *The Secret Adversary*,[4] Christie, 1922; *Murder in the Gun Room*,[5] Piper, 1953), humor (*Password Incorrect*,[6] Name, 2008), western (*Rebel Spurs*,[7] Norton, 1962), science fiction (*Seven Swords*,[8] Shea, 2008; *Living History*,[9] Essex, 2016; *The Sky Is Falling*,[10] Del Rey, 1973; *Youth*,[11] Asimov, May 1952), and adventure (*Captain Blood*,[12] Sabatini, 1922).

We construct premise sentences from these ten source texts with minimal preprocessing; unique the sentences within genres, exclude very short

sentences (under eight characters), and manually remove certain types of non-narrative writing, such as mathematical formulae, bibliographic references, and lists.

Although SNLI is collected in largely the same way as MultiNLI, and is also permissively licensed, we do not include SNLI in the MultiNLI corpus distribution. SNLI can be appended and treated as an unusually large additional CAPTIONS genre, built on image captions from the Flickr30k corpus (Young et al., 2014).

Hypothesis Collection To collect a sentence pair, we present a crowdworker with a sentence from a source text and ask them to compose three novel sentences (the hypotheses): one which is necessarily true or appropriate whenever the premise is true (paired with the premise and labeled ENTAILMENT), one which is necessarily false or inappropriate whenever the premise is true (CONTRADICTION), and one where neither condition applies (NEUTRAL). This method of data collection ensures that the three classes will be represented equally in the raw corpus.

The prompts that surround each premise sentence during hypothesis collection are slightly tailored to fit the genre of that premise sentence. We pilot these prompts prior to data collection to ensure that the instructions are clear and that they yield hypothesis sentences that fit the intended meanings of the three classes. There are five unique prompts in total: one for written non-fiction genres (SLATE, OUP, GOVERNMENT, VERBATIM, TRAVEL; Figure 1), one for spoken genres (TELEPHONE, FACE-TO-FACE), one for each of the less formal written genres (FICTION, LETTERS), and a specialized one for 9/11, tailored to fit its potentially emotional content. Each prompt is accompanied by example premises and hypothesis that are specific to each genre.

Below the instructions, we present three text fields—one for each label—followed by a field for reporting issues, and a link to the frequently asked questions (FAQ) page. We provide one FAQ page per prompt. FAQs are modeled on their SNLI counterparts (supplied by the authors of that work) and include additional curated examples, answers to genre-specific questions arising from our pilot phase, and information about logistical concerns like payment.

For both hypothesis collection and validation, we present prompts to annotators using Hybrid (gethybrid.io), a crowdsoucring platform similar to the Amazon Mechanical Turk platform used for SNLI. We used this platform to hire an organized group of workers. 387 annotators contributed through this group, and at no point was any identifying information about them, including demographic information, available to the authors.

Statistic	SNLI	MultiNLI
Pairs w/ unanimous gold label	58.3%	58.2%
Individual label = gold label	89.0%	88.7%
Individual label = author's label	85.8%	85.2%
Gold label = author's label	91.2%	92.6%
Gold label ≠ author's label	6.8%	5.6%
No gold label (no 3 labels match)	2.0%	1.8%

Table 2: Key validation statistics for SNLI (copied from Bowman et al., 2015) and MultiNLI.

Validation We perform an additional round of annotation on test and development examples to ensure accurate labelling. The validation phase follows the same procedure used for SICK (Marelli et al., 2014b) and SNLI: Workers are presented with pairs of sentences and asked to supply a single label (ENTAILMENT, CONTRADICTION, NEUTRAL) for the pair. Each pair is relabeled by four workers, yielding a total of five labels per example. Validation instructions are tailored by genre, based on the main data collection prompt (Figure 1); a single FAQ, modeled after the validation FAQ from SNLI, is provided for reference. In order to encourage thoughtful labeling, we manually label one percent of the validation examples and offer a $1 bonus each time a worker selects a label that matches ours.

For each validated sentence pair, we assign a *gold label* representing a majority vote between the initial label assigned to the pair by the original annotator, and the four additional labels assigned by validation annotators. A small number of examples did not receive a three-vote consensus on any one label. These examples are included in the distributed corpus, but are marked with '–' in the gold label field, and should not be used in standard evaluations. Table 2 shows summary statistics capturing the results of validation, alongside corresponding figures for SNLI. These statistics indicate that the labels included in MultiNLI are about as reliable as those included in SNLI, despite MultiNLI's more diverse text contents.

Genre	#Examples Train	Dev.	Test	#Wds. Prem.	'S' parses Prem.	Hyp.	Agrmt.	Model Acc. ESIM	CBOW
SNLI	*550,152*	*10,000*	*10,000*	*14.1*	*74%*	*88%*	*89.0%*	*86.7%*	*80.6 %*
FICTION	77,348	2,000	2,000	14.4	94%	97%	89.4%	73.0%	67.5%
GOVERNMENT	77,350	2,000	2,000	24.4	90%	97%	87.4%	74.8%	67.5%
SLATE	77,306	2,000	2,000	21.4	94%	98%	87.1%	67.9%	60.6%
TELEPHONE	83,348	2,000	2,000	25.9	71%	97%	88.3%	72.2%	63.7%
TRAVEL	77,350	2,000	2,000	24.9	97%	98%	89.9%	73.7%	64.6%
9/11	0	2,000	2,000	20.6	98%	99%	90.1%	71.9%	63.2%
FACE-TO-FACE	0	2,000	2,000	18.1	91%	96%	89.5%	71.2%	66.3%
LETTERS	0	2,000	2,000	20.0	95%	98%	90.1%	74.7%	68.3%
OUP	0	2,000	2,000	25.7	96%	98%	88.1%	71.7%	62.8%

MultiNLI Overall	**392,702**	**20,000**	**20,000**	**22.3**	**91%**	**98%**	**88.7%**	**72.2%**	**64.7%**

Table 3: Key statistics for the corpus by genre. The first five genres represent the *matched* section of the development and test sets, and the remaining five represent the *mismatched* section. The first three statistics provide the number of examples in each genre. *#Wds. Prem.* is the mean token count among premise sentences. *'S' parses* is the percentage of sentences for which the Stanford Parser produced a parse rooted with an 'S' (sentence) node. *Agrmt.* is the percent of individual labels that match the gold label in validated examples. *Model Acc.* gives the test accuracy for ESIM and CBOW models (trained on either SNLI or MultiNLI), as described in Section 3.

2.2 The Resulting Corpus

Table 1 shows randomly chosen development set examples from the collected corpus. Hypotheses tend to be fluent and correctly spelled, though not all are complete sentences. Punctuation is often omitted. Hypotheses can rely heavily on knowledge about the world, and often don't correspond closely with their premises in syntactic structure.

Unlabeled test data is available on Kaggle for both matched and mismatched sets as competitions that will be open indefinitely; Evaluations on a subset of the test set have previously been conducted with different leaderboards through the RepEval 2017 Workshop (Nangia et al., 2017).

The corpus is available in two formats—tab separated text and JSON Lines (`jsonl`), following SNLI. For each example, premise and hypothesis strings, unique identifiers for the pair and prompt, and the following additional fields are specified:

- `gold_label`: label used for classification. In examples rejected during the validation process, the value of this field will be '–'.
- `sentence{1,2}_parse`: Each sentence as parsed by the Stanford PCFG Parser 3.5.2 (Klein and Manning, 2003).
- `sentence{1,2}_binary_parse`: parses in unlabeled binary-branching format.
- `label[1]`: The label assigned during the creation of the sentence pair. In rare cases this may be different from `gold_label`, if a consensus of annotators chose a different label during the validation phase.
- `label[2...5]`: The four labels assigned during validation by individual annotators to each development and test example. These fields will be empty for training examples.

The current version of the corpus is freely available at `nyu.edu/projects/bowman/multinli/` for typical machine learning uses, and may be modified and redistributed. The majority of the corpus is released under the OANC's license, which allows all content to be freely used, modified, and shared under permissive terms. The data in the FICTION section falls under several permissive licenses; *Seven Swords* is available under a Creative Commons Share-Alike 3.0 Unported License, and with the explicit permission of the author, *Living History* and *Password Incorrect* are available under Creative Commons Attribution 3.0 Unported Licenses; the remaining works of fiction are in the public domain in the United States (but may be licensed differently elsewhere).

Partition The distributed corpus comes with an explicit train/test/development split. The test and development sets contain 2,000 randomly selected examples each from each of the genres, resulting in a total of 20,000 examples per set. No premise sentence occurs in more than one set.

Train	Model	SNLI	MNLI Match.	MNLI Mis.
	Most freq.	34.3	36.5	35.6
SNLI	CBOW	80.6	-	-
	BiLSTM	81.5	-	-
	ESIM	**86.7**	-	-
MNLI	CBOW	51.5	64.8	64.5
	BiLSTM	50.8	66.9	66.9
	ESIM	60.7	**72.3**	**72.1**
MNLI+ SNLI	CBOW	74.7	65.2	64.6
	BiLSTM	74.0	67.5	67.1
	ESIM	79.7	**72.4**	**71.9**

Table 4: Test set accuracies (%) for all models; *Match.* represents test set performance on the MultiNLI genres that are also represented in the training set, *Mis.* represents test set performance on the remaining ones; *Most freq.* is a trivial 'most frequent class' baseline.

Statistics Table 3 shows some additional statistics. Premise sentences in MultiNLI tend to be longer (max 401 words, mean 22.3 words) than their hypotheses (max 70 words, mean 11.4 words), and much longer, on average, than premises in SNLI (mean 14.1 words); premises in MultiNLI also tend to be parsed as complete sentences at a much higher rate on average (91%) than their SNLI counterparts (74%). We observe that the two spoken genres differ in this—with FACE-TO-FACE showing more complete sentences (91%) than TELEPHONE (71%)—and speculate that the lack of visual feedback in a telephone setting may result in a high incidence of interrupted or otherwise incomplete sentences.

Hypothesis sentences in MultiNLI generally cannot be derived from their premise sentences using only trivial editing strategies. While 2.5% of the hypotheses in SNLI differ from their premises by deletion, only 0.9% of those in MultiNLI (170 examples total) are constructed in this way. Similarly, in SNLI, 1.6% of hypotheses differ from their premises by addition, substitution, or shuffling a single word, while in MultiNLI this only happens in 1.2% of examples. The percentage of hypothesis-premise pairs with high token overlap (>37%) was comparable between MultiNLI (30% of pairs) and SNLI (29%). These statistics suggest that MultiNLI's annotations are comparable in quality to those of SNLI.

3 Baselines

To test the difficulty of the corpus, we experiment with three neural network models. The first is a simple continuous bag of words (CBOW) model in which each sentence is represented as the sum of the embedding representations of its words. The second computes representations by averaging the states of a bidirectional LSTM RNN (BiLSTM; Hochreiter and Schmidhuber, 1997) over words. For the third, we implement and evaluate Chen et al.'s Enhanced Sequential Inference Model (ESIM), which is roughly tied for the state of the art on SNLI at the time of writing. We use the base ESIM without ensembling with a TreeLSTM (as in the 'HIM' runs in that work).

The first two models produce separate vector representations for each sentence and compute label predictions for pairs of representations. To do this, they concatenate the representations for premise and hypothesis, their difference, and their element-wise product, following Mou et al. (2016b), and pass the result to a single tanh layer followed by a three-way softmax classifier.

All models are initialized with 300D reference GloVe vectors (840B token version; Pennington et al., 2014). Out-of-vocabulary (OOV) words are initialized randomly and word embeddings are fine-tuned during training. The models use 300D hidden states, as in most prior work on SNLI. We use Dropout (Srivastava et al., 2014) for regularization. For ESIM, we use a dropout rate of 0.5, following the paper. For CBOW and BiLSTM models, we tune Dropout on the SNLI development set and find that a drop rate of 0.1 works well. We use the Adam (Kingma and Ba, 2015) optimizer with default parameters. Code is available at `github.com/nyu-mll/multiNLI/`.

We train models on SNLI, MultiNLI, and a mixture; Table 4 shows the results. In the mixed setting, we use the full MultiNLI training set and randomly select 15% of the SNLI training set at each epoch, ensuring that each available genre is seen during training with roughly equal frequency.

We also train a separate CBOW model on each individual genre to establish the degree to which simple models already allow for effective transfer across genres, using a dropout rate of 0.2. When training on SNLI, a single random sample of 15% of the original training set is used. For each genre represented in the training set, the model that performs best on it was trained on that genre; a model trained only on SNLI performs worse on every genre than comparable models trained on any genre from MultiNLI.

Models trained on a single genre from MultiNLI perform well on similar genres; for example, the model trained on TELEPHONE attains the best accuracy (63%) on FACE-TO-FACE, which was nearly one point better than it received on itself. SLATE seems to be a difficult and relatively unusual genre and performance on it is relatively poor in this setting; when averaging over runs trained on SNLI and all genres in the matched section of the training set, average performance on SLATE was only 57.5%. Sentences in SLATE cover a wide range of topics and phenomena, making it hard to do well on, but also forcing models trained on it be broadly capable; the model trained on SLATE achieves the highest accuracy of any model on 9/11 (55.6%) and VERBATIM (57.2%), and relatively high accuracy on TRAVEL (57.4%) and GOVERNMENT (58.3%). We also observe that our models perform similarly on both the matched and mismatched test sets of MultiNLI. We expect genre mismatch issues to become more conspicuous as models are developed that can better fit MultiNLI's training genres.

To evaluate the contribution of sentence length to corpus difficulty, we binned premises and hypotheses by length in 25-word increments for premises and 10-word increments for hypotheses. Using the ESIM model, our strong baseline, we find a small effect (stronger for matched than mismatched) of premise length on model accuracy: accuracy decreases slightly as premise sentences increase in length. We find no effect of hypothesis length on accuracy.

4 Discussion and Analysis

4.1 Data Collection

In data collection for NLI, different annotator decisions about the coreference between entities and events across the two sentences in a pair can lead to very different assignments of pairs to labels (de Marneffe et al., 2008; Marelli et al., 2014a; Bowman et al., 2015). Drawing an example from Bowman et al., the pair *"a boat sank in the Pacific Ocean"* and *"a boat sank in the Atlantic Ocean"* can be labeled either CONTRADICTION or NEUTRAL depending on (among other things) whether the two mentions of boats are assumed to refer to the same entity in the world. This uncertainty can present a serious problem for inter-annotator agreement, since it is not clear that it is possible to define an explicit set of rules around coreference that would be easily intelligible to an untrained annotator (or any non-expert).

Bowman et al. attempt to avoid this problem by using an annotation prompt that is highly dependent on the concreteness of image descriptions; but, as we engage with the much more abstract writing that is found in, for example, government documents, there is no reason to assume *a priori* that any similar prompt and annotation strategy can work. We are surprised to find that this is not a major issue. Through a relatively straightforward trial-and-error piloting phase, followed by discussion with our annotators, we manage to design prompts for abstract genres that yield high inter-annotator agreement scores nearly identical to those of SNLI (see Table 2). These high scores suggest that our annotators agreed on a single task definition, and were able to apply it consistently across genres.

4.2 Overall Difficulty

As expected, both the increase in the diversity of linguistic phenomena in MultiNLI and its longer average sentence length conspire to make MultiNLI dramatically more difficult than SNLI. Our three baseline models perform better on SNLI than MultiNLI by about 15% when trained on the respective datasets. All three models achieve accuracy above 80% on the SNLI test set when trained only on SNLI. However, when trained on MultiNLI, only ESIM surpasses 70% accuracy on MultiNLI's test sets. When we train models on MultiNLI and downsampled SNLI, we see an expected significant improvement on SNLI, but no significant change in performance on the MultiNLI test sets, suggesting including SNLI in training doesn't drive substantial improvement. These results attest to MultiNLI's difficulty, and with its relatively high inter-annotator agreement, suggest that it presents a problem with substantial headroom for future work.

4.3 Analysis by Linguistic Phenomenon

To better understand the types of language understanding skills that MultiNLI tests, we analyze the collected corpus using a set of annotation tags chosen to reflect linguistic phenomena which are known to be potentially difficult. We use two methods to assign tags to sentences. First, we use the Penn Treebank (PTB; Marcus et al., 1993) part-of-speech tag set (via the included Stanford Parser parses) to automatically isolate sentences

Tag	Dev. Freq. SNLI	Dev. Freq. MultiNLI	Diff.	Most Frequent Label Label	Most Frequent Label %	Model Acc. CBOW	Model Acc. BiLSTM	Model Acc. ESIM
Entire Corpus	100	100	0	entailment	*∼35*	*∼65*	*∼67*	*∼72*
Pronouns (PTB)	34	68	34	entailment	34	66	68	73
Quantifiers	33	63	30	contradiction	36	66	68	73
Modals (PTB)	<1	28	28	entailment	35	65	67	72
Negation (PTB)	5	31	26	contradiction	**48**	67	70	75
WH terms (PTB)	5	30	25	entailment	35	64	65	72
Belief Verbs	<1	19	18	entailment	34	64	67	71
Time Terms	19	36	17	neutral	35	64	66	71
Discourse Mark.	<1	14	14	neutral	34	62	64	70
Presup. Triggers	8	22	14	neutral	34	65	67	73
Compr./Supr.(PTB)	3	17	14	neutral	39	61	63	69
Conditionals	4	15	11	neutral	35	65	68	73
Tense Match (PTB)	62	69	7	entailment	37	67	68	73
Interjections (PTB)	<1	5	5	entailment	36	67	70	75
>20 words	<1	5	5	entailment	**42**	65	67	76

Table 5: Dev. Freq. is the percentage of dev. set examples that include each phenomenon, ordered by greatest difference in frequency of occurrence (Diff.) between MultiNLI and SNLI. Most Frequent Label specifies which label is the most frequent for each tag in the MultiNLI dev. set, and % is its incidence. Model Acc. is the dev. set accuracy (%) by annotation tag for each baseline model (trained on MultiNLI only). (PTB) marks a tag as derived from Penn Treebank-style parser output tags (Marcus et al., 1993).

containing a range of easily-identified phenomena like comparatives. Second, we isolate sentences that contain hand-chosen key words indicative of additional interesting phenomena.

The hand-chosen tag set covers the following phenomena: QUANTIFIERS contains single words with quantificational force (see, for example, Heim and Kratzer, 1998; Szabolcsi, 2010, e.g., *many, all, few, some*); BELIEF VERBS contains sentence-embedding verbs denoting mental states (e.g., *know, believe, think*), including irregular past tense forms; TIME TERMS contains single words with abstract temporal interpretation, (e.g., *then, today*) and month names and days of the week; DISCOURSE MARKERS contains words that facilitate discourse coherence (e.g., *yet, however, but, thus, despite*); PRESUPPOSITION TRIGGERS contains words with lexical presuppositions (Stalnaker, 1974; Schlenker, 2016, e.g., *again, too, anymore*[13]); CONDITIONALS contains the word *if*. Table 5 presents the frequency of the tags in SNLI and MultiNLI, and model accuracy on MultiNLI (trained only on MultiNLI).

The incidence of tags varies by genre; the percentage of sentence pairs containing a particular annotation tag differs by a maximum over 30% across genres. Sentence pairs containing pronouns are predictably common for all genres, with 93% of Government and Face-to-face pairs including at least one. The Telephone genre has the highest percentage of sentence pairs containing one occurrence of negation, WH-words, *belief*-verbs and time terms, Verbatim has the highest percentage of pairs containing quantifiers and conversational pivots, and Letters has the highest percentage of pairs that contain one or more modals. Pairs containing comparatives and/or superlatives, which is the tag that our baseline models perform worst on, are most common in the Oxford University Press genre. Based on this, we conclude that the genres are sufficiently different, because they are not uniform with respect to the percentages of sentence pairs that contain each of the annotation tags.

The distributions of labels within each tagged subset of the corpus roughly mirrors the balanced overall distribution. The most frequent class overall (in this case, ENTAILMENT) occurs with a frequency of roughly one third (see Table 4) in most. Only two annotation tags differ from the baseline percentage of the most frequent class in the corpus by at least 5%: sentences containing negation, and sentences exceeding 20 words. Sentences that contain negation are slightly more likely than average to be labeled CONTRADICTION, reflecting a similar finding in SNLI, while long sentences are slightly more likely to be labeled ENTAILMENT.

None of the baseline models perform substantially better on any tagged set than they do on the corpus overall, with average model accuracies on sentences containing specific tags falling within

[13]Because their high frequency in the corpus, extremely common triggers like *the* were excluded from this tag.

about 3 points of overall averages. Using baseline model test accuracy overall as a metric (see Table 4), our baseline models had the most trouble on sentences containing comparatives or superlatives (losing 3-4 points each). Despite the fact that 17% of sentence pairs in the corpus contained at least one instance of comparative or superlative, our baseline models don't utilize the information present in these sentences to predict the correct label for the pair, although presence of a comparative or superlative is slightly more predictive of a NEUTRAL label.

Moreover, the baseline models perform below average on discourse markers, such as *despite* and *however*, losing roughly 2 to 3 points each. Unsurprisingly, the attention-based ESIM model performs better than the other two on sentences with greater than 20 words. Additionally, our baseline models do show slight improvements in accuracy on negation, suggesting that they may be tracking it as a predictor of CONTRADICTION.

5 Conclusion

Natural language inference makes it easy to judge the degree to which neural network models for sentence understanding capture the full meanings for natural language sentences. Existing NLI datasets like SNLI have facilitated substantial advances in modeling, but have limited headroom and coverage of the full diversity of meanings expressed in English. This paper presents a new dataset that offers dramatically greater linguistic difficulty and diversity, and also serves as a benchmark for cross-genre domain adaptation.

Our new corpus, MultiNLI, improves upon SNLI in its empirical coverage—because it includes a representative sample of text and speech from ten different genres, as opposed to just simple image captions—and its difficulty, containing a much higher percentage of sentences tagged with one or more elements from our tag set of thirteen difficult linguistic phenomena. This greater diversity is reflected in the dramatically lower baseline model performance on MultiNLI than on SNLI (see Table 5) and comparable inter-annotator agreement, suggesting that MultiNLI has a lot of headroom remaining for future work.

The MultiNLI corpus was first released in draft form in the first half of 2017, and in the time since its initial release, work by others (Conneau et al., 2017) has shown that NLI can also be an effective source task for pre-training and transfer learning in the context of sentence-to-vector models, with models trained on SNLI and MultiNLI substantially outperforming all prior models on a suite of established transfer learning benchmarks. We hope that this corpus will continue to serve for many years as a resource for the development and evaluation of methods for sentence understanding.

Acknowledgments

Abstract

Recognizing lexical semantic relations between word pairs is an important task for many applications of natural language processing. One of the mainstream approaches to this task is to exploit the lexico-syntactic paths connecting two target words, which reflect the semantic relations of word pairs. However, this method requires that the considered words co-occur in a sentence. This requirement is hardly satisfied because of Zipf's law, which states that most content words occur very rarely. In this paper, we propose novel methods with a neural model of $P(path|w_1, w_2)$ to solve this problem. Our proposed model of $P(path|w_1, w_2)$ can be learned in an unsupervised manner and can generalize the co-occurrences of word pairs and dependency paths. This model can be used to augment the path data of word pairs that do not co-occur in the corpus, and extract features capturing relational information from word pairs. Our experimental results demonstrate that our methods improve on previous neural approaches based on dependency paths and successfully solve the focused problem.

1 Introduction

The semantic relations between words are important for many natural language processing tasks, such as recognizing textual entailment (Dagan et al., 2010) and question answering (Yang et al., 2017). Moreover, these relations have been also used as features for neural methods in machine translation (Sennrich and Haddow, 2016) and relation extraction (Xu et al., 2015). This type of information is provided by manually-created semantic taxonomies, such as WordNet (Fellbaum, 1998). However, these resources are expensive to expand manually and have limited domain coverage. Thus, the automatic detection of lexico-semantic relations has been studied for several decades.

One of the most popular approaches is based on patterns that encode a specific kind of relationship (synonym, hypernym, etc.) between adjacent words. This type of approach is called a path-based method. Lexico-syntactic patterns between two words provide information on semantic relations. For example, if we see the pattern, "animals such as a dog" in a corpus, we can infer that *animal* is a hypernym of *dog*. On the basis of this assumption, Hearst (1992) detected the hypernymy relation of two words from a corpus based on several handcrafted lexico-syntactic patterns, e.g., *X such as Y*. Snow et al. (2004) used as features indicative dependency paths, in which target word pairs co-occurred, and trained a classifier with data to detect hypernymy relations.

In recent studies, Shwartz et al. (2016) proposed a neural path-based model that encoded dependency paths between two words into low-dimensional dense vectors with recurrent neural networks (RNN) for hypernymy detection. This method can prevent sparse feature space and generalize indicative dependency paths for detecting lexico-semantic relations. Their model outperformed the previous state-of-the-art path-based method. Moreover, they demonstrated that these dense path representations capture complementary information with word embeddings that contain individual word features. This was indicated by the experimental result that showed the combination of path representations and word embeddings improved classification performance. In addition, Shwartz and Dagan (2016) showed that the neural path-based approach, combined with word embeddings, is effective in recognizing multiple semantic relations.

Although path-based methods can capture the relational information between two words, these methods can obtain clues only for word pairs that

Proceedings of NAACL-HLT 2018, pages 1123–1133
New Orleans, Louisiana, June 1 - 6, 2018.

co-occur in a corpus. Even with a very large corpus, it is almost impossible to observe a co-occurrence of arbitrary word pairs. Thus, path-based methods are still limited in terms of the number of word pairs that are correctly classified.

To address this problem, we propose a novel method with modeling $P(path|w_1, w_2)$ in a neural unsupervised manner, where w_1 and w_2 are the two target words, and $path$ is a dependency path that can connect the joint co-occurrence of w_1 and w_2. A neural model of $P(path|w_1, w_2)$ can generalize co-occurrences of word pairs and dependency paths, and infer plausible dependency paths which connect two words that do not co-occur in a corpus. After unsupervised learning, this model can be used in two ways:

- Path data augmentation through predicting dependency paths that are most likely to co-occur with a given word pair.
- Feature extraction of word pairs, capturing the information of dependency paths as contexts where two words co-occur.

While previous supervised path-based methods used only a small portion of a corpus, combining our models makes it possible to use an entire corpus for learning process.

Experimental results for four common datasets of multiple lexico-semantic relations show that our methods improve the classification performance of supervised neural path-based models.

2 Background

2.1 Supervised Lexical Semantic Relation Detection

Supervised lexical semantic relation detection represents word pairs (w_1, w_2) as feature vectors $\boldsymbol{v}$ and trains a classifier with these vectors based on training data. For word pair representations $\boldsymbol{v}$, we can use the distributional information of each word and path information in which two words co-occur.

Several methods exploit word embeddings (Mikolov et al., 2013; Levy and Goldberg, 2014; Pennington et al., 2014) as distributional information. These methods use a combination of each word's embeddings, such as vector concatenation (Baroni et al., 2012; Roller and Erk, 2016) or vector difference (Roller et al., 2014; Weeds et al., 2014; Vylomova et al., 2016), as word pair representations. While these distributional supervised methods do not require co-occurrences of two words in a sentence, Levy et al. (2015) notes that these methods do not learn the relationships between two words but rather the separate property of each word, i.e., whether or not each word tends to have a target relation.

In contrast, supervised path-based methods can capture relational information between two words. These methods represent a word pair as the set of lexico-syntactic paths, which connect two target words in a corpus (Snow et al., 2004). However, these methods suffer from sparse feature space, as they cannot capture the similarity between indicative lexico-syntactic paths, e.g., *X is a species of Y* and *X is a kind of Y*.

2.2 Neural Path-based Method

A neural path-based method can avoid the sparse feature space of the previous path-based methods (Shwartz et al., 2016; Shwartz and Dagan, 2016). Instead of treating an entire dependency path as a single feature, this model encodes a sequence of edges of a dependency path into a dense vector using a long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997).

A dependency path connecting two words can be extracted from the dependency tree of a sentence. For example, given the sentence "A dog is a mammal," with *X* = *dog* and *Y* = *mammal*, the dependency path connecting the two words is `X/NOUN/nsubj/> be/VERB/ROOT/- Y/NOUN/attr/<`. Each edge of a dependency path is composed of a lemma, part of speech (POS), dependency label, and dependency direction.

Shwartz et al. (2016) represents each edge as the concatenation of its component embeddings:

$$\boldsymbol{e} = [\boldsymbol{v}_l; \boldsymbol{v}_{pos}; \boldsymbol{v}_{dep}; \boldsymbol{v}_{dir}] \quad (1)$$

where $\boldsymbol{v}_l, \boldsymbol{v}_{pos}, \boldsymbol{v}_{dep}$,and $\boldsymbol{v}_{dir}$ represent the embedding vectors of the lemma, POS, dependency label, and dependency direction respectively. This edge vector $\boldsymbol{e}$ is an input of the LSTM at each time step. Here, $\boldsymbol{h_t}$, the hidden state at time step t, is abstractly computed as:

$$\boldsymbol{h}_t = LSTM(\boldsymbol{h}_{t-1}, \boldsymbol{e}_t) \quad (2)$$

where $LSTM$ computes the current hidden state given the previous hidden state $\boldsymbol{h}_{t-1}$ and the current input edge vector $\boldsymbol{e}_t$ along with the LSTM architecture. The final hidden state vector $\boldsymbol{o}_p$ is

treated as the representation of the dependency path p.

When classifying a word pair (w_1, w_2), the word pair is represented as the average of the dependency path vectors that connect two words in a corpus:

$$\begin{aligned} \boldsymbol{v}_{(w_1,w_2)} &= \boldsymbol{v}_{paths(w_1,w_2)} \\ &= \frac{\sum_{p \in paths(w_1,w_2)} f_{p,(w_1,w_2)} \cdot \boldsymbol{o}_p}{\sum_{p \in paths(w_1,w_2)} f_{p,(w_1,w_2)}} \end{aligned} \quad (3)$$

where $paths(w_1, w_2)$ is the set of dependency paths that connects w_1 and w_2 in the corpus, and $f_{p,(w_1,w_2)}$ is the frequency of p in $paths(w_1, w_2)$. The final output of the network is calculated as follows:

$$\boldsymbol{y} = softmax(\boldsymbol{W}\boldsymbol{v}_{(w_1,w_2)} + \boldsymbol{b}) \quad (4)$$

where $\boldsymbol{W} \in \mathbb{R}^{|c| \times d}$ is a linear transformation matrix, $\boldsymbol{b} \in \mathbb{R}^{|c|}$ is a bias parameter, $|c|$ is the number of the output class, and d is the size of $\boldsymbol{v}_{(w_1,w_2)}$.

This neural path-based model can be combined with distributional methods. Shwartz et al. (2016) concatenated $\boldsymbol{v}_{paths(w_1,w_2)}$ to the word embeddings of w_1 and w_2, redefining $\boldsymbol{v}_{(w_1,w_2)}$ as:

$$\boldsymbol{v}_{(w_1,w_2)} = [\boldsymbol{v}_{w_1}; \boldsymbol{v}_{paths(w_1,w_2)}; \boldsymbol{v}_{w_2}] \quad (5)$$

where $\boldsymbol{v}_{w_1}$ and $\boldsymbol{v}_{w_2}$ are word embeddings of w_1 and w_2, respectively. This integrated model, named LexNET, exploits both path information and distributional information, and has high generalization performance for lexical semantic relation detection.

2.3 Missing Path Problem

All path-based methods, including the neural ones, suffer from data sparseness as they depend on word pair co-occurrences in a corpus. However, we cannot observe all co-occurrences of semantically related words even with a very large corpus because of Zipf's law, which states that the frequency distribution of words has a long tail; in other words, most words occur very infrequently (Hanks, 2009). In this paper, we refer to this phenomenon as the missing path problem.

This missing path problem leads to the fact that path-based models cannot find any clues for two words that do not co-occur. Thus, in the neural path-based method, $paths(w_1, w_2)$ for these word pairs is padded with an empty path, like `UNK-lemma/UNK-POS/UNK-dep/UNK-dir`. However, this process makes path-based classifiers unable to distinguish between semantically-related pairs with no co-occurrences and those that have no semantic relation.

In an attempt to solve this problem, Necsulescu et al. (2015) proposed a method that used a graph representation of a corpus. In this graph, words and dependency relations were denoted as nodes and labeled directed edges, respectively. From this graph representation, paths linking two target words can be extracted through bridging words, even if the two words do not co-occur in the corpus. They represent word pairs as the sets of paths linking word pairs on the graph and train a support vector machine classifier with training data, thereby improving recall. However, the authors reported that this method still suffered from data sparseness.

In this paper, we address this missing path problem, which generally restricts path-based methods, by neural modeling $P(path|w_1, w_2)$.

3 Method

We present a novel method for modeling $P(path|w_1, w_2)$. The purpose of this method is to address the missing path problem by generalizing the co-occurrences of word pairs and dependency paths. To model $P(path|w_1, w_2)$, we used the context-prediction approach (Collobert and Weston, 2008; Mikolov et al., 2013; Levy and Goldberg, 2014; Pennington et al., 2014), which is a widely used method for learning word embeddings. In our proposed method, word pairs and dependency paths are represented as embeddings that are updated with unsupervised learning through predicting $path$ from w_1 and w_2 (Section 3.1).

After the learning process, our model can be used to (1) augment path data by predicting the plausibility of the co-occurrence of two words and a dependency path (Section 3.2); and to (2) extract useful features from word pairs, which reflect the information of co-occurring dependency paths (Section 3.3).

3.1 Unsupervised Learning

There are many possible ways to model $P(path|w_1, w_2)$. In this paper, we present a straightforward and efficient architecture, similar to the skip-gram with negative sampling (Mikolov et al., 2013).

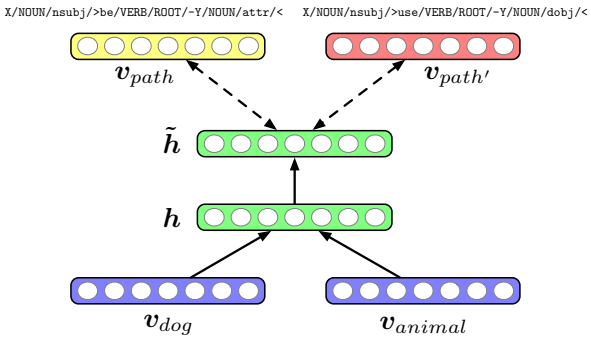

Figure 1: An illustration of our network for modeling $P(path|w_1, w_2)$. Given a word pair $(dog, animal)$, our model makes $\tilde{\boldsymbol{h}}$ of $(dog, animal)$ similar to $\boldsymbol{v}_{path}$ of the observed co-occurring dependency path `X/NOUN/nsubj/> be/VERB/ROOT/- Y/NOUN/attr/<` and dissimilar to $\boldsymbol{v}_{path'}$ of the unobserved paths, such as `X/NOUN/nsubj/> use/VERB/ROOT/- Y/NOUN/dobj/<`, through unsupervised learning.

Figure 1 depicts our network structure, which is described below.

Data and Network Architecture

We are able to extract many triples $(w_1, w_2, path)$ from a corpus after dependency parsing. We denote a set of these triples as D. These triples are the instances used for the unsupervised learning of $P(path|w_1, w_2)$. Given $(w_1, w_2, path)$, our model learns through predicting $path$ from w_1 and w_2.

We encode word pairs into dense vectors as follows:

$$\boldsymbol{h}_{(w1,w2)} = tanh(\boldsymbol{W}_1[\boldsymbol{v}_{w_1}; \boldsymbol{v}_{w_2}] + \boldsymbol{b}_1) \quad (6)$$

$$\tilde{\boldsymbol{h}}_{(w_1,w_2)} = tanh(\boldsymbol{W}_2\boldsymbol{h}_{(w1,w2)} + \boldsymbol{b}_2) \quad (7)$$

where $[\boldsymbol{v}_{w_1}; \boldsymbol{v}_{w_2}]$ is the concatenation of the word embeddings of w_1 and w_2; $\boldsymbol{W}_1$, $\boldsymbol{b}_1$, $\boldsymbol{W}_2$, and $\boldsymbol{b}_2$ are the parameter matrices and bias parameters of the two linear transformations; and $\tilde{\boldsymbol{h}}_{(w_1,w_2)}$ is the representation of the word pair.

We associate each $path$ with the embedding $\boldsymbol{v}_{path}$, initialized randomly. While we use a simple way to represent dependency paths in this paper, LSTM can be used to encode each path in the way described in Section 2.2. If LSTM is used, learning time increases but similarities among paths will be captured.

Objective

We used the negative sampling objective for training (Mikolov et al., 2013). Given the word pair representations $\tilde{\boldsymbol{h}}_{(w_1,w_2)}$ and the dependency path representations $\boldsymbol{v}_{path}$, our model was trained to distinguish real $(w_1, w_2, path)$ triples from incorrect ones. The log-likelihood objective is as follows:

$$L = \sum_{(w_1,w_2,path)\in D} \log \sigma(\boldsymbol{v}_{path} \cdot \tilde{\boldsymbol{h}}_{(w_1,w_2)}) + \sum_{(w_1,w_2,path')\in D'} \log \sigma(-\boldsymbol{v}_{path'} \cdot \tilde{\boldsymbol{h}}_{(w_1,w_2)}) \quad (8)$$

where, D' is the set of randomly generated negative samples. We constructed n triples $(w_1, w_2, path')$ for each $(w_1, w_2, path) \in D$, where n is a hyperparameter and each $path'$ is drawn according to its unigram distribution raised to the $3/4$ power. The objective L was maximized using the stochastic gradient descent algorithm.

3.2 Path Data Augmentation

After the unsupervised learning described above, our model of $P(path|w_1, w_2)$ can assign the plausibility score $\sigma(\boldsymbol{v}_{path} \cdot \tilde{\boldsymbol{h}}_{(w_1,w_2)})$ to the co-occurrences of a word pair and a dependency path. We can then append the plausible dependency paths to $paths(w_1, w_2)$, the set of dependency paths that connects w_1 and w_2 in the corpus, based on these scores.

We calculate the score of each dependency path given $(X = w_1, Y = w_2)$ and append the k dependency paths with the highest scores to $paths(w_1, w_2)$, where k is a hyperparameter. We perform the same process given $(X = w_2, Y = w_1)$ with the exception of swapping the `X` and `Y` in the dependency paths to be appended. As a result, we add $2k$ dependency paths to the set of dependency paths for each word pair. Through this data augmentation, we can obtain plausible dependency paths even when word pairs do not co-occur in the corpus. Note that we retain the empty path indicators of $paths(w_1, w_2)$, as we believe that this information contributes to classifying two unrelated words.

3.3 Feature Extractor of Word Pairs

Our model can be used as a feature extractor of word pairs. We can exploit $\tilde{\boldsymbol{h}}_{(w_1,w_2)}$ to represent the word pair (w_1, w_2). This representation captures the information of co-occurrence dependency paths of (w_1, w_2) in a generalized fashion. Thus, $\tilde{\boldsymbol{h}}_{(w_1,w_2)}$ is used to construct the pseudo-path representation $\boldsymbol{v}_{p-paths(w_1,w_2)}$. With our model, we represent the word pair (w_1, w_2) as

datasets	relations
K&H+N	hypernym, meronym, co-hyponym, random
BLESS	hypernym, meronym, co-hyponym, random
ROOT09	hypernym, co-hyponym, random
EVALution	hypernym, meronym, attribute, synonym, antonym, holonym, substance meronym

Table 1: The relation types in each dataset.

follows:

$$\boldsymbol{v}_{p-paths(w_1,w_2)} = [\tilde{\boldsymbol{h}}_{(w_1,w_2)}; \tilde{\boldsymbol{h}}_{(w_2,w_1)}] \quad (9)$$

This representation can be used for word pair classification tasks, such as lexical semantic relation detection.

4 Experiment

In this section, we examine how our method improves path-based models on several datasets for recognizing lexical semantic relations. In this paper, we focus on major noun relations, such as hypernymy, co-hypernymy, and meronymy.

4.1 Dataset

We relied on the datasets used in Shwartz and Dagan (2016); K&H+N (Necsulescu et al., 2015). BLESS (Baroni and Lenci, 2011), EVALution (Santus et al., 2015), and ROOT09 (Santus et al., 2016). These datasets were constructed with knowledge resources (e.g., WordNet, Wikipedia), crowd-sourcing, or both. We used noun pair instances of these datasets.[1] Table 1 displays the relations in each dataset used in our experiments. Note that we removed the two relations *Entails* and *MemberOf* with few instances from EVALution following Shwartz and Dagan (2016). For data splitting, we used the presplitted train/val/test sets from Shwartz and Dagan (2016) after removing all but the noun pairs from each set.

4.2 Corpus and Dependency Parsing

For path-based methods, we used the June 2017 Wikipedia dump as a corpus and extracted $(w_1, w_2, path)$ triples of noun pairs using the dependency parser of spaCy[2] to construct D. In this process, w_1 and w_2 were lemmatized with spaCy. We only used the dependency paths which occurred at least five times following the implementation of Shwartz and Dagan (2016).[3]

datasets	instances	instances with paths	proportion
K&H+N	57509	8866	15.4%
BLESS	14558	8775	60.3%
ROOT09	8602	6582	76.5%
EVALution	3240	3199	98.7%

Table 2: The number and proportion of instances whose dependency path is obtained from each dataset

Table 2 displays the number of instances and the proportion of the instances for which at least one dependency path was obtained.

4.3 Baseline

We conducted experiments with three neural path-based methods. The implementation details below follow those in Shwartz and Dagan (2016). We implemented all models using Chainer.[4]

Neural Path-Based Model (NPB). We implemented and trained the neural path-based model described in Section 2.2. We used the two-layer LSTM with 60-dimensional hidden units. An input vector was composed of embedding vectors of the lemma (50 dims), POS (4 dims), dependency label (5 dims), and dependency direction (1 dim). Regularization was applied by a dropout on each of the components embeddings (Iyyer et al., 2015; Kiperwasser and Goldberg, 2016).

LexNET. We implemented and trained the integrated model LexNET as described in Section 2.2. The LSTM details are the same as in the NPB model.

LexNET_h. This model, a variant of LexNET, has an additional hidden layer between the output layer and $\boldsymbol{v}_{(w_1,w_2)}$ of Equation (5). Because of this additional hidden layer, this model can take into account the interaction of the path information

[1] We focused only noun pairs to shorten the unsupervised learning time, though this restriction is not necessary for our methods and the unsupervised learning is still tractable.

[3] https://github.com/vered1986/LexNET

[4] https://chainer.org

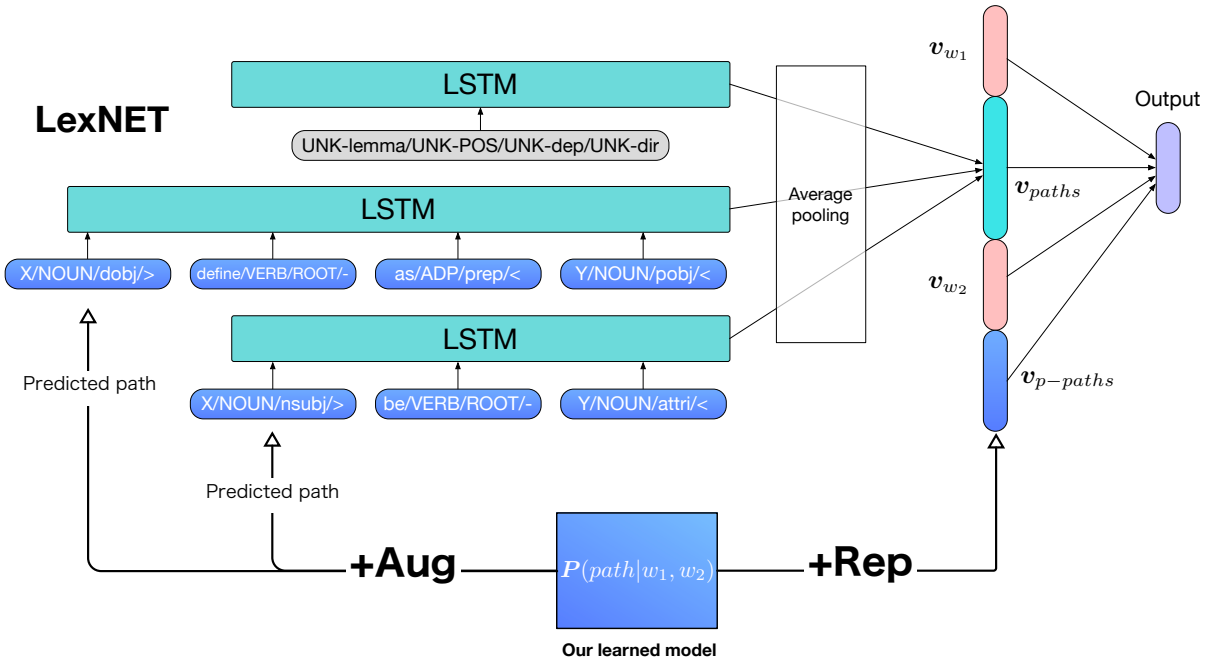

Figure 2: Illustration of +Aug and +Rep applied to LexNET. +Aug predicts plausible paths from two word embeddings, and these paths are fed into the LSTM path encoder. +Rep concatenates the pseudo-path representation $\boldsymbol{v}_{p-paths(w_1,w_2)}$ with the penultimate layer of LexNET

and distributional information of two word embeddings. The size of the additional hidden layer was set to 60.

Following Shwartz and Dagan (2016), we optimized each model using Adam (whose learning rate is 0.001) while tuning the dropout rate dr among $\{0.0, 0.2, 0.4\}$ on the validation set. The minibatch size was set to 100.

We initialized the lemma embeddings of LSTM and concatenated the word embeddings of LexNET with the pretrained 50-dimensional GloVe vector.[5] Training was stopped if performance on the validation set did not improve for seven epochs, and the best model for test evaluation was selected based on the score of the validation set.

4.4 Our Method

We implemented and trained our model of $P(path|w_1, w_2)$, described in Section 3.1, as follows. We used the most frequent 30,000 paths connecting nouns as the context paths for unsupervised learning. We initialized word embeddings with the same pretrained GloVe vector as the baseline models. For unsupervised learning data, we extracted $(w_1, w_2, path)$, whose w_1 and w_2 are included in the vocabulary of the GloVe vector, and whose $path$ is included in the context paths, from D. The number of these triples was 217,737,765.

We set the size of $\boldsymbol{h}_{(w_1,w_2)}$, $\tilde{\boldsymbol{h}}_{(w_1,w_2)}$, and $\boldsymbol{v}_{path}$ for context paths to 100. The negative sampling size n was set to 5. We trained our model for five epochs using Adam (whose learning rate is 0.001). The minibatch size was 100. To preserve the distributional regularity of the pretrained word embeddings, we did not update the input word embeddings during the unsupervised learning.

With our trained model, we applied the two methods described in Section 3.2 and 3.3 to the NPB and LexNET models as follows:

+Aug. We added the most plausible $2k$ paths to each $paths(w_1, w_2)$ as in Section 3.2. We tuned $k \in \{1, 3, 5\}$ on the validation set.

+Rep. We concatenated $\boldsymbol{v}_{p-paths(w_1,w_2)}$ in Equation (9) with the penultimate layer. To focus on the pure contribution of unsupervised learning, we did not update this component during supervised learning.

Figure 2 illustrates +Aug and +Rep applied to LexNET in the case where the two target words, w_1 and w_2, do not co-occur in the corpus.

LexNET_h	0.968	0.927	0.810	0.540
LexNET+Aug	**0.970**	0.927	0.806	0.545
LexNET+Rep	**0.970**	**0.944**	**0.832**	0.565
LexNET+Aug+Rep	0.969	0.942	0.820	**0.567**

Table 4: Classification performance of the integrated model, LexNET and LexNET_h, and those with our methods, +Aug and +Rep.

5 Result

In this section we examine how our methods improved the baseline models. Following the previous research (Shwartz and Dagan, 2016), the performance metrics were the "averaged" $F1$ of scikit-learn (Pedregosa et al., 2011), which computes the $F1$ for each relation, and reports their average weighted by the number of true instances for each relation.

5.1 Path-based Model and Path Data Augmentation

We examined whether or not our path data augmentation method +Aug contributes to the neural path-based method. The results are displayed in Table 3.

Applying our path data augmentation method improved the classification performance on each dataset. Especially for K&H+N, the large dataset where the three-fourths of word pairs had no paths, our method significantly improved the performance. This result shows that our path data augmentation effectively solves the missing path problem. Moreover, the model with our method outperforms the baseline on EVALution, in which nearly all word pairs co-occurred in the corpus. This indicates that the predicted paths provide useful information and enhance the path-based classification. We examine the paths that were predicted by our model of $P(path|w_1, w_2)$ in Section 6.1.

5.2 Integrated Model and Our Methods

We investigated how our methods using modeling $P(path|w_1, w_2)$ improved the baseline integrated model, LexNET. Table 4 displays the results.

Our proposed methods, +Aug and +Rep, improved the performance of LexNET on each dataset.[6] Moreover, the best score on each dataset was achieved by the model to which our methods were applied. These results show that our methods are also effective with the integrated models based on path information and distributional information.

The table also shows that LexNET+Rep outperforms LexNET_h, though the former has fewer parameters to be tuned during the supervised learning than the latter. This indicates that the word pair representations of our model capture information beyond the interaction of two word embeddings. We investigate the properties of our word pair representation in Section 6.2.

Finally, We found that applying both methods did not necessarily yield the best performance. A possible explanation for this is that applying both methods is redundant, as both +Aug and +Rep depend on the same model of $P(path|w_1, w_2)$.

6 Analysis

In this section, we investigate the properties of the predicted dependency paths and word pair representations of our model.

6.1 Predicted Dependency Paths

We extracted the word pairs of BLESS without co-occurring dependency paths and predicted the

[6]The improvement for K&H+N is smaller than those for the others. We think this owes to most instances of this dataset being correctly classified only by distributional information. This view is supported by Shwartz and Dagan (2016), in which LexNET hardly outperformed a distributional method for this dataset.

Table 5: Predicted paths with our model for a word pair of each relation in BLESS.

plausible dependency paths of those pairs with our model of $P(path|w_1, w_2)$. The examples are displayed in Table 5 at the top three paths. We used the bold style for the paths that we believe to be indicative or representative for a given relationship.

Our model predicted plausible and indicative dependency paths for each relation, although the predicted paths also contain some implausible or unindicative ones. For hypernymy, our model predicted variants of the is-a path according to domains, such as *X is Y manufactured* in the clothing domain and *X is a species of Y* in the animal domain. For $(owl, rump)$, which is a meronymy pair, the top predicted path was *X that Y represent*. This is not plausible for $(owl, rump)$ but is indicative for meronymy, particularly member-of relations. Moreover, domain-independent paths which indicate meronymy, such as *all X have Y*, were predicted. For $(mug, plastic)$, one of the predicted paths, *X is made from Y*, is also a domain-independent indicative path for meronymy. For co-hypernymy, our model predicted domain-specific paths, which indicate that two nouns are of the same kind. For examples, given *X leaf and Y* and *X specie and Y* of $(carrot, beans)$, we can infer that both X and Y are plants or vegetables. Likewise, given *play X, guitar, and Y* of $(cello, kazoo)$, we can infer that both X and Y are musical instruments. These examples show that our path data augmentation is effective for the missing path problem and enhances path-based models.

6.2 Visualizing Word Pair Representations

We visualized the word pair representations $\boldsymbol{v}_{p-paths(w_1,w_2)}$ to examine their specific properties. In BLESS, every pair was annotated with 17 domain class labels. For each domain, we reduced the dimensionality of the representations using t-SNE (Maaten and Hinton, 2008) and plotted the data points of the hypernyms, co-hyponyms, and meronyms. We compared our representations with the concatenation of two word embeddings (pre-trained 50-dimensional GloVe). The examples are displayed in Figure 3.

We found that our representations (the top row in Figure 3) grouped the word pairs according to their semantic relation in some specific domains based only on unsupervised learning. This property is desirable for the lexical semantic relation detection task. In contrast to our representations,

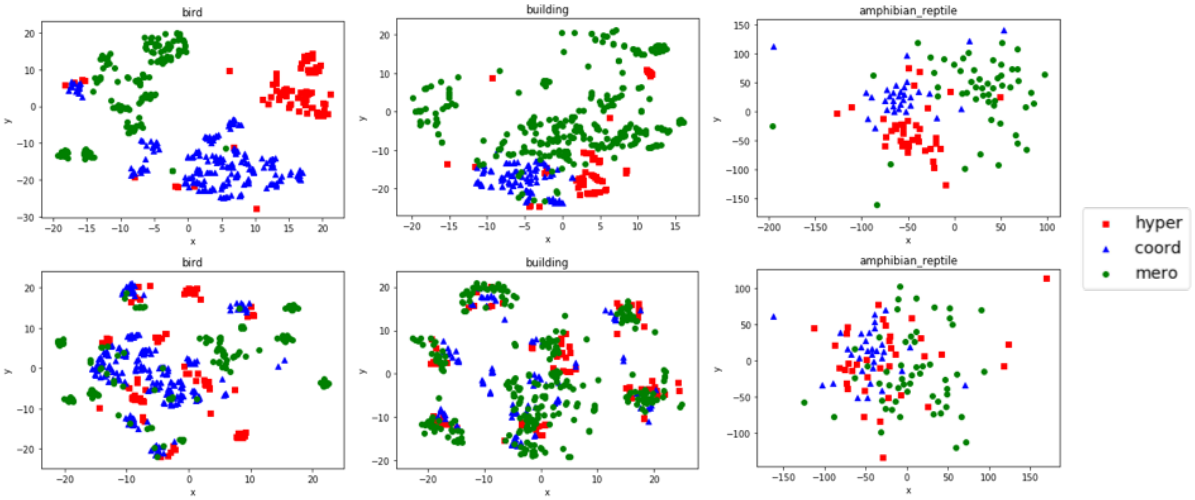

Figure 3: Visualization of the our word pair representations $\boldsymbol{v}_{p-paths(w_1,w_2)}$ (top row) and the concatenation of two word embeddings (bottom row) using t-SNE in some domains. The two axes of each plot, x and y, are the reduced dimensions using t-SNE.

the concatenation of word embeddings (the bottom row in Figure 3) has little or no such tendency in all domains. The data points of the concatenation of word embeddings are scattered or jumbled. This is because the concatenation of word embeddings cannot capture the relational information of word pairs but only the distributional information of each word (Levy et al., 2015).

This visualization further shows that our word pair representations can be used as pseudo-path representations to alleviate the missing path problem.

7 Conclusion

In this paper, we proposed the novel methods with modeling $P(path|w_1, w_2)$ to solve the missing path problem. Our neural model of $P(path|w_1, w_2)$ can be learned from a corpus in an unsupervised manner, and can generalize co-occurrences of word pairs and dependency paths. We demonstrated that this model can be applied in the two ways: (1) to augment path data by predicting plausible paths for a given word pair, and (2) to extract from word pairs useful features capturing co-occurring path information. Finally, our experiments demonstrated that our methods can improve upon the previous models and successfully solve the missing path problem.

In future work, we will explore unsupervised learning with a neural path encoder. Our model bears not only word pair representations but also dependency path representations as context vectors. Thus, we intend to apply these representations to various tasks, which path representations contribute to.

Specialising Word Vectors for Lexical Entailment

Ivan Vulić[1] and **Nikola Mrkšić**[2]

[2] PolyAI
iv250@cam.ac.uk nikola@poly-ai.com

Abstract

We present LEAR (**L**exical **E**ntailment **A**ttract-**R**epel), a novel post-processing method that transforms any input word vector space to emphasise the asymmetric relation of *lexical entailment* (LE), also known as the IS-A or hyponymy-hypernymy relation. By injecting external linguistic constraints (e.g., WordNet links) into the initial vector space, the LE specialisation procedure brings true hyponymy-hypernymy pairs closer together in the transformed Euclidean space. The proposed asymmetric distance measure adjusts the norms of word vectors to reflect the actual WordNet-style hierarchy of concepts. Simultaneously, a joint objective enforces semantic similarity using the symmetric cosine distance, yielding a vector space specialised for both lexical relations at once. LEAR specialisation achieves state-of-the-art performance in the tasks of hypernymy directionality, hypernymy detection, and graded lexical entailment, demonstrating the effectiveness and robustness of the proposed asymmetric specialisation model.

1 Introduction

Word representation learning has become a research area of central importance in NLP, with its usefulness demonstrated across application areas such as parsing (Chen and Manning, 2014), machine translation (Zou et al., 2013), and many others (Turian et al., 2010; Collobert et al., 2011). Standard techniques for inducing word embeddings rely on the *distributional hypothesis* (Harris, 1954), using co-occurrence information from large textual corpora to learn meaningful word representations (Mikolov et al., 2013; Levy and Goldberg, 2014; Pennington et al., 2014; Bojanowski et al., 2017).

A major drawback of the distributional hypothesis is that it coalesces different relationships between words, such as synonymy and topical relatedness, into a single vector space. A popular solution is to go beyond stand-alone unsupervised learning and fine-tune distributional vector spaces by using external knowledge from human- or automatically-constructed knowledge bases. This is often done as a *post-processing* step, where distributional vectors are gradually refined to satisfy linguistic constraints extracted from lexical resources such as WordNet (Faruqui et al., 2015; Mrkšić et al., 2016), the Paraphrase Database (PPDB) (Wieting et al., 2015), or BabelNet (Mrkšić et al., 2017; Vulić et al., 2017a). One advantage of post-processing methods is that they treat the input vector space as a *black box*, making them applicable to any input space.

A key property of these methods is their ability to transform the vector space by *specialising* it for a particular relationship between words.[1] Prior work has predominantly focused on distinguishing between semantic similarity and conceptual relatedness (Faruqui et al., 2015; Mrkšić et al., 2017; Vulić et al., 2017b). In this paper, we introduce a novel post-processing model which specialises vector spaces for the *lexical entailment* (LE) relation.

Word-level lexical entailment is an *asymmetric* semantic relation (Collins and Quillian, 1972; Beckwith et al., 1991). It is a key principle determining the organisation of semantic networks into hierarchical structures such as semantic ontologies (Fellbaum, 1998). Automatic reasoning about LE supports tasks such as taxonomy creation (Snow et al., 2006; Navigli et al., 2011), natural language inference (Dagan et al., 2013; Bowman et al., 2015), text generation (Biran and McKeown, 2013), and metaphor detection (Mohler et al., 2013).

Our novel LE specialisation model, termed LEAR (**L**exical **E**ntailment **A**ttract-**R**epel), is inspired by ATTRACT-REPEL, a state-of-the-art general spe-

[1] Distinguishing between synonymy and antonymy has a positive impact on real-world language understanding tasks such as Dialogue State Tracking (Mrkšić et al., 2017).

Proceedings of NAACL-HLT 2018, pages 1134–1145
New Orleans, Louisiana, June 1 - 6, 2018.

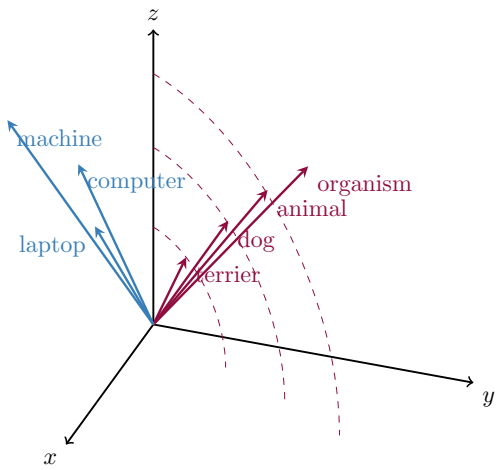

Figure 1: An illustration of LEAR specialisation. LEAR controls the arrangement of vectors in the transformed vector space by: **1)** emphasising symmetric similarity of LE pairs through cosine distance (by enforcing small angles between $\overrightarrow{terrier}$ and $\overrightarrow{dog}$ or $\overrightarrow{dog}$ and $\overrightarrow{animal}$); and **2)** by imposing an LE ordering using vector norms, adjusting them so that higher-level concepts have larger norms (e.g., $|\overrightarrow{animal}| > |\overrightarrow{dog}| > |\overrightarrow{terrier}|$).

cialisation framework (Mrkšić et al., 2017).[2] The key idea of LEAR, illustrated by Figure 1, is to pull desirable (ATTRACT) examples described by the constraints closer together, while at the same time pushing undesirable (REPEL) word pairs away from each other. Concurrently, LEAR (re-)arranges vector norms so that norm values in the Euclidean space reflect the hierarchical organisation of concepts according to the given LE constraints: put simply, higher-level concepts are assigned larger norms. Therefore, LEAR simultaneously captures the hierarchy of concepts (through vector norms) and their similarity (through their cosine distance). The two pivotal pieces of information are combined into an *asymmetric distance measure* which quantifies the LE strength in the specialised space.

After specialising four well-known input vector spaces with LEAR, we test them in three standard word-level LE tasks (Kiela et al., 2015b): **1)** hypernymy *directionality*; **2)** hypernymy *detection*; and **3)** *combined* hypernymy detection/directionality. Our specialised vectors yield notable improvements over the strongest baselines for each task, with each input space, demonstrating the effectiveness and robustness of LEAR specialisation.

[2] https://github.com/nmrksic/attract-repel

The employed asymmetric distance allows one to make graded assertions about hierarchical relationships between concepts in the specialised space. This property is evaluated using HyperLex, a recent *graded LE* dataset (Vulić et al., 2017). The LEAR-specialised vectors push state-of-the-art Spearman's correlation from 0.540 to 0.686 on the full dataset (2,616 word pairs), and from 0.512 to 0.705 on its noun subset (2,163 word pairs).

The code for the LEAR model is available from: `github.com/nmrksic/lear`.

2 Methodology

2.1 The ATTRACT-REPEL Framework

Let V be the vocabulary, A the set of ATTRACT word pairs (e.g., *intelligent* and *brilliant*), and R the set of REPEL word pairs (e.g., *vacant* and *occupied*). The ATTRACT-REPEL procedure operates over mini-batches of such pairs $\mathcal{B}_A$ and $\mathcal{B}_R$. For ease of notation, let each word pair (x_l, x_r) in these two sets correspond to a vector pair $(\mathbf{x}_l, \mathbf{x}_r)$, so that a mini-batch of k_1 word pairs is given by $\mathcal{B}_A = [(\mathbf{x}_l^1, \mathbf{x}_r^1), \ldots, (\mathbf{x}_l^{k_1}, \mathbf{x}_r^{k_1})]$ (similarly for $\mathcal{B}_R$, which consists of k_2 example pairs).

Next, the sets of pseudo-negative examples $T_A = [(\mathbf{t}_l^1, \mathbf{t}_r^1), \ldots, (\mathbf{t}_l^{k_1}, \mathbf{t}_r^{k_1})]$ and $T_R = [(\mathbf{t}_l^1, \mathbf{t}_r^1), \ldots, (\mathbf{t}_l^{k_2}, \mathbf{t}_r^{k_2})]$ are defined as pairs of *negative examples* for each ATTRACT and REPEL example pair in mini-batches $\mathcal{B}_A$ and $\mathcal{B}_R$. These negative examples are chosen from the word vectors present in $\mathcal{B}_A$ or $\mathcal{B}_R$ so that, for each ATTRACT pair $(\mathbf{x}_l, \mathbf{x}_r)$, the negative example pair $(\mathbf{t}_l, \mathbf{t}_r)$ is chosen so that $\mathbf{t}_l$ is the vector closest (in terms of cosine distance) to $\mathbf{x}_l$ and $\mathbf{t}_r$ is closest to $\mathbf{x}_r$. Similarly, for each REPEL pair $(\mathbf{x}_l, \mathbf{x}_r)$, the negative example pair $(\mathbf{t}_l, \mathbf{t}_r)$ is chosen from the remaining in-batch vectors so that $\mathbf{t}_l$ is the vector furthest away from $\mathbf{x}_l$ and $\mathbf{t}_r$ is furthest from $\mathbf{x}_r$.

The negative examples are used to: **a)** force ATTRACT pairs to be closer to each other than to their respective negative examples; and **b)** to force REPEL pairs to be further away from each other than from their negative examples. The first term of the cost function pulls ATTRACT pairs together:

$$Att(\mathcal{B}_A, T_A) = \sum_{i=1}^{k_1} \big[\, \tau\left(\delta_{att} + cos(\mathbf{x}_l^i, \mathbf{t}_l^i) - cos(\mathbf{x}_l^i, \mathbf{x}_r^i)\right) + \tau\left(\delta_{att} + cos(\mathbf{x}_r^i, \mathbf{t}_r^i) - cos(\mathbf{x}_l^i, \mathbf{x}_r^i)\right) \big] \quad (1)$$

where cos denotes cosine similarity, $\tau(x) = \max(0, x)$ is the hinge loss function and δ_{att} is the attract margin which determines how much closer these vectors should be to each other than to their respective negative examples. The second part of the cost function pushes REPEL word pairs away from each other:

$$Rep(\mathcal{B}_R, T_R) = \sum_{i=1}^{k_2} \big[\tau\left(\delta_{rep} + cos(\mathbf{x}_l^i, \mathbf{x}_r^i) - cos(\mathbf{x}_l^i, \mathbf{t}_l^i)\right) + \tau\left(\delta_{rep} + cos(\mathbf{x}_l^i, \mathbf{x}_r^i) - cos(\mathbf{x}_r^i, \mathbf{t}_r^i)\right) \big] \quad (2)$$

In addition to these two terms, an additional regularisation term is used to *preserve* the abundance of high-quality semantic content present in the distributional vector space, as long as this information does not contradict the injected linguistic constraints. If $V(\mathcal{B})$ is the set of all word vectors present in the given mini-batch, then:

$$Reg(\mathcal{B}_A, \mathcal{B}_R) = \sum_{\mathbf{x}_i \in V(\mathcal{B}_A \cup \mathcal{B}_R)} \lambda_{reg} \left\| \widehat{\mathbf{x}}_i - \mathbf{x}_i \right\|_2$$

where λ_{reg} is the L2 regularization constant and $\widehat{\mathbf{x}}_i$ denotes the original (distributional) word vector for word x_i. The full ATTRACT-REPEL cost function is given by the sum of all three terms.

2.2 LEAR: Encoding Lexical Entailment

In this section, the ATTRACT-REPEL framework is extended to model lexical entailment jointly with (symmetric) semantic similarity. To do this, the method uses an additional source of external lexical knowledge: let L be the set of *directed* lexical entailment constraints such as *(corgi, dog)*, *(dog, animal)*, or *(corgi, animal)*, with lower-level concepts on the left and higher-level ones on the right (the source of these constraints will be discussed in Section 3). The optimisation proceeds in the same way as before, considering a mini-batch of LE pairs $\mathcal{B}_L$ consisting of k_3 word pairs standing in the (directed) lexical entailment relation.

Unlike symmetric similarity, lexical entailment is an asymmetric relation which encodes a hierarchical ordering between concepts. Inferring the direction of the entailment relation between word vectors requires the use of an asymmetric distance function. We define three different ones, all of which use the word vector's norms to impose an ordering between high- and low-level concepts:

$$D_1(\mathbf{x}, \mathbf{y}) = |\mathbf{x}| - |\mathbf{y}| \quad (3)$$

$$D_2(\mathbf{x}, \mathbf{y}) = \frac{|\mathbf{x}| - |\mathbf{y}|}{|\mathbf{x}| + |\mathbf{y}|} \quad (4)$$

$$D_3(\mathbf{x}, \mathbf{y}) = \frac{|\mathbf{x}| - |\mathbf{y}|}{\max(|\mathbf{x}|, |\mathbf{y}|)} \quad (5)$$

The lexical entailment term (for the j-th asymmetric distance, $j \in 1, 2, 3$) is defined as:

$$LE_j(\mathcal{B}_L) = \sum_{i=1}^{k_3} D_j(\mathbf{x}_i, \mathbf{y}_i) \quad (6)$$

The first distance serves as the baseline: it uses the word vectors' norms to order the concepts, that is to decide which of the words is likely to be the higher-level concept. In this case, the magnitude of the difference between the two norms determines the 'intensity' of the LE relation. This is potentially problematic, as this distance does not impose a limit on the vectors' norms. The second and third metric take a more sophisticated approach, using the ratios of the differences between the two norms and either: **a)** the sum of the two norms; or **b)** the larger of the two norms. In doing that, these metrics ensure that the cost function only considers the norms' ratios. This means that the cost function no longer has the incentive to increase word vectors' norms past a certain point, as the magnitudes of norm ratios grow in size much faster than the linear relation defined by the first distance function.

To model the semantic and the LE relations jointly, the LEAR cost function jointly optimises the four terms of the expanded cost function:

$$C(\mathcal{B}_A, T_A, \mathcal{B}_R, T_R, \mathcal{B}_L, T_L) = Att(\mathcal{B}_S, T_S) + \ldots + Rep(\mathcal{B}_A, T_A) + Reg(\mathcal{B}_A, \mathcal{B}_R, \mathcal{B}_L) + \ldots + Att(\mathcal{B}_L, T_L) + LE_j(B_L)$$

LE Pairs as ATTRACT Constraints The combined cost function makes use of the batch of lexical constraints $\mathcal{B}_L$ twice: once in the defined asymmetric cost function LE_j, and once in the symmetric ATTRACT term $Att(\mathcal{B}_L, T_L)$. This means that words standing in the lexical entailment relation are forced to be similar both in terms of cosine distance (via the symmetric ATTRACT term) and in terms of the asymmetric LE distance from Eq. (6).

Decoding Lexical Entailment The defined cost function serves to encode semantic similarity and

LE relations in the same vector space. Whereas the similarity can be inferred from the standard cosine distance, the LEAR optimisation embeds lexical entailment as a combination of the symmetric ATTRACT term and the newly defined asymmetric LE_j cost function. Consequently, the metric used to determine whether two words stand in the LE relation must combine the two cost terms as well. We define the LE *decoding* metric as:

$$I_{LE}(\mathbf{x}, \mathbf{y}) = dcos(\mathbf{x}, \mathbf{y}) + D_j(\mathbf{x}, \mathbf{y}) \quad (7)$$

where $dcos(\mathbf{x}, \mathbf{y})$ denotes the cosine distance. This decoding function combines the symmetric and the asymmetric cost term, in line with the combination of the two used to perform LEAR specialisation. In the evaluation, we show that combining the two cost terms has a synergistic effect, with both terms contributing to stronger performance across all LE tasks used for evaluation.

3 Experimental Setup

Starting Distributional Vectors To test the robustness of LEAR specialisation, we experiment with a variety of well-known, publicly available English word vectors: **1)** Skip-Gram with Negative Sampling (SGNS) (Mikolov et al., 2013) trained on the Polyglot Wikipedia (Al-Rfou et al., 2013) by Levy and Goldberg (2014); **2)** GLOVE Common Crawl (Pennington et al., 2014); **3)** CONTEXT2VEC (Melamud et al., 2016), which replaces CBOW contexts with contexts based on bidirectional LSTMs (Hochreiter and Schmidhuber, 1997); and **4)** FASTTEXT (Bojanowski et al., 2017), a SGNS variant which builds word vectors as the sum of their constituent character n-gram vectors.[3]

Linguistic Constraints We use three groups of linguistic constraints in the LEAR specialisation model, covering three different relation types which are all beneficial to the specialisation process: directed **1)** *lexical entailment* (LE) *pairs*; **2)** *synonymy pairs*; and **3)** *antonymy pairs*. Synonyms are included as symmetric ATTRACT pairs (i.e., the $\mathcal{B}_A$ pairs) since they can be seen as defining a trivial symmetric IS-A relation (Rei and Briscoe, 2014; Vulić et al., 2017). For a similar reason, antonyms are clear REPEL constraints as they anti-correlate with the LE relation.[4] Synonymy and antonymy constraints are taken from prior work (Zhang et al., 2014; Ono et al., 2015): they are extracted from WordNet (Fellbaum, 1998) and Roget (Kipfer, 2009). In total, we work with 1,023,082 synonymy pairs (11.7 synonyms per word on average) and 380,873 antonymy pairs (6.5 per word).[5]

As in prior work (Nguyen et al., 2017; Nickel and Kiela, 2017), LE constraints are extracted from the WordNet hierarchy, relying on the transitivity of the LE relation. This means that we include both direct and indirect LE pairs in our set of constraints (e.g., (*pangasius, fish*), (*fish, animal*), and *(pangasius, animal)*). We retained only noun-noun and verb-verb pairs, while the rest were discarded: the final number of LE constraints is 1,545,630.[6]

Training Setup We adopt the original ATTRACT-REPEL model setup without any fine-tuning. Hyperparameter values are set to: $\delta_{att} = 0.6$, $\delta_{rep} = 0.0$, $\lambda_{reg} = 10^{-9}$ (Mrkšić et al., 2017). The models are trained for 5 epochs with the AdaGrad algorithm (Duchi et al., 2011), with batch sizes set to $k_1 = k_2 = k_3 = 128$ for faster convergence.

4 Results and Discussion

We test and analyse LEAR-specialised vector spaces in two standard word-level LE tasks used in prior work: hypernymy directionality and detection (Section 4.1) and graded LE (Section 4.2).

4.1 LE Directionality and Detection

The first evaluation uses three classification-style tasks with increased levels of difficulty. The tasks are evaluated on three datasets used extensively in the LE literature (Roller et al., 2014; Santus et al., 2014; Weeds et al., 2014; Shwartz et al., 2017; Nguyen et al., 2017), compiled into an integrated evaluation set by Kiela et al. (2015b).[7]

[3] All vectors are 300-dimensional except for the 600-dimensional CONTEXT2VEC vectors; for further details regarding the architectures and training setup of the used vector collections, we refer the reader to the original papers. We also experimented with dependency-based SGNS vectors (Levy and Goldberg, 2014), observing similar patterns in the results.

[4] In short, the question "*Is X a type of X?*" (synonymy) is trivially true, while the question "*Is ¬X a type of X?*" (antonymy) is trivially false.

[5] https://github.com/tticoin/AntonymDetection

[6] We also experimented with additional 30,491 LE constraints from the Paraphrase Database (PPDB) 2.0 (Pavlick et al., 2015). Adding them to the WordNet-based LE pairs makes no significant impact on the final performance. We also used synonymy and antonymy pairs from other sources, such as word pairs from PPDB used previously by Wieting et al. (2015), and BabelNet (Navigli and Ponzetto, 2012) used by Mrkšić et al. (2017), reaching the same conclusions.

(a) BLESS: Directionality **(b) WBLESS**: Detection **(c) BIBLESS**: Detect+direct

Figure 2: Summary of the results on three different word-level LE subtasks: (a) *directionality*; (b) *detection*; (c) *detection and directionality*. Vertical bars denote the results obtained by different input word vector spaces which are post-processed/specialised by our LEAR specialisation model using three variants of the asymmetric distance (D_1, D_2, D_3), see Section 2. Thick horizontal red lines refer to the best reported scores on each subtask for these datasets; the baseline scores are taken from Nguyen et al. (2017).

The first task, LE directionality, is conducted on 1,337 LE pairs originating from the BLESS evaluation set (Baroni and Lenci, 2011). Given a true LE pair, the task is to predict the correct hypernym. With LEAR-specialised vectors this is achieved by simply comparing the vector norms of each concept in a pair: the one with the larger norm is the hypernym (see Figure 1).

The second task, LE detection, involves a binary classification on the WBLESS dataset (Weeds et al., 2014) which comprises 1,668 word pairs standing in a variety of relations (LE, meronymy-holonymy, co-hyponymy, reversed LE, no relation). The model has to detect a true LE pair, that is, to distinguish between the pairs where the statement *X is a (type of) Y* is true from all other pairs. With LEAR vectors, this classification is based on the asymmetric distance score: if the score is above a certain threshold, we classify the pair as "true LE", otherwise as "other". While Kiela et al. (2015b) manually define the threshold value, we follow the approach of Nguyen et al. (2017) and cross-validate: in each of the 1,000 iterations, 2% of the pairs are sampled for threshold tuning, and the remaining 98% are used for testing. The reported numbers are therefore average accuracy scores.[8]

[8]We have conducted more LE directionality and detection experiments on other datasets such as EVALution (Santus et al., 2015), the $N_1 \vDash N_2$ dataset of Baroni et al. (2012), and the dataset of Lenci and Benotto (2012) with similar performances and findings. We do not report all these results for brevity and clarity of presentation.

The final task, LE detection *and* directionality, concerns a three-way classification on BIBLESS, a relabeled version of WBLESS. The task is now to distinguish both LE pairs ($\rightarrow 1$) and reversed LE pairs ($\rightarrow -1$) from other relations ($\rightarrow 0$), and then additionally select the correct hypernym in each detected LE pair. We apply the same test protocol as in the LE detection task.

Results and Analysis The original paper of Kiela et al. (2015b) reports the following best scores on each task: 0.88 (BLESS), 0.75 (WBLESS), 0.57 (BIBLESS). These scores were recently surpassed by Nguyen et al. (2017), who, instead of post-processing, combine WordNet-based constraints with an SGNS-style objective into a joint model. They report the best scores to date: 0.92 (BLESS), 0.87 (WBLESS), and 0.81 (BIBLESS).

The performance of the four LEAR-specialised word vector collections is shown in Figure 2 (together with the strongest baseline scores for each of the three tasks). The comparative analysis confirms the increased complexity of subsequent tasks. LEAR specialisation of *each* of the starting vector spaces consistently outperformed *all* baseline scores across *all* three tasks. The extent of the improvements is correlated with task difficulty: it is lowest for the easiest directionality task ($0.92 \rightarrow 0.96$), and highest for the most difficult detection plus directionality task ($0.81 \rightarrow 0.88$).

The results show that the two LEAR variants which do not rely on absolute norm values and

	Norm		Norm		Norm

animal	11.91	artifact	17.71	instrumentality	14.56
organism	20.08	object	23.55	–	–

Table 1: L2 norms for selected concepts from the WordNet hierarchy. Input: FASTTEXT; LEAR: D2.

perform a normalisation step in the asymmetric distance (D2 and D3) have an edge over the D1 variant which operates with unbounded norms. The difference in performance between D2/D3 and D1 is even more pronounced in the graded LE task (see Section 4.2). This shows that the use of unbounded vector norms diminishes the importance of the symmetric cosine distance in the combined asymmetric distance. Conversely, the synergistic combination used in D2/D3 does not suffer from this issue.

The high scores achieved with each of the four word vector collections show that LEAR is not dependent on any particular word representation architecture. Moreover, the extent of the performance improvements in each task suggests that LEAR is able to reconstruct the concept hierarchy coded in the input linguistic constraints.

Moreover, we have conducted a small experiment to verify that the LEAR method can generalise beyond what is directly coded in pairwise external constraints. A simple WordNet lookup baseline yields accuracy scores of 0.82 and 0.80 on the directionality and detection tasks, respectively. This baseline is outperformed by LEAR: its scores are 0.96 and 0.92 on the two tasks when relying on the same set of WordNet constraints.

Importance of Vector Norms To verify that the knowledge concerning the position in the semantic hierarchy actually arises from vector norms, we also manually inspect the norms after LEAR specialisation. A few examples are provided in Table 1. They indicate a desirable pattern in the norm values which imposes a hierarchical ordering on the concepts. Note that the original distributional SGNS model (Mikolov et al., 2013) does not normalise vectors to unit length after training. However, these norms are not at all correlated with the desired hierarchical ordering, and are therefore useless for LE-related applications: the non-specialised distributional SGNS model scores 0.44, 0.48, and 0.34 on the three tasks, respectively.

4.2 Graded Lexical Entailment

Asymmetric distances in the LEAR-specialised space quantify the degree of lexical entailment between any two concepts. This means that they can be used to make fine-grained assertions regarding the hierarchical relationships between concepts. We test this property on HyperLex (Vulić et al., 2017), a gold standard dataset for evaluating how well word representation models capture graded LE, grounded in the notions of *concept (proto)typicality* (Rosch, 1973; Medin et al., 1984) and *category vagueness* (Kamp and Partee, 1995; Hampton, 2007) from cognitive science. HyperLex contains 2,616 word pairs (2,163 noun pairs and 453 verb pairs) scored by human raters in the $[0, 6]$ interval following the question *"To what degree is X a (type of) Y?"*[9]

As shown by the high inter-annotator agreement on HyperLex (0.85), humans are able to consistently reason about graded LE.[10] However, current state-of-the-art representation architectures are far from this ceiling. For instance, Vulić et al. (2017) evaluate a plethora of architectures and report a high-score of only 0.320 (see the summary table in Figure 3). Two recent representation models (Nickel and Kiela, 2017; Nguyen et al., 2017) focused on the LE relation in particular (and employing the same set of WordNet-based constraints as LEAR) report the highest score of 0.540 (on the entire dataset) and 0.512 (on the noun subset).

Results and Analysis We scored all HyperLex pairs using the combined asymmetric distance described by Equation (7), and then computed Spearman's rank correlation with the ground-truth ranking. Our results, together with the strongest baseline scores, are summarised in Figure 3.

The summary table in Figure 3(c) shows the HyperLex performance of several prominent LE models. We provide only a quick outline of these models here; further details can be found in the original papers. FREQ-RATIO exploits the fact that more general concepts tend to occur more frequently in textual corpora. SGNS (COS) uses non-specialised

[9]From another perspective, one might say that graded LE provides finer-grained human judgements on a continuous scale rather than simplifying the judgements into binary discrete decisions. For instance, the HyperLex score for the pair *(girl, person)* is 5.91/6, the score for *(guest, person)* is 4.33, while the score for the reversed pair *(person, guest)* is 1.73.

[10]For further details concerning HyperLex, we refer the reader to the resource paper (Vulić et al., 2017). The dataset is available at: http://people.ds.cam.ac.uk/iv250/hyperlex.html

(c) Summary

Figure 3: Results on the graded LE task defined by HyperLex. Following Nickel and Kiela (2017), we use Spearman's rank correlation scores on: **a)** the entire dataset (2,616 noun and verb pairs); and **b)** its noun subset (2,163 pairs). The summary table shows the performance of other well-known architectures on the full HyperLex dataset, compared to the best results achieved using LEAR specialisation.

SGNS vectors and quantifies the LE strength using the symmetric cosine distance between vectors. A comparison of these models to the best-performing LEAR vectors shows the extent of the improvements achieved using the specialisation approach.

LEAR-specialised vectors also outperform SLQS-SIM (Santus et al., 2014) and VISUAL (Kiela et al., 2015b), two LE detection models similar in spirit to LEAR. These models combine symmetric semantic similarity (through cosine distance) with an asymmetric measure of lexical generality obtained either from text (SLQS-SIM) or visual data (VISUAL). The results on HyperLex indicate that the two generality-based measures are too coarse-grained for graded LE judgements. These models were originally constructed to tackle LE directionality and detection tasks (see Section 4.1), but their performance is surpassed by LEAR on those tasks as well. The VISUAL model outperforms SLQS-SIM. However, its numbers on BLESS (0.88), WBLESS (0.75), and BIBLESS (0.57) are far from the top-performing LEAR vectors (0.96, 0.92, 0.88).[11]

WN-BEST denotes the best result with asymmetric similarity measures which use the WordNet structure as their starting point (Wu and Palmer, 1994; Pedersen et al., 2004). This model can be observed as a model that directly looks up the full WordNet structure to reason about graded lexical entailment. The reported results from Figure 3(c) suggest it is more effective to quantify the LE relation strength by using WordNet as the source of constraints for specialisation models such as HYPERVEC or LEAR.

WORD2GAUSS (Vilnis and McCallum, 2015) represents words as multivariate K-dimensional Gaussians rather than points in the embedding space: it is therefore naturally asymmetric and was used in LE tasks before, but its performance on HyperLex indicates that it cannot effectively capture the subtleties required to model graded LE. However, note that the comparison is not strictly fair as WORD2GAUSS does not leverage any external knowledge. An interesting line for future research is to embed external knowledge within this representation framework.

Most importantly, LEAR outperforms three recent (and conceptually different) architectures: ORDER-EMB (Vendrov et al., 2016), POINCARÉ (Nickel and Kiela, 2017), and HYPERVEC (Nguyen et al., 2017). Like LEAR, all of these models complement distributional knowledge with external linguistic constraints extracted from WordNet. Each model uses a different strategy to exploit the hierarchical relationships encoded in these constraints (their approaches are discussed in Section 5).[12] However, LEAR, as the first LE-oriented post-processor, is able to utilise the constraints more effectively than its competitors. Another advantage of LEAR is its applicability to any input

[11] We note that SLQS and VISUAL do not leverage any external knowledge from WordNet, but the VISUAL model leverages external visual information about concepts.

[12] As discussed previously by Vulić et al. (2017), the off-the-shelf ORDER-EMB vectors were trained for the binary ungraded LE detection task: this limits their expressiveness in the graded LE task.

	WBLESS	BIBLESS	HL-A	HL-N
LEAR variant				
SYM-ONLY	0.687	0.679	0.469	0.429
ASYM-ONLY	0.867	0.824	0.529	0.565
FULL	**0.912**	**0.875**	**0.686**	**0.705**

Table 2: Analysing the importance of the synergy in the FULL LEAR model on the final performance on WBLESS, BLESS, HyperLex-All (HL-A) and HyperLex-Nouns (HL-N). Input: FASTTEXT. D2.

vector space.

Figures 3(a) and 3(b) indicate that the two LEAR variants which rely on norm ratios (D2 and D3), rather than on absolute (unbounded) norm differences (D1), achieve stronger performance on HyperLex. The highest correlation scores are again achieved by D2 with all input vector spaces.

4.3 Further Discussion

Why Symmetric + Asymmetric? In another experiment, we analyse the contributions of both LE-related terms in the LEAR combined objective function (see Section 2.2). We compare three variants of LEAR: **1)** a symmetric variant which does not arrange vector norms using the $LE_j(\mathcal{B}_L)$ term (SYM-ONLY); **2)** a variant which arranges norms, but does not use LE constraints as additional symmetric ATTRACT constraints (ASYM-ONLY); and **3)** the full LEAR model, which uses both cost terms (FULL). The results with one input space (similar results are achieved with others) are shown in Table 2. This table shows that, while the stand-alone ASYM-ONLY term seems more beneficial than the SYM-ONLY one, using the two terms jointly yields the strongest performance across all LE tasks.

LE and Semantic Similarity We also test whether the asymmetric LE term harms the (norm-independent) cosine distances used to represent semantic similarity. The LEAR model is compared to the original ATTRACT-REPEL model making use of the same set of linguistic constraints. Two true semantic similarity datasets are used for evaluation: SimLex-999 (Hill et al., 2015) and SimVerb-3500 (Gerz et al., 2016). There is no significant difference in performance between the two models, both of which yield similar results on SimLex (Spearman's rank correlation of ≈ 0.71) and SimVerb (≈ 0.70). This proves that cosine distances remain preserved during the optimization of the asymmetric objective performed by the joint LEAR model.

5 Related Work

Vector Space Specialisation A standard approach to incorporating external information into vector spaces is to pull the representations of similar words closer together. Some models integrate such constraints into the training procedure: they modify the prior or the regularisation (Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Kiela et al., 2015a), or use a variant of the SGNS-style objective (Liu et al., 2015; Osborne et al., 2016; Nguyen et al., 2017). Another class of models, popularly termed *retrofitting*, fine-tune distributional vector spaces by injecting lexical knowledge from semantic databases such as WordNet or the Paraphrase Database (Faruqui et al., 2015; Jauhar et al., 2015; Wieting et al., 2015; Nguyen et al., 2016; Mrkšić et al., 2016; Mrkšić et al., 2017).

LEAR falls into the latter category. However, while previous post-processing methods have focused almost exclusively on specialising vector spaces to emphasise semantic similarity (i.e., to distinguish between similarity and relatedness by explicitly pulling synonyms closer and pushing antonyms further apart), this paper proposed a principled methodology for specialising vector spaces for asymmetric hierarchical relations (of which *lexical entailment* is an instance). Its starting point is the state-of-the-art similarity specialisation framework of Mrkšić et al. (2017), which we extend to support the inclusion of hierarchical asymmetric relationships between words.

Word Vectors and Lexical Entailment Since the hierarchical LE relation is one of the fundamental building blocks of semantic taxonomies and hierarchical concept categorisations (Beckwith et al., 1991; Fellbaum, 1998), a significant amount of research in semantics has been invested into its automatic detection and classification. Early work relied on asymmetric directional measures (Weeds et al., 2004; Clarke, 2009; Kotlerman et al., 2010; Lenci and Benotto, 2012, i.a.) which were based on the distributional inclusion hypothesis (Geffet and Dagan, 2005) or the distributional informativeness or generality hypothesis (Herbelot and Ganesalingam, 2013; Santus et al., 2014). However, these approaches have recently been superseded by methods based on word embeddings. These methods build dense real-valued vectors for capturing the LE relation, either directly in the LE-focused space (Vilnis and McCallum, 2015; Vendrov et al.,

2016; Henderson and Popa, 2016; Nickel and Kiela, 2017; Nguyen et al., 2017) or by using the vectors as features for supervised LE detection models (Tuan et al., 2016; Shwartz et al., 2016; Nguyen et al., 2017; Glavaš and Ponzetto, 2017).

Several LE models embed useful hierarchical relations from external resources such as WordNet into LE-focused vector spaces, with solutions coming in different flavours. The model of Yu et al. (2015) is a dynamic distance-margin model optimised for the LE detection task using hierarchical WordNet constraints. This model was extended by Tuan et al. (2016) to make use of contextual sentential information. A major drawback of both models is their inability to make directionality judgements. Further, their performance has recently been surpassed by the HYPERVEC model of Nguyen et al. (2017). This model combines WordNet constraints with the SGNS distributional objective into a joint model. As such, the model is tied to the SGNS objective and any change of the distributional modelling paradigm implies a change of the entire HYPERVEC model. This makes their model less versatile than the proposed LEAR framework. Moreover, the results achieved using LEAR specialisation achieve substantially better performance across all LE tasks used for evaluation.

Another model similar in spirit to LEAR is the ORDER-EMB model of Vendrov et al. (2016), which encodes hierarchical structure by imposing a partial order in the embedding space: higher-level concepts get assigned higher per-coordinate values in a d-dimensional vector space. The model minimises the violation of the per-coordinate orderings during training by relying on hierarchical WordNet constraints between word pairs. Finally, the POINCARÉ model of Nickel and Kiela (2017) makes use of hyperbolic spaces to learn general-purpose LE embeddings based on n-dimensional Poincaré balls which encode both hierarchy and semantic similarity, again using the WordNet constraints. A similar model in hyperbolic spaces was proposed by Chamberlain et al. (2017). In this paper, we demonstrate that LE-specialised word embeddings with stronger performance can be induced using a simpler model operating in more intuitively interpretable Euclidean vector spaces.

6 Conclusion and Future Work

This paper proposed LEAR, a vector space specialisation procedure which simultaneously injects symmetric and asymmetric constraints into existing vector spaces, performing joint specialisation for two properties: *lexical entailment* and *semantic similarity*. Since the former is not symmetric, LEAR uses an asymmetric cost function which encodes the hierarchy between concepts by manipulating the norms of word vectors, assigning higher norms to higher-level concepts. Specialising the vector space for both relations has a synergistic effect: LEAR-specialised vectors attain state-of-the-art performance in judging semantic similarity and set new high scores across four different lexical entailment tasks. The code for the LEAR model is available from: `github.com/nmrksic/lear`.

In future work, we plan to apply a similar methodology to other asymmetric relations (e.g., *meronymy*), as well as to investigate fine-grained models which can account for differing path lengths from the WordNet hierarchy. We will also extend the model to reason over words unseen in input lexical resources, similar to the recent post-specialisation model oriented towards specialisation of unseen words for similarity (Vulić et al., 2018). We also plan to test the usefulness of LE-specialised vectors in downstream natural language understanding tasks. Porting the model to other languages and enabling cross-lingual applications such as cross-lingual lexical entailment (Upadhyay et al., 2018) is another future research direction.

Acknowledgments

We thank the three anonymous reviewers for their insightful comments and suggestions. We are also grateful to the TakeLab research group at the University of Zagreb for offering support to computationally intensive experiments in our hour of need. This work is supported by the ERC Consolidator Grant LEXICAL: Lexical Acquisition Across Languages (no 648909).

Abstract

Abstract Meaning Representation (AMR) research has mostly focused on English. We show that it is possible to use AMR annotations for English as a semantic representation for sentences written in other languages. We exploit an AMR parser for English and parallel corpora to learn AMR parsers for Italian, Spanish, German and Chinese. Qualitative analysis show that the new parsers overcome structural differences between the languages. We further propose a method to evaluate the parsers that does not require gold standard data in the target languages. This method highly correlates with the gold standard evaluation, obtaining a (Pearson) correlation of 0.95.

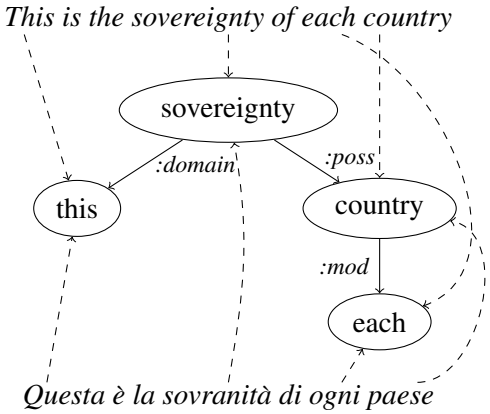

Figure 1: AMR alignments for a English sentence and its Italian translation.

1 Introduction

Abstract Meaning Representation (AMR) parsing is the process of converting natural language sentences into their corresponding AMR representations (Banarescu et al., 2013). An AMR is a graph with nodes representing the concepts of the sentence and edges representing the semantic relations between them. Most available AMR datasets large enough to train statistical models consist of pairs of English sentences and AMR graphs.

The cross-lingual properties of AMR across languages has been the subject of preliminary discussions. The AMR guidelines state that AMR is not an interlingua (Banarescu et al., 2013) and Bojar (2014) categorizes different kinds of divergences in the annotation between English AMRs and Czech AMRs. Xue et al. (2014) show that structurally aligning English AMRs with Czech and Chinese AMRs is not always possible but that refined annotation guidelines suffice to resolve some of these cases. We extend this line of research by exploring whether divergences among languages can be overcome, i.e., we investigate whether it is possible to maintain the AMR annotated for English as a semantic representation for sentences written in other languages, as in Figure 1.

We implement AMR parsers for Italian, Spanish, German and Chinese using annotation projection, where existing annotations are projected from a source language (English) to a target language through a parallel corpus (e.g., Yarowsky et al., 2001; Hwa et al., 2005; Padó and Lapata, 2009; Evang and Bos, 2016). By evaluating the parsers and manually analyzing their output, we show that the parsers are able to recover the AMR structures even when there exist structural differences between the languages, i.e., although AMR is not an interlingua it can act as one. This method also provides a quick way to prototype multilingual AMR parsers, assuming that Part-of-speech (POS) taggers, Named Entity Recognition (NER) taggers and dependency parsers are available for the target languages. We also propose an alternative approach, where Machine Translation (MT) is used to translate the input sentences into English so that an available English AMR parser can

Proceedings of NAACL-HLT 2018, pages 1146–1155
New Orleans, Louisiana, June 1 - 6, 2018.

be employed. This method is an even quicker solution which only requires translation models between the target languages and English.

Due to the lack of gold standard in the target languages, we exploit the English data to evaluate the parsers for the target languages. Henceforth, we will use the term target parser to indicate a parser for a target language. We achieve this by first learning the target parser from the gold standard English parser, and then inverting this process to learn a new English parser from the target parser. We then evaluate the resulting English parser against the gold standard. We call this "full-cycle" evaluation.

Similarly to Evang and Bos (2016), we also directly evaluate the target parser on "silver" data, obtained by parsing the English side of a parallel corpus.

In order to assess the reliability of these evaluation methods, we collected gold standard datasets for Italian, Spanish, German and Chinese by acquiring professional translations of the AMR gold standard data to these languages. We hypothesize that the full-cycle score can be used as a more reliable proxy than the silver score for evaluating the target parser. We provide evidence to this claim by comparing the three evaluation procedures (silver, full-cycle, and gold) across languages and parsers.

Our main contributions are:

- We provide evidence that AMR annotations can be successfully shared across languages.
- We propose two ways to rapidly implement non-English AMR parsers.
- We propose a novel method to evaluate non-English AMR parsers when gold annotations in the target languages are missing. This method highly correlates with gold standard evaluation, obtaining a Pearson correlation coefficient of 0.95.
- We release human translations of an AMR dataset (LDC2015E86) to Italian, Spanish, German and Chinese.

2 Cross-lingual AMR parsing

AMR is a semantic representation heavily biased towards English, where labels for nodes and edges are either English words or Propbank frames (Kingsbury and Palmer, 2002). The goal of AMR is to abstract away from the syntactic realization of the original sentences while maintaining its underlying meaning. As a consequence, different phrasings of one sentence are expected to provide identical AMR representations. This canonicalization does not always hold across languages: two sentences that express the same meaning in two different languages are not guaranteed to produce identical AMR structures (Bojar, 2014; Xue et al., 2014). However, Xue et al. (2014) show that in many cases the unlabeled AMRs are in fact shared across languages. We are encouraged by this finding and argue that it should be possible to develop algorithms that account for some of these differences when they arise. We therefore introduce a new problem, which we call cross-lingual AMR parsing: given a sentence in any language, the goal is to recover the AMR graph that was originally devised for its English translation. This task is harder than traditional AMR parsing as it requires to recover English labels as well as to deal with structural differences between languages, usually referred as translation divergence. We propose two initial solutions to this problem: by annotation projection and by machine translation.

2.1 Method 1: Annotation Projection

AMR is not grounded in the input sentence, therefore there is no need to change the AMR annotation when projecting to another language. We think of English labels for the graph nodes as ones from an independent language, which incidentally looks similar to English. However, in order to train state-of-the-art AMR parsers, we also need to project the alignments between AMR nodes and words in the sentence (henceforth called AMR alignments). We use word alignments, similarly to other annotation projection work, to project the AMR alignments to the target languages.

Our approach depends on an underlying assumption that we make: if a source word is word-aligned to a target word and it is AMR aligned with an AMR node, then the target word is also aligned to that AMR node. More formally, let $S = s_1 \dots s_{|s|}$ be the source language sentence and $T = t_1 \dots t_{|t|}$ be the target language sentence; $A_s(\cdot)$ be the AMR alignment mapping word tokens in S to the set of AMR nodes that are triggered by it; $A_t(\cdot)$ be the same function for T; v be a node in the AMR graph; and finally, $W(\cdot)$ be an alignment that maps a word in S to a subset of words in T. Then, the AMR projection assump-

tion is:

$$\forall i, j, v \;\; t_j \in W(s_i) \wedge v \in A_s(s_i) \Rightarrow v \in A_t(t_j)$$

In the example of Figure 1, *Questa* is word-aligned with *This* and therefore AMR-aligned with the node *this*, and the same logic applies to the other aligned words. The words *is*, *the* and *of* do not generate any AMR nodes, so we ignore their word alignments. We apply this method to project existing AMR annotations to other languages, which are then used to train the target parsers.

2.2 Method 2: Machine Translation

We invoke an MT system to translate the input sentence into English so that we can use an available English parser to obtain its AMR graph. Naturally, the quality of the output graph depends on the quality of the translations. If the automatic translation is close to the reference translation, then the predicted AMR graph will be close to the reference AMR graph. It is therefore evident that this method is not informative in terms of the cross-lingual properties of AMR. However, its simplicity makes it a compelling engineering solution for parsing other languages.

2.3 Evaluation

We now turn to the problem of evaluation. Let us assume that we trained a parser for a target language, for example using the annotation projection method discussed in Section 2.1. In line with rapid development of new parsers, we assume that the only gold AMR dataset available is the one released for English.

SILVER We can generate a silver test set by running an automatic (English) AMR parser on the English side of a parallel corpus and use the output AMRs as references. However, the silver test set is affected by mistakes made by the English AMR parser, therefore it may not be reliable.

FULL-CYCLE In order to perform the evaluation on a gold test set, we propose full-cycle evaluation: after learning the target parser from the English parser, we invert this process to learn a new English parser from the target parser, in the same way that we learned the target parser from the English parser. The resulting English parser is then evaluated against the (English) AMR gold standard. We hypothesize that the score of the new English parser can be used as a proxy to the score of the target parser.

GOLD To show whether the evaluation methods proposed can be used reliably, we also generated gold test AMR datasets for four target languages (Italian, Spanish, German and Chinese). In order to do so, we collected professional translations for the English sentences in the AMR test set.[1] We were then able to create pairs of human-produced sentences with human-produced AMR graphs.

A diagram summarizing the different evaluation stages is shown in Figure 2. In the case of MT-based systems, the full-cycle corresponds to first translating from English to the target language and then back to English (back-translation), and only then parsing the sentences with the English AMR parser. At the end of this process, a noisy version of the original sentence will be returned and its parsed graph will be a noisy version of the graph parsed from the original sentence.

3 Experiments

We run experiments on four languages: Italian, Spanish, German and Chinese. We use Europarl (Koehn, 2005) as the parallel corpus for Italian, Spanish and German, containing around 1.9M sentences for each language pair. For Chinese, we use the first 2M sentences from the United Nations Parallel Corpus (Ziemski et al., 2016). For each target language we extract two parallel datasets of 20,000/2,000/2,000 (train/dev/test) sentences for the two step of the annotation projection (English $\rightarrow$ target and target $\rightarrow$ English). These are used to train the AMR parsers. The projection approach also requires training the word alignments, for which we use all the remaining sentences from the parallel corpora (Europarl for Spanish/German/Italian and UN Parallel Corpus for Chinese). These are also the sentences we use to train the MT models. The gold AMR dataset is LDC2015E86, containing 16,833 training sentences, 1,368 development sentences, and 1,371 testing sentences.

Word alignments were generated using fast_align (Dyer et al., 2013), while AMR alignments were generated with JAMR (Flanigan et al., 2014). AMREager (Damonte et al., 2017) was chosen as the pre-existing English AMR parser. AMREager is an open-source AMR parser that

[1] These datasets are currently available upon request from the authors.

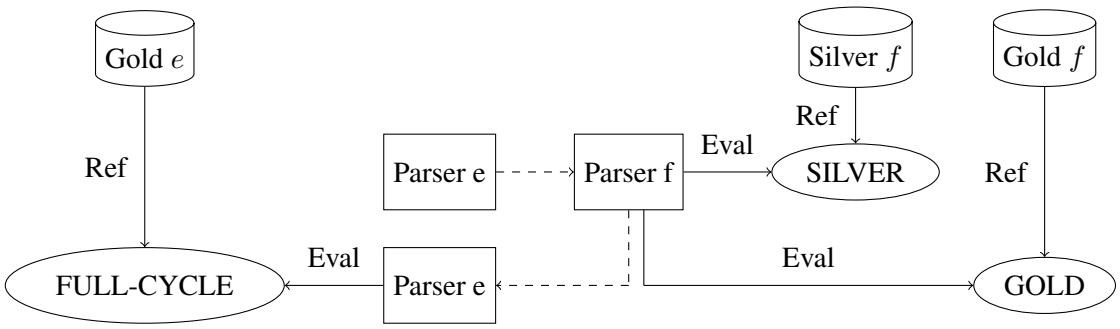

Figure 2: Description of SILVER, FULL-CYCLE and GOLD evaluations. e stands for English and f stands for the target (foreign) language. Dashed lines represent the process of transferring learning across languages (e.g. with annotation projection). SILVER uses a parsed parallel corpus as reference ("Ref"), FULL-CYCLE uses the English gold standard (Gold e) and GOLD uses the target language gold standard we collected (Silver f).

needs only minor modifications for re-use with other languages.[2] It requires tokenization, POS tagging, NER tagging and dependency parsing, which for English, German and Chinese are provided by CoreNLP (Manning et al., 2014). We use Freeling (Carreras et al., 2004) for Spanish, as CoreNLP does not provide dependency parsing for this language. Italian is not supported in CoreNLP: we use Tint (Aprosio and Moretti, 2016), a CoreNLP-compatible NLP pipeline for Italian.

In order to experiment with the approach of Section 2.2, we experimented with translations from Google Translate.[3] As Google Translate has access to a much larger training corpus, we also trained baseline MT models using Moses (Koehn et al., 2007) and Nematus (Sennrich et al., 2017), with the same training data we use for the projection method and default hyper-parameters.

Smatch (Cai and Knight, 2013) is used to evaluate AMR parsers. It looks for the best alignment between the predicted AMR and the reference AMR and it then computes precision, recall and F_1 of their edges. The original English parser achieves 65% Smatch score on the test split of LDC2015E86. Full-cycle and gold evaluations use the same dataset, while silver evaluation is performed on the split of the parallel corpora we reserved for testing. Results are shown in Table 1. The Google Translate system outperforms all other systems, but is not directly comparable to them, as it has the unfair advantage of being trained on a much larger dataset. Due to noisy JAMR alignments and silver training data involved in the annotation projection approach, the MT-based systems give in general better parsing results. The BLEU scores of all translation systems are shown in Table 2.

	System	Silver	Gold	Cycle
IT	Projection	45	43	45

	Moses	57	42	48
	Nematus	57	39	40
	GT	64	50	55

Table 1: Silver, gold and full-cycle Smatch scores for projection-based and MT-based systems.

There are several sources of noise in the annotation projection method, which affect the parsing results: 1) the parsers are trained on silver data obtained by an automatic parser for English; 2) the projection uses noisy word alignments; 3) the AMR alignments on the source side are also noisy; 4) translation divergences exist between the languages, making it sometimes difficult to project the annotation without loss of information.

[2]The multilingual adaptation of AMREager is available at http://www.github.com/mdtux89/amr-eager-multilingual. A demo is available at http://cohort.inf.ed.ac.uk/amreager.html.

4 Qualitative Analysis

Figure 3 shows examples of output parses[4] for all languages, including the AMR alignments by-product of the parsing process, that we use to discuss the mistakes made by the parsers.

In the Italian example, the only evident error is that *Infine* (*Lastly*) should be ignored. In the Spanish example, the word *medida* (*measure*) is wrongly ignored: it should be used to generate a child of the node *impact-01*. Some of the *:ARG* roles are also not correct. In the German example, *meines* (*my*) should reflect the fact that the speaker is talking about his own country. Finally, in the Chinese example, there are several mistakes including yet another concept identification mistake: *intend-01* is erroneously triggered.

Most mistakes involve concept identification. In particular, relevant words are often erroneously ignored by the parser. This is directly related to the problem of noisy word alignments in annotation projection: the parser learns what words are likely to trigger a node (or a set of nodes) in the AMR by looking at their AMR alignments (which are induced by the word alignments). If an important word consistently remains unaligned, the parser will erroneously learn to discard it. More accurate alignments are therefore crucial in order to achieve better parsing results. We computed the percentage of words in the training data that are learned to be non-content-bearing in each parser and we found that the Chinese parser, which is our least accurate parser, is the one that most suffer from this, with 33% non-content-bearing words. On the other hand, in the German parser, which is the highest scoring, only 26% of the words are non-content-bearing, which is the lowest percentage amongst all parsers.

[4]In this section, all parsed graphs were generated with the projection-based system of Section 2.1.

4.1 Translational Divergence

In order to investigate the hypothesis that AMR can be shared across these languages, we now look at translational divergence and discuss how it affects parsing, following the classification used in previous work (Dorr et al., 2002; Dorr, 1994), which identifies classes of divergences for several languages. Sulem et al. (2015) also follow the same categorization for French.

Figure 4 shows six sentences displaying these divergences. The aim of this analysis is to assess how the parsers deal with the different kind of translational divergences, regardless of the overall quality of the output.

Categorical. This divergence happens when two languages use different POS tags to express the same meaning. For example, the English sentence *I am jealous of you* is translated into Spanish as *Tengo envidia de ti* (*I have jealousy of you*). The English adjective *jealous* is translated in the Spanish noun *envidia*. In Figure 4a we note that the categorical divergence does not create problems since the parsers correctly recognized that *envidia* (*jealousy*/*envy*) should be used as the predicate, regardless of its POS.

Conflational. This divergence happens when verbs expressed in a language with a single word can be expressed with more words in another language. Two subtypes are distinguished: *manner* and *light verb*. Manner refers to a manner verb that is mapped to a motion verb plus a manner-bearing word. For example, *We will answer* is translated in the Italian sentence *Noi daremo una riposta* (*We will give an answer*), where *to answer* is translated as *daremo una risposta* (*will give an answer*). Figure 4b shows that the Italian parser generates a sensible output for this sentence by creating a single node labeled *answer-01* for the expression *dare una riposta*.

In a light verb conflational divergence, a verb is mapped to a light verb plus an additional meaning unit, such as when *I fear* is translated as *Io ho paura* (*I have fear*) in Italian: *to fear* is mapped to the light verb *ho* (*have*) plus the noun *paura* (*fear*). Figure 4e shows that also this divergence is dealt properly by the Italian parser: *ho paura* correctly triggers the root *fear-01*.

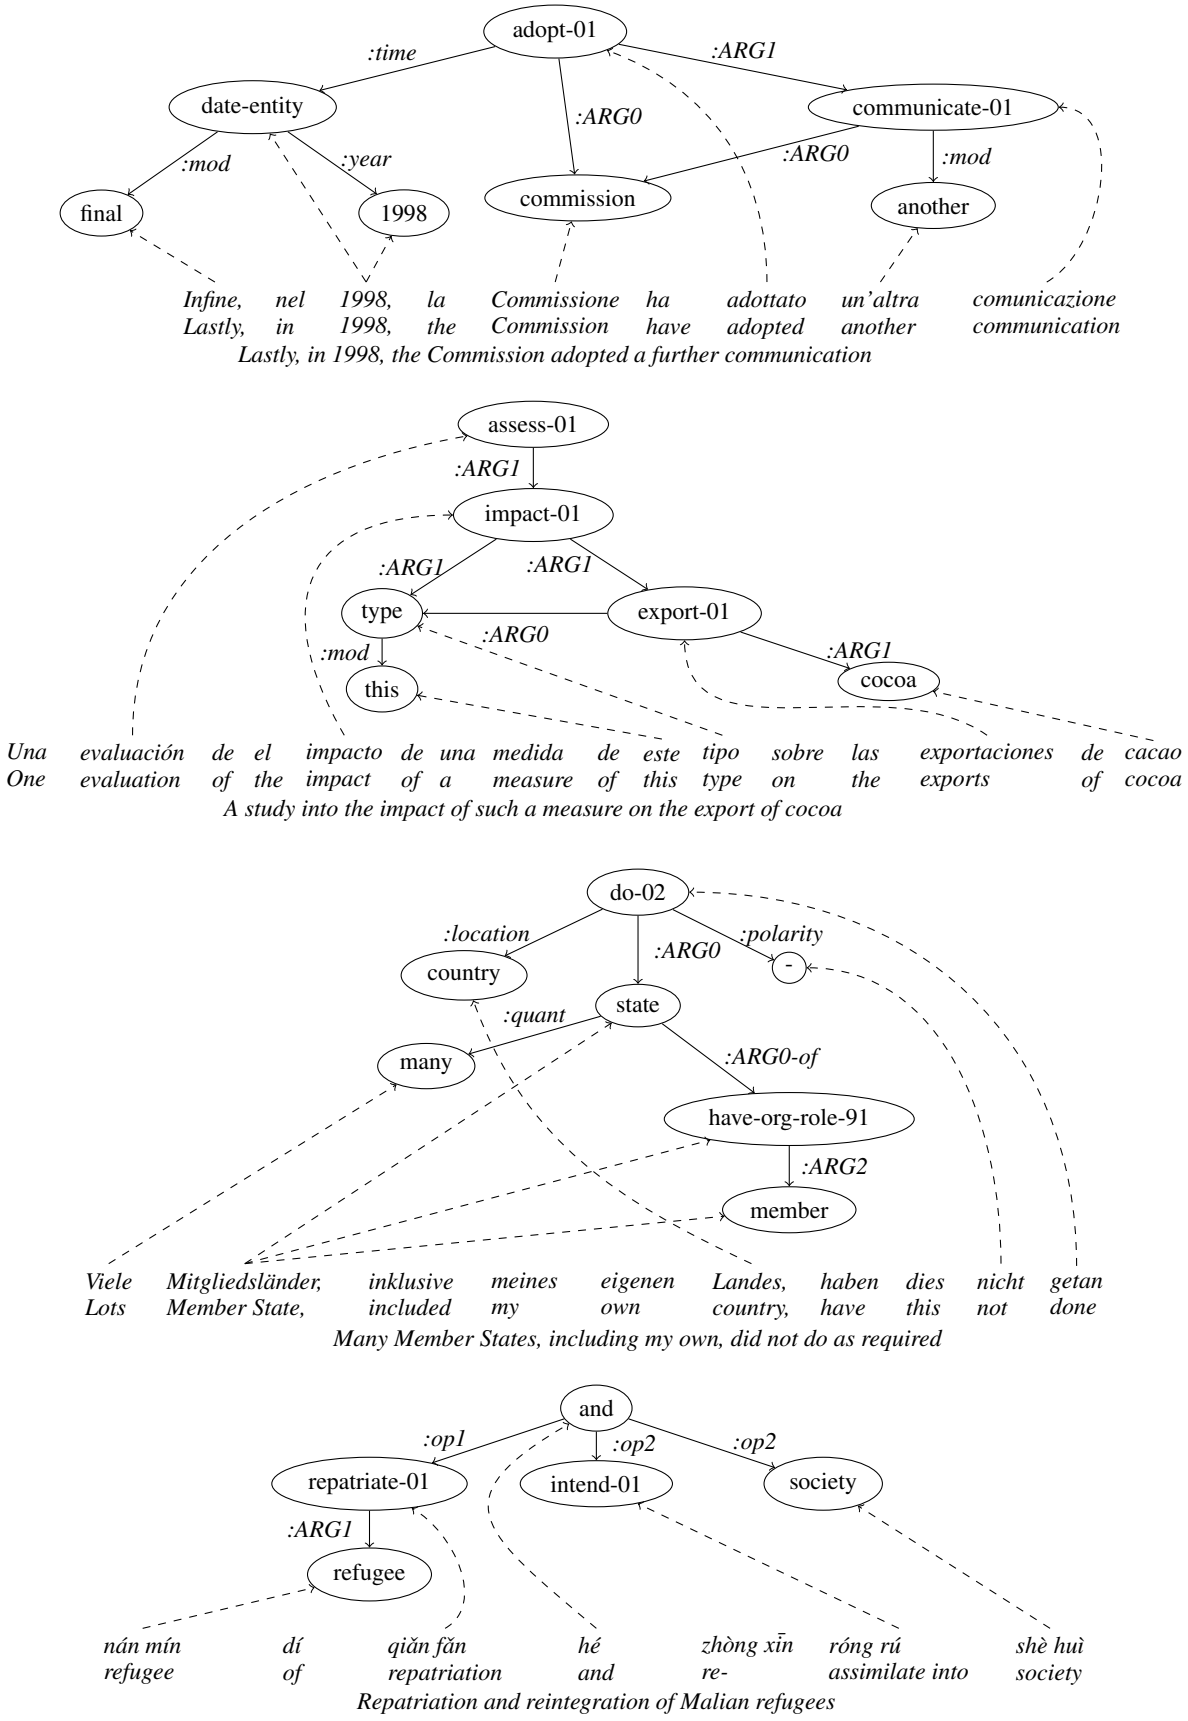

Figure 3: Parsed AMR graph and alignments (dashed lines) for an Italian sentence, a Spanish sentence, a German sentences and a Chinese sentence.

Structural. This divergence happens when verb arguments result in different syntactic configurations, for example, due to an additional PP attachment. When translating *He entered the house* with *Lui è entrato nella casa* (*He entered in the house*), the Italian translation has an additional *in* preposition. Also this parsed graph, in Figure 4c, is structurally correct. The missing node *he* is due to pronoun-dropping, which is frequent in Italian.

Head swapping. This divergence occurs when the direction of the dependency between two words is inverted. For example, *I like eating*, where *like* is head of *eating*, becomes *Ich esse gern* (*I eat likingly*) in German, where the dependency is inverted. Unlike all other examples, in this case, the German parser does not cope well with this divergence: it is unable to recognize *like-01* as the main concept in the sentence, as shown in Figure 4d.

Thematic. Finally, the parse of Figure 4f has to deal with a thematic divergence, which happens when the semantic roles of a predicate are inverted. In the sentence *I like grapes*, translated to Spanish as *Me gustan uvas*, *I* is the subject in English while *Me* is the object in Spanish. Even though we note an erroneous reentrant edge between *grape* and *I*, the thematic divergence does not create problems: the parser correctly recognizes the *:ARG0* relationship between *like-01* and *I* and the *:ARG1* relationship between *like-01* and *grape*. In this case, the edge labels are important, as this type of divergence is concerned with the semantic roles.

5 Discussion

Can AMR be shared across these languages? As mentioned in Section 2.2, the MT-based systems are not helpful in answering this question and we instead focus on the projection-based parsers. Qualitative analysis showed that the parsers are able to overcome translational divergence and that concept identification must be more accurate in order to provide good parsing results. We therefore argue that the suboptimal performance of the parsers in terms of Smatch scores is due to the many sources of noise in the annotation projection approach rather than instability of AMR across languages. We provide strong evidence that cross-lingual AMR parsing is indeed feasible and hope that the release of the gold standard test sets will motivate further work in this direction.

Are silver and full-cycle evaluations reliable? We computed the Pearson correlation coefficients for the Smatch scores of Table 1 to determine how well silver and full-cycle correlate with gold evaluation. Full-cycle correlates better than silver: the Pearson coefficient is 0.95 for full-cycle and 0.47 for silver. Figure 5 shows linear regression lines. Unlike silver, full-cycle uses the same dataset as gold evaluation and it does not contain parsing mistakes, which makes it more reliable than silver. Interestingly, if we ignore the scores obtained for Chinese, the correlation between silver and gold dramatically increases, perhaps indicating that Europarl is more suitable than the UN corpus for this task: the Pearson coefficient becomes 0.97 for full-cycle and 0.87 for silver. A good proxy for gold evaluation should rank different systems similarly. We hence computed the Kendall-tau score (Kendall, 1945), a measure for similarity between permutations, of the rankings extracted from Table 1. The results further confirm that full-cycle approximate gold better than silver does: the score is 0.40 for silver and 0.82 for full-cycle. Full cycle introduces additional noise but it is not as expensive as gold and is more reliable than silver.

6 Related Work

AMR parsing for languages other than English has made only a few steps forward. In previous work (Li et al., 2016; Xue et al., 2014; Bojar, 2014), nodes of the target graph were labeled with either English words or with words in the target language. We instead use the AMR annotation used for English for the target language as well, without translating any word. To the best of our knowledge, the only previous work that attempts to automatically parse AMR graphs for non-English sentences is by Vanderwende et al. (2015). Sentences in several languages (French, German, Spanish and Japanese) are parsed into a logical representation, which is then converted to AMR using a small set of rules. A comparison with this work is difficult, as the authors do not report results for the parsers (due to the lack of an annotated corpus) or release their code.

Besides AMR, other semantic parsing frameworks for non-English languages have been investigated (Hoffman, 1992; Cinková et al., 2009; Gesmundo et al., 2009; Evang and Bos, 2016). Evang and Bos (2016) is the most closely related to our

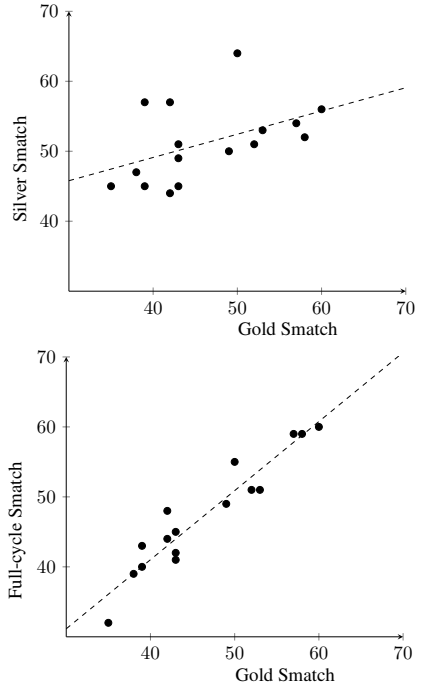

Figure 5: Linear regression lines for silver and full-cycle.

work as it uses a projection mechanism similar to ours for CCG. A crucial difference is that, in order to project CCG parse trees to the target languages, they only make use of literal translation. Previous work has also focused on assessing the stability across languages of semantic frameworks such as AMR (Xue et al., 2014; Bojar, 2014), UCCA (Sulem et al., 2015) and Propbank (Van der Plas et al., 2010).

Cross-lingual techniques can cope with the lack of labeled data on languages when this data is available in at least one language, usually English. The annotation projection method, which we follow in this work, is one way to address this problem. It was introduced for POS tagging, base noun phrase bracketing, NER tagging, and inflectional morphological analysis (Yarowsky et al., 2001) but it has also been used for dependency parsing (Hwa et al., 2005), role labeling (Padó and Lapata, 2009; Akbik et al., 2015) and semantic parsing (Evang and Bos, 2016). Another common thread of cross-lingual work is model transfer, where parameters are shared across languages (Zeman and Resnik, 2008; Cohen and Smith, 2009; Cohen et al., 2011; McDonald et al., 2011; Søgaard, 2011).

7 Conclusions

We introduced the problem of parsing AMR structures, annotated for English, from sentences written in other languages as a way to test the cross-lingual properties of AMR. We provided evidence that AMR can be indeed shared across the lan-

guages tested and that it is possible to overcome translational divergences. We further proposed a novel way to evaluate the target parsers that does not require manual annotations of the target language. The full-cycle procedure is not limited to AMR parsing and could be used for other cross-lingual problems in NLP. The results of the projection-based AMR parsers indicate that there is a vast room for improvements, especially in terms of generating better alignments. We encourage further work in this direction by releasing professional translations of the AMR test set into four languages.

Sentences with Gapping: Parsing and Reconstructing Elided Predicates

Sebastian Schuster **Joakim Nivre**‡ **Christopher D. Manning**

Abstract

Sentences with gapping, such as *Paul likes coffee and Mary tea*, lack an overt predicate to indicate the relation between two or more arguments. Surface syntax representations of such sentences are often produced poorly by parsers, and even if correct, not well suited to downstream natural language understanding tasks such as relation extraction that are typically designed to extract information from sentences with canonical clause structure. In this paper, we present two methods for parsing to a Universal Dependencies graph representation that explicitly encodes the elided material with additional nodes and edges. We find that both methods can reconstruct elided material from dependency trees with high accuracy when the parser correctly predicts the existence of a gap. We further demonstrate that one of our methods can be applied to other languages based on a case study on Swedish.

1 Introduction

Sentences with gapping (Ross, 1970) such as *Paul likes coffee and Mary tea* are characterized by having one or more conjuncts that contain multiple arguments or modifiers of an elided predicate. In this example, the predicate *likes* is elided for the relation *Mary likes tea*. While these sentences appear relatively infrequently in most written texts, they are often used to convey a lot of factual information that is highly relevant for language understanding (NLU) tasks such as open information extraction and semantic parsing. For example, consider the following sentence from the WSJ portion of the Penn Treebank (Marcus et al., 1993).

(1) Unemployment has reached 27.6% in Azerbaijan, 25.7% in Tadzhikistan, 22.8% in Uzbekistan, 18.8% in Turkmenia, 18% in Armenia and 16.3% in Kirgizia, [...]

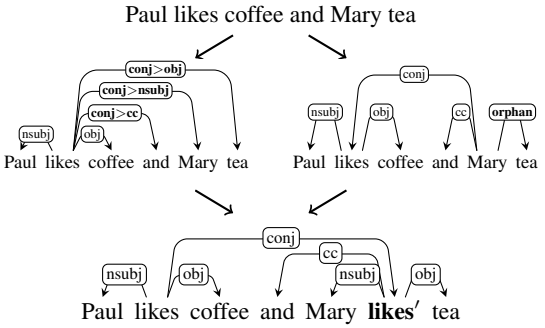

Figure 1: Overview of our two approaches. Both methods first parse a sentence with gapping to one of two different dependency tree representations and then reconstruct the elided predicate from this tree.

To extract the information about unemployment rates in the various countries, an NLU system has to identify that the percentages indicate unemployment rates and the locational modifiers indicate the corresponding country. Given only this sentence, or this sentence and a strict surface syntax representation that does not indicate elided predicates, this is a challenging task. However, given a dependency graph that reconstructs the elided predicate for each conjunct, the problem becomes much easier and methods developed to extract information from dependency trees of clauses with canonical structures are much more likely to extract the correct information from a gapped clause.

While gapping constructions receive a lot of attention in the theoretical syntax literature (e.g., Ross 1970; Jackendoff 1971; Steedman 1990; Coppock 2001; Osborne 2006; Johnson 2014; Toosarvandani 2016; Kubota and Levine 2016), they have been almost entirely neglected by the NLP community so far. The Penn Treebank explicitly annotates gapping constructions, by co-indexing arguments in the clause with a predicate and the clause with the gap, but these co-indices are not included in the standard parsing metrics

Proceedings of NAACL-HLT 2018, pages 1156–1168
New Orleans, Louisiana, June 1 - 6, 2018.

and almost all parsers ignore them.[1] Despite the sophisticated analysis of gapping within CCG (Steedman, 1990), sentences with gapping were deemed too difficult to represent within the CCGBank (Hockenmaier and Steedman, 2007). Similarly the treebanks for the Semantic Dependencies Shared Task (Oepen et al., 2015) exclude all sentences from the Wall Street Journal that contain gapping. Finally, while the tectogrammatical layer of the Prague Dependency Treebank (Bejček et al., 2013) as well as the enhanced Universal Dependencies (UD) representation (Nivre et al., 2016) provide an analysis with reconstructed nodes for gapping constructions, there exist no methods to automatically parse to these representations.

Here, we provide the first careful analysis of parsing of gapping constructions, and we present two methods for reconstructing elided predicates in sentences with gapping within the UD framework. As illustrated in Figure 1, we first parse to a dependency tree and then reconstruct the elided material. The methods differ in how much information is encoded in the dependency tree. The first method adapts an existing procedure for parsing sentences with elided function words (Seeker et al., 2012), which uses composite labels that can be deterministically turned into dependency graphs in most cases. The second method is a novel procedure that relies on the parser only to identify a gap, and then employs an unsupervised method to reconstruct the elided predicates and reattach the arguments to the reconstructed predicate. We find that both methods can reconstruct elided predicates with very high accuracy from gold standard dependency trees. When applied to the output of a parser, which often fails to identify gapping, our methods achieve a sentence-level accuracy of 32% and 34%, significantly outperforming the recently proposed constituent parser by Kummerfeld and Klein (2017).

2 Background

2.1 Gapping constructions

Gapping constructions in English come in many forms that can be broadly classified as follows.

(2) *Single predicate gaps*:
John **bought** books, and Mary ___ flowers.

(3) *Contiguous predicate-argument gap (including ACCs)*:
Eve **gave flowers** to Al and Sue ___ to Paul.
Eve **gave** a CD to Al and ___ roses to Sue.

(4) *Non-contiguous predicate-argument gap*:
Arizona **elected** Goldwater **Senator**, and Pennsylvania ___ Schwelker ___.
(Jackendoff, 1971)

(5) *Verb cluster gap*:
I **want to try to begin to write a novel** and
... Mary ___ a play.
... Mary ___ to write a play.
... Mary ___ to begin to write a play.
... Mary ___ to try to begin to write a play.
(Ross, 1970)

The defining characteristic of gapping constructions is that there is a clause that lacks a predicate (the *gap*) but still contains two or more arguments or modifiers of the elided predicate (the *remnants* or *orphans*). In most cases, the remnants have a corresponding argument or modifier (the *correspondent*) in the clause with the overt predicate.

These types of gapping also make up the majority of attested constructions in other languages. However, Wyngaerd (2007) notes that Dutch permits gaps in relative clauses, and Farudi (2013) notes that Farsi permits gaps in finite embedded clauses even if the overt predicate is not embedded.[2]

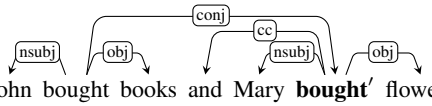
2.2 Target representation

We work within the UD framework, which aims to provide cross-linguistically consistent dependency annotations that are useful for NLP tasks. UD defines two types of representation: the *basic* UD representation which is a strict surface syntax dependency tree and the *enhanced* UD representation (Schuster and Manning, 2016) which may be a graph instead of a tree and may contain additional nodes. The analysis of gapping in the enhanced representation makes use of copy nodes for elided predicates and additional edges for elided arguments, which we both try to automatically reconstruct in this paper. In the simple case in which only one predicate was elided, there is exactly one

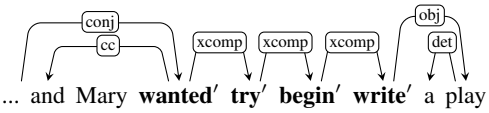
[1] To the best of our knowledge, the parser by Kummerfeld and Klein (2017) is the only parser that tries to output the co-indexing of constituents in clauses with gapping but they lack an explicit evaluation of their co-indexing prediction accuracy.

[2] See Johnson (2014) or Schuster et al. (2017) for a more comprehensive overview of cross-linguistically attested gapping constructions.

copy node for the elided predicate, which leads to a structure that is identical to the structure of the same sentence without a gap.[3]

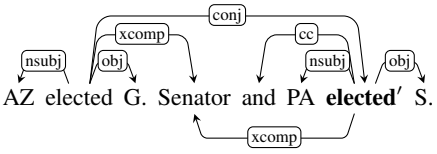


If a clause contains a more complex gap, the enhanced representation contains copies for all content words that are required to attach the remnants.



The motivation behind this analysis is that the semantically empty markers *to* are not needed for interpreting the sentence and minimizing the number of copy nodes leads to less complex graphs.

Finally, if a core argument was elided along with the predicate, we introduce additional dependencies between the copy nodes and the shared arguments, as for example, the open clausal complement (`xcomp`) dependency between the copy node and *Senator* in the following example.

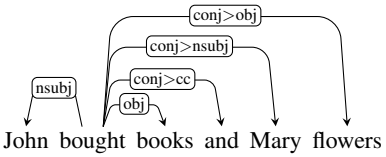


The rationale for not copying all arguments is again to keep the graph simple, while still encoding all relations between content words. Arguments can be arbitrarily complex and it seems misguided to copy entire subtrees of arguments which, e.g., could contain multiple adverbial clauses. Note that linking to existing nodes would not work in the case of verb clusters because they do not satisfy the subtree constraint.

3 Methods

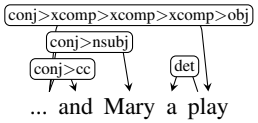
3.1 Composite relations

Our first method adapts one of the procedures by Seeker et al. (2012), which represents gaps in dependency trees by attaching dependents of an elided predicate with composite relations. These relations represent the dependency path that would have existed if nothing had been elided. For example, in the following sentence, the verb *bought*, which would have been attached to the head of the first conjunct with a `conj` relation, was elided from the second conjunct and hence all nodes that would have depended on the elided verb, are attached to the first conjunct using a composite relation consisting of `conj` and the type of argument.



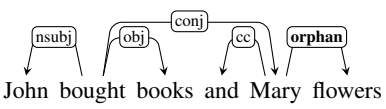
The major advantage of this approach is that the dependency tree contains information about the types of arguments and so it should be straightforward to turn dependency trees of this form into enhanced UD graphs. For most dependency trees, one can obtain the enhanced UD graph by splitting the composite relations into its atomic parts and inserting copy nodes at the splitting points.[4]

At the same time, this approach comes with the drawback of drastically increasing the label space. For sentences with more complex gaps as in (5), one has to use composite relations that consist of more than two atomic relations and theoretically, the number of composite relations is unbounded:



3.2 Orphan procedure

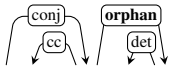
Our second method also uses a two-step approach to resolve gaps, but compared to the previous method, it puts less work on the parser. We first parse sentences to the basic UD v2 representation, which analyzes gapping constructions as follows. One remnant is promoted to be the head of the clause and all other remnants are attached to the promoted phrase. For example, in this sentence, the subject of the second clause, *Mary*, is the head of the clause and the other remnant, *flowers*, is attached to *Mary* with the special `orphan` relation:



[3] To enhance the readability of our examples, we place the copy node in the sentence where the elided predicate would have been pronounced. However, as linear order typically does not matter for extracting information with dependency patterns, our procedures only try to recover the structure of canonical sentences but not their linear order.

[4] Note that this representation does not indicate conjunct boundaries, and for sentences with multiple gapped conjuncts, it is thus unclear how many copy nodes are required.

This analysis can also be used for more complex gaps, as in the example with a gap that consists of a chain of non-finite embedded verbs in (5).



When parsing to this representation, the parser only has to identify that there is a gap but does not have to recover the elided material or determine the type of remnants. As a second step, we use an unsupervised procedure to determine which nodes to copy and how and where to attach the remnants. In developing this procedure, we made use of the fact that in the vast majority of cases, all arguments and modifiers that are expressed in gapped conjunct are also expressed in the full conjunct. The problem of determining which nodes to copy and which relations to use can thus be reduced to the problem of aligning arguments in the gapped conjunct to arguments in the full conjunct. We apply the following procedure to all sentences that contain at least one `orphan` relation.

1. Create a list F of arguments of the head of the full conjunct by considering all core argument dependents of the conjunct's head as well as clausal and nominal non-core dependents, and adverbial modifiers.
2. Create a list G of arguments in the gapped conjunct that contains the head of the gapped conjunct and all its `orphan` dependents.
3. Find the highest-scoring monotonic alignment of arguments in G to arguments in F.
4. Copy the head of the full conjunct and attach the copy node c to the head of the full conjunct with the original relation of the head of the gapped conjunct (usually `conj`).
5. For each argument $g \in G$ that has been aligned to $f \in F$, attach g to c with the same relation as the parent relation of f, e.g., if f is attached to the head of the full conjunct with an `nsubj` relation, also attach g to c with an `nsubj` relation. Attach arguments $g' \in G$ that were not aligned to any token in F to c using the general `dep` relation.
6. For each copy node c, add dependencies to all core arguments of the original node which do not have a corresponding remnant in the gapped clause. For example, if the full conjunct contains a subject, an object, and an oblique modifier but the clause with the gap, only a subject and an oblique modifier, add an object dependency between the copy node and the object in the full conjunct.

A crucial step is the third step, determining the highest-scoring alignment. This can be done straightforwardly with the sequence alignment algorithm by Needleman and Wunsch (1970) if one defines a similarity function $sim(g, f)$ that returns a similarity score between the arguments g and f. We defined sim based on the intuitions that often, parallel arguments are of the same syntactic category, that they are introduced by the same function words (e.g., the same preposition), and that they are closely related in meaning. The first intuition can be captured by penalizing mismatching POS tags, and the other two by computing the distance between argument embeddings. We compute these embeddings by averaging over the 100-dim. pretrained GloVe (Pennington et al., 2014) embeddings for each token in the argument. Given the POS tags t_g and t_f and the argument embeddings v_g and v_f, sim is defined as follows.[5]

$$sim(g, f) = -\|v_g - v_f\|_2 + \mathbb{1}\left[t_g = t_f\right] \times pos\_mismatch\_penalty$$

We set $pos\_mismatch\_penalty$, a parameter that penalizes mismatching POS tags, to -2.[6]

This procedure can be used for almost all sentences with gapping constructions. However, if parts of an argument were elided along with the main predicate, it can become necessary to copy multiple nodes. We therefore consider the alignment not only between complete arguments in the full clause and the gapped clause but also between partial arguments in the full clause and the complete arguments in the gapped clause. For example, for the sentence "*Mary wants to write a play and Sue a book*" the complete arguments of the full clause are {*Mary*, *to write a play*} and the arguments of the gapped clause are {*Sue*, *a book*}. In this case, we also consider the partial arguments {*Mary*, *a play*} and if the arguments of the gapped

[5] As suggested by one of the reviewers, we also ran a post-hoc experiment with a simpler similarity score function without the embedding distance term, which only takes into account whether the POS tags match. We found that quantitatively, the embeddings do not lead to significant better scores on the test set according to our metrics but qualitatively, they lead to better results for the examples with verb cluster gaps.

[6] We optimized this parameter on the training set by trying integer values from -1 to -15.

Table 1: Treebank statistics. The *copy nodes* row lists the number of copy nodes and the *unique composite relations* row lists the number of unique composite relations in the treebanks annotated according to the COMPOSITE analysis. The percentages are relative to the total number of sentences.

Gap type	**Frequency**
Single predicate	172
Contiguous predicate-argument	140
Non-contiguous predicate-argument	9
Verb cluster	24

Table 2: Distribution of gap types in our corpus. The classification is according to the four types of gaps that we discussed in Section 2.1.

conjunct align better to the partial arguments, we use this alignment. However, now that the token *write* is part of the dependency path between *want* and *play*, we also have to make a copy of *write* to reconstruct the UD graph of the gapped clause.

4 Experiments

Both methods rely on a dependency parser followed by a post-processing step. We evaluated the individual steps and the end-to-end performance.

4.1 Data

We used the UD English Web Treebank v2.1 (henceforth EWT; Silveira et al., 2014; Nivre et al., 2017) for training and evaluating parsers. As the treebank is relatively small and therefore only contains very few sentences with gapping, we also extracted gapping constructions from the WSJ and Brown portions of the PTB (Marcus et al., 1993) and the GENIA corpus (Ohta et al., 2002). Further, we copied sentences from the Wikipedia page on gapping[7] and from published papers on gapping. The sentences in the EWT already contain annotations with the `orphan` relation and copy nodes for the enhanced representation, and we manually added both of these annotations for the remaining examples. The composite relations can be automatically obtained from the enhanced representation by removing the copy nodes and concatenating the dependency labels, which we did to build the training and test corpus for the composite relation procedure. Table 1 shows properties of the data splits of the original treebank, the additional sentences with gapping, and their combination; Table 2 shows the number of sentences in our corpus for each of the gap types.

[7] `https://en.wikipedia.org/wiki/Gapping`, accessed on Aug 24, 2017.

4.2 Parsing experiments

Parser We used the parser by Dozat and Manning (2017) for parsing to the two different intermediate dependency representations. This parser is a graph-based parser (McDonald et al., 2005) that uses a biLSTM to compute token representations and then uses a multi-layer perceptron with biaffine attention to compute arc and label scores.

Setup We trained the parser on the COMBINED training corpus with gold tokenization, and predicted fine-grained and universal part-of-speech tags, for which we used the tagger by Dozat et al. (2017). We trained the tagger on the COMBINED training corpus. As pre-trained embeddings, we used the word2vec (Mikolov et al., 2013) embeddings that were provided for the CoNLL 2017 Shared Task (Zeman et al., 2017), and we used the same hyperparameters as Dozat et al. (2017).

Evaluation We evaluated the parseability of the two dependency representations using labeled and unlabeled attachment scores (LAS and UAS). Further, to specifically evaluate how well parsers are able to parse gapping constructions according to the two annotation schemes, we also computed the LAS and UAS just for the head tokens of remnants (LAS_g and UAS_g). For all our metrics, we excluded punctuation tokens. To determine sta-

		EWT		GAPPING	
		UAS	LAS	UAS	LAS
Dev	ORPHAN	**90.57**	87.32	**89.34**	**85.69****
	COMPOSITE	90.46	**87.37**	88.86	84.21
Test	ORPHAN	90.42	87.06	**87.44**	**83.97****

COMPOSITE	68.36	49.45	62.41	46.24

Table 4: Labeled (LAS_g) and unlabeled attachment score (UAS_g) of head tokens of remnants for parsers trained and evaluated on the UD representation (ORPHAN) and the composite relations representation (COMPOSITE) on the development and test sets of the COMBINED treebank. Results that differ significantly are marked with * ($p < 0.05$) or *** ($p < 0.001$).

tistical significance of pairwise comparisons, we performed two-tailed approximate randomization tests (Noreen, 1989; Yeh, 2000) with an adapted version of the `sigf` package (Padó, 2006).

Results Table 3 shows the overall parsing results on the development and test sets of the two treebanks. There was no significant difference between the parser that was trained on the UD representation (ORPHAN) and the parser trained on the composite representation (COMPOSITE) when tested on the EWT data sets, which is not surprising considering that there is just one sentence with gapping each in the development and the test split. When evaluated on the GAPPING datasets, the ORPHAN parser performs significantly better ($p < 0.01$) in terms of labeled attachment score, which suggests that the parser trained on the COMPOSITE representation is indeed struggling with the greatly increased label space. This is further confirmed by the attachment scores of the head tokens of remnants (Table 4). The labeled attachment score of remnants is significantly higher for the ORPHAN parser than for the COMPOSITE parser. Further, the unlabeled attachment score on the test set is also higher for the ORPHAN parser, which suggests that the COMPOSITE parser is sometimes struggling with finding the right attachment for the multiple long-distance composite dependencies.

4.3 Recovery experiments

Our second set of experiments concerns the recovery of the elided material and the reattachment of the orphans. We conducted two experiments: an oracle experiment that used gold standard dependency trees and an end-to-end experiment that used the output of the parser as input. For all experiments, we used the COMBINED treebank.

Evaluation Here, we evaluated dependency graphs and therefore used the labeled and unlabeled precision and recall metrics. However, as our two procedures are only changing the attachment of orphans, we only computed these metrics for copy nodes and their dependents. Further, we excluded punctuation and coordinating conjunctions as their attachment is usually trivial and including them would inflate scores. Lastly, we computed the sentence-level accuracy for all sentences with gapping. For this metric, we considered a sentence to be correct if all copy nodes and their dependents of a sentence were attached to the correct head with the correct label.

Oracle results The top part of Table 5 shows the results for the oracle experiment. Both methods are able to reconstruct the elided material and the canonical clause structure from gold dependency trees with high accuracy. This was expected for the COMPOSITE procedure, which can make use of the composite relations in the dependency trees, but less so for the ORPHAN procedure which has to recover the structure and the types of relations. The two methods work equally well in terms of all metrics except for the sentence-level accuracy, which is significantly higher for the COMPOSITE procedure. This difference is caused by a difference in the types of mistakes. All errors of the COMPOSITE procedure are of a structural nature and stem from copying the wrong number of nodes while the dependency labels are always correct because they are part of the dependency tree. The majority of errors of the ORPHAN procedure stem from incorrect dependency labels, and these mistakes are scattered across more examples, which leads to the lower sentence-level accuracy.

End-to-end results The middle part of Table 5 shows the results for the end-to-end experiment. The performance of both methods is considerably lower than in the oracle experiment, which is pri-

		Development					Test

	K&K 2017	-	-	-	-	0.00	-	-	-	-	0.00

Table 5: Labeled and unlabeled precision and recall as well as sentence-level accuracy of the two gapping reconstructions methods and the K&K parser on the development and test set of the COMBINED treebank. Results that differ significantly from the other result within the same section are marked with * ($p < 0.05$) or ** ($p < 0.01$).

marily driven by the much lower recall. Both methods assume that the parser detects the existence of a gap and if the parser fails to do so, neither method attempts to reconstruct the elided material. In general, precision tends to be a bit higher for the ORPHAN procedure whereas recall tends to be a bit higher for the COMPOSITE method but overall and in terms of sentence-level accuracy both methods seem to perform equally well.

Error analysis For both methods, the primary issue is low recall, which is a result of parsing errors. When the parser correctly predicts the `orphan` relation, the main sources of error for the ORPHAN procedure are missing correspondents for remnants (e.g., *[for good]* has no correspondent in *They had left the company, many for good*) or that the types of argument of the remnant and its correspondent differ (e.g., in *She was convicted of selling unregistered securities in Florida and of unlawful phone calls in Ohio*, *[of selling unregistered securities]* is an adverbial clause whereas *[of unlawful phone calls]* is an oblique modifier).

Apart from the cases where the COMPOSITE procedure leads to an incorrect structure, the remaining errors are all caused by the parser predicting the wrong composite relation.

4.4 Comparison to Kummerfeld and Klein

Kummerfeld and Klein (henceforth K&K; 2017) recently proposed a one-endpoint-crossing graph parser that is able to directly parse to PTB-style trees with traces. They also briefly discuss gapping constructions and their parser tries to output the co-indexing that is used for gapping constructions in the PTB. The EWT and all the sentences that we took from the WSJ, Brown, and GENIA treebanks already come with constituency tree annotations, and we manually annotated the remaining sentences according to the PTB guidelines (Bies et al., 1995). This allowed us to train the K&K parser with exactly the same set of sentences that we used in our previous experiments. As this parser outputs constituency trees, we could not compute dependency graph metrics for this method. For the sentence-level accuracy, we considered an example to be correct if a) each argument in the gapped conjunct was the child of a single constituent node, which in return was the sibling of the full clause/verb phrase, and b) the co-indexing of each argument in the gapped conjunct was correct. For example, the following bracketing would be considered correct despite the incorrect internal structure of the first conjunct:

$[_S[_S[_{NP\text{-}1}$ Al $]$ likes $[_{NP\text{-}2}$ coffee $]]$ and $[_S[_{NP=1}$ Sue $][_{NP=2}$ tea $]]]$

The last row of Table 5 shows the results of the K&K parser. The parser failed to output the correct constituency structure or co-indexing for every single example in the development and test sets. The parser struggled in particular with outputting the correct co-indices: For 32.5% of the test sentences with gapping, the bracketing of the gapped clause was correct but one or more of the co-indices were missing from the output.

Overall these results suggest that our dependency-based approach is much more reliable at identifying gapping constructions than the parser by K&K, which, in their defense, was optimized to output traces for other phenomena. Our method is also faster and took only seconds to parse the test set, while the K&K parser took several hours.

5 Resolving gaps in other languages

One of the appeals of the ORPHAN procedure is that it can be easily applied to other languages even if there exist no annotated enhanced dependency graphs.[8] On the one hand, this is because

[8]There is no theoretical reason that would prevent one from using the COMPOSITE procedure for other languages

our method does not make use of lexical information, and on the other hand, this is because we developed our method on top of the UD annotation scheme, which has already been applied to many languages and for which many treebanks exist.

Currently, all treebanks but the English one lack copy nodes for gapping constructions and many of them incorrectly use the `orphan` relation (Droganova and Zeman, 2017) and therefore we could not evaluate our method on a large variety of languages. In order to demonstrate that our method can be applied to other languages, we therefore did a case study on the Swedish UD treebank. The Swedish UD treebank is an automatic conversion from a section of the Talbanken (Einarsson, 1976) with extensive manual corrections. While the treebank is overall of high quality, we noticed conversion errors that led to incorrect uses of the `orphan` relation in 11 of the 29 sentences with `orphan` relations, which we excluded from our evaluation. We applied our gapping resolution procedure without any modifications to the remaining 18 sentences. We used the Swedish word2vec embeddings that were prepared for the CoNLL 2017 Shared Task. Our method correctly predicts the insertion of 29 copy nodes and is able to predict the correct structure of the enhanced representation in all cases, including complex ones with elided verb clusters such as the example in Figure 2. It also predicts the correct dependency label for 108/110 relations, leading to a labeled precision and labeled recall of 98.18%, which are both higher than the English numbers despite the fact that we optimized our procedure for English. The main reason for the higher performance seems to be that many of the Swedish examples come from informational texts from public organizations, which are more likely to be written to be clear and unambiguous. Further, the Swedish data does not contain challenging examples from the linguistic literature.

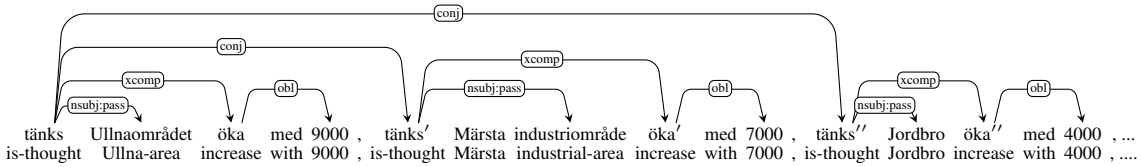
As Swedish is a Germanic language like English and thus shares many structural properties, we cannot conclude that our method is applicable to any language based on just this experiment. However, given that our method does not rely on language-specific structural patterns, we expect it to work well for a wide range of languages.

but given that UD treebanks are annotated with `orphan` relations, using the the COMPOSITE procedure would require additional manual annotations in practice.

6 Related work

Gapping constructions have been little studied in NLP, but several approaches (e.g., Dukes and Habash 2011; Simkó and Vincze 2017) parse to dependency trees with empty nodes. Seeker et al. (2012) compared three ways of parsing with empty heads: adding a transition that inserts empty nodes, using composite relation labels for nodes that depend on an elided node, and pre-inserting empties before parsing. These papers all focus on recovering nodes for elided function words such as auxiliaries; none of them attempt to recover and resolve the content word elisions of gapping. Ficler and Goldberg (2016) modified PTB annotations of argument-cluster coordinations (ACCs), i.e., gapping constructions with two post-verbal orphan phrases, which make up a subset of the gapping constructions in the PTB. While the modified annotation style leads to higher parsing accuracy of ACCs, it is specific to ACCs and does not generalize to other gapping constructions. Moreover, they did not reconstruct gapped ACC clauses. Traditional grammar-based chart parsers (Kay, 1980; Klein and Manning, 2001) did handle empty nodes and so could in principle provide a parse of gapping sentences though additional mechanisms would be needed for reconstruction. In practice, though, dealing with gapping in a grammar-based framework is not straightforward and can lead to a combinatorial explosion that slows down parsing in general, as has been noted for the English Resource Grammar (Flickinger, 2017, p.c.) and for an HPSG implementation for Norwegian (Haugereid, 2017). The grammar-based parser built with augmented transition networks (Woods, 1970) provided an extension in the form of the SYSCONJ operation (Woods, 1973) to parse some gapping constructions, but also this approach lacked explicit reconstruction mechanisms and provided only limited coverage.

There also exists a long line of work on post-processing surface-syntax constituency trees to recover traces in the PTB (Johnson, 2002; Levy and Manning, 2004; Campbell, 2004; Gabbard et al., 2006), pre-processing sentences such that they contain tokens for traces before parsing (Dienes and Dubey, 2003b), or directly parsing sentences to either PTB-style trees with empty elements or pre-processed trees that can be deterministically converted to PTB-style trees (Collins,



'The Ullna area is expected to grow by 9,000 (new workplaces), the Märsta industrial area by 7,000, Jordbro by 4,000, ...'

Figure 2: Dependency graph for part of the sentence `sv-ud-train-1102` as output by the ORPHAN procedure. The system correctly predicts the copy nodes for the matrix and the embedded verb, and correctly attaches the arguments to the copy nodes.

1997; Dienes and Dubey, 2003a; Schmid, 2006; Cai et al., 2011; Hayashi and Nagata, 2016; Kato and Matsubara, 2016; Kummerfeld and Klein, 2017). However, all of these works are primarily concerned with recovering traces for phenomena such as Wh-movement or control and raising constructions and, with the exception of Kummerfeld and Klein (2017), none of these works attempt to output the co-indexing that is used for analyzing gapping constructions. And again, none of these works try to reconstruct elided material.

Lastly, several methods have been proposed for resolving other forms of ellipsis, including VP ellipsis (Hardt, 1997; Nielsen, 2004; Lappin, 2005; McShane and Babkin, 2016) and sluicing (Anand and Hardt, 2016) but none of these methods consider gapping constructions.

7 Conclusion

We presented two methods to recover elided predicates in sentences with gapping. Our experiments suggest that both methods work equally well in a realistic end-to-end setting. While in general, recall is still low, the oracle experiments suggest that both methods can recover elided predicates from correct dependency trees, which suggests that as parsers become more and more accurate, the gap recovery accuracy should also increase.

We also demonstrated that our method can be used to automatically add the enhanced UD representation to UD treebanks in other languages than English. Apart from being useful in a parsing pipeline, we therefore also expect our method to be useful for building enhanced UD treebanks.

Reproducibility

All data, pre-trained models, system outputs as well as a package for running the enhancement procedure are available from `https://github.com/sebschu/naacl-gapping`.

Acknowledgments

Abstract

Abstract Meaning Representation (AMR) annotations are often assumed to closely mirror dependency syntax, but AMR explicitly does not require this, and the assumption has never been tested. To test it, we devise an expressive framework to align AMR graphs to dependency graphs, which we use to annotate 200 AMRs. Our annotation explains how 97% of AMR edges are evoked by words or syntax. Previously existing AMR alignment frameworks did not allow for mapping AMR onto syntax, and as a consequence they explained at most 23%. While we find that there are indeed many cases where AMR annotations closely mirror syntax, there are also pervasive differences. We use our annotations to test a baseline AMR-to-syntax aligner, finding that this task is more difficult than AMR-to-string alignment; and to pinpoint errors in an AMR parser. We make our data and code freely available for further research on AMR parsing and generation, and the relationship of AMR to syntax.

1 Introduction

Abstract Meaning Representation (AMR; Banarescu et al., 2013) is a popular framework for annotating whole sentence meaning. An AMR annotation is a directed, usually acyclic graph in which nodes represent entities and events, and edges represent relations between them, as on the right in figure 1.[1]

AMR annotations include no explicit mapping between elements of an AMR and the corresponding elements of the sentence that evoke them, and this presents a challenge to developers of machine learning systems that parse sentences to AMR or generate sentences from AMR, since they must first infer this mapping in the training data (e.g. Flanigan et al., 2014; Wang et al., 2015; Artzi et al., 2015; Flanigan et al., 2016; Pourdamghani et al., 2016; Misra and Artzi, 2016; Damonte et al., 2017; Peng et al., 2017, inter alia).[2]

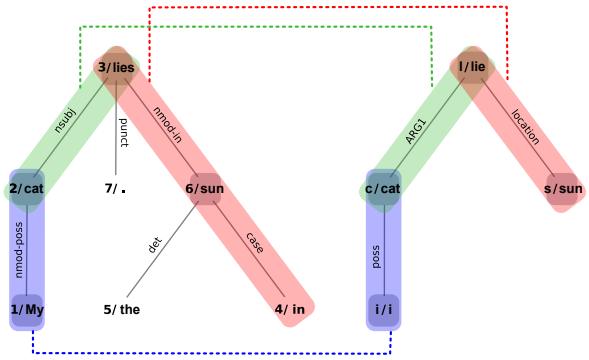

Figure 1: "My cat lies in the sun." An alignment between the dependency parse (*left*) and AMR (*right*). Nodes participating in lexical alignments are marked with boxes, but the links between them are not displayed. Structural alignments are colour-coded and linked by dotted lines. Sense numbers for concepts that are PropBank frames are omitted for brevity.

This AMR alignment problem was first formalized by Flanigan et al. (2014), who mapped AMR nodes or connected subgraphs to words or sequences of words under the assumption of a one-to-one mapping—we call this **JAMR alignment**. Pourdamghani et al. (2014) then re-formalized it so that any AMR node or edge can map to any word without a one-to-one assumption—we call this **ISI alignment**. In ISI alignments, edges often align to syntactic function words: for example, `:location` aligns to *in* in figure 1. So edge alignments allow ISI to explain more of the AMR structure than JAMR, but in a limited way: only 23% of AMR edges are aligned in the ISI corpus. This may be be-

[1] For clarity of presentation, we have constructed the sentences and AMRs shown in figures—except for figure 3, which is a simplified version of a sentence in the corpus.

[2] Some recent neural AMR sytems require minimal or no explicit alignments (Konstas et al., 2017; van Noord and Bos, 2017). But they implicitly learn them in the form of soft attention, and we believe that a clearer understanding of alignment will benefit modeling and error analysis even in these systems.

Proceedings of NAACL-HLT 2018, pages 1169–1180
New Orleans, Louisiana, June 1 - 6, 2018.

cause edges are often evoked by syntactic structure rather than words: for instance, the :ARG1 edge in figure 1 is evoked by the fact that *cat* is the subject of *lies* and not by any particular word.

Although it seems sensible to assume that all of the nodes and edges of an AMR are evoked by the words and syntax of a sentence, the existing alignment schemes do not allow for expressing that relationship. We therefore propose a framework expressive enough to align AMR to syntax (§2) and use it to align a corpus of 200 AMRs to dependency parses. We analyse our corpus and show that the addition of syntactic alignments allows us account for 97% of the AMR content.

Syntactic-semantic mappings are often assumed by AMR parsing models (e.g. Wang et al., 2015; Artzi et al., 2015; Damonte et al., 2017), which is understandable since these mappings are well-studied in linguistic theory. But AMR explicitly avoids theoretical commitment to a syntax-semantics mapping: Banarescu et al. (2013) state that "AMR is agnostic about how we might want to derive meanings from strings." If we are going to build such an assumption into our models, we should test it empirically, which we can do by analysing our corpus. We observe some pervasive structural differences between AMR and dependency syntax (§3), despite the fact that a majority of AMR edges map easily onto dependency edges.

Since syntactic alignment can largely explain AMRs, we also develop a baseline rule-based aligner for it, and show that this new task is much more difficult than lexical alignment (§4). We also show how our data can be used to analyze errors made by an AMR parser (§5). We make our annotated data and aligner freely available for further research.[3]

2 Aligning AMR to dependency syntax

Our syntactic representation is dependency grammar, which represents the sentence as a rooted, directed graph where nodes are words and edges are grammatical relations between them (Kruijff, 2006). We use Universal Dependencies (UD), a cross-lingual dependency annotation scheme, as implemented in Stanford CoreNLP (Manning et al., 2014). Within the UD framework, we use *enhanced* dependencies (Schuster and Manning, 2016), in which dependents can have more than one head, resulting in **dependency graphs** (DGs).[4]

Our alignment guidelines generalize ideas present in the existing frameworks. We want to allow many-to-many alignments, which we motivate by the observation that some phenomena cause an AMR graph to have one structure expressing the same information as multiple DG structures, and vice versa. For instance, in figure 2 the AMR subgraph representing Cruella de Vil aligns to two subgraphs in the dependency graph because of pronominal coreference. In the other direction, in figure 3 the *capabilities* node aligns to both capable nodes in the AMR, which is a result of the AMR treating conjoined adjectival modifiers as a case of ellipsis. The alignments we propose hold between subgraphs of any size. By aligning subgraphs we gain expressiveness needed to point out correspondences between semantic and syntactic structure. If AMR and DG were very similar in how they represent information, such correspondences would probably hold between subgraphs consisting of a single edge, as in figure 1 $cat \xrightarrow{\textbf{\textit{nmod:poss}}} my \sim \texttt{cat} \xrightarrow{\texttt{poss}} \texttt{I}$. However, AMR by design abstracts away from syntax and it should not be assumed that all mappings will be so clean. For example, the same figure has $lies \xrightarrow{\textbf{\textit{nmod-in}}} sun \xrightarrow{\textbf{\textit{case}}} in \sim \texttt{lies} \xrightarrow{\texttt{location}} \texttt{sun}$. Moreover, AMR represents the meaning of particular words or phrases with elaborate structures, the result of which might be that the same information is expressed by a single word and a complex AMR subgraph, as in figure 3 where AMR represents *general* as $\texttt{person} \xrightarrow{\texttt{ARG0-of}} \texttt{have-org-role} \xrightarrow{\texttt{ARG2}} \texttt{general}$.

2.1 Overview

An alignment is a link between subgraphs in an AMR and a DG which represent equivalent information. Given a sentence's DG and AMR we define an **alignment** as a mapping between an AMR subgraph and a DG subgraph. **Lexical alignments** (§2.2) hold between pairs of nodes, and nodes from either graph may participate in multiple lexical alignments. **Structural alignments** (§2.3) hold between pairs of connected subgraphs where at least one of the subgraphs contains an edge.

[3] https://github.com/ida-szubert/amr_ud

[4] We chose UD because it emphasises shallow and semantically motivated annotation, by the virtue of which it can be expected to align relatively straightforwardly to a semantic annotation such as AMR. Aligning AMR with different versions of dependency grammar (e.g. Prague) or different syntactic frameworks (e.g. CCG, TAG) would be an interesting extension of our work.

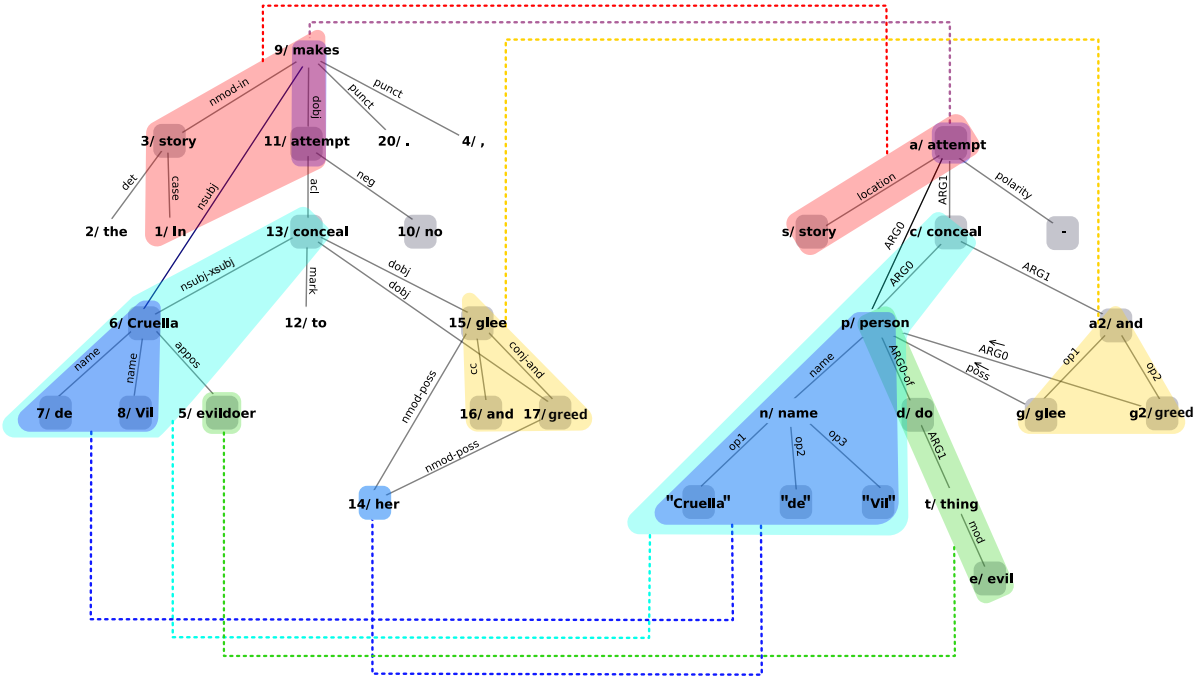

Figure 2: "In the story, evildoer Cruella de Vil makes no attempt to conceal her glee and greed." For legibility in this and following figures only a subset of the structural alignments are shown.

In the following two sections we discuss the types of alignments that our framework allows. More detailed guidelines regarding how to align particular linguistic constructions can be found in appendix A.

2.2 Lexical alignments

A lexical alignment should hold between a word and an AMR concept if the latter is judged to express the lexical meaning of the former. Node labels usually reflect their lexically aligned word or its lemma, including derivational morphology (e.g. *thirsty* ~ `thirst-01`). Thus, **string similarity** is a useful heuristic for lexical alignment.[5]

Most AMR nodes align lexically to a single word. Cases of one-to-many alignments include **coreference**, when an entity is mentioned multiple times in the sentence, and **multiword expressions** such as a verb-particle constructions (*pay off* ~ `pay-off-02`) and fixed grammatical expressions (*instead of* ~ `instead-of-91`). Occasionally an AMR node does not lexically align to any DG node. This is true for constants indicating sentence mood such as `imperative`, implicit uses of *and* to group list items, inferred concept nodes such as **entity types**, `name` in named entities, and `-91` frames like `have-org-role-91`.

Most words are lexically aligned to a single AMR node, if they are aligned at all. A word may align to multiple AMR nodes if it is **duplicated** in the AMR due to ellipsis or distributive coordination (*capabilities* aligns to `c2 / capable` and `c3 / capable` in figure 3), or if it is **morphologically decomposed** in the AMR (*evildoer* aligns to `evil` and `do-02` in figure 2). Many words are not lexically aligned to any AMR node, including **punctuation** tokens, **articles**, **copulas**, nonmodal **auxiliaries**, expletive subjects, infinitival *to*, complementizer *that*, and relative pronouns.

2.3 Structural alignments

Structural alignments primarily reflect compositional **grammatical constructions**, be they syntactic or morphological. Note that the structural alignments build upon the lexical ones. Structural alignments hold between two subgraphs, at least one of which is larger than a single node. If a subgraph includes any edges, it automatically includes nodes adjacent to those edges. Structural alignments need not be disjoint: an edge can appear in two or more distinct alignments. Nodes and edges in both AMR and DG may be unaligned.

2.3.1 Constraints on structural alignments

The ability to align subgraphs to subgraphs gives considerable flexibility in how the annotation task

[5] Exceptions include: pronouns with noun antecedents in the sentence; the `-` indicating negative polarity, which lexically aligns to *no*, *not*, and negative prefixes; modal auxiliaries, e.g., *can* ~ `possible`; normalized dates and values such as *February* ~ `2` in a `date-entity`; and `amr-unknown`, which aligns to wh-words.

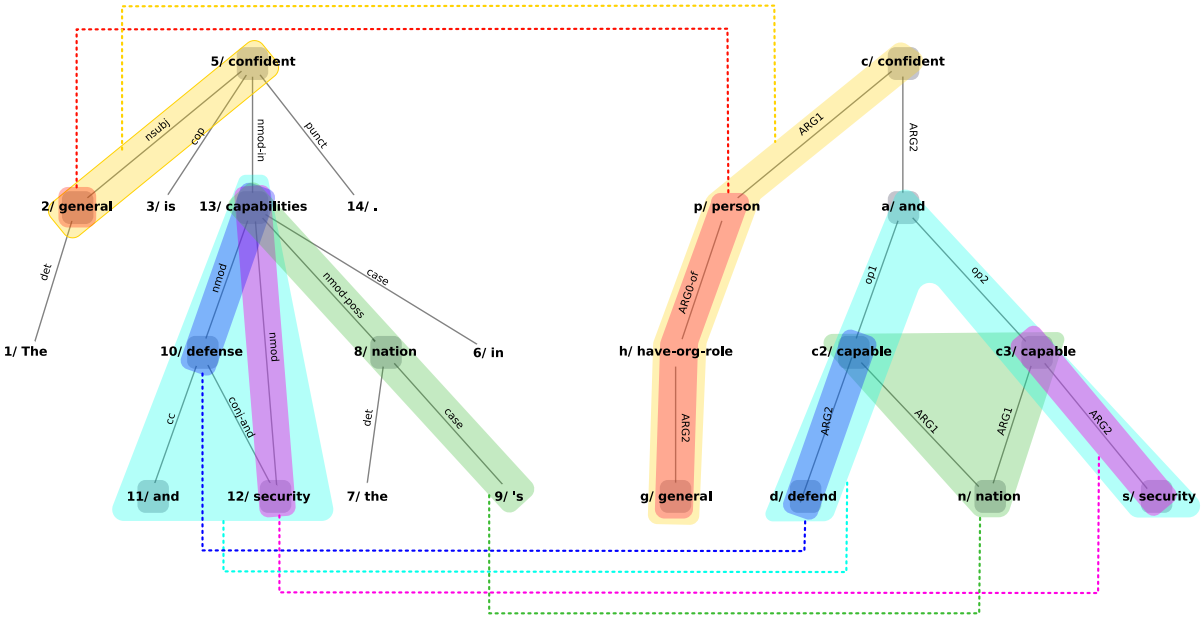

Figure 3: "The general is confident in the nation's defense and security capabilities."

can be interpreted. We establish the following principles to guide the specification of alignment:

Connectedness Principle. In an alignment $d \sim a$, d must be a connected subgraph of the DG, and a must be a connected subgraph of the AMR.

Minimality Principle. If two alignments, $d \sim a$ and $d' \sim a'$, have no dependency or AMR edges in common, then their union $d \cup d' \sim a \cup a'$ is redundant, even if it is valid. Individual alignments should be as small as possible; we believe compositionality is best captured by keeping structures minimal. Therefore, in figure 1 there is no alignment between subgraphs spanning *My*, *cat*, *lies* and `i`, `cat`, `lie`. Such subgraphs do express equivalent information, but the alignment between them decomposes neatly into smaller alignments and we record only those.

Subsumption Principle. This principle expresses the fact that our alignments are hierarchical. Structural alignments need to be consistent with lexical alignments: for subgraph a to be aligned to subgraph d, all nodes lexically aligned to nodes in a must be included in d, and vice versa. Moreover, structural alignments need to be consistent with other structural alignments. A structural alignment $d \sim a$ is valid only if, for every connected AMR subgraph $a_< \subset a$ which is aligned to a DG subgraph, $d' \sim a_<$, we also have that d' is a subgraph of d—and vice versa for every $d_< \subset d$.

Further, if a contains a node n which is not lexically aligned but which is part of a structurally aligned subgraph a' such that $d' \sim a'$, it needs to be the case that $a' \subset a \wedge d' \subset d$ or $a' \supset a \wedge d' \supset d$. (And vice versa for nodes in d.) For example, $\textit{conceal} \xrightarrow{\textbf{\textit{nsubj-xsubj}}} \textit{Cruella} \sim \texttt{conceal} \xrightarrow{\texttt{ARG0}} \texttt{person} \xrightarrow{\texttt{name}} \texttt{name} \xrightarrow{\texttt{op1}} \texttt{Cruella}$ is not a valid alignment, because the AMR side contains nodes `person` and `name`, which are not lexically aligned but which are both parts of a structural alignment marked in blue.

Coordination Principle. If an alignment contains a dependency edge between two conjuncts, or between a conjunct and a coordinating conjunction, then it must also include all conjuncts and the conjunction. This preserves the integrity of coordinate structures in alignments. For example, in figure 2 there is no alignment $\textit{glee} \xrightarrow{\textbf{\textit{cc}}} \textit{and} \sim \texttt{and} \xrightarrow{\texttt{op1}} \texttt{glee}$; only the larger structure which includes the `greed` nodes is aligned.

Named Entity Principle. Any structural alignment containing an AMR `name` node or any of the strings under it must contain the full subgraph rooted in the `name` plus the node above it specifying the entity type. This means that for example, in figure 2 there is no alignment $\textit{conceal} \xrightarrow{\textbf{\textit{nsubj-xsubj}}} \textit{Cruella} \sim \texttt{conceal} \xrightarrow{\texttt{ARG0}} \texttt{person} \xrightarrow{\texttt{name}} \texttt{name} \xrightarrow{\texttt{op1}} \texttt{"Cruella"}$. Such an alignment would also be stopped by the Subsumption Principle provided that the blue alignment of the whole name was present. The Named Entity Principle is superfluous, but is provided to explicitly describe the treatment of such constructions.

2.3.2 Typology of structural alignments

The smallest structure which can participate in a structural alignment is a single node, provided that it is aligned to a subgraph containing at least one edge. A DG node may align to an AMR subgraph if the word is morphologically decomposed or otherwise analyzed in the AMR (e.g. in figure 2, *evil-doer* ~ person$\xrightarrow{\text{ARG0-of}}$do-02$\xrightarrow{\text{ARG1}}$thing$\xrightarrow{\text{mod}}$evil). Examples of DG structures whose meaning is expressed in a single AMR node include light verb constructions, phrasal verbs, and various other multiword expressions (e.g. in figure 2, *makes*$\xrightarrow{\textbf{\textit{dobj}}}$*attempt* ~ attempt-01).

Conceptually the simplest case of structural alignment is one edge to one edge, as in the blue and green alignments in figure 1. For such an alignment to be possible, two requirements must be satisfied: nodes which are endpoints of those edges need to be aligned one-to-one; and the AMR relation and the syntactic dependency must map cleanly in terms of the relationship they express.

A one edge to multiple edges alignment arises when either of those requirements is not met. To see what happens in absence of one-to-one endpoint alignments let's look at the relation between *confident* and *general* in figure 3. The DG *general* node is aligned to an AMR subgraph: *general* ~ person$\xrightarrow{\text{ARG0-of}}$have-org-role$\xrightarrow{\text{ARG2}}$general. All alignments which involve the *general* node on the DG side need to include its aligned subgraph on the AMR side. It necessarily follows that the AMR subgraphs in those alignments will contain more edges that the DG ones; in this case the yellow subgraph in DG has 1 edge, and in AMR 3 edges. As for the second requirement, it is possible for one graph to use multiple edges to express a relationship when the other graph needs only one. This is the case for *lie*$\xrightarrow{\textbf{\textit{nmod-in}}}$*sun*$\xrightarrow{\textbf{\textit{case}}}$*in* ~ lie$\xrightarrow{\text{location}}$sun in figure 1. An example which combines both the node- and edge-related issues is marked in red in figure 2.

Finally, we also allow for many edges to many edges alignments. This may seem counterintuitive considering the assumption that we want to capture mappings between relations expressed in DG and AMR, and that we want to align minimal subgraphs. There are cases where an alignment is actually capturing a single relation, but we need to treat a subgraph as an endpoint of the edge both in DG and AMR. For instance, consider in figure 2 the relationship that holds between Cruella de Vil and concealing, expressed syntactically as an ***nsubj-xsubj*** edge and semantically as an ARG0 edge. One of the entities involved in that relationship, Cruella, is represented by a 2-edge DG subgraph and a 4-edge AMR subgraph. Consequently, the alignment covering the DG and AMR edges that relate Cruella to concealing must link subgraphs consisting respectively of 3 and 5 edges. A more difficult case of many edges to many edges alignment arises when relationships between nodes are expressed so differently in the DG and AMR that given an edge in one graph it is not possible to find in the other graph a subgraph that would convey the same information without also including some other information. Coordination has this property: e.g. in figure 2 the ***conj-and*** dependency between *glee* and *greed* has no counterpart in the AMR. There is no edge between AMR nodes aligned to those words, and the smallest AMR subgraph which contains them also contains and, which is itself lexically aligned. We cannot align *glee*$\xrightarrow{\textbf{\textit{conj-and}}}$*greed* ~ glee$\xleftarrow{\text{op1}}and\xrightarrow{\text{op2}}$greed because of the rule that all lexically aligned nodes in one subgraph must be aligned to nodes in the other subgraph. Therefore we need to extend the DG side to *and*$\xleftarrow{\textbf{\textit{cc}}}$*glee*$\xrightarrow{\textbf{\textit{conj-and}}}$*greed*.

3 Manually aligned corpus

We annotated a corpus of 200 AMR-sentence pairs (3813 aligned structures) using the guidelines of §2 and appendix A.[6]

Data selection. To create the corpus we drew a total of 200 AMR-sentence pairs: 135 from the training split of the AMR Annotation Release 1.0 (Knight et al., 2014), 55 from the training split of *The Little Prince* Corpus v1.6,[7] and 10 sentences from the Adam part of the CHILDES Brown corpus (Brown, 1973), for which AMRs were produced by an experienced annotator. Seventy items were selected to illustrate particular linguistic phenomena.[8] The remaining 130 were selected at random.

[6] We followed the precedent of previous AMR-to-sentence alignment corpora (see §4.2) in including 200 sentences in our gold standard, though ours was a different sample.

[7] https://amr.isi.edu/download/amr-bank-struct-v1.6.txt

[8] Namely: relative clauses, reflexive and non-reflexive pronominal anaphora, subject and object control, raising, exceptional case marking, coordination, wh-questions, do-support questions, ellipsis, expletives, modal verbs, light verbs, comparison constructions, and quantification.

Preprocessing. Dependency parses were obtained using Stanford CoreNLP neural network parser[9] (Chen and Manning, 2014) and manually corrected. The final parses conform to the enhanced UD guidelines,[10] except they lack enhancements for ellipsis.

Inter-annotator agreement. The corpus was created by one annotator. To assess inter-annotator agreement, a second annotator deeply familiar with UD and AMR annotated a random sample of sentences accounting for 10% of alignments in the corpus. The overall inter-annotator F_1-score was 88%, with 96% agreement on lexical alignments and 80% on structural alignments. We take this as an indication that our richly structured alignment framework as laid out in §2 is reasonably well-defined for annotators.

3.1 Coverage

To assess our attempt to explain as much of the AMR as possible, we computed the proportion of AMR nodes and edges that participate in at least one alignment. Overall, 99.3% of nodes and 97.2% of edges in AMRs are aligned. We found that 81.5% of AMR graphs have full coverage, 18.5% have at least one unaligned edge, and 7.5% have one unaligned node (none had more than one; all unaligned nodes express mood or discourse-related information: `interrogative`, `and`, and `say`). We conclude that nearly all information in an AMR is evoked by lexical items or syntactic structure.

We expected coverage of DG to be lower because punctuation and many function words are unaligned in our guidelines (§2.2). Indeed, only 71.4% of words and 65.2% of dependency edges are aligned.

3.2 Syntactic-semantic similarity

The similarity of AMR to syntax in examples like figure 1 invites the assumption of a close mapping, which often seems to be made in AMR parsers (Wang et al., 2015; Artzi et al., 2015; Misra and Artzi, 2016; Damonte et al., 2017) and aligners (Chu and Kurohashi, 2016; Chen and Palmer, 2017).[11] Such an attitude reflects decades of work in the syntax-semantics interface (Partee, 2014) and the utility of dependency syntax for other forms of semantics (e.g., Oepen et al., 2014; Reddy et al., 2016; Stanovsky et al., 2016; White et al., 2016; Zhang et al., 2017; Hershcovich et al., 2017). However, this assumption has not been empirically tested, and as Bender et al. (2015) observe, it is an assumption not guaranteed by the AMR annotation style. Having aligned a corpus of AMR-DG pairs, we are in a position to provide empirical evidence.

simple configurations			*complex configurations*		
max config.	**# sents**	**avg. words**	**max config.**	**# sents**	**avg. words**
1:1	18	8.7	2:2	21	12.9

3:1	12	13.4	3:2	13	16.8
2:0	6	5.8	3:4	12	20.3
1:3	5	13.2	3:3	10	19.1
other	9	15.2	other	64	20.9
total:	66	11.6		134	18.0

Table 1: Number of sentences whose highest alignment configurations is max config.

Are AMRs and dependency graphs structurally similar? We approach the question by analyzing the sizes of subgraphs used to align the two representations of the sentence.

We define the size of a subgraph as the number of edges it contains. If a structure consists of a single node, we say its size is 0. The **configuration** of an alignment is then the pair of sizes for its AMR and DG sides; for example, an alignment with 1 AMR edge and 2 DG edges has configuration 1:2. We call an alignment configuration *simple* if at least one of the subgraphs is a single edge, indicating that there is a single relation which the alignment captures. *Complex* configurations cover multiple relations. By principle of minimality we infer that some structural difference between the graphs prevented those relations from aligning individually.

One measure of similarity between AMR and DG graphs is the configuration of the most complex subgraph alignment between them. Configuration a:b is higher than c:d if $a+b>c+d$. However, all configurations involving 0 are lower than those which do not. A maximum of 1:1 means the graphs have only node-to-node, node-to-edge, and edge-to-edge alignments, rendering the graphs isomorphic (ignoring edge directions and unaligned nodes). In

[9] The corpus is annotated with UD v1; a release of the dataset converted to UD v2 is planned for the future. We used the pretrained dependency parsing model provided in CoreNLP with `depparse.extradependencies` set to `MAXIMAL`, and used collapsed CCprocessed dependencies.

[10] `http://universaldependencies.org/u/overview/enhanced-syntax.html`

[11] In particular, Chen and Palmer (2017) align dependency paths to AMR edges. However, their evaluation only considers node-to-node alignment, and their code and data are not available for comparison at the time of this writing.

named entities		coordination		semantic decomposition		quantities & dates		other		overall

total:	193		117		84		28		3385		**3807**

Table 2: Frequency of alignment configurations for named entities, coordination, semantically decomposed words, quantities and dates, and other phenomena.

general, if the maximum alignment configuration is a simple one, the graphs could be made isomorphic by collapsing the larger side of the alignment (e.g., in figure 2, the AMR side of the alignment *evil-doer* ~ person$\xrightarrow{\text{ARG0-of}}do\xrightarrow{\text{ARG1}}$thing$\xrightarrow{\text{mod}}$evil could be collapsed into a node).

In contrast, complex configurations imply serious structural dissimilarity, as in figure 3, where the cyan alignment has configuration 4:4.

The numbers in table 1 show that ≈33% of the sentences are *simple*.

Table 2 provides a detailed breakdown of alignment configurations in the corpus. Phenomena which often trigger complex configurations include coordination, named entities, semantically decomposed words, attachment of negation, and preposition-based concepts encoding location, time, and quantity.[12]

We observe, comparing tables 1 and 2, that while simple configurations are most frequent in the corpus, the majority of sentences have at least one alignment which is complex. It should not be assumed that AMR and DG representations of a sentence are, or could trivially be made to be, isomorphic. It is worth noting that our analysis suggests that DG and AMR could be made more similar by applying simple transformations targeting problematic constructions like coordination and named entities.

4 Evaluation of automatic aligners

We use our annotations to measure the accuracy of AMR aligners on specific phenomena that were inexpressible in previous annotation schemes. Our experiments evaluate the JAMR heuristic aligner (Flanigan et al., 2014), the ISI statistical aligner (Pourdamghani et al., 2014), and a heuristic rule-based aligner that we developed specifically for structural alignment.

4.1 Rule-based aligner

Our aligner operates in two passes: one for lexical alignment and one for structural alignment.

Lexical alignment algorithm. AMR concepts are cognate with English words, so we align them by lexical similarity. This algorithm does not make use of the DG. Before alignment, we remove sense identifiers on AMR node labels, and lemmatize DG node labels. Then for every pair of nodes a from the AMR and d from the DG we align them if any of the following conditions holds:

1. The Levenshtein distance of a and d is 15% or less of the length of the longer word.[13]
2. The label of a is the morphological negation of d (e.g. *prudent* ~ `imprudent`).[14]
3. The label of a is – (AMR's annotation of negation) and the parent of a aligns to d via rule 2.
4. The label of a is – and d is one of *no*, *none*, *not*, or *never*.
5. The label of a consists of multiple words, and the label of d matches any one of them under rule 1. (e.g. *sit* ~ `sit-down`, *war-torn* ~ `war`).[15]
6. Labels of a and d likely have the same morphological root. We determine this by segmenting each word with Morfessor (Grönroos et al., 2014) trained on Wiki data and applying rule 1 to the first morpheme of each word.

Note that if a word type is repeated in a sentence, each repetition is aligned to the same AMR nodes under the above rules.

Structural alignment algorithm. We align subgraphs using the procedure below, first from AMR to DG, then from DG to AMR. For clarity, the explanation refers to the first case.

[12] An AMR concept evoked by a preposition usually dominates the structure (after$\xrightarrow{\text{op1}}$date-entity$\xrightarrow{\text{decade}}$nineties), which is at odds with UD's prepositions-as-case-markers policy (*nineties*$\xrightarrow{\textit{case}}$*after*).

[13] Threshold was determined empirically on a 10% sample from the dataset.

[14] We use a list of morphologically negated words provided by Ulf Hermjakob.

[15] This rule misaligns some AMR-specific node types, such as *government* ~ `government-organization`.

aligner	dataset: our			ISI			JAMR		
our	89	85	**87**	88	77	82	55	81	65
ISI	71	68	70	96	85	**90**	47	67	55
JAMR	86	63	72	95	66	78	92	85	**88**

Table 3: Lexical alignment (precision, recall, F_1-score). Our *lexical* alignment algorithm does not use syntax.

Local phase. For every AMR edge e_a whose endpoints are lexically aligned nodes a_1 (aligned to d_1) and a_2 (aligned to d_2), we attempt to align minimal and connected AMR and dependency subgraphs, a' and d':

1. If there is a DG edge e_d whose endpoints are d_1 and d_2, then $a' \leftarrow e_a$ and $d' \leftarrow e_d$.
2. Otherwise, let π_d be the shortest undirected path between d_1 and d_2. If all lexically aligned nodes in π_d are aligned to a_1 or a_2, then $a' \leftarrow e_a$ and $d' \leftarrow \pi_d$.
3. Otherwise, let a'' be the smallest subgraph covering all AMR nodes that are lexically aligned to nodes in π_d. If all the nodes in a'' are aligned only to nodes in π_d, then $a' \leftarrow a''$ and $d' \leftarrow \pi_d$.
4. Otherwise, the attempt is abandoned.
5. Finally, if the top node of a' has a parent node labeled with an entity type concept, extend a' to include the parent. (This step is performed only in the AMR-to-DG step.)

Global phase. The local phase might produce alignments that violate the Subsumption Principle (§2.3.1), so we filter them out heuristically. For every pair of structural alignments, $\pi_d \sim \pi_a$ and $\pi'_d \sim \pi'_a$ where π_a overlaps with π'_a, or π_d with π'_d, if the region of overlap is not itself an aligned subgraph, we prune both alignments.[16]

4.2 Experiments

We evaluate JAMR, ISI, and our aligner on two distinct tasks.

Lexical alignment. Lexical alignment involves aligning AMR nodes to words, a task all three systems can perform. We evaluate against three datasets: our own, the JAMR dataset (Flanigan et al., 2014), and the ISI dataset (Pourdamghani et al., 2014).[17] Results (table 3) suggest that this task is already well-addressed, but also that there exist marked differences between how lexical alignment is defined in each dataset and that aligners are fine-tuned to their dataset.

For our aligner, errors are due to faulty morphological analysis, duplicated words, and both accidental string similarity between AMR concepts and words and occasional lack of similarity between concepts and words that should be aligned.

lexical alignments	prec., rec., F_1 using gold DGs			prec., rec., F_1 using automatic DGs		
gold	79	73	76	70	63	66
our aligner	68	56	61	63	48	55
ISI	65	50	57	58	44	50
JAMR	71	41	52	61	34	44

Table 4: Structural alignment (§4.1) scores, with different sources of input lexical alignments. Scores are shown for gold standard and automatic UD trees.

Structural alignment. An important goal of our experiments is to establish baselines for the structural alignment task. While we cannot evaluate the JAMR and ISI aligners directly on this task, we can use the lexical alignments they output in place of the first pass of our aligner. The only dataset for this task is our own. The results (table 4) evaluate accuracy of structural alignments only and do not count lexical alignments.

The automatic alignments have lower coverage of AMRs than the gold alignments do: our best aligner leaves 13.3% of AMR nodes and 30.0% of AMR edges unaligned, compared to 0.07% and 2.8% in the gold standard. The aligner also leaves 39.2% of DG nodes and 47.7% of DG edges unaligned, compared to 28.6% and 34.8% in the gold standard. The relatively low F-score for the gold standard lexical alignments and DGs condition suggests that substantial improvements to our structural alignment algorithm are possible. The two most common reasons for low recall were missing one of the conjuncts in a coordinate structure and aligning structures that violate the principle of minimality.

Our corpus gives alignments between AMRs and gold standard dependency parses. To see how much performance degrades when such parses are not available we also evaluate on automatic parses.[18] Both precision and recall are substantially worse when the aligner relies on automatic syntax.

5 Improving error analysis for AMR parsers

Our corpus of manually aligned AMRs can be used to identify linguistic constructions which cause

[16] This could be order-dependent since the removal of one alignment could trigger the removal of others, but our aligner does not account for this.

[17] We remove span alignments in the JAMR dataset and edge alignments in the ISI dataset.

[18] We use the CoreNLP dependency parser with settings as described in §3.

UD structure	missed	mislabeled
nsubj	103 (40%)	14 (6%)
nmod + case	74 (44%)	26 (16%)
compound	55 (41%)	7 (5%)
amod	40 (26%)	9 (6%)
dobj	40 (33%)	6 (5%)
advmod	30 (39%)	7 (9%)
cc + conj	29 (57%)	4 (8%)
nmod	21 (60%)	1 (3%)

Table 5: Error analysis of the AMR parser of Damonte et al. (2017). Frequency of dependency structures aligned to AMR edges which the automatic AMR parser missed altogether or mislabeled; absolute count (% of all such aligned structures in the corpus).

problems for an AMR parser. We parsed the sentences from our corpus with the parser of Damonte et al. (2017).[19] We map the nodes of the resulting automatic AMRs to the gold AMRs using the smatch evaluation tool (Cai and Knight, 2013), and on the basis of this mapping identify those nodes and edges of the gold AMRs which are missing or mislabeled in the automatic AMRs.

We then measured the number and rate of erroneous AMR fragments associated with each UD relation or construction (table 5). The largest proportion of recall errors were for fragments associated with the subject relation, prepositional phrases, and nominal compounds. Focusing on the subject relation, we can further say that 69% of the missing or mislabeled edges have the gold label `ARG0`, 19% `ARG1`, and the rest are distributed amongst `domain`, `ARG2`, `purpose` and `mod`. Inspecting the errors we see that phenomena underlying them include pronominal coreference, sharing arguments between conjoined predicates, auxiliary verb constructions, and control and raising.[20]

Our corpus facilitates fine-grained error analysis of AMR parsers with respect to individual syntactic constructions. We release the code for the above analysis in order to encourage syntactically-informed comparison and improvement of systems.

6 Conclusion

We have presented a new framework and corpus for aligning AMRs to dependency syntax. Our data and analysis show that the vast majority of the semantics in AMR graphs can be mapped to the lexical and syntactic structure of a sentence, though current alignment systems do not fully capture this correspondence. The syntax–semantics correspondences are often structurally divergent (non-isomorphic). Simple algorithms for lexical and structural alignment establish baselines for the new alignment task; we expect statistical models will be brought to bear on this task in future work. Our framework also facilitates syntactically-based analysis of AMR parsers. We release our data and code for the benefit of the research community.

[19] The overall smatch score of the parser on this dataset was 0.65.

[20] The missing edge counts include gold edges for which the parser failed to produce one or both endpoints.

A Details of alignment guidelines

A.1 Lexical alignments

Names. In proper names, individual strings denoting words in the name are lexically aligned, but the entity as a whole is structurally aligned.

Entity types. If the entity type is based on a common noun which occurs in the sentence, it is lexically aligned: e.g., *Jon, a clumsy man, has a cat* would involve the alignment *man* ~ `man`. Most often, however, an entity type is not explicitly mentioned in the sentence and is taken from AMR's ontology of entity types (`http://www.isi.edu/~ulf/amr/lib/ne-types.html`), in which case it will not be lexically aligned.

Case marking and prepositions. The possessive marker *'s* and many prepositions participate in structural but not lexical alignments because they are inherently relational. However, we align a preposition if it carries sufficient lexical content to be included as an AMR node (e.g., the AMR for *The cat is under the table* would include `under` $\xrightarrow{\texttt{op1}}$ `table`).

Wh-questions. The special concept `amr-unknown` aligns lexically to the wh-word whose referent is questioned. For multiword wh-expressions like *how much*, the expression is aligned structurally (not lexically) to `amr-unknown`.

Sentence mood. In AMR, non-wh questions are indicated by $\xrightarrow{\texttt{mode}}$`interrogative`, imperatives by $\xrightarrow{\texttt{mode}}$`imperative`, and exclamations/interjections by $\xrightarrow{\texttt{mode}}$`expressive`. UD parses do not encode sentence mood, which can be conveyed by non-canonical word order (subject-auxiliary inversion for questions) or argument omission (subject omission for imperatives), rather than the presence of certain relations or words. Sometimes the sentence includes an appropriate alignment point, e.g. complementizers *whether* and *if* for `interrogative`, allowing for a lexical alignment. More often the parse has no obvious alignment point, and the constant `interrogative`, `imperative`, or `expressive` is left unaligned.[21]

A.2 Structural alignments

Copulas. In UD, copulas are treated as modifiers of a predicate nominal or adjective, which is linked directly to the subject of the sentence via an ***nsubj*** dependency. We do not align copulas or the ***cop*** edge. Thus, in figure 3, there is a structural alignment between *general* $\xleftarrow{\textit{nsubj}}$ *confident* and the AMR subgraph connecting the lexically aligned nodes.

Control. The subject of the control verb and the controlled predicate are connected by the ***nsubj-xsubj*** edge, which can be structurally aligned with the corresponding AMR argument relation, as in e.g. figure 2.

Relative clauses. In enhanced UD the noun governing a relative clause and the embedded predicate are linked by edges in both directions: a "surface syntax" ***acl-relcl*** edge headed by the noun, and a "deep syntax" edge such as ***nsubj***, ***dobj***, ***iobj***, or ***nmod*** headed by the embedded predicate. Each participates in a structural alignment with the corresponding AMR subgraph. The relative pronoun is left unaligned.

Coordination. Coordination does not naturally lend itself to analysis with dependencies, and different dependency grammar traditions offer different approaches (Nivre, 2005; Mareček et al., 2013). UD follows the Stanford style, where the first conjunct serves as the head of the remaining conjuncts, and the conjunction is a dependent of one of the conjuncts.[22] In AMR the conjunction heads all the conjuncts (Prague style). In light of this mismatch, we use a subgraph alignment to group the conjunction with its conjuncts on each side. A simple example is illustrated in figure 2. A quirk of UD's approach to coordination is that it does not distinguish modifiers of the first conjunct from modifiers of the coordinate structure as a whole. The basic UD parse of *her glee and greed* is therefore ambiguous. We rely on an extra edge in the enhanced parse between *her* and *greed* to establish an alignment for the AMR edge `greed` $\xrightarrow{\texttt{ARG0}}$ `person`.

The coordination in figure 3 is more complex: the coordinated modifier *defense and security* distributes over *capabilities* (i.e., there are two kinds of capabilities). In the enhanced parse, *defense* and *security* are both attached as modifiers of *capabilities*. This is expressed semantically via **duplicate** AMR nodes labeled `capable`, each receiving different modifiers corresponding to different conjuncts. Independent of coordination, the two `capable` nodes also share a common argument, `nation`. The three syntactic modifiers give rise to three subgraph alignments, and the subgraph alignment covering the coordinate structure (cyan in the figure) envelops two of these. **Ellipsis** construc-

[21] Among the UD community there has been discussion of possibly adding sentence-level marking of mood (`https://github.com/UniversalDependencies/docs/issues/458`), which could provide a convenient alignment point.

[22] In UD version 1, and therefore the examples in this paper, the conjunction attaches to the first conjunct, whereas in version 2 it attaches to the next successive conjunct (`http://universaldependencies.org/v2/summary.html`).

tions can also trigger node duplication in AMR, requiring similar structural alignments.

Named entities. AMR annotates each named entity with a node representing the name, linked to the strings of the name and headed by an entity type. This full structure is aligned to the full name in the dependency parse.

Coreferent mentions. Coreference often causes an AMR structure to align to multiple DG subgraphs. For example, in figure 2, both the pronoun *her* and the name align to the AMR subgraph representing the entity. This mechanism suffices to represent coreference between mentions in the sentence.

Light verbs. Light verbs have no lexical alignment, but a subgraph alignment covers the light verb construction as a unit (e.g. *makes* $\xrightarrow{dobj}$ *attempt* ~ `attempt-01` in figure 2). All subgraph alignments which involve the light verb or its complement have to involve to whole unit, as shown in the alignment highlighted in red in figure 2.

Multiword expressions. In verb-particle constructions and fixed grammatical expressions the AMR node lexically aligns to all words in the expression, and additionally to the DG subgraph spanning the whole expression. (e.g. *pay* ~ `pay-off-02`, *off* ~ `pay-off-02`, and *pay* $\xrightarrow{compound\text{-}prt}$ *off* ~ `pay-off-02`).

Prepositional phrases. PP modifiers typically involve an extra dependency edge for the preposition attachment, as with *lies* $\xrightarrow{nmod\text{-}in}$ *sun* $\xrightarrow{case}$ in ~ `lie-07` $\xrightarrow{location}$ `sun`.

Semantically decomposed words. When one word has multiple lexical alignments because of morphological decomposition, there also exists a structural alignment between that word and an AMR subgraph representing the decomposition: e.g., in figure 2, *evildoer* ~ `person` $\xrightarrow{ARG0\text{-}of}$ `do-02` $\xrightarrow{ARG1}$ `thing` $\xrightarrow{mod}$ `evil`, and in figure 3, *general* ~ `person` $\xrightarrow{ARG0\text{-}of}$ `have-org-role-91` $\xrightarrow{ARG2}$ `general`. AMR decomposes certain words by convention which must always be structurally aligned, such as *ago* ~ `before` $\xrightarrow{op1}$ `now` and *government* ~ `government-organization` $\xrightarrow{ARG0\text{-}of}$ `govern-01`.

Date, time, and value expressions. These expressions are aligned similarly to named entities, even though the normalized constants may not exactly match the words in the sentence. For example, the DG structure *9:00* $\xleftarrow{nummod}$ *pm* would be represented in the AMR as `date-entity` $\xrightarrow{time}$ `21:00`; tokens *9:00* and *pm* are treated as a multiword expression: each is lexically aligned to `"21:00"`. Moreover, we also align *9:00* $\xleftarrow{nummod}$ *pm* ~ `21:00` and *9:00* $\xleftarrow{nummod}$ *pm* ~ `date-entity` $\xrightarrow{time}$ `21:00`.

End-to-end Graph-based TAG Parsing with Neural Networks

Abstract

We present a graph-based Tree Adjoining Grammar (TAG) parser that uses BiLSTMs, highway connections, and character-level CNNs. Our best end-to-end parser, which jointly performs supertagging, POS tagging, and parsing, outperforms the previously reported best results by more than 2.2 LAS and UAS points. The graph-based parsing architecture allows for global inference and rich feature representations for TAG parsing, alleviating the fundamental trade-off between transition-based and graph-based parsing systems. We also demonstrate that the proposed parser achieves state-of-the-art performance in the downstream tasks of Parsing Evaluation using Textual Entailments (PETE) and Unbounded Dependency Recovery. This provides further support for the claim that TAG is a viable formalism for problems that require rich structural analysis of sentences.

1 Introduction

Tree Adjoining Grammar (TAG, Joshi and Schabes (1997)) and Combinatory Categorial Grammar (CCG, Steedman and Baldridge (2011)) are both mildly context-sensitive grammar formalisms that are lexicalized: every elementary structure (elementary tree for TAG and category for CCG) is associated with exactly one lexical item, and every lexical item of the language is associated with a finite set of elementary structures in the grammar (Rambow and Joshi, 1994). In TAG and CCG, the task of parsing can be decomposed into two phases (e.g. TAG: Bangalore and Joshi (1999); CCG: Clark and Curran (2007)): *supertagging*, where elementary units or *supertags* are assigned to each lexical item and *parsing* where these supertags are combined together. The first phase of supertagging can be considered as "almost parsing" because supertags for a sentence almost always determine a unique parse (Bangalore and Joshi, 1999). This near uniqueness of a parse given a gold sequence of supertags has been confirmed empirically (TAG: Bangalore et al. (2009); Chung et al. (2016); Kasai et al. (2017); CCG: Lewis et al. (2016)).

We focus on TAG parsing in this work. TAG differs from CCG in having a more varied set of supertags. Concretely, the TAG-annotated version of the WSJ Penn Treebank (Marcus et al., 1993) that we use (Chen et al., 2005) includes 4727 distinct supertags (2165 occur once) while the CCG-annotated version (Hockenmaier and Steedman, 2007) only includes 1286 distinct supertags (439 occur once). This large set of supertags in TAG presents a severe challenge in supertagging and causes a large discrepancy in parsing performance with gold supertags and predicted supertags (Bangalore et al., 2009; Chung et al., 2016; Kasai et al., 2017).

In this work, we present a supertagger and a parser that substantially improve upon previously reported results. We propose crucial modifications to the bidirectional LSTM (BiLSTM) supertagger in Kasai et al. (2017). First, we use character-level Convolutional Neural Networks (CNNs) for encoding morphological information instead of suffix embeddings. Secondly, we perform concatenation after each BiLSTM layer. Lastly, we explore the impact of adding additional BiLSTM layers and highway connections. These techniques yield an increase of 1.3% in accuracy. For parsing, since the derivation tree in a lexicalized TAG is a type of dependency tree (Rambow and Joshi, 1994), we can directly apply dependency parsing models. In particular, we use the biaffine graph-based parser proposed by Dozat and Manning (2017) together with our novel techniques for supertagging.

In addition to these architectural extensions for supertagging and parsing, we also explore multi-task learning approaches for TAG parsing. Specif-

Proceedings of NAACL-HLT 2018, pages 1181–1194
New Orleans, Louisiana, June 1 - 6, 2018.

ically, we perform POS tagging, supertagging, and parsing using the same feature representations from the BiLSTMs. This joint modeling has the benefit of avoiding a time-consuming and complicated pipeline process, and instead produces a full syntactic analysis, consisting of supertags and the derivation that combines them, simultaneously. Moreover, this multi-task learning framework further improves performance in all three tasks. We hypothesize that our multi-task learning yields feature representations in the LSTM layers that are more linguistically relevant and that generalize better (Caruana, 1997). We provide support for this hypothesis by analyzing syntactic analogies across induced vector representations of supertags (Kasai et al., 2017; Friedman et al., 2017). The end-to-end TAG parser substantially outperforms the previously reported best results.

Finally, we apply our new parsers to the downstream tasks of Parsing Evaluation using Textual Entailements (PETE, Yuret et al. (2010)) and Unbounded Dependency Recovery (Rimell et al., 2009). We demonstrate that our end-to-end parser outperforms the best results in both tasks. These results illustrate that TAG is a viable formalism for tasks that benefit from the assignment of rich structural descriptions to sentences.

2 Our Models

TAG parsing can be decomposed into *supertagging* and *parsing*. Supertagging assigns to words elementary trees (supertags) chosen from a finite set, and parsing determines how these elementary trees can be combined to form a derivation tree that yield the observed sentence. The combinatory operations consist of *substitution*, which inserts obligatory arguments, and *adjunction*, which is responsible for the introduction of modifiers, function words, as well as the derivation of sentences involving long-distance dependencies. In this section, we present our supertagging models, parsing models, and joint models.

2.1 Supertagging Model

Recent work has explored neural network models for supertagging in TAG (Kasai et al., 2017) and CCG (Xu et al., 2015; Lewis et al., 2016; Vaswani et al., 2016; Xu, 2016), and has shown that such models substantially improve performance beyond non-neural models. We extend previously proposed BiLSTM-based models (Lewis et al., 2016; Kasai et al., 2017) in three ways: 1) we add character-level Convolutional Neural Networks (CNNs) to the input layer, 2) we perform concatenation of both directions of the LSTM not only after the final layer but also after each layer, and 3) we use a modified BiLSTM with highway connections.

2.1.1 Input Representations

The input for each word is represented via concatenation of a 100-dimensional embedding of the word, a 100-dimensional embedding of a predicted part of speech (POS) tag, and a 30-dimensional character-level representation from CNNs that have been found to capture morphological information (Santos and Zadrozny, 2014; Chiu and Nichols, 2016; Ma and Hovy, 2016). The CNNs encode each character in a word by a 30 dimensional vector and 30 filters produce a 30 dimensional vector for the word. We initialize the word embeddings to be the pre-trained GloVe vectors (Pennington et al., 2014); for words not in GloVe, we initialize their embedding to a zero vector. The other embeddings are randomly initialized. We obtain predicted POS tags from a BiLSTM POS tagger with the same configuration as in Ma and Hovy (2016).

2.1.2 Deep Highway BiLSTM

The core of the supertagging model is a deep bidirectional Long Short-Term Memory network (Graves and Schmidhuber, 2005). We use the following formulas to compute the activation of a single LSTM cell at time step t:

$$i_t = \sigma\left(W_i[x_t; h_{t-1}] + b_i\right) \quad (1)$$
$$f_t = \sigma\left(W_f[x_t; h_{t-1}] + b_f\right) \quad (2)$$
$$\tilde{c}_t = \tanh\left(W_c[x_t; h_{t-1}] + b_c\right) \quad (3)$$
$$o_t = \sigma\left(W_o[x_t; h_{t-1}] + b_o\right) \quad (4)$$
$$c_t = f \odot c_{t-1} + i_t \odot \tilde{c}_t \quad (5)$$
$$h_t = o \odot \tanh\left(c_t\right) \quad (6)$$

Here a semicolon ; means concatenation, $\odot$ is element-wise multiplication, and σ is the sigmoid function. In the first BiLSTM layer, the input x_t is the vector representation of word t. (The sequence is reversed for the backwards pass.) In all subsequent layers, x_t is the corresponding output from the previous BiLSTM; the output of a BiLSTM at timestep t is equal to $[h_t^f; h_t^b]$, the concatenation of hidden state corresponding to input t in the forward and backward pass. This concatenation af-

ter each layer differs from Kasai et al. (2017) and Lewis et al. (2016), where concatenation happens only after the final BiLSTM layer. We will show in a later section that concatenation after each layer contributes to improvement in performance.

We also extend the models in Kasai et al. (2017) and Lewis et al. (2016) by allowing highway connections between LSTM layers. A highway connection is a gating mechanism that combines the current and previous layer outputs, which can prevent the problem of vanishing/exploding gradients (Srivastava et al., 2015). Specifically, in networks with highway connections, we replace Eq. 6 by:

$$r_t = \sigma\left(W_r[x_t; h_{t-1}] + b_r\right)$$
$$h_t = r_t \odot o_t \odot \tanh\left(c_t\right) + (1 - r_t) \odot W_h x_t$$

Indeed, our experiments will show that highway connections play a crucial role as we add more BiLSTM layers.

We generally follow the hyperparameters chosen in Lewis et al. (2016) and Kasai et al. (2017). Specifically, we use BiLSTMs layers with 512 units each. Input, layer-to-layer, and recurrent (Gal and Ghahramani, 2016) dropout rates are all 0.5. For the CNN character-level representation, we used the hyperparameters from Ma and Hovy (2016).

We train this network, including the embeddings, by optimizing the negative log-likelihood of the observed sequences of supertags in a mini-batch stochastic fashion with the Adam optimization algorithm with batch size 100 and $\ell = 0.01$ (Kingma and Ba, 2015). In order to obtain predicted POS tags and supertags of the training data for subsequent parser input, we also perform 10-fold jackknife training. After each training epoch, we test the supertagger on the dev set. When classification accuracy does not improve on five consecutive epochs, training ends.

2.2 Parsing Model

Until recently, TAG parsers have been grammar based, requiring as input a set of elemenetary trees (supertags). For example, Bangalore et al. (2009) proposes the MICA parser, an Earley parser that exploits a TAG grammar that has been transformed into a variant of a probabilistic CFG. One advantage of such a parser is that its parses are guaranteed to be well-formed according to the TAG grammar provided as input.

More recent work, however, has shown that data-driven transition-based parsing systems outperform such grammar-based parsers (Chung et al., 2016; Kasai et al., 2017; Friedman et al., 2017). Kasai et al. (2017) and Friedman et al. (2017) achieved state-of-the-art TAG parsing performance using an unlexicalized shift-reduce parser with feed-forward neural networks that was trained on a version of the Penn Treebank that had been annotated with TAG derivations. Here, we pursue this data-driven approach, applying a graph-based parser with deep biaffine attention (Dozat and Manning, 2017) that allows for global training and inference.

2.2.1 Input Representations

The input for each word is the concatenation of a 100-dimensional embedding of the word and a 30-dimensional character-level representation obtained from CNNs in the same fashion as in the supertagger.[1] We also consider adding 100-dimensional embeddings for a predicted POS tag (Dozat and Manning, 2017) and a predicted supertag (Kasai et al., 2017; Friedman et al., 2017). The ablation experiments in Kiperwasser and Goldberg (2016) illustrated that adding predicted POS tags boosted performance in Stanford Dependencies. In Universal Dependencies, Dozat et al. (2017) empirically showed that their dependency parser gains significant improvements by using POS tags predicted by a Bi-LSTM POS tagger. Indeed, Kasai et al. (2017) and Friedman et al. (2017) demonstrated that their unlexicalized neural network TAG parsers that only get as input predicted supertags can achieve state-of-the-art performance, with lexical inputs providing no improvement in performance. We initialize word embeddings to be the pre-trained GloVe vectors as in the supertagger. The other embeddings are randomly initialized.

2.2.2 Biaffine Parser

We train our parser to predict edges between lexical items in an LTAG derivation tree. Edges are labeled by the operations together with the deep syntactic roles of substitution sites (0=underlying subject, 1=underlying direct object, 2=underlying indirect object, 3,4=oblique arguments, CO=co-head for prepositional/particle verbs, and adj=all adjuncts). Figure 1 shows our biaffine parsing ar-

[1] We fix the embedding of the ROOT token to be a 0-vector.

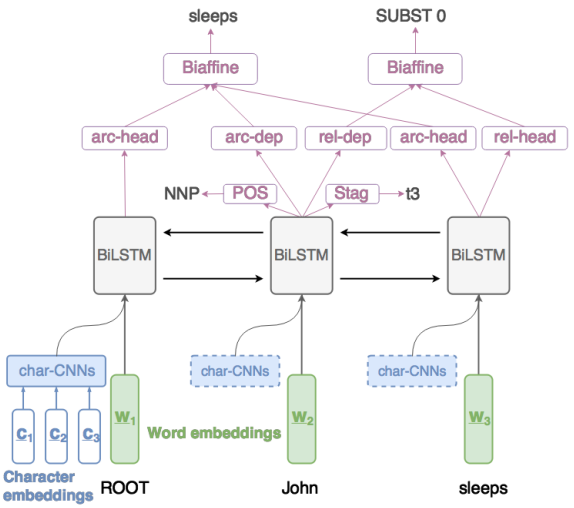

Figure 1: Biaffine parsing architecture. For the dependency from *John* to *sleeps* in the sentence *John sleeps*, the parser first predicts the head of *John* and then predicts the dependency label by combining the dependent and head representations. In the joint setting, the parser also predicts POS tags and supertags.

chitecture. Following Dozat and Manning (2017) and Kiperwasser and Goldberg (2016), we use BiLSTMs to obtain features for each word in a sentence. We add highway connections in the same fashion as our supertagging model.

We first perform unlabeled arc-factored scoring using the final output vectors from the BiLSTMs, and then label the resulting arcs. Specifically, suppose that we score edges coming into the ith word in a sentence i.e. assigning scores to the potential parents of the ith word. Denote the final output vector from the BiLSTM for the kth word by h_k and suppose that h_k is d-dimensional. Then, we produce two vectors from two separate multilayer perceptrons (MLPs) with the ReLU activation:

$$h_k^{\text{arc-dep}} = \text{MLP}^{(\text{arc-dep})}(h_k)$$
$$h_k^{\text{arc-head}} = \text{MLP}^{(\text{arc-head})}(h_k)$$

where $h_k^{\text{arc-dep}}$ and $h_k^{\text{arc-head}}$ are d_{arc}-dimensional vectors that represent the kth word as a dependent and a head respectively. Now, suppose the kth row of matrix $H^{(\text{arc-head})}$ is $h_k^{\text{arc-head}}$. Then, the probability distribution s_i over the potential heads of the ith word is computed by

$$s_i = \text{softmax}(H^{(\text{arc-head})} W^{(\text{arc})} h_i^{\text{arc-dep}} + H^{(\text{arc-head})} b^{(\text{arc})}) \quad (7)$$

where $W^{(\text{arc})} \in \mathbb{R}^{d_{arc} \times d_{arc}}$ and $b^{(arc)} \in \mathbb{R}^{d_{arc}}$. In training, we simply take the greedy maximum probability to predict the parent of each word. In the testing phase, we use the heuristics formulated by Dozat and Manning (2017) to ensure that the resulting parse is single-rooted and acyclic.

Given the head prediction of each word in the sentence, we assign labeling scores using vectors obtained from two additional MLP with ReLU. For the kth word, we obtain:

$$h_k^{\text{rel-dep}} = \text{MLP}^{(\text{rel-dep})}(h_k)$$
$$h_k^{\text{rel-head}} = \text{MLP}^{(\text{rel-head})}(h_k)$$

where $h_k^{\text{rel-dep}}, h_k^{\text{rel-head}} \in \mathbb{R}^{d_{rel}}$. Let p_i be the index of the predicted head of the ith word, and r be the number of dependency relations in the dataset. Then, the probability distribution ℓ_i over the possible dependency relations of the arc pointing from the p_ith word to the ith word is calculated by:

$$\ell_i = \text{softmax}(h_{p_i}^{T(\text{rel-head})} U^{(\text{rel})} h_i^{(\text{rel-dep})} + W^{(\text{rel})}(h_i^{(\text{rel-head})} + h_{p_i}^{(\text{rel-head})}) + b^{(\text{rel})}) \quad (8)$$

where $U^{(\text{rel})} \in \mathbb{R}^{d_{rel} \times d_{rel} \times r}$, $W^{(\text{rel})} \in \mathbb{R}^{r \times d_{rel}}$, and $b^{(\text{rel})} \in \mathbb{R}^r$.

We generally follow the hyperparameters chosen in Dozat and Manning (2017). Specifically, we use BiLSTMs layers with 400 units each. Input, layer-to-layer, and recurrent dropout rates are all 0.33. The depths of all MLPs are all 1, and the MLPs for unlabeled attachment and those for labeling contain 500 (d_{arc}) and 100 (d_{rel}) units respectively. For character-level CNNs, we use the hyperparameters from Ma and Hovy (2016).

We train this model with the Adam algorithm to minimize the sum of the cross-entropy losses from head predictions (s_i from Eq. 7) and label predictions (ℓ_i from Eq. 8) with $\ell = 0.01$ and batch size 100 (Kingma and Ba, 2015). After each training epoch, we test the parser on the dev set. When labeled attachment score (LAS)[2] does not improve on five consecutive epochs, training ends.

2.3 Joint Modeling

The simple BiLSTM feature representations for parsing presented above are conducive to joint modeling of POS tagging and supertagging; rather than using POS tags and supertags to predict a derivation tree, we can instead use the BiLSTM hidden vectors derived from lexical inputs alone

[2]We disregard pure punctuation when evaluating LAS and UAS, following prior work (Bangalore et al., 2009; Chung et al., 2016; Kasai et al., 2017; Friedman et al., 2017).

to predict POS tags and supertags along with the TAG derivation tree.

$$h_k^{\text{pos}} = \text{MLP}^{(\text{pos})}(h_k)$$
$$h_k^{\text{stag}} = \text{MLP}^{(\text{stag})}(h_k)$$

where $h_k^{\text{pos}} \in \mathbb{R}^{d_{pos}}$ and $h_k^{\text{stag}} \in \mathbb{R}^{d_{stag}}$. We obtain probability distribution over the POS tags and supertags by:

$$\text{softmax}(W^{(\text{pos})} h_k^{\text{pos}} + b^{(\text{pos})}) \quad (9)$$
$$\text{softmax}(W^{(\text{stag})} h_k^{\text{stag}} + b^{(\text{stag})}) \quad (10)$$

where $W^{(\text{pos})}$, $b^{(\text{pos})}$, $W^{(\text{stag})}$, and $b^{(\text{stag})}$ are in $\mathbb{R}^{n_{pos} \times d_{pos}}$, $\mathbb{R}^{n_{pos}}$, $\mathbb{R}^{n_{stag} \times d_{stag}}$, and $\mathbb{R}^{n_{stag}}$ respectively, with n_{pos} and n_{stag} the numbers of possible POS tags and supertags respectively.

We use the same hyperparameters as in the parser. The MLPs for POS tagging and supertagging both contain 500 units. We again train this model with the Adam algorithm to minimize the sum of the cross-entropy losses from head predictions (s_i from Eq. 7), label predictions (ℓ_i from Eq. 8), POS predictions (Eq. 9), and supertag predictions (Eq. 10) with $\ell = 0.01$ and batch size 100. After each training epoch, we test the parser on the dev set and compute the percentage of each token that is assigned the correct parent, relation, supertag, and POS tag. When the percentage does not improve on five consecutive epochs, training ends.

This joint modeling has several advantages. First, the joint model yields a full syntactic analysis simultaneously without the need for training separate models or performing jackknife training. Secondly, joint modeling introduces a bias on the hidden representations that could allow for better generalization in each task (Caruana, 1997). Indeed, in experiments described in a later section, we show empirically that predicting POS tags and supertags does indeed benefit performance on parsing (as well as the tagging tasks).

3 Results and Discussion

We follow the protocol of Bangalore et al. (2009), Chung et al. (2016), Kasai et al. (2017), and Friedman et al. (2017); we use the grammar and the TAG-annotated WSJ Penn Tree Bank extracted by Chen et al. (2005). Following that work, we use Sections 01-22 as the training set, Section 00 as the dev set, and Section 23 as the test set. The training, dev, and test sets comprise 39832, 1921, and 2415 sentences, respectively. We implement all of our models in TensorFlow (Abadi et al., 2016).[3]

3.1 Supertaggers

Our BiLSTM POS tagger yielded 97.37% and 97.53% tagging accuracy on the dev and test sets, performance on par with the state-of-the-art (Ling et al., 2015; Ma and Hovy, 2016).[4] Seen in the middle section of Table 1 is supertagging performance obtained from various model configurations. "Final concat" in the model name indicates that vectors from forward and backward pass are concatenated only after the final layer. Concatenation happens after each layer otherwise. Numbers immediately after BiLSTM indicate the numbers of layers. CNN, HW, and POS denote respectively character-level CNNs, highway connections, and pipeline POS input from our BiLSTM POS tagger. Firstly, the differences in performance between BiLSTM2 (final concat) and BiLSTM2 and between BiLSTM2 and BiLSTM2-CNN suggest an advantage to performing concatenation after each layer and adding character-level CNNs. Adding predicted POS to the input somewhat helps supertagging though the difference is small. Adding a third BiLSTM layer helps only if there are highway connections, presumably because deeper BiLSTMs are more vulnerable to the vanishing/exploding gradient problem. Our supertagging model (BiLSTM3-HW-CNN-POS) that performs best on the dev set achieves an accuracy of 90.81% on the test set, outperforming the previously best result by more than 1.3%.

3.2 Parsers

Table 3 shows parsing results on the dev set. Abbreviations for models are as before with one addition: Stag denotes pipeline supertag input from our best supertagger (BiLSTM3-HW-CNN-POS in Table 1). As with supertagging, we observe a gain from adding character-level CNNs. Interestingly, adding predicted POS tags or supertags deteriorates performance with BiLSTM3. These results suggest that morphological information and word information from character-level CNNs and word embeddings overwhelm the in-

[3] Our code is available online for easy replication of our results at https://github.com/jungokasai/graph_parser.

[4] We cannot directly compare these results because the data split is different in the POS tagging literature.

Supertagger	Dev	Test

formation from predicted POS tags and supertags. Again, highway connections become crucial as the number of layers increases. We finally evaluate the parsing model with the best dev performance (BiLSTM4-HW-CNN) on the test set (Table 3). It achieves 91.37 LAS points and 92.77 UAS points, improvements of 1.8 and 1.7 points respectively from the state-of-the-art.

3.3 Joint Models

We provide joint modeling results for supertagging and parsing in Tables 2 and 3. For these joint models, we employed the best parsing configuration (4 layers of BiLSTMs, character-level CNNs, and highway connections), with and without POS tagging added as an additional task. We can observe that our full joint model that performs

Table 3: Parsing results on the dev and test sets.

POS tagging, supertagging, and parsing further improves performance in all of the three tasks, yielding the test result of 91.89 LAS and 93.26 UAS points, an improvement of more than 2.2 points each from the state-of-the-art.

Figures 2 and 3 illustrate the relative performance of the feed-forward neural network shift-reduce TAG parser (Kasai et al., 2017) and our joint graph-based parser with respect to two of the measures explored by McDonald and Nivre (2011), namely dependency length and distance between a dependency and the root of a parse. The graph-based parser outperforms the shift-reduce parser across all conditions. Most interesting is the fact that the graph-based parser shows less of an effect of dependency length. Since the shift-reduce parser builds a parse sequentially with one parsing action depending on those that come before it, we would expect to find a propogation of errors made in establishing shorter dependencies to the establishment of longer dependencies.

Lastly, it is worth noting our joint parsing ar-

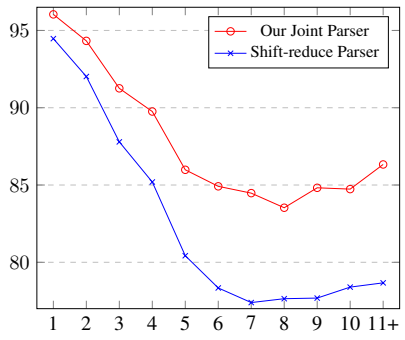

Figure 2: F1 Score with Dependency Length.

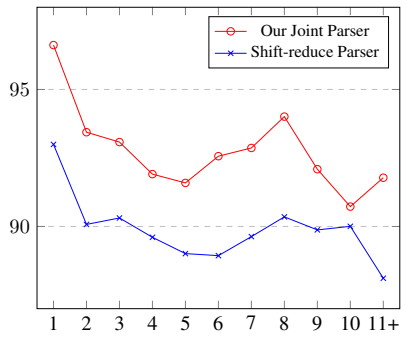

Figure 3: F1 Score with Distance to Root.

chitecture has a substantial advantage regarding parsing speed. Since POS tagging, supertagging, and parsing decisions are made independently for each word in a sentence, our system can parallelize computation once the sentence is encoded in the BiLSTM layers. Our current implementation processes 225 sentences per second on a single Tesla K80 GPU, an order of magnitude faster than the MICA system (Bangalore et al., 2009).[5]

4 Joint Modeling and Network Representations

Given the improvements we have derived from the joint models, we analyze the nature of inductive bias that results from multi-task training and attempt to provide an explanation as to why joint modeling improves performance.

4.1 Noise vs. Inductive Bias

One might argue that joint modeling improves performance merely because it adds noise to each task and prevents over-fitting. If the introduction of noise were the key, we would still expect to gain an improvement in parsing even if the target supertag were corrupted, say by shuffling the order of supertags for the entire training data (Caruana, 1997). We performed this experiment, and the result is shown as "Joint (Shuffled Stag)" in Table 3. Parsing performance falls behind the best non-joint parser by 0.7 LAS points. This suggests that inducing the parser to create representations to predict both supertags and a parse tree is beneficial for both tasks, beyond a mere introduction of noise.

4.2 Syntactic Analogies

We next analyze the induced vector representations in the output projection matrices of our supertagger and joint parsers using the syntactic analogy framework (Kasai et al., 2017). Consider, for instance, the analogy that an elementary tree representing a clause headed by a transitive verb (t27) is to a clause headed by an intransitive verb (t81) as a subject relative clause headed by a transitive verb (t99) is to a subject relative headed by an intransitive verb (t109). Following the ideas in Mikolov et al. (2013) for word analogies, we can express this structural analogy as t27 - t81 + t109 = t99 and test it by cosine similarity. Table 4 shows the results of the analogy test with 246 equations involving structural analogies with only the 300 most frequent supertags in the training data. While the embeddings (projection matrix) from the independently trained supertagger do not appear to reflect the syntax, those obtained from the joint models yield linguistic structure despite the fact that the supertag embeddings (projection matrix) is trained without any *a priori* syntactic knowledge about the elementary trees.

The best performance is obtained by the supertag representations obtained from the training of the transition-based parser Kasai et al. (2017) and Friedman et al. (2017). For the transition-based parser, it is beneficial to share statistics among the input supertags that differ only by a certain operation or property (Kasai et al., 2017) during the training phase, yielding the success in the analogy task. For example, a transitive verb supertag whose object has been filled by substitution should be treated by the parser in the same way as an intransitive verb supertag. In our graph-based parsing setting, we do not have a notion of parse history or partial derivations that directly connect intransitive and transitive verbs. However, syntactic analogies still hold to a considerable degree in the vector representations of supertags induced by our joint models, with average rank of the correct answer nearly the same as that obtained in the transition-based parser.

This analysis bolsters our hypothesis that joint training biases representation learning toward linguistically sensible structure. The supertagger is just trained to predict linear sequences of supertags. In this setting, many intervening supertags can occur, for instance, between a subject noun and its verb, and the supertagger might not be able to systematically link the presence of the two in the sequence. In the joint models, on the other hand, parsing actions will explicitly guide the network to associate the two supertags.

5 Downstream Tasks

Previous work has applied TAG parsing to the downstream tasks of syntactically-oriented textual entailment (Xu et al., 2017) and semantic role labeling (Chen and Rambow, 2003). In this work, we apply our parsers to the textual entailment and unbounded dependency recovery tasks and achieve state-of-the-art performance. These re-

[5] While such computational resources were not available in 2009, our parser differs from the MICA chart parser in being able to better exploit parallel computation enabled by modern GPUs.

Parser / Supertagger	%correct	Avg. rank
Transition-based	67.07	2.36
Our Supertagger	0.00	152.46
Our Joint (Stag)	29.27	2.55
Our Joint (POS+Stag)	30.08	2.57

Table 4: Syntactic analogy test results on the 300 most frequent supertags. Avg. rank is the average position of the correct choice in the ranked list of the closest neighbors; the top line indicates the result of using supertag embeddings that are trained jointly with a transition based parser (Friedman et al., 2017).

sults bolster the significance of the improvements gained from our joint parser and the utility of TAG parsing for downstream tasks.

5.1 PETE

Parser Evaluation using Textual Entailments (PETE) is a shared task from the SemEval-2010 Exercises on Semantic Evaluation (Yuret et al., 2010). The task was intended to evaluate syntactic parsers across different formalisms, focusing on entailments that could be determined entirely on the basis of the syntactic representations of the sentences that are involved, without recourse to lexical semantics, logical reasoning, or world knowledge. For example, syntactic knowledge alone tells us that the sentence *John, who loves Mary, saw a squirrel* entails *John saw a squirrel* and *John loves Mary* but not, for instance, that *John knows Mary* or *John saw an animal*. Prior work found the best performance was achieved with parsers using grammatical frameworks that provided rich linguistic descriptions, including CCG (Rimell and Clark, 2010; Ng et al., 2010), Minimal Recursion Semantics (MRS) (Lien, 2014), and TAG (Xu et al., 2017). Xu et al. (2017) provided a set of linguistically-motivated transformations to use TAG derivation trees to solve the PETE task. We follow their procedures and evaluation for our new parsers.

We present test results from two configurations in Table 5. One configuration is a pipeline approach that runs our BiLSTM POS tagger, supertagger, and parser. The other one is a joint approach that only uses our full joint parser. The joint method yields 78.1% in accuracy and 76.4% in F1, improvements of 2.4 and 2.7 points over the previously reported best results.

System	%A	%P	%R	F1
Rimell and Clark (2010)	72.4	79.6	62.8	70.2
Ng et al. (2010)	70.4	68.3	**80.1**	73.7
Lien (2014)	70.7	**88.6**	50.0	63.9
Xu et al. (2017)	75.7	88.1	61.5	72.5
Our Pipeline Method	77.1	86.6	66.0	74.9
Our Joint Method	**78.1**	86.3	68.6	**76.4**

Table 5: PETE test results. Precision (P), recall (R), and F1 are calculated for "entails."

5.2 Unbounded Dependency Recovery

The unbounded dependency corpus (Rimell et al., 2009) specifically evaluates parsers on unbounded dependencies, which involve a constituent moved from its original position, where an unlimited number of clause boundaries can intervene. The corpus comprises 7 constructions: object extraction from a relative clause (ObRC), object extraction from a reduced relative clause (ObRed), subject extraction from a relative clause (SbRC), free relatives (Free), object wh-questions (ObQ), right node raising (RNR), and subject extraction from an embedded clause (SbEm).

Because of variations across formalisms in their representational format for unbounded depdendencies, past work has conducted manual evaluation on this corpus (Rimell et al., 2009; Nivre et al., 2010). We instead conduct an automatic evaluation using a procedure that converts TAG parses to structures directly comparable to those specified in the unbounded dependency corpus. To this end, we apply two types of structural transformation in addition to those used for the PETE task:[6] 1) a more extensive analysis of coordination, 2) resolution of differences in dependency representations in cases involving copula verbs and co-anchors (e.g., verbal particles). See Appendix A for details. After the transformations, we simply check if the resulting dependency graphs contain target labeled arcs given in the dataset.

Table 6 shows the results. Our joint parser outperforms the other parsers, including the neural network shift-reduce TAG parser (Kasai et al., 2017). Our data-driven parsers yield relatively low performance in the ObQ and RNR constructions. Performance on ObQ is low, we expect, because of their rarity in the data on which the parser is

[6]One might argue that since the unbounded dependency evaluation is recall-based, we added too many edges by the transformations. However, it turns out that applying all the transformations for the corpus even improves performance on PETE (77.6 F1 score), which considers precision and recall, verifying that our transformations are reasonable.

System	ObRC	ObRed	SbRC	Free	ObQ	RNR	SbEm	Total	Avg
C&C (CCG)	59.3	62.6	80.0	72.6	**72.6**	**49.4**	22.4	53.6	61.1
Enju (HPSG)	47.3	65.9	82.1	76.2	32.5	47.1	32.9	54.4	54.9
Stanford (PCFG)	22.0	1.1	74.7	64.3	41.2	45.4	10.6	38.1	37.0
MST (Stanford Dependencies)	34.1	47.3	78.9	65.5	41.2	45.4	37.6	49.7	50.0
MALT (Stanford Dependencies)	40.7	50.5	**84.2**	70.2	31.2	39.7	23.5	48.0	48.5
NN Shift-Reduce TAG Parser	60.4	75.8	68.4	79.8	53.8	45.4	44.7	59.4	61.2
Our Joint Method	**72.5**	**78.0**	81.1	**85.7**	56.3	47.1	**49.4**	**64.9**	**67.0**

Table 6: Parser accuracy on the unbounded dependency corpus. The results of the first five parsers are taken from Rimell et al. (2009) and Nivre et al. (2010). The Total and Avg columns indicate the percentage of correctly recovered dependencies out of all dependencies and the average of accuracy on the 7 constructions.

trained.[7] For RNR, rarity may be an issue as well as the limits of the TAG analysis of this construction. Nonetheless, we see that the rich structural representations that a TAG parser provides enables substantial improvements in the extraction of unbounded dependencies. In the future, we hope to evaluate state-of-the-art Stanford dependency parsers automatically.

6 Related Work

The two major classes of data-driven methods for dependency parsing are often called transition-based and graph-based parsing (Kübler et al., 2009). Transition-based parsers (e.g. MALT (Nivre, 2003)) learn to predict the next transition given the input and the parse history. Graph-based parsers (e.g. MST (McDonald et al., 2005)) are trained to directly assign scores to dependency graphs.

Empirical studies have shown that a transition-based parser and a graph-based parser yield similar overall performance across languages (McDonald and Nivre, 2011), but the two strands of data-driven parsing methods manifest the fundamental trade-off of parsing algorithms. The former prefers rich feature representations with parsing history over global training and exhaustive search, and the latter allows for global training and inference at the expense of limited feature representations (Kübler et al., 2009).

Recent neural network models for transition-based and graph-based parsing can be viewed as remedies for the aforementioned limitations. Andor et al. (2016) developed a transition-based parser using feed-forward neural networks that performs global training approximated by beam search. The globally normalized objective addresses the label bias problem and makes global training effective in the transition-based parsing setting. Kiperwasser and Goldberg (2016) incorporated a dynamic oracle (Goldberg and Nivre, 2013) in a BiLSTM transition-based parser that remedies global error propagation. Kiperwasser and Goldberg (2016) and Dozat and Manning (2017) proposed graph-based parsers that have access to rich feature representations obtained from BiLSTMs.

Previous work integrated CCG supertagging and parsing using belief propagation and dual decomposition approaches (Auli and Lopez, 2011). Nguyen et al. (2017) incorporated a graph-based dependency parser (Kiperwasser and Goldberg, 2016) with POS tagging. Our work followed these lines of effort and improved TAG parsing performance.

7 Conclusion and Future Work

In this work, we presented a state-of-the-art TAG supertagger, a parser, and a joint parser that performs POS tagging, supertagging, and parsing. The joint parser has the benefit of giving a full syntactic analysis of a sentence simultaneously. Furthermore, the joint parser achieved the best performance, an improvement of over 2.2 LAS points from the previous state-of-the-art. We have also seen that the joint parser yields state-of-the-art in textual entailment and unbounded dependency recovery tasks, and raised the possibility that TAG can provide useful structural analysis of sentences for other NLP tasks. We will explore more applications of our TAG parsers in future work.

[7] The substantially better performance of the C&C parser is in fact the result of additions that were made to the training data.

A Transformations for Unbounded Dependency Recovery Corpus

For automatic evaluation on the unbounded dependency recovery corpus (UDR, Rimell et al. (2009)), we run simple conversion of dependency labels in UDR to those in our TAG grammar (See Table 7) with a couple of exceptions.

- Change arcs from verbs to wh-adverbs as in "where is the city located?" to adjunction.
- Reflect causative-inchoative alternation in the subject embedded construction. Concretely, change the role of "door" in "hold the door shut" from the subject to the object of "shut."

We then transform TAG dependency trees. Finally, we simply check if the resulting dependency graphs contain target labeled arcs given in the dataset.

Below is a full description of transformations. This set of structural transformations is applied in the order in which we will present it, so that the output of previous transformations can feed subsequent ones. In the following, we denote an arc pointing from node B to node A with label C as (A, B, C) where A and B are called the child (dependent) and the parent (head) in the relation.

A.1 Transformations from PETE

We apply three types of transformation from Xu et al. (2017) to interpret the TAG parses.

Relative Clauses When an elementary tree of a relative clause adjoins into a noun, we add a reverse arc with the label reflecting the type of the relative clause elementary tree. For a subject relative, we add a 0-labeled arc, for an object relative, we add a 1-labeled arc, and so forth.

UDR Labels	TAG Labels
nsubj, cop	0
dobj, pobj, obj2, nsubjpass	1
others (advmod etc)	ADJ

Table 7: UD to TAG label conversion.

Sentential Complements Sentential complementation in TAG derivations can be analyzed via either adjoining the higher clause into the embedded clause (necessarily so in cases of long-distance extraction from the embedded clause) or substituting the embedded clause in the higher clause. In order to normalize this divergence, for an adjunction arc involving a predicative auxiliary elementary tree (supertag), we add a reverse arc involving the 1 relation (sentential complements).

A.2 Coordination

We roughly follow the method presented in Xu et al. (2017) with extensions. Under the TAG analysis, VP coordination involves a VP-recursive auxiliary tree headed by the coordinator that includes a VP substitution node (for the second conjunct) with label 1. In order to allow the first clauses subject argument (as well as modal verbs and negations) to be shared by the second verb, we add the relevant relations to the second verb. In addition, we analyze sentential coordination cases. Sentence coordination in our TAG grammar usually happens between two complete sentences and no modifiers or arguments are shared, and therefore it can be analyzed via substituting a sentence int the coordinator with label 1. However, when sentential coordination happens between two relative clause modifiers, our TAG grammar analyzes the second clause as a complete sentence, meaning that we need to recover the extracted argument by consulting the property of the first clause. Furthermore, the deep syntactic role of the extracted argument can be different in the two relative clauses. For instance, in the sentence, "... the same stump which had impaled the car of many a guest in the past thirty years and which he refused to have removed," we need to recover an arc from removed to stump with label 1 whereas the arc from impaled to stump has label 0. To resolve this issue, when there is coordination of two relative clause modifiers, we add an edge from the head of the second clause to the modified noun with the same label as the label that under which the relative pronoun is attached to the head.

A.3 Resolving Differences in Dependency Representations

Small Clauses The UDR corpus has inconsistency with regards to small clauses. UDR gives an analysis that a small clause contains a subject and a complement as in (nsubj, guy, liar) in

"the guy who I call a liar." in the subject embedded constructions. However, in the object question and object free relative constructions, a small clause is analyzed as two arguments of the verb. For instance, UDR specifies (what, adopted, dobj) in "we adopted what I would term pseudo-capitalism." To solve this problem we add an arc from the head of the matrix clause to the subject in a small clause with label 1.

Co-anchors In our TAG grammar, Co-anchor attachment represents the substitution into a node that is construed as a co-head of an elementary tree. For instance, "for" is deemed as a co-anchor to "hope" in the sentence *"that is exactly what I'm hoping for* (Figure 4). In this case, UDR would pick the relation (what, hope, pobj). Therefore, when there is a co-anchor to a head tree, we add all arcs that involve the head tree to the co-anchor tree.

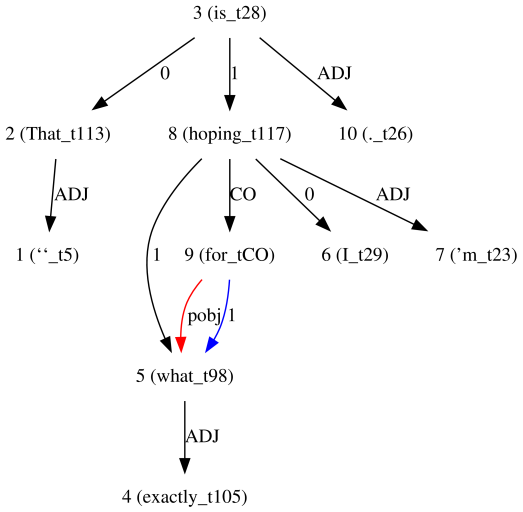

Figure 4: Co-anchor case from a sentence *"that is exactly what I'm hoping for.* The UDR gives the red arc (what, for, pobj). The blue arc (what, for, 1) is obtained from (what, hope, 1).

Wh-determiners and Wh-adverbs Our TAG grammar analyzes a wh-determiner via adjoining the noun into the wh-determiner (Figure 5). This is also true for cases where a wh-adverb is followed by an adjective and a noun as in ***how many battles*** *did she win?* In contrast, UDR corpus gives an analysis that the noun is the head of the constituent. In order to resolve this discrepancy, when a word adjoins into a wh-word,[8] we pick all arcs with the wh-word as the child and add the arcs obtained from such arcs by replacing the wh-word child by the word adjoining into the wh-word.

Copulas A copula is usually treated as a dependent to the predicate both in our TAG grammar (adjunction) and UDR. However, we found two situations where they differ from each other. First, when wh-extraction happens on the complement, as in "obviously there has been no agreement on what American conservatism is, or rather, what it should be," the TAG grammar analyzes it via substituting the wh-word ("what") into the copula ("is"). To reconcile this disagreement between the TAG grammar and UDR, when substitution happens into a *be* verb, we add the substitution into

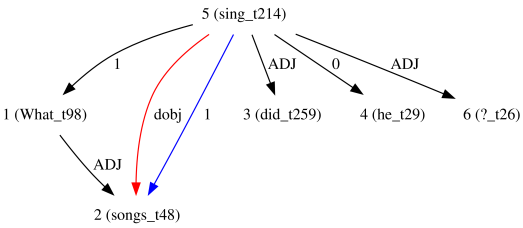

Figure 5: Wh-determiner case from a sentence *What songs did he sing?* The UDR gives the red arc (songs, sing, dobj). The blue arc (song, sing, 1) is obtained from (what, sing, 1) and (songs, what, ADJ).

[8] We considered imposing a more strict condition that the word adjoining into the wh-word is a noun, but we found cases that this method fails to cover; for example, UDR gives (dobj, get, much) for a sentence "opinion is mixed on how **much** of a boost the overall stock market would **get** even if dividend growth continues at double-digit levels."

the copula.[9] Second, UDR treats non-*be* copulas differently than *be* verbs. An example is the UDR relation (those, stayed, nsubj) "in the other hemisphere it is growing colder and nymphs, those who stayed alive through the summer, are being brought into nests for quickening and more growing" where our parser yields (those, alive, 0). For this reason, when a lemma of a verb is a non-*be* copula,[10] we add arcs involving the word to the copula adjoining into the copula.

PP attachment with multiple noun candidates We observed that PP attachment with multiple noun candidates is often at stake in UDR.[11] For instance, UDR provides (part, had, nsubj) and (several, tried, nsubj) for the sentences "... there is no part of the earth that has not had them" and "there were several on the Council who tried to live like Christians" while the TAG parser outputs (earth, had, nsubj) and (Council, tried, nsubj) respectively. While we count these cases as "wrong" since they manifest certain disambiguation (though not purely unbounded dependency recovery), we ignore superficial (conventional) differences in head selection. In our TAG grammar "a lot of people" would be headed by "lot" whereas UDR would recognize "people" as the head. Hence, when "lot/lots/kind/kinds/none of" occurs, we add all arcs with "lot/lots/kind/kinds/none" to the head of the phrase that is the object of "of."

Modals In the UDR corpus, a modal depends on an auxiliary verb following the modal, if there is one. For example, "Rosie reinvented this man, who may or may not have known about his child" is given the relation (may, have, aux). In the TAG grammar, both "may" and "have" adjoin into "known." Therefore, when the head of a modal has another child with adjunction, we add an arc from the child to the modal.

Existential *there* UDR gives the "cop" relation between an existential there and the *be* verb. For example, it gives (be, legislation, cop) in "... on how much social legislation there should be." On the other hand, our TAG grammar analyzes that "there" is attached to "be" with label 0.[12] To resolve this issue, for arcs that point into an existential there with label 0, we add a reverse edge with label 0.

Determiner modifying a sentence Finally, when a determiner followed by an adjective modifies a sentence via adjunction in our TAG as in "the more highly placed they are – that is, the more they know – the more concerned they have become," we add an edge from the verb to the adjective with label 1.

[9] We use the nltk lemmatizer (Bird et al., 2009) to identify *be* verbs.

[10] We chose " stay," "become," "seem," and "remain."

[11] This is indeed one of the problems with UDR. Performance on UDR is not purely reflective of unbounded dependency recovery.

[12] Usually, "there" is attached to the noun, not the *be* verb, but in this case, extraction is happening on the noun, so the *be* verb becomes the head. See the discussion on copulas above.

Colorless green recurrent networks dream hierarchically

Abstract

Recurrent neural networks (RNNs) have achieved impressive results in a variety of linguistic processing tasks, suggesting that they can induce non-trivial properties of language. We investigate here to what extent RNNs learn to track abstract hierarchical syntactic structure. We test whether RNNs trained with a generic language modeling objective in four languages (Italian, English, Hebrew, Russian) can predict long-distance number agreement in various constructions. We include in our evaluation nonsensical sentences where RNNs cannot rely on semantic or lexical cues ("The colorless green ideas I ate with the chair sleep furiously"), and, for Italian, we compare model performance to human intuitions. Our language-model-trained RNNs make reliable predictions about long-distance agreement, and do not lag much behind human performance. We thus bring support to the hypothesis that RNNs are not just shallow-pattern extractors, but they also acquire deeper grammatical competence.

1 Introduction

Recurrent neural networks (RNNs; Elman, 1990) are general sequence processing devices that do not explicitly encode the hierarchical structure that is thought to be essential to natural language (Everaert et al., 2015). Early work using artificial languages showed that they may nevertheless be able to approximate context-free languages (Elman, 1991). More recently, RNNs have achieved impressive results in large-scale tasks such as language modeling for speech recognition and machine translation, and are by now standard tools for sequential natural language tasks (e.g., Mikolov et al., 2010; Graves, 2012; Wu et al., 2016). This suggests that RNNs may learn to track grammatical structure even when trained on noisier natural data. The conjecture is supported by the success of RNNs as feature extractors for syntactic parsing (e.g., Cross and Huang, 2016; Kiperwasser and Goldberg, 2016; Zhang et al., 2017).

Linzen et al. (2016) directly evaluated the extent to which RNNs can approximate hierarchical structure in corpus-extracted natural language data. They tested whether RNNs can learn to predict English subject-verb agreement, a task thought to require hierarchical structure in the general case ("the girl the boys like… is or are?"). Their experiments confirmed that RNNs can, in principle, handle such constructions. However, in their study RNNs could only succeed when provided with explicit supervision on the target task. Linzen and colleagues argued that the unsupervised language modeling objective is not sufficient for RNNs to induce the syntactic knowledge necessary to cope with long-distance agreement.

The current paper reevaluates these conclusions. We strengthen the evaluation paradigm of Linzen and colleagues in several ways. Most importantly, their analysis did not rule out the possibility that RNNs might be relying on *semantic* or *collocational/frequency-based* information, rather than purely on syntactic structure. In "dogs in the neighbourhood often bark", an RNN might get the right agreement by encoding information

*The work was conducted during the internship at Facebook AI Research, Paris.

Proceedings of NAACL-HLT 2018, pages 1195–1205
New Orleans, Louisiana, June 1 - 6, 2018.

about what typically barks (dogs, not neighbourhoods), without relying on more abstract structural cues. In a follow-up study to Linzen and colleagues', Bernardy and Lappin (2017) observed that RNNs are better at long-distance agreement when they construct rich lexical representations of words, which suggests effects of this sort might indeed be at play.

We introduce a method to probe the syntactic abilities of RNNs that abstracts away from potential lexical, semantic and frequency-based confounds. Inspired by Chomsky's (1957) insight that "grammaticalness cannot be identified with meaningfulness" (p. 106), we test long-distance agreement both in standard corpus-extracted examples and in comparable nonce sentences that are grammatical but completely meaningless, e.g., (paraphrasing Chomsky): "The colorless green ideas I ate with the chair sleep furiously".

We extend the previous work in three additional ways. First, alongside English, which has few morphological cues to agreement, we examine Italian, Hebrew and Russian, which have richer morphological systems. Second, we go beyond subject-verb agreement and develop an automated method to harvest a variety of long-distance number agreement constructions from treebanks. Finally, for Italian, we collect human judgments for the tested sentences, providing an important comparison point for RNN performance.[1]

We focus on the more interesting unsupervised setup, where RNNs are trained to perform generic, large-scale language modeling (LM): they are not given explicit evidence, at training time, that they must focus on long-distance agreement, but they are rather required to track a multitude of cues that might help with word prediction in general.

Our results are encouraging. RNNs trained with a LM objective solve the long-distance agreement problem well, even on nonce sentences. The pattern is consistent across languages, and, crucially, not far from human performance in Italian. Moreover, RNN performance on language modeling (measured in terms of perplexity) is a good predictor of long-distance agreement accuracy. This suggests that the ability to capture structural generalizations is an important aspect of what makes the best RNN architectures so good at language modeling. Since our positive results contradict, to some extent, those of Linzen et al. (2016), we also replicate their relevant experiment using our best RNN (an LSTM). We outperform their models, suggesting that a careful architecture/hyperparameter search is crucial to obtain RNNs that are not only good at language modeling, but able to extract syntactic generalizations.

[1]The code to reproduce our experiments and the data used for training and evaluation, including the human judgments in Italian, can be found at https://github.com/facebookresearch/colorlessgreenRNNs.

2 Constructing a long-distance agreement benchmark

Overview. We construct our number agreement test sets as follows. **Original** sentences are automatically extracted from a dependency treebank. They are then converted into **nonce** sentences by substituting all content words with random words with the same morphology, resulting in grammatical but nonsensical sequences. An LM is evaluated on its predictions for the target (second) word in the dependency, in both the original and nonce sentences.

Long-distance agreement constructions. Agreement relations, such as subject-verb agreement in English, are an ideal test bed for the syntactic abilities of LMs, because the form of the second item (the target) is predictable from the first item (the cue). Crucially, the cue and the target are linked by a *structural* relation, where linear order in the word sequence does not matter (Everaert et al., 2015). Consider the following subject-verb agreement examples: "the girl thinks…", "the girl [you met] thinks…", "the girl [you met yesterday] thinks…", "the girl [you met yesterday through her friends] thinks…". In all these cases, the number of the main verb "thinks" is determined by its subject ("girl"), and this relation depends on the syntactic structure of the sentence, not on the linear sequence of words. As the last sentence shows, the word directly preceding the verb can even be a noun with the opposite number ("friends"), but this does not influence the structurally-determined form of the verb.

When the cue and the target are adjacent ("the girl thinks…"), an LM can predict the target without access to syntactic structure: it can simply extract the relevant morphosyntactic features of words (e.g., number) and record the co-occurrence frequencies of patterns such as N_{Plur} V_{Plur} (Mikolov et al., 2013). Thus, we focus here on *long-distance* agreement, where an arbitrary num-

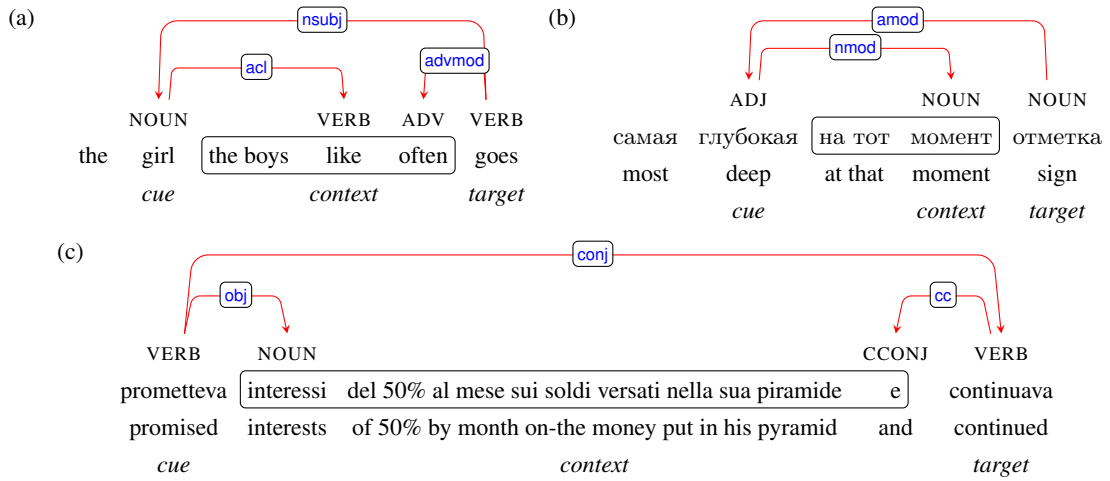

Figure 1: Example agreement constructions defined by a dependency and the separating context, in (a) English, (b) Russian and (c) Italian.

ber of words can occur between the elements of the agreement relation. We limit ourselves to *number* agreement (plural or singular), as it is the only overt agreement feature shared by all of the languages we study.

Identifying candidate constructions. We started by collecting pairs of part-of-speech (POS) tags connected by a dependency arc. Independently of which element is the head of the relation, we refer to the first item as the **cue** and to the second as the **target**. We additionally refer to the POS sequence characterizing the entire pattern as a **construction**, and to the elements in the middle as **context**.

For each candidate construction, we collected all of the contexts in the corpus that intervene between the cue and the target (we define contexts as the sequence of POS tags of the top-level nodes in the dependency subtrees). For example, for the English subject-verb agreement construction shown in Fig. 1a, the context is defined by VERB (head of the relative clause) and ADV (adverbial modifier of the target verb), which together dominate the sequence "the boys like often". For the Russian adjective-noun agreement construction in Fig. 1b, the context is NOUN, because in the dependency grammar we use the noun "moment" is the head of the prepositional phrase "at that moment", which modifies the adjective "deep". The candidate agreement pair and the context form a construction, which is characterized by a sequence of POS tags, e.g., NOUN VERB ADV VERB or VERB NOUN CCONJ VERB (Fig. 1c).

Our constructions do not necessarily correspond to standard syntactic structures. The English subject-verb agreement construction NOUN VERB VERB, for example, matches both object and subject relative clause contexts, e.g., "girl the boys like is" and "girls who stayed at home were". Conversely, standard syntactic structures might be split between different constructions, e.g., relative clause contexts occur in both NOUN VERB VERB and NOUN VERB ADV VERB constructions (the latter is illustrated by the English example in Fig. 1a).

Construction contexts can contain a variable numbers of words. Since we are interested in challenging cases, we only considered cases in which at least three tokens intervened between the cue and the target.

Excluding non-agreement constructions. In the next step, we excluded constructions in which the candidate cue and target did not agree in number in all of the instances of the construction in the treebank (if both the cue and the target were morphologically annotated for number). This step retained English subject-verb constructions, for example, but excluded verb-object constructions, since any form of a verb can appear both with singular and plural objects. To focus on robust agreement patterns, we only kept constructions with at least 10 instances of both plural and singular agreement.

When applied to the treebanks we used (see Section 3), this step resulted in between two (English) and 21 (Russian) constructions per lan-

guage. English has the poorest morphology and consequently the lowest number of patterns with identifiable morphological agreement. Only the VP-conjunction construction (Fig. 1c) was identified in all four languages. Subject-verb agreement constructions were extracted in all languages but Russian; Russian has relatively flexible word order and a noun dependent preceding a head verb is not necessarily its subject. The full list of extracted constructions in English and Italian is given in Tables 2 and 3, respectively. For the other languages, see the Supplementary Material (SM).[2]

Original sentence test set. Our "original" sentence test set included all sentences from each construction where all words from the cue and up to and including the target occurred in the LM vocabulary (Section 3), and where the singular/plural counterpart of the target occurred in the treebank and in the language model vocabulary (this is required by the evaluation procedure outlined below). The total counts of constructions and original sentences in our test sets are provided in Table 1. The average number of context words separating the cue and the target ranged from 3.6 (Hebrew) to 4.5 (Italian).

Generating nonce sentences. We generated nine nonce variants of each original sentence as follows. Each content word (noun, verb, adjective, proper noun, numeral, adverb) in the sentence was substituted by another random content word from the treebank with matching POS and morphological features. To avoid forms that are ambiguous between several POS, which are particularly frequent in English (e.g., plural noun and singular verb forms), we excluded the forms that appeared with a different POS more than 10% of the time in the treebank. Function words (determiners, pronouns, adpositions, particles) and punctuation were left intact. For example, we generated the nonce (1b) from the original sentence (1a):

(1) a. It presents the case for marriage equality and states...
b. It stays the shuttle for honesty insurance and finds...

Note that our generation procedure is based on morphological features and does not guarantee that argument structure constraints are respected (e.g., "it stays the shuttle" in (1b)).

Evaluation procedure. For each sentence in our test set, we retrieved from our treebank the form that is identical to the agreement target in all morphological features except number (e.g., "finds" instead of "find" in (1b)). Given a sentence with prefix p up to and excluding the target, we then compute the probabilities $P(t_1|p)$ and $P(t_2|p)$ for the singular and plural variants of the target, t_1 and t_2, based on the language model. Following Linzen et al. (2016), we say that the model identified the correct target if it assigned a higher probability to the form with the correct number. In (1b), for example, the model should assign a higher probability to "finds" than "find".[3]

3 Experimental setup

Treebanks. We extracted our test sets from the Italian, English, Hebrew and Russian Universal Dependency treebanks (UD, v2.0, Nivre et al., 2016). The English and Hebrew treebanks were post-processed to obtain a richer morphological annotation at the word level (see SM for details).

LM training data. Training data for Italian, English and Russian were extracted from the respective Wikipedias. We downloaded recent dumps, extracted the raw text from them using WikiExtractor[4] and tokenized it with TreeTagger (Schmid, 1995). We also used the TreeTagger lemma annotation to filter out sentences with more than 5% unknown words. For Hebrew, we used the preprocessed Wikipedia corpus made available by Yoav Goldberg.[5] We extracted 90M token subsets for each language, shuffled them by sentence and split them into training and validation sets (8-to-1 proportion). For LM training, we included the 50K most frequent words in each corpus in the vocabulary, replacing the other tokens with the UNK symbol. The validation set perplexity values we report below exclude unknown tokens.

RNN language models. We experimented with simple RNNs (sRNNs, Elman, 1990), and their most successful variant, long-short term memory models (LSTMs, Hochreiter and Schmidhu-

[2] The SM is available as a standalone file on the project's public repository.

[3] Obviously, in the nonce cases, the LMs never assigned the highest overall probability to either of the two candidates. Qualitatively, in such cases LMs assigned the largest absolute probabilities to plausible frequent words.

[4] https://github.com/attardi/wikiextractor

[5] http://u.cs.biu.ac.il/~yogo/hebwiki/

ber, 1997). We use the PyTorch RNN implementation.[6] We trained the models with two hidden layer dimensionalities (650 and 200 units), and a range of batch sizes, learning rates and dropout rates. See SM for details on hyperparameter tuning. In general, a larger hidden layer size was the best predictor of lower perplexity. Given that our LSTMs outperformed our sRNNs, our discussion of the results will focus on the former; we will use the terms LSTM and RNN interchangeably.[7]

Baselines. We consider three baselines: first, a **unigram** baseline, which picks the most frequent form in the training corpus out of the two candidate target forms (singular or plural); second, a 5-gram model with Kneser-Ney smoothing (**KN**, Kneser and Ney, 1995) trained using the IRSTLM package (Federico et al., 2008) and queried using KenLM (Heafield, 2011); and third, a **5-gram LSTM**, which only had access to windows of five tokens (Chelba et al., 2017). Compared to KN, the 5-gram LSTM can generalize to unseen n-grams thanks to its embedding layer and recurrent connections. However, it cannot discover long-distance dependency patterns that span more than five words. See SM for details on the hyperparameters of this baseline.

Human experiment in Italian. We presented the full Italian test set (119 original and 1071 nonce sentences) to human subjects through the Amazon Mechanical Turk interface.[8] We picked Italian because, being morphologically richer, it features more varied long-distance constructions than English. Subjects were requested to be native Italian speakers. They were presented with a sentence up to and excluding the target. The singular and plural forms of the target were presented below the sentence (in random order), and subjects were asked to select the more plausible form.

To prevent long-distance agreement patterns from being too salient, we mixed the test set with the same number of filler sentences. We started from original fillers, which were random treebank-extracted sentences up to a content word in singular or plural form. We then generated nonce fillers from the original ones using the procedure outlined in Section 2. A control subset of 688 fillers was manually selected by a linguistically-trained Italian native speaker as unambiguous cases. To make sure we were only using data from native (or at least highly proficient) Italian speakers, we filtered out the responses of subjects who chose the wrong target in more than 20% of the fillers.

We collected on average 9.5 judgments for each item (minimum 5 judgments). To account for the variable number of judgments across sentences, accuracy rates were first calculated within each sentence and then averaged across sentences.

4 Results

The overall results are reported in Table 1. We report results averaged across the five models with the lowest validation perplexity, as well as standard deviations across these models. In summary,

		N V V	V NP conj V
Italian	Original	$93.3_{\pm 4.1}$	$83.3_{\pm 10.4}$
	Nonce	$92.5_{\pm 2.1}$	$78.5_{\pm 1.7}$
English	Original	$89.6_{\pm 3.6}$	$67.5_{\pm 5.2}$
	Nonce	$68.7_{\pm 0.9}$	$82.5_{\pm 4.8}$
Hebrew	Original	$86.7_{\pm 9.3}$	$83.3_{\pm 5.9}$
	Nonce	$65.7_{\pm 4.1}$	$83.1_{\pm 2.8}$
Russian	Original	-	$95.2_{\pm 1.9}$
	Nonce	-	$86.7_{\pm 1.6}$

Table 2: LSTM accuracy in the constructions N V V (subject-verb agreement with an intervening embedded clause) and V NP conj V (agreement between conjoined verbs separated by a complement of the first verb).

the LSTM clearly outperformed the other LMs. Rather surprisingly, its performance on nonce sentences was only moderately lower than on original ones; in Italian this gap was only 6.6%.

The KN LM performed poorly; its accuracy on nonce sentences was comparable to that of the unigram baseline. This confirms that the number of the target in nonce sentences cannot be captured by shallow n-gram patterns. The 5-gram LSTM model greatly improved over the KN baseline; its accuracy dropped only modestly between the original and nonce sentences, demonstrating its syntactic generalization ability. Still, the results are substantially below those of the LSTM with unlimited history. This confirms that our test set contains hard long-distance agreement dependencies, and, more importantly, that the more general LSTM model can exploit broader contexts to learn about and track long-distance syntactic relations.

The increase in accuracy scores across the three LMs (KN, 5-gram LSTM and unbounded-context LSTM) correlates well with their validation perplexities in the language modeling task. We also found a strong correlation between agreement accuracy and validation perplexity across all the LSTM variants we explored in the hyperparameter search (68 models per language), with Pearson correlation coefficients ranging from $r = -0.55$ in Hebrew to $r = -0.78$ in English ($p < 0.001$ in all languages). This suggests that acquiring abstract syntactic competence is a natural component of the skills that improve the generic language modeling performance of RNNs.

Differences across languages. English was by far the hardest language. We conjecture that this is due to its poorer morphology and higher POS ambiguity, which might not encourage a generic language model to track abstract syntactic configurations. There is an alternative hypothesis, however. We only extracted two constructions for English, both of which can be argued to be linguistically complex: subject-verb agreement with an intervening embedded clause, and agreement between two conjoined verbs with a nominal complement intervening between the verbs. Yet the results on these two constructions, comparable across languages (with the exception of the subject-verb construction in Russian, which was not extracted), confirm that English is particularly hard (Table 2). A qualitative inspection suggests that the low accuracy in the verb conjunction case (67.5%) is due to ambiguous sentences such as "if you have any questions or need/needs", where the target can be re-interpreted as a noun that is acceptable in the relevant context.[9]

In languages such as Italian and Russian, which have richer morphology and less ambiguity at the part-of-speech level than English, the LSTMs show much better accuracy and a smaller gap between original and nonce sentences. These results are in line with human experimental studies that found that richer morphology correlates with fewer agreement attraction errors (Lorimor et al., 2008). The pattern of accuracy rates in general, and the accuracy for the shared V NP conj V construction in particular, are consistent with the finding that Russian is less prone to human attraction errors than Italian, which, in turn, shows less errors than English.

The largest drop in accuracy between original and nonce sentences occurred in Hebrew. A qualitative analysis of the data in this language suggests that this might be due to the numerical prevalence of a few constructions that can have multiple alternative readings, some of which can license the incorrect number. We leave a more systematic analysis of this finding for future research.

Human results. To put our results in context and provide a reasonable upper bound on the LM performance, in particular for nonce sentences, we next compare model performance to that of human

[9]The nonce condition has higher accuracy because our substitution procedure in English tends to reduce POS ambiguity.

Table 3: Subject and LSTM accuracy on the Italian test set, by construction and averaged.

subjects in Italian.

Table 3 reports the accuracy of the LSTMs and the human subjects, grouped by construction.[10] There was a consistent gap in human accuracy between original and nonce sentences (6.1% on average). The gap in accuracy between the human subjects and the model was quite small, and was similar for original and nonce sentences (2.4% and 2.9%, respectively).

In some of the harder constructions, particularly subject-verb agreement with an embedded clause, the accuracy of the LSTMs on nonce sentences was comparable to human accuracy ($92.5_{\pm 2.1}$ vs. 92.3%). To test whether the human subjects and the models struggle with the same sentences, we computed for each sentence (1) the number of times the human subjects selected the correct form of the target minus the number of times they selected the incorrect form, and (2) the difference in model log probability between the correct and incorrect form. The Spearman correlation between these quantities was significant, for both original ($p < 0.05$) and nonce sentences ($p < 0.001$). This indicates that humans were more likely to select the correct form in sentences in which the models were more confident in a correct prediction.

Moreover, some of the easiest and hardest constructions are the same for the human subjects and the models. In the easy constructions DET [AdjP] NOUN[11] and ADJ [conjoined ADJs] ADJ, one or more adjectives that intervene between the cue and the target agree in number with the target, providing shorter-distance evidence about its correct number. For example, in

(2) un film inutile ma almeno festivo e
a movie useless but at.least festive and
giovanile
youthful
"A useless but at least festive and youthful movie"

the adjective "festivo" is marked for singular number, offering a nearer reference for the target number than the cue "inutile". At the other end, NOUN [PP] VERB (participial) and NOUN [PP] ADVERB ADJ are difficult. Particularly in the nonce condition, where semantics is unhelpful or even misleading, the target could easily be interpreted as a modifier of the noun embedded in the preceding prepositional phrase. For example, for the nonce case:

(3) orto di regolamenti davvero pedonale/i
orchard of rules truly pedestrian
"truly pedestrian orchard of rules"

both the subjects and the model preferred to treat "pedestrian" as a modifier of "rules" ("orchard of truly pedestrian rules"), resulting in the wrong agreement given the intended syntactic structure.

Attractors. We define attractors as words with the same POS as the cue but the opposite number, which intervene in the linear order of the sen-

[10] The SM contains the results for the other languages broken down by construction. Note that Table 3 reports linguistically intuitive construction labels. The corresponding POS patterns are (in same order as table rows): DET ADJ NOUN, NOUN VERB PRON VERB, NOUN VERB VERB, ADJ ADJ CCONJ ADJ, NOUN ADJ PUNCT PRON VERB, NOUN NOUN ADV ADJ, NOUN NOUN VERB, VERB NOUN CCONJ VERB.

[11] The relatively low nonce LSTM performance on this construction is due to a few adjectives that could be reinterpreted as nouns.

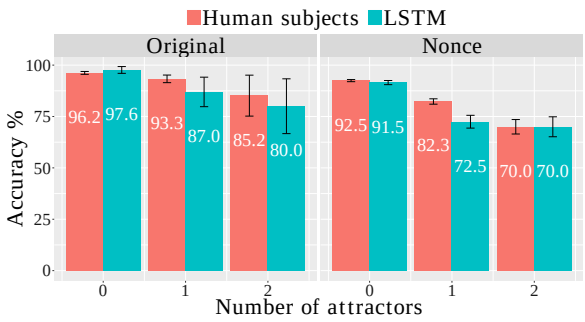

Figure 2: Accuracy by number of attractors in Italian. Human performance is shown in red and LSTM in blue (median model among top 5 ranked by perplexity). Error bars show standard error.

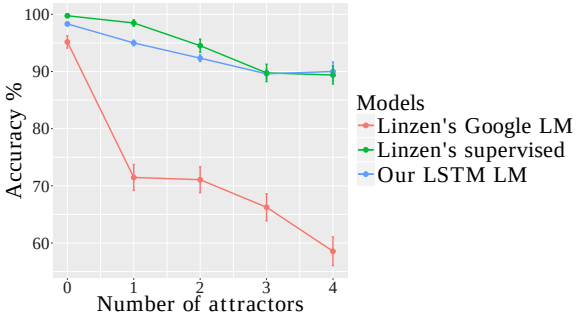

Figure 3: Linzen's attractor set. Our LM-trained LSTM (blue; "median" model) compared to their LSTM with explicit number supervision (green) and their best LM-trained LSTM (red).

tence between the cue and the target. Attractors constitute an obvious challenge for agreement processing (Bock and Miller, 1991). We show how their presence affects human and model behavior in Fig. 2. We limit our analysis to a maximum of two attractors, since there were only two original sentences in the test corpus with three attractors or more. Both model and human accuracies degraded with the number of attractors; the drop in accuracy was sharper in the nonce condition. While the model performed somewhat worse than humans, the overall pattern was comparable.

Our results suggest that the LSTM is quite robust to the presence of attractors, in contrast to what was reported by Linzen et al. (2016). We directly compared our English LSTM LM to theirs by predicting verb number on the Linzen et al. (2016) test set. We extracted sentences where all of the words between subject and verb were in our LM vocabulary. Out of those sentences, we sampled 2000 sentences with 0, 1 and 2 attractors and kept all the sentences with 3 and 4 attractors (1329 and 347 sentences, respectively). To ensure that our training set and Linzen's test set do not overlap (both are based on Wikipedia texts), we filtered out all of test sentences that appeared in our training data (187 sentences).

Fig. 3 compares our results to the results of the best LM-trained model in Linzen et al. (2016) (their "Google LM").[12] Not only did our LM greatly outperform theirs, but it approached the performance of their supervised model.[13] This difference in results points to the importance of careful tuning of LM-trained LSTMs, although we must leave to a further study a more detailed understanding of which differences crucially determine our better performance.

5 Related work

Early work showed that RNNs can, to a certain degree, handle data generated by context-free and even context-sensitive grammars (e.g., Elman, 1991, 1993; Rohde and Plaut, 1997; Christiansen and Chater, 1999; Gers and Schmidhuber, 2001; Cartling, 2008). These experiments were based on small and controlled artificial languages, in which complex hierarchical phenomena were often overrepresented compared to natural languages.

Our work, which is based on naturally occurring data, is most closely related to that of Linzen et al. (2016) and Bernardy and Lappin (2017), which we discussed in the introduction. Other recent work has focused on the morphological and grammatical knowledge that RNN-based machine-translation systems and sentence embeddings encode, typically by training classifiers to decode various linguistic properties from hidden states of the network (e.g., Adi et al., 2017; Belinkov et al., 2017; Shi et al., 2016), or looking at whether the end-to-end system correctly translates sentences with challenging constructions (Sennrich, 2017).

Previous work in neurolinguistics and psycholinguistics used jabberwocky, or pseudo-word, sentences to probe how speakers process syntactic information (Friederici et al., 2000; Moro et al.,

[12] These subject-verb agreement results are in general higher than for our own subject-verb agreement construction (NOUN VERB VERB) because the latter always includes an embedded clause, and it is therefore harder on average.

[13] Similarly high performance of LM-trained RNNs on Linzen's dataset was recently reported by Yogatama et al. (2018).

2001; Johnson and Goldberg, 2013). Such sentences are obtained by substituting original words with morphologically and phonologically acceptable nonce forms. We are not aware of work that used nonce sentences made of real words to evaluate the syntactic abilities of models or human subjects. As a proof of concept, Pereira (2000) and, later, Mikolov (2012) computed the probability of Chomsky's famous "colorless green ideas" sentence using a class-based bigram LM and an RNN, respectively, and showed that it is much higher than the probability of its shuffled ungrammatical variants.

6 Conclusion

We ran an extensive analysis of the abilities of RNNs trained on a generic language-modeling task to predict long-distance number agreement. Results were consistent across four languages and a number of constructions. They were above strong baselines even in the challenging case of nonsense sentences, and not far from human performance. We are not aware of other collections of human long-distance agreement judgments on nonsensical sentences, and we thus consider our publicly available data set an important contribution of our work, of interest to students of human language processing in general.

The constructions we considered are quite infrequent (according to a rough estimate based on the treebanks, the language in which they are most common is Hebrew, and even there they occur with average 0.8% sentence frequency). Moreover, they vary in the contexts that separate the cue and the target. So, RNNs are not simply memorizing frequent morphosyntactic sequences (which would already be impressive, for systems learning from raw text). We tentatively conclude that LM-trained RNNs can construct abstract grammatical representations of their input. This, in turn, suggests that the input itself contains enough information to trigger some form of syntactic learning in a system, such as an RNN, that does not contain an explicit prior bias in favour of syntactic structures.

In future work, we would like to better understand what kind of syntactic information RNNs are encoding, and how. On the one hand, we plan to adapt methods to inspect information flow across RNN states (e.g., Hupkes et al., 2017). On the other, we would like to expand our empirical investigation by focusing on other long-distance phenomena, such as overt case assignment (Blake, 2001) or parasitic gap licensing (Culicover and Postal, 2001). While it is more challenging to extract reliable examples of such phenomena from corpora, their study would probe more sophisticated syntactic capabilities, possibly even shedding light on the theoretical analysis of the underlying linguistic structures. Finally, it may be useful to complement the corpus-driven approach used in the current paper with constructed evaluation sentences that isolate particular syntactic phenomena, independent of their frequency in a natural corpus, as is common in psycholinguistics (Enguehard et al., 2017).

Abstract

We study few-shot learning in natural language domains. Compared to many existing works that apply either metric-based or optimization-based meta-learning to image domain with low inter-task variance, we consider a more realistic setting, where tasks are diverse. However, it imposes tremendous difficulties to existing state-of-the-art metric-based algorithms since a single metric is insufficient to capture complex task variations in natural language domain. To alleviate the problem, we propose an adaptive metric learning approach that automatically determines the best weighted combination from a set of metrics obtained from meta-training tasks for a newly seen few-shot task. Extensive quantitative evaluations on real-world sentiment analysis and dialog intent classification datasets demonstrate that the proposed method performs favorably against state-of-the-art few shot learning algorithms in terms of predictive accuracy. We make our code and data available for further study.[1]

1 Introduction

Few-shot learning (FSL) (Miller et al., 2000; Li et al., 2006; Lake et al., 2015) aims to learn classifiers from few examples per class. Recently, deep learning has been successfully exploited for FSL via learning meta-models from a large number of **meta-training tasks**. These meta-models can be then used for rapid-adaptation for the **target/meta-testing tasks** that only have few training examples. Examples of such meta-models include: (1) metric-/similarity-based models, which learn contextual, and task-specific similarity measures (Koch, 2015; Vinyals et al., 2016; Snell et al., 2017); and (2) optimization-based models, which receive the input of gradients from a FSL task and predict either model parameters or parameter updates (Ravi and Larochelle, 2017; Munkhdalai and Yu, 2017; Finn et al., 2017; Wang et al., 2017).

In the past, FSL has mainly considered image domains, where all tasks are often sampled from one huge collection of data, such as Omniglot (Lake et al., 2011) and ImageNet (Vinyals et al., 2016), making tasks come from a single domain thus related. Due to such a simplified setting, almost all previous works employ a common meta-model (metric-/optimization-based) for all few-shot tasks. However, this setting is far from the realistic scenarios in many real-world applications of few-shot text classification. For example, on an enterprise AI cloud service, many clients submit various tasks to train text classification models for business-specific purposes. The tasks could be classifying customers' comments or opinions on different products/services, monitoring public reactions to different policy changes, or determining users' intents in different types of personal assistant services. As most of the clients cannot collect enough data, their submitted tasks form a few-shot setting. Also, these tasks are significantly diverse, thus a common metric is insufficient to handle all these tasks.

We consider a more realistic FSL setting in this paper, where tasks are diverse. In such a scenario, the optimal meta-model may vary across tasks. Our solution is based on the metric-learning approach (Snell et al., 2017) and the key idea is to maintain multiple metrics for FSL. The meta-learner selects and combines multiple metrics for learning the target task using **task clustering** on the meta-training tasks. During the meta-training, we propose to first partition the meta-training tasks into clusters, making the tasks in each cluster

Proceedings of NAACL-HLT 2018, pages 1206–1215
New Orleans, Louisiana, June 1 - 6, 2018.

likely to be related. Then within each cluster, we train a deep embedding function as the metric. This ensures the common metric is only shared across tasks within the same cluster. Further, during meta-testing, each target FSL task is assigned to a task-specific metric, which is a linear combination of the metrics defined by different clusters. In this way, the diverse few-shot tasks can derive different metrics from the previous learning experience.

The key of the proposed FSL framework is the task clustering algorithm. Previous works (Kumar and Daume III, 2012; Kang et al., 2011; Crammer and Mansour, 2012; Barzilai and Crammer, 2015) mainly focused on convex objectives, and assumed the number of classes is the same across different tasks (*e.g.* binary classification is often considered). To make task clustering (i) compatible with deep networks and (ii) able to handle tasks with a various number of labels, we propose a **matrix-completion based task clustering** algorithm. The algorithm utilizes task similarity measured by cross-task transfer performance, denoted by matrix $\mathbf{S}$. The (i, j)-entry of $\mathbf{S}$ is the estimated accuracy by adapting the learned representations on the i-th (source) task to the j-th (target) task. We rely on matrix completion to deal with missing and unreliable entries in $\mathbf{S}$ and finally apply spectral clustering to generate the task partitions.

To the best of our knowledge, our work is the first one addressing the diverse few-shot learning problem and reporting results on real-world few-shot text classification problems. The experimental results show that the proposed algorithm provides significant gains on few-shot sentiment classification and dialog intent classification tasks. It provides positive feedback on the idea of using multiple meta-models (metrics) to handle diverse FSL tasks, as well as the proposed task clustering algorithm on automatically detecting related tasks.

2 Problem Definition

Few-Shot Learning Since we focus on **diverse metric-based FSL**, the problem can be formulated in two stages: (1) **meta-training**, where a set of metrics $\mathcal{M} = \{\Lambda_1, \cdots, \Lambda_K\}$ is learned on the **meta-training tasks** $\mathcal{T}$. Each Λ_i maps two input (x_1, x_2) to a scalar of similarity score. Here $\mathcal{T} = \{\mathrm{T}_1, \mathrm{T}_2, \cdots, \mathrm{T}_N\}$ is a collection of N tasks. Here K is a pre-defined number (usually $K \ll N$). Each task T_i consists of training, validation, and testing set denoted as $\left\{D_i^{train}, D_i^{valid}, D_i^{test}\right\}$, respectively. Note that the definition of $\mathcal{T}$ is a generalized version of $\mathcal{D}^{(meta-train)}$ in (Ravi and Larochelle, 2017), since each task T_i can be either few-shot (where D_i^{valid} is empty) or regular[2]. (2) **meta-testing**: the trained metrics in $\mathcal{M}$ is applied to **meta-testing tasks** denoted as $\mathcal{T}' = \{\mathrm{T}'_1, \cdots, \mathrm{T}'_{N'}\}$, where each T'_i is a few-shot learning task consisting of both training and testing data as $\left\{D_i'^{train}, D_i'^{test}\right\}$. $D_i'^{train}$ is a small labeled set for generating the prediction model M'_i for each T'_i. Specifically, M'_is are kNN-based predictors built upon the metrics in $\mathcal{M}$. We will detail the construction of M'_i in Section 3, Eq. (6). It is worth mentioning that the definition of $\mathcal{T}'$ is the same as $\mathcal{D}^{(meta-test)}$ in (Ravi and Larochelle, 2017). The **performance of few-shot learning** is the macro-average of M'_i's accuracy on all the testing set $D_i'^{test}$s.

Our definitions can be easily generalized to other meta-learning approaches (Ravi and Larochelle, 2017; Finn et al., 2017; Mishra et al., 2017). The motivation of employing multiple metrics is that when the tasks are diverse, one metric model may not be sufficient. Note that previous metric-based FSL methods can be viewed as a special case of our definition where $\mathcal{M}$ only contains a single Λ, as shown in the two base model examples below.

Base Model: Matching Networks In this paper we use the metric-based model Matching Network (MNet) (Vinyals et al., 2016) as the base metric model. The model (Figure 1b) consists of a neural network as the embedding function (**encoder**) and an augmented memory. The encoder, $f(\cdot)$, maps an input x to a d-length vector. The learned metric Λ is thus the similarity between the encoded vectors, $\Lambda(x_1, x_2) = f(x_1)^T f(x_2)$, i.e. the metric Λ is modeled by the encoder f. The augmented memory stores a support set $S = \{(x_i, y_i)\}_{i=1}^{|S|}$, where x_i is the supporting instance and y_i is its corresponding label in a one-hot format. The MNet explicitly defines a classifier M conditioned on the supporting set S. For any new data $\hat{x}$, M predicts its label via a similarity function $\alpha(.,.)$

[2]For example, the methods in (Triantafillou et al., 2017) can be viewed as training meta-models from any sampled batches from one single meta-training dataset.

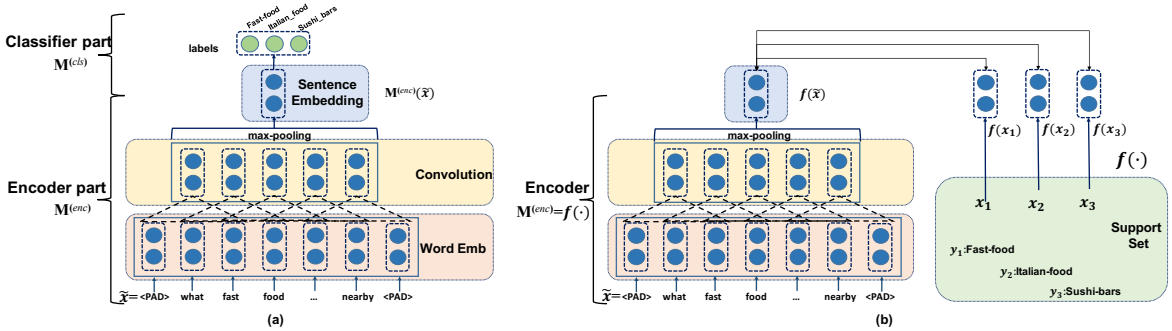

Figure 1: The Convolutional Neural Networks (CNN) used in this work: (a) A CNN classifier. The encoder component takes the sentence as input and outputs a fixed-length sentence embedding vector; the classifier component predicts class labels with the sentence embedding. (b) A Matching Network, which only contains an encoder like in (a), and makes prediction via a k-Nearest-Neighbor classifier with the similarity defined by the encoder.

between the test instance $\hat{x}$ and the support set S:

$$y = P(.|\hat{x}, S) = \sum_{i=1}^{|S|} \alpha(\hat{x}, x_i; \theta) y_i, \quad (1)$$

where we defined $\alpha(.,.)$ to be a softmax distribution given $\Lambda(\hat{x}, x_i)$, where x_i is a supporting instance, *i*.e., $\alpha(\hat{x}, x_i; \theta) = \exp(f(\hat{x})^T f(x_i)) / \sum_{j=1}^{|S|} \exp(f(\hat{x})^T f(x_j))$, where θ are the parameters of the encoder f. Thus, y is a valid distribution over the supporting set's labels $\{y_i\}_{i=1}^{|S|}$. To adapt the MNet to text classification, we choose encoder f to be a convolutional neural network (CNN) following (Kim, 2014; Johnson and Zhang, 2016). Figure 1 shows the MNet with the CNN architecture. Following (Collobert et al., 2011; Kim, 2014), the model consists of a convolution layer and a max-pooling operation over the entire sentence.

To train the MNets, we first sample the training dataset D for task T from all tasks $\mathcal{T}$, with notation simplified as $D \sim \mathcal{T}$. For each class in the sampled dataset D, we sample k random instances in that class to construct a support set S, and sample a batch of training instances B as training examples, i.e., $B, S \sim D$. The training objective is to minimize the prediction error of the training samples given the supporting set (with regard to the encoder parameters θ) as follows:

$$\mathop{\mathbb{E}}_{D\sim\mathcal{T}} \Big[\mathop{\mathbb{E}}_{B,S\sim D} \Big[\sum_{(x,y)\in B} \log(P(y|x, S; \theta)) \Big] \Big]. \quad (2)$$

Base Model: Prototypical Networks Prototypical Network (ProtoNet) (Snell et al., 2017) is a variation of Matching Network, which also depends on metric learning but builds the classifier M different from Eq. (1):

$$y = P(.|\hat{x}, S) = \sum_{i=1}^{L} \alpha(\hat{x}, S_i; \theta) y_i. \quad (3)$$

L is the number of classes and $S_i = \{x | (x, y) \in S \wedge y = y_i\}$ is the support set of class y_i. $\alpha(\hat{x}, S_i; \theta) = \exp\Big(f(\hat{x})^T \sum_{x\in S_i} f(x)\Big) / \sum_{j=1}^{L} \exp\Big(f(\hat{x})^T \sum_{x'\in S_j} f(x')\Big)$.

3 Methodology

We propose a task-clustering framework to address the diverse few-shot learning problem stated in Section 2. We have the FSL algorithm summarized in Algorithm 1. Figure 2 gives an overview of our idea. The initial step of the algorithm is a novel task clustering algorithm based on matrix completion, which is described in Section 3.1. The few-shot learning method based on task clustering is then introduced in Section 3.2.

3.1 Robust Task Clustering by Matrix Completion

Our task clustering algorithm is shown in Algorithm 2. The algorithm first evaluates the transfer performance by applying a single-task model i to another task j (Section 3.1.1), which will result in a (partially observed) cross-task transfer performance matrix $\mathbf{S}$. The matrix $\mathbf{S}$ is then cleaned and completed, giving a symmetry task similarity matrix $\mathbf{Y}$ for spectral clustering (Ng et al., 2002).

3.1.1 Estimation of Cross-Task Transfer Performance

Using single-task models, we can compute performance scores s_{ij} by adapting each M_i to each task

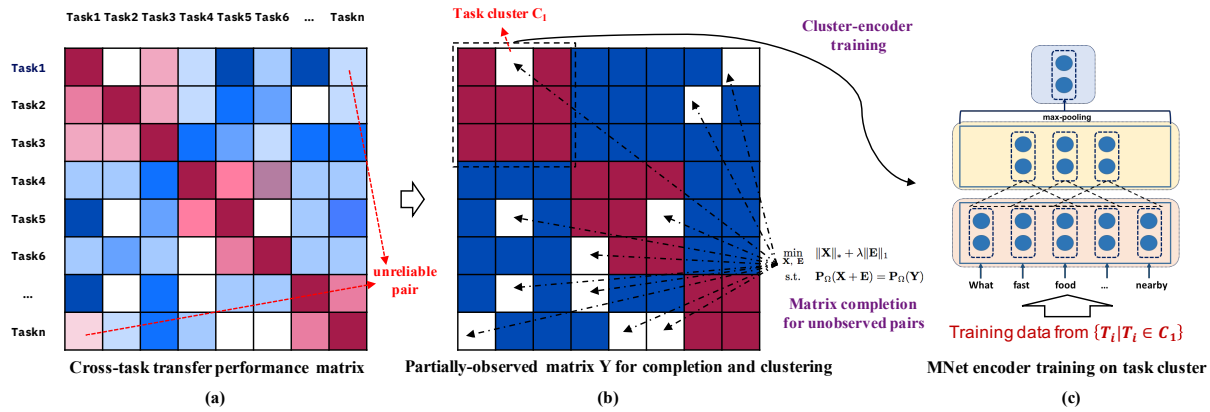

Figure 2: Overview of the idea of our multi-metric learning approach for few-shot learning. (a) an illustration of the sparse cross-tasks transfer-performance matrix with unobserved entries (white blocks) and unreliable values (top-right and bottom-left corners), where red colors indicate positive transfer and blue colors indicate negative transfer; (b) the constructed binary partially-observed matrix with low-rank constraint for matrix completion and clustering (see Section 3.1 for the details); (c) an encoder trained with the matching network objective Eq. (2) on a task cluster (tasks 1, 2 and 3 in the example).

$T_j (j \neq i)$. This forms an $n \times n$ pair-wise classification performance matrix $\mathbf{S}$, called the *transfer-performance matrix*. Note that $\mathbf{S}$ is asymmetric since usually $\mathbf{S}_{ij} \neq \mathbf{S}_{ji}$.

Algorithm 1: ROBUSTTC-FSL: Task Clustering for Few-Shot Learning

Input : N meta-training tasks $\mathcal{T}$=$\{\mathrm{T}_1, \mathrm{T}_2, \cdots, \mathrm{T}_n\}$; number of clusters K; N' target few-shot meta-testing tasks $\mathcal{T}'$

Output: Meta-model $\mathcal{M} = \{C_{1:K}$ (K task clusters), $\mathcal{F} = \{f_1, f_2, \cdots, f_K\}$ (K task encoders)$\}$. One classifier M'_i for each target task T'.

1 **Robust Task Clustering**: $C_{1:K}$ = ROBUSTTC($\mathcal{T}$,K) (Algorithm 2)
2 **Cluster-Model Training**: Train one encoder (multi-task MNet) f_i on each task cluster C_i (Section 3.2.1)
3 **Few-Shot Learning on Cluster-models**: Train a model M_{trg} on task T_{trg} with the method in Section 3.2.2.

Ideally, the transfer performance could be estimated by training a MNet on task i and directly evaluating it on task j. However, the limited training data usually lead to generally low transfer performance of single-task MNet. As a result we adopt the following approach to estimate $\mathbf{S}$:

We train a CNN classifier (Figure 1(a)) on task i, then take only the encoder M_i^{enc} from M_i and freeze it to train a classifier on task j. This gives us a new task j model, and we test this model on D_j^{valid} to get the accuracy as the transfer-performance $\mathbf{S}_{ij}$. The score shows how the representations learned on task i can be adapted to task j, thus indicating the similarity between tasks.

Algorithm 2: ROBUSTTC: Robust Task Clustering based on Matrix Completion

Input : A set of n tasks $\mathcal{T} = \{\mathrm{T}_1, \mathrm{T}_2, \cdots, \mathrm{T}_n\}$, number of task clusters K

Output: K task clusters $C_{1:K}$

1 **Learning of Single-Task Models**: train single-task models M_i for each task T_i
2 **Evaluation of Transfer-Performance Matrix**: get performance matrix $\mathbf{S}$ (Section 3.1.1)
3 **Score Filtering**: Filter the uncertain scores in $\mathbf{S}$ and construct the symmetric matrix $\mathbf{Y}$ using Eq. (4)
4 **Matrix Completion**: Complete the similar matrix $\mathbf{X}$ from $\mathbf{Y}$ using Eq. (5)
5 **Task Clustering**: $C_{1:K}$=SpectralClustering($\mathbf{X}$, K)

Remark: Out-of-Vocabulary Problem In text classification tasks, transferring an encoder with fine-tuned word embeddings from one task to another is difficult as there can be a significant difference between the two vocabularies. Hence, while learning the single-task CNN classifiers, we always make the word embeddings fixed.

3.1.2 Task Clustering Method

Directly using the transfer performance for task clustering may suffer from both efficiency and accuracy issues. First, evaluation of all entries in the matrix $\mathbf{S}$ involves conducting the source-target transfer learning $O(n^2)$ times, where n is the number of meta-training tasks. For a large number of diverse tasks where the n can be larger than 1,000, evaluation of the full matrix is unacceptable (over 1M entries to evaluate). Second, the estimated cross-task performance (i.e. some $\mathbf{S}_{ij}$ or $\mathbf{S}_{ji}$ scores) is often unreliable due to small data

size or label noise. When the number of the uncertain values is large, they can collectively mislead the clustering algorithm to output an incorrect task-partition. To address the aforementioned challenges, we propose a novel task clustering algorithm based on the theory of matrix completion (Candès and Tao, 2010). Specifically, we deal with the huge number of entries by randomly sample task pairs to evaluate the $\mathbf{S}_{ij}$ and $\mathbf{S}_{ji}$ scores. Besides, we deal with the unreliable entries and asymmetry issue by keeping only task pairs (i, j) with consistent $\mathbf{S}_{ij}$ and $\mathbf{S}_{ji}$ scores. as will be introduced in Eq. (4). Below, we describe our method in detail.

Score Filtering First, we use only reliable task pairs to generate a *partially-observed* similarity matrix $\mathbf{Y}$. Specifically, if $\mathbf{S}_{ij}$ and $\mathbf{S}_{ji}$ are high enough, then it is likely that tasks $\{i, j\}$ belong to a same cluster and share significant information. Conversely, if $\mathbf{S}_{ij}$ and $\mathbf{S}_{ji}$ are low enough, then they tend to belong to different clusters. To this end, we need to design a mechanism to determine if a performance is high or low enough. Since different tasks may vary in difficulty, a fixed threshold is not suitable. Hence, we define a dynamic threshold using the mean and standard deviation of the target task performance, i.e., $\mu_j = \text{mean}(\mathbf{S}_{:j})$ and $\sigma_j = \text{std}(\mathbf{S}_{:j})$, where $\mathbf{S}_{:j}$ is the j-th column of $\mathbf{S}$. We then introduce two positive parameters p_1 and p_2, and define high and low performance as $\mathbf{S}_{ij}$ greater than $\mu_j + p_1\sigma_j$ or lower than $\mu_j - p_2\sigma_j$, respectively. When both $\mathbf{S}_{ij}$ and $\mathbf{S}_{ji}$ are high and low enough, we set their pairwise similarity as 1 and 0, respectively. Other task pairs are treated as uncertain task pairs and are marked as unobserved, and don't influence our clustering method. This leads to a partially-observed symmetric matrix $\mathbf{Y}$, i.e.,

$$\mathbf{Y}_{ij}=\mathbf{Y}_{ji}=\begin{cases} 1 & \text{if } \mathbf{S}_{ij} > \mu_j + p_1\sigma_j \\ & \text{and } \mathbf{S}_{ji} > \mu_i + p_1\sigma_i \\ 0 & \text{if } \mathbf{S}_{ij} < \mu_j - p_2\sigma_j \\ & \text{and } \mathbf{S}_{ji} < \mu_i - p_2\sigma_i \\ \text{unobserved} & \text{otherwise} \end{cases} \quad (4)$$

Matrix Completion Given the partially observed matrix $\mathbf{Y}$, we then reconstruct the full similarity matrix $\mathbf{X} \in \mathbb{R}^{n\times n}$. We first note that the similarity matrix $\mathbf{X}$ should be of low-rank (proof deferred to appendix). Additionally, since the observed entries of $\mathbf{Y}$ are generated based on high and low enough performance, it is safe to assume that most observed entries are correct and only a few may be incorrect. Therefore, we introduce a sparse matrix $\mathbf{E}$ to capture the observed incorrect entries in $\mathbf{Y}$. Combining the two observations, $\mathbf{Y}$ can be decomposed into the sum of two matrices $\mathbf{X}$ and $\mathbf{E}$, where $\mathbf{X}$ is a low rank matrix storing similarities between task pairs, and $\mathbf{E}$ is a sparse matrix that captures the errors in $\mathbf{Y}$. The matrix completion problem can be cast as the following convex optimization problem:

$$\begin{aligned} \min_{\mathbf{X},\,\mathbf{E}} \quad & \|\mathbf{X}\|_* + \lambda\|\mathbf{E}\|_1 \\ \text{s.t.} \quad & \mathbf{P}_\Omega(\mathbf{X}+\mathbf{E}) = \mathbf{P}_\Omega(\mathbf{Y}), \end{aligned} \quad (5)$$

where $\|\circ\|_*$ denotes the matrix nuclear norm, the convex surrogate of rank function. Ω is the set of observed entries in $\mathbf{Y}$, and $\mathbf{P}_\Omega : \mathbb{R}^{n\times n} \mapsto \mathbb{R}^{n\times n}$ is a matrix projection operator defined as

$$[\mathbf{P}_\Omega(\mathbf{A})]_{ij} = \begin{cases} \mathbf{A}_{ij} & \text{if } (i,j) \in \Omega \\ 0 & \text{otherwise} \end{cases}$$

Finally, we apply spectral clustering on the matrix $\mathbf{X}$ to get the task clusters.

Remark: Sample Efficiency In the Appendix A, we show a Theorem 7.1 as well as its proof, implying that under mild conditions, the problem (5) can perfectly recover the underlying similarity matrix $\mathbf{X}^*$ if the number of observed correct entries is at least $O(n \log^2 n)$. This theoretical guarantee implies that for a large number n of training tasks, only a tiny fraction of all task pairs is needed to reliably infer similarities over all task pairs.

3.2 Few-Shot Learning with Task Clusters

3.2.1 Training Cluster Encoders

For each cluster C_k, we train a multi-task MNet model (Figure 1(b)) with all tasks in that cluster to encourage parameter sharing. The result, denoted as f_k is called the **cluster-encoder** of cluster C_k. The k-th metric of the cluster is thus $\Lambda(x_1, x_2) = f_k(x_1)^\intercal f_k(x_2)$.

3.2.2 Adapting Multiple Metrics for Few-Shot Learning

To build a predictor M with access to only a limited number of training samples, we make the prediction probability by linearly combining prediction from learned cluster-encoders:

$$p(y|x) = \sum_k \alpha_k P(y|x; f_k). \quad (6)$$

where f_k is the learned (and frozen) encoder of the k-th cluster, $\{\alpha_k\}_{k=1}^K$ are adaptable parameters trained with few-shot training examples. And the predictor $P(y|x; f_k)$ from each cluster is

$$P(y = y_l|x; f_k) = \frac{\exp\{f_k(x_l)^\intercal f_k(x)\}}{\sum_i \exp\{f_k(x_i)^\intercal f_k(x)\}} \quad (7)$$

x_l is the corresponding training sample of label y_l.

Remark: Joint Method versus Pipeline Method End-to-end joint optimization on training data becomes a popular methodology for deep learning systems, but it is not directly applicable to diverse FSL. One main reason is that deep networks could easily fit any task partitions if we optimize on training loss only, making the learned metrics not generalize, as discussed in Section 6. As a result, this work adopts a pipeline training approach and employing validation sets for task clustering. Combining reinforcement learning with meta-learning could be a potential solution to enable an end-to-end training for future work.

4 Tasks and Data Sets

We test our methods by conducting experiments on two text classification data sets. We used NLTK toolkit[3] for tokenization. The task are divided into meta-training tasks and meta-testing tasks (target tasks), where the meta-training tasks are used for clustering and cluster-encoder training. The meta-testing tasks are few-shot tasks, which are used for evaluating the method in Eq. (6).

4.1 Amazon Review Sentiment Classification

First, following Barzilai and Crammer (2015), we construct multiple tasks with the multi-domain sentiment classification (Blitzer et al., 2007) data set. The dataset consists of Amazon product reviews for 23 types of products (see Appendix D for the details). For each product domain, we construct three binary classification tasks with different thresholds on the ratings: the tasks consider a review as positive if it belongs to one of the following buckets $= 5$ stars, $>= 4$ stars or $>= 2$ stars.[4] These buckets then form the basis of the task-setup, giving us 23×3=69 tasks in total. For each domain we distribute the reviews uniformly to the 3 tasks. For evaluation, we select 12 (4×3) tasks from 4 domains (*Books, DVD, Electronics, Kitchen*) as the meta-testing (target) tasks out of all 23 domains. For the target tasks, we create 5-shot learning problems.

4.2 Real-World Tasks: User Intent Classification for Dialog System

The second dataset is from an online service which trains and serves intent classification models to various clients. The dataset comprises recorded conversations between human users and dialog systems in various domains, ranging from personal assistant to complex service-ordering or customer-service request scenarios. During classification, intent-labels[5] are assigned to user utterances (sentences). We use a total of 175 tasks from different clients, and randomly sample 10 tasks from them as our target tasks. For each meta-training task, we randomly sample 64% data into a training set, 16% into a validation set, and use the rest as the test set. The number of labels for these tasks varies a lot (from 2 to 100, see Appendix D for details), making regular k-shot settings not essentially limited-resource problems (e.g., 5-shot on 100 classes will give a good amount of 500 training instances). Hence, to adapt this to a FSL scenario, for target tasks we keep one example for each label (one-shot), plus 20 randomly picked labeled examples to create the training data. We believe this is a fairly realistic estimate of labeled examples one client could provide easily.

Remark: Evaluation of the Robustness of Algorithm 2 Our matrix-completion method could handle a large number of tasks via task-pair sampling. However, the sizes of tasks in the above two few-shot learning datasets are not too huge, so evaluation of the whole task-similarity matrix is still tractable. In our experiments, the incomplete matrices mainly come from the score-filtering step (see Eq. 4). Thus there is limited randomness involved in the generation of task clusters.

To strengthen the conclusion, we evaluate our algorithm on an additional dataset with a much larger number of tasks. The results are reported in the multi-task learning setting instead of the few-shot learning setting focused in this paper. Therefore we put the results to a non-archive version of

[3] http://www.nltk.org/

[4] Data downloaded from http://www.cs.jhu.edu/~mdredze/datasets/sentiment/, in which the 3-star samples were unavailable due to their ambiguous nature (Blitzer et al., 2007).

[5] In conversational dialog systems, intent-labels are used to guide the dialog-flow.

this paper[6] for further reference.

5 Experiments

5.1 Experiment Setup

Baselines We compare our method to the following baselines: (1) **Single-task CNN**: training a CNN model for each task individually; (2) **Single-task FastText**: training one FastText model (Joulin et al., 2016) with fixed embeddings for each individual task; (3) **Fine-tuned the holistic MTL-CNN**: a standard transfer-learning approach, which trains one MTL-CNN model on all the training tasks offline, then fine-tunes the classifier layer (i.e. $\mathrm{M}^{(cls)}$ Figure 1(a)) on each target task; (4) **Matching Network**: a metric-learning based few-shot learning model trained on all training tasks; (5) **Prototypical Network**: a variation of matching network with different prediction function as Eq. 3; (6) **Convex combining all single-task models**: training one CNN classifier on each meta-training task individually and taking the encoder, then for each target task training a linear combination of all the above single-task encoders with Eq. (6). This baseline can be viewed as a variation of our method without task clustering. We initialize all models with pre-trained 100-dim Glove embeddings (trained on 6B corpus) (Pennington et al., 2014).

Hyper-Parameter Tuning In all experiments, we set both p_1 and p_2 parameters in (4) to 0.5. This strikes a balance between obtaining enough observed entries in $\mathbf{Y}$, and ensuring that most of the retained similarities are consistent with the cluster membership. The window/hidden-layer sizes of CNN and the initialization of embeddings (random or pre-trained) are tuned during the cluster-encoder training phase, with the validation sets of meta-training tasks. We have the CNN with window size of 5 and 200 hidden units. The single-metric FSL baselines have 400 hidden units in the CNN encoders. On sentiment classification, all cluster-encoders use random initialized word embeddings for sentiment classification, and use Glove embeddings as initialization for intent classification, which is likely because the training sets of the intent tasks are usually small.

Since all the sentiment classification tasks are binary classification based on our dataset construction. A CNN classifier with binary output layer can be also trained as the cluster-encoder for each task cluster. Therefore we compared CNN classifier, matching network, and prototypical network on Amazon review, and found that CNN classifier performs similarly well as prototypical network. Since some of the Amazon review data is quite large which involves further difficulty on the computation of supporting sets, we finally use binary CNN classifiers as cluster-encoders in all the sentiment classification experiments.

Selection of the learning rate and number of training epochs for FSL settings, i.e., fitting αs in Eq. (6), is more difficult since there is no validation data in few-shot problems. Thus we pre-select a subset of meta-training tasks as meta-validation tasks and tune the two hyper-parameters on the meta-validation tasks.

5.2 Experimental Results

Table 1 shows the main results on (i) the 12 few-shot product sentiment classification tasks by leveraging the learned knowledge from the 57 previously observed tasks from other product domains; and (ii) the 10 few-shot dialog intent classification tasks by leveraging the 165 previously observed tasks from other clients' data.

Due to the limited training resources, all the supervised-learning baselines perform poorly. The two state-of-the-art metric-based FSL approaches, matching network (4) and prototypical network (5), do not perform better compared to the other baselines, since the single metric is not sufficient for all the diverse tasks. On intent classification where tasks are further diverse, all the single-metric or single-model methods (3-5) perform worse compared to the single-task CNN baseline (1). The convex combination of all the single training task models is the best performing baseline overall. However, on intent classification it only performs on par with the single-task CNN (1), which does not use any meta-learning or transfer learning techniques, mainly for two reasons: (i) with the growth of the number of meta-training tasks, the model parameters grow linearly, making the number of parameters (165 in this case) in Eq.(6) too large for the few-shot tasks to fit; (ii) the meta-training tasks in intent classification usually contain less training data, making the single-task encoders not generalize well.

In contrast, our ROBUSTTC-FSL gives consistently better results compared to all the baselines.

[6] https://arxiv.org/pdf/1708.07918.pdf

Model	Avg Acc	
	Sentiment	Intent
(1) Single-task CNN w/pre-trained emb	65.92	34.46
(2) Single-task FastText w/pre-trained emb	63.05	23.87
(3) Fine-tuned holistic MTL-CNN	76.56	30.36
(4) Matching Network (Vinyals et al., 2016)	65.73	30.42
(5) Prototypical Network (Snell et al., 2017)	68.15	31.51
(6) Convex combination of all single-task models	78.85	34.43
ROBUSTTC-FSL	**83.12**	**37.59**
Adaptive ROBUSTTC-FSL	-	**42.97**

Table 1: Accuracy of FSL on sentiment classification (Sentiment) and dialog intent classification (Intent) tasks. The target tasks of sentiment classification are 5-shot ones; and each intent target task contains one training example per class and 20 random labeled examples.

It outperforms the baselines in previous work (1-5) by a large margin of more than 6% on the sentiment classification tasks, and more than 3% on the intent classification tasks. It is also significantly better than our proposed baseline (6), showing the advantages of the usage of task clustering.

Adaptive ROBUSTTC-FSL Although the ROBUSTTC-FSL improves over baselines on intent classification, the margin is smaller compared to that on sentiment classification, because the intent classification tasks are more diverse in nature. This is also demonstrated by the training accuracy on the target tasks, where several tasks fail to find any cluster that could provide a metric that suits their training examples. To deal with this problem, we propose an improved algorithm to automatically discover whether a target task belongs to none of the task-clusters. If the task doesn't belong to any of the clusters, it cannot benefit from any previous knowledge thus falls back to single-task CNN. The target task is treated as "out-of-clusters" when none of the clusters could achieve higher than 20% accuracy (selected on meta-validation tasks) on its training data. We call this method **Adaptive ROBUSTTC-FSL**, which gives more than 5% performance boost over the best ROBUSTTC-FSL result on intent classification. Note that the adaptive approach makes no difference on the sentiment tasks, because they are more closely related so re-using cluster-encoders always achieves better results compared to single-task CNNs.

5.3 Analysis

Effect of the number of clusters Figure 3 shows the effect of cluster numbers on the two tasks. ROBUSTTC achieves best performance

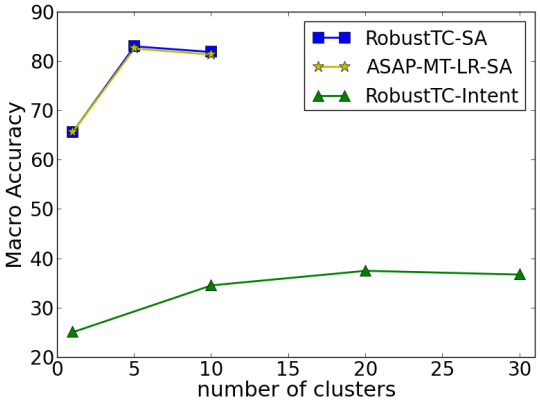

Figure 3: Effect of clusters. ROBUSTTC-SA and ROBUSTTC-Intent: the performance of our ROBUSTTC clusters on the sentiment and intent classification tasks. ASAP-MT-LR-SA: the state-of-the-art ASAP-MT-LR clusters on the sentiment-analysis tasks (the method is not applicable to the intent-classification tasks).

with 5 clusters on sentiment analysis (SA) and 20 clusters on intent classification (Intent). All clustering results significantly outperform the single-metric baselines (#cluster=1 in the figure).

Effect of the clustering algorithms Compared to previous task clustering algorithms, our ROBUSTTC is the only one that can cluster tasks with varying numbers of class labels (e.g. in intent classification tasks). Moreover, we show that even in the setting of all binary classifications tasks (e.g. the sentiment-analysis tasks) that previous task clustering research work on, our ROBUSTTC is still slightly better for the diverse FSL problems. Figure 3 compares with a state-of-the-art logistic regression based task clustering method (**ASAP-MT-LR**) (Barzilai and Crammer, 2015). Our ROBUSTTC clusters give slightly better FSL performance (e.g. 83.12 vs. 82.65 when #cluster=5).

Table 2: Visualization of clusters on the Amazon review domain. The top shows the training tasks assigned to the 10 clusters. Here the number N$\in \{2, 4, 5\}$ refers to the threshold of stars for positive reviews. At the bottom we show three tasks with largest improvement from ROBUSTTC-FSL. The top-3 most relevant task clusters (i.e. with highest weights αs in Eq.6) are highlighted with **blue bold** font.

Visualization of Task Clusters The top rows of Table 2 shows the ten clusters used to generate the sentiment classification results in Figure 3. From the results, we can see that tasks with same thresholds are usually grouped together; and tasks in similar domains also tend to appear in the same clusters, even the thresholds are slightly different (e.g. t2 vs t4 and t4 vs t5).

The bottom of the table shows the weights αs in Eq.(6) for the target tasks with the largest improvement. It confirms that our ROBUSTTC-FSL algorithm accurately adapts multiple metrics for the target tasks.

6 Related Work

Few Shot Learning FSL (Li et al., 2006; Miller et al., 2000) aims to learn classifiers for new classes with only a few training examples per class. Bayesian Program Induction (Lake et al., 2015) represents concepts as simple programs that best explain observed examples under a Bayesian criterion. Siamese neural networks rank similarity between inputs (Koch, 2015). Matching Networks (Vinyals et al., 2016) map a small labeled support set and an unlabeled example to its label, obviating the need for fine-tuning to adapt to new class types. These approaches essentially learn one metric for all tasks, which is sub-optimal when the tasks are diverse. An LSTM-based meta-learner (Ravi and Larochelle, 2017) learns the exact optimization algorithm used to train another learner neural-network classifier for the few-shot setting.

Previous FSL research usually adopts the k-shot, N-way setting, where all the few-shot tasks have the same number of N class labels, and each label has k training instances. Moreover, these few-shot tasks are usually constructed by sampling from one huge dataset, thus all the tasks are guaranteed to be related to each other. However, in real-world applications, the few-shot learning tasks could be diverse: there are different tasks with varying number of class labels and they are not guaranteed to be related to each other. As a result, a single meta-model or metric-model is usually not sufficient to handle all the few-shot tasks.

Task Clustering Previous task clustering methods measure the task relationships in terms of similarities among single-task model parameters (Kumar and Daume III, 2012; Kang et al., 2011); or jointly assign task clusters and train model parameters for each cluster to minimize the overall training loss (Crammer and Mansour, 2012; Barzilai and Crammer, 2015; Murugesan et al., 2017). These methods usually work on convex models but do not fit the deep networks, mainly because of (i) the parameters of deep networks are very high-dimensional and their similarities are not necessarily related to the functional similarities; and (ii) deep networks have flexible representation power so they may overfit to arbitrary cluster assignment if we consider training loss alone. Moreover, these methods require identical class label sets across different tasks, which does not hold in most of the realistic settings.

7 Conclusion

We propose a few-shot learning approach for diverse tasks based on task clustering. The proposed method can use multiple metrics, and performs significantly better compared to previous single-metric based methods when the few-shot tasks come from diverse domains. Future work includes generalizing our method to non-NLP problems, as well as applying the task-clustering idea to other few-shot learning frameworks (Ravi and Larochelle, 2017; Finn et al., 2017; Mishra et al., 2017; Cheng et al., 2017).

Abstract

This paper proposes a novel document representation, called Multi-Resolution Representation (MulR), to improve the early detection of risks in social media sources. The goal is to effectively identify the potential risk using as little evidence as possible and with as much anticipation as possible. MulR allows us to generate multiple "views" of the text. These views capture different semantic meanings for words and documents at different levels of granularity, which is very useful in early scenarios to model the variable amounts of evidence. The experimental evaluation shows that MulR using low resolution is better suited for modeling short documents (very early stages), whereas large documents (medium/late stages) are better modeled with higher resolutions. We evaluate the proposed ideas in two different tasks where anticipation is critical: *sexual predator detection* and *depression detection*. The experimental evaluation for these early tasks revealed that the proposed approach outperforms previous methodologies by a considerable margin.

1 Introduction

Everyday there is a huge amount of people interacting in many social media sites. Unfortunately this immense cyber-world has been misused by cyber-criminals, who hide in the depths of the web. For this reason, the social media information has been increasingly studied in the context of applications related to security, forensics and e-commerce. Recently the early prediction scenarios have attracted the attention of the scientific community (Losada et al., 2017), which aims to prevent major threats in a number of practical situations by analyzing the text as evidence (e.g., sexual harassment, cyberbullying, etc).

In Natural Language Processing this emerging field is called early text classification and the goal is to identify risky-target categories by using as few text as possible and with as much anticipation as possible. In real scenarios the amount of evidence available from users under analysis is continuously growing. Consider for instance chat rooms, or posts and comments in social networks, these text sources comprise cumulative evidence for early prediction that can be used to better capture the phenomenon under study (Escalante et al., 2017; Losada et al., 2017). This scenario has challenging particularities. For example, in early stages where 10% or 20% of the information is available it is necessary to model very short length documents, which tend to produce sparse and low discriminative representations. On the other hand late stages require to exploit as much evidence as possible to make accurate predictions. This dynamism between the document length and classification stages makes necessary an adequate representation, that naturally copes with the dynamic amount of evidence in short and long texts generated by users at each stage. Traditional textual representations, such as Bag-of-Words (BoW) (Joachims, 1998), have problems dealing with social media short texts since they cause the representation to be high dimensional and very sparse. Moreover, in the particular case of early risk prediction, class unbalance and noisy text also represent a challenge.

In this paper we propose a representation that deals with these challenges by taking advantage of word vectors into a novel methodology for representing documents. This representation generates high-level features, that we called meta-words, which capture concepts at different resolution levels. A meta-word is a primitive construction represented by a vector that summarizes the information of semantically related words. Our methodology associates words with similar semantic meaning to the same meta-words. These meta-words

Proceedings of NAACL-HLT 2018, pages 1216–1225
New Orleans, Louisiana, June 1 - 6, 2018.

are obtained by applying clustering techniques to word representations, where the resultant "centroids" comprise the meta-words. Documents are then represented by a Bag-of-Centroids (BoC), that is, a histogram accounting for the occurrence of coarse thematic/semantic primitives, i.e., the meta-words. This part of the work is inspired by the Bag-of-Visual-Words (BoVW), which is widely used in computer vision to represent images (Sivic and Zisserman, 2004; Lazebnik et al., 2006).

The key aspect for early scenarios is that the number and size of meta-words, allow us to manipulate the level of granularity or the *resolution* of the representation. This property is very useful to capture discriminative information along the growing amount of available evidence at each early stage. We thus propose a multi-resolution approach, in which primitives at different resolutions are combined to capture feature concepts at multiple levels of detail. The contributions of this paper are twofold: (i) a new Multi-Resolution (MulR) document representation, a generalization to represent documents by exploiting word-vectors at different levels of resolutions; (ii) an empirical validation of the usefulness of multiple resolution levels for early risk detection on social media documents. Our experimental results show that this approach is a promising alternative for early text classification scenarios, where there is a need to make predictions as soon as possible, with little evidence, while at the same time, being robust to incorporate more evidence as it becomes available. We recorded experimental results of an extensive evaluation of our proposed techniques over two benchmarks for early scenarios: sexual predator detection and depression detection. Results showed that in all cases our methodology outperforms state-of-the-art methodologies.

Interestingly, document representations based on partitioning the word-embedding space, like ours, are somewhat similar to topic modeling based representations. In the experimental section we also compare the performance of our method to different topic-based representations like Latent Semantic Analysis (LSA) (Deerwester et al., 1990) and Latent Dirichlet Allocation (LDA) (Blei et al., 2003). Experimental results showed that our method outperformed the reference techniques. We elaborate on the benefits and limitations of our proposed techniques later in this paper.

2 Related Work

The Early Text Categorization problem is an emerging research topic with scant work (Dulac-Arnold et al., 2011; Escalante et al., 2016, 2017). Recently, the relevance of the problem has motivated specialized forums such as eRisk-CLEF17 (Losada et al., 2017). One of the first attempts is based on processing documents in a sentence-level basis (Dulac-Arnold et al., 2011). At every time t, the method reads a sentence and attempts to determine the class of the document. The key aspect of the work is a Markov Decision Process (MDP), where each sentence is modeled in a TFIDF vector. More recently, (Escalante et al., 2016) proposed a straightforward solution for early detection scenarios by using the naïve Bayes classifier. The idea consists in training with full documents, but when partial information has to be classified, the maximum a posteriori probability was estimated over the available text. Using this simple yet effective approach, the authors obtained competitive performance with the method in (Dulac-Arnold et al., 2011). Furthermore, results reported in (Escalante et al., 2016) were the first evaluation on early sexual predator detection.

In (Escalante et al., 2017) the authors propose methods to exploit Profile Based Representations (PBR's) for words (López-Monroy et al., 2015). PBRs are Distributional Term Representations of terms in the vocabulary. Similar to word embeddings these representations build a vector for each word, which aim to extract/learn concepts from simple occurrence statistics of terms in the target classes. PBRs capture discriminative information in a very low dimensional and non-sparse space suitable for early text classification problems. In other work, (Errecalde et al., 2017) successfully adapted a version of PBR's for the problem of early depression detection in the context of the eRisk-CLEF17 shared task. The evidence about PBRs suggests that this representation can naturally cope with missing information and obtain discriminative representations for incomplete documents. Nevertheless, just as the vast majority of word embeddings in the literature for standard text classification, there is no consensus about how to exploit these term vectors to represent entire phrases or documents (e.g., the most common strategy is to average the term vectors in documents).

The proposed method is based on creating meta-

words to represent documents. Clustering words into meaningful groups based on some measure of similarity to represent text is not a new concept. One of the classic approaches is term clustering in an *unsupervised* manner that was first investigated by (Lewis, 1992). He called his method *reciprocal nearest neighbor clustering*. His method consists of joining words that are similar according to a measure of similarity. In other work, Brown et al. (1992) explored the idea of discovering similarities between words to obtain clusters at different levels. One key difference with our proposal is that in (Brown et al., 1992), terms are deterministically/probabilistically associated with a discrete class, where terms that are in the same class are similar in some aspect. However in our proposed strategy, we exploit word vectors instead of a discrete random deterministic variable (e.g., soft/hard partitions of word sets). This makes possible to discover different clusters and meta-words if we change the word representation. Thus, the proposed strategy is highly adaptable to other domains, where the specialization would be achieved by changing the word representation for the problem. In other work, Li and Jain (1998) found that term grouping helps to reduce the feature dimensionality, and at the same time, overcomes the generalization problem of feature selection. The evidence has showed that the performance of the classifier is, at least maintained (Li and Jain, 1998; Slonim and Tishby, 2001). Finally, other authors have also studied the problem of term clustering under a *supervised* scheme. For example, Baker and McCallum (1998) used a *supervised* scheme to cluster similar words. They carried out experiments using a Naive Bayes classifier and found results improvement by using a single word representation.

The methods proposed in this research work follow a line of thinking focused on the document representation rather than term representation. Hence, the proposed method takes advantage of specialized vector representation of words (e.g., PBR), but several extensions can be envisioned using other word embeddings in the literature. The benefits of our approach are that it is model independent, easy to implement, and computes lower dimensional and less-sparse representations than traditional BoW. More important, our method improves over state of the art methods, outperforming the methods in (Errecalde et al., 2017; Escalante et al., 2017) that in turn, outperform that in (Dulac-Arnold et al., 2011; Escalante et al., 2016).

3 Multi-Resolution Document Representation

We propose a multi resolution representation that allows to generate multiple "views" of the analyzed document. The intuition behind the proposal of a multi-resolution representation is that words will activate differently each view according to the amount of available text. We assume that having different resolution levels will allow to effectively represent the content of short and large texts as needed along different early stages. The proposed multi-resolution framework is depicted in Figure 1. The idea consists in associating words with similar meaning to the same meta-words in each resolution space. Documents are then represented by multiple Bag-of-Centroids (BoC), that is, multiple histograms accounting for the occurrence of coarse concepts. Hence, this representation can be seen as multiple BoW representations that incorporate multiple semantic resolutions. In Section 3.1 we describe the process to build a Bag-of-Centroids at a single resolution, then in Section 3.2 we formally present the Multi-Resolution variant.

3.1 Single Resolution: Bag of Centroids

Let $\mathcal{D} = \{(d_1, y_1), \ldots, (d_h, y_h)\}$ be a training set of h-pairs of documents d_i and class labels y_i. Also let $\mathcal{V} = \{w_1, \ldots, w_r\}$ denote the vocabulary of terms (in our case words). In order to create the Bag of Centroids (***BoC***) representation of each document, we first compute the vector representation v_i of each word w_i in the vocabulary of the collection. Note that our framework is agnostic to the underlying process for learning word representations and therefore any word vector representation can be used, for example word embeddings (Mikolov et al., 2013) or distributional term representations (Lavelli et al., 2004).

The proposed framework is based on the idea of clustering words using the semantic "distance" in the word embedding space. Thus, the first step of the algorithm consists of clustering the word embedding vectors v_i and finding the cluster centers to create the proposed meta-words. The representation of the vocabulary collection in the word embedding space W is the input for the clustering

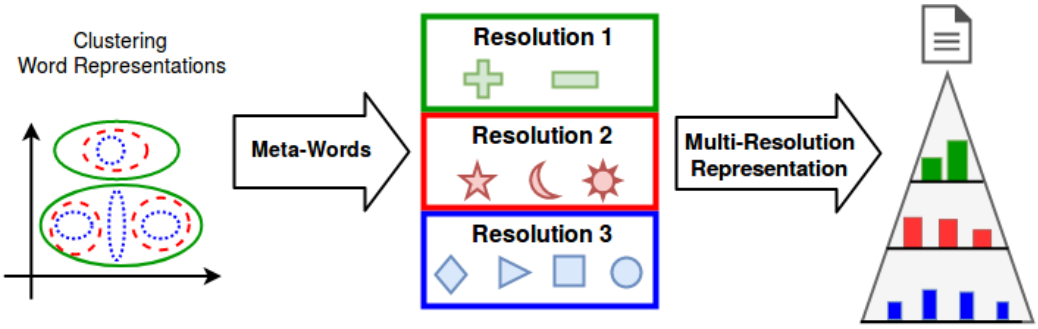

Figure 1: Algorithm to represent documents as meta-words using three hypothetical resolutions. The document is represented using the "meta-words" defined by the clustering of the vector representations of the vocabulary.

algorithm. For this purpose a variety of clustering approaches can be used. In our experimental evaluation, we explored different algorithms and found out that k-means offers a good trade-off between performance and speed. We applied k-means to the W representation to find the center of the clusters $C = \{c_1, c_2, \ldots, c_k\}$, with k being the number of selected centroids. Then, based on these cluster centers and using l_1-norm, we found a one-to-one association of each word to the *closest* cluster center in the word embedding space. In other words, for each word v_i, we can find an associated cluster center or meta-word c_u with $u \in \{1, 2, \ldots, k\}$. We denote this mapping by $c_u = closest(v_i, C)$, where $closest$ returns the centroid in C with the minimum distance to v_i. Finally, the $\mathbf{BoC}_k$ representation for each document d_j corresponds to $\mathbf{BoC}_k(d_j) = \{(c_\ell, n_\ell)\}_{\ell=1\ldots k}$ where c_ℓ corresponds to each of the k centroids and $n_\ell = |\{v_i | \forall v_i \in d_j, c_\ell = closest(v_i, C)\}|$. In other words, $\mathbf{BoC}_k(d_j)$ corresponds to a histogram of centroid frequencies, where each pair (c_ℓ, n_ℓ) represents a centroid (meta-word) and its corresponding frequency in the document.

The BoC algorithm depends on one parameter: the number of clusters used to represent each document. This parameter is associated with the level of semantic coarseness used in the representation. In this regard, coarseness refers to the level of meta-word inclusivity: the more words associated with a single meta-word, the coarser the representation. Conversely, with fewer words, the representation becomes more granular. Note that this representation has well known parallels in the extreme cases. When each word becomes a centroid, the resulting representation is equivalent to the typical BoW representation, whereas a coarser representation, with only one meta word, will be equivalent to having the average meta-word of the entire collection.

3.2 Multi-Resolution BoC

The above proposed framework is particularly suitable for incorporating multi-resolution processing, given that the main parameter is related to the granularity or coarseness of the representation. As we will show in our analysis, this property is useful for early scenarios, since few/coarse meta-words allow to better encode documents with little text, whereas many/granular meta-words are useful when more text become available. We propose to exploit this multi-resolution version of the **BoC** representation. In this extension of the basic algorithm, we use a partition of the word embedding space at multiple levels and concatenate them into a new representation. Combining the different granularities into a single representation results in a more robust document model that can help to capture different amounts of text as needed. Intuitively, the coarser levels sufficiently classify documents in early stages, while the more granular levels exploit the additional evidence from longer documents on late stages. We present quantitative and qualitative experiments that support this claim in two datasets: Sexual Predator Detection and Depression Detection.

We call this variation of the BoC representation Multi-Resolution-BoC (**MulR**). Formally: $\mathbf{MulR}(d_j) = \{\mathbf{BoC}_{k_1}(d_j) \cup \mathbf{BoC}_{k_2}(d_j) \cup \ldots \cup \mathbf{BoC}_{k_n}(d_j)\}$, where $\{k_1, k_2, \ldots k_n\}$ correspond to a set of granular levels. Figure 1 shows the general framework, graphically depicting the process involved in transforming a document into a representation based on meta-words. The figure also includes the process of multi-resolution modification described above. In the figure, the

meta-words depicted with 'blue' represent the more granular clusters, and those depicted with 'green' represent the less granular clusters. The multi-resolution BoC variation improves the performance by combining the information present at various levels of granularity. Moreover, when documents are closely related, more fine grained features allow to capture finer details and therefore produces better text classification results. This multi-resolution approach combines the advantages of both approaches to create an overall more effective classification method.

4 Data collections

For experiments we considered the two data sets described in Table 2. The tasks are Sexual Predator Detection (SPD) and Depression Detection, where clearly early detection is crucial. For the former we used the only publicly available data set for sexual predator detection (Inches and Crestani, 2012). This data set was released in the context of the sexual predator identification task at PAN-CLEF'12 and comprises a large number of chat conversations that include real sexual predators. Thus, the task approached is that of identifying those conversations that potentially include a sexual predator, as in (Villatoro-Tello et al., 2012; Escalante et al., 2013, 2016). For the depression detection task we use the dataset presented in (Losada et al., 2017). In this dataset, each instance has the post history for a user, and depressed users were self-identified as having been diagnosed with depression.

5 Evaluation Framework

For our experiments, we lower case the text in documents and use words and punctuation marks as terms[1]. The representation obtained for each document is then processed by a Support Vector Machine (SVM) with a linear kernel.

For the evaluation of the *earliness* performance, we report the performance of the different methods when using increasing amounts of textual evidence (chunk by chunk evaluation). This evaluation allows to quantify prediction performance when using partial information in documents, and it is a strategy that has been used to evaluate early classification (Escalante et al., 2016; Errecalde et al., 2017; Losada et al., 2017). For the evaluation of performance we used the $f_1 = \frac{2 \times precision \times recall}{precision + recall}$ measure. This decision was made in agreement with previous work that reports this metric for the positive class (Errecalde et al., 2017). Please note that, contrary to other measures, such as accuracy, f_1 measure accounts for the class imbalance problem when only the positive class is analyzed. This is desirable for the data sets we consider as they are highly unbalanced.

Word-vector representations: As previously mentioned, the proposed MulR representation generalizes word-vector representations and thus can extend any representation that models each term in the vocabulary using a vector. For this purpose a wide variety of word embeddings or distributional term representations could be used. Both of them exploit the distributional hypothesis to build word vectors, nonetheless they differ in the strategy to capture the relevant information. In this work we use the widely used word2vec, but also other representations that have been used in recent works for these collections. In Table 1 we describe each of the word vector representations considered for this work[2].

Baselines: The main baselines in this work are methods based on the idea of topic modeling for text classification. Topic-based representations group words into topics defined by a set of related words[3]. Given the strong relation to our method we compare our proposal against Latent Semantic Analysis (LSA) and Latent Dirichlet Allocation (LDA). Furthermore, we also compare with Bag-of-Words using Term Frequency Inverse Document Frequency, since it is a traditional baseline in text categorization tasks.

6 Experimental Results

In this section we report the experimental results for the MulR representation and the selected approaches from the state-of-the-art. In all the experiments we trained the reference classifier (SVM) using full-length documents in the training dataset. In the testing phase, each approach uses all the available information in each of the ten chunks (each chunk increases the available text in 10%). More specifically, we generate document representations starting with the first chunk, and then incrementally adding one chunk at a time. The

[1] We used terms with frequency higher than 10 in the training datasets.

[2] For distributional representations we used the framework at https://github.com/lopez-monroy/FeatureSpaceTree

[3] We empirically set to 200 the size of the concept space.

Word Representation	Description
W2V (Mikolov et al., 2013)	Word2Vec uses the Skip-ngram model to find word representations that are useful to predict the surrounding words of a sentence or a document. The method is efficient for learning high-quality vector representations of words from large amounts of text data. We empirically set to 200 the vector dimension.
DOR (Lavelli et al., 2004)	Document Occurrence Representation (DOR) captures the semantics of a word by observing occurrence distribution over documents in the corpus. DOR represents each word v_i as a vector $\mathbf{t_i} = \langle t_{i,1}, \ldots, t_{i,\|\mathcal{D}\|} \rangle$, where $\|\mathcal{D}\|$ is the number of documents in the training collection, and $t_{i,k}$ indicates the relevance of the document D_k to characterize v_i.
TCOR(Lavelli et al., 2004)	In Term Co-occurrence Representation (TCOR) the semantics of a word is captured by observing its co-occurrences with other words across documents in the corpus. Thus, each word v_i is associated to a vector $\mathbf{t_i} = \langle t_{i,1}, \ldots, t_{i,\|\mathcal{V}\|} \rangle$, where $\|\mathcal{V}\|$ indicates the vocabulary size, and $t_{i,k}$ denotes the contribution of the word v_k to the semantic description of v_i.
PBR (López-Monroy et al., 2015)	Profile Based Representation exploits occurrence-statistics of words over a set of documents in target categories. PBR represents each word $v_i \in V$ with a vector $\mathbf{t_i} = \langle t_{i,1}, \ldots, t_{i,q} \rangle$, where the $t_{i,k}$ is the degree of association between word v_i and category C_k. The target categories can be taken from the task or artificially created by means of clustering such as in (Escalante et al., 2017).
TVT (Errecalde et al., 2017)	Temporal Variation Terms (TVT) is an adapted version of PBR for early scenarios. TVT builds new artificial target classes/labels in the training set simulating a text stream to generate enriched representations of $\mathbf{t_i}$. The idea is to exploit the positive category to create a set of new artificial categories using text-fragments.

Table 1: Word vector representations for early experimentation.

Task	Data set	Training	Test

Depression det.	eRisk'17	486	401

Table 2: Data sets considered for early experimentation. There are only two classes in each dataset.

models will then make predictions incrementally as well. We report f_1 performance when using different amounts of text from test documents. For the proposed MulR representation, we build 5 different resolutions: 10, 50, 100, 500, and 1000. The goal was to generate meta-words at different levels of granularity, and we plan to further explore the impact of these resolutions in our future research.

In the following experiments, we used the word representations in Table 1 to build our proposed MulR document representation. For comparison purposes we also generate an alternative document representation by averaging (Avg) term-vectors of words in each document, which is a popular strategy to build document representations. Finally, we also compare against several traditional baselines such as the Bag-of-Words, LSA, and specialized methods in each collection (Escalante et al., 2017; Errecalde et al., 2017). We evaluate the usefulness of all these different representations in the two early classification tasks mentioned earlier.

6.1 Sexual Predators Detection

In this section we evaluate the performance of the proposed MulR and other reference methodologies for the SPD early detection task (Figure 2). We also show results for MulR and different word representations in Table 3, where several findings can be outlined. First of all, results obtained in early stages (chunk 1 to 4) using the proposed MulR are clearly superior to those obtained averaging word vectors. This is an interesting outcome, since the MulR representation seems to be useful for early scenarios independently of the word vector representation. In the particular case of MulR(TVT), the representation obtains an outstanding performance when having little information (e.g., performance between ≈71% and ≈90% before reading 50% of the text). More important, performance improves as more evidence is available (i.e., see the steady improvement up to ≈97%). These results show that MulR is a robust representation, even in the presence of different amounts of textual evidence, with a clear advantage for early classification stages.

In Figure 2 we can also observe that MulR representation outperformed, by a large margin, the proposed baselines; BoW-TFIDF, LSA, LDA. Furthermore, MulR representation obtains better performance than the work in (Escalante et al., 2017), which consists in averaging the PBRs (same that Avg-PBR) and is the state-of-the-art in early SPD. Note that different than (Escalante et al., 2017), the proposed MulR significantly improves even after reading 40% of the information. The experimental results in Table 3 also show the

Table 3: F_1 results for the chunk by chunk evaluation of different approaches in Sexual Predator Detection. The proposed MulR is evaluated using different word vector representations in the literature.

following interesting findings:

1. The most useful word vector representation is TVT (Errecalde et al., 2017). This is not surprising, since TVT is a specialized distribution term representation for early prediction scenarios.

2. Word2Vec [4] representations obtained moderate performance in all experiments. We infer that much more data of these specific social media domains are needed in order to build suitable models.

3. MulR representation is an effective solution for all early chunks, but as more text is available, the other methodologies significantly increase their discriminative power, as seen in results for later chunks. In fact, some representations such as Avg(DOR) can outperform MulR(DOR) representation in late stages. However, even under these conditions MulR(TVT) and MulR(DOR) outperform all reference methodologies.

6.2 Depression Detection

In Table 4 we show the experimental results for early depression detection. In Figure 3 we highlight the performance of the proposal and the reference methodologies. From these results we point

[4]Embeddings were trained in each dataset. We tested pretrained word embeddings for wikipedia/twitter, but the performance was worse.

Table 4: F_1 results for the chunk by chunk evaluation of different approaches in Depression Detection. The proposed MulR is evaluated using different word vector representations in the literature.

out several interesting findings. The first one is that for this collection, results obtained by the proposal are clearly superior to others in early stages. In general, we can observe the following:

1. The most useful representation in early stages was MulR(TVT), which have considerable improvements between ≈5% and ≈2% in chunks 1 to 4.

2. Word Embeddings and DOR showed a similar behavior than in SPD. But in late stages, the best representation was Avg(DOR).

3. Depression Detection problem is a much harder problem than SPD. The F_1 measure is under ≈60% in most of the results. This could be due to the highly unbalanced dataset in two ways: i) the number of instances in each class, and ii) the amount of text contained in documents.

6.3 The Relevance of Individual Resolutions

In this section we aim to study the role of the different resolutions in early scenarios.[5] The purpose of the first analysis is to observe the performance of each individual resolution in MulR. In Table 5 we show the results of MulR(TVT) under each of the five resolutions ($R_1 = 10, R_2 = 50, R_3 = 100, R_4 = 500, R_5 = 1000$) and each chunk.

[5]The number and size of resolutions, could improve the performance, but it is a future research path to enhance the characterization of specific data sets.

Sexual Predator Detection										
Method	ch_1	ch_2	ch_3	ch_4	ch_5	ch_6	ch_7	ch_8	ch_9	ch_{10}
MulR(TVT)-R1	59.88	74.71	82.17	85.82	89.19	90.19	91.51	92.61	92.42	92.51

MulR(TVT)	**71.15**	**84.00**	**88.56**	**91.66**	**94.11**	**94.92**	**95.31**	**96.50**	**97.16**	**97.43**

Table 5: F_1 results for the chunk by chunk evaluation of different approaches in Sexual Predator Detection. The best MulR(TVT) is separately evaluated under each resolution.

For early SPD the evidence is clear; as the resolution increases the performance in early stages decrease.[6] Also note that the higher the resolution, the more chunks needed to outperform the result of the previous resolution. For example, resolution R_3 outperforms R_2 in chunk 8. Also note that R_4 and R_5 needed more chunks to obtain comparable performance than R_2. Our experimental results excluding one resolution at the time showed worse performance, therefore all of them are essential in the overall classification. Clearly, this evidence shows that the MulR representation is in fact very useful.

Sexual Predator Detection					
Test set	R_1	R_2	R_3	R_4	R_5
chunk-1	4	3	2	1	0
chunk-2	3	2	3	2	0
chunk-3	3	2	2	2	1
chunk-4	3	2	3	1	1
chunk-5	3	2	3	1	1
chunk-6	3	1	4	1	1
chunk-7	3	1	3	2	1
chunk-8	2	2	1	2	3
chunk-9	3	1	1	2	3
chunk-10	3	0	2	2	3

Table 6: Post-analysis in test dataset. Distribution of the top ten meta-words according to each resolution R_i at different chunks. We used Information Gain (Hall et al., 2009) to rank meta-words in MulR(TVT).

In Table 6 we provide further evidence about the role of different resolutions. In this complementary analysis we study each chunk at test data. For this we use the MulR learned in training to represent test documents, then we compute the Information Gain using Weka (Hall et al., 2009) at each test chunk. In Table 6 we show the number of features in each resolution R_i that are present in the top ten meta-words of the MulR(TVT). The analysis complements the evidence, lower resolutions have higher IG at early chunks, whereas higher resolutions are more necessary in late chunks.

[6]The only exception to this is R_1, which has the lowest overall performance. This is somewhat expected since this space only has 10 features to represent documents.

7 Conclusions

In this paper we proposed a multi resolution representation that allows to generate multiple "views" of the document. Intuitively these views expose different semantic meanings for words and documents along different resolutions. The different resolutions allow to effectively represent the content of short and large texts at different early stages. The MulR obtained the best results reported so far on the early Sexual Predator Detection task dataset (Inches and Crestani, 2012). For Depression Detection the chunk by chunk evaluation shows promising results for MulR in early stages. What is more, it was shown that the MulR further improves the early recognition performance in the two tasks using different word representations. The relevance of the resolutions in these results is a key factor to understand the proposed MulR and future extensions. These results provide solid evidence to further research on this topic and encourage researchers to apply and evaluate the usefulness of multi-resolution features for other related *early* tasks.

Abstract

Many text classification tasks are known to be highly domain-dependent. Unfortunately, the availability of training data can vary drastically across domains. Worse still, for some domains there may not be any annotated data at all. In this work, we propose a *multinomial adversarial network*[1] (MAN) to tackle this real-world problem of multi-domain text classification (MDTC) in which labeled data may exist for multiple domains, but in insufficient amounts to train effective classifiers for one or more of the domains. We provide theoretical justifications for the MAN framework, proving that different instances of MANs are essentially minimizers of various f-divergence metrics (Ali and Silvey, 1966) among *multiple* probability distributions. MANs are thus a theoretically sound generalization of traditional adversarial networks that discriminate over *two* distributions. More specifically, for the MDTC task, MAN learns features that are invariant across multiple domains by resorting to its ability to reduce the divergence among the feature distributions of each domain. We present experimental results showing that MANs significantly outperform the prior art on the MDTC task. We also show that MANs achieve state-of-the-art performance for domains with no labeled data.

1 Introduction

Text classification is one of the most fundamental tasks in Natural Language Processing, and has found its way into a wide spectrum of NLP applications, ranging from email spam detection and social media analytics to sentiment analysis and data mining. Over the past couple of decades, supervised statistical learning methods have become the dominant approach for text classification (e.g. McCallum et al. (1998); Kim (2014); Iyyer et al. (2015)). Unfortunately, many text classification tasks are highly domain-dependent in that a text classifier trained using labeled data from one domain is likely to perform poorly on another. In the task of sentiment classification, for example, the phrase "runs fast" is usually associated with positive sentiment in the sports domain; not so when a user is reviewing the battery of an electronic device. In real applications, therefore, an adequate amount of training data from each domain of interest is typically required, and this is expensive to obtain.

Two major lines of work attempt to tackle this challenge: **domain adaptation** (Blitzer et al., 2007) and **multi-domain text classification** (MDTC) (Li and Zong, 2008). In domain adaptation, the assumption is that there is some domain with abundant training data (the source domain), and the goal is to utilize knowledge learned from the source domain to help perform classifications on another lower-resourced target domain.[2] The focus of this work, MDTC, instead simulates an arguably more realistic scenario, where labeled data may exist for multiple domains, but in insufficient amounts to train an effective classifier for one or more of the domains. Worse still, some domains may have *no* labeled data at all. The objective of MDTC is to leverage *all* the available resources in order to improve the system performance over all domains simultaneously.

One state-of-the-art system for MDTC, the CMSC system of Wu and Huang (2015), combines a classifier that is shared across all domains (for learning domain-invariant knowledge) with a set of classifiers, one per domain, each of which captures domain-specific text classification knowledge. This paradigm is sometimes known

[1] The source code of MAN is available at https://github.com/ccsasuke/man.

[2] See §6 for other variants of domain adaptation.

Proceedings of NAACL-HLT 2018, pages 1226–1240
New Orleans, Louisiana, June 1 - 6, 2018.

as the Shared-Private model (Bousmalis et al., 2016). CMSC, however, lacks an explicit mechanism to ensure that the shared classifier captures only domain-independent knowledge: the shared classifier may well also acquire some domain-specific features that are useful for a subset of the domains. We hypothesize that better performance can be obtained if this constraint were explicitly enforced.

In this paper, we thus propose Multinomial Adversarial Networks (henceforth, MANs) for the task of multi-domain text classification. In contrast to standard adversarial networks (Goodfellow et al., 2014), which serve as a tool for minimizing the divergence between *two* distributions (Nowozin et al., 2016), MANs represent a family of theoretically sound adversarial networks that, in contrast, leverage a *multinomial discriminator* to directly minimize the divergence among multiple probability distributions. And just as binomial adversarial networks have been applied to numerous tasks (e.g. image generation (Goodfellow et al., 2014), domain adaptation (Ganin et al., 2016), cross-lingual text classification (Chen et al., 2016)), we anticipate that MANs will make a versatile machine learning framework with applications beyond the MDTC task studied in this work.

We introduce the MAN architecture in §2 and prove in §3 that it directly minimizes the (generalized) f-divergence among multiple distributions so that they are indistinguishable upon successful training. Specifically for MDTC, MAN is used to overcome the aforementioned limitation in prior art where domain-specific features may sneak into the shared model. This is accomplished by relying on MAN's power of minimizing the divergence among the feature distributions of each domain. The high-level idea is that MAN will make the extracted feature distributions of each domain indistinguishable from one another, thus learning general features that are invariant across domains.

We then validate the effectiveness of MAN in experiments on two MDTC data sets. We find first that MAN significantly outperforms the state-of-the-art CMSC method (Wu and Huang, 2015) on the widely used multi-domain Amazon review dataset, and does so without relying on external resources such as sentiment lexica (§4.1). When applied to the second dataset, FDU-MTL (§4.3), we obtain similar results: MAN achieves substantially higher accuracy than the previous top-performing method, ASP-MTL (Liu et al., 2017). ASP-MTL is the first empirical attempt to use a multinomial adversarial network for multi-task learning, but is more restricted and can be viewed as a special case of MAN. In addition, we provide the first theoretical guarantees for multinomial adversarial networks (§3). Finally, while many MDTC methods such as CMSC require labeled data for each domain, MANs can be applied in cases where no labeled data exists for a subset of domains. To evaluate MAN in this semi-supervised setting, we compare MAN to a method that can accommodate unlabeled data for (only) one domain (Zhao et al., 2017), and show that MAN achieves performance comparable to the state of the art (§4.2).

2 Model

In this paper, we strive to tackle the text classification problem in the real-world setting in which texts come from a variety of domains, each with a varying amount of labeled data. Specifically, assume we have a total of N domains, N_1 *labeled domains* (denoted as Δ_L) for which there is some labeled data, and N_2 *unlabeled domains* (Δ_U) for which no annotated training instances are available. Denote $\Delta = \Delta_L \cup \Delta_U$ as the collection of all domains, with $N = N_1 + N_2$. The goal of this work, and of MDTC in general, is to improve the overall classification performance across all N domains, measured in this paper as the average[3] classification accuracy across the N domains in Δ.

2.1 Model Architecture

As shown in Figure 1, the Multinomial Adversarial Network (MAN) adopts the Shared-Private paradigm of Bousmalis et al. (2016) and consists of four components: a *shared feature extractor* $\mathcal{F}_s$, a *domain feature extractor* $\mathcal{F}_{d_i}$ for each labeled domain $d_i \in \Delta_L$, a *text classifier* $\mathcal{C}$, and a *domain discriminator* $\mathcal{D}$. The main idea of MAN is to explicitly model the domain-invariant features that are beneficial to the main classification task across all domains (i.e. the *shared features*, extracted by $\mathcal{F}_s$), as well as the domain-specific features that mainly contribute to the classification in its own domain (the *domain features*, extracted by $\mathcal{F}_d$). Here, the adversarial domain discriminator $\mathcal{D}$ has a multinomial output that takes a shared feature

[3] In this work, we use macro-average over domains, but MAN can be readily adapted for micro-average or other (weighted) averaging schemes.

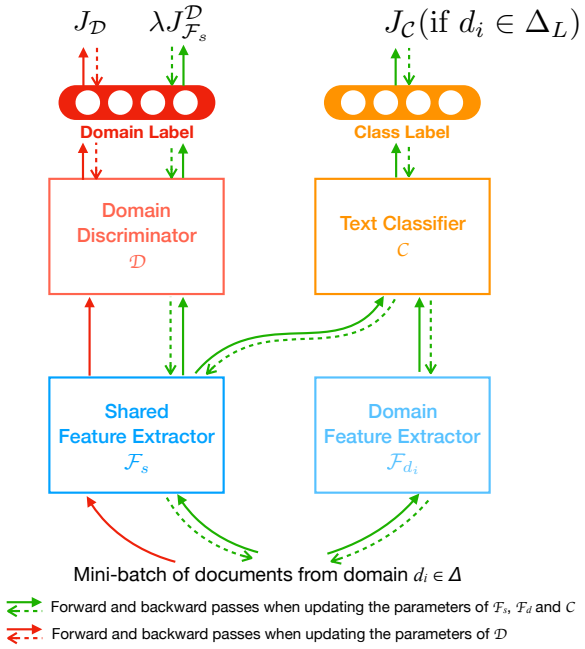

Figure 1: MAN for MDTC. The figure demonstrates the training on a mini-batch of data from one domain. One training iteration consists of one such mini-batch training from each domain. The parameters of $\mathcal{F}_s, \mathcal{F}_d, \mathcal{C}$ are updated together, and the training flows are illustrated by the green arrows. The parameters of $\mathcal{D}$ are updated separately, shown in red arrows. Solid lines indicate forward passes while dotted lines are backward passes. $J^{\mathcal{D}}_{\mathcal{F}_s}$ is the domain loss for $\mathcal{F}_s$, which is anticorrelated with $J_{\mathcal{D}}$ (e.g. $J^{\mathcal{D}}_{\mathcal{F}_s} = -J_{\mathcal{D}}$). (See §2,§3)

vector and predicts the likelihood of that sample coming from each domain. As seen in Figure 1, during the training of $\mathcal{F}_s$ (green arrows denote the training flow), $\mathcal{F}_s$ aims to confuse $\mathcal{D}$ by minimizing $J^{\mathcal{D}}_{\mathcal{F}_s}$, which is anticorrelated to $J_{\mathcal{D}}$ (detailed in §2.2), so that $\mathcal{D}$ cannot predict the domain of a sample given its shared features. The intuition is that if even a strong discriminator $\mathcal{D}$ cannot tell the domain of a sample from the extracted features, those features $\mathcal{F}_s$ learned are essentially domain invariant. By enforcing domain-invariant features to be learned by $\mathcal{F}_s$, when trained jointly via backpropagation, the set of domain feature extractors $\mathcal{F}_d$ will each learn domain-specific features beneficial within its own domain.

The architecture of each component is relatively flexible, and can be decided by the practitioners to suit their particular classification tasks. For instance, the feature extractors can adopt the form of Convolutional Neural Nets (CNN), Recurrent Neural Nets (RNN), or a Multi-Layer Perceptron (MLP), depending on the input data (see §4). The input of MAN will also be dependent on the feature

until convergence

extractor choice. The output of a (shared/domain) feature extractor is a fixed-length vector, which is considered the (shared/domain) hidden features of some given input text. On the other hand, the outputs of $\mathcal{C}$ and $\mathcal{D}$ are label probabilities for class and domain prediction, respectively. For example, both $\mathcal{C}$ and $\mathcal{D}$ can be MLPs with a softmax layer on top. In §3, we provide alternative architectures for $\mathcal{D}$ and their mathematical implications. We now present a detailed description of the MAN training in §2.2 as well as the theoretical grounds in §3.

2.2 Training

Denote the annotated corpus in a labeled domain $d_i \in \Delta_L$ as $\mathbb{X}_i$; and $(x, y) \sim \mathbb{X}_i$ is a sample drawn from the labeled data in domain d_i, where x is the input and y is the task label. On the other hand, for any domain $d_{i'} \in \Delta$, denote the unlabeled corpus as $\mathbb{U}_{i'}$. Note for the choice of unlabeled data of a labeled domain, one can use a separate unlabeled corpus or simply use the labeled data (or use both).

In Figure 1, the arrows illustrate the training flows of various components. Due to the adversarial nature of the domain discriminator $\mathcal{D}$, it is trained with a separate optimizer (red arrows), while the rest of the networks are updated with the main optimizer (green arrows). $\mathcal{C}$ is only trained on the annotated data from labeled domains, and it takes as input the concatenation of the shared and domain feature vectors. At test time, for data from

unlabeled domains with no $\mathcal{F}_d$, the domain features are set to the $\mathbf{0}$ vector for $\mathcal{C}$'s input. On the contrary, $\mathcal{D}$ only takes the shared features as input, for both labeled and unlabeled domains. The MAN training procedure is described in Algorithm 1.

In Algorithm 1, $\mathcal{L}_\mathcal{C}$ and $\mathcal{L}_\mathcal{D}$ are the loss functions of the text classifier $\mathcal{C}$ and the domain discriminator $\mathcal{D}$, respectively. As mentioned in §2.1, $\mathcal{C}$ has a $softmax$ layer on top for classification. We hence adopt the canonical negative log-likelihood (NLL) loss:

$$\mathcal{L}_\mathcal{C}(\hat{y}, y) = -\log P(\hat{y} = y) \tag{1}$$

where y is the true label and $\hat{y}$ is the $softmax$ predictions. For $\mathcal{D}$, we consider two variants of MAN. The first one is to use the NLL loss same as $\mathcal{C}$ which suits the classification task; while another option is to use the Least-Square (L2) loss that was shown to be able to alleviate the gradient vanishing problem when using the NLL loss in the adversarial setting (Mao et al., 2017):

$$\mathcal{L}_\mathcal{D}^{NLL}(\hat{d}, d) = -\log P(\hat{d} = d) \tag{2}$$

$$\mathcal{L}_\mathcal{D}^{L2}(\hat{d}, d) = \sum_{i=1}^{N} (\hat{d}_i - \mathbb{1}_{\{d=i\}})^2 \tag{3}$$

where d is the domain index of some sample and $\hat{d}$ is the prediction. Without loss of generality, we normalize $\hat{d}$ so that $\sum_{i=1}^{N} \hat{d}_i = 1$ and $\forall i : \hat{d}_i \geq 0$.

Therefore, the objectives of $\mathcal{C}$ and $\mathcal{D}$ that we are minimizing are:

$$J_\mathcal{C} = \sum_{i=1}^{N} \mathop{\mathbb{E}}_{(x,y)\sim\mathbb{X}_i} [\mathcal{L}_\mathcal{C}(\mathcal{C}(\mathcal{F}_s(x), \mathcal{F}_d(x)); y)] \tag{4}$$

$$J_\mathcal{D} = \sum_{i=1}^{N} \mathop{\mathbb{E}}_{x\sim\mathbb{U}_i} [\mathcal{L}_\mathcal{D}(\mathcal{D}(\mathcal{F}_s(x)); d)] \tag{5}$$

For the feature extractors, the training of domain feature extractors is straightforward, as their sole objective is to help $\mathcal{C}$ perform better within their own domain. Hence, $J_{\mathcal{F}_d} = J_\mathcal{C}$ for any domain d. Finally, the shared feature extractor $\mathcal{F}_s$ has two objectives: to help $\mathcal{C}$ achieve higher accuracy, and to make the feature distribution invariant across all domains. It thus leads to the following bipartite loss:

$$J_{\mathcal{F}_s} = J_{\mathcal{F}_s}^\mathcal{C} + \lambda \cdot J_{\mathcal{F}_s}^\mathcal{D}$$

where λ is a hyperparameter balancing the two parts. $J_{\mathcal{F}_s}^\mathcal{D}$ is the domain loss of $\mathcal{F}_s$ anticorrelated to $J_\mathcal{D}$:

$$(NLL) J_{\mathcal{F}_s}^\mathcal{D} = -J_\mathcal{D} \tag{6}$$

$$(L2) J_{\mathcal{F}_s}^\mathcal{D} = \sum_{i=1}^{N} \mathop{\mathbb{E}}_{x\sim\mathbb{U}_i} \left[\sum_{j=1}^{N} (\mathcal{D}_j(\mathcal{F}_s(x)) - \frac{1}{N})^2 \right] \tag{7}$$

If $\mathcal{D}$ adopts the NLL loss (6), the domain loss is simply $-J_\mathcal{D}$. For the L2 loss (7), $J_{\mathcal{F}_s}^\mathcal{D}$ intuitively translates to pushing $\mathcal{D}$ to make random predictions. See §3 for theoretical justifications.

3 Theories of Multinomial Adversarial Networks

Binomial adversarial nets are known to have theoretical connections to the minimization of various f-divergences[4] between *two* distributions (Nowozin et al., 2016). However, for adversarial training among multiple distributions, no theoretical justifications have been provided to our best knowledge, despite that this idea has recently been explored empirically (Liu et al., 2017).

In this section, we present a theoretical analysis showing the validity of MAN. In particular, we show that MAN's objective is equivalent to minimizing the total f-divergence between each of the shared feature distributions of the N domains, and the centroid of the N distributions. The choice of loss function will determine which specific f-divergence is minimized. Furthermore, with adequate model capacity, MAN achieves its optimum for either loss function if and only if all N shared feature distributions are identical, hence learning an invariant feature space across all domains.

First, consider the distribution of the shared features $\mathbf{f}$ for instances in each domain $d_i \in \Delta$:

$$P_i(\mathbf{f}) \triangleq P(\mathbf{f} = \mathcal{F}_s(x) | x \in d_i) \tag{8}$$

Combining (5) with the two loss functions (2), (3), the objective of $\mathcal{D}$ can be written as:

$$J_\mathcal{D}^{NLL} = -\sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f}\sim P_i} [\log \mathcal{D}_i(\mathbf{f})] \tag{9}$$

$$J_\mathcal{D}^{L2} = \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f}\sim P_i} \left[\sum_{j=1}^{N} (\mathcal{D}_j(\mathbf{f}) - \mathbb{1}_{\{i=j\}})^2 \right] \tag{10}$$

[4] An f-divergence (Ali and Silvey, 1966) is a function that measures the distance between two probability distributions, e.g. the KL or Jensen-Shannon divergence.

where $\mathcal{D}_i(\mathbf{f})$ is the i-th dimension of $\mathcal{D}$'s (normalized) output vector, which conceptually corresponds to the probability of $\mathcal{D}$ predicting that $\mathbf{f}$ is from domain d_i

We first derive the optimal $\mathcal{D}$ for any fixed $\mathcal{F}_s$.

Lemma 1. *For any fixed $\mathcal{F}_s$, with either NLL or L2 loss, the optimum domain discriminator $\mathcal{D}^*$ is:*

$$\mathcal{D}_i^*(\mathbf{f}) = \frac{P_i(\mathbf{f})}{\sum_{j=1}^{N} P_j(\mathbf{f})} \tag{11}$$

The proof involves an application of the *Lagrangian Multiplier* to solve the minimum value of $J_{\mathcal{D}}$, and the details can be found in the Appendix. We then have the following main theorems for the domain loss for $\mathcal{F}_s$:

Theorem 1. *Let $\overline{P} = \frac{\sum_{i=1}^{N} P_i}{N}$. When $\mathcal{D}$ is trained to its optimality, if $\mathcal{D}$ adopts the* NLL loss*:*

$$\begin{aligned} J_{\mathcal{F}_s}^{\mathcal{D}} &= -\min_{\theta_{\mathcal{D}}} J_{\mathcal{D}} = -J_{\mathcal{D}^*} \\ &= -N\log N + N \cdot JSD(P_1, P_2, \ldots, P_N) \\ &= -N\log N + \sum_{i=1}^{N} KL(P_i \| \overline{P}) \end{aligned}$$

where $JSD(\cdot)$ is the generalized Jensen-Shannon Divergence (Lin, 1991) among multiple distributions, defined as the average Kullback-Leibler divergence of each P_i to the centroid $\overline{P}$ (Aslam and Pavlu, 2007).

Theorem 2. *If $\mathcal{D}$ uses the* L2 loss*:*

$$\begin{aligned} J_{\mathcal{F}_s}^{\mathcal{D}} &= \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f}\sim P_i} \left[\sum_{j=1}^{N} (\mathcal{D}_j^*(\mathbf{f}) - \frac{1}{N})^2 \right] \\ &= \frac{1}{N} \sum_{i=1}^{N} \chi^2_{Neyman}(P_i \| \overline{P}) \end{aligned}$$

where $\chi^2_{Neyman}(\cdot\|\cdot)$ is the Neyman χ^2 divergence (Nielsen and Nock, 2014). The proof of both theorems can be found in the Appendix.

Consequently, by the non-negativity and joint convexity of the f-divergence (Csiszar and Korner, 1982), we have:

Corollary 1. *The optimum of $J_{\mathcal{F}_s}^{\mathcal{D}}$ is $-N\log N$ when using NLL loss, and 0 for the L2 loss. The optimum value above is achieved if and only if $P_1 = P_2 = \cdots = P_N = \overline{P}$ for either loss.*

Therefore, the loss of $\mathcal{F}_s$ can be interpreted as simultaneously minimizing the classification loss $J_{\mathcal{C}}$ as well as the divergence among feature distributions of all domains. It can thus learn a shared feature mapping that is invariant across domains upon successful training while being beneficial to the main classification task.

[3] Wu and Huang (2015)

Table 1: MDTC results on the Amazon dataset. Models in bold are ours while the performance of the rest is taken from Wu and Huang (2015). Numbers in parentheses indicate standard errors, calculated based on 5 runs. Bold numbers indicate the highest performance in each domain, and $*$ shows statistical significance ($p < 0.05$) over CMSC under a one-sample T-Test.

4 Experiments

4.1 Multi-Domain Text Classification

In this experiment, we compare MAN to state-of-the-art MDTC systems on the multi-domain Amazon review dataset (Blitzer et al., 2007), which is one of the most widely used MDTC datasets. Note that this dataset was already preprocessed into a bag of features (unigrams and bigrams), losing all word order information. This prohibits the use of CNNs or RNNs as feature extractors, limiting the potential performance of the system. Nonetheless, we adopt the same dataset for fair comparison and employ a MLP as our feature extractor. In particular, we take the 5000 most frequent features and represent each review as a 5000d feature vector, where feature values are raw counts of the fea-

tures. Our MLP feature extractor would then have an input size of 5000 in order to process the reviews.

The Amazon dataset contains 2000 samples for each of the four domains: *book, DVD, electronics*, and *kitchen*, with binary labels (positive, negative). Following Wu and Huang (2015), we conduct 5-way cross validation. Three out of the five folds are treated as the training set, one serves as the validation set, while the remaining is the test set. The 5-fold average test accuracy is reported.

Table 1 shows the main results. Three types of models are shown: *Domain-Specific Models Only*, where only in-domain models are trained[5]; *Shared Model Only*, where a single model is trained with all data; and *Shared-Private Models*, a combination of the previous two. Within each category, various architectures are examined, such as Least Square (LS), SVM, and Logistic Regression (LR). As explained before, we use MLP as our feature extractors for all our models (bold ones). Among our models, the ones with the MAN prefix use adversarial training, and MAN-L2 and MAN-NLL indicate MAN with the L2 loss and the NLL loss, respectively.

From Table 1, we can see that by adopting modern deep neural networks, our methods achieve superior performance within the first two model categories even without adversarial training. This is corroborated by the fact that our SP-MLP model performs comparably to CMSC, while the latter relies on external resources such as sentiment lexica. Moreover, when our multinomial adversarial nets are introduced, further improvement is observed. With both loss functions, MAN outperforms all Shared-Private baseline systems on each domain, and achieves statistically significantly higher overall performance. For our MAN-SP models, we provide the mean accuracy as well as the standard errors over five runs, to illustrate the performance variance and conduct significance tests. It can be seen that MAN's performance is relatively stable, and consistently outperforms CMSC.

4.2 Experiments for Unlabeled Domains

As CMSC requires labeled data for each domain, their experiments were naturally designed this way. In reality, however, many domains may not have any annotated corpora available. It is therefore also important to look at the performance in these unlabeled domains for a MDTC system. Fortunately, as depicted before, MAN's adversarial training only utilizes unlabeled data from each domain to learn the domain-invariant features, and can thus be used on unlabeled domains as well. During testing, only the shared feature vector is fed into $\mathcal{C}$, while the domain feature vector is set to $\mathbf{0}$.

Target Domain	Book	DVD	Elec.	Kit.	Avg.

[1] Chen et al. (2012)
[2] Ganin et al. (2016)
[3] Zhao et al. (2017)

Table 2: Results on unlabeled domains. Models in bold are our models while the rest is taken from Zhao et al. (2017). Highest domain performance is shown in bold.

In order to validate MAN's effectiveness, we compare to state-of-the-art *multi-source domain adaptation* (MS-DA) methods (see §6). Compared to standard domain adaptation methods with one source and one target domain, MS-DA allows the adaptation from multiple source domains to a single target domain. Analogically, MDTC can be viewed as *multi-source multi-target* domain adaptation, which is superior when multiple target domains exist. With multiple target domains, MS-DA will need to treat each one as an independent task, which is more expensive and cannot utilize the unlabeled data in other target domains.

In this work, we compare MAN with one recent MS-DA method, MDAN (Zhao et al., 2017). Their experiments only have one target domain to suit their approach, and we follow this setting for fair comparison. However, it is worth noting that MAN is designed for the MDTC setting, and can deal with multiple target domains at the same time, which can potentially improve the performance by taking advantage of more unlabeled data from multiple target domains during adversarial training. We adopt the same setting as Zhao et al. (2017), which is based on the same multi-domain Amazon review dataset. Each of the four domains in the dataset is treated as the target domain in four separate experiments, while the re-

[5]For our models, it means $\mathcal{F}_s$ is disabled. Similarly, for Shared Model Only, no $\mathcal{F}_d$ is used.

Table 3: Results on the FDU-MTL dataset. Bolded models are ours, while the rest is from Liu et al. (2017). Highest performance is each domain is highlighted. For our full MAN models, standard errors are shown in parenthese and statistical significance ($p < 0.01$) over ASP-MTL is indicated by *.

maining three are used as source domains.

In Table 2, the target domain is shown on top, and the test set accuracy is reported for various systems. It shows that MAN outperforms several baseline systems, such as a MLP trained on the source-domains, as well as single-source domain adaptation methods such as mSDA (Chen et al., 2012) and DANN (Ganin et al., 2016), where the training data in the multiple source domains are combined and viewed as a single domain. Finally, when compared to MDAN, MAN and MDAN each achieves higher accuracy on two out of the four target domains, and the average accuracy of MAN is similar to MDAN. Therefore, MAN achieves competitive performance for the domains without annotated corpus. Nevertheless, unlike MS-DA methods, MAN can handle multiple target domains at one time.

4.3 Experiments on the MTL Dataset

To make fair comparisons, the previous experiments follow the standard settings in the literature, where the widely adopted Amazon review dataset is used. However, this dataset has a few limitations. First, it has only four domains. In addition, the reviews are already tokenized and converted to a bag of features consisting of unigrams and bigrams. Raw review texts are hence not available in this dataset, making it impossible to use certain modern neural architectures such as CNNs and RNNs. To provide more insights on how well MAN works with other feature extractor architectures, we provide a third set of experiments on the FDU-MTL dataset (Liu et al., 2017). This dataset is created as a multi-task learning dataset with 16 *tasks*, where each task is essentially a different domain of reviews. It has 14 Amazon domains: books, electronics, DVD, kitchen, apparel, camera, health, music, toys, video, baby, magazine, software, and sports, in addition to two movie review domains from the IMDb and the MR datasets. Each domain has a development set of 200 samples, and a test set of 400 samples. The amount of training and unlabeled data vary across domains but are roughly 1400 and 2000, respectively.

We compare MAN with ASP-MTL (Liu et al., 2017) on this FDU-MTL dataset. ASP-MTL also adopts adversarial training for learning a shared feature space, and can be viewed as a special case of MAN that adopts the NLL loss (MAN-NLL) and chooses LSTM as their feature extractor. In contrast, we found a CNN-based feature extractor (Kim, 2014) achieves much better accuracy while being ~ 10 times faster. Indeed, as shown in Table 3, with or without adversarial training, our CNN models outperform LSTM ones by a large margin. When used in our MAN framework, we attain the state-of-the-art performance on every domain with a 88.4% overall accuracy, surpassing ASP-MTL by a significant margin of 2.3%.

We hypothesize the reason a LSTM performs much worse than a CNN is its lack of an attention mechanism. In ASP-MTL, only the last hidden unit is taken as the extracted features. While LSTMs are effective for representing the context for each token, it might not be powerful enough for directly encoding the entire document (Bahdanau et al., 2015). Therefore, various attention mechanisms have been introduced on top of the vanilla LSTM to select words (and contexts) most relevant for making the predictions. In our preliminary experiments, we find that a Bi-directional LSTM with the dot-product attention (Luong et al., 2015) yields better performance

than the vanilla LSTM in ASP-MTL. However, it still does not outperform CNN and is much slower. As a result, we conclude that, for text classification tasks, CNN is both effective and efficient in extracting local and higher-level features for making a single categorization.

Finally, we observe that MAN-NLL achieves slightly higher overall performance compared to MAN-L2, providing evidence for the claim in a recent study (Lucic et al., 2017) that the original GAN loss (NLL) may not be inherently inferior to the L2 loss. Moreover, the two variants excel in different domains, suggesting the possibility of further performance gain when using ensemble.

5 Implementation Details

For all three of our experiments, we use $\lambda = 0.05$ and $k = 5$ (See Algorithm 1). For both optimizers, Adam (Kingma and Ba, 2015) is used with learning rate 0.0001. The size of the shared feature vector is set to 128 while that of the domain feature vector is 64. Dropout of $p = 0.4$ is used in all components. $\mathcal{C}$ and $\mathcal{D}$ each has one hidden layer of the same size as their input ($128 + 64$ for $\mathcal{C}$ and 128 for $\mathcal{D}$). ReLU is used as the activation function. Batch normalization (Ioffe and Szegedy, 2015) is used in both $\mathcal{C}$ and $\mathcal{D}$ but not $\mathcal{F}$. We use a batch size of 8.

For our first two experiments on the Amazon review dataset, the MLP feature extractor is used. As described in §4.1, it has an input size of 5000. Two hidden layers are used, with size 1000 and 500, respectively.

For the CNN feature extractor used in the FDU-MTL experiment, a single convolution layer is used. The kernel sizes are 3, 4, and 5, and the number of kernels are 200. The convolution layers take as input the 100d word embeddings of each word in the input sequence. We use *word2vec* word embeddings (Mikolov et al., 2013) trained on a bunch of unlabeled raw Amazon reviews (Blitzer et al., 2007). After convolution, the outputs go through a ReLU layer before fed into a max pooling layer. The pooled output is then fed into a single fully connected layer to be converted into a feature vector of size either 128 or 64. More details of using CNN for text classification can be found in the original paper (Kim, 2014). MAN is implemented using PyTorch (Paszke et al., 2017).

6 Related Work

Multi-Domain Text Classification The MDTC task was first examined by Li and Zong (2008), who proposed to fuse the training data from multiple domains either at the feature level or the classifier level. The prior art of MDTC (Wu and Huang, 2015) decomposes the text classifier into a general one and a set of domain-specific ones. However, the general classifier is learned by parameter sharing and domain-specific knowledge may sneak into it. They also require external resources to help improve accuracy and compute domain similarities.

Domain Adaptation Domain Adaptation attempts to transfer the knowledge from a source domain to a target one, and the traditional form is the *single-source, single-target* (**SS,ST**) adaptation (Blitzer et al., 2006). Another variant is the **SS,MT** adaptation (Yang and Eisenstein, 2015), which tries to simultaneously transfer the knowledge to multiple target domains from a single source. However, it cannot fully take advantage the training data if it comes from multiple source domains. **MS,ST** adaptation (Mansour et al., 2009; Zhao et al., 2017) can deal with multiple source domains but only transfers to a single target domain. Therefore, when multiple target domains exist, they need to treat them as independent problems, which is more expensive and cannot utilize the additional unlabeled data in these domains. Finally, MDTC can be viewed as **MS,MT** adaptation, which is arguably more general and realistic.

Adversarial Networks The idea of adversarial networks was proposed by Goodfellow et al. (2014) for image generation, and has been applied to various NLP tasks as well (Chen et al., 2016; Yu et al., 2017). Ganin et al. (2016) first used it for the **SS,ST** domain adaptation followed by many others. Bousmalis et al. (2016) utilized adversarial training in a shared-private model for domain adaptation to learn domain-invariant features, but still focused on the **SS,ST** setting. Finally, the idea of using adversarial nets to discriminate over multiple distributions was empirically explored by a very recent work (Liu et al., 2017) under the multi-task learning setting, and can be considered as a special case of our MAN framework with the NLL domain loss. We propose MAN as a more general framework with alternative architectures for the adversarial component, and for the first time

provide theoretical justifications the multinomial adversarial nets. Moreover, Liu et al. (2017) used a LSTM without attention as their feature extractor, which we found to perform sub-optimal in the experiments. We instead chose Convolutional Neural Nets as our feature extractor that achieves higher accuracy while running an order of magnitude faster (see §4.3).

7 Conclusion

In this work, we propose a family of Multinomial Adversarial Networks (MANs) that generalize the traditional binomial adversarial nets in the sense that MAN can simultaneously minimize the difference among multiple probability distributions instead of just two. We provide theoretical justifications for two instances of MAN, MAN-NLL and MAN-L2, showing they are minimizers of two different f-divergence metrics among multiple distributions, respectively. This indicates MAN can be used to make multiple distributions indistinguishable from one another. It can hence be applied to a variety of tasks, similar to the versatile binomial adversarial nets, which have been used in many areas for making *two* distributions alike.

In this paper, we design a MAN model for the MDTC task, following the shared-private paradigm that has a shared feature extractor to learn domain-invariant features and domain feature extractors to learn domain-specific ones. MAN is used to enforce the shared feature extractor to learn only domain-invariant knowledge, by resorting to MAN's power of making indistinguishable the shared feature distributions of samples from each domain. We conduct extensive experiments, demonstrating our MAN model outperforms the prior art systems in MDTC, and achieves state-of-the-art performance on domains without labeled data when compared to multi-source domain adaptation methods.

Appendix A Proofs

A.1 Proofs for MAN-NLL

Assume we have N domains, consider the distribution of the shared features $\mathcal{F}_s$ for instances in each domain d_i:

$$P_i(\mathbf{f}) \triangleq P(\mathbf{f} = \mathcal{F}_s(x) | x \in d_i)$$

The objective that $\mathcal{D}$ attempts to minimize is:

$$J_{\mathcal{D}} = -\sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} [\log \mathcal{D}_i(\mathbf{f})] \tag{12}$$

where $\mathcal{D}_i(\mathbf{f})$ is the i-th dimension of $\mathcal{D}$'s output vector, which conceptually corresponds to the softmax probability of $\mathcal{D}$ predicting that $\mathbf{f}$ is from domain d_i. We therefore have property that for any $\mathbf{f}$:

$$\sum_{i=1}^{N} \mathcal{D}_i(\mathbf{f}) = 1 \tag{13}$$

Lemma 1. *For any fixed $\mathcal{F}_s$, the optimum domain discriminator $\mathcal{D}^*$ is:*

$$\mathcal{D}_i^*(\mathbf{f}) = \frac{P_i(\mathbf{f})}{\sum_{j=1}^{N} P_j(\mathbf{f})} \tag{14}$$

Proof. For a fixed $\mathcal{F}_s$, the optimum

$$\begin{aligned}
\mathcal{D}^* = \arg\min_{\mathcal{D}} J_{\mathcal{D}} &= \arg\min_{\mathcal{D}} -\sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} [\log \mathcal{D}_i(\mathbf{f})] \\
&= \arg\max_{\mathcal{D}} \sum_{i=1}^{N} \int_{\mathbf{f}} P_i(\mathbf{f}) \log \mathcal{D}_i(\mathbf{f}) d\mathbf{f} \\
&= \arg\max_{\mathcal{D}} \int_{\mathbf{f}} \sum_{i=1}^{N} P_i(\mathbf{f}) \log \mathcal{D}_i(\mathbf{f}) d\mathbf{f}
\end{aligned}$$

We employ the Lagrangian Multiplier to derive $\arg\max_{\mathcal{D}} \sum_{i=1}^{N} P_i(\mathbf{f}) \log \mathcal{D}_i(\mathbf{f})$ under the constraint of (13). Let

$$L(\mathcal{D}_1, \ldots, \mathcal{D}_N, \lambda) = \sum_{i=1}^{N} P_i \log \mathcal{D}_i - \lambda(\sum_{i=1}^{N} \mathcal{D}_i - 1)$$

Let $\nabla L = 0$:

$$\begin{cases} \nabla_{\mathcal{D}_i} \sum_{j=1}^{N} P_j \log \mathcal{D}_j = \lambda \nabla_{\mathcal{D}_i} (\sum_{j=1}^{N} \mathcal{D}_j - 1) \quad (\forall i) \\ \sum_{i=1}^{N} \mathcal{D}_i - 1 = 0 \end{cases}$$

Solving the two equations, we have:

$$\mathcal{D}_i^*(\mathbf{f}) = \frac{P_i(\mathbf{f})}{\sum_{j=1}^{N} P_j(\mathbf{f})}$$

□

On the other hand, the loss function of the shared feature extractor $\mathcal{F}_s$ consists of two additive components, the loss from the text classifier $\mathcal{C}$, and the loss from the domain discriminator $\mathcal{D}$:

$$J_{\mathcal{F}_s} = J_{\mathcal{F}_s}^{\mathcal{C}} + \lambda J_{\mathcal{F}_s}^{\mathcal{D}} \triangleq J_{\mathcal{C}} - \lambda J_{\mathcal{D}} \tag{15}$$

We have the following theorem for the domain loss for $\mathcal{F}_s$:

Theorem 1. *When $\mathcal{D}$ is trained to its optimality:*

$$J_{\mathcal{F}_s}^{D} = -J_{\mathcal{D}^*} = -N \log N + N \cdot JSD(P_1, P_2, \ldots, P_N) \tag{16}$$

where $JSD(\cdot)$ is the generalized Jensen-Shannon Divergence (Lin, 1991) among multiple distributions.

Proof. Let $\overline{P} = \frac{\sum_{i=1}^{N} P_i}{N}$.

There are two equivalent definitions of the generalized Jensen-Shannon divergence: the original definition based on Shannon entropy (Lin, 1991), and a reshaped one expressed as the average Kullback-Leibler divergence of each P_i to the centroid $\overline{P}$ (Aslam and Pavlu, 2007). We adopt the latter one here:

$$JSD(P_1, P_2, \ldots, P_N) \triangleq \frac{1}{N} \sum_{i=1}^{N} KL(P_i \| \overline{P}) = \frac{1}{N} \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} \left[\log \frac{P_i(\mathbf{f})}{\overline{P}(\mathbf{f})} \right] \tag{17}$$

Now substituting $\mathcal{D}^*$ into $J_{\mathcal{F}_s}^{\mathcal{D}}$:

$$\begin{aligned}
J_{\mathcal{F}_s}^{\mathcal{D}} = -J_{\mathcal{D}^*} &= \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} \left[\log \mathcal{D}_i^*(\mathbf{f}) \right] \\
&= \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} \left[\log \frac{P_i(\mathbf{f})}{\sum_{j=1}^{N} P_j(\mathbf{f})} \right] \\
&= -N \log N + \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} \left[\log \frac{P_i(\mathbf{f})}{\sum_{j=1}^{N} P_j(\mathbf{f})} + \log N \right] \\
&= -N \log N + \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} \left[\log \frac{P_i(\mathbf{f})}{\frac{\sum_{j=1}^{N} P_j(\mathbf{f})}{N}} \right] \\
&= -N \log N + \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} \left[\log \frac{P_i(\mathbf{f})}{\overline{P}} \right] \\
&= -N \log N + \sum_{i=1}^{N} KL(P_i \| \overline{P}) \\
&= -N \log N + N \cdot JSD(P_1, P_2, \ldots, P_N)
\end{aligned}$$

□

Consequently, by the non-negativity of JSD (Lin, 1991), we have the following corollary:

Corollary 1. *The optimum of $J_{\mathcal{F}_s}^{\mathcal{D}}$ is $-N \log N$, and is achieved if and only if $P_1 = P_2 = \cdots = P_N = \overline{P}$.*

A.2 Proofs for MAN-L2

The proof is similar for MAN with the L2 loss. The loss function used by $\mathcal{D}$ is, for a sample from domain d_i with shared feature vector $\mathbf{f}$:

$$\mathcal{L}_{\mathcal{D}}(\mathcal{D}(\mathbf{f}), i) = \sum_{j=1}^{N} (\mathcal{D}_j(\mathbf{f}) - \mathbb{1}_{\{i=j\}})^2 \tag{18}$$

So the objective that $\mathcal{D}$ minimizes is:

$$J_{\mathcal{D}} = \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f} \sim P_i} \left[\sum_{j=1}^{N} (\mathcal{D}_j(\mathbf{f}) - \mathbb{1}_{\{i=j\}})^2 \right] \tag{19}$$

For simplicity, we further constrain $\mathcal{D}$'s outputs to be on a simplex:

$$\sum_{i=1}^{N} \mathcal{D}_i(\mathbf{f}) = 1 \quad (\forall \mathbf{f}) \tag{20}$$

Lemma 2. *For any fixed $\mathcal{F}_s$, the optimum domain discriminator $\mathcal{D}^*$ is:*

$$\mathcal{D}_i^*(\mathbf{f}) = \frac{P_i(\mathbf{f})}{\sum_{j=1}^{N} P_j(\mathbf{f})} \tag{21}$$

Proof. For a fixed $\mathcal{F}_s$, the optimum

$$\begin{aligned}
\mathcal{D}^* = \arg\min_{\mathcal{D}} J_{\mathcal{D}} &= \arg\min_{\mathcal{D}} \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f}\sim P_i} \left[\mathcal{L}_{\mathcal{D}}(\mathcal{D}(\mathbf{f}), i)\right] \\
&= \arg\min_{\mathcal{D}} \sum_{i=1}^{N} \int_{\mathbf{f}} P_i(\mathbf{f}) \mathcal{L}_{\mathcal{D}}(\mathcal{D}(\mathbf{f}), i) d\mathbf{f} \\
&= \arg\min_{\mathcal{D}} \int_{\mathbf{f}} \sum_{i=1}^{N} P_i(\mathbf{f}) \sum_{j=1}^{N} (\mathcal{D}_j(\mathbf{f}) - \mathbb{1}_{\{i=j\}})^2 d\mathbf{f}
\end{aligned}$$

Similar to MAN-NLL, we employ the Lagrangian Multiplier to derive $\arg\max_{\mathcal{D}} \sum_{i=1}^{N} P_i(\mathbf{f}) \sum_{j=1}^{N} (\mathcal{D}_j(\mathbf{f}) - \mathbb{1}_{\{i=j\}})^2$ under the constraint of (20). Let $\nabla L = 0$:

$$\begin{cases} 2((\sum_{j=1}^{N} P_j)\mathcal{D}_i - P_i) = \lambda \quad (\forall i) \\ \sum_{i=1}^{N} \mathcal{D}_i - 1 = 0 \end{cases}$$

Solving the two equations, we have $\lambda = 0$ and:

$$\mathcal{D}_i^*(\mathbf{f}) = \frac{P_i(\mathbf{f})}{\sum_{j=1}^{N} P_j(\mathbf{f})}$$

□

For the domain loss of $\mathcal{F}_s$:

Theorem 2. *Let $\overline{P} = \frac{\sum_{i=1}^{N} P_i}{N}$. When $\mathcal{D}$ is trained to its optimality:*

$$\begin{aligned}
J_{\mathcal{F}_s}^{\mathcal{D}} &= \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f}\sim P_i} \left[\sum_{j=1}^{N} (D_j(\mathbf{f}) - \frac{1}{N})^2\right] \\
&= \frac{1}{N} \sum_{i=1}^{N} \chi^2_{Neyman}(P_i \| \overline{P})
\end{aligned} \tag{22}$$

where $\chi^2_{Neyman}(\cdot\|\cdot)$ is the Neyman χ^2 divergence (Nielsen and Nock, 2014).

Proof. Substituting $\mathcal{D}^*$ into $\mathcal{L}^{\mathcal{D}}_{\mathcal{F}_s}$:

$$
\begin{aligned}
J^{\mathcal{D}}_{\mathcal{F}_s} &= \sum_{i=1}^{N} \mathop{\mathbb{E}}_{\mathbf{f}\sim P_i} \left[\sum_{j=1}^{N} (D^*_j(\mathbf{f}) - \frac{1}{N})^2 \right] \\
&= \sum_{i=1}^{N} \int_{\mathbf{f}} P_i \sum_{j=1}^{N} (\frac{P_j}{N\overline{P}} - \frac{1}{N})^2 d\mathbf{f} \\
&= \int_{\mathbf{f}} \sum_{i=1}^{N} \sum_{j=1}^{N} P_i (\frac{P_j}{N\overline{P}} - \frac{1}{N})^2 d\mathbf{f} \\
&= \frac{1}{N^2} \sum_{j=1}^{N} \int_{\mathbf{f}} \sum_{i=1}^{N} P_i (\frac{P_j}{\overline{P}} - 1)^2 d\mathbf{f} \\
&= \frac{1}{N^2} \sum_{j=1}^{N} \int_{\mathbf{f}} N\overline{P} (\frac{P_j}{\overline{P}} - 1)^2 d\mathbf{f} \\
&= \frac{1}{N} \sum_{j=1}^{N} \int_{\mathbf{f}} \frac{(P_j - \overline{P})^2}{\overline{P}} d\mathbf{f} \\
&= \frac{1}{N} \sum_{i=1}^{N} \chi^2_{Neyman}(P_i \| \overline{P})
\end{aligned}
$$

□

Finally, by the joint convexity of f-divergence, we have the following corollary:

Corollary 2.

$$
\begin{aligned}
\mathcal{L}^{\mathcal{D}}_{\mathcal{F}_s} &= \frac{1}{N} \sum_{i=1}^{N} \chi^2_{Neyman}(P_i \| \overline{P}) \\
&\geq \chi^2_{Neyman}(\frac{1}{N} \sum_{i=1}^{N} P_i \| \frac{1}{N} \sum_{i=1}^{N} \overline{P}) \\
&= \chi^2_{Neyman}(\overline{P} \| \overline{P}) = 0
\end{aligned}
$$

and the equality is attained if and only if $P_1 = P_2 = \cdots = P_N = \overline{P}$.

Pivot Based Language Modeling for Improved Neural Domain Adaptation

Yftah Ziser and **Roi Reichart**
Faculty of Industrial Engineering and Management, Technion, IIT
syftah@campus.technion.ac.il, roiri@ie.technion.ac.il

Abstract

Representation learning with pivot-based methods and with Neural Networks (NNs) have lead to significant progress in domain adaptation for Natural Language Processing. However, most previous work that follows these approaches does not explicitly exploit the structure of the input text, and its output is most often a single representation vector for the entire text. In this paper we present the *Pivot Based Language Model (PBLM)*, a representation learning model that marries together pivot-based and NN modeling in a structure aware manner. Particularly, our model processes the information in the text with a sequential NN (LSTM) and its output consists of a context-dependent representation vector for every input word. Unlike most previous representation learning models in domain adaptation, PBLM can naturally feed structure aware text classifiers such as LSTM and CNN. We experiment with the task of cross-domain sentiment classification on 20 domain pairs and show substantial improvements over strong baselines.[1]

1 Introduction

Domain adaptation (*DA*, (Daumé III, 2007; Ben-David et al., 2010)) is a fundamental challenge in NLP, due to the reliance of many algorithms on costly labeled data which is scarce in many domains. To save annotation efforts, DA aims to import algorithms trained with labeled data from one or several domains to new ones. While DA algorithms have long been developed for many tasks and domains (e.g. (Jiang and Zhai, 2007; McClosky et al., 2010; Titov, 2011; Bollegala et al., 2011; Rush et al., 2012; Schnabel and Schütze, 2014)), the unprecedented growth of heterogeneous online content calls for more progress.

DA through Representation Learning (DReL), where the DA method induces shared representations for the examples in the source and the target domains, has become prominent in the Neural Network (NN) era. A seminal (non-NN) DReL work is structural correspondence learning (SCL) (Blitzer et al., 2006, 2007) which models the connections between pivot features – features that are frequent in the source and the target domains and are highly correlated with the task label in the source domain – and the other, non-pivot, features. While this approach explicitly models the correspondence between the source and the target domains, it has been outperformed by NN-based models, particularly those based on autoencoders (AEs, (Glorot et al., 2011; Chen et al., 2012)) which employ compress-based noise reduction to extract features that empirically support domain adaptation. Recently, Ziser and Reichart (2017) (ZR17) proposed to marry these approaches. They have presented the autoencoder-SCL models and demonstrated their superiority over a large number of previous approaches, particularly those that employ pivot-based ideas only or NNs only.

Current DReL methods, however, suffer from a fundamental limitation: they ignore the structure of their input text (usually sentence or document). This is reflected both in the way they represent their input text, typically with a single vector whose coordinates correspond to word counts or indicators across the text, and in their output which typically consists of a single vector representation. This structure-indifferent approach stands in a sharp contrast to numerous NLP algorithms where text structure plays a key role.

Moreover, learning a single feature vector per

[1] Our code is publicly available at: https://github.com/yftah89/PBLM-Domain-Adaptation.

Proceedings of NAACL-HLT 2018, pages 1241–1251
New Orleans, Louisiana, June 1 - 6, 2018.

input example, these methods can feed only task classifiers such as SVM and feed-forward NNs that take a single vector as input, but cannot feed sequential (e.g. RNNs and LSTMs (Hochreiter and Schmidhuber, 1997)) or convolution (CNNs (LeCun et al., 1998)) networks that require an input vector per word or sentence in their input. This may be a serious limitation given the excellent performance of structure aware models in a large variety of NLP tasks, including sentiment analysis and text classification (e.g.(Kim, 2014; Yogatama et al., 2017)) - prominent DA evaluation tasks.

Fig. 1 demonstrates the limitation of structure-indifferent modeling in DA for sentiment analysis. While the example review contains more positive pivot features (see definition in Sec. 2), the sentiment expressed in the review is negative. A representation learning method should encode the review structure (e.g. the role of the terms *at first* and *However*) in order to uncover the sentiment.[2]

In this paper we overcome these limitations. We present (Section 3) the *Pivot Based Language Model (PBLM)* - a domain adaptation model that (a) is aware of the structure of its input text; and (b) outputs a representation vector for every input word. Particularly, the model is a sequential NN (LSTM) that operates very similarly to LSTM language models (LSTM-LMs). The fundamental difference is that while for every input word LSTM-LMs output a hidden vector and a prediction of the next word, the output of PBLM is a hidden vector and a prediction of the next word if that word is a pivot feature or else, a generic NONE tag. Hence, PBLM not only exploits the sequential nature of its input text, but its output states can naturally feed LSTM and CNN task classifiers. Notice that PBLM is very flexible: instead of pivot based unigram prediction it can be defined to predict pivots of arbitrary length (e.g. the next bigram or trigram), or, alternatively, it can be defined over sentences or other textual units instead of words.

Following a large body of DA work, we experiment (Section 5) with the task of binary sentiment classification. We consider adaptation between each domain pair in the four product review domains of Blitzer et al. (2007) (12 domain pairs) as well as between these domains and an airline review domain (Nguyen, 2015) and vice versa (8 domain pairs). The latter 8 setups are particularly challenging as the airline reviews tend to be more negative than the product reviews (see Section 4).

[2]Pivots are defined with respect to a (source, target) domain pair. The pivots highlighted in the figure are the pivots for this review in all the setups we explored.

> I was *at first* **very excited** with my new Zyliss salad spinner - it is easy to spin and looks **great** ... . *However*, ... it doesn't get your greens very dry. I've been surprised and **disappointed** by the amount of water left on lettuce after spinning, and spinning, and spinning.

Figure 1: Example review from the kitchen appliances domain of Blitzer et al. (2007). Positive pivot features are underlined with a wavy line. Negative pivot features are underlined with a straight line. Although there are more positive pivots than negative ones, the review is negative.

We implement PBLM with two task classifiers, LSTM and CNN, and compare them to strong previous models, among which are: SCL (pivot based, no NN), the marginalized stacked denoising autoencoder model (MSDA, (Chen et al., 2012) - AE based, no pivots), the MSDA-DAN model ((Ganin et al., 2016) - AE with a Domain Adversarial Network (DAN) enhancement) and AE-SCL-SR (the best performing model of ZR17, combining AEs, pivot information and pre-trained word vectors). PBLM-LSTM and PBLM-CNN perform very similarly to each other and strongly outperform previous models. For example, PBLM-CNN achieves averaged accuracies of 80.4%, 84% and 76.2% in the 12 product domain setups, 4 product to airline setups and 4 airline to product setups, respectively, while AE-SCL-SR, the best baseline, achieves averaged accuracies of 78.1%, 78.7% and 68.1%, respectively.

2 Background and Previous Work

DA is an established challenge in machine learning in general and in NLP in particular (e.g. (Roark and Bacchiani, 2003; Chelba and Acero, 2004; Daumé III and Marcu, 2006)). While DA has several setups, the focus of this work is on unsupervised DA. In this setup we have access to unlabeled data from the the source and the target domains, but labeled data is available in the source domain only. We believe that in the current web era with the abundance of text from numerous domains, this is the most realistic setup.

Several approaches to DA have been proposed, for example: instance reweighting (Huang et al., 2007; Mansour et al., 2009), sub-sampling from

both domains (Chen et al., 2011) and learning joint target and source feature representations (DReL), the approach we take here. The rest of this section hence discusses DReL work that is relevant to our ideas, but first we describe our problem setup.

Unsupervised Domain Adaptation with DReL The pipeline of this setup typically consists of two steps: representation learning and classification. In the first step, a representation model is trained on the unlabeled data from the source and target domains. In the second step, a classifier for the supervised task is trained on the source domain labeled data. To facilitate domain adaptation, every example that is fed to the task classifier (second step) is first represented by the representation model of the first step. This is true both when the task classifier is trained and at test time when it is applied to the target domain.

An exception of this pipeline are end-to-end models that jointly learn to represent the data and to perform the classification task, exploiting the unlabeled and labeled data together. A representative member of this class of models (MSDA-DAN, (Ganin et al., 2016)) is one of our baselines.

Pivot Based Domain Adaptation This approach was proposed by Blitzer et al. (2006, 2007), through their SCL method. Its main idea is to divide the shared feature space of the source and the target domains to a set of pivot features that are frequent in both domains and have a strong impact on the source domain task classifier, and a complementary set of non-pivot features.

In SCL, after the original feature set is divided into the pivot and non-pivot subsets, this division is utilized in order to map the original feature space of both domains into a shared, low-dimensional, real-valued feature space. To do so, a binary classifier is defined for each of the pivot features. This classifier takes the non-pivot features of an input example as its representation, and is trained on the unlabeled data from both the source and the target domains, to predict whether its associated pivot feature appears in the example or not. Note that no human annotation is required for the training of these classifiers, the supervision signal is in the unlabeled data. The matrix whose columns are the weight vectors of the classifiers is post-processed with singular value decomposition (SVD) and the derived matrix maps feature vectors from the original space to the new.

Since the presentation of SCL, pivot-based DA has been researched extensively (e.g. (Pan et al., 2010; Gouws et al., 2012; Bollegala et al., 2015; Yu and Jiang, 2016; Ziser and Reichart, 2017)). PBLM is a pivot-based method but, in contrast to previous models, it relies on sequential NNs to exploit the structure of the input text. Even models such as (Bollegala et al., 2015), that embed pivots and non-pivots so that the former can predict if the latter appear in their neighborhood, learn a single representation for all the occurrences of a word in the input corpus. That is, Bollegala et al. (2015), as well as other methods that learn cross-domain word embeddings (Yang et al., 2017), learn word-type representations, rather than context specific representations. In Sec. 3 we show how PBLM's context specific outputs naturally feed structure aware task classifiers such as LSTM and CNN.

AE Based Domain Adaptation The basic elements of an autoencoder are an encoder function e and a decoder function d, and its output is a reconstruction of its input x: $r(x) = d(e(x))$. The parameters of the model are trained to minimize a loss between x and $r(x)$, such as their Kullback-Leibler (KL) divergence or their cross entropy.

Variants of AEs are prominent in recent DA literature. Examples include Stacked Denoising Autoencoders (SDA, (Vincent et al., 2008; Glorot et al., 2011) and marginalized SDA (MSDA, (Chen et al., 2012)) that is more computationally efficient and scalable to high-dimensional feature spaces than SDA, and has been extended in various manners (e.g. (Yang and Eisenstein, 2014; Clinchant et al., 2016)). Finally, models based on variational autoencoders (Kingma and Welling, 2014; Rezende et al., 2014) have recently been applied in DA (e.g. variational fair autoencoder (Louizos et al., 2016)), but in our experiments they were still not competitive with MSDA.

While AE based models have set a new state-of-the-art for DA in NLP, they are mostly based on noise reduction in the representation and do not exploit task specific and linguistic information. This paved the way for ZR17 that integrated pivot-based ideas into domain adaptation with AEs.

Combining Pivots and AEs in Domain Adaptation ZR17 combined AEs and pivot-based modeling for DA. Their basic model (AE-SCL) is a three layer feed-forward network where the non-pivot features are fed to the input layer, encoded

into a hidden representation and this hidden representation is then decoded into the pivot features of the input example. Their advanced model (AE-SCL-SR) has the same architecture but the decoding matrix consists of pre-trained embeddings of the pivot features, which encourages input documents with similar pivots to have similar hidden representations. These embeddings are induced by word2vec (Mikolov et al., 2013) trained with unlabeled data from the source and the target domains.

ZR17 have demonstrated the superiority of their models (especially, AE-SCL-SR) over SCL (pivot-based, no AE), MSDA (AE-based, no pivots) and MSDA-DAN (AE-based with adversarial enhancement, no pivots) in 16 cross-domain sentiment classification setups, including the 12 legacy setups of Blitzer et al. (2007). However, as in previous pivot based methods, AE-SCL and AE-SCL-SR learn a single, structure-indifferent, feature representation of the input text. Our core idea is to implement a pivot-based sequential neural model that exploits the structure of its input text and that its output representations can be smoothly integrated with structure aware classifiers such as LSTM and CNN. Our second goal is motivated by the strong performance of LSTM and CNN in text classification tasks (Yogatama et al., 2017).

3 Domain Adaptation with PBLMs

We now introduce our PBLM model that learns representations for DA. As PBLM is inspired by language modeling, we assume the original feature set of the NLP task classifier consists of word unigrams and bigrams. This choice of features also allows us to directly compare our work to the rich literature on DA for sentiment classification where this is the standard feature set. PBLM, however, is not limited to word n-gram features.

We start with a brief description of LSTM based language modeling (LSTM-LM, (Mikolov et al., 2010)) and then describe how PBLM modifies that model in order to learn pivot-based representations that are aware of the structure of the input text. We then show how to employ these representations in structure aware text classification (with LSTM or CNN) and how to train such PBLM-LSTM and PBLM-CNN classification pipelines.

LSTM Language Modeling LSTMs address the vanishing gradient problem commonly found in RNNs (Elman, 1990) by incorporating gating functions into their state dynamics (Hochreiter and Schmidhuber, 1997). At each time step, an LSTM maintains a hidden vector, h_t, computed in a sequence of non-linear transformations of the input x_t and the previous hidden states $h_1, \ldots, h_{t-1}$.

Given an input word, an LSTM-LM should predict the next word in the sequence. For a lexicon V, the probability of the j-th word is:

$$p(y_t = j) = \frac{e^{h_t \cdot W_j}}{\sum_{k=1}^{|V|} e^{h_t \cdot W_k}}$$

Here, W_i is a parameter vector learned by the network for each of the words in the vocabulary. The loss function we consider in this paper is the cross-entropy loss over these probabilities.

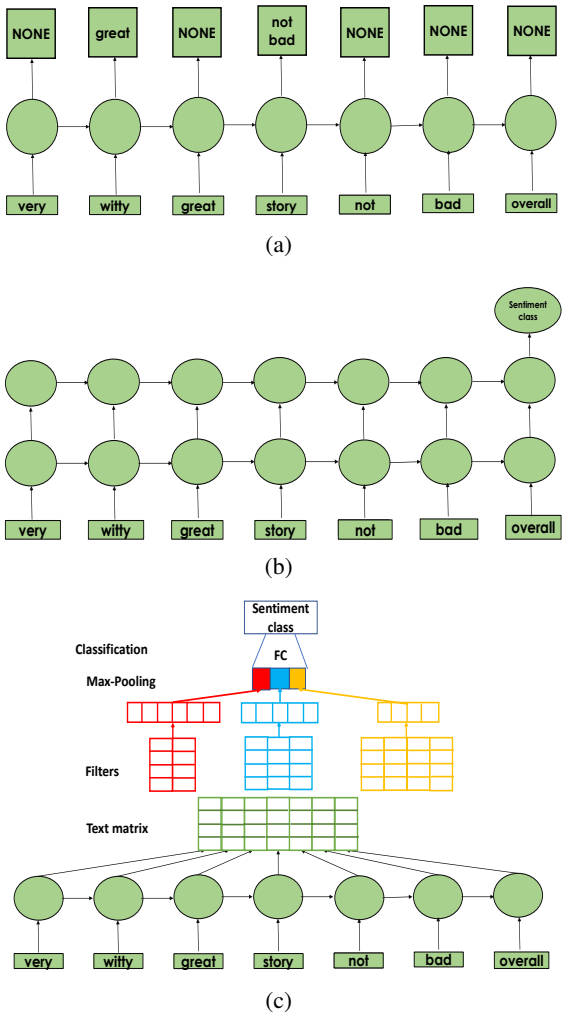

Figure 2: (a) Second order PBLM for representation learning. (b+c) PBLM based models for DA: PBLM-LSTM (b) and PBLM-CNN (c).

Representation Learning with PBLM Figure 2a provides an illustration of the PBLM model. The first (bottom) layer is an embedding layer,

where a 1-hot word vector input is multiplied by a (randomly initialized) parameter matrix before being passed to the next layer. The second layer is an LSTM that predicts the next bigram or unigram if one of these is a pivot (if both are, it predicts the bigram). Otherwise its prediction is NONE.

PBLM operates similarly to LSTM-LM. The basic difference between the models is the prediction they make for a given input word (x_t). While an LSTM-LM aims to predict the next input word, PBLM predicts the next word unigram or bigram if one of these is a pivot, and NONE otherwise.

PBLM is very flexible. It can be of any order: a k-order PBLM predicts the longest prefix of the sequence consisting of the next k words, as long as that prefix forms a pivot. If none of the prefixes forms a pivot then PBLM predicts NONE.[3] Moreover, while PBLM is defined here over word sequences, it can be defined over other sequences, e.g., the sentence sequence of a document.

Intuitively, in the example of fig. 2a a second order model is more informative for sentiment classification than a first-order model (that predicts only the next word unigram in case that word is a pivot) would be. Indeed, "not bad" conveys the relevant sentiment-related information, while "bad" is misleading with respect to that same sentiment. Notice that after the prefix "very witty" the model predicts "great" and not "great story" because in this example "great" is a pivot while "great story" is not, as "great story" is unlikely to be frequent outside the book review domain.

Figures 2a and 1 also demonstrate a major advantage of PBLM over models that learn a single text representation. From the book review example in fig. 2a, PBLM learns the connection between *witty* - an adjective that is often used to describe books, but not kitchen appliances - and *great* - a common positive adjective in both domains, and hence a pivot feature. Likewise, from the example of fig. 1 PBLM learns the connection between *easy* - an adjective that is often used to describe kitchen appliances, but not books - and *great*. That is, PBLM is able to learn the connection between *witty* and *easy* which will facilitate adaptation between the books and kitchen appliances domains. Previous work that learns a single text representation, in contrast, would learn from fig. 1 a connection between *easy* and the three pivots: *very excited*, *great* and *disappointed*. From fig. 2a such a method would learn the connection between *witty* and *great* and *not bad*. The connection between *witty* and *easy* will be much weaker.

Structure Aware Classification with PBLM Representations PBLM not only exploits the sequential nature of its input text, but its output vectors can feed LSTM (PBLM-LSTM, fig. 2b) and CNN (PBLM-CNN, fig. 2c) classifiers.

PBLM-LSTM is a three-layer model. The bottom two layers are the PBLM model of fig. 2a. When PBLM is combined with a classifier, its softmax layer (top layer of fig. 2a) is cut and only its output vectors (h_t) are passed to the next LSTM layer (third layer of fig. 2b). The final hidden vector of that layer feeds the task classifier.

Note that since we cut the PBLM softmax layer when it is combined with the task classifier, PBLM should be trained before this combination is performed. Below we describe how we exploit this modularity to facilitate domain adaptation.

In PBLM-CNN, the combination between the PBLM and the CNN is similar to fig. 2b: the PBLM's softmax layer is cut and a matrix whose columns are the h_t vectors of the PBLM is passed to the CNN. We employ K different filters of size $|h_t| \times d$, each going over the input matrix in a sliding window of d consecutive hidden vectors, and generating a $1 \times (n-d+1)$ size vector, where n is the input text length. A max pooling is performed for each of the k vectors to generate a single $1 \times K$ vector that is fed into the task classifier.

PBLM can feed structure aware classifiers other than LSTM and CNN. Moreover, PBLM can also generate a single text representation as in most previous work. This can be done, e.g., by averaging the PBLM's hidden vectors and feeding the averaged vector into a linear non-structured classifier (e.g. logistic regression) or a feed-forward NN. In Sec. 5 we demonstrate that PBLM's ability to feed structure aware classifiers such as LSTM and CNN provides substantial accuracy gains. To the best of our knowledge, PBLM is unique in its structure aware representation: previous work generated one representation per input example.

Domain Adaptation with PBLM Representations We focus on unsupervised DA where the input consists of a source domain labeled set and a plentiful of unlabeled examples form the source and the target domains. Our goal is to use the unlabeled data as a bridge between the domains.

[3] A word sequence is one of its own prefixes.

Our fundamental idea is to decouple the PBLM training which requires only unlabeled text, from the NLP classification task which is supervised and for which the required labeled example set is available only for the source domain. We hence employ a two step training procedure. First PBLM (figure 2a) is trained with unlabeled data from both the source and the target domains. Then the trained PBLM is combined with the classifier layers (top layer of fig. 2b, CNN layers of fig. 2c) and the final model is trained with the source domain labeled data to perform the classification task. As noted above, in the second step we cut the PBLM's softmax layer, only its h_t vectors are passed to the classifier. Moreover, during this step the parameters of the pre-trained PBLM are held fixed, only the parameters of the classifier layers are trained.

4 Experimental Setup

[4]**Task and Domains** Following a large body of DA work, we experiment with the task of cross-domain sentiment classification. To facilitate comparison with previous work we experiment with the product review domains of (Blitzer et al., 2007) – Books (B), DVDs (D), Electronic items (E) and Kitchen appliances (K) (12 ordered domain pairs) – replicating the experimental setup of ZR17 (including baselines, design, and hyper-parameter details). For each domain there are 2000 labeled reviews, 1000 positive and 1000 negative, and unlabeled reviews: 6000 (B), 34741 (D), 13153 (E) and 16785 (K).

To consider a more challenging setup we experiment with a domain consisting of user reviews on services rather than products. We downloaded an airline review dataset, consisting of reviews labeled by their authors (Nguyen, 2015). We randomly sampled 1000 positive and 1000 negative reviews for our labeled set, the remaining 39396 reviews form our unlabeled set. We hence have 4 product to airline and 4 airline to product setups.

Interestingly, in the product domains unlabeled reviews tend to be much more positive than in the airline domain. Particularly, in the B domain there are 6.43 positive reviews on every negative review; in D the ratio is 7.39 to 1; in E it is 3.65 to 1; and in K it is 4.61 to 1. In the airline domain there are only 1.15 positive reviews for every negative review. We hence expect DA from product to airline reviews and vice versa to be more challenging than DA from one product review domain to another.[5]

Baselines We consider the following baselines: (a) AE-SCL-SR (ZR17). We also experimented with the more basic AE-SCL but, like in ZR17, we got lower results in most cases; (b) SCL with pivot features selected using the mutual information criterion (SCL-MI, (Blitzer et al., 2007)). For this method we used the implementation of ZR17; (c) MSDA (Chen et al., 2012), with code taken from the authors' web page; (d) The MSDA-DAN model (Ganin et al., 2016) which employs a domain adversarial network (DAN) with the MSDA vectors as input. The DAN code is taken from the authors' repository; (e) The no domain adaptation case where the sentiment classifier is trained in the source domain and applied to the target domain without adaptation. For this case we consider three classifiers: logistic regression (denoted NoSt as it is not aware of its input's structure), as well as LSTM and CNN which provide a control for the importance of the structure aware task classifiers in PBLM models. To further control for this effect we compare to the PBLM-NoSt model where the PBLM output vectors (h_t vectors generated after each input word) are averaged and the averaged vector feeds the logistic regression classifier.[6]

In all the participating methods, the input features consist of word unigrams and bigrams. The division of the feature set into pivots and non-pivots is based on the the method of ZR17 that followed the work of Blitzer et al. (2007) (details are in Appendix C). The sentiment classifier employed with the SCL-MI, MSDA and AE-SCL-SR representations is the same logistic regression classifier as in the NoSt condition mentioned above. For these methods we concatenate the representation learned by the model with the original representation and this representation is fed to the classifier. MSDA-DAN jointly learns the feature representation and performs the sentiment classification task. It is hence fed by a concatenation of the original and the MSDA-induced representations.

[4]The URLs of the datasets and the code (previous models and standard packages) we used, are in Appendix A.

[5]While we have the labels for our unlabeled data, we did not use them in our research except in this analysis.

[6]We considered several additional baselines: (1) Variational fair autoencoder (Louizos et al., 2016) which performed substantially worse than the DA baselines ((a)-(d)); (2) We tried to compare to (Bollegala et al., 2015) but, similarly to ZR17, failed to replicate their results; and (3) We replaced PBLM with an LSTM-LM, but the results substantially degraded. We do not report results for these models.

Five Fold CV We employ a 5-fold cross-validation protocol as in (Blitzer et al., 2007; Ziser and Reichart, 2017). In all five folds 1600 source domain examples are randomly selected for training data and 400 for development, such that both the training and the development sets are balanced and have the same number of positive and negative reviews. The results we report are the averaged performance of each model across these 5 folds.

Hyperparameter Tuning For all previous models, we follow the tuning process described in ZR17 (paper and appendices). Hyperparameter tuning for the PBLM models and the non-adapted CNN and LSTM is described in Appendix B.

5 Results

Overall Results Table 1 presents our results. PBLM models with structure aware classifiers (PBLM-LSTM and PBLM-CNN, henceforth denoted together as S-PBLM) outperform all other alternatives in all 20 setups and three averaged evaluations (*All* columns in the tables). The gaps are quite substantial – the average accuracy of PBLM-LSTM and PBLM-CNN compared to the best baseline, AE-SCL-SR, are: 79.6% and 80.4% vs. 78.1% for the product review setups, 85% and 84% vs. 78.7% for the product to airline (service) review setups, and 76.1% and 76.2% vs. 68.1% for the airline to product review setups.

S-PBLM performance in the more challenging product to airline and airline to product setups are particularly impressive. The challenging nature of these setups stems from the presumably larger differences between product and service reviews and from the different distribution of positive and negative reviews in the unlabeled data of both domains (Sec. 4). These differences are reflected by the lower performance of the non-adapted classifiers: an averaged accuracy of 70.6%-73.1% across product domain pairs (three lower lines of the *All* column of the top table), compared to an average of 67.3%-69.9% across product to airline setups and an average of 61.3%-62.4% across airline to product setups. Moreover, while the best previous method (AE-SCL-SR) achieves an averaged accuracy of 78.1% for product domains and an averaged accuracy of 78.7% when adapting from product to airline reviews, when adapting from airline to product reviews its averaged accuracy drops to 68.1%. The S-PBLM models do consistently better in all three setups, with an averaged accuracy of 80.4%, 85% and 76.2% of the best S-PBLM model, respectively.

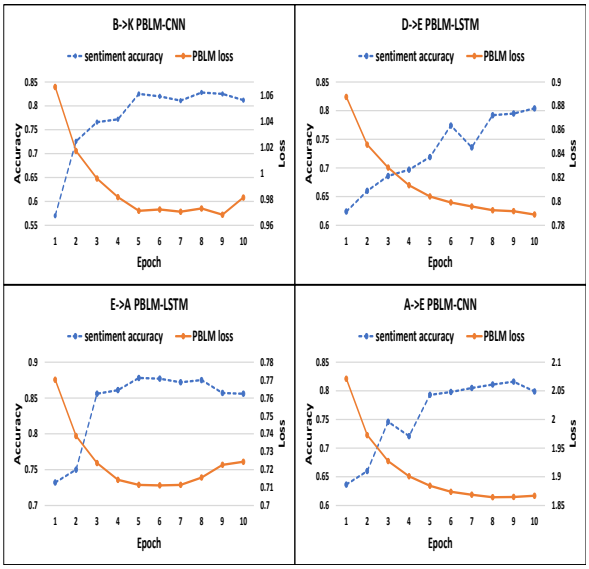

Figure 3: PBLM loss (solid, red line) vs. sentiment accuracy (dashed, blue line) of PBLM-CNN (top) and PBLM-LSTM (bottom) in four representative setups. Patterns in other setups are very similar.

Analysis of S-PBLM Strength The results shed light on the sources of the S-PBLM models success. The accuracy of these models, PBLM-LSTM and PBLM-CNN, is quite similar across setups: their accuracy gap is up to 3.1% in all 20 setups and up to 1% in the three averages (*All* columns). However, the S-PBLM models substantially outperform PBLM-NoSt that employs a structure-indifferent classifier. The averaged gaps are 5.6% (80.4% vs. 74.8%) in the product to product setups, 11.1% in the product to airline setups (85% vs. 73.9%) and 10.9% in the airline to product setups (76.2% vs. 65.3%). Hence, we can safely conclude that while the integration of PBLM with a structured task classifier has a dramatic impact on cross-domain accuracy, it is less important if that classifier is an LSTM or a CNN.

Comparison with non-adapted models reveals that structure aware modeling, as provided by LSTM and CNN, is not sufficient for high performance. Indeed, non-adapted LSTM and CNN do substantially worse than S-PBLM in all setups. Finally, comparison with AE-SCL-SR demonstrates that while the integration of pivot based learning with NNs leads to stronger results than in any other previous work, the structure awareness of the S-PBLM models substantially improves accuracy.

Table 1: Accuracy of adaption between product review domains (top table). and between product review domains and the airline (A) review domain (bottom table). All the differences between PBLM-CNN and AE-SCL-SR and between PBLM-LSTM and AE-SCL-SR are statistically significant (except from E-B in the former comparison and E-B and K-B in the latter). Statistical significance is computed with the McNemar paired test for labeling disagreements ((Gillick and Cox, 1989; Blitzer et al., 2006), $p < 0.05$).

Figure 3 further demonstrates the adequacy of the PBLM architecture for domain adaptation. The graphs demonstrate, for both S-PBLM models, a strong correlation between the PBLM cross-entropy loss values and the sentiment accuracy of the resulting PBLM-LSTM and PBLM-CNN models. We show these patterns for two product domain setups and two setups that involve a product domain and the airline domain – the patterns for the other setups of table 1 are very similar.

This analysis highlights our major contribution. We have demonstrated that it is the combination of four components that makes DA for sentiment classification very effective: (a) Neural network modeling; (b) Pivot based modeling; (c) Structure awareness of the pivot-based model; and (d) Structure awareness of the task classifier.

6 Conclusions

We addressed the task of DA in NLP and presented PBLM: a representation learning model that combines pivot-based ideas and NN modeling, in a structure aware manner. Unlike previous work, PBLM exploits the structure of its input, and its output consists of a vector per input word. PBLM-LSTM and PBLM-CNN substantially outperform strong previous models in traditional and newly presented sentiment classification DA setups.

In future we intend to extend PBLM so that it could deal with NLP tasks that require the prediction of a linguistic structure. For example, we believe that PBLM can be smoothly integrated with recent LSTM-based parsers (e.g. (Dyer et al., 2015; Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017)). We also intend to extend the reach of our approach to cross-lingual setups.

B Hyperparameter Tuning and Experimental Details

Hyperparameter Tuning As discussed in section 4 of the paper, for all previous work models, we follow the experimental setup of ZR17 (paper and appendices) including their hyperparameter estimation protocol. The hyperparameters of the PBLM models and the non-adapted CNN and LSTM are provided here. For PBLM we considered the following hyperparameteres:

- Input word embedding size: $(32, 64, 128, 256)$.
- Number of pivot features: $(100, 200, 300, 400, 500)$.
- $|h_t|$: $(128, 256, 512)$.
- PBLM model order: second order.

For the LSTM in PBLM-LSTM as well as the baseline non-adapted LSTM we considered the same $|h_t|$ and input word embedding size values as for PBLM. For PBLM-CNN and for the baseline, non-adapted, CNN we only experimented with $K = 250$ filters and with a kernel of size $d = 3$.

All the algorithms in the paper that involve a CNN or a LSTM (including the PBLM itself) are trained with the ADAM algorithm (Kingma and Ba, 2015). For this algorithm we used the parameters described in the original ADAM article:

- Learning rate: $lr = 0.001$.
- Exponential decay rate for the 1st moment estimates: $\beta_1 = 0.9$.
- Exponential decay rate for the 2nd moment estimates: $\beta_2 = 0.999$.
- Fuzz factor: $\epsilon = 1e - 08$.
- Learning rate decay over each update: $decay = 0.0$.

Experimental Details All sequential models considered in our experiments are fed with one review example at a time. For all models in the paper, punctuation is first removed from the text before it is processed by the model (sentence boundaries are still encoded). This is the only preprecessing step we employ in the paper.

We considered several alternative implementations of the PBLM-NoSt baseline. In the variant we selected the PBLM output vectors (h_t vectors generated after each word of the input review) are averaged and the averaged vector feeds a non-structured logistic regression classifier. We also tried to take only the final h_t vector of PBLM as an input to the classifier or to sum the h_t vectors instead of taking their average. These alternatives gave worse results.

C Pivot Feature Selection

As mentioned in the main paper, the division of the feature set into pivots and non-pivots is based on the unlabeled data from both the source and the target domains, using the method of ZR17 (which is in turn based on (Blitzer et al., 2007)). Here we provide the details of the pivot selection criterion.

Pivot features are frequent in the unlabeled data of both the source and the target domains, appearing at least 10 times in each, and among those features are the ones with the highest mutual information with the task (sentiment) label in the source domain labeled data. For non-pivot features we consider unigrams and bigrams that appear at least 10 times in their domain.

Abstract

Co-training is a popular semi-supervised learning framework to utilize a large amount of unlabeled data in addition to a small labeled set. Co-training methods exploit predicted labels on the unlabeled data and select samples based on prediction confidence to augment the training. However, the selection of samples in existing co-training methods is based on a predetermined policy, which ignores the sampling bias between the unlabeled and the labeled subsets, and fails to explore the data space. In this paper, we propose a novel method, Reinforced Co-Training, to select high-quality unlabeled samples to better co-train on. More specifically, our approach uses Q-learning to learn a data selection policy with a small labeled dataset, and then exploits this policy to train the co-training classifiers automatically. Experimental results on clickbait detection and generic text classification tasks demonstrate that our proposed method can obtain more accurate text classification results.

1 Introduction

Large labeled datasets are often required to obtain satisfactory performance for natural language processing tasks. However, it is time-consuming to label text corpus manually. In the meanwhile, there are abundant unlabeled text corpora available on the web. Semi-supervised methods permit learning improved supervised models by jointly train on a small labeled dataset and a large unlabeled dataset (Zhu, 2006; Chapelle et al., 2009).

Co-training is one of the widely used semi-supervised methods, where two complementary classifiers utilize large amounts of unlabeled examples to bootstrap the performance of each other iteratively (Blum and Mitchell, 1998; Nigam and Ghani, 2000). Co-training can be readily applied to NLP tasks since data in these tasks naturally have two or more views, such as multi-lingual data (Wan, 2009) and document data (headline and content) (Ghani, 2000; Denis et al., 2003). In the co-training framework, each classifier is trained on one of the two views (aka a subset of features) of both labeled and unlabeled data, under the assumption that either view is sufficient to classify. In each iteration, the co-training algorithm selects high confidence samples scored by each of the classifiers to form an auto-labeled dataset, and the other classifier is then updated with both labeled data and additional auto-labeled set. However, as shown in Figure 1, most of existing co-training methods have some disadvantages. Firstly, the sample selection step ignores distributional bias between the labeled and unlabeled sets. It is common in practice to use unlabeled datasets collected differently from the labeled set, resulting in a significant difference in their sample distribution. After iterative co-training, the sampling

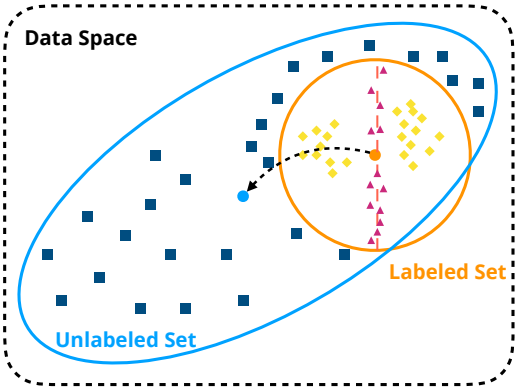

Figure 1: Illustration of sample-selection issues in co-training methods. (1) Randomly sampled unlabeled examples (□) will result in high sampling bias, which will cause bias shift towards the unlabeled dataset (←). (2) High-confidence examples (◇) will contribute little during the model training, especially for discriminating the boundary examples (△), resulting in myopic trained models.

Proceedings of NAACL-HLT 2018, pages 1252–1262
New Orleans, Louisiana, June 1 - 6, 2018.

bias may shift towards the unlabeled set, which results in poor performance of the trained model at the testing time. To remedy such bias, an ideal algorithm should select those samples according to the target (potentially unknown) testing distribution. Secondly, the existing sample selection and training can be myopic. Conventional co-training methods select unlabeled examples with high confidence predicted by trained models. This strategy often causes only those unlabeled examples that match well to the current model being picked during iteration and the model might fail to generalize to complete sample space (Zhang and Rudnicky, 2006). It relates to the well-known exploration-exploitation trade-off in machine learning tasks. An ideal co-training algorithm should explore the space thoroughly to achieve globally better performance. These intuitions inspire our work on learning a data selection policy for the unlabeled dataset in co-training.

The iterate data selection steps in co-training can be viewed as a sequential decision-making problem. To resolve both issues discussed above, we propose **Reinforced Co-Training**, a reinforcement learning (RL)-based framework for co-training. Concretely, we introduce a joint formulation of a Q-learning agent and two co-training classifiers. In contrast to previous predetermined data sampling methods of co-training, we design a Q-agent to automatically learn a data selection policy to select high-quality unlabeled examples. To better guide the policy learning of the Q-agent, we design a state representation to delivery the status of classifiers and utilize the validation set to compute the performance-driven rewards. Empirically, we indicate that our method outperforms previous related methods on clickbait detection and generic text classification problems. In summary, our main contributions are three-fold:

- We are first to propose a joint formulation of RL and co-training methods;
- Our learning algorithm can learn a good data selection policy to select high-quality unlabeled examples for better co-training;
- We show that our method can apply to large-scale document data and outperform baselines in semi-supervised text classification.

In Section 2, we outline related work in semi-supervised learning and co-training. We then describe our proposed method in Section 3. We show experimental results in Section 4. Finally, we conclude in Section 5.

2 Related Work

Semi-supervised learning algorithms have been widely used in NLP (Liang, 2005). As for text classification, Dai and Le (2015) introduce a sequence autoencoder to pre-train the parameters for the later supervised learning process. Johnson and Zhang (2015, 2016) propose a method to learn embeddings of small text regions from unlabeled data for integration into a supervised convolutional neural network (CNN) or long short-term memory network (LSTM). Miyato et al. (2016) further apply perturbations to the word embeddings and pre-train the supervised models through adversarial training. However, these methods mainly focus on learning the local word-level information and pre-trained parameters from unlabeled data, which fails to capture the overall text-level information and potential label information.

Co-training can capture the text-level information of unlabeled data and generate pseudo labels during the training, which is especially useful on unlabeled data with two distinct views (Blum and Mitchell, 1998). However, the confidence-based data selection strategies (Goldman and Zhou, 2000; Zhou and Li, 2005; Zhang and Zhou, 2011) often focus on some special regions of the input space and fail to generate an accurate estimation of data space. Zhang and Rudnicky (2006) proposes a performance-driven data selection strategy based on pseudo-accuracy and energy regularization. Meanwhile, Chawla and Karakoulas (2005) argues that the random data sampling method often causes sampling bias shift of the trained model towards the unlabeled set.

Comparing to previous related methods, our Reinforced Co-Training model can learn a performance-driven data selection policy to select high-quality unlabeled data. Furthermore, the performance estimation is more accurate due to the validation dataset and the data selection strategy is automatically learned instead of human designed. Lastly, the selected high-quality unlabeled data can not only help explore the data space but also reduce the sampling bias shift.

Our work is also related to recent studies in "learning to learn" (Maclaurin et al., 2015; Zoph and Le, 2016; Chen et al., 2017; Wichrowska et al., 2017; Yeung et al., 2017). Learning to learn

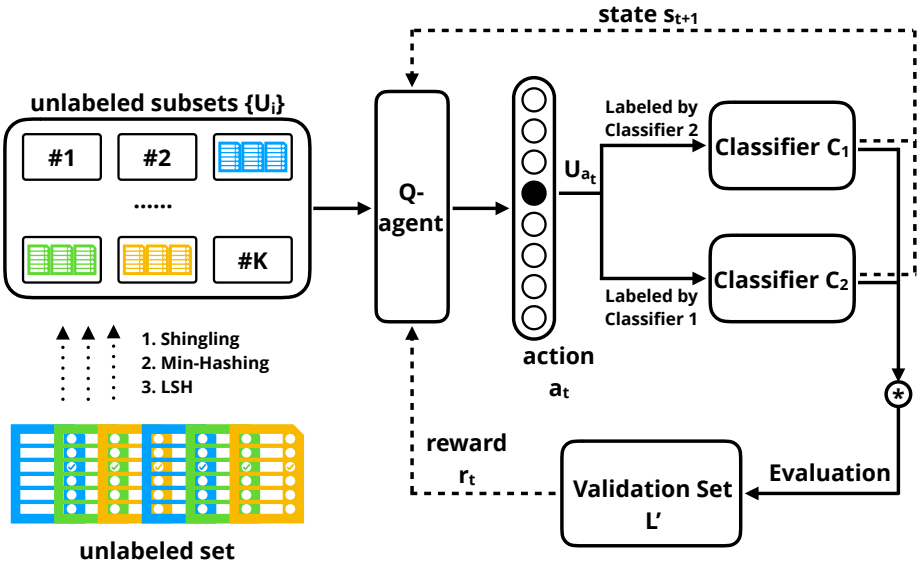

Figure 2: The Reinforced Co-Training framework.

is one of the meta-learning methods (Schmidhuber, 1987; Bengio et al., 1991), where one model is trained to learn how to optimize the parameters of another certain algorithm. While previous studies focus more on neural network optimization (Chen et al., 2017; Wichrowska et al., 2017) and few-shot learning (Vinyals et al., 2016; Ravi and Larochelle, 2016; Finn et al., 2017), we are first to explore how to learn a high-quality data selection policy in semi-supervised methods, in our case, the co-training algorithm.

3 Method

In this section, we describe our RL-based framework for co-training in detail. The conventional co-training methods follow the framework:

1. Initialize two classifiers by training on the labeled set;

2. Iteratively select a subset of unlabeled data based on a predetermined policy;

3. Iteratively update two classifiers with the selected subset of unlabeled data in addition to the labeled one.

Step 2 is the core of different co-training variants. The original co-training algorithm is equipped with a policy of selecting high-confidence samples by two classifiers. Our main idea is to improve the policy by reinforcement learning.

We formulate the data selection process as a sequential decision-making problem and the decision (action) a_t at each iteration (time step) t is to select a portion of unlabeled examples. This problem can be solved with an RL-agent by learning a policy. We first describe how we organize the large unlabeled dataset to improve the computational efficiency. Then we briefly introduce the classifier models used in co-training. After that, we describe the Q-agent, the RL-agent used in our framework and the environment in RL. The two co-training classifiers are integrated into the environment and the Q-agent can learn a good data selection policy by interacting with the environment. Finally, we describe how to train the Q-agent in our unified framework.

3.1 Partition Unlabeled Data

Considering that the number of unlabeled samples is enormous, it is not efficient for the RL-agent to select only one example at each time step t. Thus, first we want to partition documents from the unlabeled dataset into different subsets based on their similarity. At each time step t, the RL-agent applies a policy to select one subset instead of one sample and then update the two co-training classifiers, which can significantly improve the computational efficiency.

Suppose each example in the unlabeled dataset as document D, where D is the concatenation of the headline and paragraph. V is the vocabulary of

these documents. These documents are partitioned into different subsets based on Jaccard similarity, which is defined as:

$$sim(D_1, D_2) = \frac{|D_1 \cap D_2|}{|D_1 \cup D_2|}, \quad (1)$$

where $D_1, D_2 \in \mathbb{R}^{|V|}$ are the one-hot vectors of each document example.

Based on Jaccard similarity, the unlabeled examples can be split into different subsets using the following three steps, which have been widely used in large-scale web search (Rajaraman and Ullman, 2010): 1) Shingling, 2) Min-Hashing, and 3) Locality-Sensitive Hashing (LSH).

After partition, the unlabeled set U can be converted into K different subset $\{U_1, U_2, ..., U_K\}$. Meanwhile, for each subset U_i, the first added document example S_i is recorded as the representative example of the subset U_i. Choosing representative samples will help evaluate the classifiers on different subsets and obtain the state representations, which will be discussed in 3.3.1.

3.2 Classifier Models

As mentioned before, much linguistic data naturally has two or more views, such as multi-lingual data (Wan, 2009) and document data (headline + paragraph) (Ghani, 2000; Denis et al., 2003). Based on the two views of data, we can construct two classifiers respectively. At the beginning of a training episode, the two classifiers are first seeded with a small set of labeled (seeding) training data L. At each time step t, the RL-agent makes a selection action a_t, and then the unlabeled subset U_{a_t} is selected to train the two co-training classifiers. Following the standard co-training process (Blum and Mitchell, 1998), at each time step t, the classifier C_1 annotate the unlabeled subset U_{a_t} and the pseudo-labeled U_{a_t} and the small labeled set L are then used to update the classifier C_2, vice versa. In this way, we can boost the performance of C_1 and C_2 simultaneously.

3.3 Q-Learning Agent

Q-learning is a widely used method to find an optimal action-selection policy (Watkins and Dayan, 1992). The core of our model is a Q-learning agent, which is trained to learn a good policy to select high-quality unlabeled subsets for co-training. At each time step t, the agent observes the current state s_t, and selects an action a_t from a discrete set of actions $A = \{1, 2, ..., K\}$. Based on the action a_t, the two co-training classifiers C_1 and C_2 then can be updated with the unlabeled subset U_{a_t} as described in Section 3.2. After that, the agent receives a performance-driven reward r_t and the next state observation s_{t+1}. The goal of our Q-agent at each time step t is to choose the action that can maximize the future discount reward

$$R_t = \sum_{t'=t}^{T} \gamma^{t'-t} r_{t'}, \quad (2)$$

where a training episode terminates at time T and γ is the discount factor.

3.3.1 State Representation

The state representation, in our framework, is designed to deliver the status of two co-training classifiers to the Q-agent. Zhang and Rudnicky (2006) have proved that training with high-confidence examples will consequently be a process that reinforces what the current model already encodes instead of learning an accurate distribution of data space. Thus, one insight in formulating the state representation is to add some unlabeled examples with uncertainty and diversity during the training iteration. However, too much uncertainty will make two classifiers unstable, while too much diversity will cause the sampling bias shift towards the unlabeled dataset (Yeung et al., 2017). In order to automatically capture this insight and select high-quality subsects during the iteration, the Q-agent needs to fully understand the distribution of the unlabeled data.

Based on the above intuition, we formulate the agents state using the two classifiers' probability distribution on the representative example S_i of each unlabeled subset U_i. Suppose a N-class classification problem, at each time step t, we evaluate the probability distribution of two classifiers on S_i separately. The state representation then can be defined as:

$$s_t = \{P_1^1 || P_1^2, P_2^1 || P_2^2, ..., P_K^1 || P_K^2\}_t, \quad (3)$$

where P_i^1 and P_i^2 are the probability distribution of C_1 and C_2 on S_i separately, and $||$ denotes the concatenation operation. $P_i^1, P_i^2 \in \mathbb{R}^N$ and $P_i^1 || P_i^2 \in \mathbb{R}^{2N}$. Note that the state representation is re-computed at each time step t.

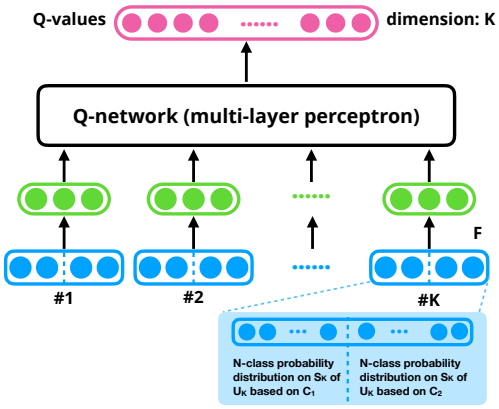

Figure 3: The structure of Q-network. It chooses a unlabeled subset from $\{U_1, U_2, ..., U_K\}$ at each time step. The state representation is computed according to the two classifiers' N-class probability distribution on the representative example S_i of each subset U_i.

3.3.2 Q-Network

The agent takes an action at at time step t using a policy

$$a_t = \max_a Q(s_t, a), \tag{4}$$

where s_t is the state representation mentioned above. The Q-value $Q(s_t, a)$ is determined by a neural network as illustrated in Figure 3. Concretely,

$$z_a = \phi(\{F(P_1^1||P_1^2), ..., F(P_K^1||P_K^2)\}; \theta), \tag{5}$$

where the function F maps state representation $P_i^1||P_i^2 \in \mathbb{R}^{2N}$ into a common embedding space of y dimensions, and $\phi(\cdot)$ is a multi-layer perception.

We then use

$$Q(s, a) = \text{softmax}(z_a) \tag{6}$$

to obtain the next action.

3.3.3 Reward Function

The agent is trained to select the high-quality unlabeled subsets to improve the performance of the two classifier C_1 and C_2. We capture this intuition by a performance-driven reward function. At time step t, the reward of each classifier is defined as the change in the classifiers accuracy after updating the unlabeled subset U_t:

$$r_t^1 = \text{Acc}_t^1(L') - \text{Acc}_{t-1}^1(L'), \tag{7}$$

where $\text{Acc}_t^1(L')$ is the model accuracy of C_1 at time step t computed on the labeled validation set L'. Then the r_t^2 is defined following the similar formulation. The final reward r_t is defined as:

$$r_t = \begin{cases} r_t^1 \times r_t^2 & \text{if } r_t^1 > 0 \text{ and } r_t^2 > 0, \\ 0 & \text{otherwise.} \end{cases}$$

Note that this reward is only available during training process.

3.4 Training and Testing

The agent is trained with the Q-learning (Watkins and Dayan, 1992), a standard reinforcement learning algorithm that can be used to learn policies for an agent interacting with an environment. In our Reinforced Co-Training framework, the environment is the classifier C_1 and C_2.

The Q-network parameters θ are learned by optimizing:

$$L_i(\theta_i) = \mathbb{E}_{s,a}[(V(\theta_{i-1}) - Q(s, a; \theta_i))^2], \tag{8}$$

where i is an iteration of optimization and

$$V(\theta_{i-1}) = \mathbb{E}_{s'}[r + \gamma \max_{a'} Q(s', a'; \theta_{i-1})|s, a]. \tag{9}$$

.

We optimize it using stochastic gradient descent. The detail of the training process is shown in Algorithm 1.

At test time, the agent and the two co-training classifiers are again run simultaneously, but without access to the labeled validation dataset. The agent selects the unlabeled subset using the learned greedy policy:

$$a_t = max_a Q(s_t, a). \tag{10}$$

After obtaining two classifiers from co-training, based on the weighted voting, the final ensemble classifier C is defined as:

$$C = \beta C_1 + (1 - \beta) C_2. \tag{11}$$

β is the weighted parameter, which can be learned by maximizing the classification accuracy on the validation set.

4 Experiments

We evaluate our proposed Reinforced Co-training method in two settings: (1) **Clickbait detection**, where obtaining the labeled data is very time-consuming and labor-intensive in this real-world problem; (2) **Generic text classification**, where we randomly set some of the labeled data as unlabeled and train our model in a controlled setting.

Algorithm 1: The algorithm of our Reinforced Co-Training method.

Given a set L of labeled seeding training data;
Given a set L' of labeled validation data;
Given K subsets $\{U_1, U_2, ..., U_K\}$ of unlabeled data;
for *episode* $\leftarrow$ *1* **to** *M* **do**
  Train C_1 & C_2 with L
  for *time step* $t \leftarrow$ *1* **to** *T* **do**
    Choose the action $a_t = \max_a Q(s_t, a)$
    Use C_1 to label the subset U_{a_t}
    Update C_2 with pseudo-labeled U_{a_t}, L
    Use C_2 to label the subset U_{a_t}
    Update C_1 with pseudo-labeled U_{a_t}, L
    Compute the reward r_t based on L'
    Compute the state representation s_{t+1}
    Update θ using $g \propto \nabla_\theta \mathbb{E}_{s,a}[(V(\theta_{i-1}) - Q(s, a; \theta_i))^2]$

4.1 Baselines

We compare our model with multiple baselines:

- **Standard Co-Training**: Co-Training with randomly choosing unlabeled examples (Blum and Mitchell, 1998).
- **Performance-driven Co-Training**: The unlabeled examples are selected based on pseudo-accuracy and energy regularization (Zhang and Rudnicky, 2006).
- **CoTrade Co-Training**: The confidence of either classifiers prediction on unlabeled examples is estimated based on specific data editing techniques, and then high-confidence examples are used to update the classifiers (Zhang and Zhou, 2011).
- **Semi-supervised Sequence Learning (Sequence-SSL)**: The model uses an LSTM sequence autoencoder to pre-train the parameters for the later supervised learning process.(Dai and Le, 2015).
- **Semi-supervised CNN with Region Embedding (Region-SSL)**: The model learns embeddings of small text regions from unlabeled data for integration into a supervised CNN (Johnson and Zhang, 2015).
- **Adversarial Semi-supervised Learning (Adversarial-SSL)**: The model apply perturbations to word embeddings into an LSTM and pre-train the supervised models through adversarial training (Miyato et al., 2016).

Table 1: Statistics of Clickbait Dataset.

4.2 Clickbait Detection

Clickbait is a pejorative term for web content whose headlines typically aim to make readers curious, but the documents usually have less relevance with the corresponding headlines (Chakraborty et al., 2016; Potthast et al., 2017; Wei and Wan, 2017). Clickbait not only wastes the readers' time but also damages the publishers' reputation, which makes detecting clickbait become an important real-world problem.

However, most of the attempts focus on news headlines, while the relevance between headlines and context is usually ignored (Chen et al., 2015; Biyani et al., 2016; Chakraborty et al., 2016). Meanwhile, the labeled data is quite limited in this problem, but the unlabeled data is easily obtained from the web (Potthast et al., 2017). Considering these two challenges, we utilize our Reinforced Co-training framework to tackle this problem and evaluate our method.

4.2.1 Datasets

We evaluate our model on a large-size clickbait dataset, Clickbait Challenge 2017 (Potthast et al., 2017). The data is collected from twitter posts including tweet headlines and paragraphs, and the training and test sets are judged on a four-point scale $[0, 0.3, 0.66, 1]$ by at least five annotators. Each sample is categorized into one class based on its average scores. The clickbait detection then can be defined as a two-class classification problem, including CLICKBAIT and NON-CLICKBAIT. There also exists an unlabeled set containing large amounts of collected samples without annotation. We then split the original test set into the validation set and final test set by 50%/50%. The statistics of this dataset are listed in Table 1.

4.2.2 Setup

For each document example in the clickbait dataset, naturally, we have two views, the headline and the paragraph. Thus, we construct the two classifiers in co-training based on these two views.

Headline Classifier The previous state-of-the-art model (Zhou, 2017) for clickbait detection uses

a self-attentive bi-directional gated recurrent unit RNN (biGRU) to model the headlines of the document and train a classifier. Following the same setting, we choose self-attentive biGRU as the headline classifier in co-training.

Paragraph Classifier The paragraphs usually have much longer sequences than the headlines. Thus, we utilize the CNN-non-static structure in Kim (2014) as the paragraph classifier to capture the paragraph information.

Note that the other three co-training baselines also use the same classifier settings.

In our Reinforce Co-Training model, we set the number of unlabeled subsets k as 80. Considering the clickbait detection as a 2-class classification problem ($N = 2$), the Q-network maps 4-d input $P_i^1||P_i^2$ in the state representation to a 3-d common embedding space ($y = 3$), with a further hidden layer of 128 units on top. The dimension k of the softmax layer is also 80.

As for the other semi-supervised baselines, Sequence-SSL, Region-SSL and Adversarial-SSL, we concatenate the headline and the paragraph as the document and train these models directly on the document data. To better analyze the experimental results, we also implement another baseline denoted as CNN (Document), which uses the CNN structure (Kim, 2014) to model the document with supervised learning. The CNN (Document) model is trained on the (seeding) training set and the validation set.

Following the previous researches (Chakraborty et al., 2016; Potthast et al., 2017), we use Precision, Recall and F1 Score to evaluate different models.

4.2.3 Results

The results of clickbait detection are shown in Table 2. From the results, we observe that: (1) Our Reinforced Co-Training model can outperform all the baselines, which indicates the capability of our methods in utilizing the unlabeled data. (2) The standard co-training is unstable due to the random data selection strategy, and the performance-driven and high-confidence data selection strategies both can improve the performance of co-training. Meanwhile, the significant improvement compared with previous co-training methods shows that the Q-agent in our model can learn a good policy to select high-quality subsets. (3) The three pre-trained based semi-supervised learning methods also show good results. We think these pre-trained based methods learn local embeddings during the unsupervised training, which may help them to recognize some important patterns in clickbait detection. (4) The self-attentive biGRU trained only on headlines of the labeled set actually show surprisingly good performance on clickbait detection, which demonstrates that most clickbait documents have obvious patterns in the headline field. The reason why CNN (Document) fails to capture these patterns may be that the concatenation of headlines and paragraphs dilutes these features. But for those cases without obvious patterns in the headline, our results demonstrate that the paragraph information is still a good supplement to detection.

Methods	**Prec.**	**Recall**	**F1 Score**
Self-attentive biGRU	0.683	0.649	0.665
CNN (Document)	0.537	0.474	0.503
Standard Co-Training	0.418	0.433	0.425
Performance Co-Training	0.581	0.629	0.604
CoTrade Co-Training	0.609	0.637	0.623
Sequence-SSL	0.595	0.589	0.592
Region-SSL	0.674	0.652	0.663
Adversarial-SSL	0.698	**0.691**	0.694
Reinforced Co-Training	**0.709**	0.684	**0.696**

Table 2: The experimental results on clickbait dataset. Prec.: precision.

	Best	**Worst**	**Average**	**STDDEV**
F1 Score	0.708	0.685	0.692	0.0068

Table 3: The robustness analysis on clickbait dataset.

4.2.4 Algorithm Robustness

Previous studies (Morimoto and Doya, 2001; Henderson et al., 2017) show that reinforcement learning-based methods usually lack robustness and are sensitive to the seeding sets and pre-trained steps. Thus, we design an experiment to detect whether our learned data section policy is sensitive to the (seeding) training set. First, based on our original data partition, we train our reinforcement learning framework to learn a Q-agent. During the test time, instead of using the same seeding set when doing comparative experiments, we randomly sample other 10 seeding sets from the labeled dataset and learn 10 classifiers based without re-training the Q-agent (data selection policy). Note that the validation set is not available during the co-training period of the test time. Finally, we evaluate these 10 classifiers using the same metric. The results are shown in Table 3.

Dataset	AG's News	DBpedia
#Classes	4	14
#Training	12,000	56,000
#Validation	12,000	56,000
#Test	7,600	70,000
#Unlabeled	96,000	448,000

Table 4: Statistics of the Text Classification Datasets.

The results demonstrate that our learning algorithm is robust to different (seeding) training sets, which indicates that the Q-agent in our model can learn a good and robust data selection policy to select high-quality unlabeled subsets to help the co-training process.

4.3 Generic Text Classification

Generic text classification is a classic problem for natural language processing, where one needs to categorized documents into pre-defined classes (Kim, 2014; Zhang et al., 2015; Johnson and Zhang, 2015, 2016; Xiao and Cho, 2016; Miyato et al., 2016). We evaluate our model on generic text classification problem to study our method in a controlled setting.

4.3.1 Datasets

Following the settings in Zhang et al. (2015), we use large-scale datasets to train and test our model. To maintain the two-view setting of the co-training method, we choose the following two datasets. The original annotated training set is then split into three sets, 10% labeled training set, 10% labeled validation set and 80% unlabeled set. The original proportion of different classes remains the same after the partition. The statistics of these two datasets are listed in Table 4.

AG's news corpus. The AGs corpus of news articles is obtained from the web and each sample has the title and description fields.

DBpedia ontology dataset. This dataset is constructed by picking 14 non-overlapping classes from DBpedia 2014. Each sample contains the title and abstract of a Wikipedia article.

4.3.2 Setup

For each document example in the above two datasets, naturally we have two views, the headline and the paragraph. Similar to clickbait detection, we also construct the two classifiers in co-training based on these two views. Following the (Kim, 2014), we set both the headline classifier and the paragraph classifier as the CNN-non-static model. Owing to that fact that the original datasets are fully labeled, we implement two other baselines: (1) CNN (Training+Validation), which is supervised trained on the partitioned training and validation sets; (2) CNN (All) which is supervised trained on the original (100%) dataset.

Methods	**AG's News**	**DBpedia**
CNN (Training+Validation)	28.32%	9.53%
CNN (All)	8.69%	0.91%
Standard Co-Training	26.52%	7.66%
Performance Co-Training	21.73%	5.84%
CoTrade Co-Training	19.06%	5.12%
Sequence-SSL	19.54%	4.64%
Region-SSL	18.27%	3.76%
Adversarial-SSL	8.45%*	0.89%*
Reinforced Co-Training	**16.64%**	**2.45%**

Table 5: The experimental results on generic text classification datasets. * Adversarial-SSL is trained on full labeled data after pre-training.

For AG's News dataset, we set the number of unlabeled subsets k as 96. The number of classes $N = 4$, and thus the Q-network maps 8-d input $P_i^1||P_i^2$ in the state representation to a 5-d common embedding space ($y = 5$), with a further hidden layer of 128 units on top. The dimension k of the softmax layer is also 96. As for DBpedia dataset, $k = 224$, $N = 14$, and $y = 10$,.

Following the previous researches (Kim, 2014), we use test error rate (%) to evaluate different models.

4.3.3 Results

The results of generic text classification are shown in Table 5. From the results, we can observe that: (1) Our Reinforced Co-Training model outperforms all the real semi-supervised baselines on two generic text classification datasets, which indicates that our method is consistent in different tasks. (2) The CNN (All) and Adversarial-SSL trained on all the original labeled data perform best, which indicates there is still an obvious gap between semi-supervised methods and full-supervised methods.

4.3.4 Algorithm Robustness

Similar to Section 4.2.4, we evaluate whether our learned data section policy is sensitive to the different partitions and (seeding) training sets. First, based on our original data partition (10%/10%/80%), we train our reinforcement learning framework. During the test time, we randomly sample other 10 data partitions instead of the one used in comparative experiments, and learn 10 ensemble classifiers based on the learned

Datasets	Best	Worst	Average	STDDEV
AG's News	14.78	17.96	16.62	1.36
DBPedia	2.18	4.06	2.75	0.94

Table 6: The robustness analysis on generic text classification. Metric: test error rate (%).

Q-agent. Note that after sample different data partitions, we will also reprocess the unlabeled sets as described in Section 3.1. We then evaluate these 10 classifiers using the same metric. The results are shown in Table 6.

The results demonstrate that our learning algorithm is robust to different (seeding) training sets and partitions of the unlabeled set, which again indicates that the Q-agent in our model is able to learn a good and robust data selection policy to select high-quality unlabeled subsets to help the co-training process.

4.4 Discussion about Stability

Previous studies (Zhang et al., 2014; Reimers and Gurevych, 2017) show that neural networks can be unstable even with the same training parameters on the same training data. As for our cases, when the two classifiers are initialized with different labeled seeding sets, they can be very unstable. However, after enough iterations with the properly selected unlabeled data, the performance would be stable generally.

Usually, the more substantial labeled training datasets will lead to more stable models. However, the problem is that the AGs News and DBpedia have 4 and 14 classes separately, while the Clickbait dataset only has 2 classes. That means the numbers of each class in AGs News, DBPedia and Clickbait actually are the same order of magnitude. Meanwhile, in our co-training setting, the prediction error is easy to accumulate because the two classifiers bootstrap the performance of each other. The classification could be harder with the increase of classes. Based on these reasons, the stability does not show a very strong correlation with the size of datasets in our experiments of Section 4.2.4 and 4.3.4.

5 Conclusion and Future Work

In this paper, we propose a novel method, Reinforced Co-Training, for training classifiers by utilizing both the labeled and unlabeled data. The Q-agent in our model can learn a good data selection policy to select high-quality unlabeled data for co-training. We evaluate our models on two tasks, clickbait detection and generic text classification. Experimental results show that our model can outperform other semi-supervised baselines, especially those conventional co-training methods. We also test the Q-agent and prove that the learned data selection policy is robust to different seeding sets and data partitions.

For future studies, we will investigate the data selection policies of other semi-supervised methods and try to learn these policies automatically. We also plan to extend our method to multi-source classification cases and utilize the multi-agent communication environment to boost the classification performance.

Abstract

We present a new approach to the design of deep networks for natural language processing (NLP), based on the general technique of Tensor Product Representations (TPRs) for encoding and processing symbol structures in distributed neural networks. A network architecture — the ***Tensor Product Generation Network*** (***TPGN***) — is proposed which is capable in principle of carrying out TPR computation, but which uses unconstrained deep learning to design its internal representations. Instantiated in a model for image-caption generation, TPGN outperforms LSTM baselines when evaluated on the COCO dataset. The TPR-capable structure enables interpretation of internal representations and operations, which prove to contain considerable grammatical content. Our caption-generation model can be interpreted as generating sequences of grammatical categories and retrieving words by their categories from a plan encoded as a distributed representation.

1 Introduction

In this paper we introduce a new architecture for natural language processing (NLP). On what type of principles can a computational architecture be founded? It would seem a sound principle to require that the hypothesis space for learning which an architecture provides include network hypotheses that are independently known to be suitable for performing the target task. Our proposed architecture makes available to deep learning network configurations that perform natural language generation by use of *Tensor Product Representations* (TPRs) (Smolensky and Legendre, 2006). Whether learning will create TPRs is unknown in advance, but what we can say with certainty is that the hypothesis space being searched during learning includes TPRs as one appropriate solution to the problem.

TPRs are a general method for generating vector-space embeddings of complex symbol structures. Prior work has proved that TPRs enable powerful symbol processing to be carried out using neural network computation (Smolensky, 2012). This includes generating parse trees that conform to a grammar (Cho et al., 2017), although incorporating such capabilities into deep learning networks such as those developed here remains for future work. The architecture presented here relies on simpler use of TPRs to generate sentences; grammars are not explicitly encoded here.

We test the proposed architecture by applying it to image-caption generation (on the MS-COCO dataset, (COCO, 2017)). The results improve upon a baseline deploying a state-of-the-art LSTM architecture (Vinyals et al., 2015), and the TPR foundations of the architecture provide greater interpretability.

Section 2 of the paper reviews TPR. Section 3 presents the proposed architecture, the *Tensor Product Generation Network* (TPGN). Section 4 describes the particular model we study for image captioning, and Section 5 presents the experimental results. Importantly, what the model has learned is interpreted in Section 5.3. Section 6 discusses the relation of the new model to previous work and Section 7 concludes.

2 Review of tensor product representation

The central idea of TPRs (Smolensky, 1990) can be appreciated by contrasting the TPR for a word string with a bag-of-words (BoW) vector-space embedding. In a BoW embedding, the vector that encodes `Jay saw Kay` is the same as the one that encodes `Kay saw Jay`: $\mathbf{J} + \mathbf{K} + \mathbf{s}$ where

*LD is currently at Citadel.

Proceedings of NAACL-HLT 2018, pages 1263–1273
New Orleans, Louisiana, June 1 - 6, 2018.

$\mathbf{J}, \mathbf{K}, \mathbf{s}$ are respectively the vector embeddings of the words Jay, Kay, saw.

A TPR embedding that avoids this confusion starts by analyzing Jay saw Kay as the set {Jay/SUBJ, Kay/OBJ, saw/VERB}. (Other analyses are possible: see Section 3.) Next we choose an embedding in a vector space V_F for Jay, Kay, saw as in the BoW case: $\mathbf{J}, \mathbf{K}, \mathbf{s}$. Then comes the step unique to TPRs: we choose an embedding in a vector space V_R for the ***roles*** SUBJ, OBJ, VERB: $\mathbf{r}_{\text{SUBJ}}, \mathbf{r}_{\text{OBJ}}, \mathbf{r}_{\text{VERB}}$. Crucially, $\mathbf{r}_{\text{SUBJ}} \neq \mathbf{r}_{\text{OBJ}}$. Finally, the TPR for Jay saw Kay is the following vector in $V_F \otimes V_R$:

$$\mathbf{v}_{\texttt{Jay saw Kay}} = \mathbf{J} \otimes \mathbf{r}_{\text{SUBJ}} + \mathbf{K} \otimes \mathbf{r}_{\text{OBJ}} + \mathbf{s} \otimes \mathbf{r}_{\text{VERB}} \quad (1)$$

Each word is tagged with the role it fills in the sentence; Jay and Kay fill different roles.

This TPR avoids the BoW confusion: $\mathbf{v}_{\texttt{Jay saw Kay}} \neq \mathbf{v}_{\texttt{Kay saw Jay}}$ because $\mathbf{J} \otimes \mathbf{r}_{\text{SUBJ}} + \mathbf{K} \otimes \mathbf{r}_{\text{OBJ}} \neq \mathbf{J} \otimes \mathbf{r}_{\text{OBJ}} + \mathbf{K} \otimes \mathbf{r}_{\text{SUBJ}}$. In the terminology of TPRs, in Jay saw Kay, Jay is the *filler* of the role SUBJ, and $\mathbf{J} \otimes \mathbf{r}_{\text{SUBJ}}$ is the vector embedding of the *filler/role binding* Jay/SUBJ. In the vector space embedding, the binding operation is the tensor — or generalized outer — product $\otimes$; i.e., $\mathbf{J} \otimes \mathbf{r}_{\text{SUBJ}}$ is a tensor with 2 indices defined by: $[\mathbf{J} \otimes \mathbf{r}_{\text{SUBJ}}]_{\varphi\rho} \equiv [\mathbf{J}]_{\varphi}[\mathbf{r}_{\text{SUBJ}}]_{\rho}$.

The tensor product can be used recursively, which is essential for the TPR embedding of recursive structures such as trees and for the computation of recursive functions over TPRs. However, in the present context, recursion will not be required, in which case the tensor product can be regarded as simply the matrix outer product (which cannot be used recursively); we can regard $\mathbf{J} \otimes \mathbf{r}_{\text{SUBJ}}$ as the matrix product $\mathbf{J}\mathbf{r}_{\text{SUBJ}}^{\top}$. Then Equation 1 becomes

$$\mathbf{v}_{\texttt{Jay saw Kay}} = \mathbf{J}\mathbf{r}_{\text{SUBJ}}^{\top} + \mathbf{K}\mathbf{r}_{\text{OBJ}}^{\top} + \mathbf{s}\mathbf{r}_{\text{VERB}}^{\top} \quad (2)$$

Note that the set of matrices (or the set of tensors with any fixed number of indices) is a vector space; thus Jay saw Kay $\mapsto \mathbf{v}_{\texttt{Jay saw Kay}}$ is a vector-space embedding of the symbol structures constituting sentences. Whether we regard $\mathbf{v}_{\texttt{Jay saw Kay}}$ as a 2-index tensor or as a matrix, we can call it simply a 'vector' since it is an element of a vector space: in the context of TPRs, 'vector' is used in a general sense and should not be taken to imply a single-indexed array.

Crucial to the computational power of TPRs and to the architecture we propose here is the notion of *unbinding*. Just as an *outer* product — the tensor product — can be used to *bind* the vector embedding a filler Jay to the vector embedding a role SUBJ, $\mathbf{J} \otimes \mathbf{r}_{\text{SUBJ}}$ or $\mathbf{J}\mathbf{r}_{\text{SUBJ}}^{\top}$, so an *inner* product can be used to take the vector embedding a structure and *unbind* a role contained within that structure, yielding the symbol that fills the role.

In the simplest case of orthonormal role vectors $\mathbf{r}_i$, to unbind role SUBJ in Jay saw Kay we can compute the matrix-vector product: $\mathbf{v}_{\texttt{Jay saw Kay}}\mathbf{r}_{\text{SUBJ}} = \mathbf{J}$ (because $\mathbf{r}_i^{\top}\mathbf{r}_j = \delta_{ij}$ when the role vectors are orthonormal). A similar situation obtains when the role vectors are not orthonormal, provided they are not linearly dependent: for each role such as SUBJ there is an *unbinding vector* $\mathbf{u}_{\text{SUBJ}}$ such that $\mathbf{r}_i^{\top}\mathbf{u}_j = \delta_{ij}$ so we get: $\mathbf{v}_{\texttt{Jay saw Kay}}\mathbf{u}_{\text{SUBJ}} = \mathbf{J}$. A role vector such as $\mathbf{r}_{\text{SUBJ}}$ and its unbinding vector $\mathbf{u}_{\text{SUBJ}}$ are said to be *duals* of each other. (If R is the matrix in which each column is a role vector $\mathbf{r}_j$, then R is invertible when the role vectors are linearly independent; then the unbinding vectors $\mathbf{u}_i$ are the rows of R^{-1}. When the $\mathbf{r}_j$ are orthonormal, $\mathbf{u}_i = \mathbf{r}_i$. Replacing the matrix inverse with the pseudo-inverse allows approximate unbinding if the role vectors are linearly dependent.)

We can now see how TPRs can be used to generate a sentence one word at a time. We start with the TPR for the sentence, e.g., $\mathbf{v}_{\texttt{Jay saw Kay}}$. From this vector we unbind the role of the first word, which is SUBJ: the embedding of the first word is thus $\mathbf{v}_{\texttt{Jay saw Kay}}\mathbf{u}_{\text{SUBJ}} = \mathbf{J}$, the embedding of Jay. Next we take the TPR for the sentence and unbind the role of the second word, which is VERB: the embedding of the second word is then $\mathbf{v}_{\texttt{Jay saw Kay}}\mathbf{u}_{\text{VERB}} = \mathbf{s}$, the embedding of saw. And so on.

To accomplish this, we need two representations to generate the t^{th} word: (i) the TPR of the sentence, $\mathbf{S}$ (or of the string of not-yet-produced words, $\mathbf{S}_t$) and (ii) the unbinding vector for the t^{th} word, $\mathbf{u}_t$. The architecture we propose will therefore be a recurrent network containing two subnetworks: (i) a subnet $\mathcal{S}$ hosting the representation $\mathbf{S}_t$, and a (ii) a subnet $\mathcal{U}$ hosting the unbinding vector $\mathbf{u}_t$. This is shown in Fig. 1.

3 A TPR-capable generation architecture

As Fig. 1 shows, the proposed Tensor Product Generation Network architecture (the dashed box labeled $\mathcal{N}$) is designed to support the technique

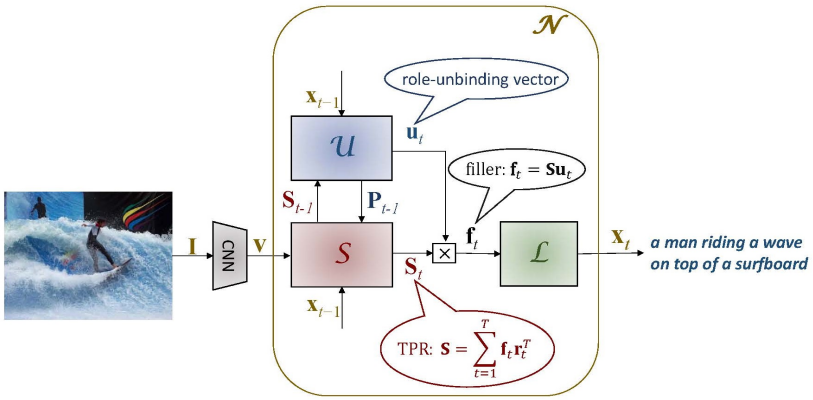

Figure 1: Architecture of TPGN, a TPR-capable generation network. "⊠" denotes the matrix-vector product.

for generation just described: the architecture is *TPR-capable*. There is a *sentence-encoding subnetwork* $\mathcal{S}$ which *could* host a TPR of the sentence to be generated, and an *unbinding subnetwork* $\mathcal{U}$ which *could* output a sequence of unbinding vectors $\mathbf{u}_t$; at time t, the embedding $\mathbf{f}_t$ of the word produced, $\mathtt{x}_t$, could then be extracted from $\mathbf{S}_t$ via the matrix-vector product (shown in the figure by "⊠"): $\mathbf{f}_t = \mathbf{S}_t\mathbf{u}_t$. The lexical-decoding subnetwork $\mathcal{L}$ converts the embedding vector $\mathbf{f}_t$ to the 1-hot vector $\mathbf{x}_t$ corresponding to the word $\mathtt{x}_t$.

Unlike some other work (Palangi et al., 2017), TPGN is not constrained to literally learn TPRs. The representations that will actually be housed in $\mathcal{S}$ and $\mathcal{U}$ are determined by end-to-end deep learning on a task: the bubbles in Fig. 1 show what *would* be the meanings of $\mathbf{S}_t$, $\mathbf{u}_t$ and $\mathbf{f}_t$ if an actual TPR scheme were instantiated in the architecture. The learned representations $\mathbf{S}_t$ will not be proven to literally be TPRs, but by analyzing the unbinding vectors $\mathbf{u}_t$ the network learns, we will gain insight into the process by which the learned matrices $\mathbf{S}_t$ give rise to the generated sentence.

The task studied here is image captioning; Fig. 1 shows that the input to this TPGN model is an image, preprocessed by a CNN which produces the initial representation in $\mathcal{S}$, $\mathbf{S}_0$. This vector $\mathbf{S}_0$ drives the entire caption-generation process: it contains all the image-specific information for producing the caption. (We will call a caption a "sentence" even though it may in fact be just a noun phrase.)

The two subnets $\mathcal{S}$ and $\mathcal{U}$ are mutually-connected LSTMs (Hochreiter and Schmidhuber, 1997): see Fig. 2. The internal hidden state of $\mathcal{U}$, $\mathbf{p}_t$, is sent as input to $\mathcal{S}$; $\mathcal{U}$ also produces output, the unbinding vector $\mathbf{u}_t$. The internal hidden state of $\mathcal{S}$, $\mathbf{S}_t$, is sent as input to $\mathcal{U}$, and also produced as output. As stated above, these two outputs are multiplied together to produce the embedding vector $\mathbf{f}_t = \mathbf{S}_t\mathbf{u}_t$ of the output word $\mathtt{x}_t$. Furthermore, the 1-hot encoding $\mathbf{x}_t$ of $\mathtt{x}_t$ is fed back at the next time step to serve as input to both $\mathcal{S}$ and $\mathcal{U}$.

What type of roles might the unbinding vectors be unbinding? A TPR for a caption could in principle be built upon *positional roles*, *syntactic/semantic roles*, or some combination of the two. In the caption `a man standing in a room with a suitcase`, the initial `a` and `man` might respectively occupy the positional roles of POS(ITION)$_1$ and POS$_2$; `standing` might occupy the syntactic role of VERB; `in` the role of SPATIAL-P(REPOSITION); while `a room with a suitcase` might fill a 5-role schema DET(ERMINER)$_1$ N(OUN)$_1$ P DET$_2$ N$_2$. In fact we will provide evidence in Sec. 5.3.2 that our network learns just this kind of hybrid role decomposition; further evidence for these particular roles is presented elsewhere.

What form of information does the sentence-encoding subnetwork $\mathcal{S}$ need to encode in $\mathbf{S}$? Continuing with the example of the previous paragraph, $\mathbf{S}$ needs to be some approximation to the TPR summing several filler/role binding matrices. In one of these bindings, a filler vector $\mathbf{f}_{\mathtt{a}}$ — which the lexical subnetwork $\mathcal{L}$ will map to the article `a` — is bound (via the outer product) to a role vector $\mathbf{r}_{\text{POS}_1}$ which is the dual of the first unbinding vector produced by the unbinding subnetwork $\mathcal{U}$: $\mathbf{u}_{\text{POS}_1}$. In the first iteration of generation the model computes $\mathbf{S}_1\mathbf{u}_{\text{POS}_1} = \mathbf{f}_{\mathtt{a}}$, which $\mathcal{L}$ then maps to `a`. Analogously, another binding approximately contained in $\mathbf{S}_2$ is $\mathbf{f}_{\mathtt{man}}\mathbf{r}_{\text{POS}_2}^{\top}$. There are corresponding approximate bindings for the remaining words

of the caption; these employ syntactic/semantic roles. One example is $\mathbf{f}_{\texttt{standing}}\mathbf{r}_V^\top$. At iteration 3, $\mathcal{U}$ decides the next word should be a verb, so it generates the unbinding vector $\mathbf{u}_V$ which when multiplied by the current output of $\mathcal{S}$, the matrix $\mathbf{S}_3$, yields a filler vector $\mathbf{f}_{\texttt{standing}}$ which $\mathcal{L}$ maps to the output `standing`. $\mathcal{S}$ decided the caption should deploy `standing` as a verb and included in $\mathbf{S}$ an approximation to the binding $\mathbf{f}_{\texttt{standing}}\mathbf{r}_V^\top$. It similarly decided the caption should deploy `in` as a spatial preposition, approximately including in $\mathbf{S}$ the binding $\mathbf{f}_{\texttt{in}}\mathbf{r}_{\text{SPATIAL-P}}^\top$; and so on for the other words in their respective roles in the caption.

4 System Description

As stated above, the unbinding subnetwork $\mathcal{U}$ and the sentence-encoding subnetwork $\mathcal{S}$ of Fig. 1 are each implemented as (1-layer, 1-directional) LSTMs (see Fig. 2); the lexical subnetwork $\mathcal{L}$ is implemented as a linear transformation followed by a softmax operation.

In the equations below, the LSTM variables internal to the $\mathcal{S}$ subnet are indexed by 1 (e.g., the forget-, input-, and output-gates are respectively $\hat{\mathbf{f}}_1, \hat{\mathbf{i}}_1, \hat{\mathbf{o}}_1$) while those of the unbinding subnet $\mathcal{U}$ are indexed by 2.

Thus the state updating equations for $\mathcal{S}$ are, for $t = 1, \cdots, T$ = caption length:

$$\hat{\mathbf{f}}_{1,t} = \sigma_g(\mathbf{W}_{1,f}\mathbf{p}_{t-1} - \mathbf{D}_{1,f}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{1,f}\hat{\mathbf{S}}_{t-1}) \quad (3)$$

$$\hat{\mathbf{i}}_{1,t} = \sigma_g(\mathbf{W}_{1,i}\mathbf{p}_{t-1} - \mathbf{D}_{1,i}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{1,i}\hat{\mathbf{S}}_{t-1}) \quad (4)$$

$$\hat{\mathbf{o}}_{1,t} = \sigma_g(\mathbf{W}_{1,o}\mathbf{p}_{t-1} - \mathbf{D}_{1,o}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{1,o}\hat{\mathbf{S}}_{t-1}) \quad (5)$$

$$\mathbf{g}_{1,t} = \sigma_h(\mathbf{W}_{1,c}\mathbf{p}_{t-1} - \mathbf{D}_{1,c}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{1,c}\hat{\mathbf{S}}_{t-1}) \quad (6)$$

$$\mathbf{c}_{1,t} = \hat{\mathbf{f}}_{1,t} \odot \mathbf{c}_{1,t-1} + \hat{\mathbf{i}}_{1,t} \odot \mathbf{g}_{1,t} \quad (7)$$

$$\hat{\mathbf{S}}_t = \hat{\mathbf{o}}_{1,t} \odot \sigma_h(\mathbf{c}_{1,t}) \quad (8)$$

Here $\hat{\mathbf{f}}_{1,t}, \hat{\mathbf{i}}_{1,t}, \hat{\mathbf{o}}_{1,t}, \mathbf{g}_{1,t}, \mathbf{c}_{1,t}, \hat{\mathbf{S}}_t \in \mathbb{R}^{d\times d}$, $\mathbf{p}_t \in \mathbb{R}^d$; $\sigma_g(\cdot)$ is the (element-wise) logistic sigmoid function; $\sigma_h(\cdot)$ is the hyperbolic tangent function; the operator $\odot$ denotes the Hadamard (element-wise) product; $\mathbf{W}_{1,f}, \mathbf{W}_{1,i}, \mathbf{W}_{1,o}, \mathbf{W}_{1,c} \in \mathbb{R}^{(d\times d)\times d}$, $\mathbf{D}_{1,f}$, $\mathbf{D}_{1,i}$, $\mathbf{D}_{1,o}$, $\mathbf{D}_{1,c} \in \mathbb{R}^{(d\times d)\times d}$, $\mathbf{U}_{1,f}$, $\mathbf{U}_{1,i}$, $\mathbf{U}_{1,o}$, $\mathbf{U}_{1,c} \in \mathbb{R}^{(d\times d)\times(d\times d)}$. For clarity, biases — included throughout the model — are omitted from all equations in this paper. The initial state $\hat{\mathbf{S}}_0$ is initialized by:

$$\hat{\mathbf{S}}_0 = \mathbf{C}_s(\mathbf{v} - \bar{\mathbf{v}}) \quad (9)$$

where $\mathbf{v} \in \mathbb{R}^{2048}$ is the vector of visual features extracted from the current image by ResNet (Gan et al., 2017) and $\bar{\mathbf{v}}$ is the mean of all such vectors; $\mathbf{C}_s \in \mathbb{R}^{(d\times d)\times 2048}$. On the output side, $\mathbf{x}_t \in \mathbb{R}^V$ is a 1-hot vector with dimension equal to the size of the caption vocabulary, V, and $\mathbf{W}_e \in \mathbb{R}^{d\times V}$ is a word embedding matrix, the i-th column of which is the embedding vector of the i-th word in the vocabulary; it is obtained by the Stanford GLoVe algorithm with zero mean (Pennington et al., 2017). $\mathbf{x}_0$ is initialized as the one-hot vector corresponding to a "start-of-sentence" symbol.

For $\mathcal{U}$ in Fig. 1, the state updating equations are:

$$\hat{\mathbf{f}}_{2,t} = \sigma_g(\hat{\mathbf{S}}_{t-1}\mathbf{w}_{2,f} - \mathbf{D}_{2,f}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{2,f}\mathbf{p}_{t-1}) \quad (10)$$

$$\hat{\mathbf{i}}_{2,t} = \sigma_g(\hat{\mathbf{S}}_{t-1}\mathbf{w}_{2,i} - \mathbf{D}_{2,i}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{2,i}\mathbf{p}_{t-1}) \quad (11)$$

$$\hat{\mathbf{o}}_{2,t} = \sigma_g(\hat{\mathbf{S}}_{t-1}\mathbf{w}_{2,o} - \mathbf{D}_{2,o}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{2,o}\mathbf{p}_{t-1}) \quad (12)$$

$$\mathbf{g}_{2,t} = \sigma_h(\hat{\mathbf{S}}_{t-1}\mathbf{w}_{2,c} - \mathbf{D}_{2,c}\mathbf{W}_e\mathbf{x}_{t-1} + \mathbf{U}_{2,c}\mathbf{p}_{t-1}) \quad (13)$$

$$\mathbf{c}_{2,t} = \hat{\mathbf{f}}_{2,t} \odot \mathbf{c}_{2,t-1} + \hat{\mathbf{i}}_{2,t} \odot \mathbf{g}_{2,t} \quad (14)$$

$$\mathbf{p}_t = \hat{\mathbf{o}}_{2,t} \odot \sigma_h(\mathbf{c}_{2,t}) \quad (15)$$

Here $\mathbf{w}_{2,f}, \mathbf{w}_{2,i}, \mathbf{w}_{2,o}, \mathbf{w}_{2,c} \in \mathbb{R}^d$, $\mathbf{D}_{2,f}$, $\mathbf{D}_{2,i}$, $\mathbf{D}_{2,o}$, $\mathbf{D}_{2,c} \in \mathbb{R}^{d\times d}$, and $\mathbf{U}_{2,f}$, $\mathbf{U}_{2,i}$, $\mathbf{U}_{2,o}$, $\mathbf{U}_{2,c}$ $\in \mathbb{R}^{d\times d}$. The initial state $\mathbf{p}_0$ is the zero vector.

The dimensionality of the crucial vectors shown in Fig. 1, $\mathbf{u}_t$ and $\mathbf{f}_t$, is increased from $d\times 1$ to $d^2\times 1$ as follows. A block-diagonal $d^2 \times d^2$ matrix $\mathbf{S}_t$ is created by placing d copies of the $d \times d$ matrix $\hat{\mathbf{S}}_t$ as blocks along the principal diagonal. This matrix is the output of the sentence-encoding subnetwork $\mathcal{S}$. Now the 'filler vector' $\mathbf{f}_t \in \mathbb{R}^{d^2}$ — 'unbound' from the sentence representation $\mathbf{S}_t$ with the 'unbinding vector' $\mathbf{u}_t$ — is obtained by Eq. (16).

$$\mathbf{f}_t = \mathbf{S}_t\mathbf{u}_t \quad (16)$$

Here $\mathbf{u}_t \in \mathbb{R}^{d^2}$, the output of the unbinding subnetwork $\mathcal{U}$, is computed as in Eq. (17), where $\mathbf{W}_u \in \mathbb{R}^{d^2\times d}$ is $\mathcal{U}$'s output weight matrix.

$$\mathbf{u}_t = \sigma_h(\mathbf{W}_u\mathbf{p}_t) \quad (17)$$

Finally, the lexical subnetwork $\mathcal{L}$ produces a decoded word $\mathbf{x}_t \in \mathbb{R}^V$ by

$$\mathbf{x}_t = \sigma_s(\mathbf{W}_x\mathbf{f}_t) \quad (18)$$

where $\sigma_s(\cdot)$ is the softmax function and $\mathbf{W}_x \in \mathbb{R}^{V\times d^2}$ is the overall output weight matrix. Since $\mathbf{W}_x$ plays the role of a word de-embedding matrix, we can set

$$\mathbf{W}_x = (\mathbf{W}_e)^\top \quad (19)$$

where $\mathbf{W}_e$ is the word-embedding matrix. Since $\mathbf{W}_e$ is pre-defined, we directly set $\mathbf{W}_x$ by Eq. (19) without training $\mathcal{L}$ through Eq. (18). Note that $\mathcal{S}$ and $\mathcal{U}$ are learned jointly through end-to-end training as shown in Algorithm 1.

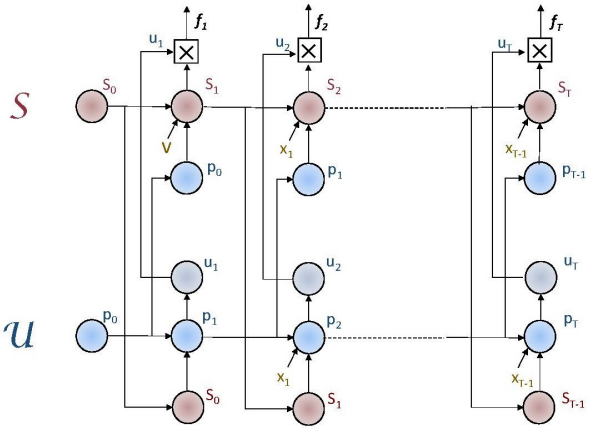

Figure 2: The sentence-encoding subnet $\mathcal{S}$ and the unbinding subnet $\mathcal{U}$ are inter-connected LSTMs; $\mathbf{v}$ encodes the visual input while the $\mathbf{x}_t$ encode the words of the output caption.

Algorithm 1 End-to-end training of $\mathcal{S}$ and $\mathcal{U}$

Input: Image feature vector $\mathbf{v}^{(i)}$ and corresponding caption $\mathbf{X}^{(i)} = [\mathbf{x}_1^{(i)}, \cdots, \mathbf{x}_T^{(i)}]$ $(i = 1, \cdots, N)$, where N is the total number of samples.
Output: $\mathbf{W}_{1,f}, \mathbf{W}_{1,i}, \mathbf{W}_{1,o}, \mathbf{W}_{1,c}, \mathbf{C}_s, \mathbf{D}_{1,f}, \mathbf{D}_{1,i}, \mathbf{D}_{1,o}, \mathbf{D}_{1,c}, \mathbf{U}_{1,f}, \mathbf{U}_{1,i}, \mathbf{U}_{1,o}, \mathbf{U}_{1,c}, \mathbf{w}_{2,f}, \mathbf{w}_{2,i}, \mathbf{w}_{2,o}, \mathbf{w}_{2,c}, \mathbf{D}_{2,f}, \mathbf{D}_{2,i}, \mathbf{D}_{2,o}, \mathbf{D}_{2,c}, \mathbf{U}_{2,f}, \mathbf{U}_{2,i}, \mathbf{U}_{2,o}, \mathbf{U}_{2,c}, \mathbf{W}_u, \mathbf{W}_x$.

5 Experimental results

5.1 Dataset

To evaluate the performance of our proposed model, we use the COCO dataset (COCO, 2017). The COCO dataset contains 123,287 images, each of which is annotated with at least 5 captions. We use the same pre-defined splits as in (Karpathy and Fei-Fei, 2015; Gan et al., 2017): 113,287 images for training, 5,000 images for validation, and 5,000 images for testing. We use the same vocabulary as that employed in (Gan et al., 2017), which consists of 8,791 words.

5.2 Evaluation

For the CNN of Fig. 1, we used ResNet-152 (He et al., 2016), pretrained on the ImageNet dataset. The feature vector $\mathbf{v}$ has 2048 dimensions. Word embedding vectors in $\mathbf{W}_e$ are downloaded from the web (Pennington et al., 2017). The model is implemented in TensorFlow (Abadi et al., 2015) with the default settings for random initialization and optimization by backpropagation.

In our experiments, we choose $d = 25$ (where d is the dimension of vector $\mathbf{p}_t$). The dimension of $\mathbf{S}_t$ is 625×625 (while $\hat{\mathbf{S}}_t$ is 25×25); the vocabulary size $V = 8,791$; the dimension of $\mathbf{u}_t$ and $\mathbf{f}_t$ is $d^2 = 625$.

The main evaluation results on the MS COCO dataset are reported in Table 5.2. The widely-used BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and CIDEr (Vedantam et al., 2015) metrics are reported in our quantitative evaluation of the performance of the proposed model. In evaluation, our baseline is the widely used CNN-LSTM captioning method originally proposed in (Vinyals et al., 2015). For comparison, we include results in that paper in the first line of Table 5.2. We also re-implemented the model using the latest ResNet features and report the results in the second line of Table 5.2. Our re-implementation of the CNN-LSTM method matches the performance reported in (Gan et al., 2017), showing that the baseline is a state-of-the-art implementation. For TPGN, we use parameter settings in a similar range to those in (Gan et al., 2017). TPGN has comparable, although slightly

Methods	METEOR	BLEU-1	BLEU-2	BLEU-3	BLEU-4	CIDEr
NIC (Vinyals et al., 2015)	0.237	0.666	0.461	0.329	0.246	0.855
CNN-LSTM	0.238	0.698	0.525	0.390	0.292	0.889
TPGN	**0.243**	**0.709**	**0.539**	**0.406**	**0.305**	**0.909**

Table 1: Performance of the proposed TPGN model on the COCO dataset.

more, parameters than the CNN-LSTM. The training time of TPGN is roughly 50% more than the CNN-LSTM model. The weights in TPGN are updated at every mini-batch; in the experiments, we use a batch size of 64 images. As shown in Table 5.2, compared to the CNN-LSTM baseline, the proposed TPGN appreciably outperforms the benchmark schemes in all metrics across the board. The improvement in BLEU-n is greater for greater n; TPGN particularly improves generation of longer subsequences. The results attest to the effectiveness of the TPGN architecture.

It is worth mentioning that this paper is aimed at developing a Tensor Product Representation (TPR) inspired network to replace the core layers in an LSTM; therefore, it is directly comparable to an LSTM baseline. So in the experiments, we focus on comparison to a strong CNN-LSTM baseline. We acknowledge that more recent papers (Xu et al., 2017; Rennie et al., 2017; Yao et al., 2017; Lu et al., 2017; Gan et al., 2017) reported better performance on the task of image captioning. Performance improvements in these more recent models are mainly due to using better image features such as those obtained by Region-based Convolutional Neural Networks (R-CNN), or using reinforcement learning (RL) to directly optimize metrics such as CIDEr, or using more complex attention mechanisms (Gan et al., 2017) to provide a better context vector for caption generation, or using an ensemble of multiple LSTMs, among others. However, the LSTM is still playing a core role in these works and we believe improvement over the core LSTM, in both performance and interpretability, is still very valuable; that is why we compare the proposed TPGN with a state-of-the-art native LSTM (the second line of Table 5.2).

5.3 Interpretation of learned unbinding vectors

To get a sense of how the sentence encodings $\mathbf{S}_t$ learned by TPGN approximate TPRs, we now investigate the meaning of the role-unbinding vector $\mathbf{u}_t$ the model uses to unbind from $\mathbf{S}_t$ — via Eq. (16) — the filler vector $\mathbf{f}_t$ that produces — via Eq. (18) — the one-hot vector $\mathbf{x}_t$ of the t^{th} generated caption word. The meaning of an unbinding vector is the meaning of the role it unbinds. Interpreting the unbinding vectors reveals the meaning of the roles in a TPR that $\mathbf{S}$ approximates.

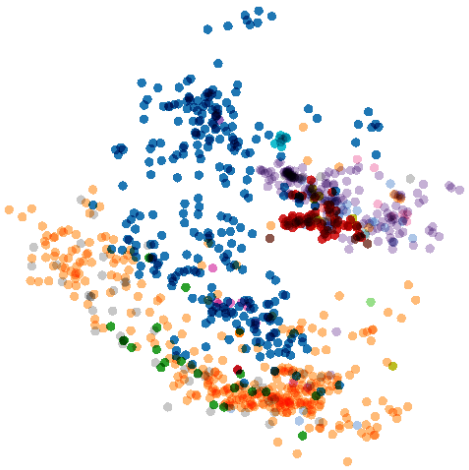

Figure 3: Unbinding vectors of 1000 words; different POS tags of words are represented by different colors.

5.3.1 Visualization of $\mathbf{u}_t$

We run the TPGN model with 5,000 test images as input, and obtain the unbinding vector $\mathbf{u}_t$ used to generate each word $\mathbf{x}_t$ in the caption of a test image. We plot 1,000 unbinding vectors $\mathbf{u}_t$, which correspond to the first 1,000 words in the resulting captions of these 5,000 test images. There are 17 parts of speech (POS) in these 1,000 words. The POS tags are obtained by the Stanford Parser (Manning, 2017).

We use the Embedding Projector in TensorBoard (Google, 2017) to plot 1,000 unbinding vectors $\mathbf{u}_t$ with a custom linear projection in TensorBoard to reduce 625 dimensions of $\mathbf{u}_t$ to 2 dimensions shown in Fig. 3 through Fig. 7.

Fig. 3 shows the unbinding vectors of 1000 words; different POS tags of words are represented by different colors. In fact, we can partition the 625-dim space of $\mathbf{u}_t$ into 17 regions, each of which

contains 76.3% words of the same type of POS on average; i.e., each region is dominated by words of one POS type. This clearly indicates that *each unbinding vector contains important grammatical information about the word it generates*. As examples, Fig. 4 to Fig. 7 show the distribution of the unbinding vectors of nouns, verbs, adjectives, and prepositions, respectively. Furthermore, we show that the subject and the object of a sentence can be distinguished based on $\mathbf{u}_t$ in (Huang et al., 2018).

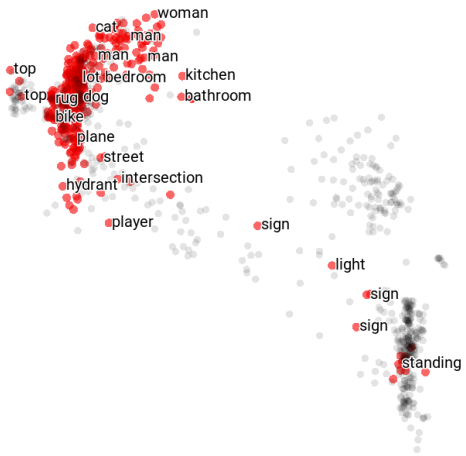

Figure 4: Unbinding vectors of 360 nouns in red and 640 words of other types of POS in grey.

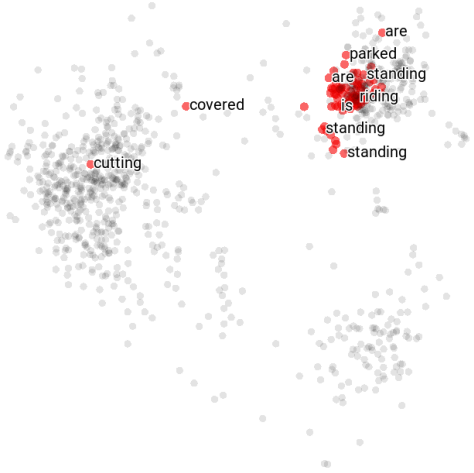

Figure 5: Unbinding vectors of 81 verbs in red and 919 words of other types of POS in grey.

5.3.2 Clustering of $\mathbf{u}_t$

Since the previous section indicates that there is a clustering structure for $\mathbf{u}_t$, in this section we partition $\mathbf{u}_t$ into N_u clusters and examine the grammar roles played by $\mathbf{u}_t$.

First, we run the trained TPGN model on the 113,287 training images, obtaining the role-

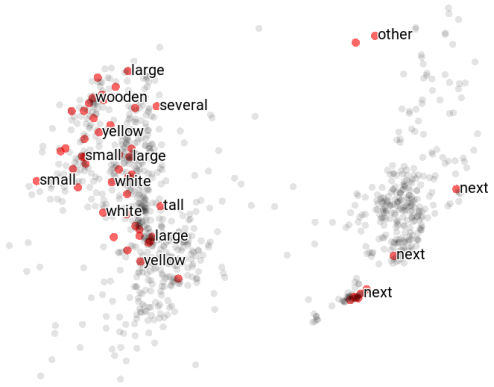

Figure 6: Unbinding vectors of 55 adjectives in red and 945 words of other types of POS in grey.

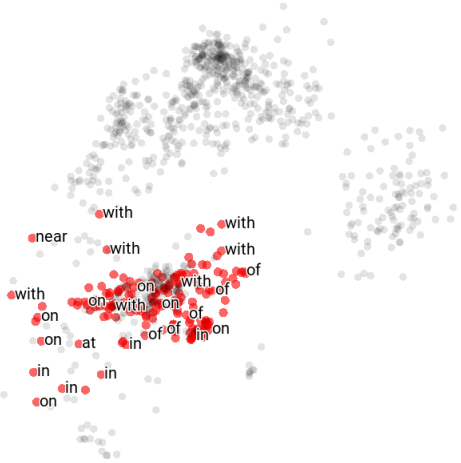

Figure 7: Unbinding vectors of 169 prepositions in red and 831 words of other types of POS in grey.

unbinding vector $\mathbf{u}_t$ used to generate each word $\mathbf{x}_t$ in the caption sentence. There are approximately 1.2 million $\mathbf{u}_t$ vectors over all the training images. We apply the K-means clustering algorithm to these vectors to obtain N_u clusters and the centroid $\boldsymbol{\mu}_i$ of each cluster i ($i = 0, \cdots, N_u - 1$).

Then, we run the TPGN model with 5,000 test images as input, and obtain the role vector $\mathbf{u}_t$ of each word $\mathbf{x}_t$ in the caption sentence of a test image. Using the nearest neighbor rule, we obtain the index i of the cluster that each $\mathbf{u}_t$ is assigned to.

The partitioning of the unbinding vectors $\mathbf{u}_t$ into $N_u = 2$ clusters exposes the most fundamental distinction made by the roles. We find that the vectors assigned to Cluster 1 generate words which are nouns, pronouns, indefinite and definite articles, and adjectives, while the vectors assigned to Cluster 0 generate verbs, prepositions, conjunctions, and adverbs. Thus Cluster 1 contains the noun-related words, Cluster 0 the verb-like words

6	Preposition (0.59), . (0.14)
8	Verb (0.37), Preposition (0.36), . (0.20)

Table 3: Interpretation of unbinding clusters ($N_u = 10$)

(verbs, prepositions and conjunctions are all potentially followed by noun-phrase complements, for example). Cross-cutting this distinction is another dimension, however: the initial word in a caption (always a determiner) is sometimes generated with a Cluster 1 unbinding vector, sometimes with a Cluster 0 vector. Outside the caption-initial position, exceptions to the nominal/verbal $\sim$ Cluster 1/0 generalization are rare, as attested by the high rates of conformity to the generalization shown in Table 5.3.1.

Table 5.3.1 shows the likelihood of correctness of this 'N/V' generalization for the words in 5,000 sentences captioned for the 5,000 test images; N_w is the number of words in the category, N_r is the number of words conforming to the generalization, and $P_c = N_r/N_w$ is the proportion conforming. We use the Natural Language Toolkit (NLTK, 2017) to identify the part of speech of each word in the captions.

A similar analysis with $N_u = 10$ clusters reveals the results shown in Table 5.3.1; these results concern the first 100 captions, which were inspected manually to identify interpretable patterns. (More comprehensive results will be discussed elsewhere.)

The clusters can be interpreted as falling into 3 groups (see Table 5.3.1). Clusters 2 and 3 are clearly positional roles: every initial word is generated by a role-unbinding vector from Cluster 2, and such vectors are not used elsewhere in the string. The same holds for Cluster 3 and the second caption word.

For caption words after the second word, position is replaced by syntactic/semantic properties for interpretation purposes. The vector clusters aside from 2 and 3 generate words with a dominant grammatical category: for example, unbinding vectors assigned to the cluster 4 generate words that are 91% likely to be prepositions, and 72% likely to be spatial prepositions. Cluster 7 generates 88% nouns and 9% adjectives, with the remaining 3% scattered across other categories. As Table 5.3.1 shows, clusters 1, 5, 7, 9 are primarily nominal, and 0, 4, 6, and 8 primarily verbal. (Only cluster 5 spans the N/V divide.)

6 Related work

This work follows a great deal of recent caption-generation literature in exploiting end-to-end deep learning with a CNN image-analysis front end producing a distributed representation that is then used to drive a natural-language generation process, typically using RNNs (Mao et al., 2015; Vinyals et al., 2015; Devlin et al., 2015; Chen and Zitnick, 2015; Donahue et al., 2015; Karpathy and Fei-Fei, 2015; Kiros et al., 2014a,b; Xu et al., 2017; Rennie et al., 2017; Yao et al., 2017; Lu et al., 2017). Our grammatical interpretation of the structural roles of words in sentences makes contact with other work that incorporates deep learning into grammatically-structured networks (Tai et al., 2015; Kumar et al., 2016; Kong et al., 2017; Andreas et al., 2015; Yogatama et al., 2016; Maillard et al., 2017; Socher et al., 2010; Pollack, 1990). Here, the network is not itself structured to match the grammatical structure of sentences being processed; the structure is fixed, but is designed to support the learning of distributed representations that incorporate structure internal to the representations themselves — filler/role structure.

TPRs are also used in NLP in (Palangi et al., 2017) but there the representation of each individual input word is constrained to be a literal TPR filler/role binding. (The idea of using the outer product to construct internal representations was also explored in (Fukui et al., 2016).) Here, by contrast, the learned representations are not themselves constrained, but the global structure of the network is designed to display the somewhat abstract property of being TPR-capable: the archi-

tecture uses the TPR unbinding operation of the matrix-vector product to extract individual words for sequential output.

7 Conclusion

Tensor Product Representation (TPR) (Smolensky, 1990) is a general technique for constructing vector embeddings of complex symbol structures in such a way that powerful symbolic functions can be computed using hand-designed neural network computation. Integrating TPR with deep learning is a largely open problem for which the work presented here proposes a general approach: design deep architectures that are TPR-capable — TPR computation is within the scope of the capabilities of the architecture in principle. For natural language generation, we proposed such an architecture, the Tensor Product Generation Network (TPGN): it embodies the TPR operation of unbinding which is used to extract particular symbols (e.g., words) from complex structures (e.g., sentences). The architecture can be interpreted as containing a part that encodes a sentence and a part that selects one structural role at a time to extract from the sentence. We applied the approach to image-caption generation, developing a TPGN model that was evaluated on the COCO dataset, on which it outperformed LSTM baselines on a range of standard metrics. Unlike standard LSTMs, however, the TPGN model admits a level of interpretability: we can see which roles are being unbound by the unbinding vectors generated internally within the model. We find such roles contain considerable grammatical information, enabling POS tag prediction for the words they generate and displaying clustering by POS.

Abstract

Contextual sequence mapping is one of the fundamental problems in Natural Language Processing. Instead of relying solely on the information presented in a text, the learning agents have access to a strong external signal given to assist the learning process. In this paper, we propose a novel family of Recurrent Neural Network unit: the *Context-dependent Additive Recurrent Neural Network* (*CARNN*) that is designed specifically to leverage this external signal. The experimental results on public datasets in the dialog problem (Babi dialog Task 6 and Frame), contextual language model (Switchboard and Penn Discourse Tree Bank) and question answering (TrecQA) show that our novel CARNN-based architectures outperform previous methods.

1 Introduction

Sequence mapping is one of the most prominent class of problems in Natural Language Processing (NLP). This is due to the fact that written language is sequential in nature. In English, a word is a sequence of characters, a sentence is a sequence of words, a paragraph is a sequence of sentences, and so on. However, understanding a piece of text may require far more than just extracting the information from that piece itself. If the piece of text is a paragraph of a document, the reader may have to consider it together with other paragraphs in the document and the topic of the document. To understand an utterance in a conversation, the utterance has to be put into the context of the conversation, which includes the goals of the participants and the dialog history. Hence the notion of context is an intrinsic component of language understanding.

Inspired by recent works in dialog systems (Seo et al., 2017; Liu and Perez, 2017), we formalize the contextual sequence mapping problem as a sequence mapping problem with a strong controlling contextual element that regulates the flow of information. The system has two sources of signals: (i) the main text input, for example, the history utterance sequence in dialog systems or the sequence of words in language modelling; and (ii) *the context signal*, e.g., the previous utterance in a dialog system, the discourse information in contextual language modelling or the question in question answering.

Our contribution in this work is two-fold. First, we propose a new family of recurrent unit, the *Context-dependent Additive Recurrent Neural Network* (*CARNN*), specifically constructed for contextual sequence mapping. Second, we design novel neural network architectures based on CARNN for dialog systems and contextual language modelling, and enhance the state of the art architecture (IWAN (Shen et al., 2017)) on question answering. Our novel building block, the CARNN, draws inspiration from the Recurrent Additive Network (Lee et al., 2017), which showed that most of the non-linearity in the successful Long Short Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997) is not necessary. In the same spirit, our CARNN unit minimizes the use of non-linearity in the model to facilitate the ease of gradient flow. We also seek to keep the number of parameters to a minimum to improve trainability.

We experiment with our models on a broad range of problems: dialog systems, contextual language modelling and question answering. Our systems outperform previous methods on several public datasets, which include the Babi Task 6 (Bordes and Weston, 2017) and the Frame dataset (Asri et al., 2017) for dialog, the Switchboard (Jurafsky et al., 1997) and Penn Discourse Tree Bank (Miltsakaki et al., 2004) for contextual language modelling, and the TrecQA

Proceedings of NAACL-HLT 2018, pages 1274–1283
New Orleans, Louisiana, June 1 - 6, 2018.

dataset (Wang et al., 2007) for question answering. We propose a different architecture for each task, but all models share the basic building block, the CARNN.

2 Background and Notation

Notation. As our paper describes several architectures with vastly different setups and input types, we introduce the following notation to maintain consistency and improve readability. First, the m-th input to the recurrent unit will be denoted $\mathbf{e}_m$. In language modelling, $\mathbf{e}_m$ is the embedding of the m-th word; while in dialog, it is the embedding of the m-th utterance (which is a combination of the embedding of the words inside the utterance, $\mathbf{x}_1^m \dots \mathbf{x}_{M_m}^m$). All the gates are denoted by $\mathbf{g}$, all the hidden vectors (outputs of the RNN) are denoted by $\mathbf{h}$. $\mathbf{W}s$ and $\mathbf{b}s$ are the RNN's parameters, σ denotes the sigmoid activation function, and $\odot$ denotes the element-wise product.

LSTM. The Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) is arguably one of the most popular building blocks for RNN. The main components of the LSTM are three gates: an input gate $\mathbf{g}_m^i$ to regulate the information flow from the input to the memory cell $\mathbf{c}_m$, a forget gate $\mathbf{g}_m^f$ to regulate the information flow from the previous time step's memory cell $\mathbf{c}_{m-1}$, and an output gate $\mathbf{g}_m^o$ that regulates how the model produces the outputs (hidden state $\mathbf{h}_m$) from the memory cell $\mathbf{c}_t$. The computations of LSTM are as follows:

$$\begin{aligned}
\tilde{\mathbf{c}}_m &= tanh(\mathbf{W}_h^c \mathbf{h}_{m-1} + \mathbf{W}_x^c \mathbf{e}_m + \mathbf{b}_c) \\
\mathbf{g}_m^i &= \sigma(\mathbf{W}_h^i \mathbf{h}_{m-1} + \mathbf{W}_x^i \mathbf{e}_m + \mathbf{b}_i) \\
\mathbf{g}_m^f &= \sigma(\mathbf{W}_h^f \mathbf{h}_{m-1} + \mathbf{W}_x^f \mathbf{e}_m + \mathbf{b}_f) \\
\mathbf{g}_m^o &= \sigma(\mathbf{W}_h^o \mathbf{h}_{m-1} + \mathbf{W}_x^o \mathbf{e}_m + \mathbf{b}_o) \\
\mathbf{c}_m &= \mathbf{g}_m^i \odot \tilde{\mathbf{c}}_m + \mathbf{g}_m^f \odot \mathbf{c}_{m-1} \\
\mathbf{h}_m &= \mathbf{g}_m^o \odot tanh(\mathbf{c}_m)
\end{aligned} \tag{1}$$

RAN. The Recurrent Additive Neural Network (RAN) (Lee et al., 2017) is an improvement over the traditional LSTM. However, there are three major differences between the two. First, RAN simplifies the output computations by removing the output gate. Second, RAN simplifies the memory cell computations by removing the direct dependency between the candidate update memory cell $\tilde{\mathbf{c}}_m$ and the previous hidden vector $\mathbf{h}_{m-1}$. Finally, RAN removes the non-linearity from the transition dynamic of RNN by removing the $tanh$ non-linearity from the $\tilde{\mathbf{c}}_m$. The equations for RAN are as follows:

$$\begin{aligned}
\tilde{\mathbf{c}}_m &= \mathbf{W}_x^c \mathbf{e}_m \\
\mathbf{g}_m^i &= \sigma(\mathbf{W}_h^i \mathbf{h}_{m-1} + \mathbf{W}_x^i \mathbf{e}_m + \mathbf{b}_i) \\
\mathbf{g}_m^f &= \sigma(\mathbf{W}_h^f \mathbf{h}_{m-1} + \mathbf{W}_x^f \mathbf{e}_m + \mathbf{b}_f) \\
\mathbf{c}_m &= \mathbf{g}_m^i \odot \tilde{\mathbf{c}}_m + \mathbf{g}_m^f \odot \mathbf{c}_{m-1} \\
\mathbf{h}_m &= s(\mathbf{c}_m)
\end{aligned} \tag{2}$$

where s can be an identity function (identity RAN) or the $tanh$ activation function ($tanh$ RAN).

As shown in (Lee et al., 2017), RAN's memory cells $\mathbf{c}_m$ can be decomposed into a weighted sum of the inputs. Their experimental results show that RAN performs as well as LSTM for language modelling, while having significantly fewer parameters.

3 The Context-dependent Additive Recurrent Neural Net (CARNN)

In this section, we describe our novel recurrent units for the context-dependent sequence mapping problem.

Our RNN units use a different gate arrangement than that used by RAN. However, if we consider a broader definition of identity RAN, i.e., an RNN where hidden unit outputs can be decomposed into a weighted sum of inputs, where the weights are functions of the gates, then our first CARNN unit (nCARNN) can be viewed as an extension of identity RAN with additional controlling context.

The next two CARNN units (iCARNN and sCARNN) further simplify the nCARNN unit to improve trainability.

3.1 Non-independent gate CARNN (nCARNN)

The main components of our recurrent units are the two gates (an update gate $\mathbf{g}^u$ and a reset gate $\mathbf{g}^f$), which jointly regulate the information from the input. The input vector, after being pushed through an affine transformation, is added into the previous hidden vector $\mathbf{h}_{m-1}$. The computations of the unit are as follows:

$$\begin{aligned}
\mathbf{g}_m^u &= \sigma(\mathbf{W}_u^c \mathbf{c} + \mathbf{W}_u^h \mathbf{h}_{m-1} + \mathbf{W}_u^e \mathbf{e}_m + \mathbf{b}_u) \\
\mathbf{g}_m^f &= \sigma(\mathbf{W}_f^c \mathbf{c} + \mathbf{W}_f^h \mathbf{h}_{m-1} + \mathbf{W}_f^e \mathbf{e}_m + \mathbf{b}_f) \\
\bar{\mathbf{e}}_m &= \mathbf{W}_{\bar{e}} \mathbf{e}_m + \mathbf{b}_{\bar{e}} \\
\mathbf{h}_m &= \mathbf{g}_m^u \odot (\mathbf{g}_m^f \odot \bar{\mathbf{e}}_m) + (1 - \mathbf{g}_m^u) \odot \mathbf{h}_{m-1}
\end{aligned} \tag{3}$$

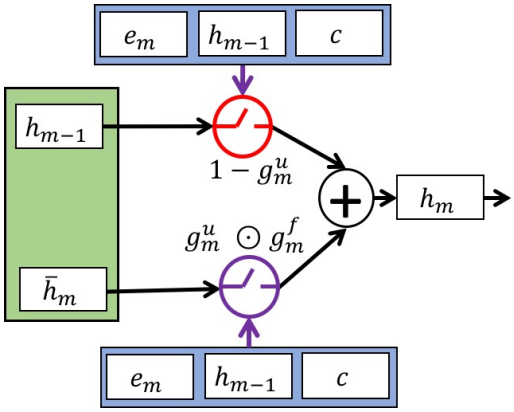

Figure 1: Context Dependent Additive Recurrent Neural Network. Note that only nCARNN has the previous hidden state $\mathbf{h}_{m-1}$ in its gate computation, iCARNN and sCARNN do not.

where $\mathbf{c}$ is the representation of the global context.

Apart from the non-linearity in the gates, our model is a linear function of the inputs. Hence, the final hidden layer of our RNN, denoted as $\mathbf{h}_M$, is a weighted sum of the inputs and a bias term $\mathbf{B}_i$ (Equation 4), where the weights are functions of the gates and $\mathbf{W}_{\bar{e}}$ is a dimension reduction matrix.

$$\begin{aligned}\mathbf{h}_M &= \mathbf{g}_M^u \odot \mathbf{g}_M^f \odot \bar{\mathbf{e}}_M + (1 - \mathbf{g}_M^u) \odot \mathbf{h}_{M-1} \\ &= \sum_{i=1}^{M} (\mathbf{g}_i^u \odot \mathbf{g}_i^f \odot \prod_{j=i+1}^{M} (1 - \mathbf{g}_j^u)) \odot \bar{\mathbf{e}}_i \\ &= \sum_{i=1}^{M} [(\mathbf{g}_i^u \odot \mathbf{g}_i^f \odot \prod_{j=i+1}^{M} (1 - \mathbf{g}_j^u)) \odot \mathbf{W}_{\bar{e}} \mathbf{e}_i + \mathbf{B}_i]\end{aligned} \tag{4}$$

From the decomposition in Equation 4, it seems that the outputs of an RNN with the nCARNN unit can be efficiently computed in parallel. That is, we can compute the weight for each input in parallel, and take their weighted sum to produce any desired hidden vector output. However, there is one obstacle: since the gates are functions of the previous hidden states, they still need to be computed sequentially. But if we assume that the external controlling context $\mathbf{c}$ is strong enough to regulate the flow of information, we can remove the previous hidden state (local context $\mathbf{h}_{m-1}$) from the gate computations, and make the RNN computations parallel. The next two variants of CARNN implement this idea by removing the local context from gate computations.

3.2 Independent gate CARNN (iCARNN)

The Gated Recurrent Unit (GRU) (Chung et al., 2014) and LSTM networks use a local context (the previous hidden state $\mathbf{h}_{m-1}$) and the current input to regulate the flow of information. In contrast, our model, relies on the global controlling context $\mathbf{c}$ at every step, and thus, might not need the local context $\mathbf{h}_{m-1}$ at all. Removing the local context can reduce the computational complexity of the model, but it may result in a loss of local sequential information. To test the effectiveness of this trade-off, we propose another variant of our unit, the *independent gate CARNN* (*iCARNN*), where the gate computations are simplified, and the gates are functions of the controlling context and the inputs. This formulation of CARNN is formally defined as follows.

$$\begin{aligned}\mathbf{g}_m^u &= \sigma(\mathbf{W}_u^c \mathbf{c} + \mathbf{W}_u^e \mathbf{e}_m + \mathbf{b}_u) \\ \mathbf{g}_m^f &= \sigma(\mathbf{W}_f^c \mathbf{c} + \mathbf{W}_f^e \mathbf{e}_m + \mathbf{b}_f) \\ \bar{\mathbf{e}}_m &= \mathbf{W}_{\bar{e}} \mathbf{e}_m + \mathbf{b}_{\bar{e}} \\ \mathbf{h}_m &= \mathbf{g}_m^u \odot (\mathbf{g}_m^f \odot \bar{\mathbf{e}}_m) + (1 - \mathbf{g}_m^u) \odot \mathbf{h}_{m-1}\end{aligned} \tag{5}$$

Compared to the traditional RNN, iCARNN's gates computations do not take into account the sequence context, i.e., the previous hidden vector computations, and the gates at all time steps can be computed in parallel. However, iCARNN, unlike memory network models (Sukhbaatar et al., 2015; Liu and Perez, 2017), still retains the sequential nature of RNN. This is because even though the gates at different time steps do not depend on each other, the hidden vector output at the m-th time step $\mathbf{h}_m$ depends on the previous gate ($\mathbf{g}_{m-1}^u$), and hence on the previous input.

3.3 Simplified candidate CARNN (sCARNN)

The standard GRU and the LSTM employ a linear transformation on the input representation before it is incorporated into the hidden representation. We have followed this convention with the previous variants of our unit. Although this transformation improves dimensional flexibility of the input/output vector, and adds representational power to the model with additional parameters, it also increases computational complexity. Fixing the output dimension to be the same as the input dimension makes it possible to reduce the computational complexity of the model. This leads us to propose another variant of the CARNN where the candidate update $\bar{\mathbf{e}}_m$ is the original embedding of the

current input (Equation 6). We call this variation the *simplified candidate CARNN* (*sCARNN*). The combination of lower gate computational complexity and the parallel-ability allow the paralleled sCARNN version to be 30% faster (30% lower training time for each epoch) than nCARNN in the question answering and dialog experiments, and 15% faster in the language model experiment. The sCARNN is formally defined as follows.

$$\begin{aligned}\mathbf{g}_m^u &= \sigma(\mathbf{W}_u^c\mathbf{c} + \mathbf{W}_u^e\mathbf{e}_m + \mathbf{b}_u)\\ \mathbf{g}_m^f &= \sigma(\mathbf{W}_f^c\mathbf{c} + \mathbf{W}_f^e\mathbf{e}_m + \mathbf{b}_f)\\ \mathbf{h}_m &= \mathbf{g}_m^u \odot (\mathbf{g}_m^f \odot \mathbf{e}_m) + (1 - \mathbf{g}_m^u) \odot \mathbf{h}_{m-1}\end{aligned} \tag{6}$$

sCARNN can still be decomposed into a weighted sum of the sequence of input elements, and retains the parallel computation capability of the iCARNN.

$$\begin{aligned}\mathbf{h}_M &= \mathbf{g}_M^u \odot \mathbf{g}_M^f \odot \mathbf{e}_m + (1 - \mathbf{g}_M^u) \odot \mathbf{h}_{M-1}\\ &= \sum_{i=1}^{M}(\mathbf{g}_i^u \odot \mathbf{g}_i^f \odot \prod_{j=i+1}^{M}(1 - \mathbf{g}_j^u)) \odot \mathbf{e}_i\end{aligned} \tag{7}$$

4 CARNN-based models for NLP problems

In this section, we explain the details of our CARNN-based architectures for end-to-end dialog, language modelling and question answering. In each of these applications, one of the main design concerns is the choice of contextual information. As we will demonstrate in this section, the controlling context $\mathbf{c}$ can be derived from various sources: a sequence of words (dialog and question answering), a class variable (language modelling). Virtually any sources of strong information that can be encoded into vectors can be used as controlling context.

4.1 End-to-end dialog

To produce a response, we first encode the whole dialog history into a real vector representation $\mathbf{h}_{his}$. To this effect, we perform two steps: first, we encode each utterance (sequence of words) into a real vector, and next, we encode this sequence of real vector representations into $\mathbf{h}_{his}$. We employ the Position Encoder (Bordes and Weston, 2017) for the first step, and CARNNs for the second step.

Summarizing individual utterances. Let's denote the sequence of word-embeddings in the m-th utterance $\mathbf{x}_1^m, \ldots \mathbf{x}_{N_m}^m$. These word embeddings are jointly trained with the model. Following previous work in end-to-end dialog systems, we opt to use the Position Encoder (Liu and Perez, 2017; Bordes and Weston, 2017) for encoding utterances.

The Position Encoder is an improvement over the average embedding of bag of words, as it takes into account the position of the words in a sequence. This encoder has been empirically shown to perform well on the Babi dialog task (Liu and Perez, 2017; Bordes and Weston, 2017); more details about the Position Encoder can be found in (Sukhbaatar et al., 2015). Let's denote the the embeddings of a sequence of utterances $\mathbf{e}_1, \ldots \mathbf{e}_{M-1}$.

Summarizing the dialog history. The CARNN models take the embeddings of the sequence of utterances and produce the final representation $\mathbf{h}_{his}$. We further enhance the output of the CARNN by adding the residual connection to the input (He et al., 2016; Tran et al., 2017), and the attention mechanism (Bahdanau et al., 2015) over the history.

$$\begin{aligned}\mathbf{h}_1, ..\mathbf{h}_{M-1} &= CARNN(\mathbf{e}_1, ..\mathbf{e}_{M-1}, \mathbf{c})\\ \forall m \in [1..M-1] &: \tilde{\mathbf{h}}_m = \mathbf{h}_m + \mathbf{e}_m\\ \alpha_1..\alpha_{M-1} &= softmax(\tilde{\mathbf{h}}_1^T\mathbf{c}, .., \tilde{\mathbf{h}}_{M-1}^T\mathbf{c})\\ \mathbf{h}_{his} &= \sum_{m=1}^{M-1}\alpha_m\tilde{\mathbf{h}_m}\end{aligned} \tag{8}$$

where α are the attention weights, $\mathbf{h}_m$ is the m-th output of the base CARNN, $\mathbf{e}_m$ is the embedding of the m-th input utterance, and $\mathbf{c} = \mathbf{e}_M$ is the context embedding.

Our model chooses the response from a set of pre-determined system answers (a task setup following Bordes and Weston (2017); Liu and Perez (2017); Seo et al. (2017)). However, in the dialog case, the answers themselves are sequences of words, and treating them as distinct classes may not be the best approach. In fact, previous work in memory networks (Liu and Perez, 2017; Bordes and Weston, 2017) employs a feature function Φ to extract features from the candidate responses. In our work, we do not use any feature extraction, and simply use the Position Encoder to encode the

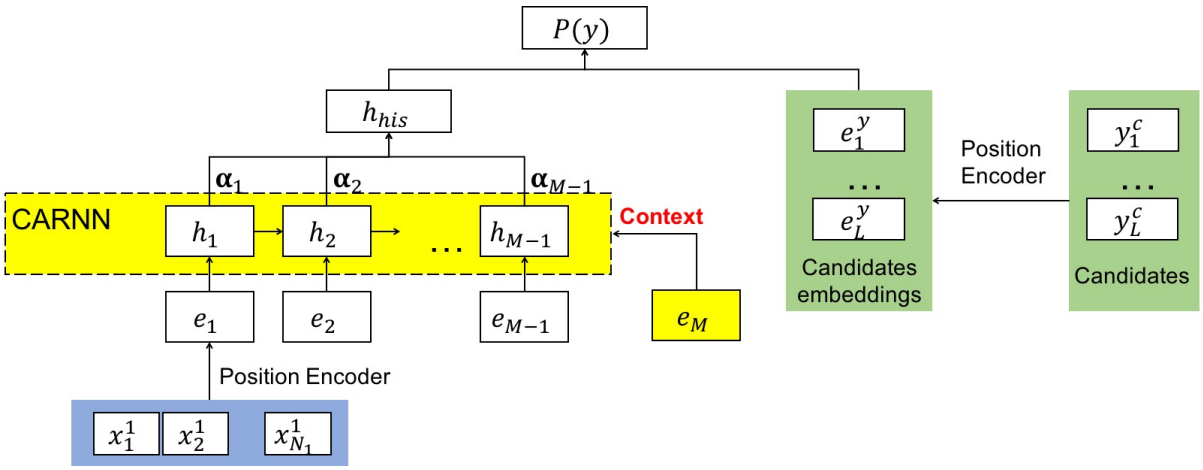

Figure 2: CARNN for dialog.

responses as shown in Figure 2, which depicts our architecture of CARNN for dialog.

$$\forall l \in [1..L] : \mathbf{e}_l = Position\_Encoder(y_l^c) \quad (9)$$

We then put a distribution over the candidate responses conditioned on the summarized dialog history $\mathbf{h}_{his}$ (Equation 10).

$$\mathbb{P}(y) = softmax(\mathbf{h}_{his}^T \mathbf{e}_1^y, ..., \mathbf{h}_{his}^T \mathbf{e}_L^y) \quad (10)$$

4.2 Contextual language model

Typically, language models operate at the sentence level, i.e., the sentences are treated independently. Several researchers have explored inter-sentence and inter-document level contextual information for language modelling (Ji et al., 2016a,b; Tran et al., 2016; Lau et al., 2017).

Following Ji et al. (2016a,b), we investigate two types of contextual information: (i) the previous sentence context; and (ii) a latent variable capturing the connection information between sentences, such as discourse relation in the Penn Discourse Tree Bank dataset or Dialog Acts in the Switchboard dataset.

Previous sentence context. The previous sentence (time-step $t-1$) contextual information is encoded by a simplified version of the nCARNN, where the global context is absent. The final hidden vector of this sequence is then fed into the current recurrent computation (time-step t) as the context for that sequence. Equation 11 shows this procedure.

$$\begin{aligned} \mathbf{c}^{t-1} &\longleftarrow nCARNN(\mathbf{e}_1^{t-1}, ..\mathbf{e}_{M^{t-1}}^{t-1}) \\ \mathbf{h}_1^t, ..\mathbf{h}_{M^{t-1}}^t &= CARNN(\mathbf{e}_1^t, ..\mathbf{e}_{M^t}^t, \mathbf{c}^{t-1}) \\ w_{m+1}^t &\sim softmax(\mathbf{W}^{(l)} \mathbf{h}_m^t + \mathbf{b}^{(l)}) \end{aligned} \quad (11)$$

Latent variable context. Ji et al. (2016b) proposed to embed the predicted latent variables using an embedding matrix, and use this real vector as the contextual information. In our work, we design a multi-task learning scenario where the previous sentence context encoder has additional supervised information obtained from the annotated latent variable (L^{t-1}). This additional information from the latent variable is only used to train the previous sentence encoder, and enhance the context $\mathbf{c}^{t-1}$ (Equation 12). During test time, the language model uses the same computation steps as the previous sentence context version.

$$\begin{aligned} \mathbb{P}(L^{t-1}) &= softmax(\mathbf{W}^{(c)} \mathbf{c}^{t-1} + \mathbf{b}^{(c)}) \\ \mathbb{L}_l^{t-1} &\sim \mathbb{P}(L^{t-1}) \end{aligned} \quad (12)$$

During training, the total loss function ($\mathbb{L}_{l,w}^t$) is the linear combination of the average log-loss from the current sentence's words ($\mathbb{L}_w^t$) and the log-loss from the previous latent variable ($\mathbb{L}_l^{t-1}$).

$$\mathbb{L}_{l,w}^t = \alpha \mathbb{L}_w^t + (1-\alpha)\mathbb{L}_l^{t-1} \quad (13)$$

where α is a linear mixing parameter. In our experiments, tuning α does not yield significant improvements, hence we set $\alpha = 0.5$.

4.3 Question answering

Answer selection is an important component of a typical question answering system. This task can be briefly described as follows: Given a question q and a candidate set of sentences $c_1, c_2, \ldots c_n$, the goal is to identify positive sentences that contain the answer. Many researchers have investigated employing neural networks for this task (Rao

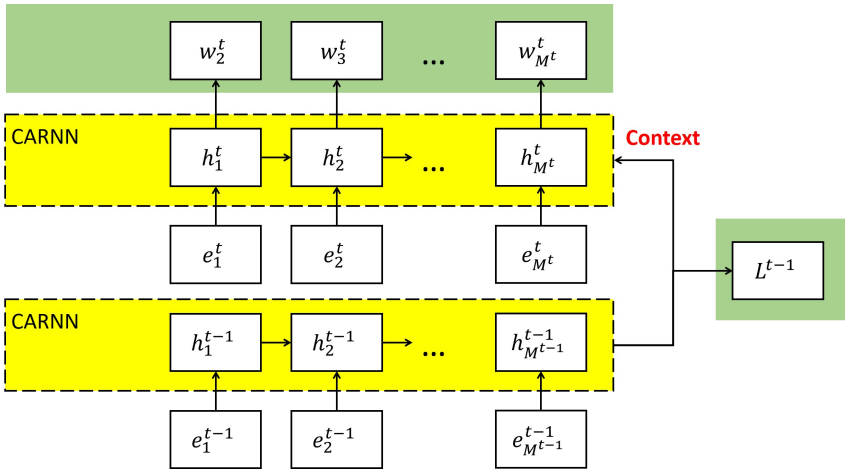

Figure 3: CARNN for context-dependent language model.

et al., 2016; Wang et al., 2017; Bian et al., 2017; Shen et al., 2017; Tay et al., 2017; He et al., 2015). Below is an example from the answer selection TrecQA corpus:

> **Question**: Who established the Nobel prize awards?
> **Positive answer**: The Nobel Prize was established in the will of Alfred Nobel, a Swede who invented dynamite and died in 1896.
> **Negative answer**: The awards aren't given in specific categories.

The IWAN model proposed in (Shen et al., 2017) achieves state-of-the-art performance on the Clean version TrecQA dataset (Wang et al., 2007) for answer selection. In general, given two sentences, the model aims to calculate a score to measure their similarity. For each sentence, the model first uses a bidirectional LSTM to obtain a context-aware representation for each position in the sentence. The representations will later be utilized by the model to compute similarity score of the two sentences according to the degree of their alignment (Shen et al., 2017).

The original IWAN model employed LSTM to encode the sentence pair into sequences of real vector representations. However, these sequences are independent, and do not take into account the information from the other sentence. In order to overcome this limitation, we enhance the IWAN model with a "cross context CARNN-based sentence encoder" that replaces the bidirectional LSTM. When the cross context CARNN sentence encoder processes a sentence, it takes the encoding of the other sentence, encoded by a Position Encoder, as the controlling context (Figure 4).

5 Experiments

5.1 End-to-end dialog

Datasets. For the dialog experiments, we focus on two popular datasets for dialog: the Babi dataset (Bordes and Weston, 2017) and the Malluba Frame dataset (Asri et al., 2017).[1]

In our main set of experiments for dialog, we use the original Babi task 6 dataset, and test on the end-to-end dialog setting (the same setting used by Seo et al. (2017); Bordes and Weston (2017); Liu and Perez (2017)). That is, the systems have to produce complete responses and learn the dialog behaviour solely from the ground truth responses without help from manual features, rules or templates. Apart from this main set of experiments, we apply our end-to-end systems as dialog managers and test on a slightly different setting in the next two sets of experiments.

In the second set of experiments, we use our end-to-end systems as "dialog managers". The only difference compared to the end-to-end dialog setting is that the systems produce templatized responses instead of complete responses. Our motivation for this dialog manager setting is that in our preliminary experiments with the Babi dataset, we found out that many of the classification errors are due to very closely related responses, all of which fit the corresponding context. We argue that if we treat the systems as dialog managers, then we can delexicalize and group similar responses. Thus following Williams et al. (2017), we construct a templatized set of responses. For example, all the

[1] Among the Babi tasks, we focus mainly on task 6, which is based on real human-machine interactions. The other five Babi datasets comprise synthetically generated data.

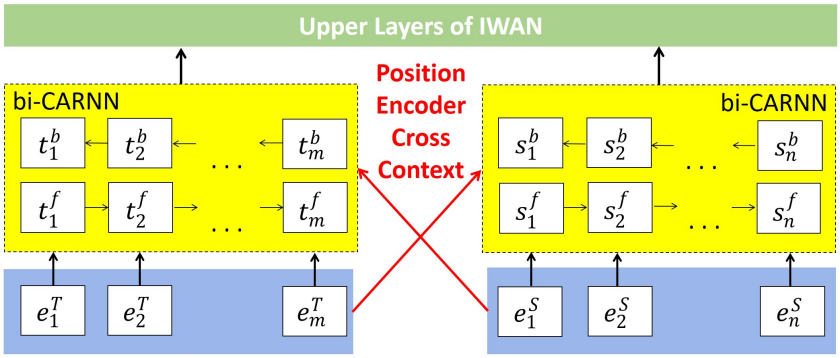

Figure 4: CARNN for Question Answering.

responses similar to *"**india_house** is in the **west** part of town"* will be grouped into *"**_name_** is in the **_loc_** part of town"*. The set of responses is reduced to 75 templatized responses. We call this new dataset "Babi reduced".[2]

The third set of experiments is conducted on the Frame dataset. The general theme in this dataset is similar to that of the Babi task 6, but the responses in the Frame dataset are generally in free form, rather than being sourced from a limited set. Thus, we define a dialog task on the Frame data set similar to the Babi reduced dialog task by simplifying and grouping the responses.[3] The final set of responses consists of 129 response classes. For the experiments on the Frame dataset, we randomly choose 80% of the conversations as the training set, and 10% each for testing and development.

Baselines. In the dialog experiments, we focus on the existing published results with end-to-end settings, namely the Memory Network (MN) (Bordes and Weston, 2017), the Gated Memory Network (GMN) (Liu and Perez, 2017) and the Query Reduction Network (QRN) (Seo et al., 2017).[4] For the Frame and Babi reduced datasets, we use the publicly available implementation of the QRN,[5] and our implementation of the GMN with hyper parameters similar to those reported by Liu and Perez (2017); Seo et al. (2017). Note that the original results presented by Seo et al. (2017), take into account partial matches (matching only a portion of the ground truth response), and hence cannot be directly translated into the standard response accuracy reported by other researchers (we have confirmed this with Seo *et al.*). For a direct comparison with the QRN, we use the evaluation settings employed in other papers (Liu and Perez, 2017; Sukhbaatar et al., 2015).

Model	Babi	Babi reduced	Frame
nCARNN	51.3%*	55.8%*	27.4%*
iCARNN	52.0%*	55.2%*	28.5%*
sCARNN	50.9%*	55.9%*	25.7%*
CARNN voting	**53.2%***	**56.9%***	**29.1%***
QRN (2017)	46.8%	54.7%	24.0%
GMN (2017)	47.4%	54.1%	23.6%
MN (2017)	41.1%	–	–

Table 1: Dialog accuracy on Babi and Frame among end-to-end systems. * indicates statistical significance with $p < 0.1$ compared to QRN.

Results and discussion. Table 1 shows the results of the end-to-end models for the dialog task. All the CARNN-based systems are implemented in Tensorflow (Abadi et al., 2015) with a hidden vector size of 1024. As seen in Table 1, our models achieve the best results, and within the variants of our models, the iCARNN either performs the best, or very close to the best on all datasets. Majority voting provides a significant boost to the performance of the CARNN models. Upon comparison with the baseline systems, CARNN models tend to perform better on instances which require the system to remember specific information through a long dialog history. In Figure 5, the user already mentioned that he/she wants to find a "cheap" restaurant, but the GMN and QRN seem to "forget" this information. We speculate that due

[2]We do not have access to Williams et al. (2017)'s template set, thus the results in Babi reduced are not comparable to those obtained by Williams et al. (2017).

[3]We use only one of the annotated *"Dialog acts"* and its first slot key as a template for the response.

[4]Williams et al. (2017) and Liu and Lane (2017) reported very strong performances (55.6% and 52.8% respectively) for the Babi dataset. However, these systems do not learn dialog behaviour solely from Babi's ground truth responses, and thus do not have end-to-end dialog setups. As stated in their papers, Williams *et al.*use hand-coded rules and task-specific templates, while Liu *et al.*employ the external users' goal annotations that are outside the Babi dataset.

[5]https://github.com/uwnlp/qrn

U: im looking for a cheap restaurant
S: ... What type of food do you want??
...5 dialog turns...
S: Could you please repeat that?
U: vietnamese food

CARNN action: api_call vietnamese R_location cheap
QRN action: api_call vietnamese R_location R_price
GMN action: api_call vietnamese R_location R_price

Figure 5: Sample dialog from our system compared to the baselines. Only CARNN's predicted action takes into account the original cheap restaurant request and matches the ground truth action (in the systems' api calls, "R_price" denotes "any price").

to the ease of training, CARNN models summarize the dialog history better, and allow for longer information dependency.

The CARNN units are originally designed in the dialog context. During model calibration, we also tested in the dialog experiments two other CARNN versions with both higher and lower complexity. The lower complexity CARNN version resembles sCARNN without the forget gate, and the higher complexity CARNN version resembles the LSTM unit with all three gates (forget, update and output), with the gates being modified from the original LSTM gates to be functions of the external contextual information. Both of these versions do not perform as well as the three main CARNN versions (48.7% and 48.6% for the high- and low-complexity versions respectively in the Babi task).

5.2 Contextual language model

Datasets. We employ two datasets for the experiments with the contextual language model: the Switchboard Dialog Act corpus and the Penn Discourse Tree Bank corpus. There are 1155 telephone conversations in the Switchboard corpus, where each conversation has an average of 176 utterances. There were originally 226 Dialog Act (DA) labels in the corpus, but they are usually clustered into 42 labels. The Penn Tree Bank corpus provides discourse relation annotation between the spans of text. We used the preprocessed data by Ji et al. (2016b), where the explicit discourse relations are mapped into a dummy relation. Our data splits are the same as those described in the baselines (Ji et al., 2016a,b).

Baselines. We compare our system with the Recurrent Neural Net (RNNLM) with LSTM unit (Ji et al., 2016a), the Document Contextual Language Model (DCLM) (Ji et al., 2016a) and the Discourse Relation Language Model (DRLM) (Ji et al., 2016b). The RNNLM's architecture is the same as that described in (Mikolov et al., 2013) with sigmoid non-linearity replaced by LSTM. The DCLM exploits the inter-sentences context by concatenating the representation of the previous sentence with the input vector (context-to-context) or the hidden vector (context-to-output). The DRLM introduces the latent variable contextual models using a generative architecture that treats Dialog Acts or discourse relations as latent variables.

Model	Penn Discourse Tree Bank	Switchboard
nCARNN (w/o latent)	96.95	30.17
iCARNN (w/o latent)	94.72	32.49
sCARNN (w/o latent)	87.39	31.50
nCARNN (with latent)	96.64	**29.72**
iCARNN (with latent)	94.16	32.16
sCARNN (with latent)	**86.68**	31.49
RNNLM (2016b)	117.8	56.0
DCLM (2016a)	112.2	45.3
DRLM (2016b)	108.3	39.6

Table 2: Perplexity on Switchboard and Penn Discourse Tree Bank.

Model	MAP	MRR
IWAN (our implementation) + nCARNN*	0.827	0.889
IWAN (our implementation) + iCARNN*	0.826	**0.907**
IWAN (our implementation) + sCARNN*	**0.829**	0.875
IWAN (our implementation)	0.794	0.879
IWAN (2017)	0.822	0.889
Compare-Aggregate (2017)	0.821	0.899
BiMPM (2017)	0.802	0.875
NCE-CNN (2016)	0.801	0.877
HyperQA (2017)	0.784	0.865

Table 3: MAP and MRR for question answering. * indicates statistical significance with $\alpha < 0.05$ in t-test compared to IWAN (our implementation).

Results and discussion. Table 2 shows the test set perplexities across the systems for the Penn Tree Bank and Switchboard datasets. Interestingly, in these experiments, the system with the least computational complexity, the sCARNN, performs best on Penn Discourse Tree Bank, and second best on Switchboard. Generally, we found out that adding the Dialog Act/Discourse supervised signal in a multi-task learning scheme provides a boost to performance, but this improvement is small.

5.3 Question answering

Datasets. The TrecQA dataset (Wang et al., 2007) is a widely-used benchmark for answer selection. There are two versions of TrecQA: original and clean. The original TrecQA consists of 1,229 training questions, 82 development questions, and 100 test questions. Recently, researchers (Rao et al., 2016; Shen et al., 2017) developed a clean version, where they removed questions in the development and test sets with no answers or only positive/negative answers. This reduced the development and test set's sizes to 65 and 68 questions respectively.

Baselines. We compare the performance of our models with that of the state-of-the-art models on the clean version of the TREC-QA dataset (Shen et al., 2017; Bian et al., 2017; Wang et al., 2017; Rao et al., 2016; Tay et al., 2017). We do not have access to the original implementation of IWAN, hence we use our implementation of the IWAN model as the basis for our models.

Results and discussion. Table 3 shows the MAP (Mean Average Precision) and MRR (Mean Reciprocal Rank) of our systems and the baselines. To the best of our knowledge, our systems outperform all previous systems on this dataset. Enhancing IWAN with cross-context CARNN statistically significantly improves performance. Among the variants, the iCARNN is the most consistent in both MAP and MRR. During our error analysis, we noted that the top answer returned by IWAN models with either LSTM or CARNNs are usually good. However, in many cases, lower ranked answers returned by the LSTM model are not as good as those produced by the CARNN models. We show an example of this in Table 4.

6 Conclusion and future work

In this paper, we propose a novel family of RNN units which are particularly useful for the contextual sequence mapping problem: the CARNNs. Together with our neural net architectures, CARNN-based systems outperform previous methods on several public datasets for dialog (Frame and Babi Task 6), question answering (TrecQA) and contextual language modelling (Switchboard and Penn Discourse Tree Bank). In the future, we plan to investigate the effectiveness of CARNN units in other sequence modelling tasks.

Question: **During what war did Nimitz serve?**

IWAN-LSTM	IWAN-iCARNN
Since the museum opened in 1983, Fredericksburg has become a haven for retired military servicemen who come to trace Nimitz's career and the events of World War II.	Since the museum opened in 1983, Fredericksburg has become a haven for retired military servicemen who come to trace Nimitz's career and the events of World War II.
Bill McCain, who graduated from West Point, chased Pancho Villa with Gen. Blackjack Pershing, served as an artillery officer during World War I and attained the rank of brigadier general.	Indeed, the ancestors of Chester W. Nimitz, the U.S. naval commander in chief of the Pacific in World War II, were among the first German pioneers to settle the area.
There was his grandfather, Admiral John "Slew" McCain, Class of 1906, a grizzled old sea dog who commanded aircraft carriers in the Pacific during World War II.	Slew McCain's peers at the Naval Academy were Chester Nimitz and William "Bull" Halsey, who would become major commanders during World War II.

Table 4: Top three answers produced by CARNN and LSTM. Blue colored answers are correct and red ones are incorrect.

Abstract

Natural language sentences, being hierarchical, can be represented at different levels of granularity, like words, subwords, or characters. But most neural machine translation systems require the sentence to be represented as a sequence at a single level of granularity. It can be difficult to determine which granularity is better for a particular translation task. In this paper, we improve the model by incorporating multiple levels of granularity. Specifically, we propose (1) an encoder with character attention which augments the (sub)word-level representation with character-level information; (2) a decoder with multiple attentions that enable the representations from different levels of granularity to control the translation cooperatively. Experiments on three translation tasks demonstrate that our proposed models outperform the standard word-based model, the subword-based model and a strong character-based model.

1 Introduction

Neural machine translation (NMT) models (Britz et al., 2017) learn to map from source language sentences to target language sentences via continuous-space intermediate representations. Since word is usually thought of as the basic unit of language communication (Jackendoff, 1992), early NMT systems built these representations starting from the word level (Sutskever et al., 2014; Bahdanau et al., 2015; Cho et al., 2014; Weng et al., 2017). Later systems tried using smaller units such as subwords to address the problem of out-of-vocabulary (OOV) words (Sennrich et al., 2016; Wu et al., 2016).

Although they obtain reasonable results, these word or sub-word methods still have some potential weaknesses. First, the learned representations of (sub)words are based purely on their contexts, but the potentially rich information inside the unit itself is seldom explored. Taking the Chinese word 被打伤 (*bei-da-shang*) as an example, the three characters in this word are a passive voice marker, "hit" and "wound", respectively. The meaning of the whole word, "to be wounded", is fairly compositional. But this compositionality is ignored if the whole word is treated as a single unit.

Secondly, obtaining the word or sub-word boundaries can be non-trivial. For languages like Chinese and Japanese, a word segmentation step is needed, which must usually be trained on labeled data. For languages like English and German, word boundaries are easy to detect, but subword boundaries need to be learned by methods like BPE. In both cases, the segmentation model is trained only in monolingual data, which may result in units that are not suitable for translation.

On the other hand, there have been multiple efforts to build models operating purely at the character level (Ling et al., 2015a; Yang et al., 2016; Lee et al., 2017). But splitting this finely can increase potential ambiguities. For example, the Chinese word 红茶 (*hong-cha*) means "black tea," but the two characters means "red" and "tea," respectively. It shows that modeling the character sequence alone may not be able to fully utilize the information at the word or sub-word level, which may also lead to an inaccurate representation. A further problem is that character sequences are longer, making them more costly to process with a recurrent neural network model (RNN).

While both word-level and character-level information can be helpful for generating better representations, current research which tries to exploit both word-level and character-level information only composed the word-level representation by character embeddings with the word boundary information (Ling et al., 2015b; Costa-jussà and

Proceedings of NAACL-HLT 2018, pages 1284–1293
New Orleans, Louisiana, June 1 - 6, 2018.

Fonollosa, 2016) or replaces the word representation with its inside characters when encountering the out-of-vocabulary words (Luong and Manning, 2016; Wu et al., 2016). In this paper, we propose a novel encoder-decoder model that makes use of both character and word information. More specifically, we augment the standard encoder to attend to individual characters to generate better source word representations (§3.1). We also augment the decoder with a second attention that attends to the source-side characters to generate better translations (§3.2).

To demonstrate the effectiveness of the proposed model, we carry out experiments on three translation tasks: Chinese-English, English-Chinese and English-German. Our experiments show that: (1) the encoder with character attention achieves significant improvements over the standard word-based attention-based NMT system and a strong character-based NMT system; (2) incorporating source character information into the decoder by our multi-scale attention mechanism yields a further improvement, and (3) our modifications also improve a subword-based NMT model. To the best of our knowledge, this is the first work that uses the source-side character information for all the (sub)words in the sentence to enhance a (sub)word-based NMT model in both the encoder and decoder.

2 Neural Machine Translation

Most NMT systems follow the encoder-decoder framework with attention mechanism proposed by Bahdanau et al. (2015). Given a source sentence $\mathbf{x} = x_1 \cdots x_l \cdots x_L$ and a target sentence $\mathbf{y} = y_1 \cdots y_j \cdots y_J$, we aim to directly model the translation probability:

$$P(\mathbf{y} \mid \mathbf{x}; \theta) = \prod_{1}^{J} P(y_j \mid \mathbf{y}_{<j}, \mathbf{x}; \theta),$$

where θ is a set of parameters and $\mathbf{y}_{<j}$ is the sequence of previously generated target words. Here, we briefly describe the underlying framework of the encoder-decoder NMT system.

2.1 Encoder

Following Bahdanau et al. (2015), we use a bidirectional RNN with gated recurrent units (GRUs) (Cho et al., 2014) to encode the source sentence:

$$\begin{aligned} \overrightarrow{h_l} &= \mathrm{GRU}(\overrightarrow{h_{l-1}}, s_l; \overrightarrow{\theta}) \\ \overleftarrow{h_l} &= \mathrm{GRU}(\overleftarrow{h_{l-1}}, s_l; \overleftarrow{\theta}) \end{aligned} \tag{1}$$

where s_l is the l-th source word's embedding, GRU is a gated recurrent unit, $\overrightarrow{\theta}$ and $\overleftarrow{\theta}$ are the parameters of forward and backward GRU, respectively; see Cho et al. (2014) for a definition.

The *annotation* of each source word x_l is obtained by concatenating the forward and backward hidden states:

$$\overleftrightarrow{h_l} = \begin{bmatrix} \overrightarrow{h_l} \\ \overleftarrow{h_l} \end{bmatrix}.$$

The whole sequence of these annotations is used by the decoder.

2.2 Decoder

The decoder is a forward RNN with GRUs predicting the translation $\mathbf{y}$ word by word. The probability of generating the j-th word y_j is:

$$P(y_j \mid \mathbf{y}_{<j}, \mathbf{x}; \theta) = \mathrm{softmax}(\begin{bmatrix} t_{j-1} \\ d_j \\ c_j \end{bmatrix})$$

where t_{j-1} is the word embedding of the $(j-1)$-th target word, d_j is the decoder's hidden state of time j, and c_j is the *context vector* at time j. The state d_j is computed as

$$d_j = \mathrm{GRU}\left(d_{j-1}, \begin{bmatrix} t_{j-1} \\ c_j \end{bmatrix}; \theta_d\right).$$

The attention mechanism computes the context vector c_i as a weighted sum of the source annotations,

$$c_j = \sum_{i=1}^{I} \alpha_{j,l} \overleftrightarrow{h_l} \tag{2}$$

where the attention weight α_{ji} is

$$\alpha_{ji} = \frac{\exp(e_{ji})}{\sum_{i'=1}^{I} \exp(e_{ji'})} \tag{3}$$

and

$$e_{jl} = v_a^{\mathrm{T}} \tanh(W_a d_{j-1} + U_a \overleftrightarrow{h_l}) \tag{4}$$

where v_a, W_a and U_a are the weight matrices of the attention model, and e_{jl} is an attention model that scores how well d_{j-1} and $\overleftrightarrow{h_l}$ match.

With this strategy, the decoder can attend to the source annotations that are most relevant at a given time.

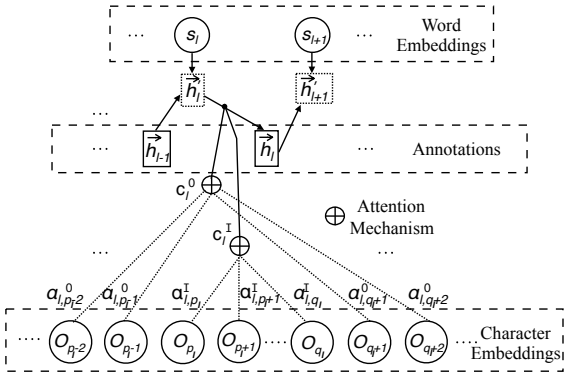

Figure 1: Forward encoder with character attention at time step l. The encoder alternates between reading word embeddings and character context vectors. ${c_l}^I$ and ${c_l}^O$ denotes the inside and outside character-level context vectors of the l-th word, respectively.

3 Character Enhanced Neural Machine Translation

In this section, we present models which make use of both character-level and word-level information in the encoder-decoder framework.

3.1 Encoder with Character Attention

The encoder maps the source sentence to a sequence of representations, which is then used by the attention mechanism. The standard encoder operates purely on (sub)words or characters. However, we want to encode both, since both levels can be linguistically significant (Xiong et al., 2017).

To incorporate multiple levels of granularity, we extend the encoder with two character-level attentions. For each source word, the characters of the whole sentence can be divided into two parts, those inside the word and those outside the word. The inside characters contain information about the internal structure of the word. The outside characters may provide information about patterns that cross word boundaries. In order to distinguish the influence of the two, we use two separate attentions, one for inside characters and one for outside characters.

Note that we compute attention directly from the character embedding sequence instead of using an additional RNN layer. This helps to avoid the vanishing gradient problem that would arise from increasing the sequence length, and also keeps the computation cost at a low level.

Figure 1 illustrates the forward encoder with character attentions. We write the character embeddings as $\mathbf{o} = o_1 \cdots o_k \cdots o_K$. Let p_l and q_l be the starting and ending character position, respectively, of word x_l. Then $o_{p_l} \cdots o_{q_l}$ are the inside characters of word x_l; $o_1 \cdots o_{p_l-1}$ and $o_{q_l+1} \cdots o_K$ are the outside characters of word x_l.

The encoder is an RNN that alternates between reading (sub)word embeddings and character-level information. At each time step, we first read the word embedding:

$$\overrightarrow{h_l}' = \mathrm{GRU}(\overrightarrow{h_{l-1}}, s_l; \overrightarrow{\theta'}) \tag{5}$$

Then we use the attention mechanisms to compute character context vectors for the inside characters:

$$c_l^I = \sum_{m=p_l}^{q_l} \alpha_{lm}^I o_m$$

$$\alpha_{lm}^I = \frac{\exp(e_{lm})}{\sum_{m'=p_l}^{q_l} \exp(e_{lm'})}$$

$$e_{lm} = v^I \cdot \tanh(W^I \overrightarrow{h_l}' + U^I o_m).$$

The outside character context vector ${c_l}^O$ is calculated in a similar way, using a different set of parameters, i.e. W^O, U^O, v^O instead of W^I, U^I, v^I.

The inside and outside character context vectors are combined by a feed-forward layer and fed into the encoder RNN, forming the character-enhanced word representation $\overrightarrow{h_l}$:

$$c_l^C = \tanh(W^I c_l^I + W^O {c_l}^O)$$

$$\overrightarrow{h_l} = \mathrm{GRU}(\overrightarrow{h_l}', c_l^C; \overrightarrow{\theta})$$

Note that this GRU does not share parameters with the GRU in (5).

The backward hidden states are calculated in a similar manner.

3.2 Decoder with Multi-Scale Attention

In order to fully exploit the character-level information, we also make extensions to the decoder, so that the character-level information can be taken into account while generating the translation.

We propose a multi-scale attention mechanism to get the relative information of current decoding step from both word-level and character-level representations. This attention mechanism is build from the high-level to the low-level representation, in order to enhance high-level representation with fine-grained internal structure and context. The multi-scale attention mechanism is built (as shown in Figure 2) from word-level to character-level.

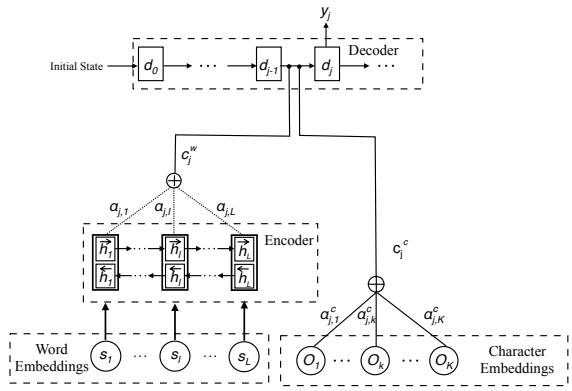

Figure 2: Illustration of the decoder with our multi-scale attention mechanism.

First, we get the word-level information. The context vector c_j^w is calculated following the standard attention model (Eq. 2–4). And the hidden state $\tilde{d}_j$ is updated.

$$\tilde{d}_j = \text{GRU}\left(d_{j-1}, \begin{bmatrix} t_{j-1} \\ c_j^w \end{bmatrix}; \tilde{\theta}_d\right), \tag{6}$$

Then we attend to the character-level representation, which provides more information about the word's internal structure. The context vector c_j^c is calculated based on the updated hidden state above,

$$\begin{aligned} c_j^c &= \sum_{k=1}^{K} \alpha_{jk}^c o_k \\ \alpha_{jk}^c &= \frac{\exp(e_{jk})}{\sum_{k'=1}^{K} \exp(e_{jk'})} \\ e_{j,k} &= v^c \cdot \tanh(W^c \tilde{d}_j + U^c o_k). \end{aligned}$$

Finally, the word-level context vector $c_j^w$and character-level context vector c_j^c are concatenated:

$$c_j = \begin{bmatrix} c_j^w \\ c_j^c \end{bmatrix}.$$

And the final context vector c_j is used to help predict the next target word.

$$P(y_j \mid \mathbf{y}_{<j}, \mathbf{x}; \theta) = \text{softmax}(\begin{bmatrix} t_{j-1} \\ d_j \\ c_j \end{bmatrix})$$

where d_j is

$$d_j = \text{GRU}(\tilde{d}_j, c_j^c; \theta_d),$$

With this mechanism, both the (sub)word-level and character-level representations could be used to predict the next translation, which helps to ensure a more robust and reasonable choice. It may also help to alleviate the under-translation problem because the character information could be a complement to the word.

4 Experiments

We conduct experiments on three translation tasks: Chinese-English (Zh-En), English-Chinese (En-Zh) and English-German (En-De). We write Zh↔En to refer to the Zh-En and En-Zh tasks together.

4.1 Datasets

For Zh↔En, the parallel training data consists of 1.6M sentence pairs extracted from LDC corpora, with 46.6M Chinese words and 52.5M English words, respectively.[1] We use the NIST MT02 evaluation data as development data, and MT03, MT04, MT05, and MT06 as test data. The Chinese side of the corpora is word segmented using ICTCLAS.[2] The English side of the corpora is lowercased and tokenized.

For En-De, we conduct our experiments on the WMT17 corpus. We use the pre-processed parallel training data for the shared news translation task provided by the task organizers.[3] The dataset consitst of 5.6M sentence pairs. We use `newstest2016` as the development set and evaluate the models on `newstest2017`.

4.2 Baselines

We compare our proposed models with several types of NMT systems:

- **NMT:** the standard attentional NMT model with words as its input (Bahdanau et al., 2015).
- **RNN-Char:** the standard attentional NMT model with characters as its input.
- **CNN-Char:** a character-based NMT model, which implements the convolutional neural network (CNN) based encoder (Costa-jussà and Fonollosa, 2016).
- **Hybrid:** the mixed word/character model proposed by Wu et al. (2016).

System	MT02	MT03	MT04	MT05	MT06	Mean	Δ
NMT	33.76	31.88	33.15	30.55	27.47	30.76	
Word-att	34.28	32.26	33.82	31.02	27.93	31.26	+0.50
Char-att	34.85	33.71	34.91	32.08	28.66	32.34	+1.58

Table 1: Performance of the encoder with character attention and the encoder with word attention. Char-att and Word-att denotes the encoder with character attention and the encoder with word attention, respectively.

- **BPE:** a subword level NMT model, which processes the source side sentence by Byte Pair Encoding (BPE) (Sennrich et al., 2016).

We used the dl4mt implementation of the attentional model,[4] reimplementing the above models.

4.3 Details

Training For Zh↔En, we filter out the sentence pairs whose source or target side contain more than 50 words. We use a shortlist of the 30,000 most frequent words in each language to train our models, covering approximately 98.2% and 99.5% of the Chinese and English tokens, respectively. The word embedding dimension is 512. The hidden layer sizes of both forward and backward sequential encoder are 1024. For fair comparison, we also set the character embedding size to 512, except for the CNN-Char system. For CNN-Char, we follow the standard setting of the original paper (Costa-jussà and Fonollosa, 2016).

For En-De, we build the baseline system using joint BPE segmentation (Sennrich et al., 2017). The number of joint BPE operations is 90,000. We use the total BPE vocabulary for each side.

We use Adadelta (Zeiler, 2012) for optimization with a mini-batch size of 32 for Zh↔En and 50 for En-De.

Decoding and evaluation We use beam search with length-normalization to approximately find the most likely translation. We set beam width to 5 for Zh↔En and 12 for En-De. The translations are evaluated by BLEU (Papineni et al., 2002). We use the `multi-bleu` script for Zh↔En,[5] and the `multi-bleu-detok` script for En-De.[6]

4.4 Results: Encoder with character attention

This set of experiments evaluates the effectiveness of our proposed character enhanced encoder. In Table 1, we first compare the encoder with character attention (Char-att) with the baseline word-based model. The result shows that our extension of the encoder can obtain significantly better performance (+1.58 BLEU).

Then, in order to investigate whether the improvement comes from the extra parameters in the character layer, we compare our model to a word embedding enhanced encoder. When the word embedding enhanced encoder encodes a word, it attends to the word's embedding and other word embedding in the sentence instead of attending to the word's inside and outside character embeddings. The results show that the word embedding enhanced encoder (Word-att) only gets a 0.5 BLEU improvement than the baseline, while our model is significantly better (+1.58 BLEU). This shows that the benefit comes from the augmented character-level information which help the word-based encoder to learn a better source-side representation.

Finally, we compare our character enhanced model with several types of systems including a strong character-based model proposed by Costa-jussà and Fonollosa (2016) and a mixed word/character model proposed by Wu et al. (2016). In Table 2, rows 2 and 2′ confirm the finding of Yang et al. (2016) that the traditional RNN model performs less well when the input is a sequence of characters. Rows 4 and 4′ indicate that Wu et al. (2016)'s scheme to combine of words and characters is effective for machine translation. Our model (row 5) outperforms other models on the Zh-En task, but only outperforms the word-based model on En-Zh. The results may suggest that the CNN and RNN methods is also strong in building the source representation.

Task	#	System	MT02	MT03	MT04	MT05	MT06	Mean	Δ

	10′	9′+Multi-att	32.36	24.91	25.79	23.42	24.88	24.75	+2.34

Table 3: Comparison of our models on top of the BPE-based NMT model and the original BPE-based model on the Chinese-English and English-Chinese translation tasks. Our models improve over the BPE baselines.

4.5 Results: Multi-scale attention

Rows 6 and 6′ in Table 2 verify that our multi-scale attention mechanism can obtain better results than baseline systems. Rows 7 and 7′ in Table 2 show that our proposed multi-scale attention mechanism further improves the performance of our encoder with character attention, yielding a significant improvement over the standard word-based model on both Zh-En (+2.02 vs. row 1) task and En-Zh translation task (+2.58 vs. row 1′).

Compared to the CNN-Char model, our model still gets +1.97 and +1.46 BLEU improvement on Zh-En and En-Zh, respectively. Compared to the mixed word/character model proposed by (Wu et al., 2016), we find that our best model gives a better result, demonstrating the benefits of exploiting the character level information during decoding.

System	Dev	Test	Δ
BPE	28.41	23.05	
Char-att	29.80	23.87	+0.82
+Multi-att	30.52	24.48	+1.43

Table 4: Case-sensitive BLEU on the English-German translation tasks. Our systems improve over a baseline BPE system.

4.6 Results: Subword-based models

Currently, subword-level NMT models are widely used for achieving open-vocabulary translation. Sennrich et al. (2016) introduced a subword-level NMT model using subword-level segmentation based on the byte pair encoding (BPE) algorithm. In this section, we investigate the effectiveness of our character enhanced model on top of the BPE model. Table 3 shows the results on the Zh-En task

(a) OOV words

Table 5: Sample translations. For each example, we show the source, the reference and the translation from our best model. "Ours" means our model with both Char-att and Multi-att.

and En-Zh translation task. Rows 8 and 8′ confirm that BPE slightly improves the performance of the word-based model. But both our character enhanced encoder and the multi-scale attention yield better results. Our best model leads to improvements of up to 1.58 BLEU and 1.68 BLEU on the Zh-En task and En-Zh translation task, respectively.

We also conduct experiments on the En-De translation task (as shown in Table 4). The result is consistent with Zh-En task and En-Zh translation tasks. Our best model obtains 1.43 BLEU improvement over the BPE model.

System	**with OOV**	**Δ**	**no OOV**	**Δ**
NMT	28.47		38.21	
Hybrid	29.83	+1.36	37.79	−0.43
Ours	30.80	+2.33	39.39	+1.18

Table 6: Translation performance on source sentences with and without OOV words. "Ours" means our model with both Char-att and Multi-att.

4.7 Analysis

We have argued that the character information is important not only for OOV words but also frequent words. To test this claim, we divided the MT03 test set into two parts according to whether

the sentence contains OOV words, and evaluated several systems on the two parts. Table 6 lists the results. Although the hybrid model achieves a better result on the sentences which contain OOV words, it actually gives a worse result on the sentences without OOV words. By contrast, our model yields the best results on both parts of the data. This shows that frequent words also benefit from fine-grained character-level information.

Table 5 shows three translation examples. Table 5(a) shows the translation of an OOV word 通信业 (*tong-xin-ye*, telecommunication industry). The baseline NMT system can't translate the whole word because it is not in the word vocabulary. The hybrid model translates the word to "communication," which is a valid translation of the first two characters 通信. This mistranslation also appears to affect other parts of the sentence adversely. Our model translates the OOV word correctly.

Table 5(b) shows two translation samples involving frequent words. For the compound word 被占领土 (*beizhanlingtu*, occupied territory), the baseline NMT system only partly translates the word as "occupation" and ignores the main part 领土 (*lingtu*, territory). The CNN-Char model, which builds up the word-level representation from characters, also cannot capture 领土 (*lingtu*). However, our model correctly translates the word as "occupied territories." (The phrase "by Israel" in the reference was inserted by the translator.) The word 东西方 (*dongxifang*, east and west) and 冷战 (*lengzhan*, cold war) are deleted by the baseline model, and even the CNN-Char model translates 东西方 (*dongxifang*) incorrectly. By contrast, our model can make use of both words and characters to translate the word 东西方 (*dongxifang*) reasonably well as "eastern and western."

5 Related Work

Many recent studies have focused on using character-level information in neural machine translation systems. These efforts could be roughly divided into the following two categories.

The first line of research attempted to build neural machine translation models purely on characters without explicit segmentation. Lee et al. (2017) proposed to directly learn the segmentation from characters by using convolution and pooling layers. Yang et al. (2016) composed the high-level representation by the character embedding and its surrounding character-level context with a bidirectional and concatenated row convolution network. Different from their models, our model aims to use characters to enhance words representation instead of depending on characters solely; our model is also much simpler.

The other line of research attempted to combine character-level information with word-level information in neural machine translation models, which is more similar with our work. Ling et al. (2015a) employed a bidirectional LSTM to compose character embeddings to form the word-level information with the help of word boundary information. Costa-jussà and Fonollosa (2016) replaced the word-lookup table with a convolutional network followed by a highway network (Srivastava et al., 2015), which learned the word-level representation by its constituent characters. Zhao and Zhang (2016) designed a *decimator* for their encoder, which effectively uses a RNN to compute a word representation from the characters of the word. These approaches only consider word boundary information and ignore the word-level meaning information itself. In contrast, our model can make use of both character-level and word-level information.

Luong and Manning (2016) proposed a hybrid scheme that consults character-level information whenever the model encounters an OOV word. Wu et al. (2016) converted the OOV words in the word-based model into the sequence of its constituent characters. These methods only focus on dealing with OOV words by augmenting the character-level information. In our work, we augment the character information to all the words.

6 Conclusion

In this paper, we have investigated the potential of using character-level information in word-based and subword-based NMT models by proposing a novel character-aware encoder-decoder framework. First, we extended the encoder with a character attention mechanism for learning better source-side representations. Then, we incorporated information about source-side characters into the decoder with a multi-scale attention, so that the character-level information can cooperate with the word-level information to better control the translation. The experiments have demonstrated the effectiveness of our models. Our analysis showed that both OOV words and frequent

words benefit from the character-level information.

Our current work only uses the character-level information in the source-side. For future work, it will be interesting to make use of finer-grained information on the target side as well.

Abstract

Recently, neural machine translation has achieved remarkable progress by introducing well-designed deep neural networks into its encoder-decoder framework. From the optimization perspective, residual connections are adopted to improve learning performance for both encoder and decoder in most of these deep architectures, and advanced attention connections are applied as well. Inspired by the success of the DenseNet model in computer vision problems, in this paper, we propose a densely connected NMT architecture (DenseNMT) that is able to train more efficiently for NMT. The proposed DenseNMT not only allows dense connection in creating new features for both encoder and decoder, but also uses the dense attention structure to improve attention quality. Our experiments on multiple datasets show that DenseNMT structure is more competitive and efficient.

1 Introduction

Neural machine translation (NMT) is a challenging task that attracts lots of attention in recent years. Starting from the encoder-decoder framework (Cho et al., 2014), NMT starts to show promising results in many language pairs. The evolving structures of NMT models in recent years have made them achieve higher scores and become more favorable. The attention mechanism (Bahdanau et al., 2015) added on top of encoder-decoder framework is shown to be very useful to automatically find alignment structure, and single-layer RNN-based structure has evolved into deeper models with more efficient transformation functions (Gehring et al., 2017; Kaiser et al., 2017; Vaswani et al., 2017).

One major challenge of NMT is that its models are hard to train in general due to the complexity of both the deep models and languages. From the optimization perspective, deeper models are hard to efficiently back-propagate the gradients, and this phenomenon as well as its solution is better explored in the computer vision society. Residual networks (ResNet) (He et al., 2016) achieve great performance in a wide range of tasks, including image classification and image segmentation. Residual connections allow features from previous layers to be accumulated to the next layer easily, and make the optimization of the model efficiently focus on refining upper layer features.

NMT is considered as a challenging problem due to its sequence-to-sequence generation framework, and the goal of comprehension and reorganizing from one language to the other. Apart from the encoder block that works as a feature generator, the decoder network combining with the attention mechanism bring new challenges to the optimization of the models. While nowadays best-performing NMT systems use residual connections, we question whether this is the most efficient way to propagate information through deep models. In this paper, inspired by the idea of using dense connections for training computer vision tasks (Huang et al., 2016), we propose a densely connected NMT framework (DenseNMT) that efficiently propagates information from the encoder to the decoder through the attention component. Taking the CNN-based deep architecture as an example, we verify the efficiency of DenseNMT. Our contributions in this work include: (i) by comparing the loss curve, we show that DenseNMT allows the model to pass information more efficiently, and speeds up training; (ii) we show through ablation study that dense con-

Proceedings of NAACL-HLT 2018, pages 1294–1303
New Orleans, Louisiana, June 1 - 6, 2018.

nections in all three blocks altogether help improve the performance, while not increasing the number of parameters; (iii) DenseNMT allows the models to achieve similar performance with much smaller embedding size; (iv) DenseNMT on IWSLT14 German-English and Turkish-English translation tasks achieves new benchmark BLEU scores, and the result on WMT14 English-German task is more competitive than the residual connections based baseline model.

2 Related Work

ResNet and DenseNet. ResNet (He et al., 2016) proposes residual connections, which directly add representation from the previous layer to the next layer. Originally proposed for image classification tasks, the residual structure have proved its efficiency in model training across a wide range of tasks, and are widely adopted in recent advanced NMT models (Wu et al., 2016; Vaswani et al., 2017; Gehring et al., 2017). Following the idea of ResNet, DenseNet (Huang et al., 2016) further improves the structure and achieves state-of-the-art results. It allows the transformations (e.g., CNN) to be directly calculated over all previous layers. The benefit of DenseNet is to encourage upper layers to create new representations instead of refining the previous ones. On other tasks such as segmentation, dense connections also achieve high performance (Jégou et al., 2017). Very recently, (Godin et al., 2017) shows that dense connections help improve language modeling as well. Our work is the first to explore dense connections for NMT tasks.

Attention mechanisms in NMT. The attention block is proven to help improve inference quality due to existence of alignment information (Bahdanau et al., 2015). Traditional sequence-to-sequence architectures (Kalchbrenner and Blunsom, 2013; Cho et al., 2014) pass the last hidden state from the encoder to the decoder; hence source sentences of different length are encoded into a fixed-size vector (i.e., the last hidden state), and the decoder should catch all the information from the vector. Later, early attention-based NMT architectures, including (Bahdanau et al., 2015), pass all the hidden states (instead of the last state) of the last encoder layer to the decoder. The decoder then uses an attention mechanism to selectively focus on those hidden states while generating each word in the target sentence. Latest architecture (Gehring et al., 2017) uses multi-step attention, which allows each decoder layer to acquire separate attention representations, in order to maintain different levels of semantic meaning. They also enhance the performance by using embeddings of input sentences. In this work, we further allow every encoder layer to directly pass the information to the decoder side.

Encoder/decoder networks. RNNs such as long short term memory (LSTM) are widely used in NMT due to their ability of modeling long-term dependencies. Recently, other more efficient structures have been proposed in substitution for RNN-based structures, which includes convolution (Gehring et al., 2017; Kaiser et al., 2017) and self-attention (Vaswani et al., 2017). More specifically, ConvS2S (Gehring et al., 2017) uses convolution filter with a gated linear unit, Transformer (Vaswani et al., 2017) uses self-attention function before a two-layer position-wise feed-forward networks, and SliceNet (Kaiser et al., 2017) uses a combination of ReLU, depthwise separable convolution, and layer normalization. The advantage of these non-sequential transformations is the significant parallel speedup as well as more advanced performances, which is the reason we select CNN-based models for our experiments.

3 DenseNMT

In this section, we introduce our DenseNMT architecture. In general, compared with residual connected NMT models, DenseNMT allows each layer to provide its information to all subsequent layers directly. Figure 1-3 show the design of our model structure by parts.

We start with the formulation of a regular NMT model. Given a set of sentence pairs $S = \{(x^i, y^i)|i=1,\cdots,N\}$, an NMT model learns parameter θ by maximizing the log-likelihood function:

$$\sum_{i=1}^{N} \log \mathcal{P}(y^i|x^i;\theta). \quad (1)$$

For every sentence pair $(x, y) \in S$, $\mathcal{P}(y|x;\theta)$ is calculated based on the decomposition:

$$\mathcal{P}(y|x;\theta) = \prod_{j=1}^{m} \mathcal{P}(y_j|y_{<j}, x;\theta), \quad (2)$$

where m is the length of sentence y. Typically, NMT models use the encoder-attention-decoder

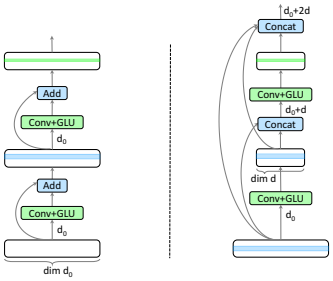

Figure 1: Comparison of dense-connected encoder and residual-connected encoder. Left: regular residual-connected encoder. Right: dense-connected encoder. Information is directly passed from blue blocks to the green block.

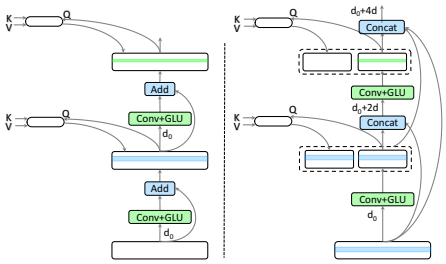

Figure 2: Comparison of dense-connected decoder and residual-connected decoder. Left: regular residual-connected decoder. Right: dense-connected decoder. Ellipsoid stands for attention block. Information is directly passed from blue blocks to the green block.

framework (Bahdanau et al., 2015), and potentially use multi-layer structure for both encoder and decoder. Given a source sentence x with length n, the encoder calculates hidden representations by layer. We denote the representation in the l-th layer as h^l, with dimension $n \times d^l$, where d^l is the dimension of features in layer l. The hidden representation at each position h^l_j is either calculated by:

$$h^l_j = \mathcal{H}^{\texttt{rec}}(h^{l-1}_j, h^l_{j-1}) \tag{3}$$

for recurrent transformation $\mathcal{H}^{\texttt{rec}}(\cdot)$ such as LSTM and GRU, or by:

$$h^l_j = \mathcal{H}^{\texttt{par}}(h^{l-1}) \tag{4}$$

for parallel transformation $\mathcal{H}^{\texttt{par}}(\cdot)$. On the other hand, the decoder layers $\{z^l\}$ follow similar structure, while getting extra representations from the encoder side. These extra representations are also called *attention*, and are especially useful for capturing alignment information.

In our experiments, we use convolution based transformation for $\mathcal{H}^{\texttt{par}}(\cdot)$ due to both its efficiency and high performance, more formally,

$$h^l_j = \texttt{GLU}([h^{l-1}_{j-r}, \cdots, h^{l-1}_{j+r}]W^l + b^l) \triangleq \mathcal{H}(h^{l-1}). \tag{5}$$

GLU is the gated linear unit proposed in (Dauphin et al., 2017) and the kernel size is $2r+1$. DenseNMT is agnostic to the transformation function, and we expect it to also work well combining with other transformations, such as LSTM, self-attention and depthwise separable convolution.

3.1 Dense encoder and decoder

Different from residual connections, later layers in the dense encoder are able to use features from all previous layers by concatenating them:

$$h^{l+1} = \mathcal{H}([h^l, h^{l-1}, \cdots, h^0]). \tag{6}$$

Here, $\mathcal{H}(\cdot)$ is defined in Eq. (5), $[\cdot]$ represents concatenation operation. Although this brings extra connections to the network, with smaller number of features per layer, the architecture encourages feature reuse, and can be more compact and expressive. As shown in Figure 1, when designing the model, the hidden size in each layer is much smaller than the hidden size of the corresponding layer in the residual-connected model.

While each encoder layer perceives information from its previous layers, each decoder layer z^{l+1} has two information sources: previous layers $z^i, i \leq l$, and attention values $a^i, i \leq l$. Therefore, in order to allow dense information flow, we redefine the generation of $(l+1)$-th layer as a nonlinear function over all its previous decoder layers and previous attentions. This can be written as:

$$z^{l+1} = \mathcal{H}([z^l, a^l, z^{l-1}, a^{l-1}, \cdots, z^1, a^1, z^0]), \tag{7}$$

where a^i is the attention value using i-th decoder layer and information from encoder side, which will be specified later. Figure 2 shows the comparison of a dense decoder with a regular residual decoder. The dimensions of both attention values and hidden layers are chosen with smaller values, yet the perceived information for each layer consists of a higher dimension vector with more representation power. The output of the decoder is a linear transformation of the concatenation of all layers by default. To compromise to the increment of dimensions, we use summary layers, which will be introduced in Section 3.3. With summary layers, the output of the decoder is only a linear transformation of the concatenation of the upper few layers.

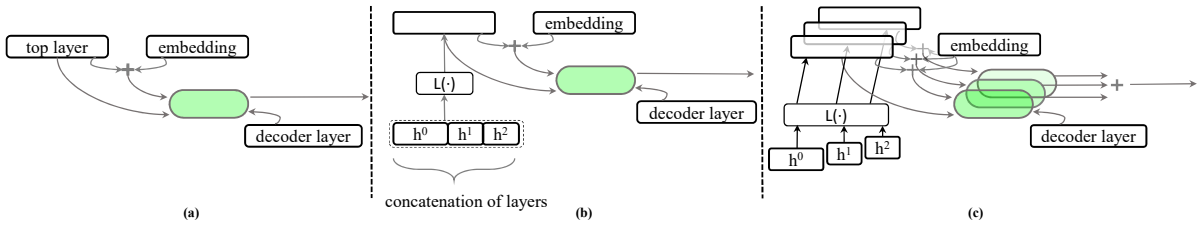

Figure 3: Illustration of DenseAtt mechanisms. For clarity, We only plot the attention block for a single decoder layer. (a): multi-step attention (Gehring et al., 2017), (b): DenseAtt-1, (c): DenseAtt-2. $\mathcal{L}(\cdot)$ is the linear projection function. The ellipsoid stands for the core attention operation as shown in Eq. (8).

3.2 Dense attention

Prior works show a trend of designing more expressive attention mechanisms (as discussed in Section 2). However, most of them only use the last encoder layer. In order to pass more abundant information from the encoder side to the decoder side, the attention block needs to be more expressive. Following the recent development of designing attention architectures, we propose DenseAtt as the dense attention block, which serves for the dense connection between the encoder and the decoder side. More specifically, two options are proposed accordingly. For each decoding step in the corresponding decoder layer, the two options both calculate attention using multiple encoder layers. The first option is more compressed, while the second option is more expressive and flexible. We name them as DenseAtt-1 and DenseAtt-2 respectively. Figure 3 shows the architecture of (a) multi-step attention (Gehring et al., 2017), (b) DenseAtt-1, and (c) DenseAtt-2 in order. In general, a popular multiplicative attention module can be written as:

$$\mathcal{F}(Q, K, V) = \texttt{Softmax}(Q \times K) \times V, \quad (8)$$

where Q, K, V represent query, key, value respectively. We will use this function $\mathcal{F}$ in the following descriptions.

DenseAtt-1 In the decoding phase, we use a layer-wise attention mechanism, such that each decoder layer absorbs different attention information to adjust its output. Instead of treating the last hidden layer as the encoder's output, we treat the concatenation of all hidden layers from encoder side as the output. The decoder layer multiplies with the encoder output to obtain the attention weights, which is then multiplied by a linear combination of the encoder output and the sentence embedding. The attention output of each layer a^l can be formally written as:

$$a^l = \mathcal{F}\left(\mathcal{L}(z^l), \mathcal{L}\left([\{h^i\}]\right), \mathcal{L}\left([\{h^i\}]\right) + \mathcal{L}(h^0)\right), \quad (9)$$

where $\mathcal{F}(\cdot,\cdot,\cdot)$ is the multiplicative attention function, $[\cdot]$ is a concatenation operation that combines all features, and $\mathcal{L}(\cdot)$ is a linear transformation function that maps each variable to a fixed dimension in order to calculate the attention value. Notice that we explicitly write the $\mathcal{L}(h^0)$ term in (9) to keep consistent with the multi-step attention mechanism, as pictorially shown in Figure 3(a).

DenseAtt-2 Notice that the transformation $\mathcal{L}([\{h^i\}])$ in DenseAtt-1 forces the encoder layers to be mixed before doing attention. Since we use multiple hidden layers from the encoder side to get an attention value, we can alternatively calculate multiple attention values before concatenating them. In another word, the decoder layer can get different attention values from different encoder layers. This can be formally expressed as:

$$a^l = \sum_{i=1}^{L} \mathcal{F}\left(\mathcal{L}(z^l), \mathcal{L}(h^i), \mathcal{L}([h^i, h^0])\right), \quad (10)$$

where the only difference from Eq. (9) is that the concatenation operation is substituted by a summation operation, and is put after the attention function $\mathcal{F}$. This method further increases the representation power in the attention block, while maintaining the same number of parameters in the model.

3.3 Summary layers

Since the number of features fed into nonlinear operation is accumulated along the path, the parameter size increases accordingly. For example, for the L-th encoder layer, the input dimension of features is $(L-1)d + d_0$, where d is the feature

dimension in previous layers, d_0 is the embedding size. In order to avoid the calculation bottleneck for later layers due to large L, we introduce the *summary layer* for deeper models. It summarizes the features for all previous layers and projects back to the embedding size, so that later layers of both the encoder and the decoder side do not need to look back further. The summary layers can be considered as contextualized word vectors in a given sentence (McCann et al., 2017). We add one summary layer after every $(\texttt{sumlen} - 1)$ layers, where `sumlen` is the hyperparameter we introduce. Accordingly, the input dimension of features is at most $(\texttt{sumlen} - 1) \cdot d + d_0$ for the last layer of the encoder. Moreover, combined with the summary layer setting, our DenseAtt mechanism allows each decoder layer to calculate the attention value focusing on the last few encoder layers, which consists of the last contextual embedding layer and several dense connected layers with low dimension. In practice, we set `sumlen` as 5 or 6.

3.4 Analysis of information flow

Figure 1 and Figure 2 show the difference of information flow compared with a residual-based encoder/decoder. For residual-based models, each layer can absorb a single high-dimensional vector from its previous layer as the only information, while for DenseNMT, each layer can utilize several low-dimensional vectors from its previous layers and a high-dimensional vector from the first layer (embedding layer) as its information. In DenseNMT, each layer directly provides information to its later layers. Therefore, the structure allows feature reuse, and encourages upper layers to focus on creating new features. Furthermore, the attention block allows the embedding vectors (as well as other hidden layers) to guide the decoder's generation more directly; therefore, during back-propagation, the gradient information can be passed directly to all encoder layers simultaneously.

4 Experimental Setup

4.1 Datasets

We use three datasets for our experiments: IWSLT14 German-English, Turkish-English, and WMT14 English-German.

We preprocess the IWSLT14 German-English dataset following byte-pair-encoding (BPE) method (Sennrich et al., 2015b)[1]. We learn 25k BPE codes using the joint corpus of source and target languages. We randomly select 7k from IWSLT14 German-English as the development set , and the test set is a concatenation of dev2010, tst2010, tst2011 and tst2012, which is widely used in prior works (Ranzato et al., 2015; Bahdanau et al., 2017; Huang et al., 2017).

For the Turkish-English translation task, we use the data provided by IWSLT14 (Cettolo et al., 2014) and the SETimes corpus (Cettolo et al., 2014) following (Sennrich et al., 2015a). After removing sentence pairs with length ratio over 9, we obtain 360k sentence pairs. Since there is little commonality between the two languages, we learn 30k size BPE codes separately for Turkish and English. In addition to this, we give another preprocessing for Turkish sentences and use word-level English corpus. For Turkish sentences, following (Gulcehre et al., 2015; Sennrich et al., 2015a), we use the morphology tool Zemberek with disambiguation by the morphological analysis (Sak et al., 2007) and removal of non-surface tokens[2]. Following (Sennrich et al., 2015a), we concatenate tst2011, tst2012, tst2013, tst2014 as our test set. We concatenate dev2010 and tst2010 as the development set.

We preprocess the WMT14 English-German[3] dataset using a BPE code size of 40k. We use the concatenation of newstest2013 and newstest2012 as the development set.

4.2 Model and architect design

As the baseline model (*BASE-4L*) for IWSLT14 German-English and Turkish-English, we use a 4-layer encoder, 4-layer decoder, residual-connected model[4], with embedding and hidden size set as 256 by default. As a comparison, we design a densely connected model with same number of layers, but the hidden size is set as 128 in order to keep the model size consistent. The models adopting DenseAtt-1, DenseAtt-2 are named as *DenseNMT-4L-1* and *DenseNMT-4L-2* respectively. In order to check the effect of dense connections on deeper models, we also construct a series of 8-layer models. We set the hidden number to be 192, such that both 4-layer models and 8-layer models have similar number of parameters.

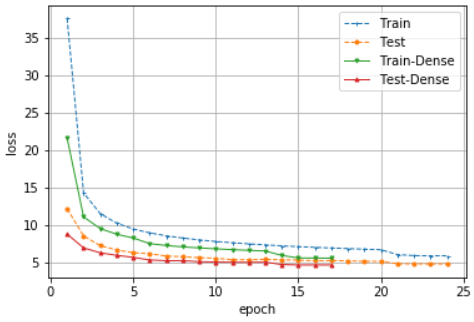

Figure 5: Training curve and test curve comparison on WMT14 English-German translation task.

For dense structured models, we set the dimension of hidden states to be 96.

Since NMT model usually allocates a large proportion of its parameters to the source/target sentence embedding and softmax matrix, we explore in our experiments to what extent decreasing the dimensions of the three parts would harm the BLEU score. We change the dimensions of the source embedding, the target embedding as well as the softmax matrix simultaneously to smaller values, and then project each word back to the original embedding dimension through a linear transformation. This significantly reduces the number of total parameters, while not influencing the upper layer structure of the model.

We also introduce three additional models we use for ablation study, all using 4-layer structure. Based on the residual connected *BASE-4L* model, (1) *DenseENC-4L* only makes encoder side dense, (2) *DenseDEC-4L* only makes decoder side dense, and (3) *DenseAtt-4L* only makes the attention dense using DenseAtt-2. There is no summary layer in the models, and both *DenseENC-4L* and *DenseDEC-4L* use hidden size 128. Again, by reducing the hidden size, we ensure that different 4-layer models have similar model sizes.

Our design for the WMT14 English-German model follows the best performance model provided in (Gehring et al., 2017). The construction of our model is straightforward: our 15-layer model *DenseNMT-En-De-15* uses dense connection with DenseAtt-2, $\texttt{sumlen} = 6$. The hidden number in each layer is $1/4$ that of the original model, while the kernel size maintains the same.

4.3 Training setting

We use Nesterov Accelerated Gradient (NAG) (Nesterov, 1983) as our optimizer, and the initial learning rate is set to 0.25. For German-English and Turkish-English experiments, the learning rate will shrink by 10 every time the validation loss increases. For the English-German dataset, in consistent with (Gehring et al., 2017), the learning rate will shrink by 10 every epoch since the first increment of validation loss. The system stops training until the learning rate is less than 10^{-4}. All models are trained end-to-end without any warmstart techniques. We set our batch size for the WMT14 English-German dataset to be 48, and additionally tune the length penalty parameter, in consistent with (Gehring et al., 2017). For other datasets, we set batch size to be 32. During inference, we use a beam size of 5.

5 Results

5.1 Training curve

We first show that DenseNMT helps information flow more efficiently by presenting the training loss curve. All hyperparameters are fixed in each plot, only the models are different. In Figure 4, the loss curves for both training and dev sets (before entering the finetuning period) are provided for De-En, Tr-En and Tr-En-morph. For clarity, we compare *DenseNMT-4L-2* with *BASE-4L*. We observe that DenseNMT models are consistently better than residual-connected models, since their loss curves are always below those of the baseline models. The effect is more obvious on the WMT14 English-German dataset. We rerun the best model provided by (Gehring et al., 2017) and compare with our model. In Figure 5, where train/test loss curve are provided, DenseNMT-En-

Table 1: BLEU score on IWSLT German-English and Turkish-English translation tasks. We compare models using different embedding sizes, and keep the model size consistent within each column.

De-15 reaches the same level of loss and starts finetuning (validation loss starts to increase) at epoch 13, which is 35% faster than the baseline.

Adding dense connections changes the architecture, and would slightly influence training speed. For the WMT14 En-De experiments, the computing time for both DenseNMT and the baseline (with similar number of parameters and same batch size) tested on single M40 GPU card are 1571 and 1710 word/s, respectively. While adding dense connections influences the per-iteration training slightly (8.1% reduction of speed), it uses many fewer epochs, and achieves a better BLEU score. In terms of training time, DenseNMT uses 29.3%(before finetuning)/22.9%(total) less time than the baseline.

5.2 DenseNMT improves accuracy with similar architectures and model sizes

	De-En	Tr-En	Tr-En-morph
BASE	30.43	20.99	20.08
DenseENC-4L	30.72	21.32	21.24
DenseDEC-4L	31.23	21.04	21.06
DenseAtt-4L	31.05	21.35	21.08
DenseNMT-4L-1	31.26	21.36	21.43
DenseNMT-4L-2	31.40	21.48	21.57

Table 2: Ablation study for encoder block, decoder block, and attention block in DenseNMT.

Table 1 shows the results for De-En, Tr-En, Tr-En-morph datasets, where the best accuracy for models with the same depth and of similar sizes are marked in boldface. In almost all genres, DenseNMT models are significantly better than the baselines. With embedding size 256, where all models achieve their best scores, DenseNMT outperforms baselines by 0.7-1.0 BLEU on De-En, 0.5-1.3 BLEU on Tr-En, 0.8-1.5 BLEU on Tr-En-morph. We observe significant gain using other embedding sizes as well.

Furthermore, in Table 2, we investigate DenseNMT models through ablation study. In order to make the comparison fair, six models listed have roughly the same number of parameters. On De-En, Tr-En and Tr-En-morph, we see improvement by making the encoder dense, making the decoder dense, and making the attention dense. Fully dense-connected model *DenseNMT-4L-1* further improves the translation accuracy. By allowing more flexibility in dense attention, *DenseNMT-4L-2* provides the highest BLEU scores for all three experiments.

From the experiments, we have seen that enlarging the information flow in the attention block benefits the models. The dense attention block provides multi-layer information transmission from the encoder to the decoder, and to the output as well. Meanwhile, as shown by the ablation study, the dense-connected encoder and decoder both give more powerful representations than the residual-connected counterparts. As a result, the integration of the three parts improve the accuracy significantly.

5.3 DenseNMT with smaller embedding size

From Table 1, we also observe that DenseNMT performs better with small embedding sizes compared to residual-connected models with regular embedding size. For example, on Tr-En model, the 8-layer *DenseNMT-8L-2* model with embedding size 64 matches the BLEU score of the 8-layer BASE model with embedding size 256, while the number of parameter of the former one is only 40% of the later one. In all genres, DenseNMT model with embedding size 128 is comparable or even better than the baseline model with embedding size 256.

While overlarge embedding sizes hurt accuracy because of overfitting issues, smaller sizes are not

preferable because of insufficient representation power. However, our dense models show that with better model design, the embedding information can be well concentrated on fewer dimensions, e.g., 64. This is extremely helpful when building models on mobile and small devices where the model size is critical. While there are other works that stress the efficiency issue by using techniques such as separable convolution (Kaiser et al., 2017), and shared embedding (Vaswani et al., 2017), our DenseNMT framework is orthogonal to those approaches. We believe that other techniques would produce more efficient models through combining with our DenseNMT framework.

	Greedy	**Beam**
MIXER (Ranzato et al., 2015)	20.73	21.83

Table 4: Accuracy on IWSLT14 German-English translation task in terms of BLEU score.

5.4 DenseNMT compares with state-of-the-art results

For the IWSLT14 German-English dataset, we compare with the best results reported from literatures. To be consistent with prior works, we also provide results using our model directly on the dataset without BPE preprocessing. As shown in Table 4, DenseNMT outperforms the phrase-structure based network NPMT (Huang et al., 2017) (with beam size 10) by 1.2 BLEU, using a smaller beam size, and outperforms the actor-critic method based algorithm (Bahdanau et al., 2017) by 2.8 BLEU. For reference, our model trained on the BPE preprocessed dataset achieves 32.26 BLEU, which is 1.93 BLEU higher than our word-based model. For Turkish-English task, we compare with (Gulcehre et al., 2015) which uses the same morphology preprocessing as our Tr-En-morph. As shown in Table 3, our baseline is higher than the previous result, and we further achieve new benchmark result with 24.36 BLEU average score. For WMT14 English-German, from Table 5, we can see that DenseNMT outperforms ConvS2S model by 0.36 BLEU score using 35% fewer training iterations and 20% fewer parameters. We also compare with another convolution based NMT model: SliceNet (Kaiser et al., 2017), which explores depthwise separable convolution architectures. SliceNet-Full matches our result, and SliceNet-Super outperforms by 0.58 BLEU score. However, both models have 2.2x more parameters than our model. We expect DenseNMT structure could help improve their performance as well.

	BLEU score
GNMT (Wu et al., 2016)	24.61
ConvS2S (Gehring et al., 2017)	25.16
SliceNet-Full (Kaiser et al., 2017)	25.5
SliceNet-Super (Kaiser et al., 2017)	26.1
DenseNMT-En-De-15	25.52

Table 5: Accuracy on WMT14 English-German translation task in terms of BLEU score.

6 Conclusion

In this work, we have proposed DenseNMT as a dense-connection framework for translation tasks, which uses the information from embeddings more efficiently, and passes abundant information from the encoder side to the decoder side. Our experiments have shown that DenseNMT is able to speed up the information flow and improve translation accuracy. For the future work, we will combine dense connections with other deep architectures, such as RNNs (Wu et al., 2016) and self-attention networks (Vaswani et al., 2017).

Abstract

For machine translation to tackle discourse phenomena, models must have access to extra-sentential linguistic context. There has been recent interest in modelling context in neural machine translation (NMT), but models have been principally evaluated with standard automatic metrics, poorly adapted to evaluating discourse phenomena. In this article, we present hand-crafted, discourse test sets, designed to test the models' ability to exploit previous source and target sentences. We investigate the performance of recently proposed multi-encoder NMT models trained on subtitles for English to French. We also explore a novel way of exploiting context from the previous sentence. Despite gains using BLEU, multi-encoder models give limited improvement in the handling of discourse phenomena: 50% accuracy on our coreference test set and 53.5% for coherence/cohesion (compared to a non-contextual baseline of 50%). A simple strategy of decoding the concatenation of the previous and current sentence leads to good performance, and our novel strategy of multi-encoding and decoding of two sentences leads to the best performance (72.5% for coreference and 57% for coherence/cohesion), highlighting the importance of target-side context.

1 Introduction

Machine translation (MT) systems typically translate sentences independently of each other. However, certain textual elements cannot be correctly translated without linguistic context, which may appear outside the current sentence. The most obvious examples of context-dependent phenomena problematic for MT are coreference (Guillou, 2016), lexical cohesion (Carpuat, 2009) and lexical disambiguation (Rios Gonzales et al., 2017), an example for each of which is given in (1-3). In each case, the English element in italic is ambiguous in terms of its French translation. The correct translation choice (in bold) is determined by linguistic context (underlined), which can be outside the current sentence. This disambiguating context can be source or target-side; the correct translation of anaphoric pronouns *it* and *they* depends on the gender of the translated antecedent (1). In lexical cohesion, a translation may depend on target factors, but may also be triggered by source effects and linguistic mechanisms such as repetition or alignment (2). In lexical disambiguation, source or target information may provide the appropriate context (3).

(1) The bee is busy. // *It* is making honey.
L'abeille$_{[f]}$ est occupée. // **Elle**$_{[f]}$/#il$_{[m]}$ fait du miel.

(2) Do you fancy some soup? // *Some soup?*
Tu veux de la soupe? // **De la soupe**/#du potage?

(3) And the code? // Still some *bugs*...
Et le code ? // Encore quelques **bugs**/#insectes...

Recent work on multi-encoder neural machine translation (NMT) appears promising for the integration of linguistic context (Zoph and Knight, 2016; Libovický and Helcl, 2017; Jean et al., 2017a; Wang et al., 2017). However models have almost only been evaluated using standard automatic metrics, which are poorly adapted to evaluating discourse phenomena. Targeted evaluation, in particular of coreference in MT, has proved to be time-consuming and laborious (Guillou, 2016).

In this article, we address the evaluation of discourse phenomena for MT and propose a novel contextual model. We present two hand-crafted, discourse test sets designed to test models' capacity to exploit linguistic context for coreference and coherence/cohesion for English to French translation. Using these sets, we review contextual NMT strategies trained on subtitles in a high-resource

Proceedings of NAACL-HLT 2018, pages 1304–1313
New Orleans, Louisiana, June 1 - 6, 2018.

setting. Our new combination of strategies outperforms previous methods according to our targeted evaluation and the standard metric BLEU.

2 Evaluating contextual phenomena

Traditional automatic metrics are notoriously problematic for the evaluation of discourse in MT (Hardmeier, 2014); discursive phenomena may have an impact on relatively few word forms with respect to their importance, meaning that improvements are overlooked, and a correct translation may depend on target-side coherence rather than similarity to a reference translation.

Coreference has been a major focus of discourse translation, spurred on by shared tasks on cross-lingual pronoun prediction (Guillou et al., 2016; Loáiciga et al., 2017). Participants were provided with lemmatised versions of reference translations,[1] in which pronoun forms were to be predicted. Evaluation in this setting (with the use of reference translations) was possible with traditional metrics, because the antecedents were fixed in advance. However there are at least two disadvantages to the approach: (i) models must be trained on lemmatised data and cannot be used in a real translation setting, and (ii) many of the pronouns did not need extra-sentential context; easier gains were seen for the pronouns with intra-sentential antecedents and therefore the leaderboard was dominated by sentence-level systems.

Guillou and Hardmeier's (2016) pronoun translation test suite succeeds in overcoming some of these problems by creating an automatic evaluation method, with a back-off manual evaluation. Manual evaluation has always been an essential part of evaluating MT quality, and targeted translation allows us to isolate a model's performance on specific linguistic phenomena; recent work using in-depth, qualitative manual evaluation (Isabelle et al., 2017; Scarton and Specia, 2015) is very informative. Isabelle et al. (2017) focus on specially constructed challenging examples in order to analyse differences between systems. They cover a wide range of linguistic phenomena, but since manual evaluation is costly and time-consuming, only a few examples per phenomenon are analysed, and it is difficult to obtain quick, quantitative feedback.

An alternative method, which overcomes the problem of costly, one-off analysis, is to evaluate models' capacity to correctly rank contrastive pairs of pre-existing translations, of which one is correct and the other incorrect. This method was used by Sennrich (2017) to assess the grammaticality of character-level NMT and again by Rios Gonzales et al. (2017) in a large-scale setting for lexical disambiguation for English-German. The method allows automatic quantitative evaluation of specific phenomena at large scale, at the cost of only testing for very specific translation errors. It is also the strategy that we will use here to evaluate translation of discourse phenomena.

2.1 Our contrastive discursive test sets

We created two contrastive test sets to help compare how well different contextual MT models handle (i) anaphoric pronoun translation and (ii) coherence and cohesion.[2] For each test set, models are assessed on their ability to rank the correct translation of an ambiguous sentence higher than the incorrect translation, using the disambiguating context provided in the previous source and/or target sentence.[3] All examples in the test sets are hand-crafted but inspired by real examples from OpenSubtitles2016 (Lison and Tiedemann, 2016) to ensure that they are credible and that vocabulary and syntactic structures are varied. The method can be used to evaluate any NMT model, by making it produce a score for a given source sentence and reference translation.

Our test sets differ from previous ones in that examples necessarily need the previous context (source and/or target-side) for the translations to be correctly ranked. Unlike the shared task test sets, the ambiguous pronouns' antecedents are guaranteed not to appear within the current sentence, meaning that, for MT systems to score highly, they must use discourse-level context. Compared to other test sets suites, ours differs in that evaluation is performed completely automatically and concentrates specifically on the model's ability to use context. Each of the test sets contains

[1] This was to avoid pronoun forms being trivial to predict from the morphological inflections of other forms within the sentence, an unrealistic setting for MT output.

[2] The test sets are freely available at https://diamt.limsi.fr/eval.html.

[3] We acknowledge that in reality, the disambiguating context is not guaranteed to be in the previous sentence (cf. Guillou (2016, p. 161), for the distribution of intra- and inter-sentential anaphoric pronouns). However it is important to first judge in a controlled way whether or not models are actually capable of using extra-sentential linguistic context at all, before investigating longer distance context.

200 contrastive pairs and is designed such that a non-contexual baseline system would achieve 50% accuracy.

	incorrect:	T'inquiète, je **la** tuerai pour toi.

Figure 1: Example block from the coreference set.

Coreference test set This set contains 50 example blocks, each containing four contrastive translation pairs (see the four examples in Fig. 1). The test set's aim is to test the integration of target-side linguistic context. Each block is defined by a source sentence containing an occurrence of the anaphoric pronoun *it* or *they* and its preceding context, containing the pronoun's nominal antecedent.[4] Four contrastive translation pairs of the previous and current source sentence are given, each with a different translation of the nominal antecedent, of which two are feminine and two are masculine per block. Each pair contains a correct translation of the current sentence, in which the pronoun's gender is coherent with the antecedent's translation, and a contrastive (incorrect) translation, in which the pronoun's gender is inversed (along with agreement linked to the pronoun choice). Two of the pairs contain what we refer to as a "semi-correct" translation of the current sentence instead of a "correct" one, for which the antecedent in the previous sentence is strangely or wrongly translated (e.g. *flies* translated as *araignées* "spiders" and *papillons* "butterflies" in Fig. 1). In the "semi-correct" translation, the pronoun, whose translation is wholly dependent on the translated antecedent, is coherent with this translation choice. These semi-correct examples assess the use of target-side context, taking into account previous translation choices.

Target pronouns are evenly distributed according to number and gender with 50 examples (25 correct and 25 semi-correct) for each of the pronoun types (m.sg, f.sg, m.pl and f.pl). Since there are only two possible translations of the current sentence per example block, an MT system can only score all examples within a block correctly if it correctly disambiguates, and a non-contextual baseline system is guaranteed to score 50%.

incorrect: C'est un peu plus **cher** que ce que je pensais.

Figure 3: Example block from the coherence/cohesion test: lexical disambiguation.

[4]The choice to use only nominal antecedents and only two anaphoric pronouns *it* and *they* is intentional in order to provide a controlled environment in which there are two contrasting alternatives for each example. This ensures that a non-contextual baseline necessarily gives a score of 50%, and also enables us to explore this simpler case before expanding the study to explore more difficult anaphoric phenomena.

Coherence and cohesion test set Coherence and cohesion concern the interpretation of a text in the context of discourse (i.e. beyond sentence level). De Beaugrande and Dressler (1981) define the dichotomous pair as representing two separate aspects: coherence relating to the consistency of the text to concepts and world knowledge, and cohesion relating to the surface formulation of the text, as expressed through linguistic mechanisms.

This set contains 100 example blocks, each containing two contrastive pairs (see Figs. 2 and 3). Each of the blocks is constructed such that there is a single ambiguous source sentence, with two possible translations provided. The use of one translation over the other is determined by disambiguation context found in the previous sentence. The context may be found on the source side, the target side or both. In each contrastive pair, the incorrect translation of the current sentence corresponds to the correct translation of the other pair, such that the block can only be entirely correct if the disambiguating context is correctly used.

All test set examples have in common that the current English sentence is ambiguous and that its correct translation into French relies on context in the previous sentence. In some cases, the correct translation is determined more by cohesion, for example the necessity to respect alignment or repetition (Fig. 2). This means that despite two translations of an English source word being synonyms (e.g. *dingue* and *fou*, "crazy"), they are not interchangeable in a discourse context, given that the chosen formulation (alignment) requires repetition of the word of the previous sentence. In other cases, lexical choice is determined more by cohesion, for example by a general semantic context provided by the previous sentence, in a more classic disambiguation setting as in Fig. 3, where the English *steeper* is ambiguous between French *cher* "more expensive" and *raide* "sharply sloped". However, these types are not mutually exclusive and the distinction is not always so clear.

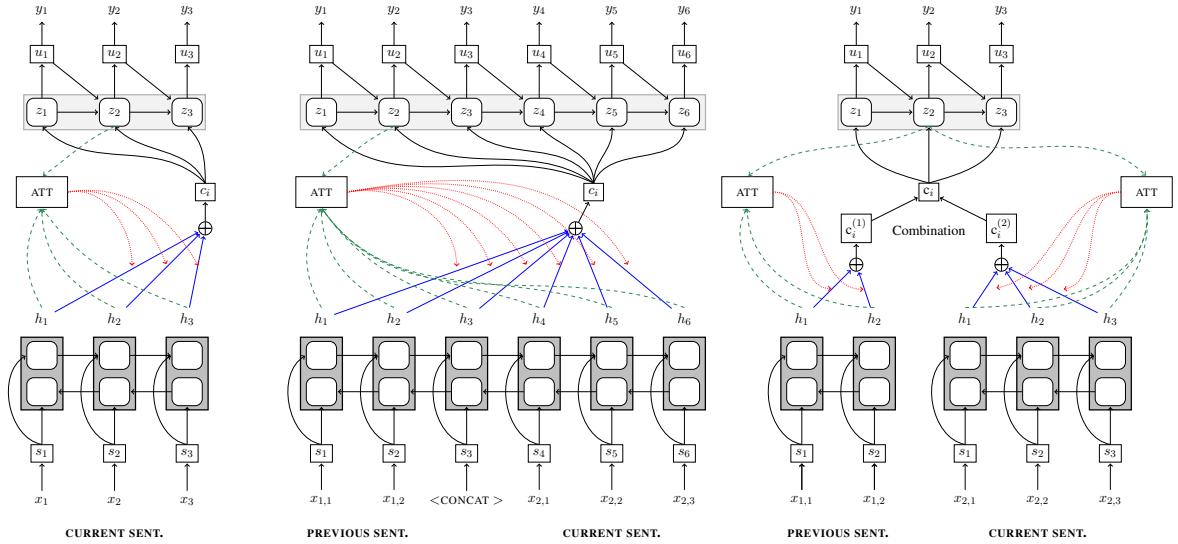
3 Contextual NMT Models

In order to correctly translate the type of phenomena mentioned in Sec. 1, translation models need to look beyond the sentence. Much of the previous work, mainly in statistical machine translation (SMT), focused on post-edition, particularly for anaphoric pronoun translation (Guillou et al., 2016; Loáiciga et al., 2017). However, coreference resolution is not yet sufficient for high quality post- or pre-edition (Bawden, 2016), and for other discourse phenomena such as lexical cohesion and lexical disambiguation, detecting the disambiguating context is far from trivial.

Recent work in NMT has explored multi-input models, which integrate the previous sentence as an auxiliary input. A simple strategy of concatenating the previous sentence to the current sentence and using a basic NMT architecture was explored by Tiedemann and Scherrer (2017), but with mixed results. A variety of multi-encoder strategies have also been tested, including using a representation of the previous sentence to initialise the main encoder and/or decoder (Wang et al., 2017) and using multiple attention mechanisms, with different strategies to combine the resulting context vectors, such as concatenation (Zoph and Knight, 2016), hierarchical attention (Libovický and Helcl, 2017) and gating (Jean et al., 2017a).

Although some of the models were evaluated in a contextual setting, for example on the cross-lingal pronoun prediction task at DiscoMT17 (Jean et al., 2017b), certain strategies only appear to give gains in a low-resource setting (Jean et al., 2017a), and, more importantly, there has yet to be an in-depth study into which strategies work best specifically for context-dependent discursive phenomena. Here we provide such a study, using the targeted test sets described in Sec. 2 to isolate and evaluate the different contextual models' capacity to exploit extra-sentential context. We test several contextual variants, using both a single encoder (Sec. 3.1) and multiple encoders (Sec. 3.2).

NMT notation All models presented are based on the widely used encoder-decoder NMT framework with attention (Bahdanau et al., 2015). At each decoder step i, the context (or summary) vector c_i of the input sequence is a weighted average of the recurrent encoder states at each input position depending on the attention weights. We refer to the recurrent state of the decoder as z_i. When multiple inputs are concerned, inputs are noted $x_j^{(k)}$, where k is the input number and j the input position. Likewise, when multiple encoders are used, $c_i^{(k)}$ refers to the k^{th} context vector where k is the encoder number. In the following section, all Ws, Us and bs are learned parameters.



(a) S2S with attention (BASELINE).

(b) Concatenate input (2-TO-2, 2-TO-1).

(c) Multi-source S2S with attention. The three combination methods tested are CONCAT, HIER and GATE.

Figure 4: The baseline model and the two contextual strategies tested (single and multi-encoder).

3.1 Single-encoder models

We train three single-source models: a baseline model and two contextual models. The baseline model translates sentences independently of each other (Fig. 4a). The two contextual models, described in (Tiedemann and Scherrer, 2017), are designed to incorporate the preceding sentence by prepending it to the current one, separated by a <CONCAT> token (Fig. 4b). The first method, which we refer to as 2-TO-2, is trained on concatenated source and target sentences, such that the previous and current sentence are translated together. The translation of the current sentence is obtained by extracting the tokens following the translated concatenation token and discarding preceding tokens.[5] The second method, 2-TO-1, follows the same principle, except that only source (and not target) sentences undergo concatenation; the model directly produces the translation of the current sentence. The comparison of these two methods allows us to assess the impact of the decoder in producing contextual translations.

3.2 Multi-encoder models

Inspired by work on multi-modal translation (Caglayan et al., 2016; Huang et al., 2016), multi-encoder translation models have recently been used to incorporate extra-sentential linguistic context in purely textual NMT (Zoph and Knight, 2016; Libovický and Helcl, 2017; Wang et al., 2017). Unlike multi-modal translation, which typically uses two complementary representations of the main input, for example a textual description and an image, linguistically contextual NMT has focused on exploiting the previous linguistic context as auxiliary input alongside the current sentence to be translated. Within this framework, we encode the previous sentence using a separate encoder (with separate parameters) to produce a context vector of the auxiliary input in a parallel fashion to the current source sentence. The two resulting context vectors $c_i^{(1)}$ and $c_i^{(2)}$ are then combined to form a single context vector c_i to be used for decoding (see Fig. 4c). We study three combination strategies here: concatenation, an attention gate and hierarchical attention. We also tested using the auxiliary context to initialise the decoder, similar to Wang et al. (2017), which was ineffective in our experiments and which we therefore do not report in this paper.

Attention concatenation The two context vectors $c_i^{(1)}$ and $c_i^{(2)}$ are concatenated and the resulting vector undergoes a linear transformation in order to return it to its original dimension to produce c_i (similar to work by Zoph and Knight (2016)).

$$c_i = W_c[c_i^{(1)}; c_i^{(2)}] + b_c \quad (1)$$

[5] Although the non-translation of the concatenation symbol is possible, in practice this was rare (<0.02%). If this occurs, the whole translation is kept.

Attention gate A gate r_i is learnt between the two vectors in order to give differing importance to the elements of each context vector, similar to the strategy of Wang et al. (2017).

$$r_i = \tanh\left(W_r c_i^{(1)} + W_s c_i^{(2)}\right) + b_r \quad (2)$$

$$c_i = r_i \odot \left(W_t c_i^{(1)}\right) + (1 - r_i) \odot \left(W_u c_i^{(2)}\right) \quad (3)$$

Hierarchical attention An additional (hierarchical) attention mechanism (Libovický and Helcl, 2017) is introduced to assign a weight to each encoder's context vector (designed for an arbitrary number of encoders).

$$e_i^{(k)} = v_b^\top \tanh\left(W_b z_{(i-1)} + U_b^{(k)} c_i^{(k)}\right) + b_e \quad (4)$$

$$\beta_i^{(k)} = \frac{\exp\left(e_i^{(k)}\right)}{\sum_{k'=1}^{K} \exp\left(e_i^{(k')}\right)} \quad (5)$$

$$c_i = \sum_{k=1}^{K} \beta_i^{(k)} U_c^{(k)} c_i^{(k)} \quad (6)$$

3.3 Novel strategy of hierarchical attention and context decoding

We also test a novel strategy of combining multiple encoders and decoding of both the previous and current sentence. We use separate, multiple encoders to encode the previous and current sentence and combine the context vectors using hierarchical attention. We train the model to produce the concatenation of the previous and current target sentences, of which the second part is kept, as in the contextual single encoder models.

4 Experiments

Each of the multi-encoder strategies is tested using the previous source and target sentences as an additional input (prefixed as S- and T- respectively) in order to test which is the most useful disambiguating context. Two additional models tested are triple-encoder models, which use both the previous source and target (prefixed as S-T-).

4.1 Data

Models are trained and tested on fan-produced parallel subtitles from OpenSubtitles2016[6] (Lison and Tiedemann, 2016). The data is first corrected using heuristics (e.g. minor corrections of OCR and encoding errors). It is then tokenised, further cleaned (keeping subtitles $\leq$80 tokens) and truecased using the Moses toolkit (Koehn et al., 2007) and finally split into subword units using BPE (Sennrich et al., 2016).[7] We run all experiments in a high-resource setting, with a training set of ≈29M parallel sentences, with vocabulary sizes of ≈55k for English and ≈60k for French.

4.2 Experimental setup

All models are sequence-to-sequence models with attention (Bahdanau et al., 2015), implemented in Nematus (Sennrich et al., 2017). Training is performed using the Adam optimiser with a learning rate of 0.0001 until convergence. We use embedding layers of dimension 512 and hidden layers of dimension 1024. For training, the maximum sentence length is 50.[8] We use batch sizes of 80, tied decoder embeddings and layer normalisation. The hyper-parameters are the same for all models and are the same as those used for the University of Edinburgh submissions to the news translation shared task at WMT16 and WMT17. Final models are ensembled using the last three checkpointed models.

Models that use the previous target sentence are trained using the previous reference translation. During translation, baseline translations are used. For the targeted evaluation, the problem does not apply since the translations that are being scored are given.

5 Results and Analysis

Overall translation quality is evaluated using the traditional automatic metric BLEU (Papineni et al., 2002) (Tab. 1) to ensure that the models do not degrade overall performance. We test the models' ability to handle discursive phenomena using the test sets described in Sec. 2 (Tab. 2). The models are described in the first half of Table 1: *#In* is the number of input sentences, the type of auxiliary input of which (previous source or target) is indicated by *Aux.*, *#Out* is the number of sentences translated, and *#Enc* is the number of encoders used to encode the input sentences. When there is a single encoder and more than one input, the input sentences are concatenated to form a single input to the encoder.

Table 1: Results (de-tokenised, cased BLEU) of the ensembled models on four different test sets, each containing three films from each film genre. The best, second- and third-best results are highlighted by decreasingly dark shades of green.

5.1 Overall performance

Results using the automatic metric BLEU are given in Tab. 1. The models are tested on four different genres of film: comedy, crime, fantasy and horror.[9] Scores vary dramatically depending on the genre and the best model is not always the same for each of the genres.

Contrary to intuition, using the previous target sentence as an auxiliary input (prefix T-) degrades the overall performance considerably. Testing at decoding time with the reference translations did not significantly improve this result, suggesting that it is unlikely to be a case of overfitting during training. The highest performing model is our novel S-HIER-TO-2 model with more than +1 over the baseline BLEU on almost all test sets. There is no clear second best model, since performance depends strongly on the test set used.

5.2 Targeted evaluation

Tab. 2 shows the results on the discourse test sets.

Coreference The multi-encoder models do not perform well on the coreference test set; all multi-encoder models giving at best random accuracy, as with the baseline. This set is designed to test the model's capacity to exploit previous target context. It is therefore unsurprising that multi-encoder models using just the previous source sentence perform poorly. It is possible that certain pronouns could be correctly predicted from the source antecedents, if the antecedent only has one possible translation. However, this non-robust way of translating pronouns is not tested by the test set. More surprisingly, the multi-encoder models using the previous target sentence also perform poorly on the test set. An explanation could be that the target sentence is not being encoded sufficiently well in this framework, resulting in poor learning. This hypothesis is supported by the low overall translation performance shown in Tab. 1.

Two models perform well on the test set: 2-TO-2 and our S-HIER-TO-2. The high scores, particularly on the less common feminine pronouns, which can only be achieved through using contextual linguistic information, show that these models are capable of using previous linguistic context to disambiguate pronouns. The progressively high performance of these models can be seen in Fig. 5, which illustrates the training progress of these models. The S-T-HIER-TO-2 model (which uses the previous target sentence as a third auxiliary input) performs much worse than S-HIER-TO-2, showing that the addition of the previous target sentence is detrimental to performance. Whilst the

[9] Each of the test sets contains three films from that genre, with varying sizes and difficulty. The number of sentences in each test set is as follows: comedy: 4,490, crime: 4,227, fantasy: 2,790 and horror: 2,158.

	Coreference (%)							Coherence/cohesion (%)

Table 2: Results on the discourse test sets (% correct). Results on the coreference set are also given for each pronoun class. CORR. and SEMI correspond respectively to the "correct" and "semi-correct" examples. The best, second- and third-best results are highlighted by decreasingly dark shades of green.

results for the "correct" examples (CORR.) are almost always higher than the "semi-correct" examples (SEMI), for which the antecedent is strangely translated, the TO-2 models also give improved results on these examples, showing that the target context is necessarily being exploited during decoding.

These results show that the translation of the previous sentence is the most important factor in the efficient use of linguistic context. Combining the S-HIER model with decoding of the previous target sentence (S-HIER-TO-2) produces some of the best results across all pronoun types, and the 2-TO-2 model performs almost always second best.

Coherence and cohesion Much less variation in scores can be seen here, suggesting that these examples are more challenging and that there is room for improvement. Unlike the coreference examples, the multi-encoder strategies exploiting the previous source sentences perform better than the baseline (up to 53.5% for S-CONCAT). Yet again, using the previous target sentence achieves near random accuracy. 2-TO-2 and 2-TO-1 achieve similarly low scores (52% and 53%), suggesting that if concatenated input is used, decoding the previous sentence does not add more information.

However, combining multi-encoding with the decoding of the previous and the current sentences (S-HIER-TO-2) greatly improves the handling of the ambiguous translations, improving the accuracy to 57%. Extending this same model to also exploit the previous target sentence (S-T-HIER-TO-2) degrades this result, giving very similar scores to T-HIER and is therefore not illustrated in FIgure 5. This provides further support for the idea that the target sentence is not encoded efficiently as an auxiliary input and adds noise to the model, whereas exploiting the target context as a bias in the recurrent decoder is more effective.

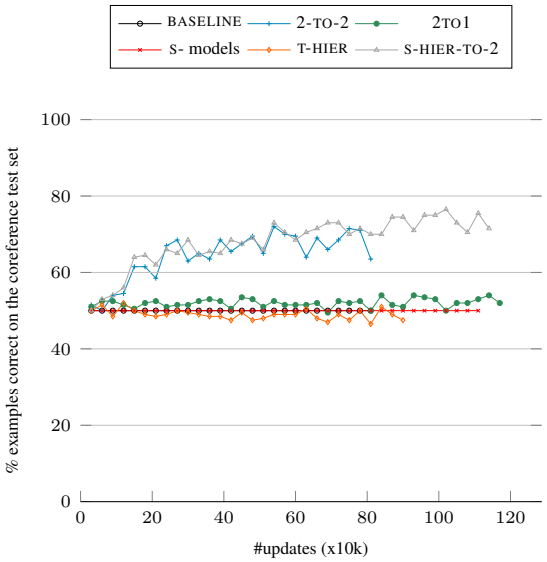

Figure 5: Progression of % correctly ranked examples (from the coreference test set) during training.

5.3 How much is the context being used?

Looking at the attention weights can sometimes offer insights into which input elements are being attended to at each step. For coreference resolution, we would expect the decoder to attend to the pronoun's antecedent. The effect is most expected when the previous target sentence is used, but it could also apply for the previous source sentence when the antecedent has only one possible translation. Unlike Tiedemann and Scherrer (2017), we do not observe increased attention between a translated pronoun and its source antecedent. Given the discourse test set results, which can only give high scores when target-side context is used, the contextual information of the type studied in this paper seems to be best exploited when channelled through the recurrent decoder node rather than when encoded through the input. This could explain why coreference is not easily seen via attention weights; the crucial information is encoded on the decoder-side rather than in the encoder.

6 Conclusion

We have presented an evaluation of discourse-level NMT models through the use of two discourse test sets targeted at coreference and lexical coherence/cohesion. We have shown that multi-encoder architectures alone have a limited capacity to exploit discourse-level context; poor results are found for coreference and more promising results for coherence/cohesion, although there is room for improvement. Our novel combination of contextual strategies greatly outperfoms existing models. This strategy uses the previous source sentence as an auxiliary input and decodes both the current and previous sentence. The observation that the decoding strategy is very effective for the handling of previous context suggests that techniques such as stream decoding, keeping a constant flow of contextual information in the recurrent node of the decoder, could be very promising for future research.

Fast Lexically Constrained Decoding with Dynamic Beam Allocation for Neural Machine Translation

Matt Post and **David Vilar**
Amazon Research
Berlin, Germany

Abstract

The end-to-end nature of neural machine translation (NMT) removes many ways of manually guiding the translation process that were available in older paradigms. Recent work, however, has introduced a new capability: *lexically constrained* or *guided* decoding, a modification to beam search that forces the inclusion of pre-specified words and phrases in the output. However, while theoretically sound, existing approaches have computational complexities that are either linear (Hokamp and Liu, 2017) or exponential (Anderson et al., 2017) in the number of constraints. We present an algorithm for lexically constrained decoding with a complexity of $\mathcal{O}(1)$ in the number of constraints. We demonstrate the algorithm's remarkable ability to properly place these constraints, and use it to explore the shaky relationship between model and BLEU scores. Our implementation is available as part of SOCKEYE.

1 Introduction

One appeal of the phrase-based statistical approach to machine translation (Koehn et al., 2003) was that it provided control over system output. For example, it was relatively easy to incorporate domain-specific dictionaries, or to force a translation choice for certain words. These kinds of interventions were useful in a range of settings, including interactive machine translation or domain adaptation. In the new paradigm of neural machine translation (NMT), these kinds of manual interventions are much more difficult, and a lot of time has been spent investigating how to restore them (cf. Arthur et al. (2016)).

At the same time, NMT has also provided new capabilities. One interesting recent innovation is *lexically constrained decoding*, a modification to beam search that allows the user to specify words and phrases that must appear in the system output (Figure 1). Two algorithms have been proposed for this: *grid beam search* (Hokamp and Liu, 2017, GBS) and *constrained beam search* (Anderson et al., 2017, CBS). These papers showed that these algorithms do a good job automatically placing constraints and improving results in tasks such as simulated post-editing, domain adaptation, and caption generation.

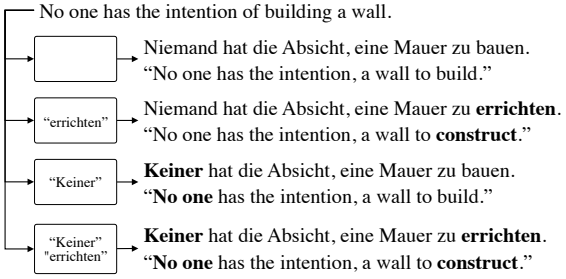

Figure 1: An example translating from English to German. The first translation is unconstrained, whereas the remaining ones have one or two constraints imposed. A word-for-word translation of the German output has been provided for the convenience of non-German speaking readers.

A downside to these algorithms is their runtime complexity: linear (GBS) or exponential (CBS) in the number of constraints. Neither paper reported decoding speeds, but the complexities alone suggest a large penalty in runtime. Beyond this, other factors of these approaches (a variable sized beam, finite-state machinery) change the decoding procedure such that it is difficult to integrate with other operations known to increase throughput, like batch decoding.

We propose and evaluate a new algorithm, *dynamic beam allocation* (DBA), that is *constant* in the number of provided constraints (Table 1). Our algorithm works by grouping together hypotheses that have met the same number of constraints into

banks (similar in spirit to the grouping of hypotheses into stacks for phrase-based decoding (Koehn et al., 2003)) and dynamically dividing a fixed-size beam across these banks at each time step. As a result, the algorithm scales easily to large constraint sets that can be created when words and phrases are expanded, for example, by sub-word processing such as BPE (Sennrich et al., 2016). We compare it to GBS and demonstrate empirically that it is significantly faster, making constrained decoding with an arbitrary number of constraints feasible with GPU-based inference. We also use the algorithm to study beam search interactions between model and metric scores, beam size, and pruning.

2 Beam Search and Grid Beam Search

Inference in statistical machine translation seeks to find the output sequence, $\hat{y}$, that maximizes the probability of a function parameterized by a model, θ, and an input sequence, x:

$$\hat{y} = \text{argmax}_{y \in \mathcal{Y}} \, p_\theta(y \mid x)$$

The space of possible translations, $\mathcal{Y}$, is the set of all sequences of words in the target language vocabulary, V_T. It is impossible to explore this entire space. Models decompose this problem into a sequence of time steps, t. At each time step, the model produces a distribution over V_T. The simplest approach to translation is therefore to run the steps of the decoder, choosing the most-probable token at each step, until either the end-of-sentence token, $\langle/\text{s}\rangle$, is generated, or some maximum output length is reached. An alternative, which explores a slightly larger portion of the search space, is beam search.

In beam search (Lowerre, 1976; Sutskever et al., 2014), the decoder maintains a *beam* of size k containing a set of active hypotheses (Algorithm 1). At each time step t, the decoder model is used to produce a distribution over the target-language vocabulary, V_T, for each of these hypotheses. This produces a large matrix of dimensions $k \times |V_T|$, that can be computed quickly with modern GPU hardware. Conceptually, a (row, column) entry (i, j) in this matrix contains the state obtained from starting from the ith state in the beam and generating the target word corresponding to the jth word of V_T. The beam for the next time step is filled by taking the states corresponding to the k-best items from this entire matrix and sorting them.

Algorithm 1 Beam search. *Inputs:* max output length N, beam size k. *Output:* highest-scoring hypothesis.

```
1: function BEAM-SEARCH(N, k)
2:     beam ← DECODER-INIT(k)
3:     for time step t in 1..N do
4:         scores = DECODER-STEP(beam)
5:         beam ← KBEST(scores)
6:     return beam[0]
7: function KBEST(scores)
8:     beam = ARGMAX_K(k, scores)
9:     return beam
```

A principal difference between beam search for phrase-based and neural MT is that in NMT, there is no recombination: each hypothesis represents a complete history, back to the first word generated. This makes it easy to record properties of the history of each hypothesis that were not possible with dynamic programming. Hokamp and Liu (2017) introduced an algorithm for forcing certain words to appear in the output called *grid beam search* (GBS). This algorithm takes a set of constraints, which are words that must appear in the output, and ensures that hypotheses have met all these constraints before they can be considered to be completed. For C constraints, this is accomplished by maintaining $C + 1$ separate beams or *banks*, $B_0, B_1, \ldots, B_C$, where B_i groups together hypotheses that have generated (or *met*) i of the constraints. Decoding proceeds as with standard beam decoding, but with the addition of bookkeeping that tracks the number of constraints met by each hypothesis, and ensures that new candidates are generated, such that each bank is filled at each time step. When beam search is complete, the hypothesis returned is the highest-scoring one in bank B_C. Conceptually, this can be thought of as adding an additional dimension to the beam, since we multiply out some base beam size b by (one plus) the number of constraints.

We note two problems with GBS:

- Decoding complexity is linear in the number of constraints: The effective beam size, $k \cdot (C + 1)$, varies with the number of constraints.
- It is impractical. The beam size changes for every sentence, whereas most decoders specify the beam size at model load time in order to optimize computation graphs, specially when running on GPUs. It also complicates beam search optimizations that increase throughput, such as batching.

Our extension, fast lexically-constrained decoding via dynamic beam allocation (DBA), addresses both of these issues. Instead of maintaining $C + 1$ beams, we maintain a single beam of size k, as with unconstrained decoding. We then dynamically allocate the slots of this beam across the constraint banks at each time step. There is still bookkeeping overhead, but this cost is constant in the number of constraints, instead of linear. The result is a practical algorithm for incorporating arbitrary target-side constraints that fits within the standard beam-decoding paradigm.

3 Dynamic Beam Allocation (DBA)

Our algorithm (Algorithm 2) is based on a small but important alteration to GBS. Instead of *multiplying* the beam by the number of constraints, we *divide*. A fixed beam size is therefore provided to the decoder, just as in standard beam search. As different sentences are processed with differing numbers of constraints, the beam is dynamically allocated to these different banks. In fact, the allocation varies not just by sentence, but across time steps in processing each individual sentence.

We need to introduce some terminology. A *word constraint* provided to the decoder is a single token in the target language vocabulary. A *phrasal constraint* is a sequence of two or more contiguous tokens. Phrasal constraints come into play when the user specifies a multi-word phrase directly (e.g., *high-ranking member*), or when a word gets broken up by subword splitting (e.g., *thou@@ ghtful*). The total number of constraints is the sum of the number of tokens across all word and phrasal constraints. It is easier for the decoder to place multiple sequential tokens in a phrasal constraint (where the permutation is fixed) compared to placing separate, independent constraints (see discussion at the end of §5), but the algorithm does not distinguish them when counting.

DBA fits nicely within standard beam decoding; we simply replace the `kbest` implementation from Algorithm 1 with one that involves a bit more bookkeeping. Instead of selecting the top-k items from the $k \times V_T$ scores matrix, the new algorithm must consider two important matters.

1. Generating a list of candidates (§3.1). Whereas the baseline beam search simply takes the top-k items from the scores matrix (a fast operation on a GPU), we now need to ensure that candidates progress through the set of provided constraints.
2. Allocating the beam across the constraint banks (§3.2). With a fixed-sized beam and an arbitrary number of constraints, we need to find an allocation strategy for dividing the beam across the constraint banks.

3.1 Generating the candidate set

We refer to Figure 2 for discussion of the algorithm. The set of candidates for the beam at time step $t + 1$ is generated from the hypotheses in the current beam at step t, which are sorted in decreasing order, with the highest-scoring hypothesis at position 1. The DECODER-STEP function of beam search generates a matrix, $scores$, where each row r corresponds to a probability distribution over all target words, expanding the hypothesis in position r in the beam. We build a set of candidates from the following items:

1. The best k tokens across all rows of $scores$ (i.e., normal top-k);
2. for each hypothesis in the beam, all unmet constraints (to ensure progress through the constraints); and
3. for each hypothesis in the beam, the single-best token (to ensure consideration of partially-completed hypotheses).

Each of these candidates is denoted by its coordinates in `scores`. The result is a set of candidates which can be grouped into banks according to how many constraints they have met, and then sorted within those banks. The new beam for timestep $t + 1$ is then built from this list according to an allocation policy (next section).

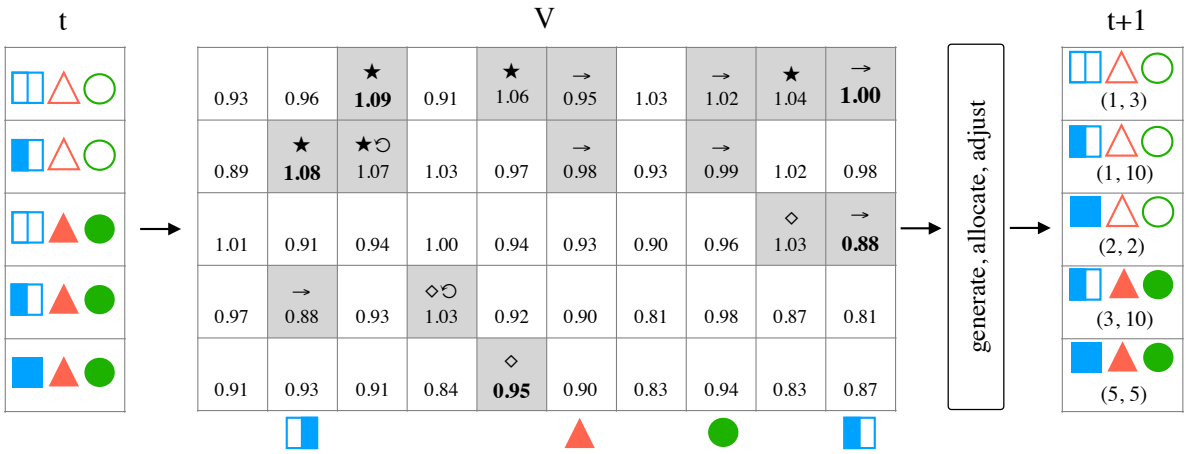

Figure 2: A single step of the constrained decoder. Along the left is the beam ($k = 5$) at time step t. The shapes in this beam represent constraints, both met (filled) and unmet (outlined). The blue square represents a phrasal constraint of length 2, which must be completed in order (left half, then right half). A step of the decoder produces a $k \times V_T$ matrix of scores. Each constraint corresponds to a single token in the vocabulary, and is marked along the bottom. Gray squares denote the set of candidates that are produced (§3.1) from the k best items (★), from extending each hypothesis with all unfilled constraints (→), and from its single-best next token (◇). Items that violate a phrasal constraint (↺) require the phrasal constraint from that hypotheses to be unwound (set to unmet). From these fifteen candidates, the beam at time step $t+1$ is filled, according to the bank allocation strategy, which here assigns one slot in the beam to each bank. The final beam includes coordinates indicating the provenance of chosen items (which are also indicated in bold in the grid).

For hypotheses partially through a phrasal constraint, special care must be taken. If a phrasal constraint has been begun, but not finished, and a token is chosen that does not match the next word of the constraint, we must reset or "unwind" those tokens in this constraint that are marked as having been met. This permits the decoder to abort the generation of a phrasal constraint, which is important in situations where a partial prefix of a phrasal constraint appears in the decoded sentence earlier than the entire phrase.

3.2 Allocating the beam

The task is to allocate a size-k beam across $C+1$ constraint banks, where C may be greater than k. We use the term *bank* to denote the portion of the beam reserved for items having met the same number of constraints (including one bank for hypotheses with zero constraints met). We use a simple allocation strategy, setting each bin size to $\lfloor k/C \rfloor$, irrespective of the timestep. Any remaining slots are assigned to the "topmost" or maximally constrained bank, C.

This may at first appear wasteful. For example, space allocated at timestep 1 to a bank representing candidates having met more than one constraint cannot be used, and similarly, for later timesteps, it seems wasteful to allocate space to bank 1. Additionally, if the number of candidates in a bank is smaller than the allocation for that bank, the beam is in danger of being underfilled. These problems are mitigated by bank adjustment (Figure 3). We provide here only a sketch of this procedure. An overfilled bank is one that has been allocated more slots than it has candidates to fill. Each such overfilled bank, in turn, gives its extra allotments to banks that have more candidates than slots, looking first to its immediate neighbors, and moving outward until it has distributed all of its extra slots. In this way, the beam is filled, up to the minimum of the beam size or the number of candidates.

3.3 Finishing

Hypotheses are not allowed to generate the end-of-sentence token, $\langle/\mathrm{s}\rangle$, unless they have met all of their constraints. When beam search is finished, the highest-scoring completed item is returned.

4 Experimental Setup

Our experiments were done using SOCKEYE (Hieber et al., 2017). We used an English–German model trained on the complete WMT'17 training corpora (Bojar et al., 2017), which we pre-

Algorithm 2 k-best extraction with DBA. *Inputs:* A $k \times |V_T|$ matrix of model states.

```
function KBEST-DBA(beam, scores)
    constraints ← [hyp.constraint for hyp in beam]
    candidates ← [(i, j, constraints[i].add(j)] for i, j in ARGMAX_K(k, scores)      ▷ Top overall k
    for 1 ≤ h ≤ k do                                                                  ▷ Go over current beam
        for all w ∈ V_T that are unmet constraints for beam[h] do                     ▷ Expand new constraints
            candidates.append( (h, w, constraints[h].add(w) ) )
        w = ARGMAX(scores[h, :])
        candidates.append( (h, w,  constraints[h].add(w)) )                           ▷ Best single word
    selected ← ALLOCATE(candidates, k)
    newBeam ← [candidates[i] for i in selected]
    return newBeam
```

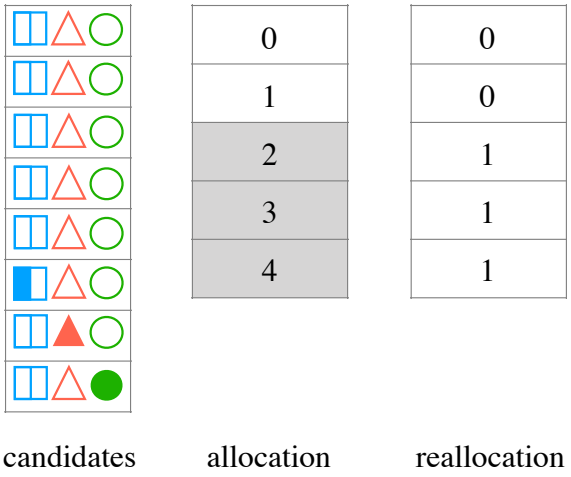

Figure 3: Beam reallocation for $k = 5$ with 4 constraints at timestep t. There are eight candidates, each having met only 0 or 1 constraint. The allocation policy gives one slot of the beam to each bank. However, there are no candidates for banks 2–4 (greyed), so their slots are redistributed to banks 0 and 1.

processed with the Moses tokenizer (preserving case) and with a joint byte-pair-encoded vocabulary with 32k merge operations (Sennrich et al., 2016). The model was a 4 layer RNN with attention. We trained using the Adam optimizer with a batch size of 80 until cross-entropy on the development data (newstest2016) stopped increasing for 10 consecutive iterations.

For decoding, we normalize completed hypotheses (those that have generated ⟨/s⟩), dividing the cumulative sentence score by the number of words. Unless otherwise noted, we apply threshold pruning to the beam, removing hypotheses whose log probability is not within 20 compared to the best completed hypothesis. This pruning is applied to all hypotheses, whether they are complete or not. (We explore the importance of this pruning in §6.3). Decoding stops when either all hypotheses still on the beam are completed or the maximum length, N, is reached. All experiments were run on a single a Volta P100 GPU. No ensembling or batching were used.

For experiments, we used the newstest2014 English–German test set (the developer version, with 2,737 sentences). All BLEU scores are computed on detokenized output using SACREBLEU (Post, 2018),[1] and are thus directly comparable to scores reported in the WMT evaluations.

5 Validation Experiment

We center our exploration of DBA by experimenting with constraints randomly selected from the references. We extract five sets of constraints: from one to four randomly selected words from the reference (`rand1` to `rand4`), and a randomly selected four-word phrase (`phr4`). We then apply BPE to these sets, which often yields a much larger number of token constraints. Statistics about these extracted phrases can be found in Table 2.

We simulate the GBS baseline within our framework. After applying BPE, We group together translations with the same number of constraints, C, and then translate them as a group, with the beam set for that group set to $b(C + 1)$, where b is the "base beam" parameter. We use $b = 10$ as reported in Hokamp et al., but also try smaller values of $b = 5$ and 1. Finally, we disable beam adjustment (§3.2), so that the space allocated to each constraint bank does not change.

Table 4 compares speeds and BLEU scores (in the legend) as a function of the number of post-

Table 2: Histogram of the number of token constraints for some constraint sets after applying BPE (model trained with 32k merge operations). *mean* denotes the mean number of constraints per sentence in the 2,737-sentence test set.

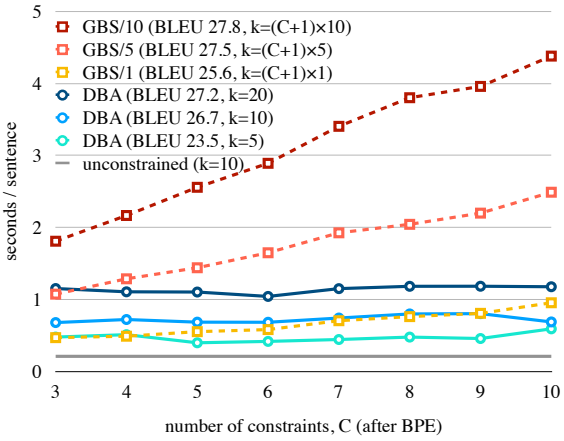

Figure 4: Running time (seconds / sentence, lower is better) as a function of the number of constraints, C (after applying BPE) on the `rand3` dataset. The unconstrained baselines have BLEU scores of 22.3, 22.3, and 22.1 for $k = 5, 10$, and 20, respectively.

BPE constraints for the `rand3` dataset. We plot all points for which there were at least 10 sentences. The times are decoding only, and exclude model loading and other setup. The linear trend in C is clear for GBS, as is the constant trend for DBA. In terms of absolute runtimes, DBA improves considerably over GBS, whose beam sizes quickly become quite large with a non-unit base beam size. On the Tesla V100 GPU, DBA ($k = 10$) takes about 0.6 seconds/sentence, regardless of the number of constraints.[2] This is about 3x slower than unconstrained decoding.

It is difficult to compare these algorithms exactly because of GBS's variable beam size. An important comparison is that between DBA ($k = 10$) and GBS/1 (base beam of 1). A beam of $k = 10$ is a common setting for decoding in general, and GBS/1 has a beam size of $k \geq 10$ for $C \geq 9$. At this setting, DBA finds better translations (BLEU 26.7 vs. 25.6) with the same runtime and with a fixed, instead of variable-sized, beam.

We note that the bank adjustment correction of the DBA algorithm allows it to work when $C >= k$. The DBA ($k = 5$) plot demonstrates this, while still finding a way to increase the BLEU score over GBS (23.5 vs. 22.3). However, while possible, low k relative to C reduces the observed improvement considerably. Looking at Figure 5 across different constraint sets, we can get a better feel for this relationship. DBA is still always able to meet the constraints even with a beam size of 5, but the quality suffers. This should not be too surprising; correctly placing independent constraints is at least as hard as finding their correct permutation, which is exponential in the number of independent constraints. But it is remarkable that the only failure to beat the baseline in terms of BLEU is when the algorithm is tasked with placing four random constraints (before BPE) with a beam size of 5. In contrast, DBA never has any trouble placing phrasal constraints (dashed lines).

[2]On a K80, it is about 1.4 seconds / sentence

6 Analysis

6.1 Placement

It's possible that the BLEU gains result from a boost in n-gram counts due to the mere presence of the reference constraints in the output, as opposed to their correct placement. This appears not to be the case. Experience examining the outputs shows its uncanny ability to sensibly place constrained words and phrases. Figure 6 contains some examples from translating a German sentence into English, manually identifying interesting phrases in the target, choosing paraphrases of those words, and then decoding with them as constraints. Note that the word weak, which doesn't fit in the semantics of the reference, is placed haphazardly.

We also confirm this correct placement quantitatively by comparing the location of the first word of each constraint in (a) the reference and (b) the output of the constrained decoder, represented as a percentage of the respective sentence lengths (Figure 7). We would not expect these numbers to

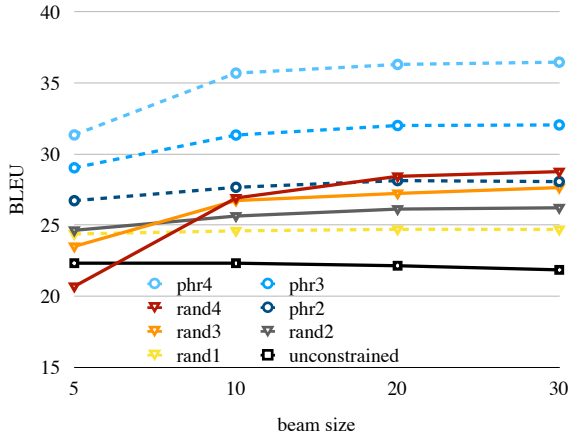

Figure 5: BLEU score as a function of beam size under DBA. All constraint sets improve as the beam gets larger (recall that the actual number of constraints increases after BPE and varies by sentence). `rand4` performs under the unconstrained baseline if the beam is too low.

	0	3	5	10	20	30
none	24.4	24.5	24.5	24.4	24.5	24.4
rand1	25.2	25.1	25.2	25.6	25.5	25.3
rand2	26.0	25.3	25.6	26.1	26.7	26.4
rand3	26.5	24.7	24.9	25.7	26.9	27.2
rand4	26.2	23.7	23.9	24.6	26.0	26.9
phr4	35.1	33.5	33.5	34.0	35.0	35.9

Table 3: BLEU scores decoding with a beam size of 10. Runtimes for unpruned systems (column 0) are nearly twice those of the other columns. But it is only at large thresholds that BLEU scores are higher than the unpruned setting.

be perfectly matched, but the strong correlation is pretty apparent (Pearson's $r = 0.82$). Together, Figures 6 and 7 provide confidence that DBA is intelligently placing the constraints.

6.2 Reference Aversion

The inference procedure in SOCKEYE maximizes the length-normalized version of the sentence's log probability. While there is no explicit training towards the metric, BLEU, modeling in machine translation assumes that better model scores correlate with better BLEU scores. However, a general repeated observation from the NMT literature is the disconnect between model score and BLEU score. For example, work has shown that opening up the beam to let the decoder find better hypotheses results in lower BLEU score (Koehn and Knowles, 2017), even as the model score rises. The phenomenon is not well understood, but it seems that NMT models have learned to travel a path straight towards their goal; as soon as they get off this path, they get lost, and can no longer function (Ott et al., 2018).

Another way to look at this problem is to ask what the neural model thinks of the references. Scoring against complete references is easy with NMT (Sennrich, 2017), but lexically-constrained decoding allows us to investigate this in finer-grained detail by including just portions of the references. We observe that forcing the decoder to include even a single word from the reference imposes a cost in model score that is inversely correlated with BLEU score, and that this grows with the number of constraints that are added (Figure 8). The NMT system seems quite averse to the references, even in small pieces, and even while it improves the BLEU score. At the same time, the hypotheses it finds in this reduced space are still good, and become better as the beam is enlargened (Figure 5). This provides a complementary finding to that of Koehn and Knowles (2017): in that setting, higher model scores found by a larger beam produce lower BLEU scores; here, lower model scores are associated with significantly higher BLEU scores.

6.3 Effects of Pruning

In the results reported above, we used a pruning threshold of 20, meaning that any hypothesis whose log probability is not within 20 of the best completed hypothesis is removed from the beam. This pruning threshold is far greater than those explored in other papers; for example, Wu et al. (2016) use 3. However, we observed two things: first, without pruning, running time for constrained decoding is nearly doubled. This increased runtime applies to both DBA and GBS in Figure 4. Second, low pruning thresholds are harmful to BLEU scores (Table 3). It is only once the thresholds reach 20 that the algorithm is able to find better BLEU scores compared to the unpruned baseline (column 0).

6.4 Garbage Generation

Why is the algorithm so slow without pruning? One might suspect that the outputs are longer, but mean output length with all constraint sets is roughly the same. The reason turns out to be that the the decoder never quits before the maximum

Figure 6: Example demonstrating the correct placement of manually chosen constraints (beam size 10). The unnatural placement of the constraint *weak* demonstrates what the model does when forced to include a word that is not a semantic fit.

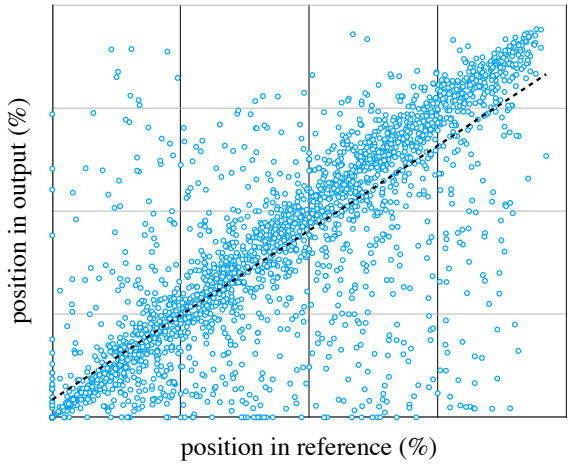

Figure 7: Location of the first word of each constraint from `phr3` in the reference versus the constrained output (Pearson's $r = 0.82$). DBA correctly places its constraints, even though no source word or alignment information is provided.

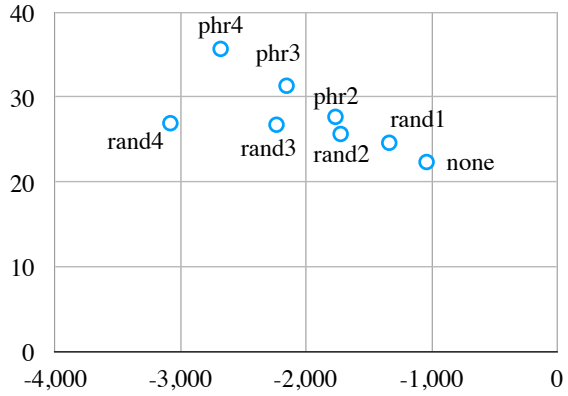

Figure 8: BLEU score as a function of model score (summed over the corpus). The reference model score is -4,396.

timestep, N. SOCKEYE's stopping criterium is to wait until all hypotheses on the beam are finished. Without pruning, the decoder generates a finished hypotheses, but continues on until the maximum timestep N, populating the rest of the beam with low-cost garbage. An example can be found in Figure 9. This may be an example of the well-attested phenomenon where NMT systems become unhinged from the source sentence, switching into "language model" mode and generating high-probable output with no end. But strangely, this doesn't seem to affect the best hypotheses, but only the rest of the beam. This seems to be more evidence of reference aversion, where the decoder, having been forced into a place it doesn't like, does not know how to generate good competing hypotheses.

An alternative to pruning is *early stopping*, which is to stop when the first complete hypothesis is generated. In our experiments, while this did fix the problem of increasing runtimes, the BLEU scores were lower.

6.5 Conclusions

By setting a large pruning threshold, we produced large speedups over GBS, and demonstrated a constant overhead in the number of constraints. Compared to GBS, our DBA algorithm makes lexically constrained decoding possible, requiring less than half a second on average on a Volta GPU with a 4-layer RNN.

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	…	41

-27.92	⟨s⟩	Er	und	Kerr	lieben	sich	weiterhin	einander	,	betonte	die	36-Jährige	.		…	

Figure 9: The sentence *He and Kerr still love each other , emphasised the 36-year-old .* translated with the constraint *noch immer , betonte* (BPE removed for readability). The first column is the log probability, which is normalized only for finished hypotheses. The decoder completes a few hypotheses well before the maximum timestep, but then fills the lower beam with garbage until forced to stop.

7 Related Work

Hokamp and Liu (2017) was novel in that it allowed the specification of arbitrary target-side words as hard constraints, implemented entirely as a restructuring of beam search, and without reference to the source. A related approach was that of Anderson et al. (2017), who extended beam search with a finite state machine whose states marked completed subsets of the set of constraints, at an exponential cost in the number of constraints.

Lexically-constrained decoding also generalizes prefix decoding (Knowles and Koehn, 2016; Wuebker et al., 2016), since the ⟨s⟩ symbol can easily be included as the first word of a constraint.

Our work here has not explored where to get lexical constraints, but considering that question naturally brings to mind attempts to improve NMT by using lexicons and phrase tables (Arthur et al., 2016; Tang et al., 2016).

Finally, another approach which shares the hard-decision made by lexically constrained decoding is the *placeholder approach* (Crego et al., 2016), wherein identifiable elements in the input are transformed to masks during preprocessing, and then replaced with their original source-language strings during postprocessing.

8 Summary

Neural machine translation removes many of the knobs from phrase-based MT that provided fine-grained control over system output. Lexically-constrained decoding restores one of these tools, providing a powerful and interesting way to influence NMT output. It requires only the specification of the target-side constraints; without any source word or alignment information, it correctly places the constraints. Although we have only tested it here with RNNs, the code works without modification with other architectures generate target-side words one-by-one, such as the Transformer (Vaswani et al., 2017).

This paper has introduced a fast and practical solution. Building on previous approaches, constrained decoding with DBA does away with linear and exponential complexity (in the number of constraints), imposing only a constant overhead. On a Volta GPU, lexically-constrained decoding with DBA is practical, requiring about 0.6 seconds per sentence on average even with 10+ constraints, well within the realm of feasibility even for applications with strict lattency requirements, like post-editing tasks. We imagine that there are further optimizations in reach that could improve this even further.

Acknowledgments We thank Felix Hieber for valuable discussions.

A Appendix: Failed Experiments

The main contribution of this paper is a fast, practical algorithmic improvement to lexically-constrained decoding. While we did not attempt to corroborate the experiments in interactive translation and domain adaptation experiments reported in (Hokamp and Liu, 2017), the gains discovered there only become more salient with this faster algorithm. We did try to apply lexical constraints in a few other settings, but without success. In the spirit of open scientific inquiry and reporting, we provide here a brief report on these experiments.

A.1 Automatic Constraint Selection

Our validation experiments (§5) demonstrate the large potential gains in BLEU score when including random phrases from the reference. Even including just a single random word from the reference increased BLEU score by a point; another point was gained from including two random words, and a four-word phrase yielded 10+ point gains. Only about 18% of these random unigrams were present in the unconstrained output (less for longer n-grams). This raises the question of whether we can automatically identify words that are likely to be in the reference and include them as constraints, in order to improve translation quality.

In order to do that, we first extracted a phrase table using Moses and filtered it with the significance testing approach proposed by Johnson et al. (2007) in order to keep only high quality phrases. We then selected the best phrase for each input sentence according to different criteria (longest phrase, higher significance, highest probability, combination of those). Unfortunately, adding such phrases as constraints when translating WMT or IWSLT data did not help.

A.2 Name Entity Translation

One topic that has received attention in the literature is the tendency of NMT systems to do poorly with rare words, and in particular, named entities (e.g., Arthur et al. (2016)). BPE helps address this by breaking down words into pieces and allowing all words to be represented in the decoder's vocabulary. But even with BPE, many times the correct translation does not follow any pattern, even at the subword level. This is specially true for named entities; e.g. "Aachen" in German is translated as "Aquisgrán" in Spanish or "Aix-la-Chapelle" in French, which bear little resemblance to the original form except for the starting letter. Named entities (NEs) also have the advantage that in several languages they are not inflected; therefore a simple lookup in a dictionary, if available, should produce the correct translation.

To the best of our knowledge, there is no publicly available parallel corpus of named entities. In order to create one, we downloaded the OpenSubtitles database (Lison and Tiedemann, 2016) for German and English and applied a simple method for extracting named entity correspondences. We first tagged the source and target sides with the Stanford NER system (Manning et al., 2014). We then selected a subset of the tags that were produced by both systems ("Person", "Location" and "Organization") and selected those sentences where they appeared only once for each language. From those we extracted the corresponding NEs, selecting the most frequent target side at the corpus level as the translation of a given source NE.

Given such a dictionary, we can add the translation of a NE found in new sentences to translate as decoding constraints. It didn't help. Manual inspection showed that the dictionary extracted with this simple method was still too noisy. We think that a manual, high-quality dictionary may provide a way to produce improvements.

Guiding Neural Machine Translation with Retrieved Translation Pieces

Abstract

One of the difficulties of neural machine translation (NMT) is the recall and appropriate translation of low-frequency words or phrases. In this paper, we propose a simple, fast, and effective method for recalling previously seen translation examples and incorporating them into the NMT decoding process. Specifically, for an input sentence, we use a search engine to retrieve sentence pairs whose source sides are similar with the input sentence, and then collect n-grams that are both in the retrieved target sentences and aligned with words that match in the source sentences, which we call "translation pieces". We compute pseudo-probabilities for each retrieved sentence based on similarities between the input sentence and the retrieved source sentences, and use these to weight the retrieved translation pieces. Finally, an existing NMT model is used to translate the input sentence, with an additional bonus given to outputs that contain the collected translation pieces. We show our method improves NMT translation results up to 6 BLEU points on three narrow domain translation tasks where repetitiveness of the target sentences is particularly salient. It also causes little increase in the translation time, and compares favorably to another alternative retrieval-based method with respect to accuracy, speed, and simplicity of implementation.

1 Introduction

Neural machine translation (NMT) (Bahdanau et al., 2014; Sennrich et al., 2016a; Wang et al., 2017b) is now the state-of-the-art in machine translation, due to its ability to be trained end-to-end on large parallel corpora and capture complex parameterized functions that generalize across a variety of syntactic and semantic phenomena. However, it has also been noted that compared to alternatives such as phrase-based translation (Koehn et al., 2003), NMT has trouble with low-frequency words or phrases (Arthur et al., 2016; Kaiser et al., 2017), and also generalizing across domains (Koehn and Knowles, 2017). A number of methods have been proposed to ameliorate these problems, including methods that incorporate symbolic knowledge such as discrete translation lexicons (Arthur et al., 2016; He et al., 2016; Chatterjee et al., 2017) and phrase tables (Zhang et al., 2017; Tang et al., 2016; Dahlmann et al., 2017), adjust model structures to be more conducive to generalization (Nguyen and Chiang, 2017), or incorporate additional information about domain (Wang et al., 2017a) or topic (Zhang et al., 2016) in translation models.

In particular, one paradigm of interest is recent work that augments NMT using *retrieval*-based models, retrieving sentence pairs from the training corpus that are most similar to the sentence that we want to translate, and then using these to bias the NMT model.[1] These methods – reminiscent of translation memory (Utiyama et al., 2011) or example-based translation (Nagao, 1984; Grefenstette, 1999) – are effective because they augment the parametric NMT model with a non-parametric translation memory that allows for increased capacity to measure features of the target technical terms or domain-specific words. Currently there are two main approaches to doing so. Li et al. (2016) and Farajian et al. (2017) use the retrieved sentence pairs to fine tune the parameters of the NMT model which is pre-trained on the whole training corpus. Gu et al. (2017) uses the retrieved sentence pairs as additional inputs to the NMT model to help NMT in translating the input sen-

[1]Note that there are existing retrieval-based methods for phrase-based and hierarchical phrase-based translation (Lopez, 2007; Germann, 2015). However, these methods do not improve translation quality but rather aim to improve the efficiency of the translation models.

Proceedings of NAACL-HLT 2018, pages 1325–1335
New Orleans, Louisiana, June 1 - 6, 2018.

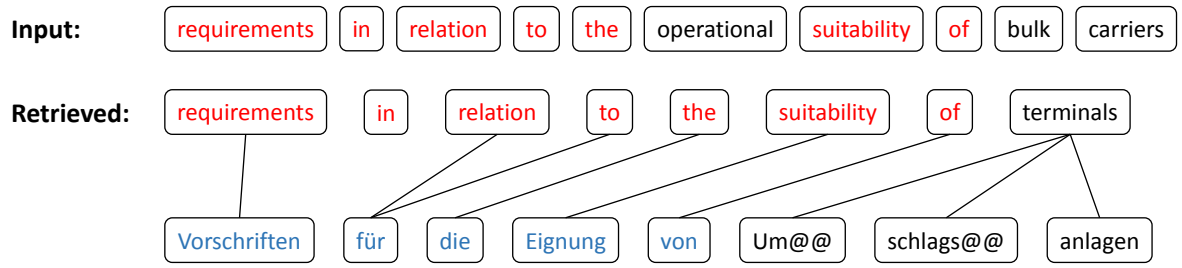

Figure 1: A word-aligned sentence pair retrieved for an input sentence. Red words are unedited words obtained by computing the edit distance between the input sentence and the retrieved source sentence. The blue part of the retrieved target sentence is collected as translation pieces for the input sentence. The target word "Umschlagsanlagen" is split into "Um@@", "schlags@@" and "anlagen" by byte pair encoding.

tence. While both of these paradigms have been proven effective, they both add significant complexity and computational/memory cost to the decoding process, and also to the training procedure. The first requires the running of several training iterations and rolling back of the model, which is costly at test time, and the second requires entirely changing the model structure which requires training the model separately, and also increases test-time computational cost by adding additional encoders.

In this paper, we propose a simple and efficient model for using retrieved sentence pairs to guide an existing NMT model at test time. Specifically, the model collects n-grams occurring in the retrieved target sentences that also match words that overlap between the input and retrieved source sentences, which we will refer to as "translation pieces" (e.g., in Figure 1, the blue part of the retrieved target sentence is collected as translation pieces for the input sentence). The method then calculates a pseudo-probability score for each of the retrieved example sentence pairs and weights the translation pieces according to this value. Finally, we up-weight NMT outputs that contain the collected translation pieces. Unlike the previous methods, this requires no change of the underlying NMT model and no updating of the NMT parameters, making it both simple and efficient to apply at test time.

We show our method improved NMT translation results up to 6 BLEU points on three translation tasks and caused little increase in the translation time. Further, we find that accuracies are comparable with the model of Gu et al. (2017), despite being significantly simpler to implement and faster at test time.

2 Attentional NMT

Our baseline NMT model is similar to the attentional model of Bahdanau et al. (2014), which includes an encoder, a decoder and an attention (alignment) model. Given a source sentence $X = \{x_1, ..., x_L\}$, the encoder learns an annotation $h_i = \left[\vec{h}_i; \overleftarrow{h}_i\right]$ for x_i using a bi-directional recurrent neural network.

The decoder generates the target translation from left to right. The probability of generating next word y_t is,[2]

$$P_{NMT}\left(y_t|y_1^{t-1}, X\right) = softmax\left(g\left(y_{t-1}, z_t, c_t\right)\right) \quad (1)$$

where z_t is a decoding state for time step t, computed by,

$$z_t = f\left(z_{t-1}, y_{t-1}, c_t\right) \quad (2)$$

c_t is a source representation for time t, calculated as,

$$c_t = \sum_{i=1}^{L} \alpha_{t,i} \cdot h_i \quad (3)$$

where $\alpha_{t,i}$ scores how well the inputs around position i and the output at position t match, computed as,

$$\alpha_{t,i} = \frac{\exp\left(a\left(z_{t-1}, h_i\right)\right)}{\sum_{j=1}^{L} \exp\left(a\left(z_{t-1}, h_j\right)\right)} \quad (4)$$

The standard decoding algorithm for NMT is beam search. That is, at each time step t, we keep n-best hypotheses. The probability of a complete

[2] g, f and a in Equation 1, 2 and 4 are nonlinear, potentially multi-layered, functions.

hypothesis is computed as,

$$\log P_{NMT}\left(Y|X\right) = \sum_{t=1}^{|Y|} \log P_{NMT}\left(y_t|y_1^{t-1}, X\right) \tag{5}$$

Finally, the translation score is normalized by sentence length to avoid too short outputs.

$$\log S_{NMT}\left(Y|X\right) = \frac{\log P_{NMT}\left(Y|X\right)}{|Y|} \tag{6}$$

3 Guiding NMT with Translation Pieces

This section describes our approach, which mainly consists of two parts:

1. retrieving candidate translation pieces from a parallel corpus for the new source sentence that we want to translate, and then
2. using the collected translation pieces to guide an existing NMT model while translating this new sentence.

At training time, we first prepare the parallel corpus that will form our database used in the retrieval of the translation pieces. Conceivably, it could be possible to use a different corpus for translation piece retrieval and NMT training, for example when using a separate corpus for domain adaptation, but for simplicity in this work we use the same corpus that was used in NMT training. As pre-processing, we use an off-the-shelf word aligner to learn word alignments for the parallel training corpus.

3.1 Retrieving Translation Pieces

At test time we are given an input sentence X. For this X, we first use the off-the-shelf search engine Lucene to search the word-aligned parallel training corpus and retrieve M source sentences $\{X^m : 1 \leq m \leq M\}$ that are similar to X. Y^m indicates the target sentence that corresponds to source sentence X^m and $\mathcal{A}^m$ is word alignments between X^m and Y^m.

For each retrieved source sentence X^m, we compute its edit distance with X as $d\left(X, X^m\right)$ using dynamic programming. We record the unedited words in X^m as $\mathcal{W}^m$, and also note the words in the target sentence Y^m that correspond to source words in $\mathcal{W}^m$, which we can presume are words that will be more likely to appear in the translated sentence for X. According to Algorithm 1, we collect n-grams (up to 4-grams) from the retrieved target sentence Y^m as possible translation pieces G_X^m for X, using word-level alignments to select n-grams that are related to X and discard n-grams that are not related to X. The final translation pieces G_X collected for X are computed as,[3]

n-grams	G_X^m
Vorschriften für die Eignung	Yes
die Eignung von	Yes
von Um@@ schlags@@ anlagen	No
Um@@ schlags@@ anlagen	No

Table 1: Examples of the collected translation pieces.

$$G_X = \bigcup_{m=1}^{M} G_X^m \tag{7}$$

Table 1 shows a few n-gram examples contained in the retrieved target sentence in Figure 1 and whether they are included in G_X^m or not. Because the retrieved source sentence in Figure 1 is highly similar with the input sentence, the translation pieces collected from its target side are highly likely to be correct translation pieces of the input sentence. However, when a retrieved source sentence is not very similar with the input sentence (e.g. only one or two words match), the translation pieces collected from its target side will be less likely to be correct translation pieces for the input sentence.

We compute a score for each $u \in G_X$ to measure how likely it is a correct translation piece for X based on sentence similarity between the retrieved source sentences and the input sentence as following,

$$\begin{aligned} &S\left(u, X, \bigcup_{m=1}^{M} \{(X^m, G_X^m)\}\right) \\ &= \max_{1 \leq m \leq M \wedge u \in G_X^m} simi\left(X, X^m\right) \end{aligned} \tag{8}$$

where $simi\left(X, X^m\right)$ is the sentence similarity computed as following (Gu et al., 2017),

$$simi\left(X, X^m\right) = 1 - \frac{d\left(X, X^m\right)}{\max\left(|X|, |X^m|\right)} \tag{9}$$

[3]Note that the extracted translation pieces are target phrases, but the target words contained in one extracted translation piece may be aligned to discontiguous source words, which is different from how phrase-based translation extracts phrase-based translation rules.

Algorithm 1 Collecting Translation Pieces

Require: $X = x_1^L$, $X^m = k_1^{L'}$, $Y^m = v_1^{L''}$, $\mathcal{A}^m$, $\mathcal{W}^m$
Ensure: G_X^m
  $G_X^m = \emptyset$
  for $i = 1$ to L'' **do**
    for $j = i$ to L'' **do**
      if $j - i = 4$ **then**
        break
      if $\exists p : (p, j) \in \mathcal{A}^m \wedge p \notin \mathcal{W}^m$ **then**
        break
      add v_i^j into G_X^m

Algorithm 2 Guiding NMT by Translation Pieces

Require: Output layer $\log P_{NMT}\left(y_t|y_1^{t-1}, X\right)$, $\mathcal{L}_X, \mathcal{D}_X$
Ensure: Updated output layer
  for u in $\mathcal{L}_X$ **do**
    $\log P_{NMT}\left(u|y_1^{t-1}, X\right) += \lambda \mathcal{D}_X\left(u\right)$
    for $i = 1$ to 3 **do**
      if $t - i < 1$ **then**
        break
      if $y_{t-i}^{t-1}, u \notin \mathcal{D}_X$ **then**
        break
      $\log P_{NMT}\left(u|y_1^{t-1}, X\right) += \lambda \mathcal{D}_X\left(y_{t-i}^{t-1}, u\right)$

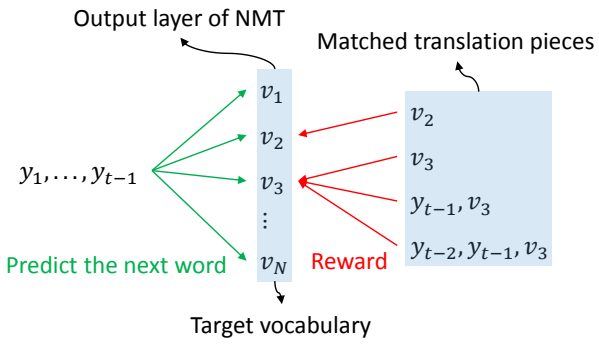

Figure 2: A simple demonstration of adding rewards for matched translation pieces into the NMT output layer.

3.2 Guiding NMT with Retrieved Translation Pieces

In the next phase, we use our NMT system to translate the input sentence. Inspired by Stahlberg et al. (2017) which rewards n-grams from syntactic translation lattices during NMT decoding, we add an additional reward for n-grams that occur in the collected translation pieces. That is, as shown in Figure 2, at each time step t, we update the probabilities over the output vocabulary and increase the probabilities of those that result in matched n-grams according to

$$\begin{aligned} &\log S_{NMT\_updated}\left(y_t|y_1^{t-1}, X\right) \\ &= \log P_{NMT}\left(y_t|y_1^{t-1}, X\right) + \\ &\lambda \sum_{n=1}^{4} \delta\left(y_{t-n+1}^t, X, \bigcup_{m=1}^{M}\{(X^m, G_X^m)\}\right), \end{aligned} \tag{10}$$

where λ can be tuned on the development set and $\delta\left(\cdot\right)$ is computed as Equation 8 if $y_{t-n+1}^t \in G_X$, otherwise $\delta\left(\cdot\right) = 0$.

To implement our method, we use a dictionary $\mathcal{D}_X$ to store translation pieces G_X and their scores for each input sentence X. At each time step t, we update the output layer probabilities by checking $\mathcal{D}_X$. However, it is inefficient to traverse all target words in the vocabulary and check whether they belong to G_X or not, because the vocabulary size is large. Instead, we only traverse target words that belong to G_X and update the corresponding output probabilities as shown in Algorithm 2. Here, $\mathcal{L}_X$ is a list that stores 1-grams contained in G_X.[4]

As we can see, our method only up-weights NMT outputs that match the retrieved translation pieces in the NMT output layer. In contrast, Li et al. (2016) and Farajian et al. (2017) use the retrieved sentence pairs to run additional training iterations and fine tune the NMT parameters for each input sentence; Gu et al. (2017) runs the NMT model for each retrieved sentence pair to obtain the NMT encoding and decoding information of the retrieved sentences as key-value memory to guide NMT for translating the new input sentence. Compared to their methods, our method adds little computational/memory cost and is simple to implement.

4 Experiment

4.1 Settings

Following Gu et al. (2017), we use version 3.0 of the JRC-Acquis corpus for our translation experiments. The JRC-Acquis corpus contains the total body of European Union (EU) law applicable in the EU Member States. It can be used as a narrow domain to test the effectiveness of our proposed method. We did translation experiments on three

[4]Note that our method does not introduce new states during decoding, because the output layer probabilities are simply updated based on history words and the next word.

Table 5: Ratio of translation length to reference length.

directions: English-to-German (en-de), English-to-French (en-fr) and English-to-Spanish (en-es).

We cleaned the data by removing repeated sentences and used the `train-truecaser.perl` script from Moses (Koehn et al., 2007) to truecase the corpus. Then we selected 2000 sentence pairs as development and test sets, respectively. The rest was used as the training set. We removed sentences longer than 80 and 100 from the training and development/test sets respectively. The final numbers of sentence pairs contained in the training, development and test sets are shown in Table 3.[5] We applied *byte pair encoding* (Sennrich et al., 2016b) and set the vocabulary size to be 20K.

For translation piece collection, we use GIZA++ (Och and Ney, 2003) and the `grow-diag-final-and` heuristic (Koehn et al., 2003) to obtain symmetric word alignments for the training set.

We trained an attentional NMT model as our baseline system. The settings for NMT are shown in Table 4. We also compared our method with the search engine guided NMT model (SGNMT, Gu et al. (2017)) in Section 4.5.

Word embedding	512
GRU dimension	1024
Optimizer	adam
Initial learning rate	0.0001
Beam size	5

Table 4: NMT settings.

[5]We put the datasets used in our experiments on Github https://github.com/jingyiz/Data-sampled-preprocessed

For each input sentence, we retrieved 100 sentence pairs from the training set using Lucene as our preliminary setting. We analyze the influence of the retrieval size in Section 4.4. The weights of translation pieces used in Equation 10 are tuned on the development set for different language pairs, resulting in weights of 1.5 for en-de and en-fr, and a weight of 1 for en-es.

4.2 Results

Table 2 shows the main experimental results. We can see that our method outperformed the baseline NMT system up to 6 BLEU points. As large BLEU gains in neural MT can also often be attributed to changes in output length, we examined the length (Table 5) and found that it did not influence the translation length significantly.

In addition, it is of interest whether how well the retrieved sentences match the input influences the search results. We measure the similarity between a test sentence X and the training corpus D_{train} by computing the sentence similarities between X and the retrieved source sentences as

$$simi\left(X, D_{train}\right) = \max_{1 \leq m \leq M} simi\left(X, X^m\right). \tag{11}$$

The similarity between the test set D_{test} and the training corpus D_{train} is measured as,

$$simi\left(D_{test}, D_{train}\right) = \frac{\sum_{X \in D_{test}} simi\left(X, D_{train}\right)}{|D_{test}|} \tag{12}$$

Our analysis demonstrated that, expectedly, the performance of our method is highly influenced by the similarity between the test set and the training set. We divided sentences in the test set into two

	whole	half-H	half-L

	Ours	60.54	78.37	47.93

Table 7: Translation results (BLEU) for the whole/divided test sets.

parts: half has higher similarities with the training corpus (half-H) and half has lower similarities with the training corpus (half-L). Table 6 shows the similarity between the training corpus and the whole/divided test sets. Table 7 shows translation results for the whole/divided test sets. As we can see, NMT generally achieved better BLEU scores for half-H and our method improved BLEU scores for half-H much more significantly than for half-L, which shows our method can be quite useful for narrow domains where similar sentences can be found.

We also tried our method on WMT 2017 English-to-German News translation task. However, we did not achieve significant improvements over the baseline attentional NMT model, likely because the test set and the training set for the WMT task have a relatively low similarity as shown in Table 8 and hence few useful translation pieces can be retrieved for our method. In contrast, the JRC-Acquis corpus provides test sentences that have much higher similarities with the training set, i.e., much more and longer translation pieces exist.

To demonstrate how the retrieved translation pieces help NMT to generate appropriate outputs, Figure 3 shows an input sentence with reference, the retrieved sentence pair with the highest sentence similarity and outputs by different systems for this input sentence with detailed scores: log NMT probabilities for each target word in T_1 and T_2; scores for matched translation pieces contained in T_1 and T_2. As we can see, NMT assigns higher probabilities to the incorrect translation T_1, even though the retrieved sentence pair whose source side is very similar with the input sentence was used for NMT training.

Table 9: Translation results (BLEU) of 1/0 reward.

However, T_2 contains more and longer translation pieces with higher scores. The five translation pieces contained only in T_2 are collected from the retrieved sentence pair shown in Figure 3, which has high sentence similarity with the input sentence. The three translation pieces contained only in T_1 are also translation pieces collected for the input sentence, but have lower scores, because they are collected from sentence pairs with lower similarities with the input sentence. This shows that computing scores for translation pieces based on sentence similarities is important for the performance of our method. If we assign score 1 to all translation pieces contained in G_X, i.e., use 1/0 reward for translation pieces and non-translation pieces, then the performance of our method decreased significantly as shown in Table 9, but still outperformed the NMT baseline significantly.

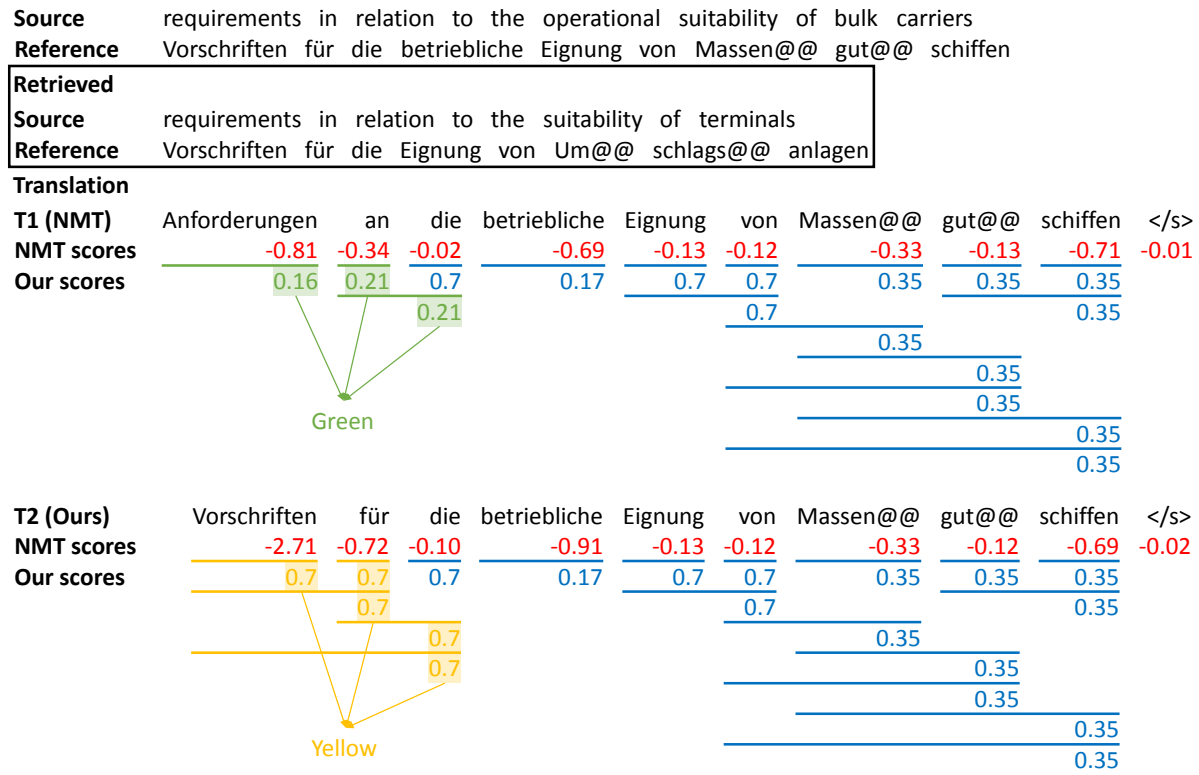

Figure 3: Translation examples. Red scores are log NMT probabilities. Green, yellow and blue scores are scores of matched translation pieces contained only in T_1, contained only in T_2, contained in both T_1 and T_2, respectively.

Table 10: $Count_\gamma$

4.3 Infrequent n-grams

The basic idea of our method is rewarding n-grams that occur in the training set during NMT decoding. We found our method is especially useful to help the translation for infrequent n-grams. First, we count how many times a target n-gram u occurs in the training set D_{train} as,

$$Occur\left(u\right) = \left|\left\{Y : \langle X, Y\rangle \in D_{train} \wedge u \in uniq\left(Y\right)\right\}\right| \tag{13}$$

where $uniq\left(Y\right)$ is the set of uniq n-grams (up to 4-grams) contained in Y.

Given system outputs $\left\{Z^k : 1 \leq k \leq K\right\}$ for the test set $\left\{X^k : 1 \leq k \leq K\right\}$ with reference $\left\{Y^k : 1 \leq k \leq K\right\}$, we count the number of correctly translated n-grams that occur γ times in the training set as,

$$Count_\gamma = \sum_{k=1}^{K} \left|\psi\left(\gamma, Z^k, Y^k\right)\right| \tag{14}$$

where

$$\psi\left(\gamma, Z^k, Y^k\right) = \left\{u : u \in \left(uniq\left(Z^k\right) \cap uniq\left(Y^k\right)\right) \wedge Occur\left(u\right) = \gamma\right\} \tag{15}$$

Table 10 shows $Count_\gamma$ for different system outputs. As we can see, our method helped little for the translation of n-grams that do not occur

in the training set, which is reasonable because we only reward n-grams that occur in the training set. However, our method helped significantly for the translation of n-grams that do occur in the training set but are infrequent (occur less than 5 times). As the frequency of n-grams increases, the improvement caused by our method decreased. We analyze that the reason why our method is especially helpful for infrequent n-grams is that NMT is trained on the whole training corpus for maximum likelihood and tends to generate more frequent n-grams while our method computes scores for the collected translation pieces based on sentence similarities and does not prefer more frequent n-grams.

4.4 Computational Considerations

Our method only collects translation pieces to help NMT for translating a new sentence and does not influence the training process of NMT. Therefore, our method does not increase the NMT training time. Table 11 shows the average time needed for translating one input sentence in the development set in our experiments. The search engine retrieval and translation piece (TP) collection time is computed on a 3.47GHz Intel Xeon X5690 machine using one CPU. The NMT decoding time is computed using one GPU GeForce GTX 1080.

As we can see, the search engine retrieval time is negligible and the increase of NMT decoding time caused by our method is also small. However, collecting translation pieces needed considerable time, although our implementation was in Python and could potentially be significantly faster in a more efficient programming language. The translation piece collection step mainly consists of two parts: computing the edit distances between the input sentence and the retrieved source sentences using dynamic programming with time complexity $O\left(n^2\right)$; collecting translation pieces using Algorithm 1 with time complexity $O\left(4n\right)$.

We changed the size of sentence pairs retrieved by the search engine and analyze its influence on translation performance and time. Figure 4, 5 and 6 show the translation piece collection time, the NMT decoding time and translation BLEU scores with different search engine retrieval sizes for the en-fr task. As we can see, as the number of retrieved sentences decreased, the time needed by translation piece collection decreased significantly, the translation performance decreased much less significantly and the NMT decoding time is further reduced. In our experiments, 10 is a good setting for the retrieval size, which gave significant BLEU score improvements and caused little increase in the total translation time compared to the NMT baseline.

Table 12: Comparison with SGNMT.

4.5 Comparison with SGNMT

We compared our method with the search engine guided NMT (SGNMT) model (Gu et al., 2017). We got their preprocessed datasets and tested our method on their datasets, in order to fairly compare our method with their reported BLEU scores.[6] Table 12 shows the results of their method and our method with the same settings for the baseline NMT system. As we can see, our method generally outperformed their method on the three translation tasks.

Considering the computational complexity, their method also performs search engine retrieval for each input sentence and computes the edit distance between the input sentence and the retrieved source sentences as our method. In addition, their method runs the NMT model for each retrieved sentence pair to obtain the NMT encoding and decoding information of the retrieved sentences as key-value memory to guide the NMT model for translating the real input sentence, which changes the NMT model structure and increases both the training-time and test-time computational cost. Specifically, at test time, running the NMT model for one retrieved sentence pair costs the same time as translating the retrieved source sentence with beam size 1. Therefore, as the number of the retrieved sentence pairs increases to the beam size of the baseline NMT model, their method doubles the translation time.

5 Conclusion

This paper presents a simple and effective method that retrieves translation pieces to guide NMT for narrow domains. We first exploit a search engine to retrieve sentence pairs whose source sides are similar with the input sentence, from which we collect and weight translation pieces for the input sentence based on word-level alignments and sentence similarities. Then we use an existing NMT model to translate this input sentence and give an additional bonus to outputs that contain the collected translation pieces. We show our method improved NMT translation results up to 6 BLEU points on three narrow domain translation tasks, caused little increase in the translation time, and compared favorably to another alternative retrieval-based method with respect to accuracy, speed, and simplicity of implementation.

[6] Only BLEU scores are reported in their paper.

Handling Homographs in Neural Machine Translation

Frederick Liu[*†], **Han Lu**[*‡], **Graham Neubig**
Language Technologies Institute

Abstract

Homographs, words with different meanings but the same surface form, have long caused difficulty for machine translation systems, as it is difficult to select the correct translation based on the context. However, with the advent of neural machine translation (NMT) systems, which can theoretically take into account global sentential context, one may hypothesize that this problem has been alleviated. In this paper, we first provide empirical evidence that existing NMT systems in fact still have significant problems in properly translating ambiguous words. We then proceed to describe methods, inspired by the word sense disambiguation literature, that model the context of the input word with context-aware word embeddings that help to differentiate the word sense before feeding it into the encoder. Experiments on three language pairs demonstrate that such models improve the performance of NMT systems both in terms of BLEU score and in the accuracy of translating homographs.[1]

1 Introduction

Neural machine translation (NMT; Sutskever et al. (2014); Bahdanau et al. (2015), §2), a method for MT that performs translation in an end-to-end fashion using neural networks, is quickly becoming the de-facto standard in MT applications due to its impressive empirical results. One of the drivers behind these results is the ability of NMT to capture long-distance context using recurrent neural networks in both the encoder, which takes the input and turns it into a continuous-space representation, and the decoder, which tracks the target-sentence state, deciding which word to output next. As a result of this ability to capture long-distance dependencies, NMT has achieved great improvements in a number of areas that have bedeviled traditional methods such as phrase-based MT (PBMT; Koehn et al. (2003)), including agreement and long-distance syntactic dependencies (Neubig et al., 2015; Bentivogli et al., 2016).

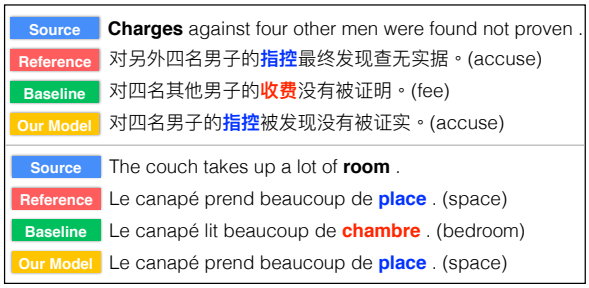

Figure 1: Homographs where the baseline system makes mistakes (red words) but our proposed system incorporating a more direct representation of context achieves the correct translation (blue words). Definitions of corresponding blue and red words are in parenthesis.

One other phenomenon that was poorly handled by PBMT was homographs – words that have the same surface form but multiple senses. As a result, PBMT systems required specific separate modules to incorporate long-term context, performing word-sense (Carpuat and Wu, 2007b; Pu et al., 2017) or phrase-sense (Carpuat and Wu, 2007a) disambiguation to improve their handling of these phenomena. Thus, we may wonder: do NMT systems suffer from the same problems when translating homographs? Or are the recurrent nets applied in the encoding step, and the strong language model in the decoding step enough to alleviate all problems of word sense ambiguity?

In §3 we first attempt to answer this question quantitatively by examining the word translation

accuracy of a baseline NMT system as a function of the number of senses that each word has. Results demonstrate that standard NMT systems make a significant number of errors on homographs, a few of which are shown in Fig. 1.

With this result in hand, we propose a method for more directly capturing contextual information that may help disambiguate difficult-to-translate homographs. Specifically, we learn from neural models for word sense disambiguation (Kalchbrenner et al., 2014; Iyyer et al., 2015; Kågebäck and Salomonsson, 2016; Yuan et al., 2016; Šuster et al., 2016), examining three methods inspired by this literature (§4). In order to incorporate this information into NMT, we examine two methods: gating the word-embeddings in the model (similarly to Choi et al. (2017)), and concatenating the context-aware representation to the word embedding (§5).

To evaluate the effectiveness of our method, we compare our context-aware models with a strong baseline (Luong et al., 2015) on the English-German, English-French, and English-Chinese WMT dataset. We show that our proposed model outperforms the baseline in the overall BLEU score across three different language pairs. Quantitative analysis demonstrates that our model performs better on translating homographs. Lastly, we show sample translations of the baseline system and our proposed model.

2 Neural Machine Translation

We follow the global-general-attention NMT architecture with input-feeding proposed by Luong et al. (2015), which we will briefly summarize here. The neural network models the conditional distribution over translations $Y = (y_1, y_2, \ldots, y_m)$ given a sentence in source language $X = (x_1, x_2, \ldots x_n)$ as $P(Y|X)$. A NMT system consists of an encoder that summarizes the source sentence X as a vector representation $\boldsymbol{h}$, and a decoder that generates a target word at each time step conditioned on both $\boldsymbol{h}$ and previous words. The conditional distribution is optimized with cross-entropy loss at each decoder output.

The encoder is usually a uni-directional or bi-directional RNN that reads the input sentence word by word. In the more standard bi-directional case, before being read by the RNN unit, each word in X is mapped to an embedding in continuous vector space by a function f_e.

$$f_e(x_t) = \boldsymbol{M_e}^\top \cdot \mathbf{1}(x_t) \tag{1}$$

$\boldsymbol{M_e} \in \mathcal{R}^{|V_s| \times d}$ is a matrix that maps a one-hot representation of x_t, $\mathbf{1}(x_t)$ to a d-dimensional vector space, and V_s is the source vocabulary. We call the word embedding computed this way Lookup embedding. The word embeddings are then read by a bi-directional RNN

$$\overrightarrow{\boldsymbol{h}}_t = \overrightarrow{\text{RNN}}_e(\overrightarrow{\boldsymbol{h}}_{t-1}, f_e(x_t)) \tag{2}$$

$$\overleftarrow{\boldsymbol{h}}_t = \overleftarrow{\text{RNN}}_e(\overleftarrow{\boldsymbol{h}}_{t+1}, f_e(x_t)) \tag{3}$$

After being read by both RNNs we can compute the actual hidden state at step t, $\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}}_t; \overleftarrow{\boldsymbol{h}}_t]$, and the encoder summarized representation $\boldsymbol{h} = \boldsymbol{h}_n$. The recurrent units $\overrightarrow{\text{RNN}}_e$ and $\overleftarrow{\text{RNN}}_e$ are usually either LSTMs (Hochreiter and Schmidhuber, 1997) or GRUs (Chung et al., 2014).

The decoder is a uni-directional RNN that decodes the tth target word conditioned on (1) previous decoder hidden state $\boldsymbol{g}_{t-1}$, (2) previous word y_{t-1} , and (3) the weighted sum of encoder hidden states $\boldsymbol{a}_t$. The decoder maintains the tth hidden state g_t as follows,

$$\boldsymbol{g}_t = \overrightarrow{\text{RNN}}_d(\boldsymbol{g}_{t-1}, f_d(y_{t-1}), \boldsymbol{a}_t) \tag{4}$$

Again, $\overrightarrow{\text{RNN}}_d$ is either LSTM or GRU, and f_d is a mapping function in target language space.

The general attention mechanism for computing the weighted encoder hidden states $\boldsymbol{a}_t$ first computes the similarity between $\boldsymbol{g}_{t-1}$ and $\boldsymbol{h}_{t'}$ for $t' = 1, 2, \ldots, n$.

$$\text{score}(\boldsymbol{g}_{t-1}, \boldsymbol{h}_{t'}) = \boldsymbol{g}_{t-1} \boldsymbol{W}_{att} \boldsymbol{h}_{t'}^\top \tag{5}$$

The similarities are then normalized through a softmax layer , which results in the weights for encoder hidden states.

$$\alpha_{t,t'} = \frac{\exp(\text{score}(\boldsymbol{g}_{t-1}, \boldsymbol{h}_{t'}))}{\sum_{k=1}^{n} \exp(\text{score}(\boldsymbol{g}_{t-1}, \boldsymbol{h}_k))} \tag{6}$$

We can then compute $\boldsymbol{a}_t$ as follows,

$$\boldsymbol{a}_t = \sum_{k=1}^{n} \alpha_{t,k} \boldsymbol{h}_k \tag{7}$$

Finally, we compute the distribution over y_t as,

$$\hat{\boldsymbol{g}}_t = \tanh(\boldsymbol{W}_1[\boldsymbol{g}_t; \boldsymbol{a}_t]) \tag{8}$$

$$p(y_t|y_{<t}, X) = \text{softmax}(\boldsymbol{W}_2 \hat{\boldsymbol{g}}_t) \tag{9}$$

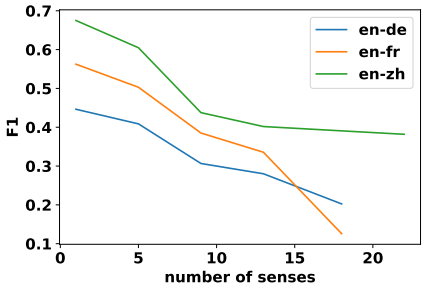

Figure 2: Translation performance of words with different numbers of senses.

3 NMT's Problems with Homographs

As described in Eqs. (2) and (3), NMT models encode the words using recurrent encoders, theoretically endowing them with the ability to handle homographs through global sentential context. However, despite the fact that they have this ability, our qualitative observation of NMT results revealed a significant number of ambiguous words being translated incorrectly, casting doubt on whether the standard NMT setup is able to appropriately learn parameters that disambiguate these word choices.

To demonstrate this more concretely, in Fig. 2 we show the translation accuracy of an NMT system with respect to words of varying levels of ambiguity. Specifically, we use the best baseline NMT system to translate three different language pairs from WMT test set (detailed in §6) and plot the F1-score of word translations by the number of senses that they have. The number of senses for a word is acquired from the Cambridge English dictionary,[2] after excluding stop words.[3]

We evaluate the translation performance of words in the source side by aligning them to the target side using `fast-align` (Dyer et al., 2013). The aligner outputs a set of target words to which the source words aligns for both the reference translation and the model translations. F1 score is calculated between the two sets of words.

After acquiring the F1 score for each word, we bucket the F1 scores by the number of senses, and plot the average score of four consecutive buckets as shown in Fig. 2. As we can see from the results, the F1 score for words decreases as the number of senses increases for three different language pairs. This demonstrates that the translation performance of current NMT systems on words with more senses is significantly decreased from that for words with fewer senses. From this result, it is evident that modern NMT architectures are not enough to resolve the problem of homographs on their own. The result corresponds to the findings in prior work (Rios et al., 2017).

[3] We use the stop word list from NLTK (Bird et al., 2009).

4 Neural Word Sense Disambiguation

Word sense disambiguation (WSD) is the task of resolving the ambiguity of homographs (Ng and Lee, 1996; Mihalcea and Faruque, 2004; Zhong and Ng, 2010; Di Marco and Navigli, 2013; Chen et al., 2014; Camacho-Collados et al., 2015), and we hypothesize that by learning from these models we can improve the ability of the NMT model to choose the correct translation for these ambiguous words. Recent research tackles this problem with neural models and has shown state-of-the art results on WSD datasets (Kågebäck and Salomonsson, 2016; Yuan et al., 2016). In this section, we will summarize three methods for WSD which we will further utilize as three different *context networks* to improve NMT.

Neural bag-of-words (NBOW) Kalchbrenner et al. (2014); Iyyer et al. (2015) have shown success by representing full sentences with a context vector, which is the average of the Lookup embeddings of the input sequence

$$\boldsymbol{c}_t = \frac{1}{n}\sum_{k=1}^{n} \boldsymbol{M}_c^\top \mathbf{1}(x_k) \tag{10}$$

This is a simple way to model sentences, but has the potential to capture the global topic of the sentence in a straightforward and coherent way. However, in this case, the context vector would be the same for every word in the input sequence.

Bi-directional LSTM (BiLSTM) Kågebäck and Salomonsson (2016) leveraged a bi-directional LSTM that learns a context vector for the target word in the input sequence and predicts the word sense with a multi-layer perceptron. Specifically, we can compute the context vector c_t for tth word similarly to bi-directional encoder as follows,

$$\overrightarrow{\boldsymbol{c}}_t = \overrightarrow{\text{RNN}}_c(\overrightarrow{\boldsymbol{c}}_{t-1}, f_c(x_t)) \tag{11}$$

$$\overleftarrow{\boldsymbol{c}}_t = \overleftarrow{\text{RNN}}_c(\overleftarrow{\boldsymbol{c}}_{t+1}, f_c(x_t)) \tag{12}$$

$$\boldsymbol{c}_t = [\overrightarrow{\boldsymbol{c}}_t; \overleftarrow{\boldsymbol{c}}_t] \quad (13)$$

$\overrightarrow{\text{RNN}}_c$, $\overleftarrow{\text{RNN}}_c$ are forward and backward LSTMs repectively, and $f_c(x_t) = \boldsymbol{M}_c^\top \mathbf{1}(x_t)$ is a function that maps a word to continous embedding space.

Held-out LSTM (HoLSTM) Yuan et al. (2016) trained a LSTM language model, which predicts a held-out word given the surrounding context, with a large amount of unlabeled text as training data. Given the context vector from this language model, they predict the word sense with a WSD classifier. Specifically, we can compute the context vector c_t for tth word by first replacing tth word with a special symbol (e.g. <$>). We then feed the replaced sequence to a uni-directional LSTM:

$$\tilde{\boldsymbol{c}}_i = \overrightarrow{\text{RNN}}_c(\tilde{\boldsymbol{c}}_{i-1}, f_c(x_i)) \quad (14)$$

Finally, we can get context vector for the tth word

$$\boldsymbol{c}_t = \tilde{\boldsymbol{c}}_n \quad (15)$$

$\overrightarrow{\text{RNN}}_c$ and f_c are defined in BiLSTM paragraph, and n is the length of the sequence. Despite the fact that the context vector is always the last hidden state of the LSTM no matter which word we are targeting, the input sequence read by the HoLSTM is actually different every time.

5 Adding Context to NMT

Now that we have several methods to incorporate global context regarding a single word, it is necessary to incorporate this context with NMT. Specifically, we propose two methods to either *Gate* or *Concatenate* a context vector $\boldsymbol{c}_t$ with the Lookup embedding $\boldsymbol{M}_e^\top \cdot \mathbf{1}(x_t)$ to form a context-aware word embedding before feeding it into the encoder as shown in Fig. 3. The detail of these methods is described below.

Gate Inspired by Choi et al. (2017), as our first method for integration of context-aware word embeddings, we use a gating function as follows:

$$f'_e(x_t) = f_e(x_t) \odot \sigma(\boldsymbol{c}_t) \quad (16)$$
$$= \boldsymbol{M}_e^\top \mathbf{1}(x_t) \odot \sigma(\boldsymbol{c}_t) \quad (17)$$

The symbol $\odot$ represents element-wise multiplication, and σ is element-wise sigmoid function.

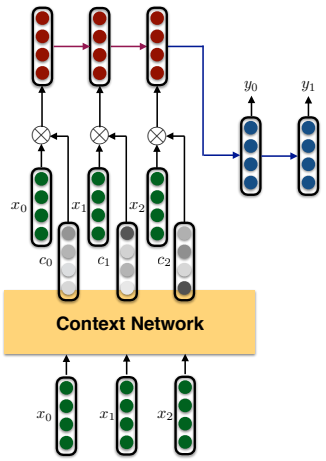

Figure 3: Illustration of our proposed model. The context network is a differentiable network that computes context vector c_t for word x_t taking the whole sequence as input. $\otimes$ represents the operation that combines original word embedding x_t with corresponding context vector c_t to form context-aware word embeddings.

Choi et al. (2017) use this method in concert with averaged embeddings from words in source language like the NBOW model above, which naturally uses the same context vectors for all time steps. In this paper, we additionally test this function with context vectors calculated using the BiLSTM and HoLSTM .

Concatenate We also propose another way for incorporating context: by concatenating the context vector with the word embeddings. This is expressed as below:

$$f'_e(x_t) = \boldsymbol{W}_3[f_e(x_t); \boldsymbol{c}_t] \quad (18)$$
$$= \boldsymbol{W}_3[\boldsymbol{M}_e^\top \mathbf{1}(x_t); \boldsymbol{c}_t] \quad (19)$$

$\boldsymbol{W}_3$ is used to project the concatenated vector back to the original d-dimensional space.

For each method can compute context vector $\boldsymbol{c}_t$ with either the NBOW, BiLSTM, or HoLSTM described in §4. We share the parameters in f_e with f_c (i.e. $\boldsymbol{M}_e = \boldsymbol{M}_c$) since the vocabulary space is the same for context network and encoder. As a result, our context network only slightly increases the number of model parameters. Details about the number of parameters of each model we use in the experiments are shown in Table 1.

6 Experiments

We evaluate our model on three different language pairs: English-French (WMT'14), and English-German (WMT'15), English-Chinese (WMT'17)

Context	Integration	uni/bi	#layers	#params	Ppl	WMT14	WMT15

Table 1: **WMT'14, WMT'15 English-German results** - We show perplexities (Ppl) on development set and tokenized BLEU on WMT'14 and WMT'15 test set of various NMT systems. We also show different settings for different systems. $\rightarrow$ represents uni-directional, and $\leftrightarrow$ represents bi-directional. We also highlight the best baseline model and the best proposed model in bold. The best baseline model will be referred as *base* or *baseline* and the best proposed model will referred to as *best* for further experiments.

with English as the source side. For German and French, we use a combination of Europarl v7, Common Crawl, and News Commentary as training set. For development set, newstest2013 is used for German and newstest2012 is used for French. For Chinese, we use a combination of News Commentary v12 and the CWMT Corpus as the training set and held out 2357 sentences as the development set. Translation performances are reported in case-sensitive BLEU on newstest2014 (2737 sentences), newstest2015 (2169 sentences) for German, newstest2013 (3000 sentences), newstest2014 (3003 sentences) for French, and newsdev2017 (2002 sentences) for Chinese.[4] Details about tokenization are as follows. For German, we use the tokenized dataset from Luong et al. (2015); for French, we used the moses (Koehn et al., 2007) tokenization script with the "-a" flag; for Chinese, we split sequences of Chinese characters, but keep sequences of non-Chinese characters as they are, using the script from IWSLT Evaluation 2015.[5]

We compare our context-aware NMT systems with strong baseline models on each dataset.

[4]We use the development set as testing data because the official test set hasn't been released.

Table 2: **Results on three different language pairs** - The best proposed models (BiLSTM+Concat+uni) are significantly better (p-value $<$ 0.001) than baseline models using paired bootstrap resampling (Koehn, 2004).

6.1 Training Details

We limit our vocabularies to be the top 50K most frequent words for both source and target language. Words not in these shortlisted vocabularies are converted into an ⟨unk⟩ token.

When training our NMT systems, following Bahdanau et al. (2015), we filter out sentence pairs whose lengths exceed 50 words and shuffle mini-batches as we proceed. We train our model with the following settings using SGD as our optimization method. (1) We start with a learning rate of 1 and we begin to halve the learning rate every

epoch once it overfits. [6] (2) We train until the model converges. (i.e. the difference between the perplexity for the current epoch and the previous epoch is less than 0.01) (3) We batched the instances with the same length and our maximum mini-batch size is 256, and (4) the normalized gradient is rescaled whenever its norm exceeds 5. (6) Dropout is applied between vertical RNN stacks with probability 0.3. Additionally, the context network is trained jointly with the encoder-decoder architecture. Our model is built upon OpenNMT (Klein et al., 2017) with the default settings unless otherwise noted.

6.2 Experimental Results

In this section, we compare our proposed context-aware NMT models with baseline models on English-German dataset. Our baseline models are encoder-decoder models using global-general attention and input feeding on the decoder side as described in §2, varying the settings on the encoder side. Our proposed model builds upon baseline models by concatenating or gating different types of context vectors. We use LSTM for encoder, decoder, and context network. The decoder is the same across baseline models and proposed models, having 500 hidden units. During testing, we use beam search with a beam size of 5. The dimension for input word embedding d is set to 500 across encoder, decoder, and context network. Settings for three different baselines are listed below.

Baseline 1: An uni-directional LSTM with 500 hidden units and 2 layers of stacking LSTM.

Baseline 2: A bi-directional LSTM with 250 hidden units and 2 layers of stacking LSTM. Each state is summarized by concatenating the hidden states of forward and backward encoder into 500 hidden units.

Baseline 3: A bi-directional LSTM with 250 hidden units and 3 layers of stacking LSTM. This can be compared with the proposed method, which adds an extra layer of computation before the word embeddings, essentially adding an extra layer.

The context network uses the below settings.

[6] We define overfitting to be when perplexity on the dev set of the current epoch is worse than the previous epoch.

NBOW: Average word embedding of the input sequence.

BiLSTM: A single-layer bi-directional LSTM with 250 hidden units. The context vector is represented by concatenating the hidden states of forward and backward LSTM into a 500 dimensional vector.

HoLSTM: A single-layer uni-directional LSTM with 500 hidden units.

The results are shown in Table 1. The first thing we observe is that the best context-aware model (results in bold in the table) achieved improvements of around 0.7 BLEU on both WMT14 and WMT15 over the respective baseline methods with 2 layers. This is in contrast to simply using a 3-layer network, which actually degrades performance, perhaps due to the vanishing gradients problem it increases the difficulty in learning.

Next, comparing different methods for incorporating context, we can see that BiLSTM performs best across all settings. HoLSTM performs slightly better than NBOW, and NBOW obviously suffers from having the same context vector for every word in the input sequence failing to outperform the corresponding baselines. Comparing the two integration methods that incorporate context into word embeddings. Both methods improve over the baseline with BiLSTM as the context network. Concatenating the context vector and the word embedding performed better than gating. Finally, in contrast to the baseline, it is not obvious whether using uni-directional or bi-directional as the encoder is better for our proposed models, particularly when BiLSTM is used for calculating the context network. This is likely due to the fact that bi-directional information is already captured by the context network, and may not be necessary in the encoder itself.

We further compared the two systems on two different languages, French and Chinese. We achieved 0.5-0.8 BLEU improvement, showing our proposed models are stable and consistent across different language pairs. The results are shown in Table 2.

To show that our 3-layer models are properly trained, we ran a 3-layer bidirectional encoder with residual networks on En-Fr and got 27.45 for WMT13 and 30.60 for WMT14, which is similarly lower than the two layer result. It should be noted that previous work such as Britz et al. (2017) have

language	System	Homograph			All Words		
		F1	Precision	Recall	F1	Precision	Recall
en → de	baseline	0.401	0.422	0.382	0.547	0.569	0.526
	best	0.426 (+*0.025*)	0.449 (+*0.027*)	0.405 (+*0.023*)	0.553 (+*0.006*)	0.576 (+*0.007*)	0.532 (+*0.006*)
en → fr	baseline	0.467	0.484	0.451	0.605	0.623	0.587
	best	0.480 (+*0.013*)	0.496 (+*0.012*)	0.465 (+*0.014*)	0.613 (+*0.008*)	0.630 (+*0.007*)	0.596 (+*0.009*)
en → zh	baseline	0.578	0.587	0.570	0.573	0.605	0.544
	best	0.590 (+*0.012*)	0.599 (+*0.012*)	0.581 (+*0.011*)	0.581 (+*0.008*)	0.612 (+*0.007*)	0.552 (+*0.008*)

Table 3: Translation results for homographs and all words in our NMT vocabulary. We compare scores for baseline and our best proposed model on three different language pairs. Improvements are in italic. We performed bootstrap resampling for 1000 times: our best model improved more on homographs than all words in terms of either f1, precision, or recall with $p < 0.05$, indicating statistical significance across all measures.

also noted that the gains for encoders beyond two layers is minimal.

6.3 Targeted Analysis

In order to examine whether our proposed model can better translate words with multiple senses, we evaluate our context-aware model on a list of homographs extracted from Wikipedia[7] compared to the baseline model on three different language pairs. For the baseline model, we choose the best-performing model, as described in §6.2.

To do so, we first acquire the translation of homographs in the source language using `fast-align` (Dyer et al., 2013). We run `fast-align` on all the parallel corpora including training data and testing data[8] because the unsupervised nature of the algorithm requires it to have a large amount of training data to obtain accurate alignments. The settings follow the default command on fast-align github page including heuristics combining forward and backward alignment. Since there might be multiple aligned words in the target language given a word in source language, we treat a match between the aligned translation of a targeted word of the reference and the translation of a given model as true positives and use F1, precision, and recall as our metrics, and take the micro-average across all the sentence pairs. [9] We calculated the scores for the 50000 words/characters from our source vocabulary using only English words. The results are shown in Table 3. The table shows two interesting results: (1) The score for the homographs is lower than the score obtained from all the words in the vocabulary. This shows that words with more meanings are harder to translate with Chinese as the only exception.[10] (2) The improvement of our proposed model over baseline model is larger on the homographs compared to all the words in vocabulary. This shows that although our context-aware model is better overall, the improvements are particularly focused on words with multiple senses, which matches the intuition behind the design of the model.

6.4 Qualitative Analysis

We show sample translations on English-Chinese WMT'17 dataset in Table 4 with three kinds of examples. We highlighted the English homograph in bold, correctly translated words in blue, and wrongly translated words in red. (1) Target homographs are translated into the correct sense with the help of context network. For the first sample translation, "meets" is correctly translated to "会见" by our model, and wrongly translated to "符合" by baseline model. In fact, "会见" is closer to the definition "come together intentionally" and "符合" is closer to "satisfy" in the English dictionary. (2) Target homographs are translated into different but similar senses for both models in the forth example. Both models translate the word "believed" to common translations "被认为" or "相信", but these meaning are both close to reference translation "据信". (3) Target homograph is translated into the wrong sense for the baseline model, but is not translated in our model in the fifth example.

[7] https://en.wikipedia.org/wiki/List_of_English_homographs

[8] Reference translation, and all the system generated translations.

[9] The link to the evaluation script – https://goo.gl/oHYR8E

[10] One potential explanation for Chinese is that because the Chinese results are generated on the character level, the automatic alignment process was less accurate.

The definitions of words in blue or red are in parenthesis.

7 Related Work

Word sense disambiguation (WSD), the task of determining the correct meaning or sense of a word in context is a long standing task in NLP (Yarowsky, 1995; Ng and Lee, 1996; Mihalcea and Faruque, 2004; Navigli, 2009; Zhong and Ng, 2010; Di Marco and Navigli, 2013; Chen et al., 2014; Camacho-Collados et al., 2015). Recent research on tackling WSD and capturing multi-senses includes work leveraging LSTM (Kågebäck and Salomonsson, 2016; Yuan et al., 2016), which we extended as a context network in our paper and predicting senses with word embeddings that capture context. Šuster et al. (2016); Kawakami and Dyer (2016) also showed that bilingual data improves WSD. In contrast to the standard WSD formulation, Vickrey et al. (2005) reformulated the task of WSD for Statistical Machine Translation (SMT) as predicting possible target translations which directly improves the accuracy of machine translation. Following this reformulation, Chan et al. (2007); Carpuat and Wu (2007a,b) integrated WSD systems into phrase-based systems. Xiong and Zhang (2014) breaks the process into two stages. First predicts the sense of the ambiguous source word. The predicted word senses together with other context features are then used to predict possible target translation. Within the framework of Neural MT, there are works that has similar motivation to ours. Choi et al. (2017) leverage the NBOW as context and gate the word-embedding on both encoder and decoder side. However, their work does not distinguish context vectors for words in the same sequence, in contrast to the method in this paper, and our results demonstrate that this is an important feature of methods that handle homographs in NMT. In addition, our quantitative analysis of the problems that homographs pose to NMT and evaluation of how context-aware models fix them was not covered in this previous work. Rios et al. (2017) tackled the problem by adding sense embedding learned with additional corpus and evaluated the performance on the sentence level with contrastive translation.

8 Conclusion

Theoretically, NMT systems should be able to handle homographs if the encoder captures the clues to translate them correctly. In this paper, we empirically show that this may not be the case; the performance of word level translation degrades as the number of senses for each word increases. We hypothesize that this is due to the fact that each word is mapped to a word vector despite them being in different contexts, and propose to integrate methods from neural WSD systems into an NMT system to alleviate this problem. We concatenated the context vector computed from the context network with the word embedding to form a context-aware word embedding, successfully improving the NMT system. We evaluated our model on three different language pairs and outperformed a strong baseline model according to BLEU score in all of them. We further evaluated our results targeting the translation of homographs, and our model performed better in terms of F1 score.

While the architectures proposed in this work do not *solve* the problem of homographs, our empirical results in Table 3 demonstrate that they do yield improvements (larger than those on other varieties of words). We hope that this paper will spark discussion on the topic, and future work will propose even more focused architectures.

Abstract

This paper proposes an approach for applying GANs to NMT. We build a conditional sequence generative adversarial net which comprises of two adversarial sub models, a generator and a discriminator. The generator aims to generate sentences which are hard to be discriminated from human-translated sentences (i.e., the golden target sentences); And the discriminator makes efforts to discriminate the machine-generated sentences from human-translated ones. The two sub models play a mini-max game and achieve the win-win situation when they reach a Nash Equilibrium. Additionally, the static sentence-level BLEU is utilized as the reinforced objective for the generator, which biases the generation towards high BLEU points. During training, both the dynamic discriminator and the static BLEU objective are employed to evaluate the generated sentences and feedback the evaluations to guide the learning of the generator. Experimental results show that the proposed model consistently outperforms the traditional RNNSearch and the newly emerged state-of-the-art Transformer on English-German and Chinese-English translation tasks.

1 Introduction

Neural machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014) which directly leverages a single neural network to transform the source sentence into the target sentence, has drawn more and more attention in both academia and industry (Shen et al., 2015; Wu et al., 2016; Johnson et al., 2016; Gehring et al., 2017; Vaswani et al., 2017). This end-to-end NMT typically consists of two sub neural networks. The encoder network reads and encodes the source sentence into the context vector representation; and the decoder network generates the target sentence word by word based on the context vector. To dynamically generate a context vector for a target word being generated, the attention mechanism which enables the model to focus on the relevant words in the source-side sentence is usually deployed. Under the encoder-decoder framework, many variants of the model structure, such as convolutional neural network (CNN) and recurrent neural network (RNN) are proposed (Bahdanau et al., 2014; Gehring et al., 2017). Recently, (Gehring et al., 2017) propose the Transformer, the first sequence transduction model based entirely on attention, achieving state-of-the-art performance on the English-German and English-French translation tasks. Despite its success, the Transformer, similar to traditional NMT models, is still optimized to maximize the likelihood estimation of the ground word (MLE) at each time step. Such an objective poses a hidden danger to NMT models. That is, the model may generate the best candidate word for the current time step yet a bad component of the whole sentence in the long run. Minimum risk training (MRT) (Shen et al., 2015) is proposed to alleviate such a limitation by adopting the sequence level objective, i.e., the sentence-level BLEU, for traditional NMT models. Yet somewhat improved, this objective still does not guarantee the translation results to be natural and sufficient. Since the BLEU point is computed as the geometric mean of the modified n-gram precisions (Papineni et al., 2002), almost all of the existing objectives essentially train NMT models to generate sentences with n-gram precisions as high as possible (MLE can be viewed to generate sentences with high 1-gram precisions). While n-gram precisions largely tell the good sentence apart from the bad one, it is widely acknowledged that higher n-gram precisions do not guarantee better sentences (Callison-Burch and Osborne, 2006; Chatterjee et al., 2007). Additionally, the manually defined objective, i.e.,

Proceedings of NAACL-HLT 2018, pages 1346–1355
New Orleans, Louisiana, June 1 - 6, 2018.

the n-gram precision, is unable to cover all crucial aspects of the data distribution and NMT models may be trained to generate suboptimal sentences (Luc et al., 2016).

In this paper, to address the limitation mentioned above, we borrow the idea of generative adversarial training from computer vision (Goodfellow et al., 2014; Denton et al., 2015) to directly train the NMT model generating sentences which are hard to be discriminated from human translations. The motivation behind is that while we can not manually define the data distribution of golden sentences comprehensively, we are able to utilize a discriminative network to learn automatically what the golden sentences look like. Following this motivation, we build a conditional sequence generative adversarial net where we jointly train two sub adversarial models: A generator generates the target-language sentence based on the input source-language sentence; And a discriminator, conditioned on the source-language sentence, predicts the probability of the target-language sentence being a human-generated one. During the training process, the generator aims to fool the discriminator into believing that its output is a human-generated sentence, and the discriminator makes efforts not to be fooled by improving its ability to distinguish the machine-generated sentence from the human-generated one. This kind of adversarial training achieves a win-win situation when the generator and discriminator reach a Nash Equilibrium (Zhao et al., 2016; Arora et al., 2017; Guimaraes et al., 2017). Besides generating the desired distribution, we also want to directly guide the generator with a static and specific objective, such as generating sentences with high BLEU points. To this end, the smoothed sentence-level BLEU (Nakov et al., 2012) is utilized as the reinforced objective for the generator. During training, we employ both the dynamic discriminator and the static BLEU objective to evaluate the generated sentences and feedback the evaluations to guide the learning of the generator. In summary, we mainly make the following contributions:

- To the best of our knowledge, this work is among the first endeavors to introduce the generative adversarial training into NMT. We directly train the NMT model to generate sentences which are hard to be discriminated from human translations. The proposed model can be applied to any end-to-end NMT systems.

- We conduct extensive experiments on English-German and Chinese-English translation tasks and we test two different NMT models, the traditional RNNSearch (Bahdanau et al., 2014) and the state-of-the-art Transformer. Experimental results show that the proposed approach consistently achieves great success.

- Last but not least, we propose the smoothed sentence-level BLEU as the static and specific objective for the generator which biases the generation towards achieving high BLEU points. We show that the proposed approach is a weighted combination of the naive GAN and MRT.

2 Background and Related Work

2.1 RNNSearch and Transformer

The RNNSearch is the traditional NMT model which has been widely explored. We follow the de facto standard implementation by (Bahdanau et al., 2014). The encoder is a bidirectional gated recurrent units that encodes the input sequence $x = (x_1, \ldots, x_m)$ and calculates the forward sequence of hidden states $(\overrightarrow{h_1}, \ldots, \overrightarrow{h_m})$, and a backward sequence of hidden states $(\overleftarrow{h_1}, \ldots, \overleftarrow{h_m})$. The final annotation vector h_j is calculated by concatenating $\overrightarrow{h_j}$ and $\overleftarrow{h_j}$. The decoder is a recurrent neural network that predicts a target sequence $y = (y_1, \ldots, y_n)$. Each word y_i is predicted on a recurrent hidden state s_i, the previously predicted word y_{i-1} and a context vector c_i. The c_i is computed as a weighted sum of the encoded annotations h_j. The weight a_{ij} of each annotation h_j is computed by the attention mechanism, which models the alignment between y_i and x_j.

The Transformer, recently proposed by (Vaswani et al., 2017), achieves state-of-the-art results on both WMT2014 English-German and WMT2014 English-French translation tasks. The encoder of Transformer is composed of a stack of six identical layers. Each layer consists of a multi-head self-attention and a simple position-wise fully connected feed-forward network. The decoder is also composed of a stack of six identical layers. In addition to the two sub-layers in each encoder layer, the decoder inserts a third

sub-layer, which performs multi-head attention over the output of the encoder stack. The Transformer can be trained significantly faster than architectures based on recurrent or convolutional layers since it allows for significantly more parallelization.

2.2 Generative adversarial nets

Generative adversarial network, has enjoyed great success in computer vision and has been widely applied to image generation (Zhu et al., 2017; Radford et al., 2015). The conditional generative adversarial nets (Gauthier, 2014) apply an extension of generative adversarial network to a conditional setting, which enables the networks to condition on some arbitrary external data. Some recent works have begun to apply the generative adversarial training into the NLP area: (Chen et al., 2016) apply the idea of generative adversarial training to sentiment analysis and (Zhang et al., 2017) use the idea to domain adaptation tasks. For sequence generation problem, (Yu et al., 2016) leverage policy gradient reinforcement learning to back-propagate the reward from the discriminator, showing presentable results for poem generation, speech language generation and music generation. Similarly, (Zhang et al., 2016) generate the text from random noise via adversarial training. A striking difference from the works mentioned above is that, our work is in the conditional setting where the target-language sentence is generated conditioned on the source-language one. In parallel to our work, (Li et al., 2017) propose a similar conditional sequence generative adversarial training for dialogue generation. They use a hierarchical long-short term memory (LSTM) architecture for the discriminator. In contrast to their approach, we apply the CNN-based discriminator for the machine translation task. Furthermore, we propose to utilize the sentence-level BLEU as the specific objective for the generator. Detailed training strategies for the proposed model and extensive quantitative results are reported. We noticed that (Wu et al., 2017) is exploring the potential of GAN in NMT too. There are some differences in training strategies and experimental settings between (Wu et al., 2017) and this work. And the most significant difference is that we propose a novel BLEU-reinforced GAN for NMT [1].

3 The Approach

3.1 Model overview

In this section, we describe the architecture of the proposed BLEU reinforced conditional sequence generative adversarial net (referred to as BR-CSGAN) in detail. The sentence generation process is viewed as a sequence of actions that are taken according to a policy regulated by the generator. In this work, we take the policy gradient training strategies following (Yu et al., 2016). The whole architecture of the proposed model is depicted in figure 1. The model mainly consists of three sub modules:

Generator Based on the source-language sentences, the generator G aims to generate target-language sentences indistinguishable from human translations.

Discriminator The discriminator D, conditioned on the source-language sentences, tries to distinguish the machine-generated sentences from human translations. D can be viewed as a dynamic objective since it is updated synchronously with G.

BLEU objective The sentence-level BLEU Q serves as the reinforced objective, guiding the generation towards high BLEU points. Q is a static function which will not be updated during training.

3.2 Generator

Resembling NMT models, the generator G defines the policy that generates the target sentence y given the source sentence x. The generator takes exactly the same architecture with NMT models. Note that we do not assume the specific architecture of the generator. To verify the effectiveness of the proposed method, we take two different architectures for the generator, the RNNSearch [2] and Transformer [3].

3.3 Discriminator

Recently, the deep discriminative models such as the CNN and RNN have shown a high performance in complicated sequence classification tasks. Here, the discriminator is implemented based on the CNN architecture.

Since sentences generated by the generator have variable lengths, the CNN padding is used to transform the sentences to sequences with fixed length

[3] https://github.com/tensorflow/tensor2tensor

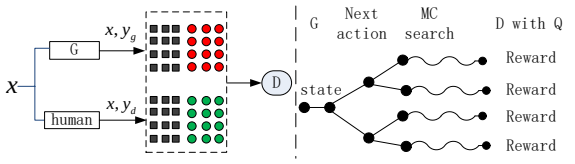

Figure 1: The Illustration of the proposed BR-CSGAN. Left: D is trained over the real sentence pairs translated by the human and the generated sentence pairs by G. Note that D is a conditional discriminator. Right: G is trained by police gradient where the final reward is provided by D and Q.

T, which is the maximum length set for the output of the generator. Given the source-language sequence $x_1, \ldots, x_T$ and target-language sequence $y_1, \ldots, y_T$, we build the source matrix $X_{1:T}$ and target matrix $Y_{1:T}$ respectively as:

$$X_{1:T} = x_1; x_2; \ldots; x_T \tag{1}$$

and

$$Y_{1:T} = y_1; y_2; \ldots; y_T \tag{2}$$

where x_t, $y_t \in R^k$ is the k-dimensional word embedding and the semicolon is the concatenation operator. For the source matrix $X_{1:T}$, a kernel $w_j \in R^{l \times k}$ applies a convolutional operation to a window size of l words to produce a series of feature maps:

$$c_{ji} = \rho(BN(w_j \otimes X_{i:i+l-1} + b)) \tag{3}$$

where $\otimes$ operator is the summation of element-wise production and b is a bias term. ρ is a non-linear activation function which is implemented as ReLu in this paper. Note that the batch normalization (Ioffe and Szegedy, 2015) which accelerates the training significantly, is applied to the input of the activation function (BN in equation 3). To get the final feature with respect to kernel w_j, a max-over-time pooling operation is leveraged over the feature maps:

$$\widetilde{c}_j = max\{c_{j1}, \ldots, c_{jT-l+1}\} \tag{4}$$

We use various numbers of kernels with different window sizes to extract different features, which are then concatenated to form the source-language sentence representation c_x. Identically, the target-language sentence representation c_y can be extracted from the target matrix $Y_{1:T}$. Finally, given the source-language sentence, the probability that the target-language sentence is being real can be computed as:

$$p = \sigma(V[c_x; c_y]) \tag{5}$$

where V is the transform matrix which transforms the concatenation of c_x and c_y into a 2-dimension embedding and σ is the logistic function.

3.4 BLEU objective

We apply the smoothed sentence-level BLEU as the specific objective for the generator. Given the generated sentence y_g and the the ground true sentence y_d, the objective Q calculates a reward $Q(y_g, y_d)$, which measures the n-gram precisions of the generated sentence y_g. Identical to the output of the discriminator, the $Q(y_g, y_d)$ also ranges from zero to one, which makes it easier to fuse Q and D.

3.5 Policy Gradient Training

Following (Yu et al., 2016), the objective of the generator G is defined as to generate a sequence from the start state to maximize its expected end reward. Formally, the objective function is computed as:

$$J(\theta) = \sum_{Y_{1:T}} G_\theta(Y_{1:T}|X) \cdot R^{G_\theta}_{D,Q}(Y_{1:T-1}, X, y_T, Y^*)$$

where θ represents the parameters in G, $Y_{1:T} = y_1, \ldots, y_T$ indicates the generated target sequence, X is the source-language sentence, Y^* represents the ground true target sentence. $R^{G_\theta}_{D,Q}$ is the action-value function of a target-language sentence given the source sentence X, i.e. the expected accumulative reward starting from the state $(Y_{1:T-1}, X)$, taking action y_T, and following the policy G_θ. To estimate the action-value function, we consider the estimated probability of being real by the discriminator D and the output of the BLEU objective Q as the reward:

$$R^{G_\theta}_{D,Q}(Y_{1:T-1}, X, y_T, Y^*) =$$
$$\lambda(D(X, Y_{1:T}) - b(X, Y_{1:T})) + (1 - \lambda)Q(Y_{1:T}, Y^*)$$

where b(X,Y) denotes the baseline value to reduce the variance of the reward. Practically, we take b(X,Y) as a constant, 0.5 for simplicity. And the λ is a hyper-parameter. The question is that, given the source sequence, D only provides a reward value for a finished target sequence. If $Y_{1:T}$ is not a finished target sequence, the value of $D(X, Y_{1:T})$ makes no sense. Therefore, we cannot get the

action-value for an intermediate state directly. To evaluate the action-value for an intermediate state, the Monte Carlo search under the policy of G_θ is applied to sample the unknown tokens. Each search ends until the end of sentence token is sampled or the sampled sentence reaches the maximum length. To obtain more stable reward and reduce the variance, we represent an N-time Monte Carlo search as:

$$\{Y^1_{1:T_1}, \ldots, Y^N_{1:T_N}\} = MC^{G_\theta}((Y_{1:t}, X), N)$$

where T_i represents the length of the sentence sampled by the i'th Monte Carlo search. $(Y_{1:t}, X) = (y_1, \ldots, y_t, X)$ is the current state and $Y^N_{t+1:T_N}$ is sampled based on the policy G_θ. The discriminator provides N rewards for the sampled N sentences respectively. The final reward for the intermediate state is calculated as the average of the N rewards. Hence, for the target sentence with the length T, we compute the reward for y_t in the sentence level as:

$$R^{G_\theta}_{D,Q}(Y_{1:t-1}, X, y_T, Y^*) =$$
$$\begin{cases} \frac{1}{N}\sum_{n=1}^{N} \lambda(D(X, Y^n_{1:T_n}) - b(X, Y^n_{1:T_n})) + (1-\lambda)Q(Y_{1:T_n}, Y*) & t < T \\ \lambda(D(X, Y_{1:t}) - b(X, Y_{1:t})) + (1-\lambda)Q(Y_{1:t}, Y^*) & t = T \end{cases}$$

Using the discriminator as a reward function can further improve the generator iteratively by dynamically updating the discriminator. Once we get more realistic generated sequences, we re-train the discriminator as:

$$\min -\mathbb{E}_{X,Y\in P_{data}}[\log D(X,Y)] - \mathbb{E}_{X,Y\in G}[\log(1 - D(X,Y))]$$

After updating the discriminator, we are ready to re-train the generator. The gradient of the objective function $J(\theta)$ w.r.t the generator's parameter θ is calculated as:

$$\nabla J(\theta) = \frac{1}{T}\sum_{t=1}^{T}\sum_{y_t} R^{G_\theta}_{D,Q}(Y_{1:t-1}, X, y_T, Y^*) \cdot \nabla_\theta(G_\theta(y_t|Y_{1:t-1}, X))$$
$$= \frac{1}{T}\sum_{t=1}^{T} \mathbb{E}_{y_t\in G_\theta}[R^{G_\theta}_{D,Q}(Y_{1:t-1}, X, y_T, Y^*) \cdot \nabla_\theta \log p(y_t|Y_{1:t-1}, X)]$$

3.6 Training strategies

GANs are widely criticized for its unstable training since the generator and discriminator need to be carefully synchronized. To make this work easier to reproduce, this paper gives detailed strategies for training the proposed model.

Firstly, we use the maximum likelihood estimation to pre-train the generator on the parallel training set until the best translation performance is achieved. Then, generate the machine-generated sentences by using the generator to decode the training data. We simply use the greedy sampling method instead of the beam search method for decoding. Next, pre-train the discriminator on the combination of the true parallel data and the machine-generated data until the classification accuracy achieves at ξ. Finally, we jointly train the generator and discriminator. The generator is trained with the policy gradient training method. However, in our practice, we find that updating the generator only with the simple policy gradient training leads to unstableness. To alleviate this issue, we adopt the teacher forcing approach which is similar to (Lamb et al., 2016; Li et al., 2017). We directly make the discriminator to automatically assign a reward of 1 to the golden target-language sentence and the generator uses this reward to update itself on the true parallel example. We run the teacher forcing training for one time once the generator is updated by the policy gradient training. After the generator gets updated, we use the new stronger generator to generate η more realistic sentences, which are then used to train the discriminator. Following (Arjovsky et al., 2017), we clamp the weights of the discriminator to a fixed box ($[-\epsilon,\epsilon]$) after each gradient update. We perform one optimization step for the discriminator for each step of the generator. In our practice, we set ξ as 0.82, η as 5000, ϵ as 1.0 and the N for Monte Carlo search as 20.

4 Experiments and Results

We evaluate our BR-CSGAN on English-German and Chinese-English translation tasks and we test two different architectures for the generator, the traditional RNNSearch and the newly emerged state-of-the-art Transformer.

4.1 Data sets and preprocessing

English-German: For English-German translation, we conduct our experiments on the publicly available corpora used extensively as benchmark for NMT systems, WMT'14 En-De. This data set contains 4.5M sentence pairs [4]. Sentences are encoded using byte-pair encoding (Sennrich et al., 2015), which has a shared source-target vocabulary of about 37000 tokens. We report results on newstest2014. The newstest2013 is used as validation.

[4] http://nlp.stanford.edu/projects/nmt

Model	Chinese-English				English-German
	NIST03	NIST04	NIST05	average	newstest2014
RNNSearch (Bahdanau et al., 2014)	33.93	35.67	32.24	33.94	21.2
Transformer (Vaswani et al., 2017)	42.23	42.17	41.02	41.80	27.30
RNNSearch+BR-CSGAN($\lambda = 1.0$)	35.21	36.51	33.45	35.05	22.1
RNNSearch+BR-CSGAN($\lambda = 0.7$)	35.97	37.32	34.03	**35.77**	**22.89**
RNNSearch+BR-CSGAN($\lambda = 0$)	34.57	35.93	33.07	34.52	21.75
Transformer+BR-CSGAN($\lambda = 1.0$)	42.67	42.79	41.54	42.30	27.75
Transformer+BR-CSGAN($\lambda = 0.8$)	43.01	42.96	41.86	**42.61**	**27.92**
Transformer+BR-CSGAN($\lambda = 0$)	42.41	42.74	41.29	42.14	27.49

Table 1: BLEU score on Chinese-English and English-German translation tasks. The hyper-parameter λ is selected according to the development set. For the Transformer, following (Vaswani et al., 2017), we report the result of a single model obtained by averaging the 5 checkpoints around the best model selected on the development set.

Chinese-English: For Chinese-English translation, our training data consists of 1.6M sentence pairs randomly extracted from LDC corpora [5]. Both the source and target sentences are encoded with byte-pair encoding and the tokens in the source and target vocabulary is about 38000 and 34000 respectively [6]. We choose the NIST02 as the development set. For testing, we use NIST03, NIST04 and NIST05 data sets.

To speed up the training procedure, sentences of length over 50 words are removed when we conduct experiments on the RNNSearch model. This is widely used by previous works (Ranzato et al., 2015; Shen et al., 2015; Yang et al., 2016).

4.2 Model parameters and evaluation

For the Transformer, following the base model in (Vaswani et al., 2017), we set the dimension of word embedding as 512, dropout rate as 0.1 and the head number as 8. The encoder and decoder both have a stack of 6 layers. We use beam search with a beam size of 4 and length penalty $\alpha = 0.6$. For the RNNSearch, following (Bahdanau et al., 2014), We set the hidden units for both encoders and decoders as 512. The dimension of the word embedding is also set as 512. We do not apply dropout for training the RNNSearch. During testing, we use beam search with a beam size of 10 and length penalty is not applied.

All models are implemented in TensorFlow (Abadi et al., 2015) and trained on up to four K80 GPUs synchronously in a multi-GPU setup on a single machine [7]. We stop training when the model achieves no improvement for the tenth evaluation on the development set. BLEU (Papineni et al., 2002) is utilized as the evaluation metric. We apply the script *mteval-v11b.pl* to evaluate the Chinese-English translation and utilize the script *multi-belu.pl* for English-German translation [8].

4.3 Main results

The model of RNNSearch is optimized with the mini-batch of 64 examples. It takes about 30 hours to pre-train the RNNSearch on the Chinese-English data set and 46 hours on the English-German data set. During generative adversarial training, it takes about 35 hours on the Chinese-English data set and about 50 hours on the English-German data set. For the Transformer, each training batch contains a set of sentence pairs containing approximately 25000 source tokens and 25000 target tokens. On the Chinese-English data set, it takes about 15 hours to do pre-training and 20 hours to do generative adversarial training. On the English-German data set, it takes about 35 hours for the pre-training and 40 hours for the generative adversarial training.

Table 1 shows the BLEU score on Chinese-English and English-German test sets. On the RNNSearch model, the naive GAN (i.e., the line of RNNSearch+BR-CSGAN (λ=1) in table 1) achieves improvement up to +1.11 BLEU points averagely on Chinese-English test sets and +0.9 BLEU points on English-German test set. Armed

[5] LDC2002L27, LDC2002T01, LDC2002E18, LDC2003E07, LDC2004T08, LDC2004E12, LDC2005T10

[6] When doing BPE for Chinese, we need to do word segmentation first and the following steps are the same with BPE for English.

[7] The code we used to train and evaluate our models can be found at https://github.com/ZhenYangIACAS/NMT_GAN

[8] https://github.com/moses-smt/mosesdecoder/blob/617e8c8/scripts/generic/multi-bleu.perl;mteval-v11b.pl

with the BLEU objective, the BR-CSGAN (the line of RNNSearch+BR-CSGAN (λ=0.7)) leads to more significant improvements, +1.83 BLEU points averagely on Chinese-English translation and +1.69 BLEU points on English-German translation. We also test the translation performance when the RNNSearch is only guided by the static BLEU objective (the line of RNNSearch+BR-CSGAN (λ=0)), and we only get +0.58 BLEU points improvement on Chinese-English translation and +0.55 BLEU points improvement on English-German. Experiments on the Transformer show the same trends. While the Transformer has achieved state-of-the-art translation performances, our approach still achieves +0.81 BLEU points improvement on Chinese-English translation and +0.62 BLEU points improvement on English-German.

These results indicate that the proposed BR-CSGAN consistently outperforms the baselines and it shows better translation performance than the naive GAN and the model guided only by the BLEU objective.

5 Analysis

5.1 Compared with MRT

We show that MRT (Shen et al., 2015) is an extreme case of our approach. Considering a sentence pair (x, y), the training objective of MRT is calculated as

$$\widehat{J}(\theta') = \sum_{y^s \in S(x)} p(y^s|x;\theta')\Delta(y^s, y)$$

where $\Delta(y^s, y)$ is a loss function (i.e., the sentence-level BLEU used in this paper) that measures the discrepancy between a predicted translation y^s and the training example y, $S(x)$ represents the set which contains all of the predictions given the input x, and θ' is the parameters of the NMT model. Unfortunately, this objective is usually intractable due to the exponential search space. To alleviate this problem, a subset of the search space is sampled to approximate this objective. In this paper, when we set λ as zero, the objective for the proposed BR-CSGAN comes to

$$J(\theta)_{\lambda=0} = \sum_{Y_{1:T}} G_\theta(Y_{1:T}|X) \cdot Q(Y_{1:T}, Y^*)$$

where the $Q(Y_{1:T}, Y^*)$ is also a loss function between the predicted translation $Y_{1:T}$ and the training example Y^*. It is easy to be found that, under this condition (i.e., λ set as zero), the proposed BR-CSGAN optimizes almost the same objective with MRT. The only difference is that the reinforcement learning procedure is utilized in BR-CSGAN to maximize the total reward and MRT instead applies random sampling to approximate the risk. Actually, the BR-CSGAN is a weighted sum of the naive GAN (λ=1) and MRT (λ=0), and it incorporates the advantages of the two approaches. Specifically, compared to naive GAN which is trained without specific objective guidance, BR-CSGAN utilizes the BLEU objective to guide the generator to generate sentences with higher BLEU points. And compared to MRT which is trained only with the static objective, the BR-CSGAN applies a dynamic discriminator which updates synchronously with the generator, to feedback the dynamic rewards for the generator. Table 2 compares the translation performance between the MRT and BR-CSGAN on Chinese-English and English-German translation tasks. We only conduct experiments on the RNNSearch because we only get the open-source implementation of MRT on the RNNSearch [9]. Results show that the proposed BR-CSGAN consistently outperforms the MRT on the Chinese-English and English-German translations.

Model	Chinese-English average	English-German newstest2014
RNNSearch	33.94	21.2
MRT (Shen et al., 2015)	34.64	21.6
BR-CSGAN($\lambda = 0.7$)	35.77	22.89

Table 2: BLEU score on Chinese-English and English-German translation tasks for MRT and BR-CSGAN.

5.2 When to stop pre-training

The initial accuracy ξ of the discriminator which is viewed as a hyper-parameter, can be set carefully during the process of pre-training. A natural question is that when shall we end the pre-training. Do we need to pre-train the discriminator with the highest accuracy? To answer this question, we test the impact of the initial accuracy of the discriminator. We pre-train five discriminators which have the accuracy as 0.6, 0.7, 0.8, 0.9 and 0.95 respectively. With the five discriminators, we train five different BR-CSGAN models (with the generator as RNNSearch and λ set as 0.7) and test

[9]The open-source implementation can be found at: https://github.com/EdinburghNLP/nematus

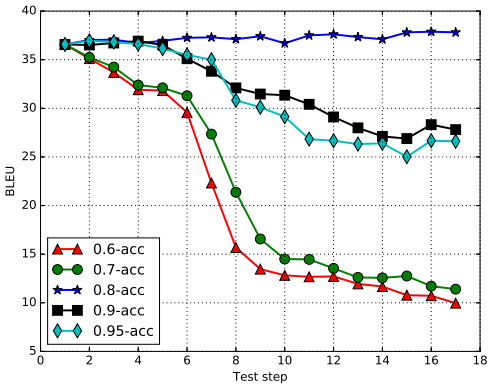

Figure 2: BLEU score on the development set for the BR-CSGAN where the discriminators have different initial accuracy. "0.6-acc" means the initial accuracy is 0.6. We report the results on the Chinese-English translation tasks. RNNSearch is taken as the generator.

their translation performances on the development set at regular intervals. Figure 2 reports the results and we can find that the initial accuracy of the discriminator shows great impacts on the translation performance of the proposed BR-CSGAN. From figure 2, we show that the initial accuracy of the discriminator needs to be set carefully and either it is too high (0.9 and 0.95) or too low (0.6 and 0.7), the model performs badly [10]. This suggests that it is important for the generator and discriminator to keep a balanced relationship at the beginning of the generative adversarial training. If the discriminator is too strong, the generator is always penalized for its bad predictions and gets no idea about right predictions. Hence, the generator is discouraged all the time and the performance gets worse and worse. On the other hand, if the discriminator is too weak, the discriminator is unable to give right guidance for the generator, i.e. the gradient direction for updating the generator is random. Empirically, we pre-train the discriminator until its accuracy reaches around 0.8.

5.3 Sample times for Monto Carol search

We are also curious about how the sample times N for Monte Carlo search affects the translation performance. Intuitively, if N is set as a small number, the intermediate reward for each word may be incorrect since there is a large variance for the Monto Carol search when the sample time is too small. And if otherwise, the computation shall be very time consuming because we need to do much more sampling. Therefore, there is a trade-off between the accuracy and computation complexity here. We investigate this problem on the Chinese-English translation task. Table 3 presents the translation performance of the BR-CSGAN on the test sets when the N are set from 5 to 30 with interval 5. From table 3, the proposed model achieves no improvement than the baseline (i.e., the pre-trained generator) when N are set less than 15 and the BLEU scores are not reported on the table. As a matter of fact, the translation performance of the model gets worse and worse. We conjecture that the approximated reward is far from the expected reward due to the large variance when N is set too small, and gives wrong gradient directions for model updating. Since the training for GAN is not stable, the wrong gradient direction exacerbates the unstableness and results in the BLEU getting worse and worse. With the increasing of N, the translation performance of the model gets improved. However, with N set larger than 20, we get little improvement than the model with N set as 20 and the training time exceeds our expectation.

[10] To make the illustration simple and clear, we only depict the results when the RNNSearch acts as the generator.

N	NIST02	NIST03	NIST04	NIST05
0	36.87	33.93	35.67	32.24
5	-	-	-	-
10	-	-	-	-
15	37.34	34.91	36.09	33.45
20	38.58	35.97	37.32	34.03
25	38.65	36.04	37.52	33.91
30	38.74	36.01	37.54	33.76

Table 3: The translation performance of the BR-CSGAN with different N for Monte Carlo search. "-" means that the proposed model shows no improvement than the pre-trained generator or it can not be trained stably. With N set as 0, it is referred to as the pre-trained generator. Similarly, we only report results on the RNNSearch and λ is set as 0.7.

6 Conclusion and Future Work

In this work, we propose the BR-CSGAN which leverages the BLEU reinforced generative adversarial net to improve the NMT. We show that the proposed approach is a weighted combination of the naive GAN and MRT. To verify the effectiveness of our approach, we test two different architectures for the generator, the traditional RNNSearch and the state-of-the-art Transformer.

Extensive experiments on Chinese-English and English-German translation tasks show that our approach consistently achieves significant improvements. In the future, we would like to try multi-adversarial framework which consists of multi discriminators and generators for GAN.

Neural Machine Translation for Bilingually Scarce Scenarios: A Deep Multi-task Learning Approach

Poorya Zaremoodi **Gholamreza Haffari**

first.last@monash.edu

Abstract

Neural machine translation requires large amounts of parallel training text to learn a reasonable-quality translation model. This is particularly inconvenient for language pairs for which enough parallel text is not available. In this paper, we use monolingual linguistic resources in the source side to address this challenging problem based on a multi-task learning approach. More specifically, we scaffold the machine translation task on auxiliary tasks including semantic parsing, syntactic parsing, and named-entity recognition. This effectively injects semantic and/or syntactic knowledge into the translation model, which would otherwise require a large amount of training bitext. We empirically evaluate and show the effectiveness of our multi-task learning approach on three translation tasks: English-to-French, English-to-Farsi, and English-to-Vietnamese.

1 Introduction

Neural Machine Translation (NMT) with attentional encoder-decoder architectures (Luong et al., 2015; Bahdanau et al., 2015) has revolutionised machine translation, and achieved state-of-the-art for several language pairs. However, NMT is notorious for its need for large amounts of bilingual data (Koehn and Knowles, 2017) to achieve reasonable translation quality. Leveraging existing monolingual resources is a potential approach for compensating this requirement in bilingually scarce scenarios. Ideally, semantic and syntactic knowledge learned from existing linguistic resources provides NMT with proper inductive biases, leading to increased generalisation and better translation quality.

Multi-task learning (MTL) is an effective approach to inject knowledge into a task, which is learned from other related tasks. Various recent works have attempted to improve NMT with an MTL approach (Peng et al., 2017; Liu et al., 2017; Zhang and Zong, 2016); however, they either do not make use of curated linguistic resources (Domhan and Hieber, 2017; Zhang and Zong, 2016), or their MTL architectures are restrictive yielding mediocre improvements (Niehues and Cho, 2017). The current research leaves open how to best leverage curated linguistic resources in a suitable MTL framework to improve NMT.

In this paper, we make use of curated monolingual linguistic resources in the source side to improve NMT in bilingually scarce scenarios. More specifically, we scaffold the machine translation task on auxiliary tasks including semantic parsing, syntactic parsing, and named-entity recognition. This is achieved by casting the auxiliary tasks as sequence-to-sequence (SEQ2SEQ) transduction tasks, and tie the parameters of their encoders and/or decoders with those of the main translation task. Our MTL architectures makes use of deep stacked encoders and decoders, where the parameters of the top layers are shared across the tasks. We further make use of adversarial training to prevent contamination of common knowledge with task-specific information.

We present empirical results on translating from English into French, Vietnamese, and Farsi; three target languages with varying degree of divergence compared to English. Our extensive empirical results demonstrate the effectiveness of our MTL approach in substantially improving the translation quality for these three translation tasks in bilingually scarce scenarios.

2 Neural SEQ2SEQ Transduction

Our MTL is based on the attentional encoder-decoder architecture for SEQ2SEQ transduction. It contains an encoder to *read* the input sentence, and an attentional decoder to *generate* the output.

Proceedings of NAACL-HLT 2018, pages 1356–1365
New Orleans, Louisiana, June 1 - 6, 2018.

Encoder The encoder is a bi-directional RNN whose hidden states represent tokens of the input sequence. These representations capture information not only of the corresponding token, but also other tokens in the sequence to leverage the context. The bi-directional RNN consists of two RNNs running in the left-to-right and right-to-left directions over the input sequence:

$$\begin{aligned}\overrightarrow{\boldsymbol{h}}_i &= \mathrm{RNN}(\overrightarrow{\boldsymbol{h}}_{i-1}, \boldsymbol{E}_S[x_i]) \\ \overleftarrow{\boldsymbol{h}}_i &= \mathrm{RNN}(\overleftarrow{\boldsymbol{h}}_{i+1}, \boldsymbol{E}_S[x_i])\end{aligned}$$

where $\boldsymbol{E}_S[x_i]$ is the embedding of the token x_i from the embedding table $\boldsymbol{E}_S$ of the input (source) space, and $\overrightarrow{\boldsymbol{h}}_i$ and $\overleftarrow{\boldsymbol{h}}_i$ are the hidden states of the forward and backward RNNs which can be based on the LSTM (long-short term memory) (Hochreiter and Schmidhuber, 1997) or GRU (gated-recurrent unit) (Chung et al., 2014) units. Each source token is then represented by the concatenation of the corresponding bidirectional hidden states, $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i]$.

Decoder. The backbone of the decoder is a unidirectional RNN which generates the token of the output one-by-one from left to right. The generation of each token y_j is conditioned on all of the previously generated tokens $\boldsymbol{y}_{<j}$ via the state of the RNN decoder $\boldsymbol{s}_j$, and the input sequence via a *dynamic* context vector $\boldsymbol{c}_j$ (explained shortly):

$$\begin{aligned}y_j &\sim \mathrm{softmax}(\boldsymbol{W}_y \cdot \boldsymbol{r}_j + \boldsymbol{b}_r) && (1)\\ \boldsymbol{r}_j &= \tanh(\boldsymbol{s}_j + \boldsymbol{W}_{rc} \cdot \boldsymbol{c}_j + \boldsymbol{W}_{rj} \cdot \boldsymbol{E}_T[y_{j-1}]) && (2)\\ \boldsymbol{s}_j &= \tanh(\boldsymbol{W}_s \cdot \boldsymbol{s}_{j-1} + \boldsymbol{W}_{sj} \cdot \boldsymbol{E}_T[y_{j-1}] + \boldsymbol{W}_{sc} \cdot \boldsymbol{c}_j)\end{aligned}$$

where $\boldsymbol{E}_T[y_j]$ is the embedding of the token y_j from the embedding table $\boldsymbol{E}_T$ of the output (target) space, and the $\boldsymbol{W}$ matrices and $\boldsymbol{b}_r$ vector are the parameters.

A crucial element of the decoder is the *attention* mechanism which dynamically attends to relevant parts of the input sequence necessary for generating the next token in the output sequence. Before generating the next token t_j, the decoder computes the attention vector $\boldsymbol{\alpha}_j$ over the input token:

$$\begin{aligned}\boldsymbol{\alpha}_j &= \mathrm{softmax}(\boldsymbol{a}_j)\\ a_{ji} &= \boldsymbol{v} \cdot \tanh(\boldsymbol{W}_{ae} \cdot \boldsymbol{h}_i + \mathbf{W}_{at} \cdot \boldsymbol{s}_{j-1})\end{aligned}$$

which intuitively is similar to the notion of *alignment* in word/phrase-based statistical MT (Brown et al., 1993). The attention vector is then used to compute a fixed-length dynamic representation of the source sentence

$$\boldsymbol{c}_j = \sum_i \alpha_{ji} \boldsymbol{h}_i. \qquad (3)$$

which is conditioned upon in the RNN decoder when computing the next state or generating the output word (as mentioned above).

Training and Decoding. The model parameters are trained end-to-end by maximising the (regularised) log-likelihood of the training data

$$\arg\max_{\boldsymbol{\theta}} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{D}} \sum_{j=1}^{|\boldsymbol{y}|} \log P_{\boldsymbol{\theta}}(y_j|\boldsymbol{y}_{<j}, \boldsymbol{x})$$

where the above conditional probability is defined according to eqn (1). Usually drop-out is employed to prevent over-fitting on the training data. In the decoding time, the best output sequence for a given input sequence is produced by

$$\arg\max_{\boldsymbol{y}} P_{\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{x}) = \prod_j P_{\boldsymbol{\theta}}(y_j|\boldsymbol{y}_{<j}\boldsymbol{x}).$$

Usually greedy decoding or beam search algorithms are employed to find an approximate solution, since solving the above optimisation problem exactly is computationally hard.

3 SEQ2SEQ Multi-Task Learning

We consider an extension of the basic SEQ2SEQ model where the encoder and decoder are equipped with deep stacked layers. Presumably, deeper layers capture more abstract information about a task, hence they can be used as a mechanism to share useful generalisable information among multiple tasks.

Deep Stacked Encoder. The deep encoder consists of multiple layers, where the hidden states in layer $\ell-1$ are the inputs to the hidden states at the next layer ℓ. That is,

$$\begin{aligned}\overrightarrow{\boldsymbol{h}}_i^{\ell} &= \overrightarrow{\mathrm{RNN}}^{\ell}_{\boldsymbol{\theta}_{\ell,enc}}(\overrightarrow{\boldsymbol{h}}_{i-1}^{\ell}, \boldsymbol{h}_i^{\ell-1})\\ \overleftarrow{\boldsymbol{h}}_i^{\ell} &= \overleftarrow{\mathrm{RNN}}^{\ell}_{\boldsymbol{\theta}_{\ell,enc}}(\overleftarrow{\boldsymbol{h}}_{i-1}^{\ell}, \boldsymbol{h}_i^{\ell-1})\end{aligned}$$

where $\boldsymbol{h}_i^{\ell} = [\overrightarrow{\boldsymbol{h}}_i^{\ell}; \overleftarrow{\boldsymbol{h}}_i^{\ell}]$ is the hidden state of the ℓ'th layer RNN encoder for the i'th source sentence word. The inputs to the first layer forward/backward RNNs are the source word embeddings $\boldsymbol{E}_S[x_i]$. The representation of the source sentence is then the concatenation of the hidden states for all layers $\boldsymbol{h}_i = [\boldsymbol{h}_i^1; \ldots; \boldsymbol{h}_i^L]$ which is then used by the decoder.

Deep Stacked Decoder. Similar to the multi-layer RNN encoder, the decoder RNN has multiple layers:

$$\boldsymbol{s}_j^\ell = \text{RNN}^\ell_{\boldsymbol{\theta}_{\ell,dec}}(\boldsymbol{s}_{j-1}^\ell, \boldsymbol{s}_j^{\ell-1})$$

where the inputs to the first layer RNNs are

$$\boldsymbol{W}_{sj} \cdot \boldsymbol{E}_T[y_{j-1}] + \boldsymbol{W}_{sc} \cdot \boldsymbol{c}_j$$

in which $\boldsymbol{c}_j$ is the dynamic source context, as defined in eqn 3. The state of the decoder is then the concatenation of the hidden states for all layers: $\boldsymbol{s}_j = [\boldsymbol{s}_j^1; \ldots; \boldsymbol{s}_j^L]$ which is then used in eqn 2 as part of the "output generation module".

Shared Layer MTL. We share the deep layer RNNs in the encoders and/or decoders across the tasks, as a mechanism to share abstract knowledge and increase model generalisation.

Suppose we have a total of $M+1$ tasks, consisting of the main task plus M auxiliary tasks. Let $\boldsymbol{\Theta}^m_{enc} = \{\boldsymbol{\theta}^m_{\ell,enc}\}_{\ell=1}^{L}$ and $\boldsymbol{\Theta}^m_{dec} = \{\boldsymbol{\theta}^m_{\ell',dec}\}_{\ell'=1}^{L'}$ be the parameters of multi-layer encoder and decoder for the task m. Let $\{\boldsymbol{\Theta}^m_{enc}, \boldsymbol{\Theta}^m_{dec}\}_{m=1}^{M}$ and $\{\boldsymbol{\Theta}^0_{enc}, \boldsymbol{\Theta}^0_{dec}\}$ be the RNN parameters for the auxiliary tasks and the main task, respectively. We share the parameters of the deep-level encoders and decoders of the auxiliary tasks with those of the main task. That is,

$$\begin{aligned} \forall m \in [1,..,M]\ \forall \ell \in [L^m_{enc},..,L] \quad &: \quad \boldsymbol{\theta}^m_{\ell,enc} = \boldsymbol{\theta}^0_{\ell,enc} \\ \forall m \in [1,..,M]\ \forall \ell' \in [L'^m_{dec},..,L'] \quad &: \quad \boldsymbol{\theta}^m_{\ell',dec} = \boldsymbol{\theta}^0_{\ell',dec} \end{aligned}$$

where L^m_{enc} and L'^m_{dec} specify the deep-layer RNNs need to be shared parameters. Other parameters to share across the tasks include those of the attention module, the source/target embedding tables, and the output generation module. As an extreme case, we can share *all* the parameters of SEQ2SEQ architectures across the tasks.

Training Objective. Suppose we are given a collection of $M+1$ SEQ2SEQ transductions tasks, each of which is associated with a training set $\mathcal{D}_m := \{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}_{i=1}^{N_m}$. The parameters are learned by maximising the MTL training objective:

$$\mathcal{L}_{mtl}(\boldsymbol{\Theta}_{mtl}) := \sum_{m=0}^{M} \frac{\gamma_m}{|\mathcal{D}_m|} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{D}_m} \log P_{\boldsymbol{\Theta}_m}(\boldsymbol{y}|\boldsymbol{x}) \tag{4}$$

where $\boldsymbol{\Theta}_{mtl}$ denotes all the parameters of the MTL architecture, $|\mathcal{D}_m|$ denotes the size of the training set for the task m, and γ_m balances out its influence in the training objective.

Training Schedule. Variants of stochastic gradient descent (SGD) can be used to optimise the objective in order to learn the parameters. Making the best use of tasks with different objective geometries is challenging, e.g. due to the scale of their gradients. One strategy for making an SGD update is to select the tasks from which the next data items should be chosen. In our training schedule, we randomly select a training data item from the main task, and pair it with a data item selected from a randomly selected auxiliary task for making the next SGD update. This ensures the presence of training signal from the main task in all SGD updates, and avoids the training signal being washed out by the auxiliary tasks.

4 Adversarial Training

The learned shared knowledge can be contaminated by task-specific information. We address this issue by adding an adversarial objective. The basic idea is to augment the MTL training objective with additional terms, so that the identity of a task cannot be predicted from its data items by the representations resulted from the shared encoder/decoder RNN layers.

Task Discriminator. The goal of the task discriminator is to predict the identity of a task for a data item based on the representations of the share layers. More specifically, our task discriminator consists of two RNNs with LSTM units, each of which encodes the sequence of hidden states in the shared layers of the encoder and the decoder.[1] The last hidden states of these two RNNs are then concatenated, giving rise to a fixed dimensional vector summarising the representations in the shared layers. The summary vector is passed through a fully connected layer followed by a $\mathrm{softmax}$ to predict the probability distribution over the tasks:

$$\begin{aligned} P_{\boldsymbol{\Theta}_d}(\text{task id}|\boldsymbol{h}_d) &\sim \mathrm{softmax}(\boldsymbol{W}_d\boldsymbol{h}_d + \boldsymbol{b}_d) \\ \boldsymbol{h}_d &:= \mathrm{disLSTMs}(\mathrm{shrRep}_{\boldsymbol{\Theta}_{mtl}}(\boldsymbol{x}, \boldsymbol{y})) \end{aligned}$$

where $\mathrm{disLSTMs}$ denotes the discriminator LSTMs, $\mathrm{shrRep}_{\boldsymbol{\Theta}_{mtl}}(\boldsymbol{x}, \boldsymbol{y})$ denotes the representations in the shared layer of deep encoders and decoders in the MTL architecture, and $\boldsymbol{\Theta}_d$ includes the $\mathrm{disLSTMs}$ parameters as well as $\{\boldsymbol{W}_d, \boldsymbol{b}_d\}$.

[1] When multiple layers are shared, we concatenate their hidden states at each time step, which is then input to the task discriminator's LSTMs.

Adversarial Objective. Inspired by (Chen et al., 2017), we add two additional terms to the MTL training objective in eqn 4. The first term is $\mathcal{L}_{adv1}(\mathbf{\Theta}_d)$ defined as:

$$\sum_{m=0}^{M} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{D}_m} \log P_{\mathbf{\Theta}_d}(m|\,\text{disLSTMs}(\text{shrRep}_{\mathbf{\Theta}_{mtl}}(\boldsymbol{x},\boldsymbol{y}))).$$

Maximising the above objective over $\mathbf{\Theta}_d$ ensures proper training of the discriminator to predict the identity of the task. The second term ensures that the parameters of the shared layers are trained so that they confuse the discriminator by maximising the entropy of its predicted distribution over the task identities. That is, we add the term $\mathcal{L}_{adv2}(\mathbf{\Theta}_{mtl})$ to the training objective defined as:

$$\sum_{m=0}^{M} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{D}_m} H\big[P_{\mathbf{\Theta}_d}(.|\,\text{disLSTMs}(\text{shrRep}_{\mathbf{\Theta}_{mtl}}(\boldsymbol{x},\boldsymbol{y})))\big]$$

where $H[.]$ is the entropy of a distribution. In summary, the adversarial training leads to the following optimisation

$$\arg\max_{\mathbf{\Theta}_d,\mathbf{\Theta}_{mtl}} \mathcal{L}_{mtl}(\mathbf{\Theta}_{mtl})+\mathcal{L}_{adv1}(\mathbf{\Theta}_d)+\lambda\mathcal{L}_{adv2}(\mathbf{\Theta}_{mtl}).$$

We maximise the above objective by SGD, and update the parameters by alternating between optimising $\mathcal{L}_{mtl}(\mathbf{\Theta}_{mtl}) + \lambda\mathcal{L}_{adv2}(\mathbf{\Theta}_{mtl})$ and $\mathcal{L}_{adv1}(\mathbf{\Theta}_d)$.

5 Experiments

5.1 Bilingual Corpora

We use three language-pairs, translating from English to French, Farsi, and Vietnamese. We have chosen these languages to analyse the effect of multi-task learning on languages with different underlying linguistic structures. The sentences are segmented using BPE (Sennrich et al., 2016) on the union of source and target vocabularies for English-French and English-Vietnamese. For English-Farsi, BPE is performed using separate vocabularies due to the disjoint alphabets. We use a special <UNK> token to replace unknown BPE units in the test and development sets.

Table 1 show some statistics about the bilingual corpora. Further details about the corpora and their pre-processing is as follows:

- The English-French corpus is a random subset of EuroParlv7 as distributed to WMT2014. Sentence pairs in which either the source or the target has length more than 80 (before applying BPE) have been removed. The BPE is performed with a 30k total vocabulary size. The "news-test2012" and "news-test-2013" portions are used for validation and test sets, respectively.

	Train	Dev	Test
En → Fr	98,846	5,357	5,357
En → Fa	98,158	3,000	4,000
En → vi	133,290	1,553	1,268

Table 1: The statistics of bilingual corpora.

- The English-Farsi corpus is assembled from all the parallel news text in LDC2016E93 *Farsi Representative Language Pack* from the Linguistic Data Consortium, combined with English-Farsi parallel subtitles from the TED corpus (Tiedemann, 2012). Since the TED subtitles are user-contributed, this text contained considerable variation in the encoding of its Perso-Arabic characters. To address this issue, we have normalized the corpus using the Hazm toolkit[2]. Sentence pairs in which one of the sentences has more than 80 (before applying BPE) are removed, and BPE is performed with a 30k vocabulary size. Random subsets of this corpus (3k and 4k sentences each) are held out as validation and test sets, respectively.

- The English-Vietnamese is from the translation task in IWSLT 2015, and we use the preprocessed version provided by (Luong and Manning, 2015). The sentence pairs in which at least one of their sentences had more than 300 units (after applying BPE) are removed. "tst2012" and "tst2013" parts are used for validation and test sets, respectively.

5.2 Auxiliary Tasks

We have chosen the following auxiliary tasks to provide the NMT model with syntactic and/or semantic knowledge, in order to enhance the quality of translation:

Named-Entity Recognition (NER). With a small bilingual training corpus, it would be hard for the NMT model to learn how to translate rarely occurring named-entities. Through the NER task,

[2] www.sobhe.ir/hazm

the model hopefully learns the skill to recognize named entities. Speculatively, it would then enables leaning translation patterns by masking out named entities. The NER data comes from the CONLL shared task.[3]

Syntactic Parsing. This task enables NMT to learn the phrase structure of the input sentence, which would then be useful in better re-orderings. This would be most useful for language pairs with high syntactic divergence. The parsing data comes from the Penn Tree Bank with the standard split for training, development, and test (Marcus et al., 1993). We linearise the constituency trees, in order to turn syntactic parsing as a SEQ2SEQ transduction (Vinyals et al., 2015).

Semantic Parsing. A good translation should preserve the meaning. Learning from the semantic parsing task enables the NMT model to pay attention to a meaning abstraction of the source sentence, in order to convey it to the target translation. We have made use of the Abstract Meaning Representation (AMR) corpus Release 2.0 (LDC2017T10), which pairs English sentences AMR meaning graphs. We linearise the AMR graphs, in order to convert semantic parsing as a SEQ2SEQ transduction problem (Konstas et al., 2017).

5.3 Models and Baselines

We have implemented the proposed multi-task learning architecture in C++ using DyNet (Neubig et al., 2017), on top of Mantis (Cohn et al., 2016) which is an implementation of the attentional SEQ2SEQ NMT model in (**?**). In our multi-task architecture, we do partial sharing of parameters, where the parameters of the top 2 stacked layers are shared among the encoders of the tasks. Moreover, we share the parameters of the top layer stacked decoder among the tasks. Source and target embedding tables are shared among the tasks, while the attention component is task-specific. [4] We compare against the following baselines:

- Baseline 1: The vanila SEQ2SEQ model without any multi-tasking.
- Baseline 2: The multi-tasking architecture proposed in (Niehues and Cho, 2017), which is a special case of our approach where the parameters of all 3 stacked layers are shared among the tasks.[5] They have not used deep stacked layers in encoder and decoder as we do, so we extend their work to make it comparable with ours.

The configuration of models is as follows. The encoders and decoders make use of GRU units with 400 hidden dimensions, and the attention component has 200 dimensions. For training, we used Adam algorithm (Kingma and Ba, 2014) with the initial learning rate of 0.003 for all of the tasks. Learning rates are halved when the performance on the corresponding dev set decreased. In order to speed-up the training, we use mini-batching with the size of 32. Dropout rates for both encoder and decoder are set to 0.5, and models are trained for 50 epochs where the best models is selected based on the perplexity on the dev set. λ for the adversarial training is set to 0.5. Once trained, the NMT model translates using the greedy search. We use BLEU (Papineni et al., 2002) to measure translation quality. [6]

5.4 Results

Table 2 reports the BLEU scores and perplexities for the baseline and our proposed method on the three aforementioned translation tasks. It can be seen that the performance of multi-task learning models are better than Baseline 1 (only MT task). This confirms that adding auxiliary tasks helps to increase the performance of the machine translation task.

As expected, the effect of different tasks are not similar across the language pairs, possibly due to the following reasons: (i) these translation tasks datasets come from different domains so they have various degree of domain relatedness to the auxiliary tasks, and (ii) the BLEU scores of the Baseline 1 show that the three translation models are on different quality levels which may entail that they benefit from auxiliary knowledge on different levels. In order to improve a model with low quality translations due to language divergence, syntactic knowledge can be more helpful as they help better reorderings. In a higher-quality model, however, semantic knowledge can be more useful as

[3] https://www.clips.uantwerpen.be/conll2003/ner

[4] In our experiments, models with task-specific attention components achieved better results than those sharing them.

[5] We have used their best performing architecture and changed the training schedule to ours.

Table 3: Our method (partial parameter sharing) against Baseline 2 (full parameter sharing).

a higher-level linguistic knowledge. This pattern can be seen in the reported results: syntactic parsing leads to more improvement on Farsi translation which has a low BLEU score and high language divergence to English, and semantic parsing yields more improvement on the Vietnamese translation task which already has a high BLEU score. The NER task has led to a steady improvement in all the translation tasks, as it leads to better handling of named entities.

We have further added adversarial training to ensure the shared representation learned by the encoder is not contaminated by the task-specific information. The results are in the last row of Table 2. The experiments show that adversarial training leads to further gains in MTL translation quality, except when translating into Farsi. We speculate this is due to the low quality of NMT for Farsi, where updating shared parameters with respect to the entropy of discriminator's predicted distribution may negatively affect the model.

Table 3 compares our multi-task learning approach to Baseline 2. As Table 3, our partial parameter sharing mechanism is more effective than fully sharing the parameters (Baseline 2), due to its flexibility in allowing access to private task-specific knowledge. We also applied the adaptation technique (Niehues and Cho, 2017) as follows. Upon finishing MTL training, we continue to train only on the MT task for another 20 epochs, and choose the best model based on perplexity on dev set. Adaptation has led to consistent gains in the performance of our MTL architecture and Baseline 2.

5.5 Analysis

How many layers of encoder/decoder to share? Figure 2 show the results of changing the number of shared layers in encoder and decoder based on the En→Vi translation task. The results confirm that partial sharing of stacked layers is better than full sharing. Intuitively, partial sharing provides the model with an opportunity to learn task specific skills via the private layers, while leveraging the knowledge learned from other tasks via shared layers.

Statistics of gold n-grams in MTL translations. Generating high order gold n-grams is hard. We analyse the effect of syntactic and semantic knowledge on generating gold n-grams in translations.

For each sentence, we first extract n-grams in the gold translation, and then compute the number of n-grams which are common with the generated translations. Finally, after aggregating the results over the entire test set, we compute the percentage of additional gold n-grams generated by each MTL model compared to the ones in single-task MT model. The results are depicted in Figure 1. Interestingly, the MTL models generate more correct n-grams relative to the vanilla NMT model, as n increases.

Effect of the NER task. The NMT model has difficulty translating rarely occurring named-entities, particularly when the bilingual parallel data is scarce. We expect learning from the NER task leads the MTL model to recognize named-entities and learn underlying patterns for translating them. The top part in Table 4 shows an example of such situation. As seen, the MTL is able to recognize all of the named-entities in the sentence and translate the while the single-task model

Table 4: Example of translations on Farsi test set. In this examples each Farsi word is replaced with its English translation, and the order of words is reversed (Farsi is written right-to-left). The structure of Farsi is Subject-Object-Verb (SOV), leading to different word orders in English and Reference sentences.

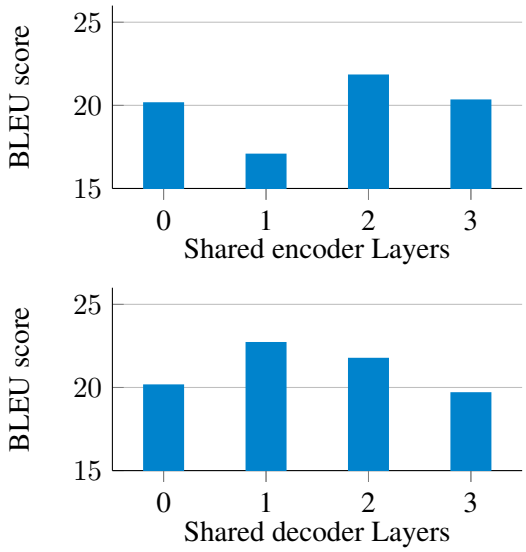

Figure 2: BLEU scores for different numbers of shared layers in (top) encoder while no layer is shared in decoder, and (bottom) decoder while no layer is shared in encoder

missed "India".

For more analysis, we have applied a Farsi POS tagger (Feely et al., 2014) to gold translations. Then, we extracted n-grams with at least one noun in them, and report the statistics of correct such n-grams, similar to what reported in Figure 1. The resulting statistics is depicted in Figure 3. As seen, the MTL model trained on MT and NER tasks leads to generation of more correct unigram noun phrases relative to the vanilla NMT, as n increases.

Effect of the semantic parsing task. Semantic parsing encourages a precise understanding of the source text, which would then be useful for conveying the correct meaning to the translation. The middle part in Table 4 is an example translation, showing that semantic parsing has helped NMT by understanding that "the subject sees the object via subject's screens".

Effect of the syntactic parsing task. Recognizing the syntactic structure of the source sentence helps NMT to better translate phrases. The bottom part of Table 4 shows an example translation demonstrating such case. The source sentence is talking about "a method for controlling the

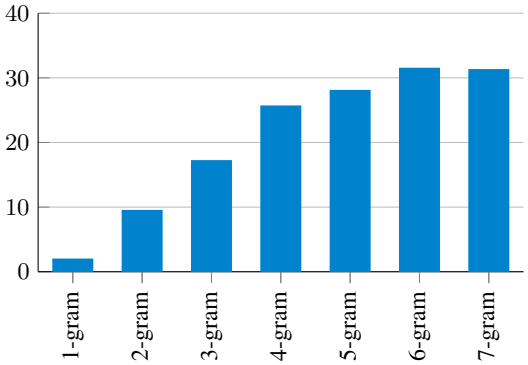

Figure 3: Percentage of more corrected n-grams with at least one noun generated by MT+NER model compared with the only MT model (only MT).

traffic", which is correctly translated by the MTL model while vanilla NMT has mistakenly translated it to "controlled traffic".

6 Related Work

Multi-task learning has attracted attention to improve NMT in recent work. (Zhang and Zong, 2016) has made use of monolingual data in the source language in a multitask learning framework by sharing encoder in the attentional encoder-decoder model. Their auxiliary task is to reorder the source text to make it close to the target language word order. (Domhan and Hieber, 2017) proposed a two-layer stacked decoder, which the bottom layer is trained on language modelling on the target language text. The next word is jointly predicted by the bottom layer language model and the top layer attentional RNN decoder. They reported only moderate improvements over the baseline and fall short against using synthetic parallel data. (Dalvi et al., 2017) investigated the amount of learned morphology and how it can be injected using MTL. Our method is related to what they call joint data-learning, where they share all of the SEQ2SEQ components among the tasks.

(Belinkov et al., 2017a; Shi et al., 2016; Belinkov et al., 2017b) investigate syntax/semantics phenomena learned as a byproduct of SEQ2SEQ NMT training. We, in turn, investigate the effect of injecting syntax/semantic on learning NMT using MTL.

The closet work to ours is (Niehues and Cho, 2017), which has made use of part-of-speech tagging and named-entity recognition tasks to improve NMT. They have used the attentional encoder-decoder with a shallow architecture, and share different parts eg the encoder, decoder, and attention. They report the best performance with fully sharing the encoder. In contrast, our architecture uses partial sharing on deep stacked encoder and decoder components, and the results show that it is critical for NMT improvement in MTL. Furthermore, we propose adversarial training to prevent contamination of shared knowledge with task specific details.

Taking another approach to MTL, (Søgaard and Goldberg, 2016) and (Hashimoto et al., 2017) have proposed architectures by stacking up tasks on top of each other according to their linguistic level, eg from lower level tasks (POS tagging) to higher level tasks (parsing). In this approach, each task uses predicted annotations and hidden states of the lower-level tasks for making a better prediction. This is contrast to the approach taken in this paper where models with shared parameters are trained jointly on multiple tasks.

More broadly, deep multitask learning has been used for various NLP problems, including graph-based parsing (Chen and Ye, 2011) and keyphrase boundary classification (Augenstein and Søgaard, 2017) . (Chen et al., 2017) has applied multi-task learning for Chinese word segmentation, and (Liu et al., 2017) applied it for text classification problem. Both of these works have used adversarial training to make sure the shared layer extract only common knowledge.

MTL has been used effectively to learn from multimodal data. (Luong et al., 2016) has proposed MTL architectures for neural SEQ2SEQ transduction for tasks including MT, image caption generation, and parsing. They fully share the encoders (many-to-one), the decoders (one-to-many), or some of the encoders and decoders (many-to-many). (Pasunuru and Bansal, 2017) have made use of an MTL approach to improve video captioning with auxiliary tasks including video prediction and logical language entailment based on a many-to-many architecture.

7 Conclusions and Future Work

We have presented an approach to improve NMT in bilingually scarce scenarios, by leveraging curated linguistic resources in the source, including semantic parsing, syntactic parsing, and named entity recognition. This is achieved via an effective MTL architecture, based on deep stacked en-

coders and decoders, to share common knowledge among the MT and auxiliary tasks. Our experimental results show substantial improvements in the translation quality, when translating from English to French, Vietnamese, and Farsi in bilingually scarce scenarios. For future work, we would like to investigate architectures which allow automatic parameter tying among the tasks (Ruder et al., 2017).

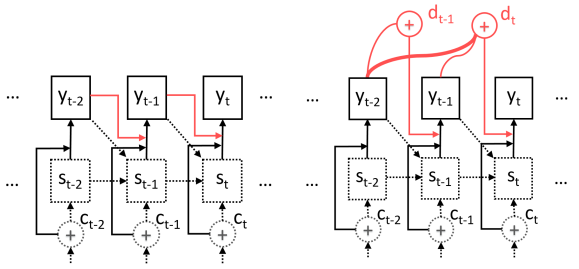
Abstract

Neural sequence-to-sequence networks with attention have achieved remarkable performance for machine translation. One of the reasons for their effectiveness is their ability to capture relevant source-side contextual information at each time-step prediction through an attention mechanism. However, the target-side context is solely based on the sequence model which, in practice, is prone to a recency bias and lacks the ability to capture effectively non-sequential dependencies among words. To address this limitation, we propose a target-side-attentive residual recurrent network for decoding, where attention over previous words contributes directly to the prediction of the next word. The residual learning facilitates the flow of information from the distant past and is able to emphasize any of the previously translated words, hence it gains access to a wider context. The proposed model outperforms a neural MT baseline as well as a memory and self-attention network on three language pairs. The analysis of the attention learned by the decoder confirms that it emphasizes a wider context, and that it captures syntactic-like structures.

1 Introduction

Neural machine translation (NMT) has recently become the state-of-the-art approach to machine translation (Bojar et al., 2016). Several architectures have been proposed for this task (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Gehring et al., 2017; Vaswani et al., 2017), but the attention-based NMT model designed by Bahdanau et al. (2015) is still considered the de-facto baseline. This architecture is composed of two recurrent neural networks (RNNs), an encoder and a decoder, and an attention mechanism between them for modeling a soft word-alignment. First, the model encodes the complete source sentence, and then decodes one word at a time. The decoder has access to all the context on the source side through the attention mechanism. However, on the target side, the contextual information is represented only through a fixed-length vector, namely the hidden state of the decoder. As observed by Bahdanau et al. (2015), this creates a bottleneck which hinders the ability of the sequential model to learn longer-term information effectively.



(a) Baseline NMT decoder (b) Self-attentive residual dec.

Figure 1: Comparison between the decoder of the baseline NMT and the proposed decoder with self-attentive residual connections.

As pointed out by Cheng et al. (2016), sequential models present two main problems for natural language processing. First, the memory of the encoder is shared across multiple words and is prone to bias towards the recent past. Second, such models do not fully capture the structural composition of language. To address these limitations, several recent models have been proposed, namely memory networks (Cheng et al., 2016; Tran et al., 2016; Wang et al., 2016) and self-attention networks (Daniluk et al., 2016; Liu and Lapata, 2018). We experimented with these methods, applying them to NMT: *memory RNN* (Cheng et al., 2016) and *self-attentive RNN* (Daniluk et al., 2016). How-

ever, we observed no significant gains in performance over the baseline architecture.

In this paper, we propose a self-attentive residual recurrent decoder, presented in Figure 1b, which, if unfolded over time, represents a densely-connected residual network. The self-attentive residual connections focus selectively on previously translated words and propagate useful information to the output of the decoder, within an attention-based NMT architecture. The attention paid to the previously predicted words is analogous to a read-only memory operation, and enables the learning of syntactic-like structures which are useful for the translation task.

Our evaluation on three language pairs shows that the proposed model improves over several baselines, with only a small increase in computational overhead. In contrast, other similar approaches have lower scores but a higher computational overhead. The contributions of this paper can be summarized as follows:

- We propose and compare several options for using self-attentive residual learning within a standard decoder, which facilitates the flow of contextual information on the target side.
- We demonstrate consistent improvements over a standard baseline, and two advanced variants, which make use of memory and self-attention on three language pairs (English-to-Chinese, Spanish-to-English, and English-to-German).
- We perform an ablation study and analyze the learned attention function, providing additional insights on its actual contributions.

2 Related Work

Several studies have been proposed to enhance sequential models by capturing longer contexts. Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) is the most commonly used recurrent neural network (RNN), because its internal memory allows to retain information from a more distant past than a vanilla RNN. Several studies attempt to increase the memory capacity of LSTMs by using memory networks (Weston et al., 2015; Sukhbaatar et al., 2015). For instance, Cheng et al. (2016) incorporate different memory cells for each previous output representation, which are later accessed by an attention mechanism. Tran et al. (2016) include a memory block to access recent input words in a selective manner. Both methods show improvements on language modeling. For NMT, Wang et al. (2016) presented a decoder enhanced with an external shared memory. Memory networks extend the capacity of the network and have the potential to read, write, and forget information. Our method, which attends over previously predicted words, can be seen as a read-only memory, which is simpler but computationally more efficient because it does not require additional memory space.

Other studies aim to improve the modeling of source-side contextual information, for example through a context-aware encoder using self-attention (Zhang et al., 2017), or a recurrent attention NMT (Yang et al., 2017) that is aware of previously attended words on the source-side in order to better predict which words will be attended in future. Additionally, variational NMT (Zhang et al., 2016a) introduces a latent variable to model the underlying semantics of source sentences. In contrast to these studies, we focus instead on the contextual information *on the target side*.

The application of self-attention mechanisms to RNNs have been previously studied, and in general, they seem to capture syntactic dependencies among distant words (Liu and Lapata, 2018; Soltani and Jiang, 2016; Lee et al., 2017; Lin et al., 2017). Daniluk et al. (2016) explore different approaches to self-attention for language modeling, leading to improvements over a baseline LSTM and over memory-augmented methods. However, the methods do not fully utilize a longer context. The main difference with our approach is that we apply attention on the output embeddings rather than the hidden states. Thus, the connections are independent of the recurrent layer representations, which is beneficial to NMT, as we show below.

Our model relies on residual connections, which have been shown to improve the learning process of deep neural networks by addressing the vanishing gradient problem (He et al., 2016). These connections create a direct path from previous layers, helping the transmission of information. Recently, several architectures using residual connections with LSTMs have been proposed for sequence prediction (Zhang et al., 2016b; Kim et al., 2017; Zilly et al., 2017; Wang and Tian, 2016). To our knowledge, our study is the first one to use self-attentive residual connections within residual RNNs for NMT. In parallel to our study, a similar method was recently proposed for sentiment analysis (Wang, 2017).

3 Background: Neural Machine Translation

Neural machine translation aims to compute the conditional distribution of emitting a sentence in a target language given a sentence in a source language, denoted by $p_\Theta(y|x)$, where Θ is the set of parameters of the neural model, and $y = \{y_1, ..., y_n\}$ and $x = \{x_1, ..., x_m\}$ are respectively the representations of source and target sentences as sequences of words. The parameters Θ are learned by training a sequence-to-sequence neural model on a corpus of parallel sentences. In particular, the learning objective is to maximize the following conditional log-likelihood:

$$\max_{\Theta} \frac{1}{N} \sum_{n=1}^{N} \log(p_\Theta(y|x)) \quad (1)$$

The models typically use gated recurrent units (GRUs) (Cho et al., 2014) or LSTMs (Hochreiter and Schmidhuber, 1997). Their architecture has three main components: an encoder, a decoder, and an attention mechanism.

The goal of the encoder is to build meaningful representations of the source sentences. It consists of a bidirectional RNN which includes contextual information from past and future words into the vector representation h_i of a particular word vector x_i, formally defined as follows:

$$h_i = [\overrightarrow{h_i}, \overleftarrow{h_i}] \quad (2)$$

Here, $\overrightarrow{h_i} = f(x_i, h_{i-1})$ and $\overleftarrow{h_i} = f(x_i, h_{i+1})$ are the hidden states of the forward and backward passes of the bidirectional RNN respectively, and f is a non-linear function.

The decoder (see Figure 1a) is in essence a recurrent language model. At each time step, it predicts a target word y_t conditioned over the previous words and the information from the encoder using the following posterior probability:

$$p(y_t|y_1, ..., y_{t-1}, c_t) \approx g(s_t, y_{t-1}, c_t) \quad (3)$$

where g is a non-linear multilayer function. The hidden state of the decoder s_t is defined as:

$$s_t = f(s_{t-1}, y_{t-1}, c_t) \quad (4)$$

and depends on a *context vector* c_t that is computed by the attention mechanism.

The attention mechanism allows the decoder to select which parts of the source sentence are more useful to predict the next output word. This goal is achieved by considering a weighted sum over all hidden states of the encoder as follows:

$$c_t = \sum_{i=1}^{m} \alpha_i^t h_i \quad (5)$$

where α_i^t is a weight calculated using a normalized exponential function a, also known as *alignment function*, which computes how good is the match between the input at position $i \in \{1, ..., n\}$ and the output at position t:

$$\alpha_i^t = softmax(e_i^t) \quad (6)$$

$$e_i^t = a(s_{t-1}, h_i) \quad (7)$$

Different types of alignment functions have been used for NMT, as investigated by Luong et al. (2015). Here, we use the one originally defined by Bahdanau et al. (2015).

4 Self-Attentive Residual Decoder

The decoder of the attention-based NMT model uses a skip connection from the previously predicted word to the output classifier in order to enhance the performance of translation. As we can see in Eq. (3), the probability of a particular word is calculated by a function g which takes as input the hidden state of the recurrent layer s_t, the representation of the previously predicted word y_{t-1}, and the context vector c_t. Within g, these quantities are typically summed up after going through simple linear transformations, hence the addition of y_{t-1} is indeed a skip connection as in residual networks (He et al., 2016). In theory, s_t should be sufficient for predicting the next word given that it is dependent on the other two local-context components according to Eq. (4). However, the y_{t-1} quantity makes the model emphasize the last predicted word for generating the next word. How can we make the model consider a broader context?

To answer this question, we propose to include into the decoder's formula skip connections not only from the previous time step y_{t-1}, but from all previous time steps from y_0 to y_{t-1}. This defines a residual recurrent network which, unfolded over time, can be seen as a densely connected residual network. These connections are applied to all previously predicted words, and reinforce the memory of the recurrent layer towards what has been translated so far. At each time step, the model

decides which of the previously predicted words should be emphasized to predict the next one. In order to deal with the dynamic length of this new input, we use a target-side summary vector d_t that can be interpreted as the representation of the decoded sentence until the time t in the word embedding space. We therefore modify Eq. (3) replacing y_{t-1} with d_t:

$$p(y_t|y_1, ..., y_{t-1}, c_t) \approx g(s_t, d_t, c_t) \quad (8)$$

The replacement of y_{t-1} with d_t means that the number of parameters added to the model is dependent only on the calculation of d_t. Figure 1b illustrates the change made to the decoder. We define two methods for summarizing the context into d_t, which are described in the following sections.

4.1 Mean Residual Connections

One simple way to aggregate information from multiple word embeddings is by averaging them. This average can be seen as the sentence representation until time t. We hypothesize that this representation is more informative than using only the embedding of the previous word. Formally:

$$d_t^{avg} = \frac{1}{t-1} \sum_{i=1}^{t-1} y_i \quad (9)$$

4.2 Self-Attentive Residual Connections

Averaging is a simple and cheap way to aggregate information from multiple words, but may not be sufficient for all kinds of dependencies. Instead, we propose a dynamic way to aggregate information in each sentence, such that different words have different importance according to their relation with the prediction of the next word. We propose to use a shared self-attention mechanism to obtain a summary representation of the translation, i.e. a *weighted average representation* of the words translated from y_0 to y_{t-1}. This mechanism aims to model, in part, important non-sequential dependencies among words, and serves as a complementary memory to the recurrent layer.

$$d_t^{cavg} = \sum_{i=1}^{t-1} \alpha_i^t y_i \quad (10)$$

$$\alpha_i^t = softmax(e_i^t) \quad (11)$$

The weights of the attention model are computed by a scoring function e_i^t that predicts how important each previous word (y_0, ..., or y_{t-1}) is for the current prediction y_t.

We experiment with two different scoring functions, as follows:

$$e_i^t = v^\intercal tanh(W_y y_i + W_s s_t) \ \textit{(content+scope)} \quad (12)$$

$$\text{or } e_i^t = v^\intercal tanh(W_y y_i) \ \textit{(content)} \quad (13)$$

where $v \in \mathbb{R}^e$, $W_y \in \mathbb{R}^{e \times e}$, and $W_s \in \mathbb{R}^{e \times d}$ are weight matrices, e and d are the dimensions of the embeddings and hidden states respectively. Firstly, we study the scoring function noted *content+scope*, as proposed by Bahdanau et al. (2015) for NMT. Secondly, we explore a scoring function noted as *content*, which is calculated based only on the previous hidden states of the decoder, as proposed by Pappas and Popescu-Belis (2017). In contrast to the first attention function, which makes use of the hidden vector s_t, the second one is based only on the previous word representations, therefore, it is independent of the current prediction representation. However, the normalization of this function still depends on t.

5 Other Self-Attentive Networks

To compare our approach with similar studies, we adapted two representative self-attentive networks for application to NMT.

5.1 Memory RNN

The *Memory RNN* decoder is based on the proposal by Cheng et al. (2016) to modify an LSTM layer to include a memory with different cells for each previous output representation. Thus at each time step, the hidden layer can select past information dynamically from the memory. To adapt it to our framework, we modify Eq. (4) as:

$$s_t = f(\tilde{s}_t, y_{t-1}, c_t) \quad (14)$$

$$\text{where} \quad \tilde{s}_t = \sum_{i=1}^{t-1} \alpha_i^t s_i \quad (15)$$

$$\alpha_i^t = softmax(e_i^t) \quad (16)$$

$$e_i^t = a(h_i, y_{t-1}, \tilde{s}_{t-1}) \quad (17)$$

5.2 Self-Attentive RNN

The *Self-Attentive RNN* is the simplest one proposed by Daniluk et al. (2016), and incorporates a summary vector from past predictions calculated with an attention mechanism. Here, the attention is applied over previous hidden states. This decoder is formulated as follows:

$$p(y_t|y_1, ..., y_{t-1}, c_t) \approx g(s_t, y_{t-1}, c_t, \tilde{s}_t) \quad (18)$$

$$\text{where} \quad \tilde{s}_t = \sum_{i=1}^{t-1} \alpha_i^t s_i \tag{19}$$

$$\alpha_i^t = softmax(e_i^t) \tag{20}$$

$$e_i^t = a(s_i, s_t) \tag{21}$$

Additional details of the formulations in Sections 3, 4, and 5 are described in the Appendix A.

6 Experimental Settings

6.1 Datasets

To evaluate the proposed MT models in different conditions, we select three language pairs with increasing amounts of training data: English-Chinese (0.5M sentence pairs), Spanish-English (2.1M), and English-German (4.5M).

For English-to-Chinese, we use a subset of the UN parallel corpus (Rafalovitch and Dale, 2009)[1], with 0.5M sentence pairs for training, 2K for development, and 2K for testing. For training Spanish-to-English MT, we use a subset of WMT 2013 (Bojar et al., 2013), corresponding to Europarl v7 and News Commentary v11 with ca. 2.1M sentence pairs. Newstest2012 and Newstest2013 were used for development and testing respectively. Finally, we use the complete English-to-German set from WMT 2016 (Bojar et al., 2016) with a total of ca. 4.5M sentence pairs. The development set is Newstest2013, and the testing set is Newstest2014. Additionally, we include as testing sets Newstest2015 and Newstest2016, for comparison with the state of the art. We report translation quality using (a) BLEU over *tokenized* and *truecased* texts, and (b) NIST BLEU over *detokenized* and *detruecased* texts[2].

6.2 Model Configuration

We use the implementation of the attention-based NMT baseline provided in `dl4mt-tutorial`[3] developed in Python using Theano (Theano Development Team, 2016). The system implements an attention-based NMT model, described above, using one layer of GRUs (Cho et al., 2014). The vocabulary size is 25K for English-to-Chinese NMT, and 50K for Spanish-to-English and English-German. We use the byte pair encoding (BPE) strategy for out-of-vocabulary words (Sennrich et al., 2016b). For all cases, the maximum sentence length of the training samples is 50, the dimension of the word embeddings is 500, and the dimension of the hidden layers is 1,024. We use dropout with a probability of 0.5 after each layer. The parameters of the models are initialized randomly from a standard normal distribution scaled to a factor of 0.01. The loss function is optimized using Adadelta (Zeiler, 2012) with $\epsilon = 10^{-6}$ and $\rho = 0.95$ as in the original paper. The systems were trained in 7–12 days for each model on a Tesla K40 GPU at the speed of about 1,000 words/sec.

7 Analysis of the Results

Table 1 shows the BLEU scores and the number of parameters used by the different NMT models. Along with the NMT baseline, we included a statistical machine translation (SMT) model based on Moses (Koehn et al., 2007) with the same training/tuning/test data as the NMT. The performance of *memory RNN* is similar to the baseline and, as confirmed later, its focus of attention is mainly on the prediction at $t-1$. The *self-attentive RNN* method is inferior to the baseline, which can be attributed to the overhead on the hidden vectors that have to learn the recurrent representations and the attention simultaneously. The proposed models outperform the baseline, and the best scores are obtained by the NMT model with *self-attentive residual connections*. Despite their simplicity, the *mean residual connections* already improve the translation, without increasing the number of parameters.

Tables 2 and 3 show further experiments with the proposed methods on various English-German test sets, compared to several previous systems.

Table 3: NIST BLEU scores on *detokenized* and *detruecased* text for English-to-German on *Newstest (NT) 2014, 2015, 2016*. Significance test: * $p < 0.05$, ** $p < 0.01$. The Winning WMT systems are listed in the text below.

Table 2 shows BLEU values calculated by *multi-bleu*, and includes the NMT system proposed by Luong et al. (2015) which replaces unknown predicted words with the most strongly aligned word on the source sentence. Also, the table includes other systems described in Section 2. Additionally, Table 3 shows values calculated by the NIST BLEU scorer, as well as results reported by the "Winning WMT" systems for each test set respectively: UEDIN-SYNTAX (Williams et al., 2014), UEDIN-SYNTAX (Williams et al., 2015), and UEDIN-NMT (Sennrich et al., 2016a). Also, we include the results reported by Sennrich et al. (2016b) for a baseline encoder-decoder NMT with BPE for unknown words similar to our configuration, and finally the system proposed by Nadejde et al. (2017), an explicit syntax-aware NMT that introduces combinatory categorial grammar (CCG) supertags on the target side by predicting words and tags alternately. The comparison with this work is relevant for the analysis described later in Section 8.2. The results confirm that the *self-attentive residual connections* improve significantly the translations. To evaluate the significance of the improvements against the NMT baseline, we performed a one-tailed paired t-test.

Content+Scope	23.1	25.6
Content	**24.0**	**26.3**

Table 4: BLEU scores for two scoring variants of the attention function of the proposed decoder.

7.1 Impact of the Attention Function

We now examine the two scoring functions that can be used for the *self-attentive residual connections* model presented in Eq. (12), considering English-to-Chinese and Spanish-to-English. The BLEU scores are presented in Table 4: the best option is the *content* matching function, which depends only on the word embeddings. The *content+scope* function, which depends additionally on the hidden representation of the current prediction is better than the baseline but scores lower than *content*. The idea that the importance of the context depends on the current prediction is appealing, because it can be interpreted as learning internal dependencies among words. However, the experimental results show that it does not necessarily lead to the best translation. On the contrary, the *content* attention function may be extracting representations of the whole sentence which are easier to learn and generalize.

7.2 Performance According to Human Evaluation

Manual evaluation on samples of 50 sentences for each language pair helped to corroborate the conclusions obtained from the BLEU scores, and to provide a qualitative understanding of the improvements brought by our model. For each language, we employed one evaluator who was a native speaker of the target language and had good knowledge of the source language. The evaluators ranked three translations of the same source sentence – one from each of our models: *baseline*, *mean residual connections*, and *self-attentive residual connections* – according to their translation quality. The three translations were presented in a random order, so that the system that had generated them could not be identified. To integrate

	Ranking (%)								
System	**En–Zh**			**Es–En**			**En–De**		
	>	=	<	>	=	<	>	=	<
Mean vs. Baseline	26	56	18	20	64	16	28	58	24
Self-attentive vs. Baseline	28	60	12	28	56	16	32	54	14
Self-attentive vs. Mean	24	62	14	28	58	14	32	56	12

Table 5: Human evaluation of sentence-level translation quality on three language pairs. We compare the models in pairs, indicating the percentages of sentences that were ranked higher (>), equal to (=), or lower (<) for the first system with respect to the second one. The values correspond to percentages (%).

Systems	d	**Perplexity**
LSTM (Daniluk et al., 2016)	300	85.2
LSTM + Attention (Daniluk et al., 2016)	296	82.0
LSTM + 4-gram (Daniluk et al., 2016)	968	75.9
LSTM + Mean residual connections	296	80.2
LSTM + Self-attentive residual connections	296	80.4

Table 6: Evaluation of the proposed methods on language modeling. The number of parameter for all models is 47M.

the judgments, we proceed in pairs, and count the number of times each system was ranked higher, equal to, or lower than another competing system. The results shown in Table 5 indicate that the *self-attentive residual connections* model outperforms the one with *mean residual connections*, and both outperform the baseline, for all three language pairs. The rankings are thus identical to those obtained using BLEU in Tables 1 and 3.

7.3 Performance on Language Modeling

To examine whether language modeling (LM) can benefit from the proposed method, we incorporate the residual connections into a neural LM. We use the same setting as Daniluk et al. (2016) for a corpus of Wikipedia articles (22.5M words), and we compare with two methods proposed in the same paper, namely attention LSTM and 4-gram LSTM. As shown in Table 6, the proposed models outperform the LSTM baseline as well as the self-attention model, but not the 4-gram LSTM. Experiments using 4-gram LSTM for NMT showed poor performance (13.9 BLEU points for English-Chinese) which can be attributed to the difference between the LM and NMT tasks. Both tasks predict one word at a time conditioned over previous words, however, in NMT the previous target-word-inputs are not given, they have to be generated by the decoder. Thus, the output could be conditioned over previous erroneous predictions

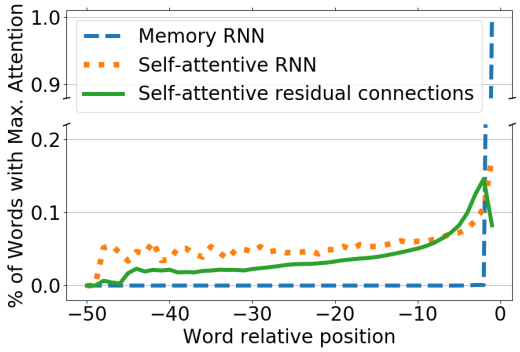

Figure 2: Percentage of words that received maximum attention at a given relative position, ranging from -1 to -50 (maximum length).

affecting in higher proportion the 4-gram LSTM model. This shows that even if a model improves language modeling, it does not necessarily improve machine translation.

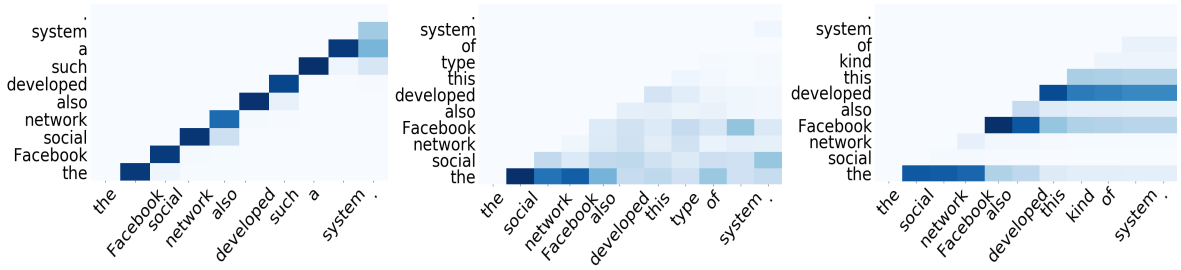
8 Qualitative Analysis

8.1 Distribution of Attention

Figure 2 shows a comparison of the distribution of attention of the different self-attentive models described in this paper, on Spanish-to-English NMT (the other two language pairs exhibit similar distributions). The values correspond to the number of words which received maximal attention for each relative position (x-axis). We selected, at each prediction, the preceding word with maximal weight, and counted its relative position. We normalized the count by the number of previous words at the time of each prediction.

We observe that the *memory RNN* almost always selects the immediately previous word ($t-1$) and ignores the rest of the context. On the contrary, the other two models distribute attention more evenly among all previous words. In particular, the *self-attentive RNN* uses a longer context than the *self-attentive residual connections* but, as the performance on BLEU score shows, this fact does not necessarily mean better translation.

Figure 3 shows the attention to previous words generated by each model for one sentence translated from Spanish to English. The matrices present the target-side attention weights, with the vertical axis indicating the previous words, and the color shades at each position (cell) representing the attention weights. The weights of the *memory RNN* are concentrated on the diagonal, indicating that the attention is generally located on



(a) Memory RNN (b) Self-attentive RNN (c) Self-attentive residual connections

Figure 3: Matrix of distribution of the attention weights to previous words. The vertical axis represents the previous words. A darker shade indicates a higher attention weight.

the previous word, which makes the model almost equivalent to the baseline. The weights of the *self-attentive RNN* show that attention is more distributed towards the distant past, and they vary for each word because the attention function depends on the current prediction. This model tries to find dependencies among words, although complex relations seem difficult to learn. On the contrary, the proposed *self-attentive residual connections* model strongly focuses on particular words, and we present a wider analysis of it in the following section.

8.2 Structures Learned by the Model

When visualizing the matrix of attention weights generated by our model (Figure 3c), we observed the formation of sub-phrases which are grouped depending on their attention to previous words. To build the sub-phrases in a deterministic fashion, we implemented Algorithm 1, which iteratively splits the sentence into two sub-phrases every time the focus of attention changes to a new word, from left-to-right. The results are binary tree structures containing the sub-phrases, exemplified in Figure 4.

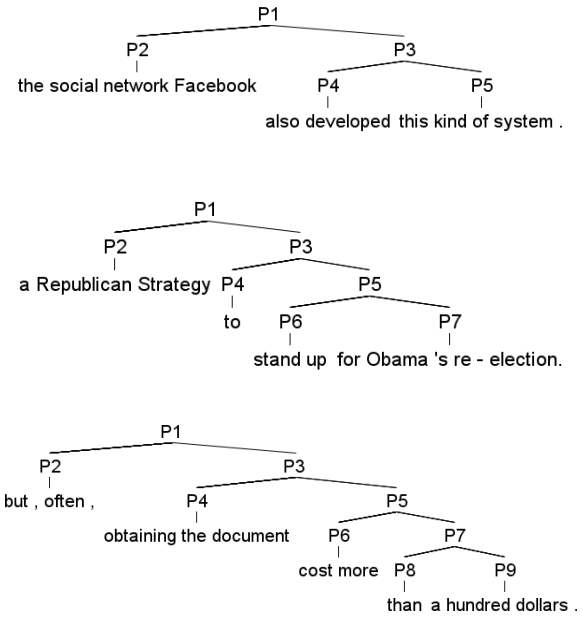

Figure 4: Examples of hypothesized syntactic structures obtained with Algorithm 1.

We formally evaluate the syntactic properties of the binary tree structures by comparing them with the results of an automatic constituent parser (Manning et al., 2014), using the ParsEval approach (Black et al., 1991), i.e. by counting the precision and recall of constituents, excluding single words. Our models reaches a precision of 0.56, which is better than the precision of 0.45 obtained by a trivial right-branched tree model[4]. Note that these structures were neither optimized for parsing nor learned using part-of-speech tagging as most parsers do. Our interpretation of the results is that they are "syntactic-like" structures. However, given the simplicity of the model, they could

[4]A model constructed by dividing iteratively one word and the rest of the sentence, from left-to-right.

also be viewed as more limited structures, similar to sentence chunks.

8.3 Translation Examples

Table 7 shows examples of translations produced with the baseline and the *self-attentive residual connections* model. The first part shows examples for which the proposed model reached a higher BLEU score than the baseline. Here, the structure of the sentences, or at least the word order, are improved. The second part contains examples where the baseline achieved better BLEU score than our model. In the first example, the structure of the sentence is different but the content and quality are similar, while in the second one lexical choices differ from the reference.

9 Conclusion

We presented a novel decoder which uses self-attentive residual connections to previously translated words in order to enrich the target-side contextual information in NMT. To cope with the variable lengths of previous predictions, we proposed two methods for context summarization: *mean residual connections* and *self-attentive residual connections*. Additionally, we showed how similar previous proposals, designed for language modeling, can be adapted to NMT. We evaluated the methods over three language pairs: Chinese-to-English, Spanish-to-English, and English-to-German. In each case, we improved the BLEU score compared to the NMT baseline and two variants with memory-augmented decoders. A manual evaluation over a small set of sentences for each language pair confirmed the improvement. Finally, a qualitative analysis showed that the proposed model distributes weights throughout an entire sentence, and learns structures resembling syntactic ones.

As future work, we plan to enrich the present attention mechanism with the *key-value-prediction* technique (Daniluk et al., 2016; Miller et al., 2016) which was shown to be useful for language modeling. Moreover, we will incorporate relative positional information to the attention function. To encourage further research in *self-attentive residual connections* for NMT an other similar tasks, our code is made publicly available[5].

A Detailed Architecture

This appendix describes in detail the implementation of the *self-attentive residual decoder* for NMT, which builds on the attention-based NMT implementation of `dl4mt-tutorial`[6].

The input of the model is a source sentence denoted as 1-of-k coded vector, where each element of the sequence corresponds to a word:

$$x = (x_1, x_2, ..., x_m), x_i \in \mathbb{R}^V$$

and the output is a target sentence denoted as well as 1-of-k coded vector:

$$y = (y_1, y_2, ..., y_n), y_i \in \mathbb{R}^V$$

where V is the size of the vocabulary of target and source side, m and n are the lengths of the source and target sentences respectively. We omit the bias vectors for simplicity.

A.1 Encoder

Each word of the source sentence is embedded in a e-dimensional vector space using the embedding matrix $\bar{E} \in \mathbb{R}^{e \times V}$. The hidden states are $2d$-dimensional vectors modeled by a bi-directional GRU. The forward states $\overrightarrow{h} = (\overrightarrow{h}_1, ..., \overrightarrow{h}_m)$ are computed as:

$$\overrightarrow{h}_i = \overrightarrow{z}_i \odot \overrightarrow{h}_{i-1} + (1 - \overrightarrow{z}_i) \odot \overrightarrow{h}'_i$$

where

$$\overrightarrow{h}'_i = tanh(\overrightarrow{W}\bar{E}x_i + \overrightarrow{U}[\overrightarrow{r}_i \odot \overrightarrow{h}_{i-1}])$$
$$\overrightarrow{z}_i = \sigma(\overrightarrow{W}_z\bar{E}x_i + \overrightarrow{U}_z\overrightarrow{h}_{i-1})$$
$$\overrightarrow{r}_i = \sigma(\overrightarrow{W}_r\bar{E}x_i + \overrightarrow{U}_r\overrightarrow{h}_{i-1})$$

Here, $\overrightarrow{W}, \overrightarrow{W}_z, \overrightarrow{W}_r \in \mathbb{R}^{d \times e}$ and $\overrightarrow{U}, \overrightarrow{U}_z, \overrightarrow{U}_r \in \mathbb{R}^{d \times d}$ are weight matrices. The backward states $\overleftarrow{h} = (\overleftarrow{h}_1, ..., \overleftarrow{h}_m)$ are computed in similar manner. The embedding matrix $\bar{E}$ is shared for both passes, and the final hidden states are formed by the concatenation of them:

$$h_i = \begin{bmatrix} \overrightarrow{h}_i \\ \overleftarrow{h}_i \end{bmatrix}$$

A.2 Attention Mechanism

The *context vector* at time t is calculated by:

$$c_t = \sum_{i=1}^{m} \alpha_i^t h_i$$

[6] https://github.com/nyu-dl/dl4mt-tutorial

where

$$\alpha_i^t = \frac{exp(e_i^t)}{\sum_j exp(e_j^t)}$$
$$e_i^t = v_a^\intercal tanh(W_d s_{t-1} + W_e h_i)$$

Here, $v_a \in \mathbb{R}^d$, $W_d \in \mathbb{R}^{d \times d}$ and $W_e \in \mathbb{R}^{d \times 2d}$ are weight matrices.

A.3 Decoder

The input of the decoder are the previous word y_{t-1} and the *context vector* c_t, the objective is to predict y_t. The hidden states of the decoder $s = (s_1, ..., s_n)$ are initialized with the mean of the *context vectors*:

$$s_0 = tanh(W_{init} \frac{1}{m} \sum_{i=1}^{m} c_i)$$

where $W_{init} \in \mathbb{R}^{d \times 2d}$ is a weight matrix, m is the size of the source sentence. The following hidden states are calculated with a GRU conditioned over the *context vector* at tine t as follows:

$$s_t = z_t \odot s'_t + (1 - z_t) \odot s''_t$$

where

$$s''_t = tanh(Ey_{t-1} + U[r_t \odot s_{t-1}] + Cc_t)$$
$$z_i = \sigma(W_z Ey_{t-1} + U_z s_{t-1} + C_z c_t)$$
$$r_i = \sigma(W_r Ey_{t-1} + U_r s_{t-1} + C_r c_t)$$

Here, $E \in \mathbb{R}^{e \times V}$ is the embedding matrix for the target language. $W, W_z, W_r \in \mathbb{R}^{d \times e}$, $U, U_z, U_r \in \mathbb{R}^{d \times d}$, and $C, C_z, C_r \in \mathbb{R}^{d \times 2d}$ are weight matrices. The intermediate vector s'_t is calculated from a simple GRU:

$$s'_t = GRU(y_{t-1}, s_{t-1})$$

In the attention-based NMT model, the probability of a target word y_t is given by:

$$p(y_t|s_t, y_{t-1}, c_t) = softmax(W_o tanh(W_{st} s_t + W_{yt} y_{t-1} + W_{ct} c_t))$$

Here, $W_o \in \mathbb{R}^{V \times e}$, $W_{st} \in \mathbb{R}^{e \times d}$, $W_{yt} \in \mathbb{R}^{e \times e}$, $W_{ct} \in \mathbb{R}^{e \times 2d}$ are weight matrices.

A.3.1 Self-Attentive Residual Connections

In our model, the probability of a target word y_t is given by:

$$p(y_t|s_t, d_t, c_t) = softmax(W_o tanh(W_{st} s_t + W_{dt} d_t + W_{ct} c_t))$$

Here, $W_o \in \mathbb{R}^{V \times e}$, $W_{st} \in \mathbb{R}^{e \times d}$, $W_{dt}, W_{yt} \in \mathbb{R}^{e \times e}$, $W_{ct} \in \mathbb{R}^{e \times 2d}$ are weight matrices. The summary vector d_t can be calculated in different manners based on previous words y_1 to y_{t-1}. First, a simple average:

$$d_t^{avg} = \frac{1}{t-1} \sum_{i=1}^{t-1} y_i$$

The second, by using an attention mechanism:

$$d_t^{cavg} = \sum_{i=1}^{t-1} \alpha_i^t y_i$$
$$\alpha_i^t = \frac{exp(e_i^t)}{\sum_{j=1}^{t-1} exp(e_j^t)}$$
$$e_i^t = v^\intercal tanh(W_y y_i)$$

where $v \in \mathbb{R}^e$, $W_y \in \mathbb{R}^{e \times e}$ are weight matrices.

A.3.2 Memory RNN

This model modifies the recurrent layer of the decoder as follows:

$$s_t = z_t \odot s'_t + (1 - z_t) \odot s''_t$$

where

$$s''_t = tanh(Ey_{t-1} + U[r_t \odot \tilde{s}_t] + Cc_t)$$
$$z_i = \sigma(W_z Ey_{t-1} + U_z \tilde{s}_t + C_z c_t)$$
$$r_i = \sigma(W_r Ey_{t-1} + U_r \tilde{s}_t + C_r c_t)$$

Here, $E \in \mathbb{R}^{e \times V}$ is the embedding matrix for the target language. $W, W_z, W_r \in \mathbb{R}^{d \times e}$, $U, U_z, U_r \in \mathbb{R}^{d \times d}$, and $C, C_z, C_r \in \mathbb{R}^{d \times 2d}$ are weight matrices. The intermediate vector s'_t is calculated from a simple GRU:

$$s'_t = GRU(y_{t-1}, \tilde{s}_t)$$

The recurrent vector $\tilde{s}_t$ is calculated as following:

$$\tilde{s}_t = \sum_{i=1}^{t-1} \alpha_i^t s_i$$

where

$$\alpha_i^t = \frac{exp(e_i^t)}{\sum_{j=1}^{t-1} exp(e_j^t)}$$
$$e_i^t = v^\intercal tanh(W_m s_i + W_s s_t)$$

where $v \in \mathbb{R}^d$, $W_m \in \mathbb{R}^{d \times d}$, and $W_s \in \mathbb{R}^{d \times d}$ are weight matrices.

A.3.3 Self-Attentive RNN

The formulation of this decoder is as following:

$$p(y_t|y_1, ..., y_{t-1}, c_t) \approx softmax(W_o tanh(\\ W_{st}s_t + W_{yt}y_{t-1} + W_{ct}c_t + W_{mt}\tilde{s}_t))$$

Here, $W_o \in \mathbb{R}^{V \times e}$, $W_{st} \in \mathbb{R}^{e \times d}$, $W_{yt} \in \mathbb{R}^{e \times e}$, $W_{ct} \in \mathbb{R}^{e \times 2d}$, and $W_{mt} \in \mathbb{R}^{e \times d}$ are weight matrices.

$$\tilde{s}_t = \sum_{i=1}^{t-1} \alpha_i^t s_i$$
$$\alpha_i^t = \frac{exp(e_i^t)}{\sum_{j=1}^{t-1} exp(e_j^t)}$$
$$e_i^t = v^\intercal tanh(W_m s_i + W_s s_t)$$

where $v \in \mathbb{R}^d$, $W_m \in \mathbb{R}^{d \times d}$, and $W_s \in \mathbb{R}^{d \times d}$ are weight matrices.

Target Foresight based Attention for Neural Machine Translation*

Abstract

in neural machine translation, an attention model is used to identify the aligned source words for a target word (target foresight word) in order to select translation context, but it does not make use of any information of this target foresight word at all. previous work proposed an approach to improve the attention model by explicitly accessing this target foresight word and demonstrated the substantial gains in alignment task. however, this approach is useless in machine translation task on which the target foresight word is unavailable. in this paper, we propose a new attention model enhanced by the implicit information of target foresight word oriented to both alignment and translation tasks. empirical experiments on chinese-to-english and japanese-to-english datasets show that the proposed attention model delivers significant improvements in terms of both alignment error rate and bleu.

1 Introduction

Since neural machine translation (NMT) was proposed (Bahdanau et al., 2014), it has been attracted increasing interests in machine translation community (Luong et al., 2015b; Tu et al., 2016; Feng et al., 2016; Cohn et al., 2016). NMT not only yields impressive translation performance in practice, but also has appealing model architecture in essence. Compared with traditional statistical machine translation (Koehn et al., 2003; Chiang, 2005), one of advantages in NMT is that its architecture combines language model, translation model and alignment between source and target words in a unified manner rather than a pipeline manner, and it thereby has the potential to alleviate the issue of error propagation.

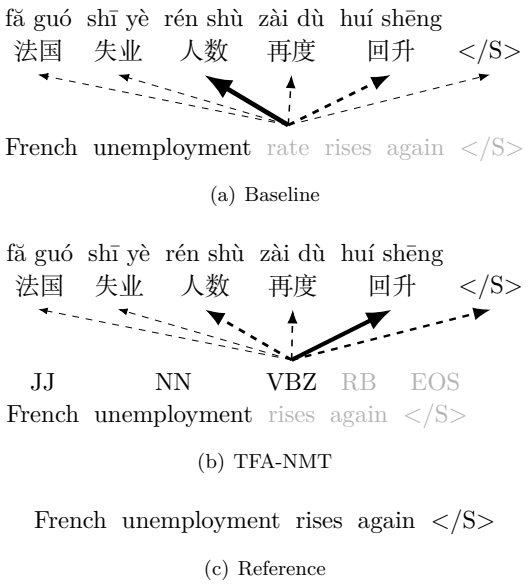

Figure 1: A running example to motivate the proposed model. (a) The baseline obtains a translation error due to the incorrect attention. (b) With the help of the target foresight information "VBZ", TFA-NMT is likely to figure out the exact translation as the reference in (c). The light font denotes the target words to be translated in future. Both dashed or solid arrowed lines denote the alignments and solid one denotes the 1-best alignment.

In NMT, the attention mechanism plays an important role. It calculates the alignments of a target word with respect to the source words for translation context selection. Although the source words are always available in inference, the target word, called target foresight word, [1]

*Work done when X. Li interning at Tencent AI Lab. L. Liu is the corresponding author.

[1]Note that the concept of foresight word in our translation task is not exactly the same as the original concept in alignment task (Peter et al., 2017). However, both of them share a common idea that foresight word should be at a later time step, and thus we respect the work in Peter et al. (2017) and maintain the same concept for easier understanding.

Proceedings of NAACL-HLT 2018, pages 1380–1390
New Orleans, Louisiana, June 1 - 6, 2018.

i.e. the first light color word in Figure 1(a), is not known but to be translated at the next time step. Therefore, this may lead to inadequate modeling for attention mechanism (Liu et al., 2016a; Peter et al., 2017). Regarding to this, Peter et al. (2017) explicitly feed this target word into the attention model, and demonstrate the significant improvements in alignment accuracy. Unfortunately, this approach relies on the premise that the target foresight word is available in advance in its alignment scenario, and thus it can not be used in the translation scenario.

To address this issue, in this paper, we propose a target foresight based attention (TFA) model oriented to both alignment and translation tasks. Its basic idea includes two steps: it firstly designs an auxiliary mechanism to predict some information for the target foresight word which is helpful for alignment; and then it feeds the predicted result into the attention model for translation. For the sake of efficiency, instead of predicting the target foresight word with large vocabulary size, we only predict its partial information, i.e. part-of-speech tag, which is proved to be helpful for word alignment (Liu et al., 2005). Figure 1(b) shows the main idea of TFA based on NMT. In order to remit the negative effects due to the prediction errors, we feed the distribution of the prediction result instead of the maximum a posteriori result into the attention model. In addition, since the target foresight words are available during the training, we jointly learn the prediction model for the target foresight words and the translation model in a supervised manner.

This paper makes the following contributions:

- It proposes a novel TFA-NMT for neural machine translation by using an auxiliary mechanism to predict the target foresight word which is subsequently used to enhance the attention model.
- It empirically shows that the proposed TFA-NMT can lead to better alignment accuracy, and achieves significant improvements on both Chinese-to-English and Japanese-to-English translation tasks.

2 Background

Given a source sentence $\mathbf{x} = \{x_1, \ldots, x_m\}$ with length m and a target sentence $\mathbf{y} = \{y_1, \ldots, y_n\}$ with length n, neural machine translation aims to model the conditional probability $P(\mathbf{y} \mid \mathbf{x})$:

$$P(\mathbf{y} \mid \mathbf{x}) = \prod_{i=1}^{n} P(y_i \mid \mathbf{y}_{<i}, \mathbf{x}), \quad (1)$$

where $\mathbf{y}_{<i} = \{y_1, \ldots, y_{i-1}\}$ denotes a prefix of $\mathbf{y}$ with length $i-1$.

To achieve this, neural machine translation adopts recurrent neural network (RNN) under the encoder-decoder framework (Bahdanau et al., 2014). In encoding, an encoder reads the source sentence $\mathbf{x}$ into a sequence of representation vectors by a bidirectional recurrent neural network. Suppose h_i denotes the representation vector for x_i, and let $\mathbf{h} = \{h_1, \ldots, h_m\}$. In decoding, a decoder sequentially generates a target word according to $P(y_i \mid \mathbf{y}_{<i}, \mathbf{x})$ by using another RNN.

In Eq.(1), the distribution $P(y_i \mid \mathbf{y}_{<i}, \mathbf{x})$ is used to generate y_i as follows:

$$P(y_i \mid \mathbf{y}_{<i}, \mathbf{x}) = \mathrm{softmax}(\phi(y_{i-1}, s_i, c_i)), \quad (2)$$

where ϕ represents a feedforward neural network, c_i is the context vector from $\mathbf{h}$ to infer y_i, and s_i denotes the hidden state at timestamp i via the decoding RNN represented by f:

$$s_i = f(s_{i-1}, y_{i-1}, c_i). \quad (3)$$

Bahdanau et al. (2014) propose an attention model to define the context c_i, inspired by the alignment model in statistical machine translation.

Given the last hidden state s_{i-1} and the encoding vectors $\mathbf{h}$, an attention model is based on a distribution consisting of α_{ij} as follows:

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{m} \exp(e_{ik})},$$

where e_{ij} is computed by a feedforward neural network represented by a:

$$e_{ij} = a(s_{i-1}, h_j). \quad (4)$$

The quantity α_{ij} denotes the possibility of target word y_i aligns to the source word x_j encoded by h_j. According to α_{ij}, the context

vector c_i is defined as the weighted sum of $\mathbf{h}$:

$$c_i = \sum_{j=1}^{m} \alpha_{ij} h_j. \quad (5)$$

In this way, when translating the target word y_i, the decoder will pay more attention to its aligned source words with respect to the distribution $\alpha_i = \{\alpha_{i1}, \cdots, \alpha_{im}\}$. Figure 2 shows a slice of the entire architecture for NMT at timestamp i.

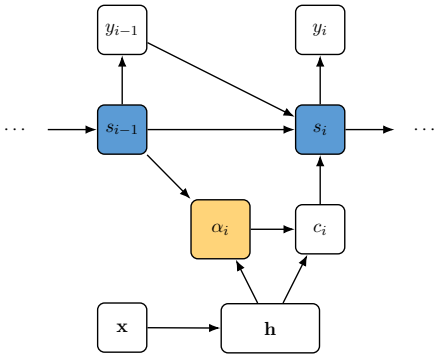

Figure 2: One slice of the architecture of Neural Machine Translation based on a generic attention.

Unfortunately, even though the entire translation $\mathbf{y}$ is available in training, during the inference it is unknown in advance but to be generated sequentially. Specifically, when calculating α_i, one can make use of the information only from $\mathbf{x}$ and $\mathbf{y}_{<i}$ but nothing from y_i. Therefore, it is difficult to certainly specify which source words should be aligned to an unknown target word y_i. This might lead to the inadequacy of the attention model (Liu et al., 2016a; Peter et al., 2017), as explained in Figure 1(a).

3 Target Foresight Attention

In order to alleviate the issue of inadequate modeling for attention in NMT, in this section, we propose the target foresight attention for NMT, which foresees some related information of the unknown target foresight word to improve its alignments regarding to source words. The basic idea of the proposed attention model includes two steps as following:

- It firstly introduce a model to predict some information of the target foresight word. (§3.1)
- It then feeds the predicted result about the foresight target word into the attention as an additional input. (§3.2)

Therefore, as shown in Figure 1(b), when translating the third word, if the prediction model shows it to be a "VBZ", the attention model is likely to align it to the verb words such as "huí shēng" rather than "rén shù" in the source side, and then the corrected word "rises" will be translated.

3.1 Target Foresight Prediction

Ideally, it is possible to build a model to directly predict the target foresight word itself. In practice, it will be inefficient due to its large vocabulary size. As a result, we instead build a model to predict the partial information of the target foresight word, such as part-of-speech (POS) tag or word cluster, which has limited vocabulary size. In this paper, we use the POS tag as the partial information of a target foresight word because POS tag is helpful to word alignment proved by Liu et al. (2005). Furthermore, predicting a POS tag is easier than a target foresight word, so the predicted result will be more reliable for the downstream application on attention.

Suppose u_i denotes a variable indicating the POS tag of a target foresight word y_i. Our aim is to define a prediction model of u_i prior to calculate the attention probability. For simplicity, this prediction model is generally represented as $\beta_i = P(u_i \mid \mathbf{y}_{<i}, \mathbf{x})$. We consider three variant prediction models in a coarse-to-fine manner as follows.

3.1.1 Model 1

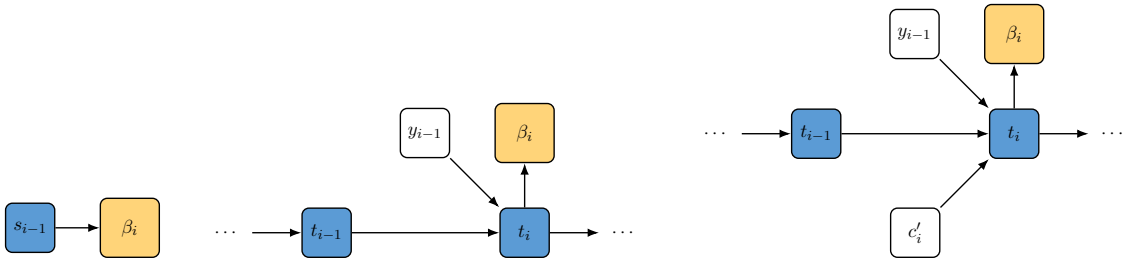
It is straightforward to define this prediction model directly based on the hidden states of the RNN in decoder by using a neural network. Formally, one can use the following equation:

$$\beta_i = P\left(u_i \mid \mathbf{y}_{<i}, \mathbf{x}\right) = \text{softmax}\left(\psi(y_{i-1}, s_{i-1})\right), \quad (6)$$

where ψ is implemented by a feedforward neural network. Note that Eq.(6) only depends on the decoding RNN hidden state s_{i-1} and it is very simple to implementation. Figure 3(a) shows its architecture.

3.1.2 Model 2

Unlike Eq.(6) relying on the same hidden s_{i-1} as the decoder, we design a specialized RNN



(a) model 1 (b) model 2 (c) model 3

Figure 3: The prediction coarse-to-fine models for target foresight information: (a) Model 1 using only the decoding hidden state s_{i-1}. (b) Model 2 using a hidden state t_i from a specialized RNN. (c) Models using a hidden state from a specialized RNN enhanced by the representation vector c'_i of $\mathbf{x}$ similar to Eq.(5).

to provide a particular hidden state for prediction of u_i. This improved prediction model is defined as follows:

$$\beta_i = P\left(u_i \mid \mathbf{y}_{<i}, \mathbf{x}\right) = \text{softmax}\left(\psi(y_{i-1}, t_i)\right), \tag{7}$$

where t_i is the hidden state of the specialized RNN defined by a GRU unit, i.e. $t_i = g(t_{i-1}, y_{i-1})$. This prediction model architecture is shown in Figure 3(b).

3.1.3 Model 3

In model 2, the specialized RNN for u_i only cares about the target sentence $\mathbf{y}$ and ignores the information from the source sentence $\mathbf{x}$. We define a fine-grained model by taking a context vector c'_i from $\mathbf{x}$ as an additional input:

$$\beta_i = P\left(u_i \mid \mathbf{y}_{<i}, \mathbf{x}\right) = \text{softmax}\left(\psi(y_{i-1}, t_i, c'_i)\right), \tag{8}$$

where c'_i is a context vector extracted from $\mathbf{x}$ in a way similar to c_i in Eq.(5),[2] and $t_i = g(t_{i-1}, y_{i-1}, c'_i)$ is the hidden state of the specialized RNN. The architecture of this model is shown in Figure 3(c).

3.2 Feeding the Prediction Model

Suppose we have the prediction result $P(u_i \mid \mathbf{y}_{<i}, \mathbf{x})$, then we consider to feed it into the attention model. Firstly, it is natural to feed the prediction into attention by using maximum a posteriori (MAP) strategy:

$$e_{ij} = a(s_{i-1}, h_j, z_i), \tag{9}$$

where a is the function for attention similar to Eq.(4) but includes an additional input z_i, which is the MAP result of $P(u_i \mid \mathbf{y}_{<i}, \mathbf{x})$:

$$z_i = \mathbf{z}\big(\operatorname*{argmax}_{u_i} P\left(u_i \mid \mathbf{y}_{<i}, \mathbf{x}\right)\big), \tag{10}$$

where $\mathbf{z}$ denotes the embeddings of the POS tags of target foresight words, and $\mathbf{z}(u_i)$ returns the embedding of a particular POS tag u_i.

Note that in Eq.(10) the accuracy of $P(u_i \mid \mathbf{y}_{<i}, \mathbf{x})$ is important to the attention model. For example, suppose at timestamp i, the ground-truth POS tag is "NN", but one has $P(u_i = \text{NN} \mid \mathbf{y}_{<i}, \mathbf{x}) = 0.4$ and $P(u_i = \text{VV} \mid \mathbf{y}_{<i}, \mathbf{x}) = 0.41$. In this case, the prediction model selects "VV" as the POS tag of the target foresight word and ignores the ground-truth tag "NN". Then the attention model takes this error signal and may align the target foresight word to a verb word. Subsequently, this might lead to a translation error.

Therefore, we propose another method to integrate the expected embedding of u_i according to $P(u_i \mid \mathbf{y}_{<i}, \mathbf{x})$ into attention as follows:

$$z_i = \sum_{u_i} \mathbf{z}(u_i) P\left(u_i \mid \mathbf{y}_{<i}, \mathbf{x}\right). \tag{11}$$

In this way, z_i can take into account all possible POS tags u_i including the ground-truth result.

Until now, we can obtain the entire architecture of the proposed target foresight attention based NMT (TFA-NMT), as shown in Figure 4. Comparing Figure 4 with Figure 2, the only difference is the variable z_i, which is

[2] In our preliminary experiments, we tried c_i, but we found c'_i performs better.

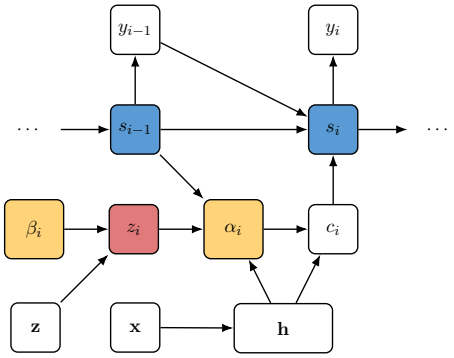


Figure 4: Neural machine translation with target Foresight attention. β_i is derived from Figure 3, z_i is from Eq.(10-11), and other nodes are similar to ones in Figure 2.

obtained from Eq.(10-11) and the prediction model as shown in Figure 3.

Note that the proposed TFA-NMT models the target foresight word, which is a future word regarding to the current time step, to conduct attention calculation. In this sense, it employs the idea of modeling future and thus resembles to the work in (Zheng et al., 2017). The main difference is that TFA-NMT models the future from the target side whereas Zheng et al. (2017) models the future from the source side. In addition, Weng et al. (2017) imposes a regularization term by using future words during training. Unlike our approach, their approach does not use future words during the inference because these words are unavailable. Anyway, it is possible to put both their approach and our approach together for further improvements.

3.3 Learning and Inference

Suppose a set of training data is denoted by $\{\langle \mathbf{x}^k, \mathbf{y}^k, \mathbf{u}^k \rangle \mid k = 1, \cdots, K\}$. Here $\mathbf{x}^k$, $\mathbf{y}^k$ and $\mathbf{u}^k$ denotes a source sentence, a target sentence and a POS tag sequence of $\mathbf{y}^k$, respectively. Then one can jointly train both the translation model for $\mathbf{y}^k$ and the prediction model for $\mathbf{u}^k$ by minimizing the loss function:

$$\ell = -\sum_k \sum_i \big(\log P(y_i^k \mid \mathbf{y}_{<i}^k, \mathbf{x}^k) + \lambda \log P(u_i^k \mid \mathbf{y}_{<i}^k, \mathbf{x}^k) \big), \quad (12)$$

where $P(y_i^k \mid \mathbf{y}_{<i}^k, \mathbf{x}^k)$ is the translation model similar to Eq.(2) with target foresight attention, and $P(u_i^k \mid \mathbf{y}_{<i}^k, \mathbf{x}^k)$ is the target foresight prediction model as defined in Eq.(6-8), respectively. $\lambda \geq 0$ is a hyper-parameter that balances the preference between the translation model and target foresight prediction model.

According to the training objective, the proposed TFA-NMT resembles to the multi-task learning, since it jointly learns two tasks similar to (Evgeniou and Pontil, 2004; Luong et al., 2015a). The difference of our approach is obviously: in this work the prediction result of one model is integrated into the other model, while in their works, two models only share some common hidden states.

In inference, we implement two different decoding methods according two different ways to integrate the foresight prediction model into attention as described in §3.2. For the MAP feeding style, we optimize u_i according to the loss function in Eq.(12) by beam search besides optimizing y_i. However, for the expectation feeding style, we maintain the standard beam search algorithm only regarding to the translation model, i.e. by setting $\lambda = 0$.

4 Experiments

We conduct experiments on Chinese-to-English and Japanese-to-English translation tasks. The specific analyses are based on Chinese-to-English task, and the generalization ability is shown by Japanese-to-English task. Case-insensitive 4-gram BLEU is used to evaluate translation quality, and the multi-bleu.perl is adopted as its implementation.

4.1 Setup

Data The training data for Chinese-to-English task consists of 1.8M sentence pairs from NIST2008 Open Machine Campaign, with 40.1M Chinese words and 48.3M English words respectively. The development set is chosen as NIST2002 (878 sentences) and the test sets are NIST2005 (1082 sentences), NIST2006 (1664 sentences), and NIST2008 (1357 sentences).

For Japanese-to-English translation, we adopt the data sets from NTCIR-9 patent translation task (Goto et al., 2013). The training data consists of 2.0M sentence pairs with 53.4M Japanese words and 49.3M English words, the development and test sets respectively contain 2000 sentences with a single ref-

Model	# Para.	Speed		Performance	
		Train	*Decode*	*BLEU*	*FPA*

+MODEL1	+2M	1844.9	72.0	38.83	69.03
+MODEL2	+12M	1666.1	70.1	39.26	69.95
+MODEL3	+27M	1485.2	59.1	**40.63**	**71.91**

Table 1: Speeds and performances of the proposed models. "Speed" is measured in words/second for both training and decoding, and performances are measured in terms of BLEU scores ("BLEU") and foresight prediction accuracy ("FPA") on the development set. Higher BLEU and FPA scores denote better performance.

erence, following (Goto et al., 2013; Liu et al., 2016b) for further comparison.

Implementation We compare the proposed models with two strong baselines from SMT and NMT:

- MOSES (Koehn et al., 2007): an open source phrased based translation system with default configuration.
- NEMATUS (Sennrich et al., 2017): an generic attention based NMT.

We implement the proposed models on top of NEMATUS. We use Stanford Log-linear Part-Of-Speech Tagger (Toutanova et al., 2003) to produce POS tags for the English side. For both Chinese-to-English and Japanese-to-English tasks, we limit the vocabularies to the most frequent 30K words for both sides. All the out-of-vocabulary words are mapped to a spacial token "UNK". Only the sentences of length up to 50 words are used in training, with 80 sentences in a batch. The dimension of word embedding is 620. The dimensions of both feed forward NN and RNN hidden layer are 1000. The beam size for decoding is 12, and the cost function is optimized by Adadelta with hyper-parameters suggested by Zeiler (2012). Particularly for TFA-NMT, the foresight embedding is also 620, and the hyper-parameter λ is 1.

4.2 Impact of Components

We conduct analyses on Chinese-to-English translation task, to investigate the impact of the added components and to figure out their best configuration for further testing in the next subsection.

4.2.1 Model Architectures

Table 1 lists the speeds and performances of the proposed models. Clearly the proposed approach improves the translation quality in all cases, although there are still considerable differences among the proposed variants.

Model Complexity The proposed models introduce a few parameters to the NMT baseline system NEMATUS, which has 105M parameters. The most complex model (i.e., MODEL3) introduces 27M new parameters, which are small compared with the baseline model. As seen, the proposed models significantly slows down the training speed, which we attribute to the new softmax operation over the foresight tags and more gradient operations associated with the new training objective, i.e., Eq.(12). For decoding, the most complex model reduces speed by around 30%, which is the cost of the proposed approach for improving translation quality.

Performance We measure the performance with BLEU and the result is shown in Table 1. MODEL1 marginally improves performance by guiding the decoder states to embed information for predicting foresight tags. MODEL2 achieves further improvement by introducing a new specific hidden layer to explicitly separate the predict function from the decoder states. MODEL3 achieves the best performance by adopting an independent attention model to attend corresponding source parts for foresight prediction, which may not be the same as the attended source parts for translation. We conduct the significant test using Kevin Gimpel's toolkit (Clark et al., 2011). We found that MODEL1 is not signif-

Type	Perc.	FPA	AER	
		OURS	BASE	OURS
Noun	30.13%	77.49	28.97	26.50
Verb	12.39%	71.94	37.06	33.93
Adj.	9.43%	55.99	34.67	31.86
Prep.	14.66%	79.40	**84.04**	**76.95**
Dete.	10.08%	72.06	80.15	76.51
Punc.	8.01%	74.89	**91.74**	**66.51**
Others	15.30%	81.22	53.64	39.11
All	100%	74.87	49.67	42.56

Table 2: Performances on syntactic categories. "BASE" denotes "NEMATUS", and OURS denotes the proposed model.

icantly better than baseline, but MODEL2 is significantly better with p<0.05 and MODEL3 is significantly better with p<0.01. Given that simply introducing an additional layer ("+2-LAYER") does not produce any improvement on this data, we believe the gain of our model is not only from the more introduced parameters. Besides, we augment the word embedding by concatenating the POS tag embedding, proposed by (Sennrich and Haddow, 2016), the BLEU is 38.96, which indicating the improvement of our model is not only from the POS tagging. In order to further validate the improvements of variant proposed models, we evaluate the foresight prediction accuracy (FPA) for three proposed prediction models. We found that the fine-grained MODEL3 achieves the best FPA, indicating a good estimated foresight is very important to obtain the gains in terms of BLEU.

4.2.2 Analysis on Syntactic Categories

In this experiment, we investigate which category of generated words benefit most from the proposed approach in terms of alignments measured by alignment error rate (AER) (Och, 2003). We carry out experiments on the evaluation dataset from (Liu and Sun, 2015), which contains 900 manually aligned Chinese-English sentence pairs. Following (Luong et al., 2015b), we force-decode both the bilingual sentences including source and reference sentences to obtain the attention matrices, and then we extract one-to-one alignments by picking up the source word with the highest alignment confidence as the hard alignment. As shown in Table 2, the AER improvements are modest for content words such as Noun, Verb, and adjective ("Adj.") words; but there are substantial improvements for function words such as preposition words ("Prep.") and punctuations ("Punc.").

Train (λ)	Decode	BLEU	$\bigtriangledown$
1	EXP	40.63	–
0	EXP	39.36	-1.27
1	MAP	40.34	-0.29

Table 3: Effect of foresight supervision signal in training (i.e., λ) and foresight representations in decoding: EXP for expectation and MAP for maximum a posteriori.

The reason can be explained as follows. The content words are easy to align with AER under 38 as shown in Table 2, and thus it is more difficult to gain over the BASE. On the other hand, as depicted in Table 2, function words are inherently more difficult than content words. These findings satisfy the linguistic intuition: content words tend to be less involved in multiple potential correspondences than function words, and function words tend to be attached to content words, as pointed out by Pianta and Bentivogli (2004). Fortunately, TFA-NMT can predict the POS tag for target foresight word with high confidence and thus it can improve the alignment quality by using of POS tags, which is useful for alignment task (Liu et al., 2005).

It is surprising that the AER for "Prep.", "Det." and "Punc." is relatively low especially for BASE. The main reason can be explained from the quantities y_{i-1}, s_i, and c_i in Eq.(2) as follows. These highly frequent function words are usually easy to be translated by using the history information from y_{i-1} and s_i even if c_i is not confident enough. For example, it is relatively easy to guess the "comma" by using the history words in language model task, where there are no bilingual information at all. Therefore, during the training, the model tries to adjust the parameters for highly frequent words from y_{i-1} and s_i while neglecting the attention model.

4.2.3 Foresight Strategies

Table 3 shows the performances of different foresight strategies in both training and de-

coding. Without an explicit objective to guide the training of foresight prediction model (i.e., $\lambda = 0$), the performance decreases by 1.27 BLEU points. When feeding the best foresight predicted result to the attention model (i.e., MAP), the performance decreases by 0.29 BLEU points. We attribute this to the propagation of prediction errors, which can be alleviated by using a weighted representation of all predicted results (i.e., EXP).

In the following experiments, we use "$\lambda = 1$ and EXP" as the default setting for the final system TFA-NMT.

4.3 Main Results

Chinese-to-English Task Table 4 shows the translation performances for the Chinese-to-English translation task. As seen, the proposed approach significantly outperforms the baseline system (i.e., NEMATUS) in all cases, demonstrating the effectiveness and university of our model.

Japanese-to-English Task Table 5 shows the translation quality of the NMT baseline and our TFA-NMT on Japanese-to-English task. From the table, we can see that our model still achieves a significant improvement of 1.22 and 1.31 BLEU points on the development and test set, respectively. This shows that the proposed approach works well across different language pairs.

5 Related Work

Attention model becomes a standard component for many applications due to its ability of dynamically selecting the informative context from sequential representations. For example, Xu et al. (2015) propose an attention based neural network for image caption task and advance the state-of-the-art results; Yin et al. (2015) put the attention structure between a pair of convolution networks for answer selection, paraphrase identification and textual entailment tasks. In the context of machine translation, the idea of attention based neural networks has been pioneered by Bahdanau et al. (2014); Luong et al. (2015b) and achieved impressive results over the traditional statistical machine translation. Since then many research works have been devoted to improve the neural machine translation by enhancing attention models.

Tu et al. (2016) design a coverage vector for the translation history and then integrates it into the attention model. Similarly, Meng et al. (2016) maintain a tag vector to keep track of the attention history and Sankaran et al. (2016) memorize historical alignments and accumulate them as temporal memory to improve the attention model. In addition, Zhang et al. (2017) improve the attention with a gated operator for encoding states and a decoding state, and and Dutil et al. (2017) enhance attention through a planning mechanism. Furthermore, Feng et al. (2016) adopt a recurrent structure for attention to take long-term dependencies into account, Zhou et al. (2017) propose a look-ahead attention by additionally modeling the translation history, and Cohn et al. (2016) incorporate structural biases into attention models. Recently Chen et al. (2017) introduce the syntactic knowledge into attention models. These works are essentially similar to the propose approach, since we introduce auxiliary information from a target foresight word into the attention model. However, there is a significant difference between our approach and their approaches. Our auxiliary information biases to the word to be translated at next timestep while theirs biases to the information available so far at the current timestep, and thereby our approach is orthogonal to theirs.

The works mentioned above improve the attention models by access auxiliary information, and thus they modify the structure of attention models in both inference and learning. In contrast, Mi et al. (2016); Liu et al. (2016b); Chen et al. (2016) maintain the structure of the attention models in inference but utilize some external signals to supervise the outputs of attention models during the learning. They improve the generalization abilities of attention models by use of the external aligners as the signals, which typically yield alignment results accurate enough to guide the learning of attention.

6 Conclusion

It has been argued that the traditional attention model in neural machine translation suf-

fers from model inadequacy due to the lack of information from the target foresight word (Peter et al., 2017; Liu et al., 2016a). To address this issue, this paper proposes a new attention model, which can serve for both alignment and translation tasks, by implicitly making use of the target foresight word. Empirical experiments on Chinese-to-English and Japanese-to-English tasks demonstrate that the proposed attention based NMT delivers substantial gains in terms of both BLEU and AER scores.

In future work, it is promising to exploit other target foresight information such as word cluster besides the POS tags in this paper, and it is also interesting to apply this idea on top of other attention models such as the local attention in Luong et al. (2015b).

Abstract

The main motivation for developing context-sensitive lemmatizers is to improve performance on unseen and ambiguous words. Yet previous systems have not carefully evaluated whether the use of context actually helps in these cases. We introduce Lematus, a lemmatizer based on a standard encoder-decoder architecture, which incorporates character-level sentence context. We evaluate its lemmatization accuracy across 20 languages in both a full data setting and a lower-resource setting with 10k training examples in each language. In both settings, we show that including context significantly improves results against a context-free version of the model. Context helps more for ambiguous words than for unseen words, though the latter has a greater effect on overall performance differences between languages. We also compare to three previous context-sensitive lemmatization systems, which all use pre-extracted edit trees as well as hand-selected features and/or additional sources of information such as tagged training data. Without using any of these, our context-sensitive model outperforms the best competitor system (Lemming) in the full-data setting, and performs on par in the lower-resource setting.

1 Introduction

Lemmatization is the process of determining the dictionary form of a word (e.g. *swim*) given one of its inflected variants (e.g. *swims*, *swimming*, *swam*, *swum*). Data-driven lemmatizers face two main challenges: first, to generalize beyond the training data in order to lemmatize unseen words; and second, to disambiguate ambiguous wordforms from their sentence context. In Latvian, for example, the wordform "*ceļu*" is ambiguous when considered in isolation: it could be an inflected variant of the verb "*celt*" (*to lift*) or the nouns "*celis*" (*knee*) or "*ceļš*" (*road*); without context, the lemmatizer can only guess.

By definition, sentence context (or latent information derived from it, such as the target word's morphosyntactic tags) is needed in order to correctly lemmatize ambiguous forms such as the example above. Previous researchers have also assumed that context should help in lemmatizing unseen words (Chrupała, 2006; Müller et al., 2015)—i.e., that the context contains useful features above and beyond those in the wordform itself. Nevertheless, we are not aware of any previous work that has attempted to quantify how much (or even whether) context actually helps in both of these cases. Several previous papers on context-sensitive lemmatization have reported results on unseen words (Chrupała, 2006; Chrupała et al., 2008; Müller et al., 2015; Chakrabarty et al., 2017), and some have compared versions of their systems that use context in different ways (Müller et al., 2015; Chakrabarty et al., 2017), but there are few if any direct comparisons between context-sensitive and context-free systems, nor have results been reported on ambiguous forms.

This paper presents *Lematus*—a system that adapts the neural machine translation framework of Sennrich et al. (2017) to learn context sensitive lemmatization using an encoder-decoder model. Context is represented simply using the character contexts of each form to be lemmatized, meaning that our system requires fewer training resources than previous systems: only a corpus with its lemmatized forms, without the need for POS tags (Chrupała et al., 2008; Müller et al., 2015) or word embeddings trained on a much larger corpus (Chakrabarty et al., 2017). We evaluate Lematus on data from 20 typologically varied languages, both using the full training data from the Universal Dependencies project (Nivre et al., 2017), as well as a lower-resource scenario with only 10k training tokens per language. We compare results to three previous systems and to a context-free version of our own system, including results on both unseen

Proceedings of NAACL-HLT 2018, pages 1391–1400
New Orleans, Louisiana, June 1 - 6, 2018.

and ambiguous words. We also examine the extent to which the rate of unseen and ambiguous words in a language can predict lemmatization performance.

On average across the 20 languages, the context-sensitive version of Lematus achieves significantly higher lemmatization accuracy than its context-free counterpart in both the low-resource and full-data settings. It also outperforms the best competitor system (Lemming; Müller et al. 2015) in the full-data setting, and does as well as Lemming in the low-resource setting. Thus, even without explicitly training on or predicting POS tags, Lematus seems able to implicitly learn similar information from the raw character context.

Analysis of our full-data results shows that including context in the model improves its accuracy more on ambiguous words (from 88.8% to 92.4% on average) than on unseen words (from 83.6% to 84.3% on average). This suggests that, to the extent that unseen words can be correctly lemmatized at all, the wordform itself provides much of the information needed to do so, and Lematus effectively exploits that information—indeed, Lematus without context outperforms all previous context-sensitive models on lemmatizing unseen words.

Finally, our cross-linguistic analysis indicates that the proportions of unseen words and ambiguous words in a language are anti-correlated. Altogether, then, our results suggest that context-free neural lemmatization is surprisingly effective, and may be a reasonable option if the language contains many unseen words but few ambiguous ones. Context is likely to help in most languages, but the main boost is for languages with higher ambiguity.

2 Background and Baseline Systems

Early work on context-sensitive lemmatization focused on disambiguation: given a set of analyses produced by a hand-built morphological analyzer (typically including both lemmas and morphosyntactic tags), choose the best one in context (Oflazer and Kuruöz, 1994; Ezeiza et al., 1998; Hakkani-Tür et al., 2002). Here, we focus on systems learning to generate the lemmas and tags without a pre-existing analyzer (Erjavec and Džeroski, 2004; Chrupała, 2006). The three systems we use as baselines follow Chrupała (2006) in treating the task as a classification problem, where the system learns to choose which of a set of *edit scripts* or *edit trees* (previously induced from the aligned wordform-lemma pairs) should be applied to transform each wordform into the correct lemma.

Two of our baselines, **Morfette**[1] (Chrupała et al., 2008) and **Lemming**[2] (Müller et al., 2015), learn from morphologically annotated corpora to jointly tag each word and lemmatize it by choosing an edit script. Morfette consists of two log-linear classifiers—one for lemmatization and one for tagging—which are combined using beam search to find the best sequence of lemma-tag pairs for all words in the input sentence. Lemming (which proves to be the strongest baseline) also consists of two log-linear components (a classifier for lemmatization and a sequence model for tagging), which are combined either using a pipeline (first tag, then lemmatize) or through joint inference. The lemmatization model uses a variety of features from the edit trees, alignments, orthography of the lemma, and morphosyntactic tags.

In experiments on six languages, Müller et al. (2015) showed that the joint Lemming model worked better than the pipelined model, and that adding morphosyntactic features helped. They also demonstrated improvements over an earlier context-free baseline model (Jiampojamarn et al., 2008). However, they did not evaluate on ambiguous forms, nor directly compare context-sensitive and context-free versions of their own model.

Our third baseline, **Ch-2017**[3] (Chakrabarty et al., 2017) uses a neural network rather than a log-linear model, but still treats lemmatization as a classification task to choose the correct edit tree. (Like our model, Ch-2017 does not perform morphological tagging.) The model composes syntactic and semantic information using two successive bidirectional GRU networks. The first bidirectional GRU network is similar to the character to word model by Ling et al. (2015) and learns syntactic information. The semantic information comes from word embeddings pre-trained on much larger corpora. The second GRU uses a composition of the semantic and syntactic embeddings for the edit tree classification task.

Rather than treating lemmatization as classification, our own model is inspired by recent work on morphological reinflection. As defined by two recent Shared Tasks (Cotterell et al., 2016, 2017), a morphological reinflection system gets as input

[1] https://sites.google.com/site/morfetteweb/

[2] http://cistern.cis.lmu.de/lemming

[3] https://github.com/onkarpandit00786/neural-lemmatizer

some inflected wordform (and possibly its morphosyntactic tags) along with a set of target tags. The system must produce the correct inflected form for the target tags. In the 2016 SIGMORPHON Shared Task, various neural sequence-to-sequence models gave the best results (Aharoni et al., 2016; Kann and Schütze, 2016; Östling, 2016). We base our work closely on one of these (Kann and Schütze, 2016), which also won one of the 2017 tasks (Bergmanis et al., 2017). Our lemmatization task can be viewed as a specific type of reinflection, but instead of assuming that tags are given in the input (or that the system simply has to guess the tags from the wordform itself, as in some of the Shared Tasks), we investigate whether the information available from the tags can instead be inferred from sentence context.

3 Model Description

Our model is based on the network architecture proposed by Sennrich et al. (2017), which implements an attentional encoder-decoder architecture similar to that of Bahdanau et al. (2015). Namely, our model is a deep attentional encoder-decoder with a 2-layer bidirectional encoder with a gated recurrent unit (GRU) (Cho et al., 2014) and a 2-layer decoder with a conditional GRU (Sennrich et al., 2017) in the first layer followed by a GRU in the second layer. For more architectural details see (Sennrich et al., 2017).

A default implementation of this architecture is available in the *Nematus* toolkit,[4] which we used as our starting point. However, Sennrich et al. (2017) used their model for machine translation, while we work on lemmatization. Since our task is closer to the problem of morphological reinflection described above, we changed some of the default model parameters to follow those used in systems that performed well in the 2016 and 2017 SIGMORPHON Shared Tasks (Kann and Schütze, 2016; Bergmanis et al., 2017). Specifically, we reduced the number of hidden units to 100 and the encoder and decoder embedding size to 300.

The input sequence is a space-separated character representation of a word in its N-character left and right sentence context. For example, with $N = 15$, the Latvian word *ceļu* (the genitive plural of the noun *ceļš*, meaning *road*) could be input as:

```
s a k a <s> p a š v a l d ī b u
<lc> c e ļ u <rc>
u n <s> i e l u <s> r e ģ i s t r
```

where <s>, <lc>, <rc> stand for word boundary, left and right context markers respectively. The target output is a sequence of characters forming the lemma of the word: `c e ļ š`

4 Datasets

We contend that the difficulty of the lemmatization task largely depends on three factors: morphological productivity, lexical ambiguity and morphological regularity. One aim of our work is to investigate the extent to which it is possible to predict lemmatization performance for a particular language by operationalizing and measuring these properties. Therefore in this section we provide statistics and some analysis of the datasets used in our experiments. We use the standard splits of the Universal Dependency Treebank (UDT) v2.0[5] (Nivre et al., 2017) datasets for 20 languages: Arabic, Basque, Croatian, Dutch[6], Estonian, Finnish, German, Greek, Hindi, Hungarian, Italian, Latvian, Polish, Portuguese, Romanian, Russian, Slovak, Slovene, Turkish and Urdu. See Figure 1 for training and development data sizes.

Because the amount of training data varies widely between languages, we perform some of our language analysis (and later, system evaluation) on a subset of the data, where we use only the first 10k tokens in each language for training. The 10k setting provides a clearer comparison between languages in terms of their productivity, ambiguity, and regularity, and also gives a sense of how much training data is needed to achieve good performance.

One of the main purposes of data-driven lemmatization is to handle unseen words at test time, yet languages with differing morphological productivity will have very different proportions of unseen words. Figure 2 shows the percentage of tokens in the development sets of each language that are not seen in training. Two conditions are given: the full training/development sets, and train/dev sets that are controlled in size across languages. For

[4] https://github.com/EdinburghNLP/nematus

[5] UTD v2.0 datasets are archived at http://hdl.handle.net/11234/1-1983

[6] We use UDT v2.1 dataset for Dutch due to inconsistencies in v2.0.

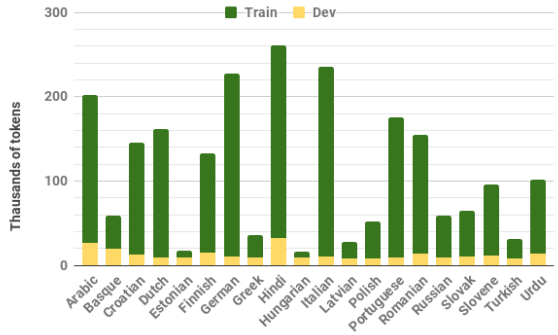

Figure 1: Training and development set sizes for each language, in thousands.

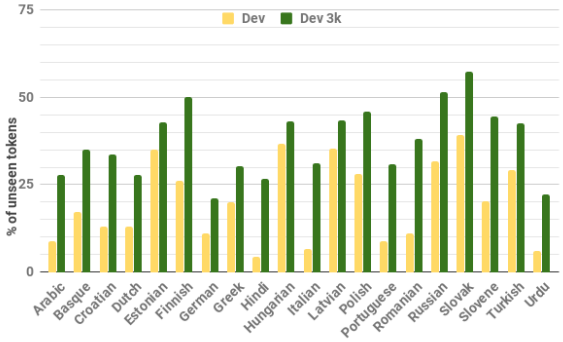

Figure 2: Percent of tokens unseen in training. Dev (yellow): within full development sets with respect to the full training sets. Dev 3k (green): within the first 3k tokens of development sets with respect to the first 10k tokens of training sets.

the languages with large data sets, the percentage of unseen words is (unsurprisingly) higher when training data is reduced to 10k. However, these differences are often small compared to the differences between languages, suggesting that productivity is likely to affect lemmatization performance as much as training data size.

Lexical ambiguity is the other major motivation for context-sensitive lemmatization. To quantify how frequently lemmatizers have to rely on context, Figure 3 shows the percentage of ambiguous tokens in each language, in either the full or reduced training sets. We define ambiguity empirically: ambiguous tokens are wordforms occurring with more than one lemma within the training set.

Overall, the level of measured ambiguity tends to be lower than the proportion of unseen tokens. Many of the languages with high productivity (e.g., Russian, Slovak, Slovene, Turkish) have low levels of ambiguity, while others (Arabic, Urdu) trend the opposite way. Indeed, across all 20 languages,

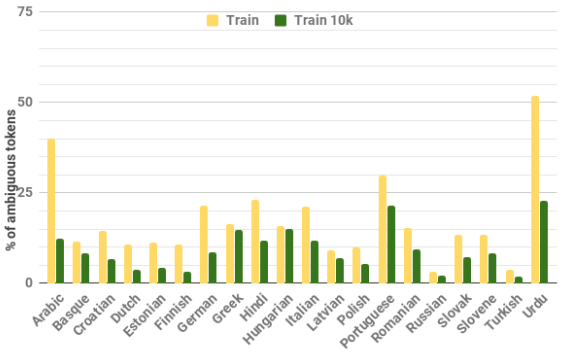

Figure 3: Percent of ambiguous tokens within the first 10k tokens of training sets and full training sets. Ambiguous tokens are word forms occurring with more than one lemma in the training set.

the levels of productivity and ambiguity are negatively correlated, with a rank correlation of -0.57 after controlling for training data size.[7] This is not surprising, since given a set of morphosyntactic functions, they must either be expressed using distinct forms (leading to higher productivity) or non-distinct forms (leading to higher ambiguity).

The final characteristic that we would expect to make some languages easier than others is morphological regularity, but it is unclear how to measure this property directly without an in-depth understanding of the morphophonological rules of a language. Nevertheless, the presence of many irregular forms, or other phenomena such as vowel harmony or spelling changes, complicates lemmatization and will likely affect accuracy.

5 Experimental Setup

Training Parameters[8] We use a mini batch size of 60 and a maximum sequence length of 75. For training we use stochastic gradient descent, Adadelta (Zeiler, 2012), with a gradient clipping threshold of 1.0, recurrent Bayesian dropout probability 0.2 (Gal and Ghahramani, 2016) and weight normalization (Salimans and Kingma, 2016). We use early stopping with patience 10 (Prechelt, 1998). We use the first 10 epochs as a burn-in period, after which at the end of every second epoch

[7] That is, the correlation is computed between the values in Figure 2 Dev 3k (unseen words wrt the first 10k training tokens for each language) and Figure 3 Train 10k (ambiguous words in the first 10k training tokens for each language). The correlation is significantly different from zero with $p < 0.01$.

[8] Training parameters were tunned/verified on the standard splits of UDT training and development sets for Spanish and Catalan, therefore the results on these languages are not included in our evaluation.

we evaluate the current model's lemmatization exact match accuracy on the development set and keep this model if it performs better than the previous best model. When making predictions we use beam-search decoding with a beam of size 12.

Baselines To train models we use the default settings for Morfette and Lemming. Ch-2017 requires word embeddings, for which we use *fastText*[9] (Bojanowski et al., 2017). For Ch-2017 we set the number of training epochs to 100 and implement early stopping with patience 10.[10] We leave the remaining model parameters as suggested by Chakrabarty et al. (2017).

We also use a lookup-based baseline (**Baseline**). For words that have been observed in training, it outputs the most frequent lemma (or the first observed lemma, if the options are equally frequent). For unseen words it outputs the wordform itself as the hypothesized lemma.

Context Representation We aim to use a context representation that works well across multiple languages, rather than to tune the context individually to each language. In preliminary experiments, we explored several different context representations: words, sub-word units, and N surrounding characters, for different values of N. These experiments were carried out on only six languages. Three of these (Latvian, Polish and Turkish) were also used in our main experiments, while three (Bulgarian, Hebrew, and Persian) were not, due to problems getting all the baseline systems to run on those languages.

For the word level context representation (**Words**), we use all words in the left and the right sentence contexts. For the character level context representations (**N-Ch**) we experiment with $N = 0$, 5, 10, 15, 20, or 25 characters of left and right contexts. For the sub-word unit context representation, we use byte pair encoding (**BPE**) (Gage, 1994), which has shown good results for neural machine translation (Sennrich et al., 2016). BPE is a data compression algorithm that iteratively replaces the most frequent pair of symbols (here, characters) in a sequence with a single new symbol. BPE has a single parameter—the number of merge operations. Suitable values for this parameter depend on the application and vary from 10k in language modeling (Vania and Lopez, 2017) to 50k in machine translation (Sennrich et al., 2016). We aim to use BPE to extract a few salient and frequently occurring strings, such as affixes, therefore we set the number of BPE merge operations to 500. We use BPE-encoded left and right sentence contexts that amount up to 20 characters of the original text.

Since we hoped to use context to help with ambiguous words, we looked specifically at ambiguous word performance in choosing the best context representation.[11] Table 1 summarizes Lematus' performance on ambiguous tokens using different sentence context representations. There is no context representation that works best for all six languages, but the 20-Ch system seems to work reasonably well in all cases, and the best on average. We therefore use the 20-Ch context in our main experiments.

Note that this choice was based on a relatively small number of experiments and it is quite possible that further tuning the BPE parameter, or the number of BPE units or words of context (or tuning separately for each language) could lead to better overall results.

Evaluation To evaluate models, we use test and development set lemmatization exact match accuracy. When calculating lemmatization accuracy we ignore casing of the tokens and ommit punctuation tokens and those tokens that contain digits or any of the following characters: `@+._/`.

6 Results and Discussion

Results on Complete Datasets Development set accuracies for all languages and systems in the full data setting are provided in Figure 4a, with results on unseen and ambiguous words in Figures 4b and 4c. Overall, Lematus 20-Ch outperforms the previous systems, Morfette, Lemming and Ch-2017, on 20, 15 and 20 languages respectively. In addition, Figure 4 makes it clear that the major benefit of all the systems over the baseline is for unseen words: in fact, for ambiguous words, the baseline even outperforms some of the systems in a few languages. Comparing the two versions of Lematus, we can see that Lematus 20-Ch does consistently better

[9] https://github.com/facebookresearch/fastText/blob/master/pretrained-vectors.md

[10] We do so because it is unclear what stopping criterion was used by Chakrabarty et al. (2017) Their suggested default for the number of training epochs is 6, yet the values used in their experiments vary from 15 for Hindi to 80 for Bengali.

[11] The percentage of ambiguous tokens in the training sets of Bulgarian, Hebrew and Persian are 8.4%, 16.6% and 7.6% respectively; for the other languages, see Figure 3.

	Baseline	0-Ch	5-Ch	10-Ch	15-Ch	20-Ch	25-Ch	BPE	Words

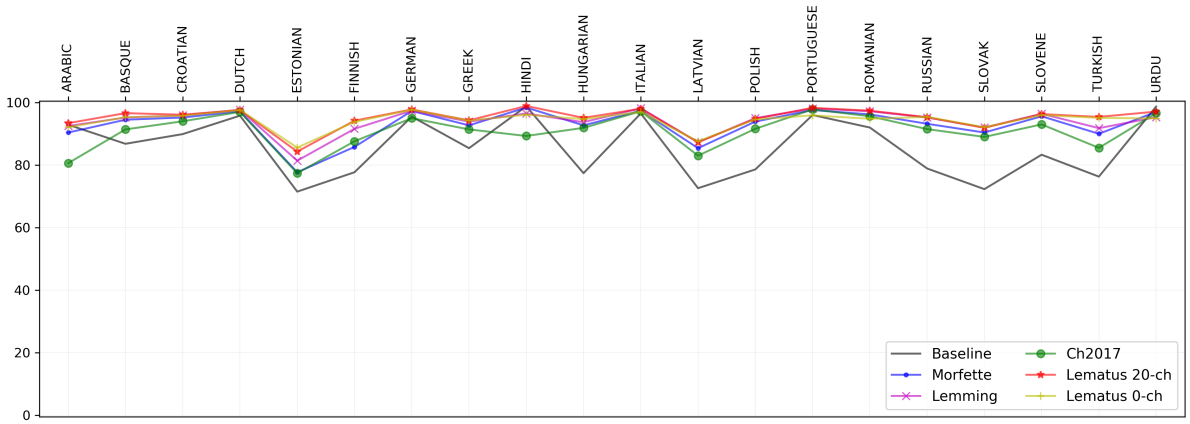
Table 2: Lemmatization exact match accuracy, averaged across all 20 languages. In the full training scenario (first five columns) results are given for All, Unseen, Ambiguous, and Seen Unambiguous tokens. (Note that ambiguity is empirical: is a type seen with more than one lemma in training?) We compare Lematus with/without context (20-Ch/0-Ch), the most frequent lemma baseline, and three previous systems. The numerically highest score in each column is bold; *, †, and ‡ indicate statistically significant improvements over Lemming, Lematus 0-Ch and 20-Ch, respectively (all $p < 0.05$; see text for details).

on ambiguous tokens than Lematus 0-Ch, whereas their performance on unseen tokens (and thus, overall) is much more similar. In fact, on unseen words, Lematus 0-Ch outperforms the context-sensitive baselines Morfette, Lemming and Ch-2017 on 18, 12 and 17 languages respectively. These results suggest that a good context-free model can do surprisingly well on unseen words, and the added model complexity and annotation requirements of earlier context-sensitive models are not always justified.

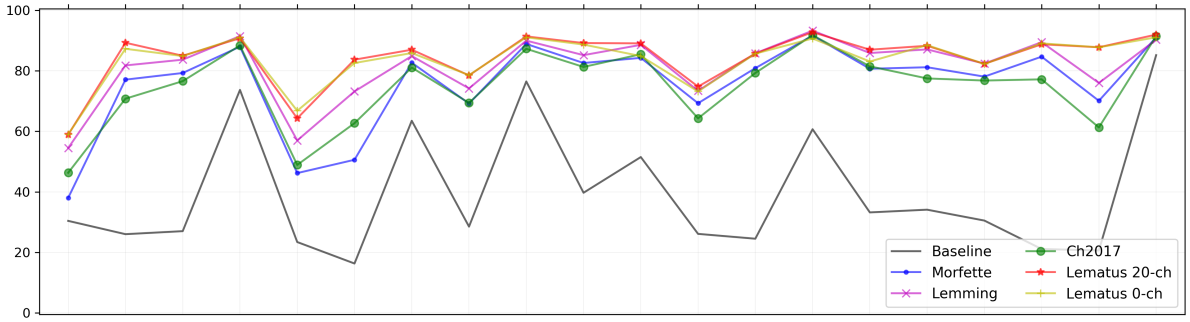
As further evidence of these claims, we summarize in Table 2 each system's average performance over all languages for both the development and test sets. In addition to performance breakdown into unseen and ambiguous words we also report each system's performance on tokens that were both seen and unambiguous in training. No system achieves 100% accuracy on seen unambiguous tokens—even the lookup baseline achieves only 99%, indicating that about 1% of tokens that appeared unambiguous in training occur with a previously unseen lemma in the development set. In principle, context-based systems could outperform the baseline on these words, but in practice none of them do. Indeed, switching to a dictionary lookup baseline for seen unambiguous words would slightly improve the performance of all models (though it would not change the overall ranking of the systems).

We tested for statistically significant differences between the results of Lemming (the numerically best-performing competitor system) and our two systems (Lematus 0-Ch and Lematus 20-Ch) using a Monte Carlo method: for each comparison (say, between 0-Ch and 20-Ch on unseen words), we generated 10000 random samples, where each sample randomly swapped the two systems' results for each language with probability .5. We then obtained a p-value by computing the proportion of samples for which the difference in average results was at least as large as the difference observed in our experiments.

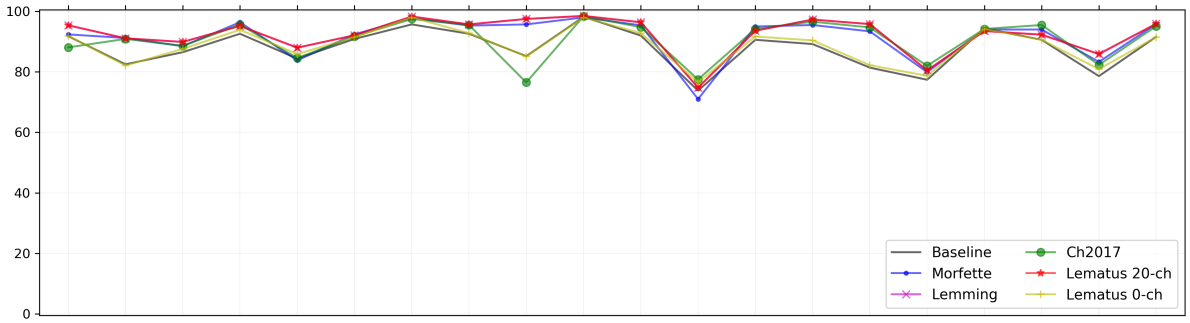
Because the results of 0-Ch and 20-Ch are highly correlated across languages, all differences between these systems, except for results on seen unambiguous tokens, are significant ($p < 0.01$ for dev set All, $p < 0.05$ for Unseen, $p < 0.001$ for Ambig, and $p < 0.01$ for test set All; $p > 0.1$ for



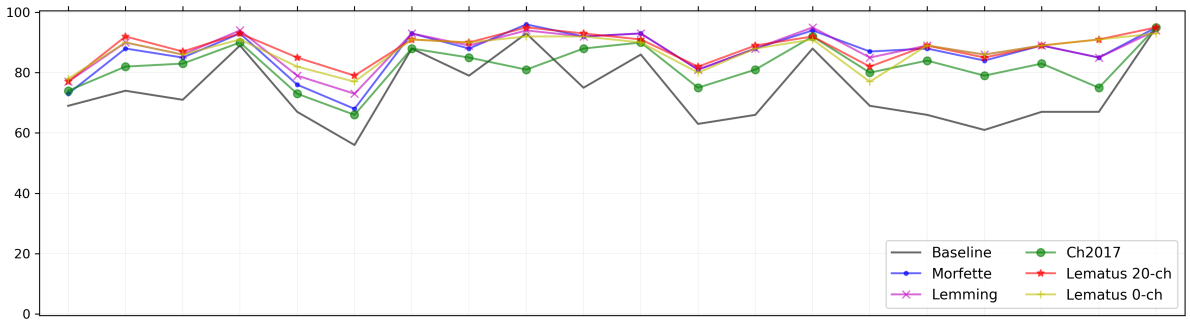
(a) **All tokens.** Models were trained on full training sets.



(b) **Unseen tokens.** Models were trained on full training sets.



(c) **Ambiguous tokens.** Models were trained on full training sets.



(d) **All tokens**. Models were trained on the first **10K** of the training sets.

Figure 4: Lemmatization exact match accuracy on development sets for each language.

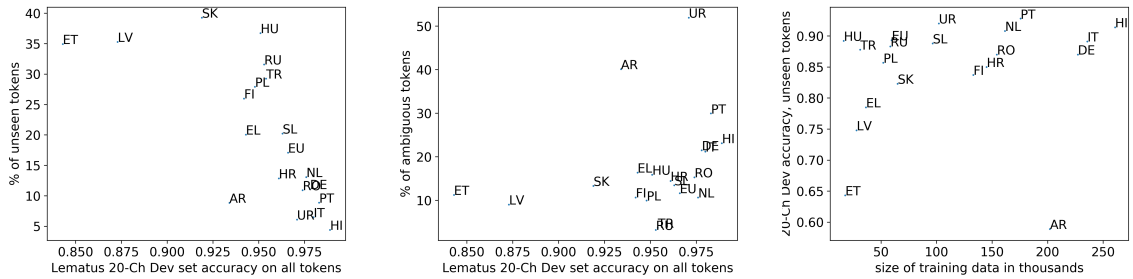


Figure 5: Lemmatization accuracy of Lematus 20-Ch on *all* dev set tokens vs percent of unseen tokens (left) or percent of ambiguous tokens (middle); accuracy on *unseen* tokens vs training set size (right).

dev set SeenUA). Lemming does as well as Lematus 20-Ch on ambiguous and SeenUA words, but its accuracy on unseen words is lower ($p < 0.001$), leading to worse performance overall ($p < 0.01$ on both dev and test). Interestingly, even Lematus 0-Ch does better than Lemming on unseen words ($p < 0.02$), and performs on par overall ($p = 0.28$). So, although including context clearly can help (compare Lematus 20-Ch vs 0-Ch), and Lemming exploits this advantage for ambiguous words, a good context-free model can still do very well. Overall, our models do as well or better than the earlier ones, without the added model complexity and annotation requirements. On the other hand, although our context-sensitive model does improve somewhat over its context-free counterpart, there is still some way to go, since average performance on unseen and ambiguous words is still 84% and 92% respectively.

Results on 10k Datasets Figure 4d shows the results on all tokens for each language in the 10k training setting, with averages in Table 2. On average, limiting training data to the first 10k examples resulted in an 82% reduction of training sets, and we see an average drop in test set performance of 5.6-6.8 percentage points for all systems except Ch-2017, which drops by about 10 percent. When comparing the 0-Ch and 20-Ch versions of Lematus we found the same pattern of significances as in the full data setting ($p < 0.01$), however the two best systems (Lematus 20-Ch and Lemming) are statistically equivalent on the test sets, as are Lemming and Lematus 0-Ch.

Patterns Across Languages In Section 4, we hypothesized that the success of data-driven lemmatization depends on a language's productivity, ambiguity, and regularity. We now explore the extent to which our results support this hypothesis. First, we examine the correlation between the overall performance of our best system on each language and the percentage of unseen (Figure 5, left) or ambiguous words (Figure 5, middle) in that language. As expected, there is a strong negative correlation between the percentage of unseen words and the accuracy of Lematus 20-Ch: the rank correlation is $R = -0.73$ ($p < 0.001$; we use rank correlation because it is less sensitive to outliers than is linear correlation, and the plot clearly shows several outliers.) In contrast to our original prediction, however, Lematus 20-Ch is actually *more* accurate for languages with greater ambiguity ($R = 0.44$, $p = 0.05$). The most likely explanation is that ambiguity is negatively correlated with productivity. Since there tend to be more unseen than ambiguous words, and since accuracy is typically lower for unseen than ambiguous words, higher ambiguity (which implies fewer unseen words) can actually lead to higher overall accuracy.

Our earlier results also suggested that the main benefit of Lematus 20-Ch over Lematus 0-Ch is for ambiguous words. To confirm this, we looked at the extent to which the *difference* in performance between the two systems correlates with the percentage of unseen or ambiguous words in a language. As expected, this analysis suggests that including context in the model helps more for languages with more ambiguity ($R = 0.67, p < 0.001$). In contrast, Lematus 20-Ch provides *less* benefit over Lematus 0-Ch for the languages with more unseen words ($R = -0.75, p < 0.0001$). Again, we assume the latter result is due to the negative correlation between ambiguity and productivity.

So far, our results and analysis show a clear relationship between productivity and ambiguity, and also suggest that using context for lemmatization may be unnecessary (or at least less beneficial) for languages with many unseen words but low am-

biguity. However, there are remaining differences between languages that are more difficult to explain. For example, one might expect that for languages with more training data, the system would learn better generalizations and lemmatization accuracy on unseen words would be higher. However, Figure 5 (right), which plots accuracy on *unseen* words in each language as a function of training data size, illustrates that there is no significant correlation between the two variables ($R = 0.32$, $p = 0.16$). In some languages (e.g., Hungarian, in the top left) Lematus performs very well on unseen words even with little training data, while in others (e.g., Arabic, along the bottom) it performs poorly despite relatively large training data. We assume that regularity (and perhaps the nonconcatenative nature of Arabic) must be playing an important role here, but we leave for future work the question of how to operationalize and measure regularity in order to further test this hypothesis.

7 Conclusion

We presented Lematus, a simple sequence-to-sequence neural model for lemmatization that uses character-level context. On average across 20 languages, we showed that even without using context, this model performs as well or better than three previous systems that treated lemmatization as an edit tree classification problem and required POS tags (Chrupała et al., 2008; Müller et al., 2015) or word embeddings trained on a much larger corpus (Chakrabarty et al., 2017). We also showed that with both larger and smaller training datasets, including context boosts performance further by improving accuracy on both unseen and (especially) ambiguous words.

Finally, our analysis suggests that lemmatization accuracy tends to be higher for languages with *low* productivity (as measured by the proportion of unseen words at test time), but more surprisingly also for languages with *high* ambiguity—perhaps because high ambiguity is also associated with low productivity. We also found that the amount of training data available for each language is not a good predictor of performance on unseen words, suggesting that morphological regularity or other language-specific characteristics are playing an important role. Understanding the causes of these differences is likely to be important for further improving neural lemmatization.

Abstract

Recognizing named entities in a document is a key task in many NLP applications. Although current state-of-the-art approaches to this task reach a high performance on clean text (e.g. newswire genres), those algorithms dramatically degrade when they are moved to noisy environments such as social media domains. We present two systems that address the challenges of processing social media data using character-level phonetics and phonology, word embeddings, and Part-of-Speech tags as features. The first model is a multitask end-to-end Bidirectional Long Short-Term Memory (BLSTM)-Conditional Random Field (CRF) network whose output layer contains two CRF classifiers. The second model uses a multitask BLSTM network as feature extractor that transfers the learning to a CRF classifier for the final prediction. Our systems outperform the current F1 scores of the state of the art on the Workshop on Noisy User-generated Text 2017 dataset by 2.45% and 3.69%, establishing a more suitable approach for social media environments.

1 Introduction

One of the core tasks in Natural Language Processing (NLP) is Named Entity Recognition (NER). NER is a sequence tagging task that consists in selecting the words that describe entities and recognizing their types (e.g., a person, location, company, etc.). Figure 1 shows examples of sentences from different domains that contain named entities. Recognizing entities in running text is typically one of the first tasks in the pipeline of many NLP applications, including machine translation, summarization, sentiment analysis, and question answering.

Traditional machine learning systems have proven to be effective in formal text, where grammatical errors are minimal and writers stick to the rules of the written language (Florian et al., 2003a; Chieu and Ng, 2003a). However, those traditional systems dramatically fail on informal text, where improper grammatical structures, spelling inconsistencies, and slang vocabulary prevail (Ritter et al., 2011). For instance, Table 1 shows a snapshot of NER systems' performance during the last years, where the results drop from 96.49% to 41.86% on the F1 metric as we move from formal to informal text. Although the results are not directly comparable because they consider different conditions and challenges, they serve as strong evidence that the NER task in social media is far from being solved.

Figure 1: Examples from the CoNLL 2003 and the WNUT 2017 datasets. The noise from the WNUT dataset makes a clear difference from one text to the other, establishing new challenges to the current state-of-the-art systems on formal text. The words in bold are grouped to described the entities.

Recently, researchers have approached NER using different neural network architectures. For instance, Chiu and Nichols (2016) proposed a neural model using Convolutional Neural Networks (CNN) for characters and a bidirectional Long Short Term Memory (LSTM) for words. Their model learned from word embeddings, capitalization, and lexicon features. On a slightly different approach, Lample et al. (2016) used a BLSTM with a CRF at the output layer, re-

Table 1: Results on different NER shared tasks. The performance degrades as the systems are moved to social media (SM) environments. The last row considers multiple SM domains, such as Twitter, YouTube, Reddit, and StackExchange.

moving the dependencies on external resources. Moreover, Ma and Hovy (2016) proposed an end-to-end BLSTM-CNN-CRF network, whose loss function is based on the maximum log-likelihood estimation of the CRF. These architectures were benchmarked on the standard CoNLL 2003 dataset (Tjong Kim Sang and De Meulder, 2003). Although most of the work has focused on formal datasets, similar approaches have been evaluated on SM domains (Strauss et al., 2016; Derczynski et al., 2017). In the Workshop on Noisy User-generated Text (WNUT) 2016, Limsopatham and Collier (2016), the winners of the NER shared task, used a BLSTM-CRF model that induced features from an orthographic representation of the text. Later, in the WNUT 2017 shared task, the best performing system used a multitask network that transferred the learning to a CRF classifier for the final prediction (Aguilar et al., 2017).

In this work we focus on addressing the challenges of the NER task found in social media environments. We propose that what is traditionally categorized as noise (i.e., misspellings, inconsistent orthography, emerging abbreviations, and slang) should be modeled *as is* since it is an inherent characteristic of SM text. Specifically, the proposed models attempt to address i) misspellings using subword level representations, ii) grammatical mistakes with SM-oriented Part-of-Speech tags (Owoputi et al., 2013), iii) sound-driven text with phonetic and phonological features (Bharadwaj et al., 2016), and iv) the intrinsic skewness of NER datasets by applying class weights. It is worth noting that our models do not rely on capitalization or any external resources such as gazetteers. The reasons are that capitalization is arbitrarily used on SM environments, and gazetteers are expensive resources to develop for a scenario where novel entities constantly and rapidly emerge (Derczynski et al., 2017; Augenstein et al., 2017).

Based on our experiments, we have seen that a multitask variation of the proposed networks improves the results over a single-task network. Additionally, this multitask version, paired with phonetic and phonological features, outperforms previous state-of-the-art results on the WNUT 2017 dataset, and the same models obtain reasonable results with respect to the state of the art on the CoNLL 2003 dataset (Tjong Kim Sang and De Meulder, 2003).

The rest of the paper is organized as follows: §2 presents the proposed features, the formal description of the models, and the implementation details. §3 describes the datasets and their challenges. On §4, we show the evaluation process of our models and the results. We explain the performance of the models on §5. §6 describes related work and, finally, we draw conclusions on §7.

2 Methods

Our methods are based on two main strategies: i) a representation of the input text using complementary features that are more suitable to social media environments, and ii) a fusion of these features by using a multitask neural network model whose main goal is to learn how entities are contextualized with and without the entity type information.

2.1 Feature representation

Semantic features. Semantic features play a crucial role in our pipeline as they provide contextual information to the model. This information allows the model to infer the presence of entities as well as the entity types. We use the pretrained word embedding model provided by Godin et al. (2015). This model has been trained on 1 million tweets (roughly 1% of the tweets in a year) with the skipgram algorithm. We take advantage of this resource as it easily adapts to other SM environments besides Twitter (Aguilar et al., 2017).

Syntactic features. Syntactic features help the models deal with word disambiguation based on

Sentence	IPA
u hav to b KIDDDDING me	/ju hæv tə bi kɪdɪŋ mi/
you have to be kidding me	/ju hæv tə bi kɪdɪŋ mi/

Table 2: Examples of both noisy and normalized text. In both cases, the mappings to the International Phonetic Alphabet (IPA) are the same.

the grammatical role that the words play on a sentence. That is, a word that can be a verb or a noun in different scenarios may conflict with the interpretations of the models; however, by providing syntactical information the models can improve their decisions. We capture grammatical patterns using the Part-of-Speech (POS) tagger provided by Owoputi et al. (2013). This POS tagger has custom labels that are suitable to SM data (i.e., the tagger considers emojis, hashtags, URLs and others).

Phonetic and phonological features. We also consider the phonetic and phonological aspects of the data at the character level. In Table 2 we show an example of two phrases: the first sentence is taken from SM, and the second one is its normalized representation. Even though the spellings of both phrases are significantly different, by using the phonological (articulatory) aspects of those phrases it is possible to map them to the same phonetic representation. In other words, our assumption is that social media writers heavily rely on the way that words sound while they write. We use the Epitran[1] library (Bharadwaj et al., 2016), which transliterates graphemes to phonemes with the International Phonetic Alphabet (IPA). In addition to the IPA phonemes, we also use the phonological (articulatory) features generated by the PanPhon[2] library (Mortensen et al., 2016). These features provide articulatory information such as the way the mouth and nasal areas are involved in the elaboration of sounds while people speak.

2.2 Models

We have experimented with two models. In the first one, we use an end-to-end BLSTM-CRF network with a multitask output layer comprised of one CRF per task, similar to Yang et al. (2016). In the second one, we define a stacked model that is based on two phases: i) a multitask neural network and ii) a CRF classifier. In the first phase, the network acts as a feature extractor, and then, for the second phase, it transfers the learning to a CRF classifier for the final predictions (see Figure 3). In both cases, the multitask layer is defined with the following two tasks:

- **Segmentation**. This task focuses on the Begin-Inside-Outside (BIO scheme) level of the tokens. That is, for a given NE, the model has to predict whether a word is B, I, or O regardless of the entity type. The idea is to let the models learn how entities are treated in general, rather than associating the types to certain contexts. This task acts as a regularizer of the primary task to prevent overfitting.

- **Categorization**. In this case, the models have to predict the types of the entities along with the BIO scheme (e.g., B-person, I-person, etc.), which represent the final labels.

We formalize the definitions of our models as follows: let $X = [x_1, x_2, ..., x_n]$ be a sample sentence where x_i is the i^{th} word in the sequence. Then, let $\alpha : V_x \rightarrow \mathbb{R}^{dim_x}$ be a word embedding, and let $\mathbf{x} = [\alpha(x_1), \ldots, \alpha(x_n)]$ be the word embedding matrix for the sample sentence such that V_x is the vocabulary and dim_x is the dimension of the embedding space. Similarly, let $\beta : V_p \rightarrow \mathbb{R}^{dim_p}$ be the POS tag embedding, and let $\mathbf{p} = [\beta(p_1), \ldots, \beta(p_n)]$ be the POS tag embedding matrix for the sample sentence such that V_p is the set of Part-of-Speech tags and dim_p is the dimension of the embedding space. Notice that the POS tag embedding matrix $\mathbf{p}$ is learned during training. Also, let $Q = [q_1, q_2, ..., q_m]$ be the phonetic letters of a word; let $\gamma : V_q \rightarrow \mathbb{R}^{|V_q|+dim_{PanPhon}}$ be an embedding that maps each phonetic character to a one-hot vector of the International Phonetic Alphabet (V_q) concatenated with the 21 ($dim_{PanPhon}$) phonological features of the PanPhon library (tongue position, movement of lips, etc.) (Bharadwaj et al., 2016); and let $\mathbf{q} = [\gamma(q_1), ..., \gamma(q_m)]$ be the matrix representation of the word-level phonetics and phonology.

We first apply an LSTM (Hochreiter and Schmidhuber, 1997) to the $\mathbf{q}$ matrix on forward and backward directions. Then we concatenate the output from both directions:

$$\overrightarrow{\mathbf{h}} = \text{LSTM}(\{\mathbf{q}_1, \mathbf{q}_2, ..., \mathbf{q}_m\})$$
$$\overleftarrow{\mathbf{h}} = \text{LSTM}(\{\mathbf{q}_m, \mathbf{q}_{m-1}, ..., \mathbf{q}_1\})$$
$$\mathbf{h} = [\overrightarrow{\mathbf{h}}; \overleftarrow{\mathbf{h}}]$$

[1] https://github.com/dmort27/epitran
[2] https://github.com/dmort27/panphon

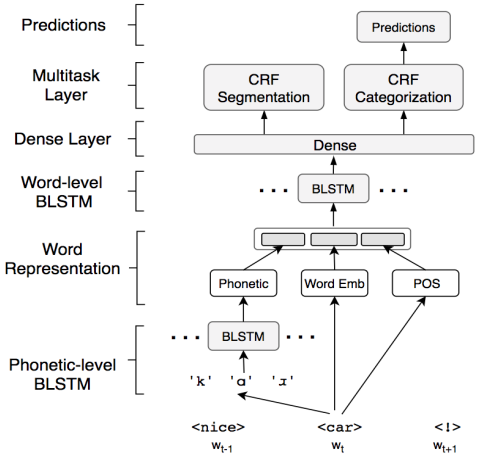

Figure 2: This is an end-to-end system that uses the CRF loss function as the objective function of the network. It also uses multitask learning on the output layer.

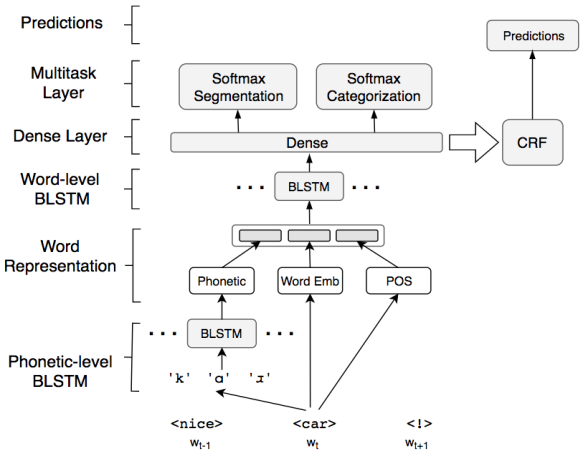

Figure 3: This is a stacked model that uses a network as feature extractor, and then it transfers the learning to a CRF classifier. The network uses multitask learning to capture the features.

This vector not only encodes the phonetic and phonological features, but it also captures some morphological patterns at the character level based on the IPA representations. Then, we concatenate this vector with the word and POS tag representations: $\mathbf{a} = [\mathbf{x}_t; \mathbf{p}_t; \mathbf{h}_t]$. We feed this representation to another bidirectional LSTM network (Dyer et al., 2015), similar to the BLSTM described for the character level. The bidirectional LSTM generates a word-level representation that accounts for the context in the sentence using semantics, syntax, phonetics and phonological aspects. We feed this representation to a fully-connected layer:

$$\mathbf{r}_i = \text{BLSTM}(\{\mathbf{a}_1, \mathbf{a}_2, ...\mathbf{a}_n\}) \quad (1)$$

$$\mathbf{z}_i = \text{ReLU}(\mathbf{W}_a \mathbf{r}_i + \mathbf{b}) \quad (2)$$

At this point, both models share the same definition. From here, we describe the multitask learning characteristics for each model separately.

End-to-end model. For the end-to-end network (see Figure 2), we define an output layer based on two Conditional Random Fields (Lafferty et al., 2001), each assigned to one of the tasks. The idea of adding a CRF to the model is to capture the relation of the output probabilities of the network with respect to the whole sequence. This means that the CRFs will maximize the log-likelihood of the entire sequence, which allows the model to learn very specific constraints from the data (e.g., a label *I-location* cannot be followed by *I-person*). Following Ma and Hovy (2016), we formalize the definition of the CRF as follows: let $\mathbf{y} = [y_1, y_2, ..., y_n]$ be the labels for a sequence $\mathbf{x}$, where y_i represents the i^{th} label of the $\mathbf{x}_i$ token in the sentence. Next, we calculate the conditional probability of seeing $\mathbf{y}$ given the extracted features $\mathbf{z}$ from the network and the weights $\mathbf{W}$ associated to the labels:

$$p(\mathbf{y}|\mathbf{z}; \mathbf{W}) = \frac{\exp(\mathbf{W}_y \Phi(\mathbf{z}, \mathbf{y}))}{\sum_{\mathbf{y}' \in \mathbf{y}} \exp(\mathbf{W}_y \Phi(\mathbf{z}, \mathbf{y}'))}$$

Where Φ is a feature function that codifies the interactions between consecutive labels, y_t and y_{t+1}, as well as the interactions between labels and words, represented by z_t. Then, the objective function for one CRF is defined by the maximum log-likelihood of this probability. However, we are running two CRFs as the objective function:

$$\mathcal{L}_1(\mathbf{z}, \mathbf{W}) = \log p(\mathbf{y}_{seg}|\mathbf{z}; \mathbf{W})$$
$$\mathcal{L}_2(\mathbf{z}, \mathbf{W}) = \log p(\mathbf{y}_{cat}|\mathbf{z}; \mathbf{W})$$
$$L(\mathbf{z}, \mathbf{W}) = \alpha \mathcal{L}_1(\mathbf{z}, \mathbf{W}) + \mathcal{L}_2(\mathbf{z}, \mathbf{W})$$

Where $\mathcal{L}_1$ is the loss function of the segmentation task with labels $\mathbf{y}_{seg}$. Similarly, $\mathcal{L}_2$ is the loss function of the categorization task with labels $\mathbf{y}_{cat}$. L is the loss function that accounts for both tasks, where the segmentation task is weighted by an α scalar.

Stacked model. For this model, we use a multitask network as a feature extractor whose loss function is defined as a categorical cross entropy (see Figure 3). We apply a softmax activation function to produce the probability distribution over the labels, and then we calculate the loss as

follows:

$$H_1(\mathbf{y}, \mathbf{z}) = -\sum_{\mathbf{z}_i} \mathbf{y} \log(softmax(\mathbf{W}_{seg}\mathbf{z}_i + \mathbf{b}))$$

$$H_2(\mathbf{y}, \mathbf{z}) = -\sum_{\mathbf{z}_i} \mathbf{y} \log(softmax(\mathbf{W}_{cat}\mathbf{z}_i + \mathbf{b}))$$

$$L(\mathbf{y}, \mathbf{z}) = \alpha H_1(\mathbf{z}, \mathbf{W}_{seg}) + H_2(\mathbf{z}, \mathbf{W}_{cat})$$

After training the multitask network, we take the activation outputs from Equation 2. These vectors are used as features to train a Conditional Random Fields classifier. The definition of the CRF is the same as the one described for the end-to-end network.

2.3 Implementation details

We have performed a very simple preprocessing on the data, which consists in replacing URLs, emojis, tags, and numbers with predefined tokens. Additionally, the vocabulary of the pretrained word embeddings was not sufficient to cover all the words in the WNUT dataset (i.e., training, validation, and testing sets have OOV words). We handled this situation using the Facebook library FastText (Bojanowski et al., 2016). This library can produce an embedding vector from the subword level of the word (i.e., ngrams). The advantage of FastText over other embedding learning algorithms is that we can still extract useful embeddings for OOV words from their subword embeddings. For instance, if there is a missing letter in one word, the subword-level vector will be reasonably close to the vector of the correct spelling.

The models have been trained using weighted classes, which forces the models to pay more attention to the labels that are less frequent. This is a very important step since the NE datasets usually show a skewed distribution, where the NE tokens represent approximately 10% of the entire corpus. Although weighting classes improves the recall of the model, we tried to be sensitive to this aspect as the model can be forced to predict entities even in cases where there are none. The weights were experimentally defined, keeping the same distribution but decreasing the loss on non-entity tokens.

Additionally, we defined our models using the following hyperparameters: the phonetic and phonological BLSTM at the character level uses 64 units per direction, which adds up to 128 units. Similarly, the word level BLSTM uses 100 units per direction, which accounts for a total of 200 units. The fully-connected layer has 100 neurons, and it uses a Rectified Linear Unit (ReLU) activation function. We also use a dropout operation before and after each BLSTM component. This forces the networks to find different paths to predict the data, which ultimately improves the generalization capabilities (i.e., they do not rely on a single path for certain inputs). The dropout value is 0.5. For the stacked model we use the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001.

Corpus	Dataset	Classes	% Unique
CoNLL 2003	Train	4	26%
	Dev	4	40%
	Test	4	41%
WNUT 2017	Train	6	75%
	Dev	6	85%
	Test	6	80%

Table 3: Percentage of unique NEs in two benchmark datasets, the one from CoNLL 2003 and the one used in the 2017 shared task held by the WNUT workshop.

3 Datasets

Social media (SM) captures the fast evolving behavior of the language, and, as its influence in society grows, SM platforms play an important role in language understanding. We focus this work on the WNUT 2017 dataset for NER (Derczynski et al., 2017). This dataset covers multiple SM platforms and suits perfectly the purpose of this work. Table 5 shows the distribution of the dataset and its classes. The training set uses tweets, whereas the development set is based on YouTube comments. The testing set combines content from Reddit and StackExchange. The cross domain nature of the dataset establishes an additional challenge to the task. For instance, besides the particularities of the domains (e.g., length of the sentences, domain-specific expressions such as hashtags, emojis and others), the users tend to address different topics on each of the SM domains with different levels of relaxed language and style (Ritter et al., 2011; Strauss et al., 2016; Derczynski et al., 2017). Moreover, the predominant factors in those SM environments are the emerging and rare entities. As stated by Derczynski et al. (2017), *emerging* describes the entity instances that started to appear in context recently (e.g., a movie title released a

Statistics	Train	Dev	Test
Posts	3,395	1,009	1,287
Tokens	62,729	15,733	23,394
NE tokens	3,160	1,250	1,589
NE tokens (%)	5.04	7.95	6.79

Table 4: General statistics of the WNUT 2017 dataset. It is worth noting that the NE tokens account for less than 10% on any dataset, which shows the inherent skewness of the task.

corporation	267	209	86
TOTAL	3,160	1,250	1,589

Table 5: Classes and their frequency distribution on the WNUT 2017 dataset.

year ago), whereas *rare* depicts the entities that appear less than certain number of times. It is worth noting that this dataset presents a great challenge to systems that rely on external resources due to the rare and emerging properties.

We also consider the CoNLL 2003 dataset (Tjong Kim Sang and De Meulder, 2003) as it has been used as the standard dataset for NER benchmarks. However, we emphasize that both datasets present significantly different challenges and, thus, some relevant aspects in CoNLL 2003 may not be that relevant in the WNUT 2017 dataset. For example, capitalization is a crucial feature in newswire text, but it is less important in SM data since users tend to arbitrarily alter the character casing. Moreover, the target classes on the WNUT 2017 dataset cover the CoNLL 2003 classes plus fine-grained classes such as *creative-work* (e.g., movie titles, T.V. shows, etc.), *group* (e.g., sports teams, music bands, etc.), and *product*. The additional classes are more heterogeneous, and thus, it makes the task more difficult to generalize. Furthermore, Table 3 shows the percentage of unique tokens of the WNUT 2017 dataset, which certainly shows a great diversity compared to the CoNLL 2003 dataset.

4 Experiments and results

We mainly focus our experiments on the WNUT 2017 dataset. However, we consider relevant to compare our approach to the standard CoNLL 2003 dataset where current state-of-the-art systems are benchmarked. This section addresses the experiments and results of both datasets.

4.1 WNUT 2017 experiments

In this section we discuss the experiments of the proposed approaches. We compare our models and describe the contribution of each component of the stacked system. Additionally, we compare our results against the state of the art in the WNUT 2017 dataset.

Stacked vs. end-to-end model. Table 6 shows that the stacked system has a lower precision than the end-to-end model, but its recall is the highest. This means that the stacked model is slightly better at generalizing than the other models since it can detect a more diverse set of entities. The surface form F1 metric (Derczynski et al., 2017) supports that intuition as well. It assigns a better F1 score to the stacked system (43.90%) than to the end-to-end model (42.79%) because the former finds more *rare* and *emerging* entities than the latter. Moreover, Table 6 also shows that the precision of the end-to-end model is higher than the rest of the systems. This tends to capture the most frequent entities and leave behind the *rare* ones, which explains the different behaviors between the precision and recall of both models.

Stacked model. The feature extractor contains a category task that can produce predictions of the test set. We explored predicting the final labels with the feature extractor and compared the results against the predictions of the CRF classifier. We noticed that the CRF always outperformed the network. For the best scores the feature extractor achieved 40.64% whereas the CRF reached 45.55%. This is consistent with previous research (Lample et al., 2016; Aguilar et al., 2017) in that the individual output probabilities of the network do not consider the whole sequence, and thus, a sequential algorithm such as a CRF can improve the results by learning global constraints (i.e., the *B-person* cannot be followed by *I-corporation*).

Ablation experiment. We explored the contribution of the features and different aspects of our models. For instance, we tried a BLSTM network using pretrained word embeddings only. The re-

Classes	Precision (%)			Recall (%)			F1 (%)		
	Stacked	E2E	WNUT	Stacked	E2E	WNUT	Stacked	E2E	WNUT

Table 6: The class-level and overall results of our systems on the WNUT 2017 dataset. WNUT represents the winning system of the shared task (UH-RiTUAL), E2E is the end-to-end model, and Stacked shows the results of the stacked model. Both systems considerably outperform the state-of-the-art results. Between the end-to-end and the stacked models, the former gets better overall precision while the latter stands out on recall.

Model	F1	Delta
Stacked Model	**45.55**	
- Multitask Learning	44.76	-0.79
- Character phonetics	43.83	-0.93
- Weighted classes	41.25	-2.58
- POS tag vectors	40.15	-1.10
- FastText OOV vectors	39.78	-0.37
- Pretrained embeddings	12.72	-27.06

Table 7: We performed an ablation experiment on the stacked model. The results in the table are the average of the scores of three iterations.

sults of this model set our baseline on a 39.78% F1-score (see Table 7). This score is considerably close to the state-of-the-art performance, but improvements beyond that are small. For instance, Table 7 shows an ablation experiment using the stacked model. The ablation reveals that weighting the classes is the most influential factor, which accounts for a 2.58% of F1 score improvement. This aligns with the fact that the data is highly skewed, and thus, the model should pay more attention to the less frequent classes. The second most important aspect is the POS tags, which enhance the results by 1.10%. This improvement suggests that POS tags are important whether the dataset is from a noisy environment or not since other researchers have found positive effects by using this feature on formal text (Huang et al., 2015). Almost equally influential are the phonetic and phonological features that push the F1 score by 0.93%. According to the ablation experiment, using phonetic and phonology along with the pretrained word embeddings and POS tags can reach an F1 measure of 41.81%, which is a very similar result to the state-of-the-art score, but with a simpler and more suitable model for SM environments (i.e., without gazetteers or capitalization).

We explored the multitask learning aspect by empirically trying multiple combinations of auxiliary tasks. The best combination is the standard NER categorization along with the segmentation task. The segmentation slightly improves the binary task proposed by Aguilar et al. (2017) by around 0.3%. Additionally, trying the binarization, segmentation, and categorization tasks together drops the results by around 0.2% with respect to the categorization paired with the binary task. Moreover, the ablation experiment shows that the multitask layer boosts the performance of the stacked model with 0.79% of F1 score.

For the OOV problem, we use FastText to provide vectors to 2,333 words (around 13% of the vocabulary). However, the ablation experiment shows a small improvement, which suggests that those words did not substantially contribute to the meaning of the context. Another aspect that we explored was adding all the letters of the dataset to the character level of the stacked model without modifying the casing. Surprisingly, the models produced a slightly worse result (around -0.5%). Our intuition is that the character aspects are already captured by the model with the phonetic (IPA) representation, and the arbitrary use of capitalization renders this information useless. It is also worth noting that having phonetics instead of a language-dependent alphabet allows the adaptability of this approach to other languages.

State of the art comparison. Table 6 shows that our end-to-end and stacked models significantly outperform the state-of-the-art score by 2.28% and 3.69% F1 points, respectively. In the case of the stacked system, the precision and recall outper-

No	**Predictions**

Table 8: Examples of the predictions of our stacked model in the Reddit domain of the WNUT 2017 dataset. The bold words are the gold labels, and the underlined words are the predictions of our model. The model matches the entity types of the labeled data.

form the winning system of the shared task (UH-RiTUAL) across all the classes. Moreover, even though the UH-RiTUAL system uses gazetteers, it only outperforms the recall of the end-to-end model on the *corporation* class. These results can be explained by the entity diversity of the dataset, where the *emerging* and *rare* properties are difficult to capture with external resources.

4.2 CoNLL 2003 evaluation

We also benchmarked our approach on a standard CoNLL 2003 dataset for the NER task. The stacked model reached 89.01% while the end-to-end model achieved 88.98% on the F1 metric. Although the state-of-the-art performance is 91.21% (Ma and Hovy, 2016), our approach targets SM domains and, consequently, our models disregard some of the important aspects on formal text while still getting reasonable results. For instance, Ma and Hovy (2016) input the text to their model *as is*, which indirectly introduce capitalization to the morphological analysis at the character level. This aspect becomes relevant in this dataset because entities are usually capitalized on formal text. As explained before, our models do not rely on capitalization because the characters are represented by the International Phonetic Alphabet, which does not differentiate between lower and upper cases.

5 Analysis

Table 8 shows some predictions of our stacked model on the WNUT 2017 test set. In example number 1, the model is able to correctly label *Srinagar* as *person*, even though the model does not rely on gazetteers or capitalization. It is also important to mention that the word was not in the training or development set, which means that the network had to infer the entity purely from the context. Moreover, the second example shows that the model has problems to determine whether the article *the* belongs to an NE or not. This is an ambiguous problem that even humans struggle with. This example also has a variation on spelling for the words *Defence* and *Organisation*. We suspect that the mitigation of OOV words using the FastText library helped in this case. Also, from the phonetic perspective, the model treated the word *Defence* as if it was the word *Defense* because both words map to the same IPA sequence, /dɪfɛns/. In the third case, the model is not able to identify the NE *Scout*, even though the context makes it fairly easy.

6 Related work

In its former years, NER systems focused on newswire text, where the goal was to identify mainly three types of entities: *person*, *corporation*, and *location*. These entity types were originally proposed in the 6th Message Understanding Conference (MUC-6) (Grishman and Sundheim, 1996b). In MUC-7, the majority of the systems were based on heavily hand-crafted features and manually elaborated rules (Borthwick et al., 1998). Some years later, many researchers incorporated machine learning algorithms to their systems, but there was still a strong dependency on external resources and domain-specific features and rules (Tjong Kim Sang and De Meulder, 2003). In addition, the majority of the systems used Maximum Entropy (Bender et al., 2003; Chieu and Ng, 2003b; Curran and Clark, 2003; Florian et al., 2003b; Klein et al., 2003) and Hidden Markov Models (Florian et al., 2003b; Klein et al., 2003; Mayfield et al., 2003; Whitelaw and Patrick, 2003). Furthermore, McCallum and Li (2003) used a CRF combined with web-augmented lexicons. The features were selected by hand-crafted rules and refined based on their relevance to the domain of the entities. Moreover, Nothman et al. (2013) used Wikipedia resources to take advantage of structured data and reduce the human-annotated labels. In general, the results of the systems were reasonable for formal text, yet the scalability and the expensive detailed rules were not; their systems were difficult to maintain and adapt to other domains where different rules were needed.

Recently, NER has been focused on noisy data as a result of the growth in social media users. However, the limits of the previous systems dramatically affected the results on noisy domains. For instance, Derczynski et al. (2014) evaluated multiple NER tools in noisy environments: Stanford NER (Finkel et al., 2005), ANNIE (Cunningham et al., 2002), among others. They reported that the majority of the tools were not capable of adapting to the noisy conditions showing a drop in performance of around 40% on a F1-score metric. This motivated many researchers to solve the problem using different techniques. In 2015, Baldwin et al. (2015) organized a NER shared task at the 1st Workshop on Noisy User-generated Text (WNUT), where three of the participants used word embedding as features to train their traditional machine learning algorithms (Godin et al., 2015; Toh et al., 2015; Cherry et al., 2015). The shared task introduced noisy data as well as more difficult entity types to identify (e.g., tv show, product, sports team, movie, music artist, etc.). Notably, the WNUT 2016 and 2017 were predominated by neural network systems (Limsopatham and Collier, 2016; Aguilar et al., 2017).

Deep neural networks have proven to be effective for NER. The state-of-the-art and the most competitive architectures can be characterized by the use of recurrent neural networks (Chiu and Nichols, 2016) combined with CRF (Lample et al., 2016; Ma and Hovy, 2016; Peng and Dredze, 2016; Bharadwaj et al., 2016; Aguilar et al., 2017). Our work primarily focuses on social media data and explores more suitable variations and combinations of those models. The most important differences of our approach and previous works are i) the use of phonetics and phonology (articulatory) features at the character level to model SM noise, ii) consistent BLSTMs for character and word levels, iii) the segmentation and categorization tasks, iv) a multitask neural network that transfers the learning without using lexicons or gazetteers, and v) weighted classes to handle the inherent skewness of the datasets.

7 Conclusions

This paper proposed two models for NER on social media environments. The first one is a stacked model that uses a multitask BLSTM network as a feature extractor to transfer the learning to a CRF classifier. The second one is an end-to-end multitask BLSTM-CRF model whose output layer has a CRF per task. Both models improve the state-of-the-art results on the WNUT 2017 dataset, where the data comes from multiple SM domains (i.e., Twitter, YouTube, Reddit, and StackExchange). Instead of working on normalizing text, we designed representations that are robust to inherent properties of SM data: inconsistent spellings, diverse vocabulary, and flexible grammar. Considering that SM is a prevalent communication channel that constantly generates massive amounts of data, it is practical to design NLP tools to process this domain *as is*. In this sense, we showed that the phonetic and phonological features are useful to capture sound-driven writing. This approach avoids the standard normalization process and boosts prediction performance. Furthermore, the use of multitask learning with segmentation and categorization is important to improve the results of the models. Finally, the weighted classes force the model to pay more attention on skewed datasets. We showed that these components can point to more suitable approaches for NER on social media data.

Abstract

We propose several ways of reusing subword embeddings and other weights in subword-aware neural language models. The proposed techniques do not benefit a competitive character-aware model, but some of them improve the performance of syllable- and morpheme-aware models while showing significant reductions in model sizes. We discover a simple hands-on principle: in a multi-layer input embedding model, layers should be tied consecutively bottom-up if reused at output. Our best morpheme-aware model with properly reused weights beats the competitive word-level model by a large margin across multiple languages and has 20%–87% fewer parameters.

1 Introduction

A statistical language model (LM) is a model which assigns a probability to a sequence of words. It is used in speech recognition, machine translation, part-of-speech tagging, information retrieval and other applications. Data sparsity is a major problem in building traditional n-gram language models, which assume that the probability of a word only depends on the previous n words. To deal with potentially severe problems when confronted with any n-grams that have not explicitly been seen before, some form of smoothing is necessary.

Recent progress in statistical language modeling is connected with neural language models (NLM), which tackle the data sparsity problem by representing words as vectors. Typically this is done twice: at input (to embed the current word of a sequence into a vector space) and at output (to embed candidates for the next word of a sequence). Especially successful are the models in which the architecture of the neural network between input and output is recurrent (Mikolov et al., 2010), which we refer to as recurrent neural network language models (RNNLM).

Tying input and output word embeddings in word-level RNNLM is a regularization technique, which was introduced earlier (Bengio et al., 2001; Mnih and Hinton, 2007) but has been widely used relatively recently, and there is empirical evidence (Press and Wolf, 2017) as well as theoretical justification (Inan et al., 2017) that such a simple trick improves language modeling quality while decreasing the total number of trainable parameters almost two-fold, since most of the parameters are due to embedding matrices. Unfortunately, this regularization technique is not directly applicable to subword-aware neural language models as they receive subwords at input and return words at output. This raises the following questions: Is it possible to reuse embeddings and other parameters in subword-aware neural language models? Would it benefit language modeling quality? We experimented with different subword units, embedding models, and ways of reusing parameters, and our answer to both questions is as follows: There are several ways to reuse weights in subword-aware neural language models, and none of them improve a competitive character-aware model, but some of them do benefit syllable- and morpheme-aware models, while giving significant reductions in model sizes. A simple morpheme-aware model that sums morpheme embeddings of a word benefits most from appropriate weight tying, showing a significant gain over the competitive word-level baseline across different languages and data set sizes. Another contribution of this paper is the discovery of a hands-on principle that in a multi-layer input embedding model, layers should be tied consecutively bottom-up if reused at output.

The source code for the morpheme-aware model is available at `https://github.com/zh3nis/morph-sum`.

2 Related Work

Subword-aware NLM: There has been a large number of publications in the last 2–3 years on subword-level and subword-aware NLMs,[1] especially for the cases when subwords are characters (Ling et al., 2015; Kim et al., 2016; Verwimp et al., 2017) or morphemes (Botha and Blunsom, 2014; Qiu et al., 2014; Cotterell and Schütze, 2015). Less work has been done on syllable-level or syllable-aware NLMs (Mikolov et al., 2012; Assylbekov et al., 2017; Yu et al., 2017). For a thorough and up-to-date review of the previous work on subword-aware neural language modeling we refer the reader to the paper by Vania and Lopez (2017), where the authors systematically compare different subword units (characters, character trigrams, BPE, morphs/morphemes) and different representation models (CNN, Bi-LSTM, summation) on languages with various morphological typology.

Tying weights in NLM: Reusing embeddings in word-level neural language models is a technique which was used earlier (Bengio et al., 2001; Mnih and Hinton, 2007) and studied in more details recently (Inan et al., 2017; Press and Wolf, 2017). However, not much work has been done on reusing parameters in subword-aware or subword-level language models. Jozefowicz et al. (2016) reused the *CharCNN* architecture of Kim et al. (2016) to dynamically generate softmax word embeddings without sharing parameters with an input word-embedding sub-network. They managed to significantly reduce the total number of parameters for large models trained on a huge dataset in English (1B tokens) with a large vocabulary (800K tokens) at the expense of deteriorated performance. Labeau and Allauzen (2017) used similar approach to augment the output word representations with subword-based embeddings. They experimented with characters and morphological decompositions, and tried different compositional models (CNN, Bi-LSTM, concatenation) on Czech dataset consisting of 4.7M tokens. They were not tying weights between input and output representations, since their preliminary experiments with tied weights gave worse results.

Our approach differs in the following aspects: we focus on the ways to *reuse* weights at output, seek both model size reduction *and* performance improvement in subword-aware language models, try different subword units (characters, syllables, and morphemes), and make evaluation on small (1M–2M tokens) and medium (17M–51M tokens) data sets across multiple languages.

[1] *Subword-level* LMs rely on subword-level inputs and make predictions at the level of subwords; *subword-aware* LMs also rely on subword-level inputs but make predictions at the level of words.

3 Recurrent Neural Language Model

Let $\mathcal{W}$ be a finite vocabulary of words. We assume that words have already been converted into indices. Let $\mathbf{E}^{\text{in}}_{\mathcal{W}} \in \mathbb{R}^{|\mathcal{W}| \times d_{\mathcal{W}}}$ be an input embedding matrix for words — i.e., it is a matrix in which the wth row (denoted as $\mathbf{w}$) corresponds to an embedding of the word $w \in \mathcal{W}$.

Based on word embeddings $\mathbf{w_{1:k}} = \mathbf{w_1}, \ldots, \mathbf{w_k}$ for a sequence of words $w_{1:k}$, a typical word-level RNN language model produces a sequence of states $\mathbf{h_{1:k}}$ according to

$$\mathbf{h_t} = \text{RNNCell}(\mathbf{w_t}, \mathbf{h_{t-1}}), \quad \mathbf{h_0} = \mathbf{0}. \tag{1}$$

The last state $\mathbf{h_k}$ is assumed to contain information on the whole sequence $w_{1:k}$ and is further used for predicting the next word w_{k+1} of a sequence according to the probability distribution

$$\Pr(w_{k+1}|w_{1:k}) = \text{softmax}(\mathbf{h_k}\mathbf{E}^{\text{out}}_{\mathcal{W}} + \mathbf{b}), \tag{2}$$

where $\mathbf{E}^{\text{out}}_{\mathcal{W}} \in \mathbb{R}^{d_{\text{LM}} \times |\mathcal{W}|}$ is an output embedding matrix, $\mathbf{b} \in \mathbb{R}^{|\mathcal{W}|}$ is a bias term, and d_{LM} is a state size of the RNN.

Subword-based word embeddings: One of the more recent advancements in neural language modeling has to do with segmenting words at input into subword units (such as characters, syllables, morphemes, etc.) and composing each word's embedding from the embeddings of its subwords. Formally, let $\mathcal{S}$ be a finite vocabulary of subwords,[2] and let $\mathbf{E}^{\text{in}}_{\mathcal{S}} \in \mathbb{R}^{|\mathcal{S}| \times d_{\mathcal{S}}}$ be an input embedding matrix for subwords. Any word $w \in \mathcal{W}$ is a sequence of its subwords $(s_1, s_2, \ldots, s_{n_w}) = \sigma(w)$, and hence can be represented as a sequence of the corresponding subword vectors:

$$[\mathbf{s_1}, \mathbf{s_2}, \ldots, \mathbf{s_{n_w}}]. \tag{3}$$

A subword-based word embedding model $E(\cdot; \mathbf{E}^{\text{in}}_{\mathcal{S}}, \mathbf{\Theta}^{\text{in}})$ with parameters $(\mathbf{E}^{\text{in}}_{\mathcal{S}}, \mathbf{\Theta}^{\text{in}})$ constructs a word vector $\mathbf{x}$ from the sequence of subword vectors (3), i.e.

$$\mathbf{x} = E(\sigma(w); \mathbf{E}^{\text{in}}_{\mathcal{S}}, \mathbf{\Theta}^{\text{in}}), \tag{4}$$

[2] As in the case of words, we assume that subwords have already been converted into indices.

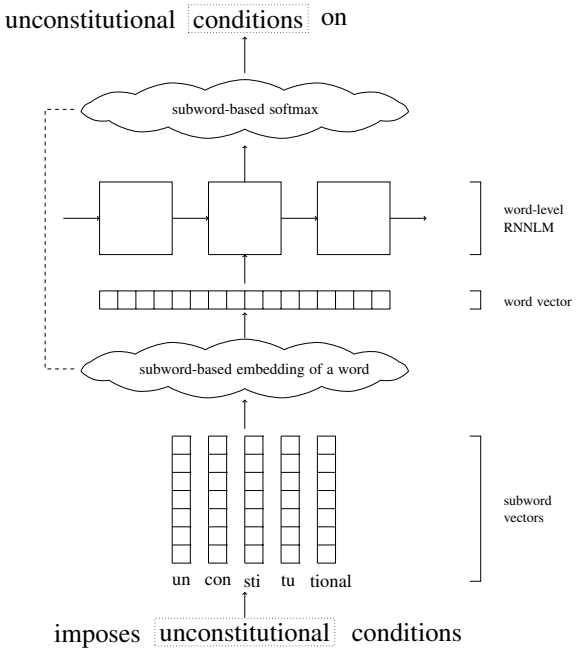

Figure 1: Subword-aware RNNLM with subword-based softmax.

which is then fed into a RNNLM (1) instead of a plain embedding $\mathbf{w}$. The additional parameters $\mathbf{\Theta}^{\text{in}}$ correspond to the way the embedding model constructs the word vector: for instance, in the *CharCNN* model of Kim et al. (2016), $\mathbf{\Theta}^{\text{in}}$ are the weights of the convolutional and highway layers.

Reusing word embeddings: Another recent technique in word-level neural language modeling is tying input and output word embeddings:

$$\mathbf{E}^{\text{in}}_{\mathcal{W}} = \left(\mathbf{E}^{\text{out}}_{\mathcal{W}}\right)^T,$$

under the assumption that $d_{\mathcal{W}} = d_{\text{LM}}$. Although being useful for word-level language modeling (Press and Wolf, 2017; Inan et al., 2017), this regularization technique is not directly applicable to subword-aware language models, as they receive subword embeddings at input and return word embeddings at output. In the next section we describe a simple technique to allow reusing subword embeddings $\mathbf{E}^{\text{in}}_{\mathcal{S}}$ as well as other parameters $\mathbf{\Theta}^{\text{in}}$ in a subword-aware RNNLM.

4 Reusing Weights

Let $\mathbf{E}^{\text{out}}_{\mathcal{S}}$ be an output embedding matrix for subwords and let us modify the softmax layer (2) so that it utilizes $\mathbf{E}^{\text{out}}_{\mathcal{S}}$ instead of the word embedding matrix $\mathbf{E}^{\text{out}}_{\mathcal{W}}$. The idea is fairly straightforward: we reuse an embedding model (4) to construct a new word embedding matrix:

$$\hat{\mathbf{E}}^{\text{out}}_{\mathcal{W}} = [E(\sigma(w); \mathbf{E}^{\text{out}}_{\mathcal{S}}, \mathbf{\Theta}^{\text{out}}) \text{ for } w \in \mathcal{W}], \quad (5)$$

and use $\hat{\mathbf{E}}^{\text{out}}_{\mathcal{W}}$ instead of $\mathbf{E}^{\text{out}}_{\mathcal{W}}$ in the softmax layer (2). Such modification of the softmax layer will be referred to as *subword-based softmax*. The overall architecture of a subword-aware RNNLM with subword-based softmax is given in Figure 1. Such a model allows several options for reusing embeddings and weights, which are discussed below.

- Reusing neither subword embeddings nor embedding model weights: As was shown by Jozefowicz et al. (2015), this can significantly reduce the total number of parameters for large models trained on huge datasets (1B tokens) with large vocabularies (800K tokens). However, we do not expect significant reductions on smaller data sets (1-2M tokens) with smaller vocabularies (10-30K tokens), which we use in our main experiments.
- Reusing subword embeddings (*RE*) can be done by setting $\mathbf{E}^{\text{out}}_{\mathcal{S}} = \mathbf{E}^{\text{in}}_{\mathcal{S}}$ in (5). This will give a significant reduction in model size for models with $|\mathbf{E}^{\text{in}}_{\mathcal{S}}| \gg |\mathbf{\Theta}^{\text{in}}|$,[3] such as the morpheme-aware model of Botha and Blunsom (2014).
- Reusing weights of the embedding model (*RW*) can be done by setting $\mathbf{\Theta}^{\text{out}} = \mathbf{\Theta}^{\text{in}}$. Unlike the previous option, this should significantly reduce sizes of models with $|\mathbf{E}^{\text{in}}_{\mathcal{S}}| \ll |\mathbf{\Theta}^{\text{in}}|$, such as the character-aware model of Kim et al. (2016).
- Reusing both subword embeddings and weights of the embedding model (*RE+RW*) can be done by setting $\mathbf{E}^{\text{out}}_{\mathcal{S}} = \mathbf{E}^{\text{in}}_{\mathcal{S}}$ and $\mathbf{\Theta}^{\text{out}} = \mathbf{\Theta}^{\text{in}}$ simultaneously in (5). This should significantly reduce the number of trainable parameters in any subword-aware model. Here we use exactly the same word representations both at input and at output, so this option corresponds to the reusing of plain word embeddings in pure word-level language models.

5 Experimental Setup

Data sets: All models are trained and evaluated on the PTB (Marcus et al., 1993) and the WikiText-2 (Merity et al., 2017) data sets. For the PTB we utilize the standard training (0-20), validation (21-22), and test (23-24) splits along with preprocessing per Mikolov et al. (2010). WikiText-2 is an alternative to PTB, which is approximately two times as large in size and three times as large

[3] $|\mathbf{A}|$ denotes number of elements in $\mathbf{A}$.

in vocabulary (Table 1).

Data set	T	$\lvert\mathcal{W}\rvert$	$\lvert\mathcal{S}\rvert$	$\lvert\mathcal{M}\rvert$
PTB	0.9M	10K	5.9K	3.4K
WikiText-2	2.1M	33K	19.5K	8.8K

Table 1: Corpus statistics. T = number of tokens in training set; $|\mathcal{W}|$ = word vocabulary size; $|\mathcal{S}|$ = syllable vocabulary size; $|\mathcal{M}|$ = morph vocabulary size.

Subword-based embedding models: We experiment with existing representational models which have previously proven effective for language modeling.

- *CharCNN* (Kim et al., 2016) is a character-aware convolutional model, which performs on par with the 2014–2015 state-of-the-art word-level LSTM model (Zaremba et al., 2014) despite having 60% fewer parameters.
- *SylConcat* is a simple concatenation of syllable embeddings suggested by Assylbekov et al. (2017), which underperforms *CharCNN* but has fewer parameters and is trained faster.
- *MorphSum* is a summation of morpheme embeddings, which is similar to the approach of Botha and Blunsom (2014) with one important difference: the embedding of the word itself is not included into the sum. We do this since other models do not utilize word embeddings.

In all subword-aware language models we inject a stack of two highway layers (Srivastava et al., 2015) right before the word-level RNNLM as done by Kim et al. (2016), and the non-linear activation in any of these highway layers is a ReLU. The highway layer size is denoted by d_{HW}.

Word-level RNNLM: There is a large variety of RNN cells to choose from in (1). To make our results directly comparable to the previous work of Inan et al. (2017), Press and Wolf (2017) on reusing word embeddings we select a rather conventional architecture – a stack of two LSTM cells (Hochreiter and Schmidhuber, 1997).

Hyperparameters: We experiment with two configurations for the state size d_{LM} of the word-level RNNLM: 200 (small models) and 650 (medium-sized models). In what follows values outside brackets correspond to small models, and values within brackets correspond to medium models.

- *CharCNN:* We use the same hyperparameters as in the work of Kim et al. (2016), where "large model" stands for what we call "medium-sized model".
- *SylConcat:* $d_{\mathcal{S}} = 50$ (200), $d_{\text{HW}} = 200$ (800). These choices are guided by the work of Assylbekov et al. (2017).
- *MorphSum*: $d_{\mathcal{S}} = d_{\text{HW}} = 200$ (650). These choices are guided by Kim et al. (2016).

Optimizaton method is guided by the previous works (Zaremba et al., 2014; Gal and Ghahramani, 2016) on word-level language modeling with LSTMs. See Appendix A for details.

Syllabification and morphological segmentation: True syllabification of a word requires its grapheme-to-phoneme conversion and then its splitting up into syllables based on some rules. True morphological segmentation requires rather expensive morphological analysis and disambiguation tools. Since these are not always available for under-resourced languages, we decided to utilize Liang's widely-used hyphenation algorithm (Liang, 1983) and an unsupervised morphological segmentation tool, Morfessor 2.0 (Virpioja et al., 2013), as approximations to syllabification and morphological segmentation respectively. We use the default configuration of Morfessor 2.0. Syllable and morpheme vocabulary sizes for both PTB and WikiText-2 are reported in Table 1.

6 Results

In order to investigate the extent to which each of our proposed options benefits the language modeling task, we evaluate all four modifications (no reusing, RE, RW, RE+RW) for each subword-aware model against their original versions and word-level baselines. The results of evaluation are given in Table 2. We have both negative and positive findings which are summarized below.

Negative results:

- The 'no reusing' and RW options should never be applied in subword-aware language models as they deteriorate the performance.
- Neither of the reusing options benefits *CharCNN* when compared to the original model with a plain softmax layer.

Positive results:

- The *RE+RW* option puts *CharCNN*'s performance close to that of the original version, while reducing the model size by 30–75%.
- The *RE* and *RE+RW* are the best reusing options for *SylConcat*, which make it on par with the original *CharCNN* model, despite having 35–75% fewer parameters.

Model	PTB				Wikitext-2

Table 2: Results. The pure word-level models and original versions of subword-aware models (with regular softmax) serve as baselines. Reusing the input embedding architecture at output in *CharCNN* leads to prohibitively slow models when trained on WikiText-2 (≈800 tokens/sec on NVIDIA Titan X Pascal); we therefore abandoned evaluation of these configurations.

- The *RE* and *RE+RW* configurations benefit *MorphSum* making it not only better than its original version but also better than all other models and significantly smaller than the word-level model with reused embeddings.

In what follows we proceed to analyze the obtained results.

6.1 CharCNN is biased towards surface form

We hypothesize that the reason *CharCNN* does not benefit from tied weights is that CNN over character embeddings is an excessively flexible model which learns to adapt to a surface form more than to semantics. To validate this hypothesis we pick several words[4] from the English PTB vocabulary and consider their nearest neighbors under cosine similarity as produced by the medium-sized models (with the regular softmax layer) at input (Table 3). As we can see from the examples, the *CharCNN* model is somewhat more biased towards surface forms at input than *SylConcat* and *MorphSum*.[5] When *CharCNN* is reused to generate a softmax embedding matrix this bias is propagated to output embeddings as well (Table 3).

6.2 Tying weights bottom-up

From Table 2 one can notice that tying weights without tying subword embeddings (*RW*) *always* results in worse performance than the tying both weights and embeddings (*RE+RW*). Recall that subword embedding lookup is done before the weights of subword-aware embedding model are used (see Figure 1). This leads us to the following

Conjecture. *Let* $\mathbf{E}^{in}_{\mathcal{S}} = \mathbf{\Theta}^{in}_0, \mathbf{\Theta}^{in}_1, \mathbf{\Theta}^{in}_2, \dots, \mathbf{\Theta}^{in}_n$ *be the parameters of the consecutive layers of a subword-aware input embedding model (4), i.e.* $\mathbf{x} = \mathbf{x}^{(n)} = f_n\left(\mathbf{x}^{(n-1)}; \mathbf{\Theta}^{in}_n\right)$, $\dots$, $\mathbf{x}^{(1)} = f_1\left(\mathbf{x}^{(0)}; \mathbf{\Theta}^{in}_1\right)$, $\mathbf{x}^{(0)} = f_0\left(\sigma(w); \mathbf{E}^{in}_{\mathcal{S}}\right)$ *and let* $\mathbf{E}^{out}_{\mathcal{S}} = \mathbf{\Theta}^{out}_0, \mathbf{\Theta}^{out}_1, \mathbf{\Theta}^{out}_2, \dots, \mathbf{\Theta}^{out}_n$ *be the parameters of the consecutive layers of a subword-aware embedding model used to generate the output projection matrix (5). Let* A *be a subword-aware neu-*

[4] We pick the same words as Kim et al. (2016).

[5] A similar observation for character-aware NLMs was made by Vania and Lopez (2017).

Table 3: Nearest neighbors based on cosine similarity. We underline character ngrams in words which are close to the given word orthographically rather than semantically. The `pyphen` syllabifier, which is used in *SylConcat*, failed to segment the word 'looooook' into syllables, and therefore its neighbors are not available.

ral language model in which the first $(j+1)$ layers of input and output embedding sub-networks have tied weights:

$$\forall i = \overline{0, j} : \quad \mathbf{\Theta}_i^{in} = \mathbf{\Theta}_i^{out},$$

and let B be a model in which at least one layer below the $(j+1)^{th}$ layer has untied weights:

$$\exists i = \overline{0, j-1} : \quad \mathbf{\Theta}_i^{in} \neq \mathbf{\Theta}_i^{out},\ \mathbf{\Theta}_j^{in} = \mathbf{\Theta}_j^{out}.$$

Then model B performs at most as well as model A, i.e. $PPL_A \leq PPL_B$.

To test this conjecture empirically, we conduct the following experiments: in all three embedding models (*CharCNN*, *SylConcat*, and *MorphSum*), we reuse different combinations of layers. If an embedding model has n layers, there are 2^n ways to reuse them, as each layer can either be tied or untied at input and output. However, there are two particular configurations for each of the embedding models that do not interest us: (i) when neither of the layers is reused, or (ii) when only the very first embedding layer is reused. Hence, for each model we need to check $2^n - 2$ configurations. For faster experimentation we evaluate only small-sized models on PTB. The results are reported in Table 4. As we can see, the experiments in general reject our conjecture: in *SylConcat* leaving an untied first highway layer between tied embedding and second highway layers (denote this as HW_2+Emb) turned out to be slightly better than tying all three layers (HW_2+HW_1+Emb). Recall, that a highway is a weighted average between nonlinear and identity transformations of the incoming vector:

$$\mathbf{x} \mapsto \mathbf{t} \odot \text{ReLU}(\mathbf{x}\mathbf{A} + \mathbf{b}) + (\mathbf{1} - \mathbf{t}) \odot \mathbf{x},$$

where $\mathbf{t} = \sigma(\mathbf{x}\mathbf{W} + \mathbf{c})$ is a transform gate, $\mathbf{A}$, $\mathbf{W}$, $\mathbf{b}$ and $\mathbf{c}$ are trainable parameters, and $\odot$ is the element-wise multiplication operator. To find out why leaving an untied highway below a tied one is beneficial in *SylConcat*, we compare the distributions of the transform gate values $\mathbf{t}$ from the first highway layers of both configurations, HW_2+Emb and HW_2+HW_1+Emb, in *SylConcat* and *MorphSum* (Figure 2).

We can see that *SylConcat* heavily relies on nonlinearity in the first highway layer, while *MorphSum* does not utilize much of it. This means that in MorphSum, the highway is close to an identity operator ($\mathbf{t} \approx \mathbf{0}$), and does not transform the sum of morpheme vectors much, either at input or at output. Therefore, tying the first highway layer is natural to *Morh-Sum*. *SylConcat*, on the other hand, applies non-linear transformations to the concatenation of syllable vectors, and hence makes additional preparations of the word vector for the needs of the RNNLM at input and for Softmax prediction at output. These needs differ from each other (as shown in the next subsection). This is why *SylConcat* benefits from an additional degree of freedom when the first highway is left untied.

Despite not being true in all cases, and due to being true in many cases, we believe that the above-mentioned conjecture is still useful. In short it can be summarized as a practical hands-

Table 4: Reusing different combinations of layers in small *CharCNN* (left), small *SylConcat* (top right) and small *MorphSum* on PTB data. "✓" means that the layer is reused at output.

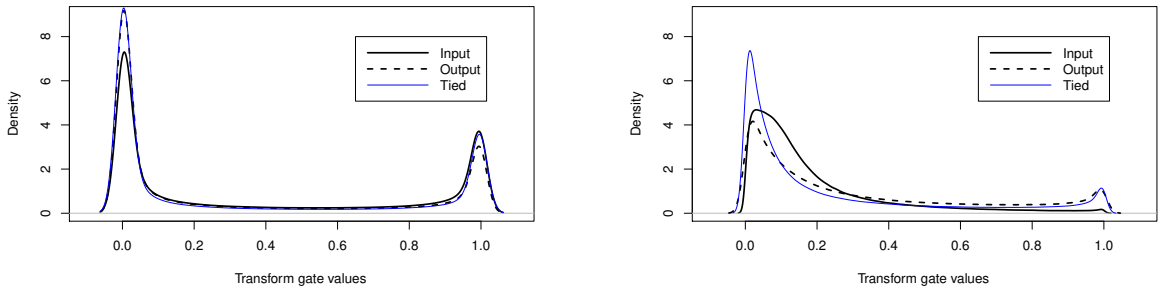

Figure 2: Kernel density estimations of the transform gate values of the first highway layers in *SylConcat* (left) and *MorphSum*. Values corresponding to 'Input' and 'Output' curves come from the HW_2+Emb configurations, while those corresponding to 'Tied' curves come from the HW_2+HW_1+Emb configurations.

on rule:

Layers should be tied consecutively bottom-up,

i.e. one should not leave untied layer(s) below a tied one. Keep in mind that this rule does not guarantee a performance increase as more and more layers are tied. It only says that leaving untied weights below the tied ones is likely to be worse than not doing so.

6.3 Difference between input and output embeddings

One can notice from the results of our experiments (Table 4) that having an untied second highway layer above the first one always leads to better performance than when it is tied. This means that there is a benefit in letting word embeddings slightly differ at input and output, i.e. by specializing them for the needs of RNNLM at input and of Softmax at output. This specialization is quite natural, as input and output representations of words have two different purposes: input representations send a signal to the RNNLM about the current word in a sequence, while output representations are needed to predict the next word given *all* the preceding words. The difference between input and output word representations is discussed in greater detail by Garten et al. (2015) and Press and Wolf (2017). Here we decided to verify the difference indirectly: we test whether intrinsic dimensionality of word embeddings significantly differs at input and output. For this, we apply principal component analysis to word embeddings produced by all models in "no reusing" mode. The results are given in Figure 3, where we can see that dimensionalities of input and output embeddings differ in the word-level model, *CharCNN*, and *SylConcat* models, but the difference is less significant in *MorphSum* model. Interestingly, in word-level and *MorphSum* models the output embeddings have more principal components than the input ones. In *CharCNN* and *SylConcat*, however, results are to other way around. We defer the study of this phenomenon to the future work.

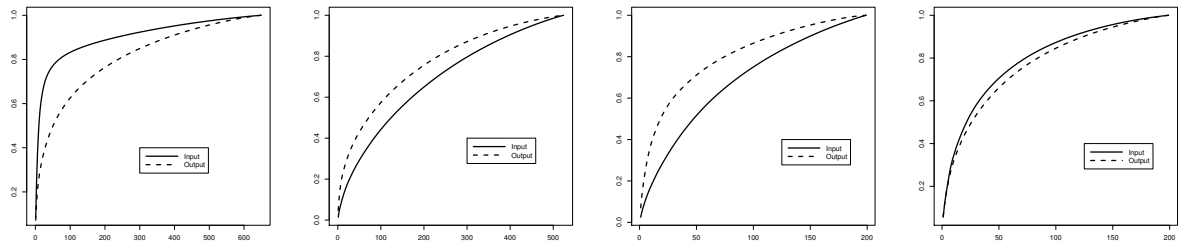

Figure 3: PCA applied to input and word embeddings produced by different models. Horizontal axis corresponds to number of principal components, vertical axis corresponds to percentage of total variance to retain. From left to right: word-level model, *CharCNN*, *SylConcat*, *MorphSum*.

6.4 CharCNN generalizes better than MorphSum

One may expect larger units to work better than smaller units, but smaller units to generalize better than larger units. This certainly depends on how one defines generalizability of a language model. If it is an ability to model unseen text with *unseen* words, then, indeed, character-aware models may perform better than syllable- or morpheme-aware ones. This can be partially seen from Table 3, where the OOV words are better handled by *CharCNN* in terms of in-vocabulary nearest neighbors. However, to fully validate the above-mentioned expectation we conduct additional experiments: we train two models, *CharCNN* and *MorphSum*, on PTB and then we evaluate them on the test set of Wikitext-2 (245K words, 10K word-types). Some words in Wikitext-2 contain characters or morphemes that are not present in PTB, and therefore such words cannot be embedded by *CharCNN* or *MorphSum* correspondingly. Such words were replaced by the `<unk>` token, and we call them new OOVs[6]. The results of our experiments are reported in Table 5. Indeed, *CharCNN* faces less OOVs on unseen text, and thus generalizes better than *MorphSum*.

Model	# new OOVs	PPL
CharCNN + RE + RW	3659	306.8
MorphSum + RE + RW	4195	316.2

Table 5: Training on PTB and testing on Wikitext-2.

6.5 Performance on non-English Data

According to Table 2, *MorphSum+RE+RW* comfortably outperforms the strong baseline *Word+RE* (Inan et al., 2017). It is interesting to see whether this advantage extends to non-English languages which have richer morphology. For this purpose we conduct evaluation of both models on small (1M tokens) and medium (17M–51M tokens) data in five languages (see corpora statistics in Appendix B). Due to hardware constraints we only train the small models on medium-sized data. We used the same architectures for all languages and did not perform any language-specific tuning of hyperparameters, which are specified in Appendix A. The results are provided in Table 6. As one can see, the advantage of the morpheme-aware model over the word-level one is even more pronounced for non-English data. Also, we can notice that the gain is larger for small data sets. We hypothesize that the advantage of *MorphSum+RE+RW* over *Word+RE* diminishes with the decrease of type-token ratio (TTR). A scatterplot of PPL change versus TTR (Figure 4) supports this hypothesis. Moreover, there is a strong correlation between these two quantities: $\hat{\rho}(\Delta\text{PPL}, \text{TTR}) = 0.84$, i.e. one can predict the mean decrease in PPL from the TTR of a text with a simple linear regression:

$$\Delta\text{PPL} \approx 2,109 \times \text{TTR}.$$

	Model	FR	ES	DE	CS	RU

Table 7: Replacing LSTM with AWD-LSTM.

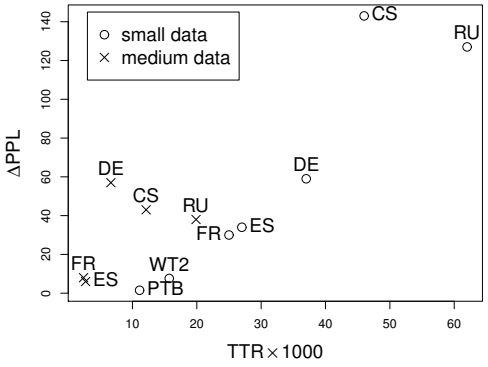

Figure 4: PPL improvement vs TTR. $\Delta\text{PPL} = \text{PPL}_{\text{Word+RE}} - \text{PPL}_{\text{MorphSum+RE+RW}}$.

6.6 Replacing LSTM with AWD-LSTM

The empirical perplexities in Table 2 are way above the current state-of-the-art on the same datasets (Melis et al., 2018). However, the approach of Melis et al. (2018) requires thousands of evaluations and is feasible for researchers who have access to hundreds of GPUs. Unfortunately, we do not have such access. Also, the authors do not disclose the optimal hyperparameters they found, and thus we could not reproduce their models. There is another state-of-the-art language model, AWD-LSTM (Merity et al., 2018), which has open-source code. We replaced this model's word embedding layer with the *MorphSum* subnetwork and fully reused morpheme embeddings and other weights of *MorphSum* at output. We refer to such modification as *AWD-LSTM-MorphSum + RE + RW*. We trained both models without fine-tuning (due to time constraints) and we did not use embedding dropout (section 4.3 of Merity et al. (2018)) in either model, as it is not obvious how embeddings should be dropped in the case of *AWD-LSTM-MorphSum*. The results of evaluation on the PTB, Wikitext-2, and non-English datasets are given in Table 7.

Although *AWD-LSTM-MorphSum* is on par with *AWD-LSTM-Word* on PTB and is slightly better on Wikitext-2, replacing plain word embeddings with the subword-aware model with appropriately reused parameters is crucial for non-English data. Notice that AWD-LSTM underperforms LSTM (used by us) on Czech dataset (cf. Table 6). We think that the hyperparameters of AWD-LSTM in Merity et al. (2018) are thoroughly tuned for PTB and Wikitext-2 and may poorly generalize to other datasets.

7 Conclusion

There is no single best way to reuse parameters in all subword-aware neural language models: the reusing method should be tailored to each type of subword unit and embedding model. However, instead of testing an exponential (w.r.t. sub-network depth) number of configurations, it is sufficient to check only those where weights are tied consecutively bottom-up.

Despite being similar, input and output embeddings solve different tasks. Thus, fully tying input and output embedding sub-networks in subword-aware neural language models is worse than letting them be slightly different. This raises the question whether the same is true for pure word-level models, and we defer its study to our future work.

One of our best configurations, a simple morpheme-aware model which sums morpheme embeddings and fully reuses the embedding sub-network, outperforms the competitive word-level language model while significantly reducing the number of trainable parameters. However, the performance gain diminishes with the increase of training set size.

A Optimization

Training the models involves minimizing the negative log-likelihood over the corpus $w_{1:K}$:

$$-\sum_{k=1}^{T} \log \Pr(w_k|w_{1:k-1}) \longrightarrow \min,$$

by truncated BPTT (Werbos, 1990). We backpropagate for 35 time steps using stochastic gradient descent where the learning rate is initially set to

- 1.0 in small word-level models,
- 0.5 in small and medium *CharCNN*, medium *SylConcat* (SS, SS+RW) models,
- 0.7 in all other models,

and start decaying it with a constant rate after a certain epoch. This is 5 and 10 for the small word-level and all other networks respectively except *CharCNN*, for which it is 12. The decay rate is 0.9. The initial values for learning rates were tuned as follows: for each model we start with 1.0 and decrease it by 0.1 until there is convergence at the very first epoch. We use a batch size of 20. We train for 70 epochs. Parameters of the models are randomly initialized uniformly in $[-0.1, 0.1]$ and in $[-0.05, 0.05]$ for the small and medium networks, except the forget bias of the word-level LSTM, which is initialized to 1, and the transform bias of the highway layer, which is initialized to values around -2. For regularization we use a variant of variational dropout (Gal and Ghahramani, 2016) proposed by Inan et al. (2017). For PTB, the dropout rates are 0.3 and 0.5 for the small and medium models. For Wikitext-2, the dropout rates are 0.2 and 0.4 for the small and medium models. We clip the norm of the gradients (normalized by minibatch size) at 5.

For non-English small-sized data sets (Data-S) we use the same hyperparameters as for PTB. To speed up training on non-English medium-sized data (Data-M) we use a batch size of 100 and sampled softmax (Jean et al., 2015) with the number of samples equal to 20% of the vocabulary size (Chen et al., 2016).

University of California, Santa Barbara
william@cs.ucsb.edu

Abstract

We propose generative models for three types of extra-grammatical word formation phenomena abounding in English slang: *Blends, Clippings, and Reduplicatives*. Adopting a data-driven approach coupled with linguistic knowledge, we propose simple models with state of the art performance on human annotated gold standard datasets. Overall, our models reveal insights into the generative processes of word formation in slang – insights which are increasingly relevant in the context of the rising prevalence of slang and non-standard varieties on the Internet.

1 Introduction

Linguistic analysis of slang has traditionally received little attention with some arguing that research on slang be assigned to an *"extra-linguistic darkness"* (Labov, 1972). However, Eble (2012) argues that the emergence of social media has predominantly increased the usage of slang and non standard forms and *"slang is now worldwide the vocabulary of choice of young people"*[1]. This increasing pervasiveness has recently motivated research on slang and the linguistic phenomena it manifests. Most notable are the works of (Mattiello, 2005, 2008, 2013), who argues that slang exhibits extra-grammatical properties that distinguish it from the standard form.
