A Prompt Templates

Prompt A.1: Extracting Bias Type and Quote for Debate Topic

You are tasked with identifying if any of the following types of bias are present in the given medical note. If so, name the bias type and provide the quote that highlights the bias type in the given medical note. The definitions for bias type are:

{other bias type definitions. . . }

Stigmatizing Language – Stigmatizing language is any language in clinical documentation that portrays the patient in a negative or judgmental way—by expressing doubt about their credibility, implying they are difficult, noncompliant, or deceptive, or by using language that casts their behavior, attitude, or emotional state in a negative light. This includes both overt and subtle wording that reflects blame, shame, or disrespect. Example: "claims to see a therapist".

Note: You are supposed to answer the bias and the corresponding quote which highlights the bias in the form: `[{"bias_type":"", "quote":""},{"bias_type":"", "quote":""}]`. Please write as many bias type as you can.

Note: Your output should explicitly be in the above mentioned format and do not give any other justification. If no bias is found, just answer `[{"bias_type":"", "quote":""]}`. Do not repeat the same bias type with the same quote. Make sure your answer starts with only one "[" and ends with only one "]". You can add as many unique bias types and quote pairs within the brackets in the given format.

Medical Note:

`##medical_note##`

Answer:

Prompt A.2: Prompt used for self-reflection framework

You are a medical language model trained to identify bias in clinical notes. You previously predicted bias type in the input paragraph and the corresponding quote that highlights the bias. Now reflect on that decision. Based on the definition for bias type and input paragraph, was your prediction for bias type correct? Use the information to determine whether the quote, as it appears in the paragraph, matches the bias_type. You are supposed to answer a single digit 1 if there exists bias mentioned above, else answer single digit 0. Your answer should explicitly be a single digit 1 or 0. Do not explain or justify your answer.

###Note####: Ensure that you do not give any justification and reasoning for your answer.

###Example1:

****quote****: "The patient is non-compliant with their medication regimen."

****Paragraph****: "Despite multiple counseling sessions, the patient is non-compliant with their medication regimen and shows little interest in improving their condition."

****bias type****: Explicit Bias

**** The definition of Explicit Bias is ****: Explicit forms of bias include preferences, beliefs, and attitudes of which people are generally consciously aware, endorsed, and can be identified and communicated (e.g., labeling a patient as

'non-compliant' or 'irresponsible').)
Answer: 1
Example2:
****quote****: "feeling tired during the day."
****Paragraph****: "The patient reports feeling tired during the day but denies any issues with sleep or recent lifestyle changes. Vitals are within normal range."
****bias type****: Explicit Bias
**** The definition of Explicit Bias is ****: Overtly negative or judgmental language used in a medical note (e.g., labeling a patient as 'non-compliant' or 'irresponsible')
Answer: 0
Question:
****quote****: ##quote##
****Paragraph****: ##paragraph##
****bias type****: Stigmatizing Language
**** The definition of Stigmatizing Language is ****:
##definition##.
Answer:

Prompt A.3: Prompt for Moderator

You are a moderator overseeing a multi-agent debate involving medical bias detection. Two expert agents will analyze the same medical note and debate whether the given bias type is present, and if so, which type and why. After each round, you must assess both perspectives and decide if a consensus is reached.

Prompt A.4: Prompt for Affirmative Agent

The debate topic is ##debate_topic##
It was previously predicted that the given bias type in the input paragraph and the corresponding quote highlights the bias. Now reflect on that decision with your reasoning. Based on the definition for bias type and input paragraph, was the prediction for bias type correct? Please provide your single reasoning in less than 3 sentences. Your reasoning should be focused on the mentioned bias type. Do not introduce new type of bias. You are not supposed to ask any questions.

Prompt A.5: Prompt for Negative Agent

##aff_ans##
You are supposed to disagree with my answer. Please provide your single reasoning in less than 3 sentences. Your reasoning should be focused on the mentioned bias type. Do not introduce new type of bias. You are not supposed to ask any questions.

Prompt A.6: Prompt for Judge Reflection

Affirmative side's answer: ##aff_ans##
Negative side's answer: ##neg_ans##
Write down key pointers addressed by different experts that could be crucial to reflect on before making judgement. You are not supposed to introduce your personal pointers. Try to limit the pointers to as low as 5 sentences.

Prompt A.7: Prompt for Judge Decision

Now, based on the debate topic:
##debate_topic## Provide only one reasoning and the final decision on whether the given bias exists, and explanation. Respond strictly in JSON format: `{"Presence":"True/False","Reason": ""}`. You should provide the result in a single JSON form. Do not give more than one json answer. Your response should be explicitly in the given json format where json key and values are double quoted. You are not allowed to give any more clarification apart from the single json form.

Learning to Combine AI Annotations for Improved Biomedical Relevance Labeling

Abstract

Accurate labeling of relevance between biomedical abstracts is essential for improving information retrieval, semantic similarity modeling, training of ranking systems and other Natural Language Processing tasks. However, manual annotations are time-consuming, labor intensive and costly. Studies show that large language models (LLMs) can facilitate automated annotation, but their performance still falls short of human expert-level accuracy, especially in domain-specific tasks.

It has been shown that combining annotations from multiple non-expert annotators can achieve performance comparable to, or even exceeding, that of trained experts. Based on this evidence, we treat AI-generated annotations as contributions from non-expert annotators and combine them using Learning to Rank framework. Our results show significant improvement in overall annotation quality. The proposed method looks promising to reduce reliance on human annotation while maintaining reliable performance for large-scale biomedical applications.

1 Introduction

Recent studies have examined the effectiveness of large language models (LLMs) for annotation and relevance labeling in both general NLP and biomedical domains (Lu et al., 2024; Jin et al., 2023b). In computational linguistics, LLM annotations have been shown to effectively complement human annotation workflows (Gligoric et al., 2025). In biomedical contexts, LLMs have demonstrated strong performance in structured tasks such as clinical information extraction, but still require careful prompt design and iterative refinement to achieve reliable results (Hein et al., 2025). However, multiple studies emphasize that LLM-generated annotations remain imperfect, exhibiting biases and inconsistencies that necessitate human oversight or validation (Xia et al., 2025; Tan et al., 2024). In complex scientific tasks, including systematic review and evidence synthesis, human experts continue to outperform LLMs, highlighting limitations in domain-specific reasoning and reliability (Sollini et al., 2025; Wang et al., 2024). Overall, current evidence suggests that LLMs can approximate non-expert human annotators but fall short of expert-level performance, motivating their use as efficient yet noisy annotators rather than replacements for human expertise.

Wilbur (1996) showed the pooled results of the untrained judges were almost as good as the pooled results for the trained judges and better than any single trained judge. Motivated by this finding, we treat annotations generated by LLMs as noisy and imperfect signals. Analogous to untrained annotators, in this work, we aggregate outputs from multiple LLM judgments using diverse prompts to improve annotation quality.

Wilbur and Kim (2006) studied probabilistic methods for weighting annotators based on global statistical inference from pooled judgments, showing that aggregating multiple annotations improves the prediction of held-out labels and leads to more reliable gold standards. However, their framework treats human annotations as absolute labels rather than subjective or relative assessments. For example, when two annotators assign different relevance scores to the same document pair, this is considered a disagreement, without accounting for potential agreement in ranking.

If two annotators produce perfectly aligned rankings over a set of document pairs, they may be considered fully equivalent from a rank-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 502–507
July 3-4, 2026 ©2026 Association for Computational Linguistics

ing perspective. In this study, we adopt the latter view by emphasizing agreement in ranking. This perspective is particularly aligned with traditional and modern information retrieval methods, such as BM25 (Robertson and Zaragoza, 2009) and embedding-based models such as MedCPT (Jin et al., 2023a). To incorporate such heterogeneous relevance signals, we move beyond absolute agreement and instead employ a pairwise learning-to-rank model based on gradient boosted decision trees using XGBoost (Chen and Guestrin, 2016; Burges et al., 2005), enabling effective training over diverse scoring methods.

In evaluating how well a method aligns with a gold standard, a variety of metrics have been proposed. In traditional information retrieval, Mean Average Precision (MAP) (Buckley and Voorhees, 2000) and Normalized Discounted Cumulative Gain (NDCG) (Järvelin and Kekäläinen, 2002) are among the most widely used measures. For assessing inter-annotator agreement, metrics such as Cohen's kappa and Spearman's rank correlation are commonly applied. MAP and NDCG place strong emphasis on top-ranked documents, making them inherently biased toward agreement at higher ranks. Cohen's kappa avoids this top-rank bias, but measures absolute agreement and does not account for consistency in ranking. In contrast, Spearman's rank correlation captures agreement in relative ordering and is not affected by bias of the top-rank or differences in absolute annotation scales, making it more suitable for evaluating ranking consistency.

2 Data Sets

RELISH is one of the largest expert-annotated dataset for article similarity, containing approximately 196,000 annotated pairs of PubMed abstracts derived from about 3,200 query articles. For each query article, the retrieved documents are assigned relevance scores on a three-point scale (1–3) that correspond to irrelevant, partially relevant and relevant.(Brown et al., 2020).

NCBI Dataset (Wilbur, 1996) consists of 5,000 PubMed abstract pairs derived from 100 query abstracts, each annotated on a 1–4 relevance scale by 13 judges (seven trained judges and six untrained judges).

3 Method

We consider seven annotation methods, including three text similarity approaches (BM25, MedCPT, and LitSense2 (Yeganova et al., 2025)) and four AI-based variants derived from different prompting strategies (Prompt 1–4). We denote these methods as F1–F7, corresponding to Prompt 1–4, BM25, MedCPT, and LitSense2, respectively. For AI-based annotation, we use GPT-5.1 and the actual prompts used for generating AI annotations are provided in the appendix. Due to the cost of annotation, we sample 272 queries from the test set defined by (Zhang et al., 2022), a subset of RELISH. This subset provides a practical balance between annotation cost and maintaining a sufficiently large sample for reliable evaluation. Hereafter, "the dataset" denotes the 272 queries together with their retrieved, annotated abstracts. As mentioned in the Introduction, given a query, our goal is to learn a model that aligns the ranking it produces with human judgments as closely as possible. To achieve this, we adopt a pairwise learning-to-rank (LTR) approach (Chen and Guestrin, 2016; Burges et al., 2005) rather than an NDCG-based LTR method commonly used in information retrieval.

4 Results

We randomly split the dataset into three folds, using two folds for training and the remaining one for testing. To show the qualities of individual AI rankers in the training and test sets, we compute the Spearman correlation for each individual AI ranker against the corresponding human judgments, as shown in Table 1 and Table 2.

Also, to assess how well individual untrained annotators align with trained experts, we use the NCBI dataset. Let T denote the set of seven trained annotators and U the set of six untrained annotators. For each trained annotator $t \in T$ and untrained annotator $u \in U$, let $\rho_{t,u}$ denote the Spearman correlation between their annotations. First, we average correlations across trained annotators for each

untrained annotator:

$$\rho_u = \frac{1}{|T|} \sum_{t \in T} \rho_{t,u} \tag{1}$$

We then average these values across all untrained annotators to obtain the overall agreement between untrained and trained annotators, denoted $\bar{\rho}_U$:

$$\bar{\rho}_U = \frac{1}{|U|} \sum_{u \in U} \rho_u \tag{2}$$

The results for ρ_u for $u \in U$ and $\bar{\rho}_U$ are shown in Table 3.

From Tables 1 - Table 3, untrained human annotations may outperform both AI and traditional retrieval methods, while exhibiting similar standard deviations across the three sets. This comparison between NCBI data and RELISH data has two limitations. First, judgments on the RELISH data are on a scale from 1-3, for NCBI dataset they are on a scale from 1-4. Second, instructions to the judges on the RELISH task defined relevance as "topically relevant to the seed article; within the same specific sub-field of research, i.e. an article that would be interesting to read further or could have been cited within the original work" (Brown et al., 2020). Instructions for the NCBI data task were to "judge a document relevant to a query if and only if you would wish to read the full document if you were given the task of writing the query document."(Wilbur, 1996)

Next, we apply Learning-to-Rank (LTR) with a leave-one-out (LOO) strategy to the training set to select an optimal combination of features. We evaluated all possible combinations of the seven features (i.e., $2^7 - 1 = 127$)

Judges	ρ_u

using the Spearman correlation measure. Table 4 shows the top 7 feature sets ranked by Spearman correlation, with the subset [F1, F2, F3, F4, F7] achieving the highest performance and selected as the optimal combination. With the optimal feature combination [F1, F2, F3, F4, F7], we retrain the model on the training set to obtain the final optimal model $M_{optimal}$. At this stage, we emphasize that the test set remains completely unseen during the model selection and training process. We then apply $M_{optimal}$ to the held-out test set to obtain predicted scores, achieving a Spearman correlation of 0.460, which markedly outperforms all individual features on the test set, with differences that are statistically significant (see Table 5).

Similarly to the evaluation of untrained human annotators against trained experts, we assess how well trained annotators agree with each other, using the same overall agreement measure defined for the untrained annotators. Let T denote the set of seven trained annotators. For any pair of distinct annotators $t, t' \in T$ with $t \neq t'$, let $\rho_{t,t'}$ denote the Spearman correlation between their annotations. For

Table 5: Spearman correlation on the test set and Wilcoxon signed-rank test p-values comparing individual feature-based methods against the final model $M_{optimal}$.

each annotator $t \in T$, we first average the correlations with all other annotators:

$$\rho_t = \frac{1}{|T|-1} \sum_{t' \in T, t' \neq t} \rho_{t,t'}. \quad (3)$$

We then average these values across all trained annotators to obtain the overall agreement between trained annotators, denoted $\bar{\rho}_T$:

$$\bar{\rho}_T = \frac{1}{|T|} \sum_{t \in T} \rho_t. \quad (4)$$

The results for ρ_t for $t \in T$ and $\bar{\rho}_T$ are shown in Table 6. The overall Spearman correlation is $\bar{\rho}_T = 0.453$, which is lower than the Spearman correlation obtained by the model $M_{optimal}$ (0.460). This suggests that the model $M_{optimal}$ may achieve annotation quality comparable to that of human experts.

5 Conclusions

We explored seven heterogeneous annotation scores, comprising four LLM-based annotations generated using four different prompts and three scores derived from traditional retrieval methods, and investigate how to best combine them. Based on comparisons with human annotators, we find that each individual feature score used in our study falls short of untrained human performance. An LTR model with pairwise ranking optimization is then employed to select and combine the most effective feature combination, yielding an optimal model. The resulting model significantly outperforms each individual feature scores. Furthermore, the model may achieve annotation quality comparable to that of human experts.

6 Limitations and Future Work.

Our evaluation uses 272 RELISH queries due to LLM annotation cost, which may limit generalization. Comparisons with NCBI annotations are also imperfect due to differences in relevance scales, document pairs and annotator instructions. In future work, we will scale evaluation using multiple open-source LLMs instead of a single model to study a larger query set. We also aim to investigate whether aggregating or pooling outputs from multiple weaker-performing LLMs can achieve performance comparable to stronger, more expensive models. We will see how well our optimal model performs on the NCBI data.

A AI Prompts

PROMPT1 = "You are an expert on the biomedical literature. Here I give you two excerpts, labelled passage A and passage B. Tell me if the entities mentioned in passage A are also being discussed in passage B. If the entities from passage A are discussed in passage B tell me if passage B seems to be saying the same thing about them or if it is just too unclear to say. After you have analyzed the passages give a final answer as

an integer: 3 if passage B says all that A says and possibly more; 2 if only part of what A says is also said in B; 1 if passage A and passage B appear to be completely unrelated. Return only a single integer from 1 to 3. Do not include explanations."

PROMPT2 ="You are an expert in biomedical literature analysis. You will receive two text excerpts labeled Passage A and Passage B. For each passage, internally determine: Sentence 1: the primary research problem addressed by the study. Sentence 2: the primary method or approach used to address that problem. Do not output these sentences; use them only for internal reasoning. Then compare Passage A and Passage B based on these internally derived sentences and output exactly one integer according to the rules below: 3: Passage B fully covers the same problem and method as Passage A, and may include additional information. 2: Passage B overlaps with Passage A in either the problem or the method, but not fully. 1: Passage A and Passage B are unrelated in both problem and method. Output requirements: Output only one digit: 1, 2, or 3. Do not include explanations, labels, or any additional text."

PROMPT3="You are an expert in biomedical literature analysis. You will receive two text excerpts labeled Passage A and Passage B. For each passage, internally determine the following: Sentence 1: Summarize Passage A in one sentence describing the main problem this study is trying to solve. Sentence 2: Summarize Passage B in one sentence describing the main problem this study is trying to solve. Do not output these sentences; use them only for internal reasoning. Then compare Passage A and Passage B based on these internally derived sentences and output exactly one integer according to the rules below: 3: Sentence 2 fully covers the same problem to solve as Sentence 1 and may include additional information. 2: Sentence 2 overlaps with Sentence 1 in the problem to solve, but not fully. 1: Sentence 1 and Sentence 2 are unrelated in the problems they aim to solve. Output requirements: Output only one digit: 1, 2, or 3. Do not include explanations, labels, or any additional text."

PROMPT4 ="You are an expert in biomedical literature analysis. You will receive two paragraphs labeled Paragraph A and Paragraph B. For each paragraph, internally determine the main conclusions being addressed in one sentence. Do not output these sentences; use them only for internal reasoning. Then compare Paragraph A and Paragraph B based on these internally derived problems and output exactly one integer according to the rules below: 3: Paragraph B addresses the same main problem as Paragraph A and may include additional information. 2: Paragraph B partially overlaps with the main problem addressed in Paragraph A. 1: Paragraph B addresses a different problem and is not relevant to Paragraph A. Output requirements: Output only one digit: 1, 2, or 3. Do not include explanations, labels, or any additional text."

When Does Retrieval Beat Direct LLM Diagnosis in Rare Disease? An Empirical Study of Ontology Coverage

Abstract

Recent high-complexity agentic systems such as DeepRare perform strongly on rare disease diagnosis benchmarks, but it remains unclear when gains come from structured knowledge access and when they come from parametric LLM knowledge. We compare phenotype-based retrieval, LLM reranking, and unrestricted LLM diagnosis across seven benchmarks covering 10,382 cases. We find a clear performance crossover driven by retrieval coverage—the fraction of cases whose true diagnosis is within the retriever's top-50: on high-coverage datasets, ontology-based retrieval dominates; on low-coverage datasets, open-ended LLM diagnosis takes the lead. Building on this, adding an LLM reranker over retrieved candidates further improves accuracy across our patient-case benchmarks, closing most of the remaining gap to agentic systems (within 2 pp on MME and LIRICAL). We trace the crossover to two structural failure modes of ontology-based retrieval—annotation sparsity and phenotypic homogeneity—and show that aggregate scores across mixed benchmarks can hide these qualitatively different diagnostic settings. These findings motivate per-dataset evaluation and hybrid diagnostic systems that combine retrieval, reranking, and parametric LLM generation based on case characteristics.

1 Introduction

Rare diseases collectively affect over 300 million people worldwide (Wakap et al., 2020), yet patients frequently endure a "diagnostic odyssey" exceeding five years (Schieppati et al., 2008). The sheer number of rare diseases—over 10,000 with known genetic etiology (Haendel et al., 2020)—and limited clinician familiarity with any individual condition make automated diagnostic support a pressing need.

Phenotype-driven diagnosis tools address this by matching patient symptoms, encoded as Human Phenotype Ontology (HPO) terms (Köhler et al., 2021), against curated disease–phenotype annotations. PhenoDP (Wen et al., 2025), a recent deep-learning-based toolkit, combines information-content (IC)-based, phi-coefficient-based, and semantic similarity measures over the HPO Annotation (HPOA) knowledge base to rank candidate diseases, achieving state-of-the-art results among phenotype-based methods.

At the other end of the complexity spectrum, the DeepRare system (Zhao et al., 2026) represents a multi-agent architecture integrating over 40 specialized tools, more than 10 biomedical knowledge sources, web-scale retrieval, and self-reflective reasoning to achieve 57.2% average Recall@1 across seven rare-disease benchmarks. This raises a natural question: *how much of this performance comes from querying curated disease–phenotype ontologies versus relying on knowledge encoded in model parameters?*

We investigate this through two complementary experiments. First, we evaluate a simple two-stage pipeline—PhenoDP retrieval followed by LLM reranking—and compare it against both unrestricted LLM diagnosis and DeepRare's per-dataset results. On the high-coverage patient-case benchmarks, the reranking pipeline is competitive with DeepRare (70.0% vs. 70.0% on MME; 54.1% vs. 56.0% on LIRICAL), despite using only two components and no runtime knowledge search beyond PhenoDP's pre-indexed HPOA annotations. On the DDD (Deciphering Developmental Disorders) disease-profile benchmark, retrieval also scores higher than DeepRare's reported number (59.0% vs. 43.0%), but DDD consists of disease-level HPO bundles rather than patient cases and overlaps ontologically with HPOA, so we treat this more as an upper bound on how well ontology-aligned benchmarks can be matched than as a head-to-head capability comparison (§3.5).

Second, comparing the two diagnostic approaches—ontology-based retrieval and unre-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 508–518

stricted LLM generation—across seven datasets reveals a *performance crossover*: which approach wins is determined by *retrieval coverage*, the fraction of patient presentations for which PhenoDP successfully places the true diagnosis in its top-50 candidates. Coverage reflects whether the retriever can successfully match a patient's HPO terms to the correct disease; it fails primarily when the target disease is sparsely characterized in the HPOA knowledge base, and secondarily when the patient's phenotype set is small or when the target disease is phenotypically indistinguishable from related conditions. On high-coverage datasets, ontology-based retrieval dominates; on low-coverage datasets, the unrestricted LLM takes the lead. This crossover is invisible in aggregate metrics.

This paper makes four contributions. First, we show that LLM reranking improves on pure ontology-based retrieval on every patient-case benchmark we evaluate; on the high-coverage benchmarks MME (70.0% vs. 70.0%) and LIRICAL (54.1% vs. 56.0%), an open-weight two-component pipeline reaches numbers comparable to DeepRare, although the small sample sizes (n=40 for MME) and unmatched evaluation conditions mean these comparisons should be read as approximate rather than head-to-head (§3.5, Limitations). Second, we observe a performance crossover between ontology-based retrieval and unrestricted LLM diagnosis that tracks retrieval coverage: in our seven benchmarks, datasets above 70% coverage favor retrieval and datasets below 60% favor unrestricted LLM generation. Because no benchmark in our study falls in the 60–70% transition zone, the boundary should be read as a hypothesis consistent with these observations rather than a located threshold. Per-dataset comparisons are supported by McNemar tests and bootstrap CIs. Third, through error analysis of non-retrievable cases, we identify annotation sparsity and phenotypic homogeneity as the two structural failure modes that determine where ontology-based retrieval breaks down. Finally, an oracle analysis shows that the two approaches succeed on largely different cases, and an empirical evaluation of a *pooled* score-based threshold router shows that a single retriever-confidence threshold pooled across datasets fails to close the oracle gap—pointing to input-modality features, or to per-dataset thresholding which we did not evaluate, as candidate routing signals.

2 Related Work

Automated diagnosis for rare diseases has been pursued along two tracks: phenotype-based retrieval tools that operate over curated ontologies, and more recently, general-purpose LLMs applied to clinical reasoning. Our work connects these two lines.

On the retrieval side, tools such as Exomiser (Smedley et al., 2015), LIRICAL (Robinson et al., 2020), and PubCaseFinder (Fujiwara et al., 2018) compute semantic similarity between a patient's HPO terms and the annotations of candidate diseases in the HPOA knowledge base (Köhler et al., 2021); PubCaseFinder additionally indexes published case reports to widen its evidence base. PhenoDP (Wen et al., 2025), which we use as the retrieval backbone in this work, continues this line by combining information-content-based, phi-coefficient-based, and learned semantic similarity. Ontology-anchored methods of this kind are bounded by the completeness of HPOA annotations, so diseases or cases that are under-annotated in HPOA or phenotypically similar to many others are systematically hard to retrieve.

Retrieve-and-rerank pipelines are a standard pattern in open-domain QA and information retrieval, where a fast recall-oriented retriever is followed by a stronger but more expensive reranker (Karpukhin et al., 2020; Nogueira and Cho, 2019). We apply this pattern to ontology-based rare disease diagnosis.

On the LLM side, general-purpose models have been evaluated for clinical reasoning both closed-book (Singhal et al., 2023; Nori et al., 2023) and in rare-disease-specific settings (Chen et al., 2024; Shyr et al., 2024). Domain-adapted biomedical LMs (Luo et al., 2022; Christophe et al., 2024; Google DeepMind, 2025) extend this line. A separate thread couples LLMs with retrieval: retrieval-augmented generation is increasingly used in biomedical question answering (Xiong et al., 2024), typically grounding LLMs in unstructured literature rather than curated ontologies. DeepRare (Zhao et al., 2026) combines LLM reasoning with more than 40 external tools and over 10 biomedical knowledge sources, achieving state-of-the-art performance on several rare-disease benchmarks.

Most closely related to our work are systems that combine an HPO-based phenotype retriever with downstream refinement, but to our knowledge no prior work has systematically compared retriever-only, retrieve-and-rerank, and unrestricted LLM di-

agnosis across a comparable range of benchmarks, or characterized *when* each approach has the advantage and why.

3 Methods

3.1 Task and Metrics

Given a clinical vignette with HPO-encoded phenotypes rendered as natural language, produce a ranked list of OMIM disease diagnoses. We report Recall@k (R@k) and MRR under **strict OMIM ID matching**. Statistical significance: paired McNemar's test; uncertainty: bootstrap 95% CIs (10,000 resamples). Code, prompts, and per-case outputs are released at https://github.com/mofty8/BioNLP26.

We define **coverage** as the fraction of cases where the truth disease appears in PhenoDP's top-50 retrieved candidates. This is a property of each case—a case is *covered* if PhenoDP ranks its true diagnosis within the top 50, regardless of how many HPO terms the patient presents with. Cases where truth is absent from the top 50 are **non-retrievable**—they represent a hard ceiling for any retrieval-based approach that uses the same candidate pool. We measure coverage using PhenoDP as a concrete retriever, but the failure modes we document (§5.1) are properties of HPO/HPOA-anchored retrieval in general and are not specific to PhenoDP's scoring function.

3.2 Retriever: PhenoDP

PhenoDP (Wen et al., 2025) is a deep-learning-based toolkit whose Ranker module scores candidate diseases by combining three similarity measures between a patient's HPO terms and each disease's HPOA profile: information-content (IC) similarity, phi-coefficient similarity after graph propagation, and semantic similarity via contrastive embeddings. Wen et al. (2025) report that IC dominates, phi contributes, and semantic similarity is minimal; in practice PhenoDP's ranking is driven primarily by term-level information content. The Ranker searches the full HPOA knowledge base (12,717 annotated diseases) and returns up to 50 candidates per case; its performance is therefore bounded by HPOA completeness—a limitation central to our analysis.

3.3 Reranking and Unrestricted Diagnosis

We evaluate the LLM under two conditions that share an input format but differ in whether a retriever is present.

Retrieve-and-rerank. The LLM reranker receives (i) a clinical narrative generated by PP2Prompt (Reuter et al., 2024), which converts HPO terms into natural language, and (ii) PhenoDP's top-k candidates ($k \in \{3, 5, 10\}$). Unless otherwise noted, we report top-10 results as this consistently yielded the best performance. We evaluate two prompt strategies: a *rule-gated* prompt with explicit conditional rules (preserve the retriever's ordering when the top-1 score exceeds rank-2 by a large margin, unless specific phenotypic contradictions are identified; full template in Appendix D), and a *narrative* prompt adapted from PP2Prompt (Reuter et al., 2024) that presents candidates without conditional gates and allows free reordering.

Unrestricted LLM diagnosis. The LLM receives only the clinical narrative and produces up to 10 ranked diagnoses from parametric knowledge, with no retriever input.

3.4 Models

For reranking: Gemma-3 27B (Gemma Team, 2025), Gemma-4 31B,[1] Llama-3.3 70B (Meta AI, 2024). For unrestricted diagnosis: additionally Med42-70B and Med42-8B (Christophe et al., 2024), MedGemma-27B (Google DeepMind, 2025), and Qwen2.5-32B (Qwen Team, 2024); Table 2 shows the two strongest open-LLM baselines, and full results for all seven models are in Appendix A. All open-weight, instruction-tuned, temperature 0.

3.5 Datasets

We evaluate on seven benchmarks (Table 1): Phenopackets (Wen et al., 2025), four RareBench subsets (Chen et al., 2024) (LIRICAL, Matchmaker Exchange [MME], RAMEDIS, Hereditary Monogenic Syndromes [HMS]), MyGene2 (Chong et al., 2020), and DDD[2]—curated disease-level HPO profiles from the Deciphering Developmental Disorders database, the same source used by DeepRare. Our DDD subset (n=2,248) differs slightly

[1] Gemma-4 (https://blog.google/innovation-and-ai/technology/developers-tools/gemma-4/); no separate technical report was available at the time of this evaluation, so we cite the official announcement and release the exact checkpoint identifier alongside our code.

[2] https://www.deciphergenomics.org/ddd/ddgenes

Dataset	Type	n	Dis.	Cov (%)	HPOA med
Phenopackets	Lit	6901	500	81.5	47
LIRICAL	Lit	370	411	85.7	43
MME	Clin	40	28	95.0	47
DDD	Curated	2248	2171	79.2	22
MyGene2	CR	131	37	70.2	42
RAMEDIS	CR†	624	160	56.7	31
HMS	Clin	68	101	48.5	50

Table 1: Datasets (10,382 cases total). Shaded rows are *low-coverage* (<60%). **Type** codes: Lit = published case reports with author-provided HPO terms; Clin = prospectively collected hospital records; CR = case reports with HPO terms mapped post hoc; Curated = disease-level HPO profiles from DECIPHER (DDD is not directly comparable to patient-level benchmarks; see §3.5). **Columns**: n evaluable cases; **Dis.** unique truth diseases; **Cov** retrieval coverage (fraction of cases whose truth is in PhenoDP's top-50); **HPOA med** median HPOA annotations for the truth diseases. †RAMEDIS HPO terms were manually mapped from clinical descriptions by Chen et al. (2024). HMS uses the n=68 OMIM-evaluable subset; MyGene2 uses the n=131 PhenoDP-compatible subset.

from DeepRare's (n=2,283) due to filtering for PhenoDP-compatible OMIM diseases; we were unable to exactly reproduce their case selection as the original split is not publicly available. For HMS, the original dataset contains 88 cases; 20 are annotated with ORPHA-only IDs corresponding to non-Mendelian immune disease groupings that do not map to specific OMIM entries and therefore lack the HPOA phenotype annotations required by the retrieval stack, leaving 68 evaluable cases.

4 Results

4.1 Cross-Approach Comparison

Table 2 presents results across the three approaches (retriever alone, retrieve-and-rerank, unrestricted LLM) alongside DeepRare's published numbers. DeepRare results are taken directly from their supplementary table (Zhao et al., 2026); direct numerical comparison is approximate throughout, as DeepRare does not report Phenopackets results and evaluation conditions may differ from ours. Two main patterns emerge.

The reranker improves over retrieval. On Phenopackets, the best reranker (Gemma-4 31B, rule-gated, top-10) improves R@1 from 51.2% to 54.3% (+3.1 pp, McNemar $p < 0.0001$; 262 promotions vs. 67 demotions). On MME, +5.0 pp (65.0% → 70.0%). On LIRICAL, +1.4 pp. On RAMEDIS, the narrative prompt achieves the largest gain: +12.9 pp (10.3% → 23.2%, Gemma-3 27B). The reranker does not improve on DDD (59.0% → 59.0%): DDD is a curated disease-level benchmark whose phenotype profiles are drawn from the same ontological sources as HPOA, so the ranking the retriever produces largely reflects alignment between two versions of the same knowledge base (see §3.5 and Limitations). The combined pipeline reaches numbers comparable to DeepRare DS-V3 on MME (70.0% vs. 70.0%, n=40) and is within 2.5 pp of DeepRare GPT-4o (72.5%), and is similarly close on LIRICAL (54.1% vs. 56.0%). We caution that these comparisons are approximate rather than head-to-head: our pipeline uses open-weight models up to 31–70B against DeepRare's GPT-4o / DeepSeek-V3 backbones, DeepRare's case selection and prompting may differ from ours, and the MME and LIRICAL sample sizes (40 and 370) give wide bootstrap CIs (Table 3). The point is that an open-weight two-component pipeline is in the same neighborhood on high-coverage datasets, not that it is statistically equivalent.

The performance crossover across datasets. On MME, retrieval achieves 65.0% versus the unrestricted LLM's 5.0% (a 60.0 pp gap in favor of retrieval). On RAMEDIS, the LLM achieves 46.8% versus the retriever's 10.3% (a 36.5 pp gap in the opposite direction). This crossover is statistically significant on six of seven benchmarks (McNemar $p < 0.0001$; Table 3); HMS (n=68 shared cases) does not reach conventional significance (p=0.052) due to limited statistical power.

4.2 The Regime Shift

Figure 1 visualizes the regime shift from two angles. The scatter plot (a) shows retrieval coverage is strongly associated with which approach dominates, with the datasets in our study separating into two clusters: five at ≥70% coverage and two at ≤57%, with no observations in the 60–70% range. The boundary should therefore be read as a hypothesis consistent with these data rather than a located threshold; identifying its precise location requires benchmarks in the transition zone. The bar chart (b), with datasets ordered by decreasing coverage, makes the crossover visible: reading left to right, the dominant system switches from retrieval (blue) to unrestricted LLM (orange).

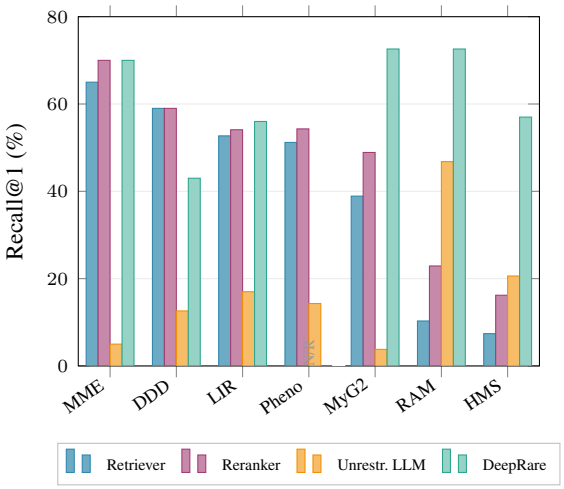
RAMEDIS	G3/Narr/10	10.3	**23.2**	+12.9	78	25
HMS	G3/Narr/10	7.4	**16.2**	+8.8	7	0

Table 4: Reranker performance by dataset, reporting the *best (model, prompt, top-k) configuration on each dataset's test set*; these numbers therefore upper-bound what a single fixed configuration would obtain and should not be read as a held-out estimate (see Limitations and Appendix B for the full Phenopackets grid). **Config** format: Model/Prompt/top-k, where G4=Gemma-4 31B, G3=Gemma-3 27B, L3=Llama-3.3 70B; Rule=rule-gated prompt, Narr=narrative prompt; 10=top-10 candidates. **Ret/Rer**: retriever/reranker R@1 (%). **P**: promotions (reranker moves truth to a higher rank). **D**: demotions (reranker moves truth to a lower rank). DDD is excluded: all configurations yield Δ=0.0 pp. The narrative prompt dominates in the LLM-dominant setting; the rule-gated prompt is optimal in the retrieval-dominant setting (Phenopackets).



4.3 Reranker Analysis: Per-Subset and Conditional

Table 4 disaggregates the reranker analysis by dataset (DDD excluded, as discussed in §4). First, the reranker improves R@1 on every dataset, with gains ranging from +1.4 pp (LIRICAL) to +12.9 pp (RAMEDIS). On Phenopackets, the 3.9:1 promotion-to-demotion ratio is driven by clean cases like neurofibromatosis type 1 (204 in-window cases: 103 promotions to rank 1, zero demotions); the most-harmed disease is Aarskog-Scott syndrome (15 promotions against 48 demotions), which is consistently confused with Noonan syndrome—the two share facial dysmorphism and short stature but have distinct causal genes. Second, prompt strategy interacts with the dominant approach: the rule-gated prompt excels on Phenopackets (where retrieval is strong and conservative reranking avoids harmful demotions), while the narrative prompt is necessary on RAMEDIS, HMS, and MyGene2 (where the retriever has more room for improvement). Third, the rule-gated prompt is the strongest configuration only on Phenopackets, where retriever scores are well-separated and its conditional rules are triggered; on the shorter RareBench narratives the narrative prompt is chosen as best in Table 4.

Conditional performance on retrievable cases. The overall R@1 numbers in Table 2 mix two effects: how often the retriever places the correct answer in its top-k window (coverage), and how well

(a) Coverage is strongly associated with the dominant approach. All datasets with >70% coverage fall in the retrieval-dominant setting; both with <60% fall in the LLM-dominant setting. Unrestricted LLM: Llama-3.3 70B.

(b) R@1 by approach (decreasing coverage left→right). The crossover is visible. DeepRare adds most value in the LLM-dominant setting (right). Phenopackets not reported by DeepRare.

Figure 1: The diagnostic regime shift. (a) In our seven benchmarks, coverage is associated with which approach dominates; observations cluster at ≥70% or ≤57%, with no data in the 60–70% transition zone, so the crossover boundary is a hypothesis consistent with the data rather than a located threshold. (b) Grouped bars reveal the crossover between approaches.

the reranker reorders candidates once the correct answer is present. To isolate the reranker's discrimination ability, we report a *conditional* ("fair") evaluation restricted to cases where the truth disease is within the retriever's top-k—i.e., cases the retriever could in principle solve and that the reranker actually sees. On RareBench (Llama-3.3, narrative, top-10; LIRICAL + MME + RAMEDIS + HMS, 1,102 cases total), the reranker achieves 65.4% R@1 on the 573 cases whose truth is within the top-10 window, versus the retriever's 50.6% on the same subset (+14.8 pp). On Phenopackets (Gemma-4, rule-gated, top-10), 75.5% versus 71.2% (+4.3 pp). These conditional gains are substantially larger than the overall gains in Table 2, confirming that the LLM adds real clinical reasoning value when the correct answer is already in the candidate set—the modest overall gains are partly an artifact of the hard retrieval ceiling imposed by non-retrievable cases.

5 Explaining the Regime Shift

5.1 Non-Retrievable Cases

The regime shift is directly linked to *non-retrievability*. Table 5 shows the mapping is sharp: the two LLM-regime datasets (RAMEDIS 43.3%, HMS 51.5%) have non-retrievable rates clearly above the retrieval-regime range (5.0–29.8%), and the ordering by non-retrievable rate matches the ordering by which approach wins.

Dataset	Total	Non-ret	Rate	Regime
MME	40	2	5.0%	Retrieval
LIRICAL	370	53	14.3%	Retrieval
Phenopackets	6,901	1,278	18.5%	Retrieval
MyGene2	131	39	29.8%	Retrieval
RAMEDIS	624	270	43.3%	LLM
HMS	68	35	51.5%	LLM

Table 5: Non-retrievable rates align with the regime. DDD is excluded as a curated disease-level benchmark rather than a patient-case dataset (§3.5).

Analysis of the 1,278 non-retrievable cases in the Phenopackets benchmark reveals two structural failure modes:

Annotation sparsity. Non-retrievable diseases have median 24 HPOA entries versus 52 for retrievable ones. Diseases with <20 annotations have 22–37% non-retrievable rates; those with >40 are retrieved at 88.4%. Example: *congenital adrenal hyperplasia (21-hydroxylase deficiency)*—50 cases, only 12 HPOA annotations, 100% non-retrievable.

Phenotypic homogeneity. Developmental and epileptic encephalopathy (DEE) subtypes share near-identical HPO profiles despite distinct genetics: DEE-4 (430 cases, 48% non-retrievable), DEE-11 (260 cases, 82%). HPO-based retrieval cannot disambiguate them. Homogeneity failures are dis-

Dataset	Ret	LLM	Oracle‡	Δ	LLM-only†

LIRICAL	52.7	15.9	**59.7**	+7.0	26
MME	65.0	2.5	**67.5**	+2.5	1
DDD	59.0	12.6	**61.8**	+2.8	63
MyGene2	38.9	3.8	**41.2**	+2.3	3
RAMEDIS	10.3	46.8	**51.1**	+4.3	255
HMS	7.4	20.6	**26.5**	+5.9	13

Table 6: Complementarity of retrieval and unrestricted LLM (Med42 70B) across all seven benchmarks. ‡**Oracle**: R@1 of a hypothetical perfect router that always selects whichever approach answers each case correctly—an upper bound on hybrid system performance. Δ: gain over the better single system. †**LLM-only**: cases answered correctly by the unrestricted LLM but not by the retriever—i.e., cases where only parametric LLM knowledge suffices. Shaded rows: LLM-dominant datasets. Complementarity holds on every dataset; the largest per-dataset oracle gains are LIRICAL +7.0, Phenopackets +5.5, and HMS +5.9.

sociable from sparsity: Xia-Gibbs syndrome is 86% non-retrievable despite 187 HPOA annotations (Appendix C), because its dense profile overlaps with many other syndromic neurodevelopmental disorders.

At category level, epilepsy/neurological (40.2%) and immunodeficiency (42.0%) are highest risk, driven by sparse annotations and phenotypic overlap. Mitochondrial diseases (1.9%) and RASopathies (1.3%) are rarely missed, owing to distinctive phenotypes and rich annotations (median 113 and 56 HPOA entries, respectively). The same sparse-annotation signature appears on other benchmarks: on HMS, non-retrievable diseases have a mean of 8.0 HPOA entries vs. 23.0 for retrievable ones; on RAMEDIS, 23.9 vs. 36.2.

5.2 Complementarity of Retrieval and LLM Diagnosis

Table 6 quantifies how much could be gained by a hybrid system that combines both approaches. A hypothetical perfect router—one that selects whichever approach answers each case correctly—would improve over the better single system by 2.3–7.0 pp across all seven datasets. The key insight is that the two approaches succeed on largely non-overlapping cases. On Phenopackets, 376 patient cases (5.5%) are answered correctly only by the unrestricted LLM; these are predominantly non-retrievable cases where the true disease is absent from PhenoDP's top-50 and only parametric LLM knowledge can recover the answer. On RAMEDIS, 255 cases (40.9%) fall in this category, consistent with its high non-retrievable rate.

These results motivate hybrid systems that combine retrieval and LLM generation. We evaluate a score-based router in §6, finding that retriever confidence alone is insufficient to close the gap and that input-modality features are needed.

6 Discussion

Where agentic complexity adds value. On low-coverage datasets, DeepRare substantially outperforms our pipeline (41–50 pp on RAMEDIS and HMS), suggesting that richer runtime knowledge access matters most in these settings. On high-coverage patient-case datasets (MME and LIRICAL, with n=40 and n=370), our open-weight two-component pipeline lands in the same neighborhood as DeepRare (DDD is excluded from this comparison; see §3.5). We stop short of calling the pipeline "competitive" in a statistical sense: at these sample sizes, a single case flip on MME shifts R@1 by 2.5 pp, and our pipeline uses 31–70B open-weight rerankers against DeepRare's GPT-4o / DeepSeek-V3 backbones under evaluation conditions we could not exactly reproduce. The interpretable claim is structural: on high-coverage settings the simpler pipeline reaches a similar operating point with a smaller open-weight backbone, while on low-coverage settings agentic complexity is doing real work that retrieval-plus-reranking cannot replace. This still supports a practical design principle—route high-coverage cases through a lightweight pipeline and reserve the more resource-intensive agentic system for the cases that genuinely need it—but the boundary of when each is sufficient should be set on larger benchmarks under matched evaluation conditions.

Implications for evaluation. Aggregate metrics across heterogeneous benchmarks obscure the regime shift. Two systems with the same overall average can have very different per-dataset profiles—strong on high-coverage cases but weak on low-coverage ones, or the reverse—and these profiles have very different clinical implications. We recommend per-dataset reporting with explicit coverage characterization, so that readers can understand which cases each system actually handles well.

Toward hybrid systems: a negative result on *pooled* score-based routing. The oracle analysis (Table 6) shows that retrieval and unrestricted LLM

generation succeed on largely non-overlapping cases, with a perfect router improving 2.3–7.0 pp over the better single system across all seven datasets. We tested whether a *single* pooled threshold over PhenoDP confidence signals can serve as a practical routing rule: route to the retriever if a confidence statistic exceeds a threshold τ, otherwise escalate to the LLM. We evaluated four candidate signals: (i) the rank-1 similarity score, (ii) the margin between rank-1 and rank-2 scores, (iii) the coefficient of variation (CV) across the 50 candidate scores—a high CV indicates that one disease scores substantially above the others, while a low CV suggests the candidates are tightly clustered—and (iv) the product of rank-1 similarity and CV. A pooled threshold sweep on rank-1 similarity (N=10,379) finds τ^*=0.705, recovering +1.2 pp (16% of the oracle gap) in-sample; in a leave-one-dataset-out evaluation, the router *hurts* on five of seven held-out datasets (micro-average: 49.7% vs. 50.1% retriever baseline). The other three signals behave similarly: none improve over the single-score baseline in the leave-one-dataset-out setting. This result speaks only to pooled thresholding; per-dataset thresholds, learned routers, and confidence signals derived from sources other than PhenoDP's own scores were not evaluated.

Why a pooled threshold fails. The failure is structural rather than a tuning issue. RAMEDIS, where the LLM leads by 35 pp (46% vs. 10%), needs $\tau \to \infty$ (always escalate to the LLM), while Phenopackets and DDD, where retrieval leads by ≈37 and ≈46 pp respectively, need $\tau \to 0$ (never escalate). A single pooled threshold calibrated on the mix is miscalibrated for both, and no monotone confidence signal over the retriever's own scores can resolve this tension with a pooled rule. This does not rule out per-dataset thresholding or learned routers, which we did not evaluate here.

What a useful router would need. Effective case-level routing requires a signal that reflects *input modality*—whether a case is expressed as structured HPO terms (favoring retrieval) or free-text clinical narrative (favoring parametric LLM knowledge)—rather than retriever confidence alone. Candidate features include HPO annotation density, clinical concept density, and the ratio of specific to general phenotype terms. A learned router combining these with the PhenoDP confidence signals above could in principle exploit the 2–7 pp oracle gains identified in Table 6; pairing such a router with the reranker studied here is a natural next step.

Limitations

Several aspects of this study warrant caution.

1. **Benchmark composition.** Our strongest results are on literature-derived and curated benchmarks (Phenopackets, LIRICAL, MME, DDD), which tend to be the easier diagnostic settings (Zhao et al., 2026); the patterns we report may not transfer to more complex, real-world clinical presentations with noisy phenotypes and incomplete workups.
2. **Model scope.** We evaluate only open-weight models up to 70B parameters; frontier proprietary models used as rerankers could yield different results.
3. **DeepRare comparison.** The comparison uses DeepRare's published per-dataset numbers, which may have been obtained under evaluation conditions different from ours (e.g., different case selection, metrics, or prompting); cross-paper comparisons should be treated as approximate.
4. **DDD is not a patient-case benchmark.** Our DDD subset (n=2,248) does not exactly match DeepRare's (n=2,283) due to filtering for PhenoDP-compatible OMIM diseases. Beyond this case-selection gap, DDD is a curated disease-level HPO profile benchmark rather than a set of individual patient cases, and its phenotype annotations are drawn from the same ontological sources as HPOA, so any retrieval score on DDD partly reflects alignment between two versions of the same knowledge base and overstates the ceiling for real patient cases.
5. **HMS statistical power.** HMS has only 68 evaluable cases (after excluding the 20 ORPHA-only cases without OMIM/HPOA entries), which limits statistical power; our McNemar test on HMS does not reach conventional significance (p=0.052).
6. **Seven-dataset coverage axis.** The coverage-based account of the regime shift is built on seven datasets. Additional benchmarks—particularly ones with moderate coverage in the 60–70% range that lies in the transition zone—would strengthen the empirical case.

7. **Per-dataset configuration selection.** The reranker numbers we report in Tables 2 and 4 use the best (model, prompt, top-k) configuration selected on each dataset's test set. They therefore upper-bound what a single fixed configuration would achieve and do not constitute a held-out estimate. We report a full Phenopackets configuration grid in Appendix B to characterize sensitivity, but analogous grids on the remaining datasets and leave-one-dataset-out configuration selection were beyond the scope of this study.

8. **Retrospective evaluation.** All benchmarks used here have known ground truth. We do not evaluate how any of these systems perform prospectively in clinical workflows, where the distribution of cases and the cost of errors may differ substantially from benchmark conditions.

Ethics Statement

All datasets used here are publicly available and, where applicable, released under protocols covering research use; we did not collect or contact patients, and no new protected health information was generated.

This work is a retrospective methodological study, not a clinical system: none of the pipelines we evaluate are safe for deployment without prospective validation, human oversight, and local calibration. Rare disease diagnosis has asymmetric costs—missed diagnoses prolong the diagnostic odyssey, incorrect ones can trigger unnecessary interventions—so any deployment should treat system output as a suggestion to a clinician, not an answer, and should abstain on low-confidence cases and on regimes outside the system's demonstrated competence (e.g., the low-coverage regime identified here).

Both components inherit biases from their training data. HPOA is not uniformly complete, and the resulting annotation gaps drive the non-retrievability failures we study, producing structural performance disparities across diseases and, by extension, across the patient groups most affected by them. Parametric LLMs over-represent literature-reported presentations, and our benchmarks skew toward published case reports and curated profiles; the numbers here should not be read as predictive of performance on pediatric, low-resource, or non-Western presentations.

Code, prompts, and per-case outputs are released at https://github.com/mofty8/BioNLP26.

Llama-3.3	Narr	3	51.8	+0.6	.568
Gemma-4	Narr	10	50.7	−0.6	.575
Gemma-3	Narr	10	48.8	−2.5	.565

Table 8: Phenopackets reranker grid (n=6,901, PhenoDP baseline: 51.2%). The rule-gated prompt consistently improves; the narrative prompt can harm on this high-coverage dataset.

Annotation sparsity: congenital adrenal hyperplasia (21-hydroxylase deficiency). This is the single most striking failure in the Phenopackets benchmark: 50 patient cases, all 50 non-retrievable (100%). The disease has only 12 HPO annotations in HPOA—a fraction of the 52-term median for retrievable diseases. Patient phenotype sets typically include electrolyte disturbance, virilization, ambiguous genitalia, salt wasting, and adrenal crisis, but the sparse HPOA profile does not encode enough of these terms for the information-content-based similarity used by PhenoDP to pull the disease into the top-50. An unrestricted LLM, by contrast, recognizes the classic clinical pattern from training text and returns the correct diagnosis immediately. This is a clean illustration of why coverage, not reasoning, is the bottleneck in such cases: no amount of LLM reranking can rescue a candidate that is never retrieved.

Phenotypic homogeneity: the DEE cluster. Developmental and epileptic encephalopathies (DEE-4, DEE-9, DEE-11, and related subtypes) share nearly identical HPO profiles despite distinct underlying genes (KCNQ2, SCN1A, STXBP1, and others). DEE-4 accounts for 430 cases in Phenopackets with a 48% non-retrievable rate; DEE-11 ac-

counts for 260 cases with an 82% non-retrievable rate. When truth is in the top-50, the retriever ranks several phenotypically indistinguishable subtypes together, and the information needed to disambiguate—gene panels, age at onset, EEG pattern, response to specific anti-epileptic drugs—is not encoded in the HPO terms the retriever sees. This is the homogeneity failure mode: retrieval has no mechanism to break ties between entities that look the same in ontology space. Xia-Gibbs syndrome (65 cases, 86% non-retrievable despite 187 HPOA annotations) fails for the same reason at a broader scale—its phenotype profile is dense but overlaps with many other syndromic neurodevelopmental disorders.

Category-level pattern. These case-level failures aggregate into category-level signatures (§5.1). Immunodeficiency (42.0%) and epilepsy/neurological (40.2%) categories are dominated by sparse-annotation or phenotypically overlapping disease families and account for most non-retrievable cases. Mitochondrial diseases (1.9%) and RASopathies (1.3%) are rarely missed—both have distinctive multi-system phenotypes and dense annotations (median 113 and 56 HPOA entries, respectively). The practical implication is that non-retrievability is predictable from disease identity, not random; a routing policy that escalates cases in the high-risk categories to an LLM is therefore a sensible starting point for hybrid systems (§6).

D Prompt Templates

For reproducibility, we include the literal prompt templates used for the rule-gated and narrative reranking conditions. Both prompts consume (i) the PP2Prompt-generated clinical narrative and (ii) PhenoDP's top-k candidates with similarity scores; models are asked to return a ranked list of k OMIM IDs (inference settings are described in §3). The rule-gated prompt enforces three conservative gates (score-gap, obligatory-feature, default-to-retriever) and changes the ranking in $<5\%$ of cases on Phenopackets. The narrative prompt, adapted from PP2Prompt (Reuter et al., 2024), omits the gates and produces 3–5$\times$ more rank changes; it is beneficial on low-coverage datasets but can harm high-coverage ones (e.g., DDD: -4.7 pp).

Rule-gated prompt.

```
You are an expert clinical geneticist.
You will rerank candidate rare diseases
for a patient. Apply the following rules
in order before changing the ranking.

[Score-gap gate]
- If rank-1 score exceeds rank-2 by >= 0.15,
  preserve the retriever's ordering unless
  a Condition A or Condition B violation
  is identified.
- If rank-1 score exceeds rank-2 by >= 0.03
  but < 0.15, you may swap rank-1 and rank-2
  only if a Condition A or Condition B
  violation is identified for rank-1.

[Condition A: obligatory absent feature]
Demote a candidate if ALL four hold:
  (1) the candidate has an obligatory
      HPO feature (frequency "always"
      or "very frequent") in HPOA,
  (2) that feature is in a clinically
      testable category for this patient
      (not age- or assessment-gated),
  (3) the patient record explicitly lists
      the feature as absent (negated),
  (4) absence is not trivially explained
      by the patient's age or workup stage.

[Condition B: biological impossibility]
Demote a candidate if the patient has a
finding that is biologically incompatible
with the candidate disease (e.g., male
patient with an X-linked female-specific
disorder).

[Same-gene spectrum rule]
When multiple candidates differ only in
severity labels for the same gene (e.g.,
"mild" vs. "severe" forms of the same
allelic series), preserve the retriever's
order unless a clear severity marker in
the patient record favors a different form.

[Numbered-subtype rule]
When candidates are numbered subtypes of
the same disease family (e.g., DEE-4 vs.
DEE-11), do not reorder unless a gene,
biomarker, or distinctive phenotype is
explicitly named in the patient record.

Patient narrative:
{narrative}

Candidate diseases (top-{k}):
{candidates_with_scores}

Output: a ranked list of {k} OMIM IDs,
one per line, most likely first. Include
a one-sentence justification for every
change you make relative to the retriever
order, referencing specific HPO terms or
conditions above.
```

Narrative prompt.

```
You are an expert clinical geneticist.
Read the patient narrative carefully and
rank the candidate rare diseases from
most to least likely.

Patient narrative:
{narrative}

Candidate diseases (top-{k}):
{candidates_with_scores}

Produce a ranked list of {k} OMIM IDs,
one per line, most likely first. Base your
ranking on clinical judgment: consider
the full phenotype picture, obligatory
features, and which candidate best
explains the patient. Provide a brief
justification for your top pick.
```

BioCoref: Benchmarking Biomedical Coreference Resolution with LLMs

Abstract

Coreference resolution in biomedical texts presents unique challenges due to complex domain-specific terminology, high ambiguity in mention forms, and long-distance dependencies between coreferring expressions. In this work, we present a comprehensive evaluation of generative large language models (LLMs) for coreference resolution in the biomedical domain. Using the CRAFT corpus as our benchmark, we assess the LLMs' performance with four prompting experiments that vary in their use of local, contextual enrichment, and domain-specific cues such as abbreviations and entity dictionaries. We benchmark these approaches against a discriminative span-based encoder, SpanBERT, to compare the efficacy of generative versus discriminative methods. Our results demonstrate that while LLMs exhibit strong surface-level coreference capabilities, especially when supplemented with domain-grounding prompts, their performance remains sensitive to long-range context and mentions ambiguity. Notably, the LLaMA 8B and 17B models show superior precision and F1 scores under entity-augmented prompting, highlighting the potential of lightweight prompt engineering for enhancing LLM utility in biomedical NLP tasks.

1 Introduction

Coreference resolution is the process of identifying entities mentioned in text and grouping all mentions that refer to the same underlying entity (Liu et al., 2023). In the biomedical domain, coreference resolution is a particularly difficult task and has been identified as a key bottleneck in biomedical text mining (Lu and Poesio, 2021). Research articles in this domain often contain dense, technical language, frequent use of abbreviations, and complex referential expressions that rely on domain-specific background knowledge. For instance, resolving a phrase like "the same strain" in a methods section may require linking it back to the "C57BL/6J mice" mentioned several paragraphs earlier, with no intervening repetition or synonyms. Similarly, phrases such as "the compound" may ambiguously refer to any of several chemical entities introduced earlier in experimental descriptions, particularly when multiple drugs or treatments are discussed in parallel. In such cases, surface string similarity offers little guidance; instead, linguistic disambiguation must be informed by contextual and semantic cues.

Adding to the challenge, many biomedical entities share identical surface forms, e.g., a gene and its corresponding protein often have the same name or abbreviation which can confuse automated systems. When clustered by identical surface strings, approximately 65% of the coreference clusters in CRAFT corpus (Cohen et al., 2017b) consist of repeated mentions (Li et al., 2022), emphasizing the need for models that can handle referential ambiguity. Moreover, many coreference links span large textual distances, exceeding the effective context window of conventional models (Lu and Poesio, 2021; Li et al., 2022). These long-range dependencies and requirements for specialized knowledge contribute to the poor generalization of general-domain coreference systems in biomedical contexts.

Given the emergence of increasingly capable large language models (LLMs), a natural question arises: how well can these general purpose models perform coreference resolution in specialized domains like biomedicine, without any task-specific fine-tuning (Gan et al., 2024)? LLMs have demonstrated remarkable abilities in complex reasoning and language understanding via prompt-based zero-shot or few-shot learning, often surpassing traditional models in general-domain tasks. This raises the possibility that their extensive pretraining enables them to handle intricate referential structures, even in domain-specific contexts. While biomedi-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 519–530
July 3-4, 2026 ©2026 Association for Computational Linguistics

cal coreference remains a demanding task, recent advances suggest that with well-designed prompts and minimal scaffolding, LLMs may be more capable than previously assumed.

In this work, we evaluate coreference resolution in biomedical texts using two contrasting approaches: a span-based model (SpanBERT-Large) (Joshi et al., 2020) trained on general-domain data, and several generative LLMs (LLaMA series) (Touvron et al., 2023) prompted to resolve coreference without fine-tuning. Our experiments use the CRAFT corpus, a richly annotated biomedical dataset.

The contributions and objectives of this paper are summarized as follows:

- **Benchmarking open-weight LLMs** We compare three LLaMA models under different prompting strategies: local-only, contextual, abbreviation-aware, and entity-aware against a span-based baseline, reporting performance on the CRAFT corpus.
- **Domain Analysis:** We identify coreference challenges unique to biomedical text, such as identical mention strings and abbreviation ambiguity, and analyze how each model type handles them through qualitative examples and error patterns.

2 Related Work

Coreference resolution in biomedical text is a particularly challenging task due to complex domain-specific terminology, high referential ambiguity, and long-range dependencies. Traditional span-based models such as the end-to-end neural coreference models such as SpanBERT (Joshi et al., 2020) have demonstrated strong performance in general domains. However, their reliance on limited context windows and the need for supervised fine-tuning limits their applicability in biomedical settings, where coreference often requires broader semantic grounding.

Traditional approaches also include rule-based and statistical systems (O'Connor and Heilman, 2013; Ng and Cardie, 2002; Soon et al., 2001), followed by neural architectures such as the mention-ranking model (Clark and Manning, 2016) and end-to-end span-ranking networks (Lee et al., 2017; Durrett and Klein, 2013; Wiseman et al., 2015; Lee et al., 2018). SpanBERT (Joshi et al., 2020) further improved coreference resolution by introducing span-centric pretraining objectives, achieving state-of-the-art results on the OntoNotes (Dobrovolskii, 2021) benchmark. Despite these advances, such models rely heavily on supervised training and domain-specific tuning, limiting their generalizability to out-of-domain settings like biomedical text.

Large language models (LLMs) like OpenAI GPT (Radford et al., 2018) and LLaMA have demonstrated strong zero-shot capabilities in various NLP tasks (Brown et al., 2020; Touvron et al., 2023), including aspects of coreference. Recent studies evaluated LLMs' abilities on pronoun resolution and Winograd schemas (Liu et al., 2024; Wu et al., 2020) for other downstream tasks such as question-answering and query-based span prediction problems. However, few studies have directly assessed LLMs on span-based or noun phrase coreference, particularly in long or technical documents. Most relevant to our work are recent prompting frameworks that use generative models for structured information extraction (Xie et al., 2022), though coreference-specific prompting remains underexplored, especially in specialized domains like biomedical literature.

3 Methods and Materials

3.1 Data

The Colorado Richly Annotated Full-Text (CRAFT) corpus (Cohen et al., 2017a) is a biomedical dataset of 67 full-text, open-access journal articles drawn from PubMed Central, with extensive manual annotations for biomedical concepts, syntactic structure, and coreference identity chains, In Version 2.0[1]. For our experiments, we evaluate language models on 50 articles selected at random, which contained more than 80K entities coreferenced to test the LLMs one.[2].

Three stacking properties make CRAFT uniquely demanding for large language models. First, its coreference chains stretch across *full* journal articles rather than short excerpts: as shown in Figure 1, while 76.14% of coreferential links fall within 500 words, over 23% extend up to 12,000 words, well beyond the effective context window of most conventional neural architectures. Second, roughly 65% of its coreference clusters consist of mentions with identical surface strings, for example, a gene and its cognate protein sharing a name or abbreviation, forcing models to disambiguate

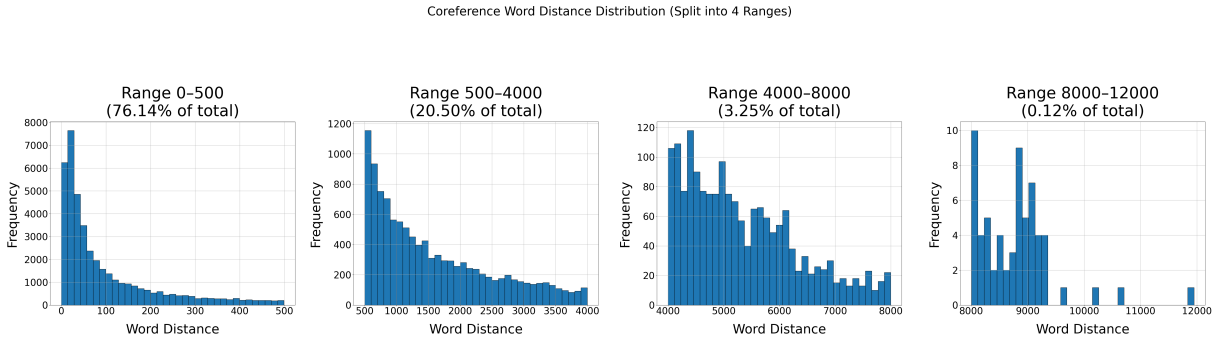

Figure 1: Distribution of word distances between coreferent mentions in biomedical texts, grouped into four ranges.

on semantics rather than lexical cues. Third, CRAFT's dense domain-specific terminology and pervasive abbreviation use cause general-domain systems to collapse: an out-of-the-box coreference resolver achieves only $F_1 = 0.14$ (B^3) on CRAFT, and even a domain-adapted rule-based system reaches only $F_1 = 0.42$ (Cohen et al., 2017a). These properties set CRAFT apart from otherwise strong alternatives. The closest runner-up for hard coreference evaluation is LitBank (Bamman et al., 2020), a challenging long-document complement to OntoNotes (Pradhan et al., 2013) that contains 210,532 tokens across 100 works of English fiction, with an average document length of 2,105 words, roughly four times longer than OntoNotes' 467-token average, and whose narratives form the backbone of recent LLM-oriented coreference benchmarks such as IdentifyMe (Manikantan et al., 2024). However, LitBank truncates each work to its first 2,000 tokens, covers only six ACE-style entity categories, and consists of general-domain prose. CRAFT, by contrast, pairs full-article context with the identical-surface ambiguity and specialized-knowledge demands described above, and couples its coreference layer to eight ontology-grounded semantic classes that yield a 76% increase in named-entity coverage through IDENTITY chains (Cohen et al., 2017a). These factors together establish CRAFT as a strictly harder benchmark than LitBank for evaluating LLM coreference capabilities.

3.2 Models

For our span-based baseline, we evaluate **SpanBERT-large-cased** model (Joshi et al., 2020), a span-optimized transformer pretrained on masked span prediction, on one experiment of coreferencing resolution. Input documents are segmented into 150-word chunks using `Stanza` (Qi et al., 2020), and 500 words in a another experiment setting. We normalized the document chunking sizes using stanza for all the experiments to assure the same chunk indices production for proper evaluation. After chunking the document, noun/pronoun mentions are extracted via `spaCy` (Vasiliev, 2020). Each mention is encoded using SpanBERT's final-layer embeddings and clustered via agglomerative clustering with cosine similarity ($\tau = 0.4$) to group together mentions that semantically refer to the same entity, approximating coreference. For the generative approach, we evaluate three open-weight LLaMA models on each of the 4 coreferencing experiments:

- **LLaMA 3.3 70B-Instruct** (Meta AI, 2024b): a high-capacity model (128k context) released in April 2024.
- **Llama-3.1-8B-Instruct** (Meta AI, 2024a): a compact model optimized for efficient text-only inference.
- **LLaMA 4 Scout 17B** (Meta AI, 2025): a 2025 multimodal model with a 10M-token context window and Mixture-of-Experts architecture.

4 Experiments

We evaluate four prompt-based strategies for coreference resolution using large language models over CRAFT-formatted biomedical texts. Each document D is split into paragraphs $p_1, \ldots, p_N$, each containing approximately 200 words. Using Stanza, we segment the text into sentences and iteratively append them to each paragraph chunk until the 200-word threshold is reached. If the last sentence causes the word count to exceed 200, it is deferred to the next paragraph. The goal is to

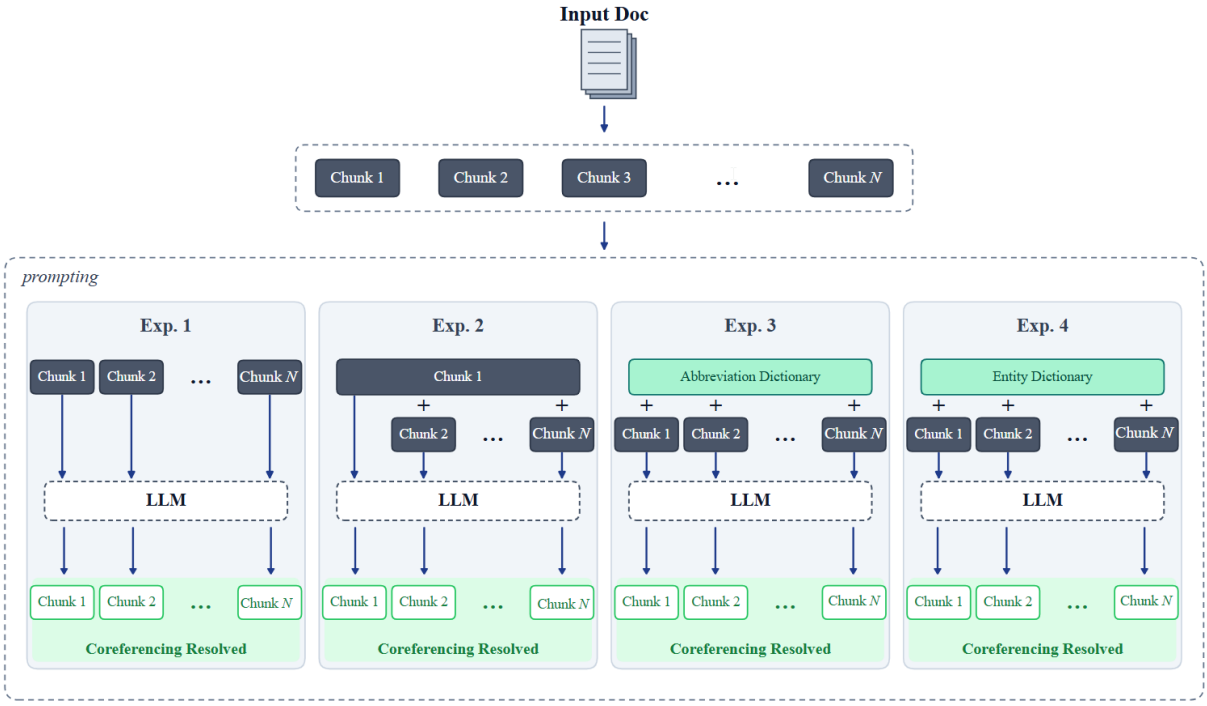

Figure 2: Overview of the coreference resolution pipeline under four prompting strategies. Each chunk is processed by an LLM independently (Exp. 1), with prior context (Exp. 2), or with auxiliary inputs such as abbreviation (Exp. 3) or entity dictionaries (Exp. 4).

output the set of detected mentions M_i, their corresponding resolutions A_i, and a "resolved" version of each paragraph R_i, where each p_i is independently rewritten. Formally:

- Let $\text{LLM}_\phi(\cdot)$ denote the output of the LLM with prompt ϕ.
- Let M_i be the set of coreferent mentions detected in paragraph p_i.
- Let A_i be the set of antecedent resolutions for M_i.
- Let R_i be the rewritten paragraph p_i with all mentions in M_i resolved using A_i.
- The reconstructed document is $\hat{D} = [R_1, \ldots, R_N]$.

The coreference resolution task involves resolving 4 categories: pronouns, definite and indefinite noun phrases, and abbreviations, as illustrated in Table 1.

To evaluate how different categories of auxiliary information affect coreference resolution, we design four prompting configurations: (1) a local-only setup with no external context, (2) a reference-based setup that incorporates the first paragraph as a fixed disambiguation source, (3) an abbreviation-aware setup using a dictionary of extracted abbreviation-definition pairs, and (4) an entity-aware setup using a list of biomedical entities extracted from the document. Algorithm 1 summarizes these 4 styles of the prompting experiments.

Coreference Type	Example Expressions
Pronouns	*it*, *these*, *those*, *its*, *their*
Definite noun phrases	*the gene*, *such results*
Indefinite noun phrases	*a protein*, *some genes*, *one of the enzymes*
Abbreviations	*IOP* $\rightarrow$ *intraocular pressure*

Table 1: Coreference categories and example expressions used in our experiments.

Figure 2 provides an overview of the experimental pipeline used to assess the effectiveness of LLMs across these different coreference categories.

4.1 Experiment 1: Local-Only Resolution (Baseline)

$$R_i = \text{LLM}_{\text{local}}(p_i)$$

In this initial experiment, we investigate the effectiveness of local coreference resolution by prompting LLMs to resolve coreference chains within short, isolated 200-word segments of a biomedical article. Each chunk is independently passed to the LLM. The goal is to assess how well the model performs coreference resolution without any cross-paragraph or global context.

This design reflects a naïve but computationally inexpensive strategy: it minimizes prompt complexity and token limits, while simulating how local context alone may or may not suffice for resolving biomedical coreference phenomena. We made a separate inference run for the 4 coreferencing categories.

This framework allows us to isolate and quantify the limitations of local-only resolution in biomedical texts. It also establishes a baseline against which we can measure subsequent experiments incorporating other resources, such as abbreviation expansion (Experiment 3).

4.2 Experiment 2: Coreference Resolution with Local and Reference Context

$$R_i = \text{LLM}_{\text{ref}}(p_1, p_i)$$

- **Prompt:** Provide p_1 and p_i, instructing the LLM to use the former to disambiguate references in the latter.
- **Purpose:** Test the incremental benefit of a reference paragraph for resolving inter-sentential and cross-paragraph coreferring mentions, without overloading the prompt size.

Building upon the limitations identified in Experiment 1, where coreference resolution was performed in isolation within 200-word chunks, we introduce an additional layer of local context to guide the LLM. In this experiment, each prompt to the model includes not only the target paragraph, but also the first 200-word paragraph in the paper, which carries most of the referential information introduced in the paper and can therefore act as an answer key for the unresolved references in the target paragraph.

Each prompt is structured with two segments: a reference block (Paragraph 1) and a focus block (Paragraph n), with explicit instructions for the LLM to resolve all ambiguous mentions in the focus block using context from the reference. This experiment assesses the impact of lightweight contextual bridging on coreference resolution quality. Compared to the purely local setting in Experiment 1, this approach tests whether even a single paragraph of surrounding context can significantly improve the coherence and referential clarity of LLM-generated outputs, without exceeding typical token limits or requiring full-document inputs.

Algorithm 1 Prompt-Based Coreference Resolution

Require: Document D, ExperimentType $\in$ {LOCAL, REF_CTX, ABBR, ENTITY}, Model LLM
Ensure: ResolvedDocument $\hat{D}$, MentionSets $\mathcal{M}$, ResolutionSets $\mathcal{A}$

Split D into paragraphs: $[p_1, p_2, \ldots, p_N]$
Initialize auxiliary content $C \leftarrow \emptyset$
if ExperimentType = ABBR **or** ExperimentType = ENTITY **then**
  $C \leftarrow$ EXTRACTCONTEXTINFO(D, type=ExperimentType)
end if
Initialize $\hat{D} \leftarrow$ [ ], $\mathcal{M} \leftarrow$ [ ], $\mathcal{A} \leftarrow$ [ ]
for $i = 1$ to N **do**
  $p \leftarrow p_i$
  if ExperimentType = REF_CTX **then**
    reference $\leftarrow p_1$ {Use Paragraph 1 as fixed reference}
  else
    reference $\leftarrow \emptyset$
  end if
  prompt $\leftarrow$ BUILDPROMPT(reference, p, C, ExperimentType)
  response $\leftarrow$ QUERYLLM(LLM, prompt)
  result $\leftarrow$ PARSEJSON(response)
  $\hat{D}$.append(result["Rewritten_Paragraph"])
  $\mathcal{M}$.append(result["Extracted_Expressions"])
  $\mathcal{A}$.append(result["Resolutions"])
end for
return $\hat{D}$, $\mathcal{M}$, $\mathcal{A}$

4.3 Experiment 3: Abbreviation-Aware Coreference Resolution Using LLM-Extracted Dictionaries

Let $A = \{(a_j, \alpha_j)\}$ be abbreviation-definition pairs extracted from the first 750 words using the GPT-4o.

$$R_i = \text{LLM}_{\text{abbr}}(A; p_i)$$

- **Prompt:** "Here is a list of abbreviations A.

the model is requested to extract all the coreferencing categories in separate runs, then, rewrite paragraph p_i by expanding ambiguous abbreviations and resolving references."

- **Purpose:** Leverage explicit abbreviation knowledge to aid disambiguation of biological mentions.

Biomedical texts frequently employ abbreviations for complex names, which can cause substantial ambiguity in coreference resolution. In this experiment, we assess whether providing LLMs with a structured abbreviation dictionary improves coreference resolution compared to unstructured context, such as the reference paragraphs used in Experiment 2. To build this dictionary, we parse the first 750 wordsof each document using Stanza and extract abbreviation-definition pairs (e.g., APP = "amyloid precursor protein") using the GPT-4o interface. These pairs are then validated against the CRAFT corpus. The resulting Abbreviation List is passed as auxiliary input during prompting.

4.4 Experiment 4: Entity-Aware Coreference Resolution Using LLM-Extracted Dictionaries

Let $E = \{e_k\}$ be key biomedical entities extracted from the first 750 words using GPT4o.

$$R_i = \text{LLM}_{\text{entity}}(E; p_i)$$

- **Prompt:** "Here is a list of detected biomedical entities E. Extract all the coreferencing mentions, then, rewrite paragraph pi by expanding ambiguous abbreviations and resolving references"

- **Purpose:** Provide broader semantic grounding than abbreviations alone, to evaluate whether entity awareness supports coherent coreference resolution.

In this experiment, we examine whether incorporating explicit biomedical entity information into the prompting process can enhance the performance of large language models on coreference resolution. Instead of only relying on implicit context or abbreviation mappings, we provide the LLM with a curated Entity List; a list of biomedical terms extracted using GPT-4o interface from the first 750 words of each document and validated against the CRAFT corpus to ensure correctness.

Table 2: LLaMA models performance metrics for LOCAL and REF_CTX tasks

Size	Task	P	R	F1
70B	LOCAL	0.800	0.458	0.583
	REF_CTX	0.805	0.390	0.525
17B	LOCAL	0.825	0.613	0.704
	REF_CTX	0.850	**0.573**	**0.685**
8B	LOCAL	**0.874**	**0.723**	**0.791**
	REF_CTX	**0.906**	0.539	0.676

This entity list serves as a form of semantic grounding. For each paragraph in the input article, the LLM is prompted with both the paragraph and the corresponding entity list. The model is then asked to resolve any ambiguous mentions by aligning them with the most probable entry in the entity list and rewriting the paragraph accordingly.

5 Results Analysis

The span-based baseline SpanBERT-large achieves an F1 of only 0.1322, highlighting the difficulty of biomedical coreference resolution for traditional models constrained by limited context windows, domain-specific terminology, and a mismatch between general-domain fine-tuning and specialized biomedical discourse.

To ensure accurate evaluation, we removed 9,335 gold-standard annotations from the selected CRAFT articles that lacked relation entries as the ones that don't connect to original source cannot be validates for coreferencing resolution. We then matched predicted resolutions against the remaining ∼83,608 annotated spans using case-insensitive partial character overlap ($\geq$2 characters). Predictions were extracted from structured JSON when available, or via a fallback regex parser. Precision, recall, and F1 were computed at the mention level, with unmatched predictions treated as false positives and missed gold spans as false negatives.

Our results reveal consistent patterns in how generative LLMs perform on biomedical coreference resolution:

Model Scale vs. Effectiveness.
Surprisingly, the 8B and 17B LLaMA models outperform the 70B variant across all experiments, indicating that scale alone does not drive coreference performance in domain-specific, fine-grained

Table 3: LLaMA models performance metrics for `abb_dictionary` and `entity_dictionary` tasks

Size	Task	P	R	F1
70B	ABBR	0.844	0.395	0.538
	ENTITY	0.826	0.379	0.519
17B	ABBR	**0.919**	0.400	0.558
	ENTITY	**0.891**	**0.633**	**0.740**
8B	ABBR	0.868	**0.653**	**0.745**
	ENTITY	0.882	0.551	0.678

Table 4: LLaMA models performance metrics for distance-aware local coreference resolution

Size	P	R	F1
70B	0.794	0.430	0.557
17B	0.841	0.554	0.668
8B	**0.892**	**0.601**	**0.718**

reasoning tasks. A likely explanation is that smaller models generalize more conservatively and commit fewer overconfident errors, whereas larger models, despite stronger generative capacity, appear more susceptible to prompt misalignment and semantic overreach.

To further probe local-only performance, we ran an additional variant of Experiment 1 in which paragraphs were selected not by a sequential 200-word window but by the most frequent reference distance observed in CRAFT (500 words), testing whether LLMs benefit from input chunks that align with natural coreference distances. Results appear in Table 4.

Impact of Coreference Distance.
The distance-aware local variant yields only marginal precision gains and a noticeable drop in recall and F1 for LLaMA 17B and 8B, indicating that proximity alone is insufficient for robust coreference; many biomedical entities require contextual cues beyond sentence-local information. LLaMA 8B still achieves the highest F1, confirming its strong span-level sensitivity, yet the degradation with larger context corroborates what we observe in Experiment 2 (`REF_CTX`).

Reference Context Has Mixed Effects.
In Experiment 2, which incorporates a fixed reference paragraph to aid disambiguation, recall often drops compared to the purely local setup (Experiment 1), particularly for LLaMA 8B and 70B. This suggests that, without fine-tuning or explicit multi-span integration mechanisms, LLMs may not reliably incorporate reference paragraphs into their reasoning. Prior work has observed that transformer-based models tend to prioritize recent tokens or local context unless explicitly guided otherwise, which could explain the degraded performance here.

Structured Dictionaries Improve Recall.
The abbreviation-aware settings (Experiments 3) yield measurable recall and F1 gains, most visibly for the 8B model, which reaches recall of 0.653 and 0.745 in `ABBR`. When supplied with structured input; abbreviation definitions, even smaller models like the 8B one can more reliably identify correct antecedents. These findings align with prior evidence that structured, grounded prompting improves information extraction, particularly when domain-specific context is required.

Overall, these results highlight both the promise and the current limitations of generative LLMs for biomedical coreference: while auxiliary signals such as abbreviation and entity dictionaries meaningfully boost performance, LLMs still struggle to integrate multi-paragraph context and resolve less explicit coreferences, underscoring the need for domain-specific adaptation or hybrid approaches that combine generative models with symbolic or retrieval-based components.

Coreference Type Sensitivity and Model Behavior.

To better understand how LLMs handle different forms of coreference, we evaluated each model across four categories; pronouns, indefinite noun phrases, abbreviations, and definite noun phrases, under the `LOCAL`, `REF_CTX`, `ABBR`, and `ENTITY` setups. Because CRAFT does not label coreference types, we built a post-processing pipeline that classifies predicted and gold mentions via lexical heuristics: pronouns, indefinite expressions, and abbreviations are identified by exact matches against dictionaries we manually compiled (available on our GitHub), and the remaining mentions are treated as definite noun phrases. Per-type precision, recall, and F1 are then computed from the model's original prediction labels.

As shown in Figure 3, pronoun coreference consistently yields the highest F1 across all LLaMA

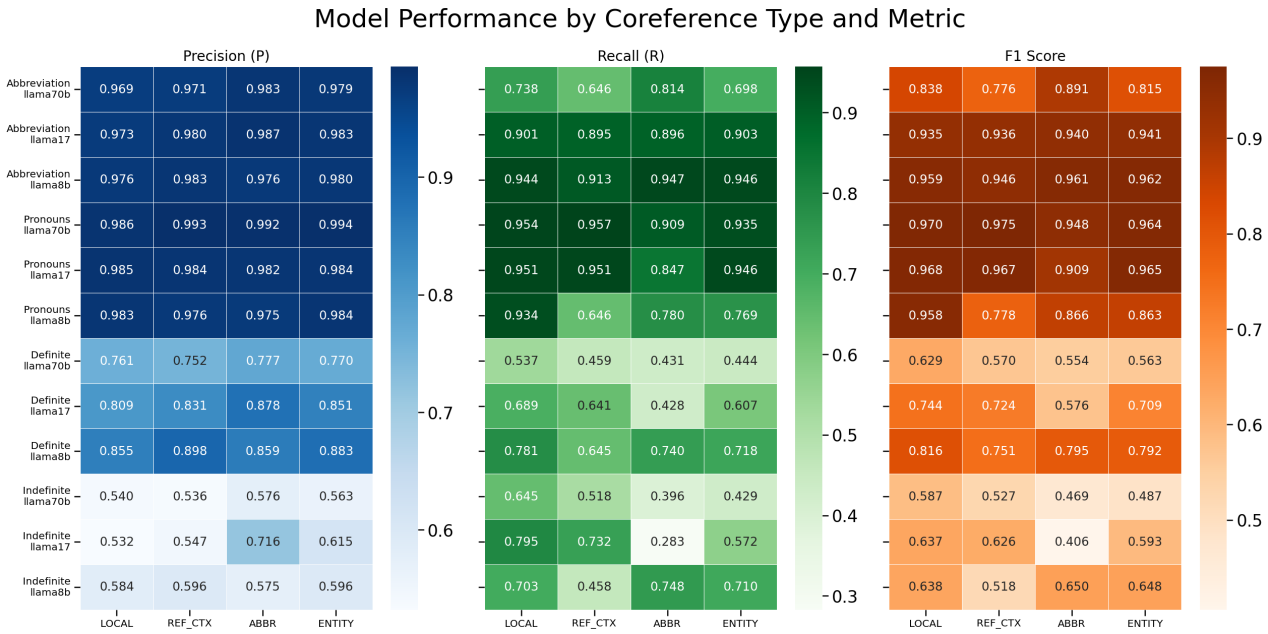

Figure 3: Heatmap of precision, recall, and F1 scores for LLaMA models (70B, 17B, 8B) across four experimental setups (LOCAL, REF CTX, ABBR, ENTITY) and coreference categories (pronouns, indefinite NPs, abbreviations, definite NPs).

models, peaking at 0.975 for LLaMA 70B under REF_CTX, likely because pronouns are heavily represented in pretraining corpora and rely on short-range syntactic cues; complementary evidence from Figure 4 in Appendix A shows pronouns are also resolved in high absolute counts, especially by LLaMA 17B under minimal context.

Abbreviation coreference is similarly strong, particularly under ABBR and ENTITY: injecting abbreviation dictionaries produces noticeable gains in both F1 (e.g., 0.961 for LLaMA 8B in ABBR) and resolved-mention counts, confirming that domain-specific cues substantially aid biomedical abbreviation understanding.

Definite noun phrase resolution reaches moderate F1, with LLaMA 8B highest in LOCAL (F1: 0.816), but both metrics and counts decline slightly under ABBR and ENTITY, likely due to contextual noise from input augmentation, suggesting that local syntactic proximity matters more for definite noun phrases than external cues. Indefinite noun phrases pose the greatest challenge: F1 is lowest across all models and experiments, with LLaMA 17B marginally stronger in REF_CTX and LOCAL. Notably, although LLaMA 70B leads in pronoun F1, it consistently underperforms elsewhere in both metrics and counts, indicating that larger models may be more prone to distraction or overfitting in domain-specific settings.

6 Conclusion

Our study presented a systematic evaluation of generative large language models (LLMs) for coreference resolution in the biomedical domain. We benchmarked three LLaMA models across four prompt-based settings and compared them to a span-based baseline, using the richly annotated CRAFT corpus for evaluation.

Our findings show that LLMs can resolve coreference with reasonable precision, but often suffer from low recall without explicit cues. Notably, smaller models like LLaMA 8B frequently outperformed larger ones, especially when provided with structured input such as abbreviation. In contrast, injecting additional free-text context offered limited benefit and sometimes degraded performance.

Overall, these results highlight the nuanced relationship between model size, coreference category, and the design of contextual input. They emphasize that targeted domain-specific augmentation, such as structured dictionaries, can have a greater impact on performance than model scale alone. Notably, smaller models can match or even exceed the performance of larger ones when paired with carefully designed prompts. Future directions should explore fine-tuning strategies, integration of external biomedical knowledge, and hybrid generative extractive systems to further enhance recall and robustness.

7 Appendix A

7.1 Additional Experiment Results

Figure 4 reports the absolute number of coreference mentions extracted by each LLaMA model (70B, 17B, 8B) under the four experimental setups (LOCAL, REF_CTX, ABBR, ENTITY), broken out by coreference category: pronouns, indefinite noun phrases, abbreviations, and definite noun phrases. The panel-wise y-axis ranges differ substantially across categories, reflecting the relative frequency with which each coreference type occurs in the CRAFT articles; definite noun phrases and abbreviations are by far the most numerous classes, while pronouns and indefinite noun phrases appear at an order of magnitude smaller scale.

Two patterns stand out. First, pronoun and definite-noun-phrase extraction are dominated by the larger models under minimal context, with LLaMA 70B and LLaMA 17B producing the highest counts in the LOCAL and REF_CTX conditions and then tapering off under the dictionary-augmented prompts, consistent with their high pronoun F1 scores in Figure 3 and the short-range syntactic nature of these mentions. Second, abbreviation extraction shows the opposite trend: LLaMA 8B produces the largest number of resolved abbreviations, and its count grows sharply under the ABBR and ENTITY prompts, mirroring the 0.961 F1 it achieves on abbreviations in the ABBR setup. Indefinite noun phrases follow a middle pattern, with LLaMA 17B leading in the lower-context conditions (LOCAL, REF_CTX) and all three models converging once structured dictionaries are supplied. Together these counts reinforce the quantitative findings from Tables 2 and 3: structured domain cues disproportionately benefit the smaller 8B model, particularly on the abbreviation-heavy categories where biomedical grounding matters most.

7.2 Computational Resouces

All open-weight LLM experiments were conducted on a high-performance Google Cloud VM instance of type `a2-highgpu-8g`, equipped with 96 vCPUs, 680 GB of RAM, and 8 NVIDIA A100 GPUs (40 GB each). The environment was provisioned with the c0-deeplearning-common-cu118-v20241118-debian-11-py310 boot disk image, ensuring compatibility with CUDA 11.8 and PyTorch 2.x frameworks.

8 Appendix B

8.1 Prompt Template

To guide the language model's behavior consistently across experiments, we employ a structured system prompt for each coreference type, and this prompt instructs the model to identify and resolve only a targeted subset of coreference expressions. In this example, the focus is on definite noun phrase coreferences within a paragraph, while explicitly excluding pronouns, indefinite expressions, and abbreviations.

The same system-prompt skeleton is reused across all four experimental setups, with only the

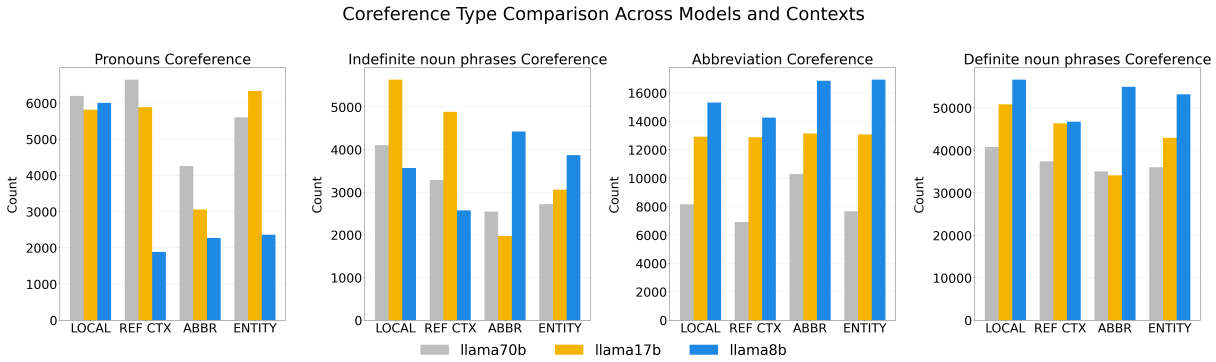

Figure 4: Extracted coreference type counts by model and context.

auxiliary-context block changing: LOCAL uses the skeleton verbatim, REF_CTX prepends the first paragraph of the article as a fixed reference block, ABBR injects the extracted abbreviation–definition pairs $\mathcal{A}$, and ENTITY injects the extracted biomedical entity list $\mathcal{E}$. The abbreviation and entity dictionaries used in Experiments 3 and 4 are themselves produced by a separate GPT-4o extraction prompt applied to the first 750 words of each document and validated against the CRAFT gold annotations. The four coreference categories (pronouns, definite noun phrases, indefinite noun phrases, and abbreviations) are resolved in independent inference runs; only the "ONLY X" clause and the accompanying skip list change between runs, while the JSON output schema remains identical. All LLaMA inferences are run with temperature 0 and top-$p = 1$ to maximize determinism, with `max_new_tokens` set to accommodate the full rewritten paragraph plus its JSON envelope. Model responses are first parsed as strict JSON; when parsing fails, a fallback regex extractor recovers the `Extracted_Expressions`, `Resolutions`, and `Rewritten_Paragraph` fields and the example is retained only if all three are present. Malformed outputs that cannot be recovered are discarded and counted as empty predictions for evaluation.

System Prompt

You are a scientific language model with expert-level understanding of coreference resolution.
Your task is to extract and resolve ONLY **definite noun phrase coreferences** (e.g., "the gene", "these proteins", "such results") within the paragraph.
Skip the following:

- Pronouns (e.g., "it", "they")
- Indefinite noun phrases (e.g., "a result", "some proteins")
- Abbreviations (e.g., "IOP")

Follow these steps:

1. Extract coreference expressions that appear *verbatim* in the paragraph. **Do NOT invent or rephrase them**.
2. For each expression, resolve it to its correct antecedent using context from the same paragraph.
3. Rewrite the paragraph by substituting each extracted expression with its resolved referent.

DO NOT paraphrase, summarize, add, remove, or reorder any content. **Preserve the original wording and sentence structure, except for the substitutions.**

Expected JSON Output Schema:

Abstract

Extracting structured cancer registry information from pathology and medical reports is challenging due to heterogeneous reporting styles and implicit clinical reasoning. We propose a modular multi-agent framework that decomposes registry abstraction into semantic chunking, retrieval, field-specific extraction, validation, evaluation, and aggregation stages.

The dataset includes 818 annotated cancer cases from Sultan Qaboos University Hospital. Evaluation in this study focuses on breast (n=454) and colorectal (n=174) reports across grade, morphology, TNM staging, and laterality extraction tasks. The framework is compared against prompt-based LLaMA 3.3 baselines using accuracy and weighted/macro F1-score metrics.

The proposed framework improved performance in context-dependent tasks, particularly grade extraction, where weighted F1-score increased from 0.71 to 0.78 for breast cancer and from 0.56 to 0.67 for colorectal cancer. Improvements were also observed for colorectal laterality extraction. For other extraction tasks, particularly highly structured tasks such as TNM staging and morphology extraction, the multi-agent framework achieved performance comparable to direct prompting.

Although the baseline achieved slightly higher average weighted F1-scores overall, the proposed framework provides improved modularity, traceability, and pipeline-level interpretability through explicit intermediate reasoning stages, supporting error analysis and future clinician-guided refinement.

1 Introduction

Cancer registries are essential for epidemiological surveillance, clinical research, and healthcare planning. However, key registry variables such as grade, morphology, TNM staging, and laterality are often embedded in free-text pathology reports, making abstraction labor-intensive, difficult to scale, and prone to inter-annotator variability.

Extracting structured information from clinical narratives remains challenging due to heterogeneous documentation styles, implicit terminology, and contextual ambiguity. While transformer models and large language models (LLMs) improved clinical text understanding and structured output generation, single-pass prompting approaches remain vulnerable to hallucination, inconsistency, and weak grounding when extracting multiple interdependent variables.

Recent advances in agentic LLM systems offer an alternative by decomposing complex tasks into modular reasoning stages. The ReAct paradigm demonstrated that combining reasoning and action improves performance and interpretability (Yao et al., 2022). Building on this idea, biomedical agentic systems incorporated planning, orchestration, and tool use (Abbasian et al., 2024; Li et al., 2025), while surveys and benchmark studies characterized these paradigms in biomedicine (Lin et al., 2024; Xu and Sankar, 2025; Yang et al., 2025; Radi et al., 2025; Gorenshtein et al., 2025). In oncology, agentic frameworks have been explored for decision support, diagnostic reasoning, and treatment planning (Ferber et al., 2025; Chen et al., 2025; Çağatay Umut Öğdü et al., 2025; Kuerbanjiang et al., 2025; Inoue et al., 2025; Zhao et al., 2025a). In parallel, LLM-based approaches have also been investigated for structured extraction from pathology and oncology reports (Chow et al., 2025; Gupta et al., 2025; Hart and Bergamaschi, 2026).

Despite this progress, existing approaches often focus on isolated tasks, single cancer types, or direct prompting strategies with limited visibility into intermediate reasoning stages and failure sources.

In this work, we propose an open-source multi-agent framework for structured cancer registry extraction from pathology and medical reports,

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 531–551
July 3-4, 2026 ©2026 Association for Computational Linguistics

focusing on breast and colorectal cancer. Implemented as a sequential LangGraph[1] workflow, the framework performs semantic chunking, field-conditioned retrieval, field-specific extraction, validation, evaluation, and aggregation. Unlike direct prompting, the system stores intermediate outputs across stages, enabling pipeline-level traceability and allowing failures to be linked to specific stages such as retrieval, extraction, normalization, or aggregation. This design supports structured auditing and future clinician-guided refinement for clinical information extraction.

2 Related Work

2.1 Clinical Information Extraction from Pathology Reports

Clinical information extraction evolved from rule-based systems to transformer-based and LLM-based approaches. Although transformer models improved generalization across tasks such as named entity recognition and relation extraction, pathology reports remain challenging due to dense terminology, implicit structure, and contextual ambiguity.

Recent studies demonstrated that LLMs can perform structured extraction from clinical and pathology documents without extensive task-specific training. Chow et al. (2025) demonstrated strong performance of open-weight LLMs for schema-aligned pathology abstraction. Hart and Bergamaschi (2026) proposed an agent-based framework for breast cancer pathology extraction, while Gupta et al. (2025) introduced a hierarchical agentic system for large-scale oncology data extraction. However, these approaches mainly focus on single-task extraction, institution-specific workflows, or direct prompting strategies with limited pipeline-level interpretability.

2.2 LLM Agents in Biomedicine and Oncology

Agentic AI expands the capabilities of LLMs by enabling iterative reasoning, external tool interaction, memory utilization, and coordinated multi-step problem solving (Yao et al., 2022; Xu and Sankar, 2025; Yang et al., 2025; Radi et al., 2025; Zhao et al., 2025b; Abdollahi et al., 2025). Foundational work such as ReAct demonstrated the advantages of integrating reasoning with action execution (Yao et al., 2022), while subsequent studies proposed biomedical agentic frameworks incorporating orchestration and tool-assisted workflows (Abbasian et al., 2024; Lin et al., 2024; Li et al., 2025; Inoue et al., 2025). Recent surveys further emphasized the growing applications of agentic AI in clinical decision-making, research automation, and biomedical knowledge synthesis (Xu and Sankar, 2025; Yang et al., 2025; Radi et al., 2025; Zhao et al., 2025b; Abdollahi et al., 2025).

In oncology, agentic frameworks have been explored for decision support, diagnostic reasoning, treatment planning (Ferber et al., 2025; Chen et al., 2025; Kuerbanjiang et al., 2025; Liu et al., 2026), and biomedical research applications such as drug discovery and biomarker reasoning (Inoue et al., 2025; Zuo et al., 2025; Jin et al., 2025; Huang et al., 2025; Bazgir et al., 2025). However, most work focuses on decision support or research workflows rather than structured cancer registry extraction from heterogeneous pathology documentation.

2.3 Research Gap

Despite progress in clinical information extraction and agentic AI, several gaps remain at their intersection. Existing approaches often rely on direct prompting strategies that process entire reports in a single inference step. While effective for explicit patterns such as TNM expressions, these approaches provide limited visibility into intermediate reasoning stages and extraction failures. In cancer registry abstraction, clinically relevant evidence may be distributed across multiple report sections, expressed implicitly, or embedded within noisy longitudinal documentation.

To address these limitations, we propose a modular multi-agent framework implemented as a sequential LangGraph workflow that performs semantic chunking, field-conditioned retrieval, field-specific extraction, validation, evaluation, and aggregation. The framework additionally stores intermediate outputs across stages, enabling pipeline-level traceability, structured auditing, and future clinician-guided refinement.

3 Methodology

3.1 Study Overview

We propose a modular multi-agent framework for structured cancer registry extraction from pathology and medical reports, targeting clinically relevant variables including grade, morphology, TNM staging, and laterality. Unlike single-pass LLM

[1] https://github.com/langchain-ai/langgraph

prompting, the framework decomposes extraction into sequential specialized stages implemented as a directed LangGraph workflow. Agents operate over a shared state and progressively refine intermediate outputs, enabling modular execution, structured auditing, and pipeline-level traceability.

3.2 Dataset

The dataset was collected from Sultan Qaboos University Hospital and includes 818 annotated cancer cases. Clinical reports were independently reviewed by trained pathologists, with disagreements adjudicated by a senior pathologist to establish the final gold standard annotations. Inter-annotator agreement analysis across registry variables and cancer types is provided in Appendix B.

Although the overall dataset contains multiple cancer types, the current study focuses on breast (n=454) and colorectal (n=174) reports for evaluation across four registry variables: grade, morphology, TNM staging, and laterality.

3.3 Multi-Agent Architecture

The proposed system consists of sequential specialized agents, as illustrated in Figure 1. Additional implementation details and source code availability are provided in Code Availabilty section.

- **Chunking Agent:** Segments reports into semantically coherent chunks and assigns field-relevance labels.
- **Retriever Agent:** Selects field-specific evidence relevant to grade, morphology, TNM staging, and laterality extraction. Retrieval is used to reduce irrelevant context and improve extraction focus for context-dependent variables.
- **Field-Specific Extraction Agents:** Dedicated agents independently extract grade, morphology, T, N, M, and laterality using task-specific prompts and structured output constraints.
- **Reviewer Agent:** Validates outputs, enforces schema consistency, and repairs malformed predictions.
- **Evaluator Agent:** Computes evaluation metrics when reference labels are available, or estimates confidence using evidence alignment and internal consistency.
- **Aggregation Agent:** Consolidates validated outputs into a unified structured record containing predictions, normalized labels, confidence scores, and supporting evidence.

All prompts are provided in Appendix D. Prompt design was iteratively refined through experimental evaluation and error inspection to improve schema consistency and extraction reliability across fields.

3.4 Workflow Orchestration

The pipeline is implemented using LangGraph as a directed execution graph operating over a shared state containing reports, retrieved evidence, intermediate outputs, predictions, and confidence scores. This design enables modular execution, transparent information flow, and stage-level error tracing.

3.5 Model Communication Protocol (MCP)

We introduce a lightweight Model Communication Protocol (MCP) that standardizes communication between agents through unified schemas for inputs, outputs, intermediate states, and metadata. MCP supports consistent state updates, logging, and reproducible execution across the pipeline.

3.6 Persistent Audit Database

A SQLite-based persistence module stores reports, intermediate outputs, predictions, and confidence values across runs, supporting auditing, traceability, and future refinement.

3.7 Implementation Details

The framework is implemented in Python using LangGraph. LLaMA 3.3 (70B) is deployed locally through Ollama (v0.4.7) to preserve data privacy. The system runs on Ubuntu 22.04 LTS with Python 3.10, Streamlit for visualization, and Pandas for data processing. Experiments were conducted using two NVIDIA RTX 6000 Ada GPUs (48 GB each) with CUDA 13.0.

3.8 Baseline Method

As a baseline, we implement direct prompt-based extraction using LLaMA 3.3 without task decomposition, retrieval, or intermediate reasoning stages. Multiple prompting strategies were evaluated, including simple/prefix prompting (direct extraction instructions), cloze prompting (fill-in-the-blank style extraction), anticipatory prompting (guiding the model with preparatory contextual instructions), chain-of-thought prompting (step-wise reasoning

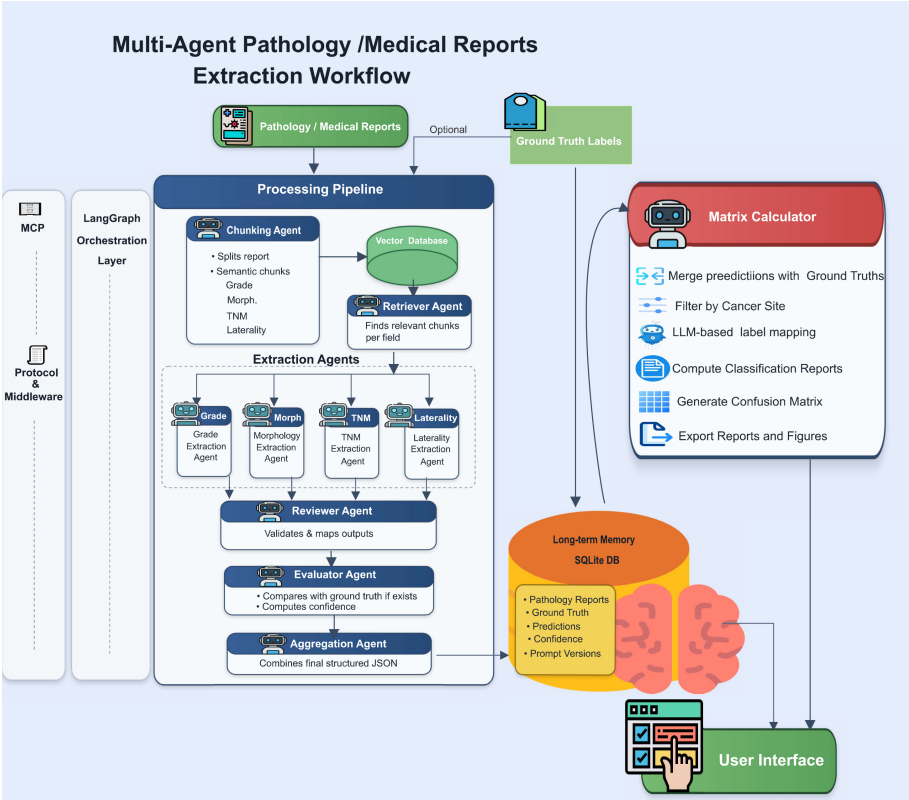

Figure 1: Overview of the proposed multi-agent framework. The pipeline consists of sequential agents for chunking, retrieval, field-specific extraction, validation, evaluation, and aggregation coordinated through a shared state.

before prediction), and heuristic prompting (rule-guided extraction instructions). For each extraction task, the best-performing baseline prompting strategy was selected for comparison against the proposed multi-agent framework. Detailed baseline prompts are provided in Appendix C.

Compared to direct prompting, the proposed multi-agent framework introduces additional computational overhead due to sequential agent execution, retrieval stages, and intermediate validation steps. However, the current study primarily focuses on extraction quality, interpretability, and traceability rather than runtime optimization.

3.9 Evaluation Metrics

Performance is evaluated using accuracy, macro-averaged, and weighted precision, recall, and F1-score. Macro metrics assess performance equally across classes, while weighted metrics account for class imbalance and reflect real-world clinical distributions.

Predictions are evaluated using exact-label matching against ground-truth registry annotations.

4 Results and Discussion

This section compares the proposed multi-agent framework with prompt-based LLaMA 3.3 baselines for breast and colorectal cancer registry extraction across grade, morphology, TNM staging, and laterality tasks. Because several fields are imbalanced, weighted F1-score is used as the primary metric, while macro metrics evaluate class-balanced performance.

Overall, results reveal task-dependent behavior. The multi-agent framework improves context-dependent tasks such as grade extraction and colorectal laterality, while achieving performance comparable to direct prompting for highly structured fields such as TNM staging and morphology.

4.1 Grade Extraction Performance

Table 1 summarizes grade extraction performance across breast and colorectal cancer sites. Figure 2 presents weighted metrics, while weighted F1-only and macro-level comparisons are provided in Appendix A (Figures 8 and 9).

For breast cancer, the multi-agent framework improved weighted F1-score from 0.71 to 0.78 and accuracy from 0.64 to 0.73. For colorectal cancer,

Table 1: Comparative performance for grade extraction in breast and colorectal cancer.

Site	Method	Acc	P_w	R_w	$F1_w$	P_m	R_m	$F1_m$
Breast	Baseline-Anticipatory	0.64	0.83	0.64	0.71	0.55	0.61	0.51
Breast	Multi-Agent	0.73	0.83	0.73	0.78	0.58	0.54	0.56
Colorectal	Baseline-Anticipatory	0.44	0.85	0.44	0.56	0.40	0.34	0.34
Colorectal	Multi-Agent	0.59	0.80	0.59	0.67	0.34	0.30	0.31

Table 2: Comparative performance for morphology extraction in breast and colorectal cancer.

Site	Method	Acc	P_w	R_w	$F1_w$	P_m	R_m	$F1_m$
Breast	Baseline-Anticipatory	0.75	0.91	0.75	0.82	0.34	0.40	0.33
Breast	Multi-Agent	0.72	0.92	0.72	0.80	0.35	0.54	0.34
Colorectal	Baseline-Simple	0.86	0.87	0.86	0.87	0.31	0.31	0.31
Colorectal	Multi-Agent	0.67	0.99	0.67	0.80	0.33	0.23	0.27

weighted F1-score increased from 0.56 to 0.67 and accuracy from 0.44 to 0.59. These improvements suggest that decomposition and field-specific evidence retrieval are beneficial when grade-related information is context-dependent or distributed across multiple report sections.

However, the slight decrease in colorectal macro F1-score indicates reduced sensitivity for less frequent classes. Overall, grade extraction represents the strongest advantage of the proposed multi-agent framework over direct prompting.

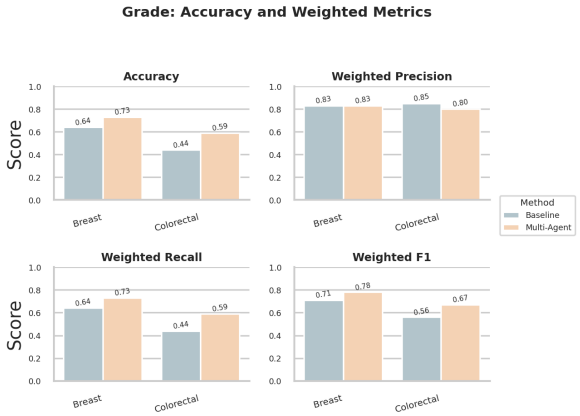

Figure 2: Accuracy, weighted precision, weighted recall, and weighted F1-score comparison between the baseline and the multi-agent framework for grade extraction across breast and colorectal cancer sites.

4.2 Morphology Extraction Performance

Table 2 and Figure 3 summarize morphology extraction performance. Additional weighted F1-only and macro-level comparisons are provided in Figures 10 and 11. For breast cancer, the multi-agent framework remained close to the baseline, with weighted F1-score decreasing slightly from 0.82 to 0.80 while macro F1-score improved marginally from 0.33 to 0.34. In colorectal cancer, the baseline achieved higher weighted F1-score, increasing from 0.80 to 0.87 (+0.07) compared to the multi-agent framework.

These findings suggest that morphology extraction often depends on explicit histologic terminology that can already be captured effectively through direct prompting. Additional retrieval and normalization stages may occasionally introduce information loss or normalization inconsistencies, particularly for less frequent morphology classes.

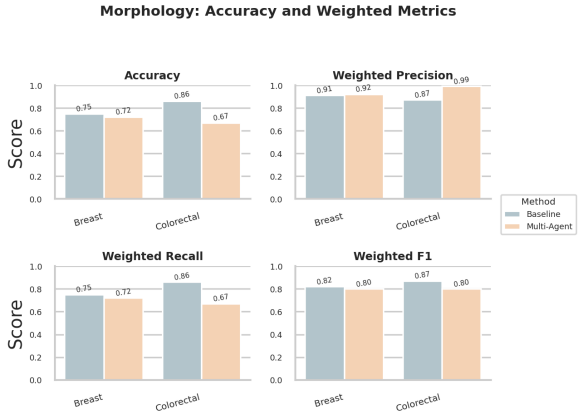

Figure 3: Accuracy, weighted precision, recall, and weighted F1-score comparison between the baseline and the multi-agent framework for morphology extraction across breast and colorectal cancer sites.

4.3 TNM Extraction Performance

Table 3 and Figure 4 summarize TNM extraction performance. Additional weighted F1-only and macro-level analyses are provided in Figures 12, 13, 14, 15, 16, and 17. Across TNM components, the baseline generally achieved stronger weighted performance, particularly for T and M categories. This is expected because TNM staging often appears in concise and standardized forms that are well suited to direct prompting. In contrast, the multi-agent framework introduces additional chunking, retrieval, and normalization stages that may occasionally reduce useful contextual information.

4.3.1 T Category

For T-stage extraction, the baseline outperformed the multi-agent framework in both cancer sites. In breast cancer, weighted F1-score decreased from 0.75 to 0.66, while in colorectal cancer it decreased slightly from 0.60 to 0.59. The T sub-figure in Figure 4 confirms that the baseline achieves stronger weighted metrics across both sites, particularly in

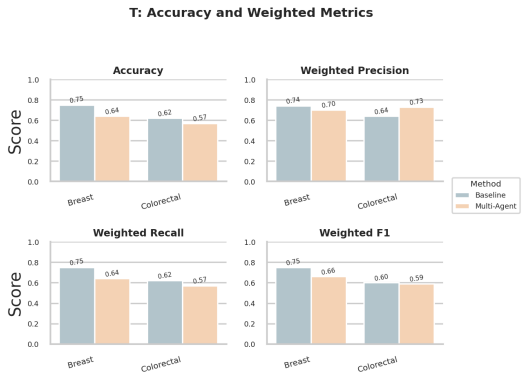
breast cancer. These findings suggest that T-stage extraction relies heavily on concise and standardized expressions that can already be captured effectively through direct prompting.

4.3.2 N Category

For N-stage extraction, the multi-agent framework achieved performance comparable to the baseline in breast cancer, with weighted F1-scores of 0.62 for both approaches while slightly improving macro F1-score. In colorectal cancer, the baseline achieved higher weighted F1-score, whereas the multi-agent framework showed slightly improved macro-level behavior. The N sub-figure in Figure 4 illustrates this site-dependent trend.

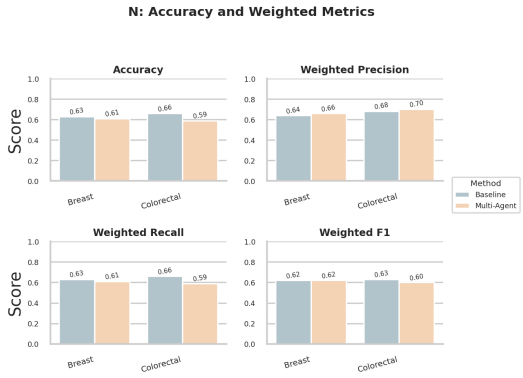
4.3.3 M Category

For M-stage extraction, the baseline consistently outperformed the multi-agent framework across both cancer sites. In breast cancer, weighted F1-score decreased from 0.60 to 0.48, while in colorectal cancer it decreased from 0.66 to 0.48. The M sub-figure in Figure 4 highlights a clear precision–recall trade-off: although the multi-agent framework achieved higher precision in some settings, it suffered from substantially lower recall, suggesting conservative predictions that missed metastasis-related cases.



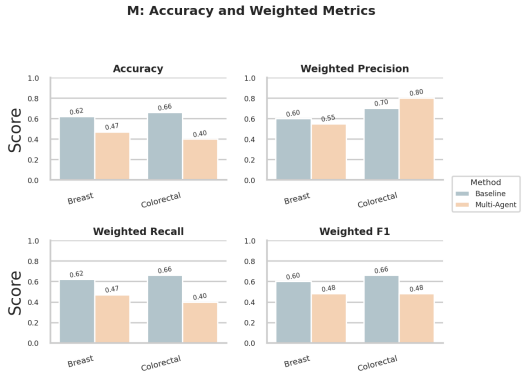
4.4 Laterality Extraction Performance

Table 4 and Figure 5 summarize laterality extraction performance. Weighted F1-only and macro-level comparisons are shown in Figures 18 and 19.



Laterality extraction showed site-dependent behavior. In breast cancer, both approaches achieved high performance, with weighted F1-score of 0.92 for the baseline and 0.91 for the multi-agent framework. Figure 5 confirms that differences across weighted metrics are minimal in this setting.

In colorectal cancer, the multi-agent framework improved weighted F1-score from 0.45 to 0.50 and macro F1-score from 0.22 to 0.27. The corresponding figure suggests that these gains are associated with improved recall and better handling of less explicit laterality expressions.



Overall, laterality emerged as one of the more stable extraction tasks, particularly in breast cancer where laterality is often explicitly stated. These findings further suggest that decomposition and field-specific retrieval are beneficial when laterality information is expressed inconsistently or implicitly across report sections.

T-stage

N-stage

M-stage

Figure 4: Accuracy, weighted precision, recall, and weighted F1-score comparison for TNM extraction across breast and colorectal cancer sites.

4.5 Overall Cross-Field Performance Analysis

To assess global system behavior, we analyze weighted F1-scores across all extraction tasks (grade, morphology, TNM, and laterality) using radar plots for each cancer site.

Figures 6 and 7 show that the multi-agent framework redistributes performance across tasks rather than uniformly improving all of them. In breast cancer, the largest gain is observed in grade extraction, while morphology and laterality remain competitive and TNM categories, particularly T

Table 3: Comparative performance for TNM extraction in breast and colorectal cancer.

Cat.	Site	Method	Acc	P_w	R_w	$F1_w$	P_m	R_m	$F1_m$

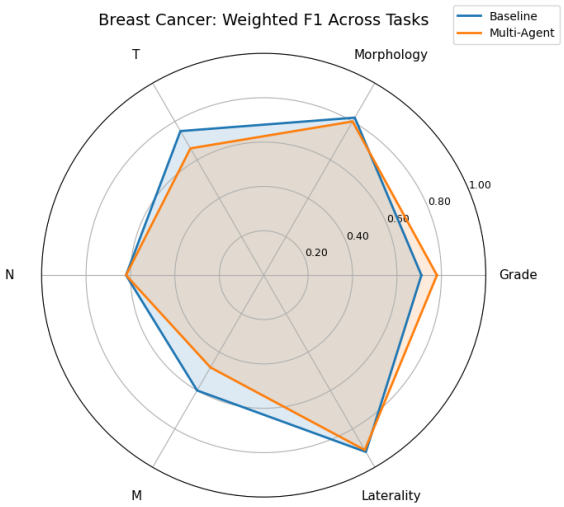

Figure 6: Weighted F1-score comparison across extraction tasks for breast cancer.

Table 5: Average weighted F1-score across all extraction tasks for each cancer site.

Site	Baseline	Multi-Agent
Breast	0.74	0.71
Colorectal	0.63	0.61

and M, favor the baseline. In colorectal cancer, the multi-agent framework improves grade and laterality but underperforms in morphology and M-stage extraction.

Table 5 reports the average weighted F1-score across tasks. The baseline achieves slightly higher overall averages in both breast (0.74 vs. 0.71) and colorectal (0.63 vs. 0.61). However, these aggregate results mask important task-dependent differences and varying levels of clinical complexity.

The baseline performs better in highly structured tasks such as TNM staging and morphology extraction, where clinically relevant information often appears in concise and standardized forms. In contrast, the multi-agent framework demonstrates clear advantages in more context-dependent tasks such as grade extraction and colorectal laterality, where evidence may be distributed across sections or expressed implicitly.

Pipeline-level inspection suggests that performance degradation primarily originates from retrieval and normalization stages rather than extraction itself. For structured fields, chunking and retrieval may occasionally remove useful context or introduce unnecessary normalization steps. In contrast, decomposition improves extraction when contextual reasoning and evidence localization are required.

A formal ablation study isolating the contribution of chunking, retrieval, and normalization stages was not conducted in the current study, as the primary objective was to evaluate the overall

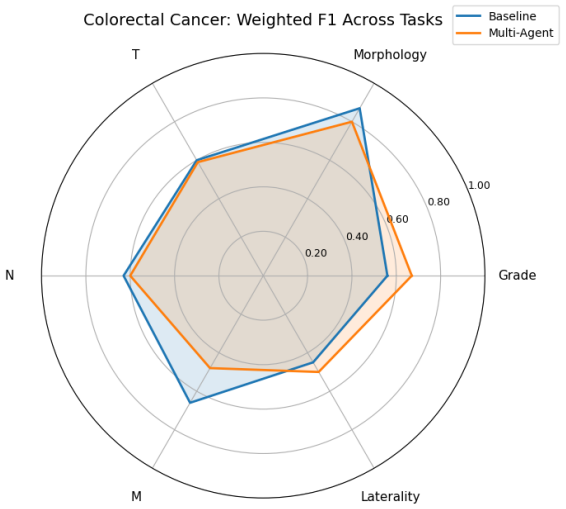

Figure 7: Weighted F1-score comparison across extraction tasks for colorectal cancer.

behavior and clinical applicability of the complete end-to-end framework.

Overall, the proposed framework should not be viewed solely as a score-maximizing alternative, but as a modular and auditable extraction pipeline that supports structured reasoning, traceability, and systematic error analysis.

5 Future Work

Future work will focus on improving retrieval-aware extraction, adaptive chunk selection, and rare-class calibration, particularly for conservative settings such as M-stage extraction where recall degradation was observed. Since performance varies across tasks, future optimization should target field-specific pipeline behavior rather than uniformly increasing model complexity.

Future work will also investigate clinician-guided validation and interactive correction workflows to support targeted refinement of ambiguous predictions. Such feedback may help improve schema normalization, reduce context-related extraction errors, and support iterative prompt and model refinement.

Future evaluation across institutions with different reporting conventions is necessary to better assess generalization and robustness.

Additional directions include evaluating domain-specific biomedical LLMs, comparing alternative prompting strategies more systematically, extending the framework to additional cancer registry fields and cancer sites, and evaluating generalization across institutions with different reporting conventions.

6 Conclusion

In this study, we proposed a modular multi-agent framework for extracting structured cancer registry information from pathology and medical reports. Implemented as a sequential LangGraph workflow, the system decomposes extraction into semantic chunking, retrieval, field-specific extraction, validation, evaluation, and aggregation stages, enabling structured intermediate outputs and pipeline-level traceability.

Experimental results demonstrate that performance is strongly task dependent. The multi-agent framework provides clear advantages in context-dependent tasks such as grade extraction and colorectal laterality, while direct prompting performs better in highly structured tasks such as TNM staging and morphology extraction. These findings highlight an important trade-off between reasoning-driven decomposition and direct pattern-based extraction.

Beyond aggregate performance, the proposed framework provides practical benefits through modular execution, structured auditing, and interpretable intermediate outputs that support error analysis and future refinement. Overall, this work positions multi-agent clinical information extraction as a promising and extensible direction for reliable cancer registry abstraction and future clinically guided NLP systems.

A Additional Results

This appendix provides supplementary visualizations for weighted F1-only comparisons and macro-level comparisons across extraction tasks.

A.1 Grade Extraction

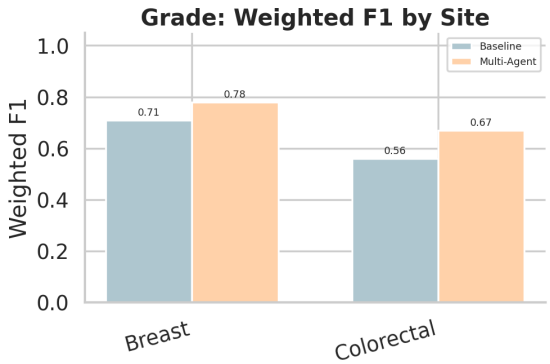

Figure 8: Weighted F1-score comparison between the prompt-based baseline and the multi-agent framework for grade extraction across breast and colorectal cancer sites.

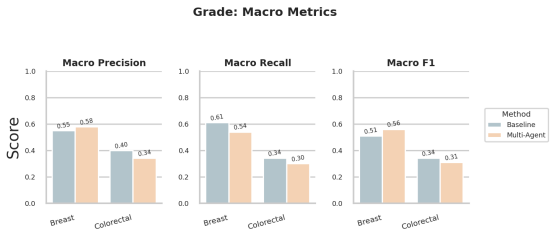

Figure 9: Macro precision, recall, and F1-score comparison between the baseline and the multi-agent framework for grade extraction across breast and colorectal cancer sites.

A.2 Morphology Extraction

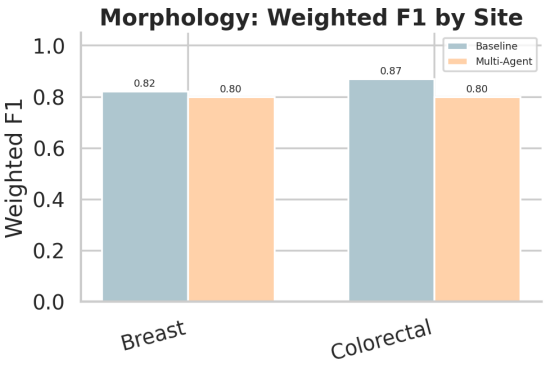

Figure 10: Weighted F1-score comparison between the baseline and the multi-agent framework for morphology extraction across breast and colorectal cancer sites.

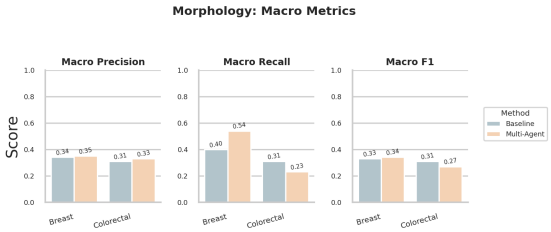

Figure 11: Macro precision, recall, and F1-score comparison between the baseline and the multi-agent framework for morphology extraction across breast and colorectal cancer sites.

A.3 T-Stage Extraction

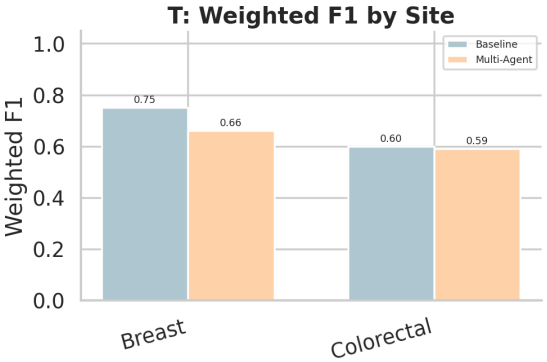

Figure 12: Weighted F1-score comparison between the baseline and the multi-agent framework for T-stage extraction across breast and colorectal cancer sites.

Figure 13: Macro precision, recall, and F1-score comparison between the baseline and the multi-agent framework for T-stage extraction across breast and colorectal cancer sites.

A.4 N-Stage Extraction

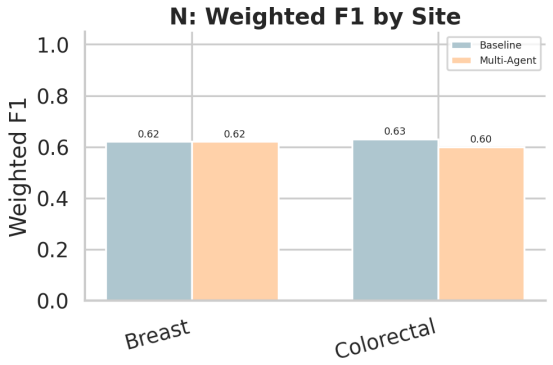

Figure 14: Weighted F1-score comparison between the baseline and the multi-agent framework for N-stage extraction across breast and colorectal cancer sites.

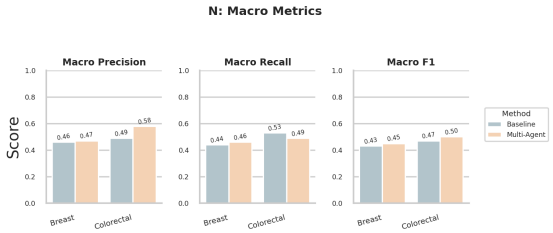

Figure 15: Macro precision, recall, and F1-score comparison between the baseline and the multi-agent framework for N-stage extraction across breast and colorectal cancer sites.

A.5 M-Stage Extraction

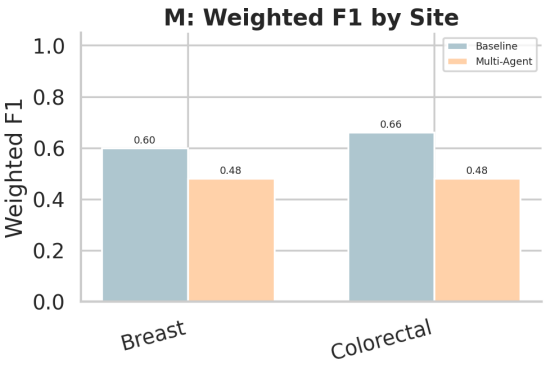

Figure 16: Weighted F1-score comparison between the baseline and the multi-agent framework for M-stage extraction across breast and colorectal cancer sites.

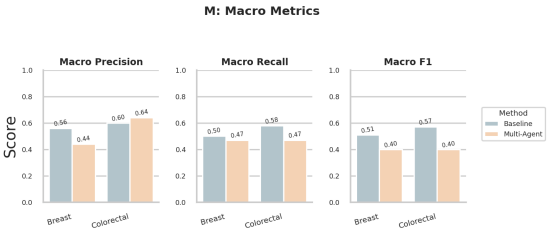

Figure 17: Macro precision, recall, and F1-score comparison between the baseline and the multi-agent framework for M-stage extraction across breast and colorectal cancer sites.

A.6 Laterality Extraction

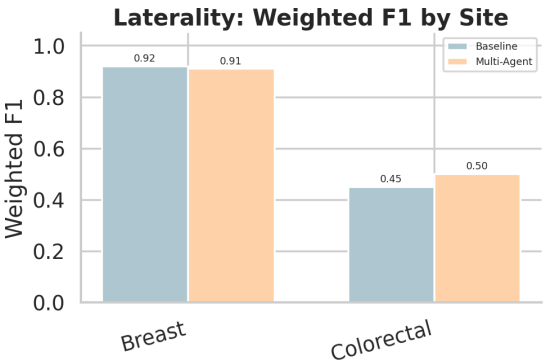

Figure 18: Weighted F1-score comparison between the baseline and the multi-agent framework for laterality extraction across breast and colorectal cancer sites.

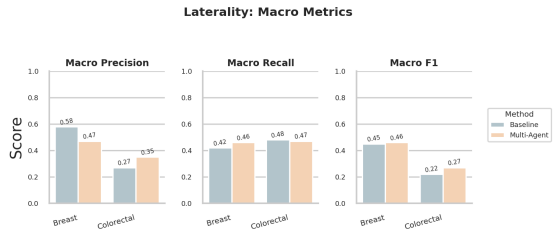

Figure 19: Macro precision, recall, and F1-score comparison between the baseline and the multi-agent framework for laterality extraction across breast and colorectal cancer sites.

B Inter-Annotator Agreement (IAA)

To assess the reliability of the gold-standard annotations, inter-annotator agreement (IAA) was evaluated across all registry variables using Cohen's κ coefficient and percentage agreement. The overall agreement across all fields was $\kappa = 0.917$, with a percentage agreement of 91.99%, indicating high consistency between annotators.

B.1 Overall Agreement Across Registry Fields

Table 6 presents the overall agreement for each registry variable. All fields demonstrate strong agreement, with most achieving "almost perfect" consistency.

Table 6: Overall inter-annotator agreement across registry variables.

Field	Cohen's κ	% Agreement	Interpretation
GRADE	0.968	97.83	Almost perfect
STAGE	0.909	92.05	Almost perfect
MORPHOLOGY	0.981	98.71	Almost perfect
T	0.820	86.80	Almost perfect
N	0.904	92.64	Almost perfect
M	0.812	88.48	Substantial
LATERALITY	0.869	90.33	Almost perfect

B.2 IAA by Cancer Type

Table 7 reports agreement stratified by cancer type. Agreement remains consistently high across most cancer sites, with slight variability observed in more complex fields such as T, N, and M staging, particularly for colorectal and thyroid cases.

C Baseline Prompt Designs

This appendix presents the prompt designs used for the baseline prompt-based LLM extraction. Multiple prompting strategies were explored, including prefix, cloze, anticipatory, chain-of-thought, and heuristic prompting.

Table 7: Inter-annotator agreement stratified by cancer type.

Cancer Type	Field	κ	%	Interpretation
Breast	GRADE	0.975	98.83	Almost perfect
	STAGE	0.944	95.48	Almost perfect
	MORPHOLOGY	0.914	96.47	Almost perfect
	T	0.916	94.96	Almost perfect
	N	0.933	95.88	Almost perfect
	M	0.930	95.88	Almost perfect
	LATERALITY	0.958	97.50	Almost perfect
Colorectal	GRADE	0.852	91.49	Almost perfect
	STAGE	0.889	91.49	Almost perfect
	MORPHOLOGY	0.964	97.87	Almost perfect
	T	0.576	73.49	Moderate
	N	0.918	92.42	Almost perfect
	M	0.784	85.38	Substantial
	LATERALITY	0.854	91.49	Almost perfect
Prostate	GRADE	0.992	99.03	Almost perfect
	STAGE	0.983	98.06	Almost perfect
	MORPHOLOGY	0.986	98.71	Almost perfect
	T	0.879	87.74	Almost perfect
	N	0.903	90.32	Almost perfect
	M	0.735	80.65	Substantial
	LATERALITY	0.873	90.32	Almost perfect
Thyroid	GRADE	0.934	97.80	Almost perfect
	STAGE	0.416	24.53	Moderate
	MORPHOLOGY	0.979	99.72	Almost perfect
	T	0.702	71.49	Substantial
	N	0.255	34.84	Fair
	M	0.512	70.57	Moderate
	LATERALITY	0.701	86.88	Substantial

C.1 Grade Extraction Prompts

Table 8: Prompt designs for grade extraction.

Prompt Type	Prompt Text
Prefix (p1)	Extract only the numerical tumor grade from the medical report and return it in the JSON template. Ignore additional details. If multiple grades are mentioned, select the final diagnostic grade from the *Impression* section when available. Use the highest numerical tumor grade from the most recent relevant pathology-based report (e.g., pathology or biopsy) and ignore non-pathology reports.
Cloze (p2)	The tumor grade in the text is ___, the grading system used (if available) is ___, and the individual score components (if available) are ___. From the following concatenated clinical notes, extract the highest tumor grade mentioned across all relevant reports. Ignore unrelated or irrelevant sections. The highest tumor grade in the text is ___, the grading system used (if available) is ___, and the individual score components (if available) are ___.
Anticipatory (p3)	[Input 1:] How can tumor grade information be identified in a medical report? [Input 2:] For each tumor mentioned in the given medical report, extract the reported grade. If multiple grades are mentioned, select the final diagnostic grade from the *Impression* section and return only the numerical grade. [Input 1:] How can tumor grade information be identified in a medical history? [Input 2:] For each tumor mentioned in the patient's medical history, extract the highest relevant tumor grade from the most recent pathology report. If multiple grades are mentioned in that report, select the final diagnostic grade from the *Impression* or equivalent summary section. Ignore irrelevant or outdated reports and return only the numerical grade.
Chain-of-Thought (p4)	**EXAMPLE:** Identify and extract the tumor grade from the medical report. If the grading system and its components are mentioned, include them. **TEXT:** "Microscopic examination reveals an invasive ductal carcinoma with moderate tubule formation (score = 2), marked pleomorphism (score = 3), and 5 mitoses per 10 high-power fields (score = 2). Based on these features, the tumor is classified as Nottingham Grade II." **QUESTION 1:** What is the tumor grade mentioned in the medical report? **ANSWER 1:** The tumor grade is II (explicitly stated as Nottingham Grade II). **QUESTION 2:** What grading system is used in the report, if available? **ANSWER 2:** The grading system used is Nottingham. **QUESTION 3:** Is there any additional information about the tumor that should be noted? **ANSWER 3:** No additional features such as necrosis were mentioned. **QUESTION:** Using the stored example, extract the tumor grade, grading system, and score components from the following medical report. **TEXT:** `<text>`
Heuristic (p5)	[Input 1:] First, store these rules in memory: If the tumor grade is explicitly mentioned with a number, use that as the grade. If the grading system is Nottingham, check for component scores such as tubule formation, pleomorphism, and mitotic count. If the grade is described as "Grade I," "Grade II," or "Grade III," classify it accordingly. If it is described as "low," "moderate," or "high," map these to Grade I, II, or III, respectively. If the grading system is not mentioned but descriptors such as "well differentiated," "moderately differentiated," or "poorly differentiated" are used, assign Grade I, II, or III based on those terms. If the grade remains ambiguous, infer it from contextual clues. [Input 2:] Given the patient's full medical record history, extract the tumor grade, grading system, and individual component scores, if available, from the most recent pathology report that discusses tumor grading. Ignore irrelevant or outdated reports without pathology-based grading. Extract: (i) the highest relevant tumor grade in the most recent pathology document, (ii) the grading system used, and (iii) component scores such as tubule formation, pleomorphism, and mitotic count, when available.

C.2 Morphology Extraction Prompts

Table 9: Prompt designs for morphology extraction.

Prompt Type	Prompt Text
Prefix (p1)	Extract the most relevant morphology from the latest pathology report in the patient's medical history (e.g., pathology or biopsy). If available, prioritize the final morphology stated in the *Impression* or *Diagnosis* section. Select the final answer from the predefined label list: Adenocarcinoma, NOS; Carcinoma, NOS; Follicular adenocarcinoma, NOS; Infiltrating duct carcinoma, NOS; Lobular carcinoma, NOS; Medullary carcinoma, NOS; Mucinous adenocarcinoma; Neoplasm, malignant; Signet ring cell carcinoma. Ignore non-pathology reports. Return only the result in the specified JSON format without additional details.
Cloze (p2)	From the following concatenated clinical notes, extract the most relevant morphology from the latest pathology report. Ignore unrelated or irrelevant sections. The morphology mentioned in the text is ___, and the specific carcinoma type (if available) is ___. Select the final morphology from the predefined label list and return only the result in the specified JSON format.
Anticipatory (p3)	[Input 1:] How can morphology information be identified in a medical report history? [Input 2:] For each tumor mentioned in the patient's medical history, extract the most relevant morphology reported in the most recent pathology report. If multiple morphology types are mentioned, select the most relevant one. Prioritize the final morphology stated in the *Impression* or equivalent summary section. Ignore irrelevant or outdated reports. Choose the final answer from the predefined label list and return only the result in JSON format.
Chain-of-Thought (p4)	**EXAMPLE:** Identify and extract the morphology from the most recent pathology report. If multiple morphology types are mentioned, select the most relevant one, prioritizing the final diagnosis. **TEXT:** "The pathology report reveals features consistent with invasive ductal carcinoma. The diagnosis concludes invasive ductal carcinoma, NOS." **QUESTION 1:** What morphology is mentioned? **ANSWER 1:** Infiltrating duct carcinoma, NOS. **QUESTION 2:** Are there additional morphology types? **ANSWER 2:** No additional morphology types are introduced. **QUESTION 3:** What is the final morphology? **ANSWER 3:** Infiltrating duct carcinoma, NOS. **TEXT:** "Microscopic examination reveals mucinous adenocarcinoma with signet ring features. The final diagnosis is mucinous adenocarcinoma." **QUESTION 1:** What morphology is mentioned? **ANSWER 1:** Mucinous adenocarcinoma. **QUESTION 2:** Are additional patterns mentioned? **ANSWER 2:** Yes, signet ring features are mentioned, but not as the final diagnosis. **QUESTION 3:** What is the final morphology? **ANSWER 3:** Mucinous adenocarcinoma. Choose the final morphology from the predefined label list.
Heuristic (p5)	[Input 1:] First, apply the following rules: If morphology is explicitly stated, use it directly. If descriptors such as "ductal," "lobular," or "invasive" appear, map them to the corresponding morphology category. Terms such as "mucinous" map to Mucinous adenocarcinoma, and "signet ring" maps to Signet ring cell carcinoma. If only "adenocarcinoma" is mentioned without specification, classify as Adenocarcinoma, NOS. If only "carcinoma" is mentioned, classify as Carcinoma, NOS. Ambiguous descriptions should be mapped to Neoplasm, malignant. [Input 2:] From the patient's full medical history, extract the morphology from the most recent relevant pathology report. Ignore irrelevant or outdated reports. Select one label from the predefined list and return only the result in JSON format.

C.3 TNM Extraction Prompts

Table 10: Prompt designs for TNM staging extraction.

Prompt Type	Prompt Text
Prefix (p1)	Extract the most relevant TNM staging information from the most recent pathology or oncology report that mentions tumor staging. For each component (T, N, and M), extract the appropriate stage based on the findings. If substages (like T2bN1cM0) are mentioned, only extract the letter and numerical stage associated with each. Ignore non-pathology reports and irrelevant sections. Return the final TNM staging in the JSON template provided. Use the gold standard labels below to fill in each category: T: T0, T1, T2, T3, T4, Tis, Tmic, Tx N: N0, N1, N2, N3, Nx M: M0, M1, Mx
Cloze (p2)	From the following concatenated clinical notes, extract the TNM staging information based on the most relevant pathology report. Ignore unrelated or irrelevant sections. The T stage in the text is ___, the N stage in the text is ___, and the M stage in the text is ___. Ensure that the stages are chosen from the following gold standard labels: T: T0, T1, T2, T3, T4, Tis, Tmic, Tx N: N0, N1, N2, N3, Nx M: M0, M1, Mx If substages like T2bN1cM0 are mentioned, extract only the letter and numerical stage for each component. Your final response should be in the given JSON format.
Anticipatory (p3)	[Input 1:] How to identify TNM staging information in a medical report history? [Input 2:] For each tumor mentioned in the patient's medical history, extract the TNM staging information reported in the most recent pathology report. The TNM staging consists of the primary tumor stage (T), the regional lymph node stage (N), and the distant metastasis stage (M). If any substages are mentioned, extract only the letter and numerical stage associated with each component (e.g., T2bN1cM0 would be T2, N1, M0). Ignore irrelevant or outdated reports. Return the TNM stages in the provided JSON format. T: T0, T1, T2, T3, T4, Tis, Tmic, Tx N: N0, N1, N2, N3, Nx M: M0, M1, Mx
Chain-of-Thought (p4)	EXAMPLE: Identify and extract the TNM staging from the most recent relevant pathology report. If the staging includes substages (e.g., T2b, N1c), extract only the main stage component (e.g., T2, N1). Use only the values from the gold standard label list. TEXT: "The pathology report states: Tumor shows invasion into muscularis propria consistent with T2b staging. There is evidence of one positive regional lymph node (N1c). No distant metastasis identified (M0)." QUESTION 1: What is the T stage mentioned in the report? ANSWER 1: The report mentions T2b, so the T stage is T2. QUESTION 2: What is the N stage mentioned in the report? ANSWER 2: The report mentions N1c, so the N stage is N1. QUESTION 3: What is the M stage mentioned in the report? ANSWER 3: The report states M0 explicitly, so the M stage is M0. FINAL RESPONSE: T: "T2", N: "N1", M: "M0" Valid Label Options: T: T0, T1, T2, T3, T4, Tis, Tmic, Tx N: N0, N1, N2, N3, Nx M: M0, M1, Mx
Heuristic (p5)	[Input 1:] First, store these rules in memory: - If the T, N, or M stage is explicitly mentioned (e.g., "T2b", "N1c", "M0"), extract only the main stage (e.g., T2, N1, M0). - If a range of stages is given (e.g., "T1–T2", "N0–N1"), choose the highest one. - If only descriptive terms are used (e.g., "localized invasion," "no nodal involvement," "distant spread detected"), infer the TNM stage from context: "Localized tumor" → likely T1 or T2 "No lymph node involvement" → N0 "Metastatic disease" → M1 Prioritize the most recent relevant pathology report in the patient's medical history. Ignore outdated or irrelevant notes (e.g., preoperative assessments, non-pathology documentation). Use only the following label options for the final output: T: T0, T1, T2, T3, T4, Tis, Tmic, Tx N: N0, N1, N2, N3, Nx M: M0, M1, Mx [Input 2:] Given the patient's full medical record history, extract the TNM staging by identifying the most recent pathology report that provides clear staging information. Apply the rules above to extract: - T stage (primary tumor) - N stage (regional lymph nodes) - M stage (distant metastasis) Return your final answer in the given JSON format. Only use the values from the predefined label lists. Do not generate your own stages.

C.4 Laterality Extraction Prompts

Table 11: Prompt designs for laterality extraction.

Prompt Type	Prompt Text
Prefix (p1)	Extract the tumor laterality from the latest pathology report in the patient's medical history (e.g., pathology, biopsy). If available, prioritize the final laterality mentioned in the 'Impression' or 'Diagnosis' section. Choose your final answer from the following list: - bilateral involvement - left, primary organ - right, primary organ - paired, lat. unknown - not a paired site/un Ignore non-pathology reports. Return ONLY in the given JSON format, with a single key-value pair. Do NOT include additional qualifiers, sites, modifiers, or nested fields.
Cloze (p2)	From the following concatenated clinical notes, extract the tumor laterality from the latest pathology report. Ignore unrelated or irrelevant sections. The tumor laterality mentioned in the text is ___. Choose the laterality from the following list, and return ONLY in the given JSON format: - bilateral involvement - left, primary organ - right, primary organ - paired, lat. unknown - not a paired site/un
Anticipatory (p3)	[Input 1:] How to identify tumor laterality in a medical report history? [Input 2:] For each tumor mentioned in the patient's medical history, extract the laterality reported in the latest pathology report. If laterality is mentioned in multiple places within the same report, prioritize the clearest and most complete expression, especially from the 'Impression', 'Diagnosis', or equivalent summary sections. Anticipate ambiguities such as paired organs without a side specified, and distinguish between bilateral, unilateral, and unknown cases. Ignore outdated or irrelevant reports. Choose the laterality from the following options, and return ONLY in the given JSON format: - bilateral involvement - left, primary organ - right, primary organ - paired, lat. unknown - not a paired site/un
Chain-of-Thought (p4)	INSTRUCTIONS: Identify and extract the laterality from the most recent pathology report. If laterality is mentioned multiple times, prioritize the clearest and most definitive expression, especially from the 'Impression', 'Diagnosis', or equivalent summary sections. TEXT: "The tumor is located in the right breast, with no evidence of contralateral involvement. The final diagnosis section confirms malignancy in the right breast." QUESTION 1: What laterality is mentioned in the medical report? ANSWER 1: The laterality mentioned is right, primary organ (explicitly stated as right breast). QUESTION 2: Are there any ambiguous or conflicting laterality statements elsewhere in the report? ANSWER 2: No conflicting laterality is reported; all references are to the right side. QUESTION 3: What is the final laterality you would assign to this tumor based on the report? ANSWER 3: The final laterality assigned is right, primary organ. TEXT: "Pathology notes indicate bilateral lesions, with suspicious masses observed in both lobes. The diagnosis section confirms bilateral malignancy." QUESTION 1: What laterality is mentioned in the medical report? ANSWER 1: The laterality mentioned is bilateral involvement. QUESTION 2: Are there any ambiguous or conflicting laterality statements elsewhere in the report? ANSWER 2: No, the statement about bilateral malignancy is consistent. QUESTION 3: What is the final laterality you would assign to this tumor based on the report? ANSWER 3: The final laterality assigned is bilateral involvement. Choose the laterality from the following options: - bilateral involvement - left, primary organ - right, primary organ - paired, lat. unknown - not a paired site/un
Heuristic (p5)	[Input 1:] First, store these rules in memory: - If laterality is explicitly stated as right, left, or bilateral, use that information as the laterality type. - If the tumor is located in a paired organ (e.g., breast, kidney, lung), and the report mentions both sides, classify it as bilateral involvement. - If only one side is referenced (e.g., "mass in the right lobe"), assign left, primary organ or right, primary organ accordingly. - If the site is a paired organ but the laterality is not specified, classify it as paired, lat. unknown. - If the tumor occurs in an organ that is not paired (e.g., stomach, pancreas), classify it as not a paired site/un. [Input 2:] Given the patient's full medical report history, extract the laterality, ensuring you choose one of the gold standard labels. Identify the most recent relevant pathology report that includes a laterality mention. Ignore reports that are outdated or do not include laterality cues relevant to a paired primary tumor site. Use the rules mentioned above to extract: - The laterality of the tumor described in the most recent relevant pathology report. Make sure to choose the laterality from the following list: - bilateral involvement - left, primary organ - right, primary organ - paired, lat. unknown - not a paired site/un

D Multi-Agent Prompt Designs

D.1 Chunking Agent Prompt

Table 12: Prompt design for the chunking agent.

Component	Prompt Text

Prompt	You are a medical NLP system that segments ANY clinical text (even if it has no pathology-style headers) into semantically meaningful chunks.
	Output requirements - Return ONLY a single JSON object (no markdown, no explanations). - Schema (strict):
	`{`
	`  "chunk": [`
	`  {`
	`  "section": "string",`
	`  "text": "string",`
	`  "focus": "grade | morphology | tnm | laterality | treatment | other"`
	`  }`
	`  ]`
	`}`
	- The "chunk" array MUST be non-empty (never return an empty list). - Each item MUST have all three fields. - "focus" must be exactly one of: grade, morphology, tnm, laterality, treatment, other.
	Coverage & missing categories (very important) - Never fabricate text. - If a category (e.g., grade) is completely absent in the input, simply do NOT emit a chunk for that category. Downstream will treat missing categories as None. - The overall output MUST still contain at least one chunk. If no focal info is found, emit a single fallback chunk: - section: "other" - text: a short verbatim excerpt from the input (e.g., the first 1–3 sentences or the most informative line) - focus: "other"
	General rules (works for messy text) - The input may be free text, clinic letters, summaries, MDT notes, radiology-pathology blends, bullet lists, tables, or copy-paste artifacts. - If there are no formal headers, infer a best-fit "section" from this shortlist: ["diagnosis","gross","microscopy","immuno","comment","staging","clinical","treatment","history","other"]. - If the text mixes topics, split into small focused chunks (~1–4 sentences) and assign the primary focus: • grade → tumor grading phrases (e.g., "grade 2", "moderately differentiated", "Gleason group 3") • morphology → histologic type/cell type (e.g., "invasive ductal carcinoma", "adenocarcinoma", "papillary carcinoma") • tnm → any T/N/M mentions, stage group, pathologic vs clinical, even partial like "pT3", "N1", "M0", or "indeterminate" • laterality → left/right/bilateral/unifocal/multifocal; single-site organs can be "not applicable" only if clearly stated • treatment → surgery, chemo, radio, hormonal, targeted, immuno; past or planned • other → demographics, dates, admin, unrelated text - Keep each "text" verbatim (trim only leading/trailing whitespace and bullets). Do NOT invent placeholders like "none" or "[absent]".
	Normalization hints BEFORE deciding focus - TNM appears as "pT3 N1 M0", "T3N1M0", "T3 N1 (Mx)", embedded in sentences, or on separate lines. - Grades: prose ("moderately differentiated"), numerals ("grade II/2"), Gleason groups/scores. - Laterality: "Lt", "Rt", "B/L", "bilat." map to left/right/bilateral. - Morphology often near "diagnosis", "type", "histology", "consistent with".
	Edge cases & guarantees - If you cannot find any obvious clinical focus, still emit the fallback "other" chunk (see Coverage). - If TNM elements are scattered (e.g., T far from N), use multiple tnm chunks. - Prefer short, precise chunks over one giant block.
	Pathology/clinical text: `{report}`

D.2 Retriever Agent Prompt

Table 13: Prompt design for the retriever agent.

Component	Prompt Text

Prompt	You are a medical AI assistant helping extract information from pathology report chunks.
	Goal: Find the chunks most relevant to the field: **{field}**
	Chunks: `{chunks_text}`
	Instructions: - Return only relevant chunks for the field - Return ONLY JSON array of strings - If none → return []
	Example:
	`[`
	`  "Grade 2 tumor with moderate atypia."`
	`]`
	or
	`[]`
	No explanation.

D.3 Grade Extraction Agent Prompt

Table 14: Prompt design for the grade extraction agent.

Component	Prompt Text

Prompt	You are an expert medical assistant specialized in cancer pathology information extraction.
	Task: extract tumor grade.
	Return JSON only:
	1. "grade stated" 2. "grade estimated" (must be from valid values) 3. "grade_CD" 4. "grade_evidence"
	VALID VALUES: `{valid_values_bulleted}`
	Rules: - If no info → Unknown - Confidence 0–1 - Evidence = short quote
	Input: `{context}`
	Output:
	`{`
	`  "grade stated": "...",`
	`  "grade estimated": "...",`
	`  "grade_CD": 0.0,`
	`  "grade_evidence": "..."`
	`}`

D.4 Morphology Extraction Agent Prompt

Table 15: Prompt design for the morphology extraction agent.

Component	Prompt Text
Prompt	You are a medical language model specialized in extracting tumor morphology from pathology reports. Your task is to extract and estimate the tumor **morphology** from the given report sections below. Please output the following four key-value pairs: 1. "morphology stated": <The morphology as written in the pathology report, even if not standardized. If no morphology is directly stated, return "Unknown">, 2. "morphology estimated": <The closest standardized morphology based on the list below. Use your clinical knowledge to resolve synonymy or near matches. If unsure, return "Unknown">, 3. "morphology_CD": <Certainty degree of the estimation between 0.00 and 1.00>, 4. "morphology_evidence": <Key text or rationale supporting your estimation> Valid standardized morphologies: - Adenocarcinoma, NOS - Carcinoma, NOS - Follicular adenocarcinoma, NOS - Infiltrating duct carcinoma, NOS - Lobular carcinoma, NOS - Medullary carcinoma, NOS - Mucinous adenocarcinoma - Neoplasm, malignant - Signet ring cell carcinoma - Unknown Report Excerpt: `{context}` Output Format (JSON Only): `{ "morphology stated": "...", "morphology estimated": "...", "morphology_CD": ..., "morphology_evidence": "..." }`

D.5 TNM Extraction Agent Prompt

Table 16: Prompt design for the TNM extraction agent.

Component	Prompt Text
Prompt	You are a clinical information extraction assistant. Your task is to extract the patient's **TNM stage** from the pathology report excerpt below. Please extract the following key-value pairs for each TNM component: **T (Primary Tumor), N (Lymph Nodes), and M (Metastasis)**. Each component should have the following 4 fields: 1. "<component> stated": <As written in the pathology report — e.g., "T2", "N1", "M0", or "Unknown">, 2. "<component> estimated": <Your best estimate based on AJCC 7th edition, if the stated value is missing or ambiguous. Use "Unknown" if not inferable>, 3. "<component>_CD": <Certainty degree of the estimation from 0.00 to 1.00>, 4. "<component>_evidence": <Supporting text or reasoning from the report> Allowed values: - **T (Primary Tumor)**: ["T0", "Tis", "Tmic", "T1", "T2", "T3", "T4", "Tx", "Unknown"] - **N (Regional Lymph Nodes)**: ["N0", "N1", "N2", "N3", "Nx", "Unknown"] - **M (Distant Metastasis)**: ["M0", "M1", "Mx", "Unknown"] Report Sections: `{context}` Output Format (JSON Only): `{ "T stated": "...", "T estimated": "...", "T_CD": ..., "T_evidence": "...", "N stated": "...", "N estimated": "...", "N_CD": ..., "N_evidence": "...", "M stated": "...", "M estimated": "...", "M_CD": ..., "M_evidence": "..." }`

D.6 Laterality Extraction Agent Prompt

Table 17: Prompt design for the laterality extraction agent.

Component	Prompt Text

Prompt	You are an expert medical assistant specialized in cancer pathology information extraction.
	Your task is to extract and estimate the **tumor laterality** from the provided pathology report excerpt below.
	Please extract the following four key-value pairs related to the **tumor laterality**:
	1. "laterality stated": <The laterality as explicitly mentioned in the pathology report: "left", "right", "bilateral involvement", or "not primary site/unpaired">,
	2. "laterality estimated": <Your best estimate of laterality based on clinical knowledge. Use "not primary site/unpaired" if unclear or unpaired organ>,
	3. "laterality_CD": <Certainty Degree between 0.00 and 1.00 reflecting confidence in the estimation>,
	4. "laterality_evidence": <A short explanation or quote from the input text that supports your estimation>
	Valid laterality values: ["left", "right", "bilateral involvement", "not primary site/unpaired"]
	Input: `{context}`
	Output Format (JSON Only):
	`{`
	`  "laterality stated": "...",`
	`  "laterality estimated": "...",`
	`  "laterality_CD": ...,`
	`  "laterality_evidence": "..."`
	`}`

D.7 Reviewer Agent Prompt

Table 18: Prompt design for the reviewer agent.

Component	Prompt Text

Return specification	`{`
	`  "grade_valid": true or false,`
	`  "morphology_valid": true or false,`
	`  "morphology_mapped": "..." or null,`
	`  "tnm_valid": true or false,`
	`  "laterality_valid": true or false or null,`
	`  "treatment_valid": true or false or null,`
	`  "comment": "<summarize inconsistencies or mapping decisions>"`
	`}`

Prompt	You are a clinical reviewer. Validate and map the extracted fields from a pathology report. Output **ONLY** a single JSON object; no prose, no markdown, no code fences. Input values: - Tumor Grade: `{grade}` - Morphology: `{morphology}` - TNM Stage: `{tnm}` - Laterality: `{laterality}` - Treatment: `{treatment}` Accepted Grade Values: ["Grade I", "Grade II", "Grade III", "Unknown"] Accepted Morphology Values: ["Adenocarcinoma, NOS", "Carcinoma, NOS", "Follicular adenocarcinoma, NOS", "Infiltrating duct carcinoma, NOS", "Lobular carcinoma, NOS", "Medullary carcinoma, NOS", "Mucinous adenocarcinoma", "Neoplasm, malignant", "Signet ring cell carcinoma", "Unknown"] Accepted TNM Components: - T: ["T0", "Tis", "Tmic", "T1", "T2", "T3", "T4", "Tx", "Unknown"] - N: ["N0", "N1", "N2", "N3", "Nx", "Unknown"] - M: ["M0", "M1", "Mx", "Unknown"] Accepted Laterality Values: ["left, primary organ", "not a paired site/un", "paired, lat. unknown", "right, primary organ", "total colon", "unknown"] Accepted Treatment Values: ["chemotherapy", "chemotherapy + radiotherapy", "chemotherapy + surgery", "chemotherapy + surgery + radiotherapy", "chemotherapy+hormonal", "chemotherapy+radiotherapy", "hormonal", "invalid code.", "neoadjuvant chemotherapy+surgery+radiotherapy+hormonal", "radical prostatectomy", "radiotherapy + surgery", "surgery", "surgery+chemotherapy", "surgery+chemotherapy+hormonal", "surgery+chemotherapy+radiotherapy", "surgery+chemotherapy+radiotherapy+hormonal", "surgery+hormonal", "surgery+radiotherapy+hormonal", "total thyroidectomy", "unknown"] Rules: - If you are unsure, use null for $*_v alid fields that can be unknown, or false when it clearly doesn't match. - DO NOT include any explanations; return JSON only.$ Return JSON exactly in this shape: `{return_spec}`

Component	Prompt Text
Repair prompt	You will receive text that SHOULD be a JSON object with the following keys and types: {return_spec} Fix it if needed and return ONLY a valid JSON object. No comments, no markdown, no code fences. Text: {bad}

D.8 Evaluator Agent Prompt

Table 19: Prompt design for the evaluator agent.

Component	Prompt Text

Prompt	You are a clinical NLP evaluator.
	Your task is to estimate the confidence score (from 0 to 100) for the accuracy of each extracted field from a pathology report: - Tumor **grade** - Tumor **morphology** - **TNM stage** - **Laterality** - **Treatment**
	Base your estimate on: - Whether the extracted value is complete and clinically valid - Whether it follows accepted terminology - Whether it is likely justified based on context
	Input Fields: - Grade: {grade} - Morphology: {morphology} - TNM: {tnm} - Laterality: {laterality} - Treatment: {treatment}
	Output Format (JSON Only):
	`{`
	`  "grade_confidence": integer (0-100),`
	`  "morphology_confidence": integer (0-100),`
	`  "tnm_confidence": integer (0-100),`
	`  "laterality_confidence": integer (0-100),`
	`  "treatment_confidence": integer (0-100)`
	`}`

Role in pipeline	The evaluator agent performs two complementary functions: 1. **Ground-truth comparison (deterministic)**: It compares extracted values against reference annotations (if available) and assigns correctness flags: `grade_correct, morphology_correct, tnm_correct, laterality_correct, treatment_correct` 2. **Confidence estimation (LLM-based)**: If ground truth is partially or fully unavailable, the agent invokes the LLM to assign confidence scores (0–100) for each field. This dual strategy ensures: - objective evaluation when labels exist - robust fallback when labels are missing

D.9 Aggregation Agent Prompt

Table 20: Prompt design for the aggregation agent.

Component	Prompt Text
Prompt	You are a clinical summarization assistant. Your task is to compile a structured report using STRICT JSON format. Important: - DO NOT return markdown or explanation. - DO NOT wrap the JSON in "'`json` or any formatting. - Return ONLY valid JSON exactly matching this structure: {json_spec} Input variables: Grade: {grade}, Stated: {grade_stated}, Estimated: {grade_estimated}, Confidence: {grade_confidence}, Valid: {grade_valid}, Correct: {grade_correct}, Evidence: {grade_evidence} Morphology: {morphology}, Stated: {morphology_stated}, Estimated: {morphology_estimated}, Confidence: {morphology_confidence}, Valid: {morphology_valid}, Correct: {morphology_correct}, Evidence: {morphology_evidence} TNM: {tnm}, Confidence: {tnm_confidence}, Valid: {tnm_valid}, Correct: {tnm_correct} T: Stated: {t_stated}, Estimated: {t_estimated}, Evidence: {t_evidence} N: Stated: {n_stated}, Estimated: {n_estimated}, Evidence: {n_evidence} M: Stated: {m_stated}, Estimated: {m_estimated}, Evidence: {m_evidence} Laterality: {laterality}, Stated: {laterality_stated}, Estimated: {laterality_estimated}, Confidence: {laterality_confidence}, Valid: {laterality_valid}, Correct: {laterality_correct}, Evidence: {laterality_evidence} Treatment: {treatment}, Stated: {treatment_stated}, Estimated: {treatment_estimated}, Confidence: {treatment_confidence}, Valid: {treatment_valid}, Correct: {treatment_correct}, Evidence: {treatment_evidence}

Component	Prompt Text
Repair prompt	You will receive a model output that SHOULD be valid JSON matching this schema: `{json_spec}` The text may contain extra words, code fences, or invalid JSON. Return ONLY a corrected JSON object that strictly conforms to the schema above. No markdown, no explanation. Text to fix: `{bad}`

D.10 Matrix Calculator Agent Prompt

Table 21: Prompt design for the matrix calculator agent.

Component	Prompt Text
Role	LLM-only, ground-truth-driven evaluation utility for the Matrix Calculator app. The closed set is built from ground-truth unique labels for the current site × category. The LLM must choose **one** option from a numbered list and return only the corresponding number. For TNM categories, substages are collapsed to parent labels for both ground truth and valid labels. MRN alignment is preserved without duplicate collapsing.
LLM mapping prompt	You are a medical coding normalizer. Category: `{category}` Select the single BEST match for the raw prediction from the options below. OPTIONS (answer with the number only): `{numbered}` RAW PREDICTION: "`{raw_value}`" Rules: - Output ONLY the number (e.g., 2). No words. - Choose the closest semantic match. - Handle synonyms, abbreviations, Roman numerals, punctuation, and casing. - If meaning is unknown or unclear, choose the option labeled `unknown` when available.
Strict retry prompt	You are a medical coding normalizer. Category: `{category}` Select the single BEST match for the raw prediction from the options below. OPTIONS (answer with the number only): `{numbered}` RAW PREDICTION: "`{raw_value}`" Rules: - Output ONLY the number (e.g., 2). No words. - Choose the closest semantic match. - Handle synonyms, abbreviations, Roman numerals, punctuation, and casing. - If meaning is unknown or unclear, choose the option labeled `unknown` when available. IMPORTANT: Respond with ONLY the number of the chosen option. No other text.
Evaluation logic	For each category (`grade`, `morphology`, `t`, `n`, `m`, `laterality`), the agent: - resolves the corresponding prediction and ground-truth columns, - builds the valid closed set from site-specific ground-truth labels, - maps predictions into that closed set using the LLM, - computes classification metrics using `classification_report`, - computes a confusion matrix using `confusion_matrix`.
TNM parent collapse	For TNM categories, substages are collapsed to parent labels before evaluation. Examples include: - `pT1a` → `t1` - `Tis` → `tis` - `N1c` → `n1` - `M0` → `m0` - unknown or empty values → `unknown`

BioConflict: A Benchmark for Evaluating Large Language Models in Biomedical Contradiction Detection and Consensus Synthesis

Abstract

Resolving contradictions in biomedical literature requires more than factual recall; it demands identifying the hidden variables that explain divergent findings. Existing NLI benchmarks such as MedNLI operate at the sentence level and fail to capture document-level conflicts driven by differences in dosage, cell type, or study design. We introduce BioConflict, a benchmark of 250 expert-annotated paper pairs (500 abstracts) across ten biomedical topics, formalizing three tasks: conflict detection, contextual variable extraction, and consensus synthesis. We evaluate five general-purpose large language models and two domain-specific baselines, finding that general-purpose large language models achieve strong conflict detection (F1 up to 0.89) but exhibit brittle reasoning in synthesis, while domain-specific models lag significantly on all generative tasks. These findings highlight the need for context-aware biomedical AI capable of resolving, not merely retrieving, conflicting scientific evidence.

1 Introduction

The validity of scientific conclusions in biomedicine is often contingent on the specific context in which an experiment was conducted. A single molecule can act as both a therapeutic agent and a toxin depending on its concentration, timing of administration, or the genetic background of the host. TGF-beta, for example, functions as a tumor suppressor in early-stage cancer yet drives metastasis in advanced disease. This kind of context-dependence is not an anomaly; it is the norm across molecular biology, pharmacology, and epidemiology. Detecting these contradictions is essential for sound clinical literature review, yet the sheer volume of new publications makes manual synthesis increasingly impractical. PubMed now contains over 36 million entries and receives more than one million new records per year (Lu, 2011; Jin et al., 2024), a rate that makes exhaustive human curation impossible at scale.

Prior BioNLP work has made substantial progress on information extraction. Benchmarks like BLURB (Gu et al., 2022) cover named entity recognition, relation extraction, and question answering, and have driven real advances in domain-specific pretraining. Contradiction detection, however, has largely been treated as a variant of Natural Language Inference (NLI). MedNLI (Romanov and Shivade, 2018) is the most prominent clinical NLI dataset. It is physician-annotated, grounded in patient records from MIMIC-III, and has served as a strong benchmark for biomedical language understanding. MedNLI operates on isolated sentence pairs drawn from clinical notes. Real scientific conflicts, however, are cross-document phenomena. They arise when two full studies, each internally valid, reach incompatible conclusions because they differ in ways that neither abstract makes explicit, such as the cancer stage of the patient cohort, whether the drug formulation was selective or non-selective, or whether dietary exposure was measured in cups per day or grams of caffeine. These distinctions are difficult to capture in sentence-level NLI settings.

The rise of Retrieval-Augmented Generation (Lewis et al., 2020) makes cross-document conflict resolution practically urgent. When a clinical decision support system retrieves two contradictory papers in response to a query, the model must either adjudicate between them or produce a synthesis that explains the discrepancy in terms a clinician can act on. Current evidence suggests that models often absorb retrieved context even when it conflicts with their pretraining knowledge, but they are equally capable of hallucinating confident-sounding justifications for incorrect or unsupported claims (Huang et al., 2025). The "lost-in-the-middle" effect (Liu et al., 2024) compounds this: when relevant information is buried in a long

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 552–558
July 3-4, 2026 ©2026 Association for Computational Linguistics

prompt, models systematically underweight it relative to content near the beginning or end of the context window.

BioConflict is designed to probe all three of these failure modes in a unified benchmark. Our contributions are: (1) a gold-standard corpus of 250 paper pairs spanning ten topics with documented recurring conflicts; (2) three evaluation tasks of increasing cognitive complexity, namely conflict detection, contextual variable extraction, and consensus synthesis; and (3) a systematic evaluation of five general-purpose large language models and two domain-specific models, revealing consistent gaps between classification performance and generative reasoning quality.

2 Methodology

2.1 Topic Selection and Corpus Construction

We selected ten biomedical topics on the basis of two criteria: the topic has generated a substantial peer-reviewed literature with documented conflicting findings, and the conflict can be traced to at least one identifiable hidden variable rather than outright experimental error. The selected topics span three broad areas: molecular signaling pathways (NOTCH, ROS, TGF-beta, Autophagy, p53), pharmacological interventions (Beta-blockers, Metformin, VEGF inhibitors), and epidemiological health claims (Coffee, Vitamin D). For each topic we retrieved 50 papers from PubMed and manually curated 25 opposing pairs, yielding 250 pairs and 500 abstracts in total. Table 1 lists each topic, the nature of its primary conflict, and the key hidden variable that explains the divergence.

Abstracts were retrieved via the NCBI Entrez API using Biopython's Bio.Entrez module (Cock et al., 2009). We used batched fetching of 200 identifiers per call to remain within the 3-requests-per-second rate limit. All content in BioConflict consists of authentic peer-reviewed text; no synthetic or model-generated abstracts were included.

2.2 Benchmark Tasks

BioConflict evaluates models on three tasks of increasing complexity, designed so that failure on a later task cannot be attributed solely to deficiencies measured by an earlier one.

Task 1: Conflict Detection. Given two abstracts, the model classifies their relationship into one of six categories: Direct Contradiction, Context-dependent (both correct under different conditions), Methodological Difference, Population or Species Difference, Temporal Difference, or Dose-dependent. This taxonomy goes beyond binary NLI entailment. A model must not only recognize that a disagreement exists but correctly identify its scientific basis, which requires integrating information from both abstracts simultaneously rather than evaluating each in isolation.

Task 2: Contextual Variable Extraction. Given the same abstract pair, the model must extract the specific hidden variable that explains why the two papers reached different conclusions. Acceptable extractions include named entities such as cancer stage, drug selectivity, dosage range, cell line, or study design type. Scoring uses a strict binary criterion in which an extraction is correct only if the value, unit, and any relevant time-point all match the expert-verified label exactly. Partial credit is not given.

Task 3: Consensus Synthesis. The most demanding task requires the model to generate a "Golden Consensus" statement that reconciles the apparent conflict by explicitly invoking the hidden variable from Task 2. A correct synthesis for the TGF-beta topic, for instance, must articulate that TGF-beta suppresses tumor growth in early-stage carcinomas via the canonical SMAD pathway, but promotes epithelial-mesenchymal transition and metastasis in advanced tumors through SMAD-independent signaling. Outputs are evaluated using the G-Eval framework (Liu et al., 2023), in which GPT-o3-mini acts as an LLM judge with chain-of-thought prompting and scores each synthesis on factuality, resolution quality, and clinical grounding on a 1–5 Likert scale.

2.3 Annotation Protocol and Model Selection

Ground truth for all three tasks was established through a multi-annotator expert annotation process using a custom interface built in Google Colab. Multiple annotators independently annotated each paper pair, recording a free-text description of the conflict, identifying the hidden variable with its exact value and units where applicable, and writing a Golden Consensus statement. Disagreements were resolved through adjudication, where annotators reviewed conflicting labels and reached a final consensus after joint discussion. Cases lacking a clearly identifiable conflict, or those containing abstracts of insufficient quality, were excluded prior to inclusion in the final benchmark. Inter-annotator

agreement was assessed on a subset of the data, showing substantial agreement for conflict classification and consistent alignment on variable extraction.

We evaluated two classes of models. Domain-specific baselines were BioBERT (Lee et al., 2020), fine-tuned from BERT-base on PubMed and PMC full texts, and PubMedBERT (Gu et al., 2022), pretrained from scratch on PubMed abstracts with an in-domain vocabulary. This vocabulary avoids fragmenting domain-specific terms such as *acetyltransferase* into semantically meaningless subword pieces, which has been shown to benefit downstream biomedical NLP performance. The general-purpose large language models evaluated were GPT-4o (OpenAI, 2024), Claude 3.5 Sonnet (Anthropic, 2024), Llama 3.1 (70B) (Grattafiori et al., 2024), Qwen2.5-VL-7B (Bai et al., 2025), and Gemma-3-12B (Gemma Team et al., 2025). All models were evaluated at temperature 0.0 with identical prompts across tasks.

3 Results

Across all three tasks, general-purpose large language models substantially outperformed domain-specific baselines, with the performance gap widening on Tasks 2 and 3. Table 2 reports the complete results.

3.1 Task 1: Conflict Detection

GPT-4o achieved the highest F1 (0.89), followed by Claude 3.5 Sonnet (0.87) and Llama 3.1 (0.85). Gemma-3-12B (0.81) outperformed Qwen2.5-VL-7B (0.79) despite its smaller size. The dominant error was misclassifying methodological differences as direct contradictions, indicating reliance on surface-level disagreement. PubMedBERT (0.74) outperformed BioBERT (0.50), but both struggled with cross-document reasoning, often failing to integrate information across abstracts.

3.2 Task 2: Contextual Variable Extraction

Variable extraction accuracy varied substantially by clinical domain (Table 3). Models performed best in Cardiology and Infectiology, where the key moderating variables are well-standardized across the literature. A model can learn that hypertension status and diabetes comorbidity are typical moderators in cardiovascular studies and perform well without deep mechanistic knowledge. Performance dropped sharply in Oncology and molecular signaling topics, where correctly identifying the hidden variable required pathway-level understanding. In the p53 topic, for example, the distinguishing variable is often the specific mutation type, which determines whether the protein retains partial transcriptional activity; this cannot be inferred from clinical vocabulary patterns alone.

The dominant error type across all large language models (75% of failures) was incorrect unit extraction: a model identified the right variable category but extracted the wrong value or unit, for instance reporting a Vitamin D threshold in ng/mL when the paper used nmol/L. Formula misapplication also appeared frequently in topics requiring threshold comparisons, where models used outdated clinical reference ranges drawn from pretraining data rather than the values stated in the abstract being evaluated.

3.3 Task 3: Consensus Synthesis

GPT-4o and Claude 3.5 Sonnet scored 4.7 and 4.6 respectively, producing syntheses that correctly identified the hidden variable and reconciled both findings. Llama 3.1 scored 4.3, occasionally failing to invoke the hidden variable explicitly even when Task 2 extraction had been correct. Gemma-3-12B (4.0) produced coherent syntheses that identified the conflict type but sometimes lacked clinical specificity. Qwen2.5-VL-7B (3.8) inconsistently grounded reconciliations in the precise values from the abstracts. PubMedBERT and BioBERT scored 2.2 and 2.0 respectively, typically paraphrasing one abstract rather than producing a genuine reconciliation. The GPT-o3-mini judge achieved ICC(2,1) = 0.818 (95% CI: 0.772–0.854) against human raters, with highest agreement on Factuality and lowest on Resolution.

4 Discussion

BioConflict reveals a consistent pattern: models are far more capable at detecting that a conflict exists than at explaining why or synthesizing a resolution. Three failure modes account for most of the gap.

Contextual hallucination. Models sometimes produced mechanistic justifications absent from either abstract. In the beta-blocker topic, one model fabricated a receptor selectivity profile to explain a survival discrepancy (Huang et al., 2025), a confabulation that could directly influence prescribing decisions.

Topic ID	Biological Focus	Nature of Conflict	Key Hidden Variable(s)
NOTCH_dual_role	Notch signaling	Oncogene vs. Tumor Suppressor	Tissue Type / Cell Lineage
ROS_dual_role	Reactive Oxygen Species	Survival vs. Apoptosis	Concentration / ROS Species
TGF-beta_dual	TGF-beta signaling	Suppression vs. Metastasis	Cancer Stage
VEGF_inhibitors	Angiogenesis	Response vs. Resistance	Hypoxia Status / Splicing
autophagy_dual	Cellular recycling	Suppression vs. Promotion	Tumor Microenvironment
beta_blockers	Beta-adrenergic signaling	Improved Survival vs. No Effect	Selective vs. Non-selective
coffee_health	Caffeine consumption	Benefit vs. Risk	Dosage (cups per day)
metformin_cancer	Antidiabetic agent	Prevention vs. No Effect	Study Design (Obs vs. RCT)
p53_context	Tumor protein 53	Apoptosis vs. Senescence	Mutation Type / Stress Type
vitamin_D_cancer	Supplementation	Prevention vs. No Effect	Baseline Deficiency Level

Table 1: BioConflict topics, conflicts, and key hidden variables.

Model	Task 1: Conflict Detection (F1)	Task 2: Variable Extraction (Acc)	Task 3: Consensus Synthesis (G-Eval)
GPT-4o	0.89	0.84	4.7 / 5.0
Claude 3.5 Sonnet	0.87	0.81	4.6 / 5.0
Llama 3.1 (70B)	0.85	0.78	4.3 / 5.0
Qwen2.5-VL-7B	0.79	0.74	3.8 / 5.0
Gemma-3-12B	0.81	0.76	4.0 / 5.0
PubMedBERT	0.74	0.62	2.2 / 5.0
BioBERT	0.50	0.54	2.0 / 5.0
Human Expert	0.98	0.95	4.9 / 5.0

Table 2: Performance across all three BioConflict tasks. G-Eval scores range from 1–5.

Lost-in-the-middle. Models underweighted information in the middle of long prompts (Liu et al., 2024), which is particularly harmful here since the determining variable typically sits in the Methods section, the interior of any combined prompt.

Numerical imprecision. Conflicts often hinge on whether a value crosses a clinical threshold. LLMs misapplied unit conversions or used outdated reference ranges from pretraining; agentic pipelines with code execution can largely eliminate this (Lewis et al., 2020).

Domain pretraining and scale. PubMedBERT's in-domain vocabulary helps on NER (Gu et al., 2022) but does not extend to cross-document reasoning. General-purpose large language models outperformed both domain-specific baselines by large margins, and open-source 70B models (Llama 3.1, Qwen2.5) close most of the gap on Tasks 1 and 2; Task 3 synthesis is where the largest gap remains.

5 Conclusion

BioConflict establishes a new evaluation standard for biomedical conflict reasoning, moving beyond sentence-level NLI to contradiction resolution and consensus synthesis. Our results show that general-purpose large language models detect conflicts reliably but fall short of generating clinically sound reconciliations.

Limitations

The use of abstracts omits methodological detail that sometimes fully explains a conflict. The 250-pair sample may underrepresent ambiguous or emerging disputes, as topics were chosen partly because their conflicts are well-characterized. The LLM-as-judge framework is susceptible to verbosity and self-preference biases (Liu et al., 2023).

A Reliability Metrics

Inter-rater reliability between the LLM judge and human expert annotations is quantified using Cohen's kappa (κ) and the Intraclass Correlation Coefficient ICC(2,1), which treats raters as random effects in a two-way model:

$$\kappa = \frac{p_o - p_e}{1 - p_e} \tag{1}$$

where p_o is the observed proportion of agreement and p_e is the expected proportion under chance. Values of $\kappa > 0.8$ are conventionally interpreted as near-perfect agreement. For continuous Likert scores, ICC(2,1) is preferred; values above 0.75 indicate good reliability. GPT-o3-mini achieved ICC = 0.818 (95% CI: 0.772–0.854). A model judge is flagged for lenience bias if $P(\text{model score} > \text{human score}) \geq 0.95$ across the evaluation set; no flagging occurred for GPT-o3-mini in our Task 3 evaluation.

B Task 1 Prompt: Conflict Detection

The following prompt was used for all Task 1 conflict detection evaluations. All models were queried at temperature 0.0 with this identical prompt. No few-shot examples were provided; all models were evaluated in a zero-shot setting.

```
You are an expert biomedical
researcher tasked with
classifying the relationship
between two scientific abstracts.
You will be given two abstracts
(Paper A and Paper B) from
the peer-reviewed biomedical
literature.  Your task is to
classify their relationship into
exactly one of the following six
categories:

1.  Direct Contradiction:  The
two papers report mutually
incompatible findings with
no contextual qualifier that
reconciles them.

2.  Context-dependent:  Both
papers are correct, but under
different conditions (e.g.,
different tissue types, cancer
stages, or experimental models).

3.  Methodological Difference:
The divergence in findings is
attributable to differences in
study design, assay type, or
measurement approach.

4.  Population or Species
Difference:  The findings
differ because the studies
were conducted in different
populations, species, or cell
lines.

5.  Temporal Difference:  The
findings differ because the
studies examined different time
points or disease stages.

6.  Dose-dependent:  The
findings differ because the
studies used different doses,
concentrations, or exposure
levels of the agent under
investigation.

Read both abstracts carefully
before classifying.  Your
classification must reflect
the underlying scientific
basis for the divergence,
not surface-level lexical
disagreement.

Paper A: {abstract_a}

Paper B: {abstract_b}

Return only valid JSON:

six category names above>",
"rationale":  "one or two
sentences"}
```

C Task 2 Prompt: Contextual Variable Extraction

The following prompt was used for all Task 2 contextual variable extraction evaluations. All models were queried at temperature 0.0 with this identical prompt in a zero-shot setting. Scoring was applied post-hoc using a strict binary criterion: an extraction was marked correct only if the variable category, value, unit, and any relevant time-point all matched the expert-verified label exactly. Partial credit was not given.

```
You are an expert biomedical
researcher.  You will be given
two abstracts (Paper A and
Paper B) that reach different
conclusions on the same topic.

Your task is to identify the
single hidden variable that
best explains why the two papers
reached different conclusions.
The hidden variable must be
extracted directly from the text
of the abstracts.  Do not infer
or introduce information that is
not explicitly stated in either
abstract.

Report the hidden variable
with all of the following
fields:  (1) the variable
category (e.g., cancer stage,
drug selectivity, dosage, cell
line, study design); (2) the
exact value or descriptor as
stated in each abstract; (3)
the unit of measurement where
applicable; and (4) the relevant
time-point if the variable is
time-dependent.

Paper A: {abstract_a}

Paper B: {abstract_b}

Return only valid JSON:
{"variable_category":  "string",
"value_paper_a":  "string",
"value_paper_b":  "string",
"unit":  "string or null",
"time_point":  "string or null"}
```

D Task 3 Prompt: LLM Judge (G-Eval)

The following prompt was used for all Task 3 G-Eval evaluations. The hidden variable label from Task 2 annotation was inserted programmatically at the `[VARIABLE]` placeholder.

```
You are an expert medical judge
evaluating a consensus statement
generated from two contradictory
biomedical abstracts.

Criteria:  (1) Factuality:
the consensus contains no
claims unsupported by either
abstract.  (2) Resolution:  the
consensus correctly explains
the disagreement by invoking
the hidden variable.  (3)
Clinical Precision:  the
language is specific enough
to be actionable.

Steps:  State the primary
conclusion of Paper A. State
```

```
the primary conclusion of Paper
B. Identify the hidden variable
[VARIABLE]. Assess whether the
generated consensus correctly
uses this variable to bridge the
two conclusions.

Assign a score from 1 to 5.
Score 5 indicates a synthesis

Tokenization Granularity and Medical Term Representations in Language Models

Vojtěch Lanz and Pavel Pecina
Charles University, Faculty of Mathematics and Physics
Institute of Formal and Applied Linguistics
{lanz,pecina}@ufal.mff.cuni.cz

Abstract

We investigate how tokenization granularity affects the representation of medical terminology in language models. Prior work links tokenization granularity to downstream performance under contextualized settings for specifically pretrained and fine-tuned models. We instead ask whether this relationship already emerges at the level of isolated term representations across existing pretrained models. We introduce an intrinsic definition retrieval task using UMLS term-definition pairs, with comparison to WordNet. We show that despite substantially heavier fragmentation of medical terminology, the models remain relatively robust in maintaining semantic alignment between medical terms and their definitions. At the same time, tokenization granularity still correlates with retrieval performance, indicating that effects previously observed in downstream biomedical tasks are already reflected at the level of isolated term representations. Encoder models benefit primarily from whole-token preservation, while for decoder LLMs, tokenization effects emerge mainly at deeper retrieval ranks.

1 Introduction

Tokenization is the first processing step for language models and directly shapes their input representations, thereby influencing overall performance. In practice, tokenizers are typically trained on general-domain corpora (Grattafiori et al., 2024; Jiang et al., 2023; Team et al., 2025; Abdin et al., 2024) and reused when adapting models to specialized domains (Christophe et al., 2024; Labrak et al., 2024b; Sellergren et al., 2025; Corbeil et al., 2025). This mismatch is particularly pronounced in the clinical and biomedical setting, where terminology often differs substantially from general language. As a result, medical terms are frequently segmented into subword units that carry little or no standalone semantic or morphological meaning (Cruz Díaz and Maña López, 2015; Jimenez Gutierrez et al., 2023).

Previous work suggests that contemporary language models are relatively robust to suboptimal tokenization, eventually relying on contextual cues to recover the meaning of poorly segmented clinical terms (Jimenez Gutierrez et al., 2023; Jeong et al., 2023). However, other studies report modest improvements from more suitable segmentation (Ashfaq et al., 2025; Xie, 2026; Jeong et al., 2023). At the same time, recent findings indicate that tokenization granularity can correlate with downstream task performance, particularly in encoder-based architectures trained for domain-specific biomedical applications (Labrak et al., 2024a).

In this work, we revisit this question from a different perspective. Rather than evaluating performance on standard downstream tasks that provide rich contextual signals, we focus on the ability of models to represent medical terms in isolation. We investigate whether tokenization granularity correlates with how effectively models encode medical terminology in their embedding spaces. The emphasis is on the consistency and stability of these representations in semantic alignment and embedding-space proximity, and whether models preserve a coherent representation of a medical concept despite differences in tokenization granularity. We conduct a comparison across publicly available models, including both encoder and decoder architectures, to assess their behavior under inefficient tokenization of medical terms.

To this end, we use UMLS term–definition pairs (Bodenreider, 2004) and frame the task as definition retrieval, where a model must associate a medical term with its correct definition. This setup allows us to assess whether the embedding of a term is relatively closer to its correct definition than to semantically related but distinct ones, avoiding reliance on absolute similarity scores, which could otherwise place many medical concepts close to-

gether and obscure meaningful differences. We then analyze how performance on this task correlates with tokenizer granularity across models. To provide a general-domain reference point for interpretation, we include a parallel evaluation based on WordNet term–definition pairs (Miller, 1995). The complete source code is available at GitHub[1].

2 Setup

2.1 Data

For our experiments, we use term–definition pairs extracted from UMLS. For comparison, we also consider a general-domain term–definition dataset derived from WordNet. To ensure comparability across models, including those primarily designed for English, we restrict the data to English terms with English definitions.

To maintain a fair evaluation setup for the definition retrieval task, we retain only one term per semantic concept. Specifically, in UMLS we select a single term per concept unique identifier (CUI), and in WordNet we select a single term per synset. To avoid ambiguity arising from multiple surface forms with different senses, we remove duplicate term occurrences.

The final datasets consist of hundreds of thousands of pairs for UMLS and tens of thousands of pairs for WordNet. Table 1 reports the number of final pairs as well as the average number of words per term and per definition. We observe that both terms and definitions in UMLS are approximately three times longer than those in WordNet.

2.2 Tokenization Granularity

To measure how well tokenization preserves word integrity, or conversely how much it fragments words into subword units, we use two metrics: average number of tokens per word (*Avg tokens per word*) and the percentage of out-of-vocabulary words (*OOV words (%)*). OOV words (%) is computed as the proportion of words that are split into more than one token by the tokenizer.

2.3 Definition Retrieval Task

The retrieval task aims to find the most relevant definition for a given term based on cosine similarity among all available definitions. To evaluate performance, we report the *Success@k* curve ($k \in 1, 10, 100, 1000, 2000$), which measures the percentage of queries where the correct definition is within the top k retrieved results.

2.4 Models

We evaluate encoder-based models and decoder large language models, covering general-purpose, biomedical, and multilingual pretraining regimes.

Encoders include general-domain models such as BERT (cased and uncased) (Devlin et al., 2019) and ModernBERT (Warner et al., 2025), medical models such as BioBERT (Lee et al., 2020), ClinicalBERT (Alsentzer et al., 2019), and Clinical ModernBERT (Lee et al., 2025), as well as multilingual models including mBERT, Distil mBERT (Devlin et al., 2019), mmBERT (Marone et al., 2025), and XLM-R (base and large) (Conneau et al., 2019).

Decoders include general instruction-tuned LLMs such as LLaMA3 (Grattafiori et al., 2024), Mistral (Jiang et al., 2023), Phi-3.5 Mini (Abdin et al., 2024), and Gemma3 (Team et al., 2025), as well as biomedical variants such as BioMistral (Labrak et al., 2024b), Med42 (Christophe et al., 2024), MediPhi (Corbeil et al., 2025), and MedGemma (Sellergren et al., 2025).

For all models, we extract representations from the final hidden layer and apply mean pooling over token embeddings to obtain a single vector. We use this representation for both encoders and decoders to ensure consistency.

3 Results and Analysis

3.1 Tokenization Granularity Across Domains

Building on our evaluation setup, we first analyze how tokenization granularity varies across domains and model families.

We analyze UMLS terms and their definitions separately and compare them with their general-domain counterpart based on WordNet in Table 2, reporting averages across all models (Section 2.4).

The UMLS terms are consistently segmented into more fine-grained subword units than their cor-

Avg tokens per word	2.53	1.79	2.31	1.32	1.41	1.57	1.36	1.80	2.38
OOV words (%)	53.04	31.33	61.13	18.09	24.20	26.83	17.37	33.83	48.74

Table 2: Tokenization statistics averaged across all encoder and decoder models for UMLS and WordNet (terms vs. definitions) and general corpora, including BookSum chapters, Wikipedia pages, PubMed articles, emrQA clinical reports, and Stroke Discharge Summaries (SDS) from UK hospitals.

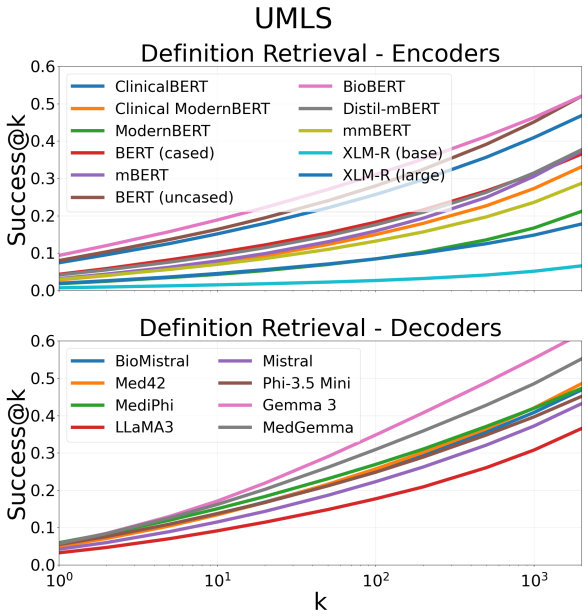

Figure 1: Definition retrieval performance on UMLS measured by Success@k. Encoder models are shown on the top and decoder models on the bottom.

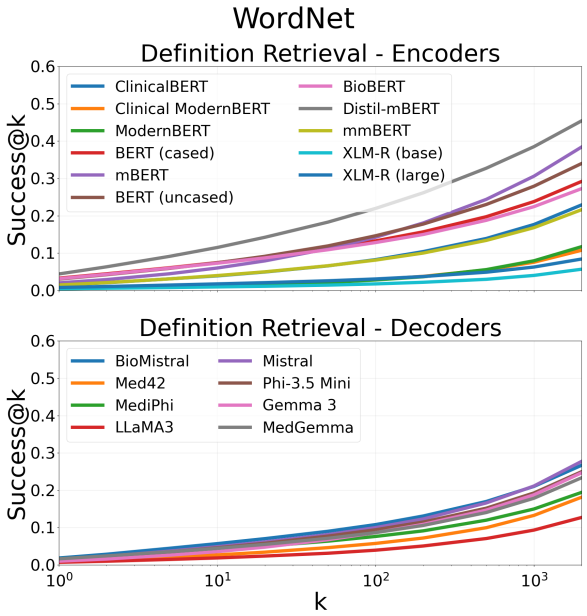

Figure 2: Definition retrieval performance on WordNet measured by Success@k. Encoder models are shown on the top and decoder models on the bottom.

responding definitions. A similar effect is observed in WordNet, indicating that lexical specificity also plays a role in general-domain resources. This consistent gap between terms and definitions suggests that isolated terminological expressions are generally more difficult to represent in subword-based tokenization schemes than more descriptive, sentence-level text, even when the latter is drawn from the same domain and contains many common lexical items. However, fragmentation is most pronounced in UMLS, suggesting higher terminological density in the medical domain.

OOV rates show a different pattern: WordNet terms have slightly higher OOV rates than UMLS. As shown in Table 1, UMLS terms are three times longer, which increases the likelihood of including vocabulary-friendly components such as numbers or stopwords, likely explaining this difference.

To assess how representative the term–definition results are in relation to larger and more practical text sources, we extend the analysis to document-level corpora. We evaluate tokenization on emrQA clinical reports (Pampari et al., 2018), BookSum chapters (Kryscinski et al., 2022), Wikipedia (Foundation), and PubMed articles (Cohan et al., 2018). To control for corpus size, we sample PubMed, BookSum, and Wikipedia documents to match the number of words in emrQA. Tokenization in BookSum and PubMed closely matches WordNet definitions, while Wikipedia shows slightly higher fragmentation. In contrast, emrQA clinical reports align more closely with UMLS definitions. We further analyze a specialized set of 600 stroke discharge summaries from UK hospitals (SDS), which shows fragmentation approaching UMLS-level values, highlighting the effect of clinical specificity on subword segmentation.

A detailed per-model breakdown is provided in Appendix A, along with qualitative tokenization examples in Appendix B.

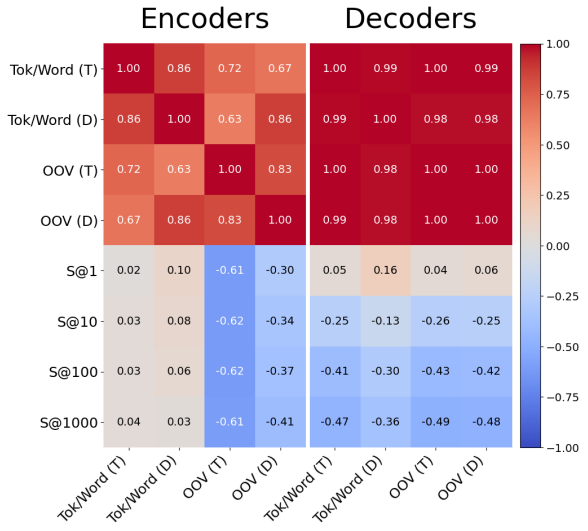

Figure 3: Pearson correlation matrices for UMLS models, separately for encoders (left) and decoders (right). The matrices report correlations between retrieval performance (Success@k, denoted as S@k for $k \in \{1, 10, 100, 1000\}$) and tokenization granularity, including average tokens per word (Tok/Word) and out-of-vocabulary rate (OOV), computed separately for terms (T) and definitions (D).

3.2 Definition Retrieval Performance

We evaluate how well term representations align with their corresponding definitions using a definition retrieval task, which measures the robustness of the embedding space to semantic similarity of the same medical concept represented in different forms. Figures 1 and 2 report Success@k curves for encoder and decoder models on UMLS and WordNet term–definition pairs, allowing a direct comparison of models in terms of retrieval performance and the strength of their semantic alignment.

On UMLS, clinically pre-trained encoders consistently outperform general-domain and multilingual models. This advantage is less pronounced for decoder models, which nevertheless show relatively stable retrieval behavior across architectures.

In contrast, performance on WordNet decreases, despite the smaller candidate pool making the task easier. Drop is more evident for decoder models, which exhibit weaker discrimination in this setting.

These results suggest that models are well adapted to the medical domain, even though tokenization is more fragmented for UMLS compared to WordNet. This indicates a degree of robustness of models to tokenization granularity in semantic representation and alignment of concepts.

3.3 Correlation Between Tokenization and Definition Retrieval

To investigate whether tokenization granularity is related to how well models embed medical terms, we analyze UMLS pairs and measure the correlation between tokenization metrics and the ability of models to place term representations close to their correct definitions in the embedding space. We report Pearson correlations in Figure 3 for encoder and decoder models separately. This allows us to assess whether a consistent trend exists across models, i.e., whether models that split words into more subword units tend to exhibit weaker alignment between terms and their corresponding definitions.

From the results, we observe that for encoder models, the average number of tokens per word (Tok/Word) shows little to no correlation with retrieval performance. In contrast, the proportion of words represented as a single token (OOV) in both definitions and, in particular, terms exhibits a strong correlation with performance across all values of k in Success@k. For decoder models, performance begins to correlate more strongly with tokenization metrics only at higher values of k (i.e., $k = 100$ and $k = 1000$), where both Tok/Word and OOV rate become relevant.

An additional observation is that, for decoder models, tokenization metrics are almost perfectly correlated between terms and definitions, whereas encoders show greater variation.

Overall, the results indicate that tokenization granularity is reflected in how models represent medical terms in their vector space. For encoder models, retrieval performance is largely insensitive to how finely words are split once tokenized; the key factor is whether a word is preserved as a single token. For decoder models, tokenization has little effect on the proximity of term and definition representations, but its influence becomes more apparent when considering a broader neighborhood of nearby representations.

4 Discussion

Although we use definition retrieval as an intrinsic evaluation, it provides a direct and transparent way to assess how a model encodes medical concepts in its embedding space without additional training. It allows us to measure whether term embeddings are consistently and meaningfully aligned with term definitions and how effectively and consistently the model internalizes and represents these concepts.

Although tokenization granularity correlates with retrieval performance, this does not directly indicate its impact on downstream tasks. While previous work has studied such effects in downstream biomedical settings (Labrak et al., 2024a), the general significance and generality of this relationship remain unclear and might vary between tasks.

In addition, we find that English-domain-specific encoders outperform general-domain multilingual models for medical terminology, despite its strong Latin and Greek origins (Jimenez Gutierrez et al., 2023). This contrasts with the findings in span-based clinical question answering (Lanz and Pecina, 2025), where multilingual models tend to perform better. This discrepancy suggests that improvements in multilingual models in downstream question-answering tasks are likely driven by their stronger ability to model contextual interactions and relational structure, rather than by the superior quality of isolated term representations in the embedding space of encoder models. In contrast, for decoder models, no clear advantage of domain-specific pretraining is observed in terms of consistent semantic representation quality.

5 Conclusion

We studied how tokenization granularity relates to the ability of language models to represent medical terms without contextual support, using a definition retrieval task built on UMLS and a WordNet comparison. Our results show that medical terms are more fragmented than general-domain ones, yet models remain largely robust. However, tokenization still plays a role: for encoders, performance depends mainly on whether terms are preserved as single tokens, while for decoders, its effect appears at larger retrieval depths. Overall, tokenization does not fully determine performance, but it influences how medical terms are structured in the embedding space.

Limitations

Our analysis focuses on intrinsic representation properties and does not evaluate downstream task performance; thus, it does not directly capture effects previously observed in task-based studies of tokenization granularity. While definition retrieval provides a controlled proxy for assessing term–definition alignment in embedding space, it remains an indirect measure of representation quality. Finally, our experiments are limited to UMLS-derived term–definition pairs, which restricts coverage to curated medical terminology and may not reflect broader medical and clinical language.

Abstract

While Large Language Models (LLMs) have advanced clinical dialogue-to-note generation, direct transcript-only prompting can still fail in clinically important ways. In real-world physician–patient encounters, clinically salient evidence is noisy, distributed across turns, and frequently revised. Transcript-only generation is therefore vulnerable to hallucinated facts, section leakage, and final-state errors. Conversely, coarse intermediate scaffolds such as basic entity extraction fail to capture negation, temporality, and evolving problem–plan relationships.

To address this, we propose **Clinical Atomic Propositions (CAPs)**, a dialogue-aware intermediate representation for LLM-based note generation. CAPs extract standalone clinical assertions while explicitly preserving essential modifiers such as verification status, temporality, speaker source, and action type. We further introduce an optional **event consolidation layer** that reorganizes CAPs into problem-oriented care bundles, explicitly linking grounded evidence to planned actions before rendering. We evaluate sectioned-note generation as the main setting and include SOAP-template rendering as an ablation. This decomposition targets faithful, controllable note generation while producing evidence-linked structure that can support future audit and verification.

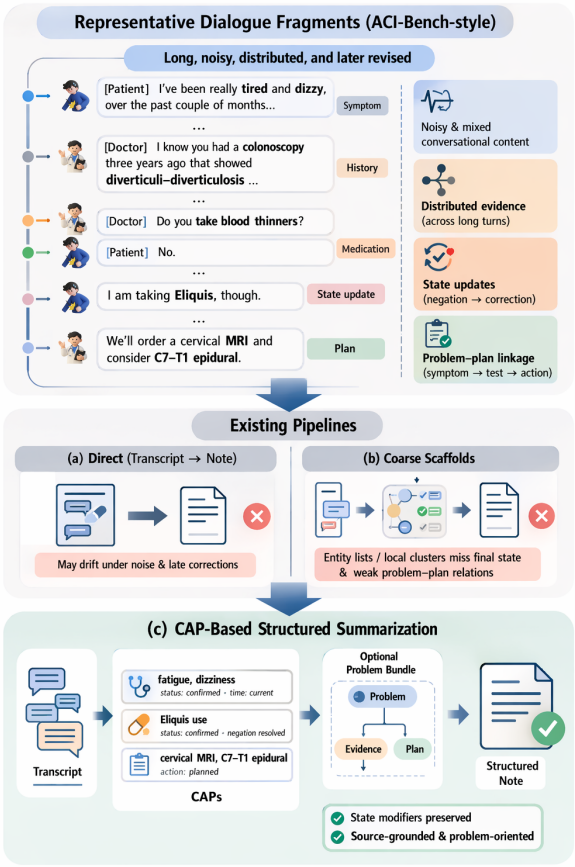

Figure 1: Why faithful dialogue-to-note generation is difficult: evidence is noisy, scattered, and later-updated; CAP makes intermediate clinical facts explicit before rendering.

1 Introduction

LLMs make it easy to prompt for a clinical note directly from a physician–patient transcript, but this convenience moves safety-critical decisions into an opaque long-context generation step (Ben Abacha et al., 2023; Giorgi et al., 2023; Krishna et al., 2021; Michalopoulos et al., 2022). The central challenge is no longer fluency alone. A useful note must be readable, *source-grounded*, clinically faithful, and section-appropriate, while preserving facts that are noisy, distributed across turns, and often revised over time. Transcript-only generation is therefore vulnerable to omission, section leakage, unsupported fill-in, and incorrect final-state tracking.

A growing line of work therefore uses *structure-first* pipelines, including section filtering, utterance clustering, and entity-centric scaffolds (Krishna et al., 2021; Michalopoulos et al., 2022; Nair et al., 2023). These approaches help by giving the final generator a smaller, more organized input. How-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 572–594
July 3-4, 2026 ©2026 Association for Computational Linguistics

ever, each scaffold can lose a different clinical relation. A proximity-based cluster may split an early statement from a later correction; an entity/status list may record that a medication is present without preserving the full claim or its timing; and a section-level filter may collect relevant text without saying which problem a finding or plan supports. As Figure 1 illustrates, the failure is often not that every relevant mention is absent, but that the *final clinically grounded state* and the problem–evidence–plan structure are not preserved.

We address this gap with **Clinical Atomic Propositions (CAPs)**, a dialogue-aware intermediate representation that converts raw dialogue into standalone, source-grounded clinical assertions. CAPs preserve the modifiers that are most critical for faithful note generation, including verification status, temporality, speaker/source, and action type. A list of correct propositions is still not necessarily a note-ready structure, so we additionally introduce an optional **event consolidation layer** that groups CAPs into problem-oriented care bundles before rendering. This separates two roles that are often conflated in transcript-only generation: preserving source-grounded facts and organizing those facts into clinically coherent assessment and plan structure.

Our work makes three main contributions:

- **Source-grounded proposition scaffold.** We introduce CAPs as a proposition-level intermediate representation for clinical dialogue-to-note generation that preserves clinically important modifiers beyond entity presence alone, including verification status, temporality, speaker/source, and action type.
- **Problem-oriented structural alignment.** We design and evaluate an optional event-consolidation step, inspired by problem-oriented documentation and lightweight FHIR semantics, that groups grounded facts into problem-centered care bundles. Our analysis characterizes when this organization helps and when compression can introduce omissions.
- **Reproducible evaluation and release.** We evaluate on ACI-Bench (Yim et al., 2023) using explicit cohort filtering criteria for reproducibility. We include prompt-based reimplementations of Cluster2Sent and MEDSUM-ENT, reuse the MEDSUM-ENT GPT-R/P/F1 metric family, and adapt the same recall/precision/F1 logic to CAP-space semantic auditing. We evaluate sectioned-note rendering as the main task and SOAP-template rendering as an ablation. We release the code, prompts, postprocessing scripts, intermediate representations, and generated sectioned/SOAP notes in a public repository: `https://github.com/sallyy1/CAP-ACL-2026`.

2 Related Work

Structure-first clinical dialogue understanding and note generation. Recent work increasingly treats doctor–patient dialogue summarization as a *structure-then-generate* problem rather than pure long-context generation (Ben Abacha et al., 2023; Giorgi et al., 2023). Cluster2Sent (Krishna et al., 2021) selects section-relevant utterances and clusters nearby evidence; MedicalSum (Michalopoulos et al., 2022) and ClinicSum (Neupane et al., 2024) use guided or retrieval-filtered SOAP inputs; and MEDSUM-ENT (Nair et al., 2023) extracts entities with present/absent/unknown status labels before summarization. Adjacent work also models clinical dialogue through task-specific labels, including note-section classification and medical-order extraction (Chen et al., 2023; Corbeil et al., 2025), demonstrating that schema-constrained outputs can facilitate clinical understanding. However, existing scaffolds are usually section-level, proximity-based, task-specific, or entity/status-based. They help organize material, but do not directly represent self-contained clinical claims with source evidence, temporal status, and problem–action linkage.

From clinical IE to proposition-level representations. Clinical information extraction traditionally maps unstructured notes into entities, modifiers, and relations, and recent LLM-based IE continues this line with clinical NER/RE models and tools such as Kiwi (Hu et al., 2026). FHIR-oriented text mining and commercial systems also show the value of interoperable extraction: for example, Azure AI Language Text Analytics for health can return a FHIR resource bundle, while Azure Health Data Services provides a managed FHIR service (Daumke et al., 2019; Microsoft, 2025, 2026). These efforts support interoperability, but a dialogue-aware note scaffold must also decide which evolving claim is finally supported, how negation and temporality apply, and how evidence/actions attach to problems. Proposition-level verification work such as VeriFact(Chung et al.,

2025) motivates this granularity by decomposing clinical text into simple statements for fact checking. CAP adapts this idea before rendering: it extracts evidence-linked, FHIR-inspired propositions from dialogue, then optionally consolidates them into problem-oriented bundles for note generation.

3 Motivation and Problem Setting

Clinical dialogue-to-note generation is difficult because clinically important evidence is noisy, distributed, and frequently revised across the encounter. This creates four recurring challenges for transcript-only or coarse-scaffold generation.

Motivation challenges.

- **Noisy dialogue:** salient evidence is interleaved with low-value conversational content.
- **Lay expression vs. over-abstraction:** patient language must be normalized without losing negation, uncertainty, temporality, or medication nuance.
- **Brittle state tracking:** key facts are revised over time, including symptom status, resolved uncertainty, medication use, and downstream plans.
- **Baseline limitations:** Direct is vulnerable to noise and section leakage, Cluster2Sent is local, and MEDSUM-ENT can miss problem-linked organization and state–plan separation.

Given a transcript X, our goal is to generate a clinical note Y that is clinically faithful, section-appropriate, and source-grounded. We ask:

Research questions.

- **RQ1: Source-grounded preservation.** Can a normalized intermediate representation better preserve clinically salient source content?
- **RQ2: Clinical state fidelity.** Can it better retain negation, uncertainty, temporality, and medication state or change?
- **RQ3: Problem-oriented organization.** Can it better support problem–evidence–plan linkage and final note structure?

Figure 2 illustrates the CAP pipeline, while Tables 1, 2, and 3 summarize the running example, FHIR-inspired CAP-type schema, and compared method scaffolds.

4 Method

4.1 Pipeline Overview

We decompose dialogue-to-note generation into a structure-first pipeline:

$$X \rightarrow C \rightarrow E \rightarrow Y, \tag{1}$$

where X is the dialogue transcript, C is a set of **Clinical Atomic Propositions (CAPs)**, E is an optional **problem-oriented consolidation plan** ("event" bundles), and Y is the rendered clinical note. CAPs provide a source-grounded content inventory, while event consolidation aligns that inventory to problem-oriented documentation practice (POMR/SOAP) by grouping evidence and actions under an anchor problem. The renderer then writes the final sectioned or SOAP note from the selected scaffold.

4.2 Clinical Atomic Propositions

A **Clinical Atomic Proposition (CAP)** is a standalone clinical assertion that is verifiable against the dialogue and close to the semantic grain of a note sentence. A CAP is not just an entity mention. It records the clinical claim plus state modifiers such as verification status, temporality, speaker/source, numeric attributes, and whether the claim describes current state or an intended action. CAPs are extracted automatically by prompted, schema-constrained JSON generation; we do not manually author them at test time.

The CAP schema is *FHIR-inspired* rather than FHIR-native (Health Level Seven International, 2019; Ayaz et al., 2021). Table 2 lists the canonical `cap_types` used in this paper. While FHIR is designed primarily for interoperable health-data exchange, CAP adopts its resource-oriented separation of clinical concepts to define a compact middle schema for note generation. This schema separates condition-like problems, observation-like evidence, current medication state, medication changes, and planned actions. The distinction is central for dialogue: for example, "taking Eliquis" and "order an MRI" should not be collapsed into the same kind of fact. The small CAP-extraction dev check is reported in Appendix B.

4.3 Event Consolidation and Rendering

Consistent with the Problem-Oriented Medical Record (POMR) (Weed, 1968), clinical notes are typically organized around problems with linked

Stage	D2N026-style late medication update
Dialogue X	"Do you take blood thinners?" → "No." → later correction: "I am taking **Eliquis**, though." The physician also discusses a **cervical MRI** and tentative **C7–T1 epidural**.
CAPs C	Separate source-grounded propositions preserve the corrected final state, e.g., `MedicationStatement: patient currently taking Eliquis; Order: cervical MRI planned; ProcedurePlan: C7-T1 epidural discussed`.
Bundle E	The bundler groups these CAPs under an anchor problem such as `Problem: cervical radiculopathy`, with linked evidence and plan slots.
Note Y	The renderer realizes the corrected state and plan in prose, e.g., Eliquis use, cervical MRI, and possible C7–T1 epidural.

Table 1: Running example for the proposed $X \rightarrow C \rightarrow E \rightarrow Y$ pipeline.

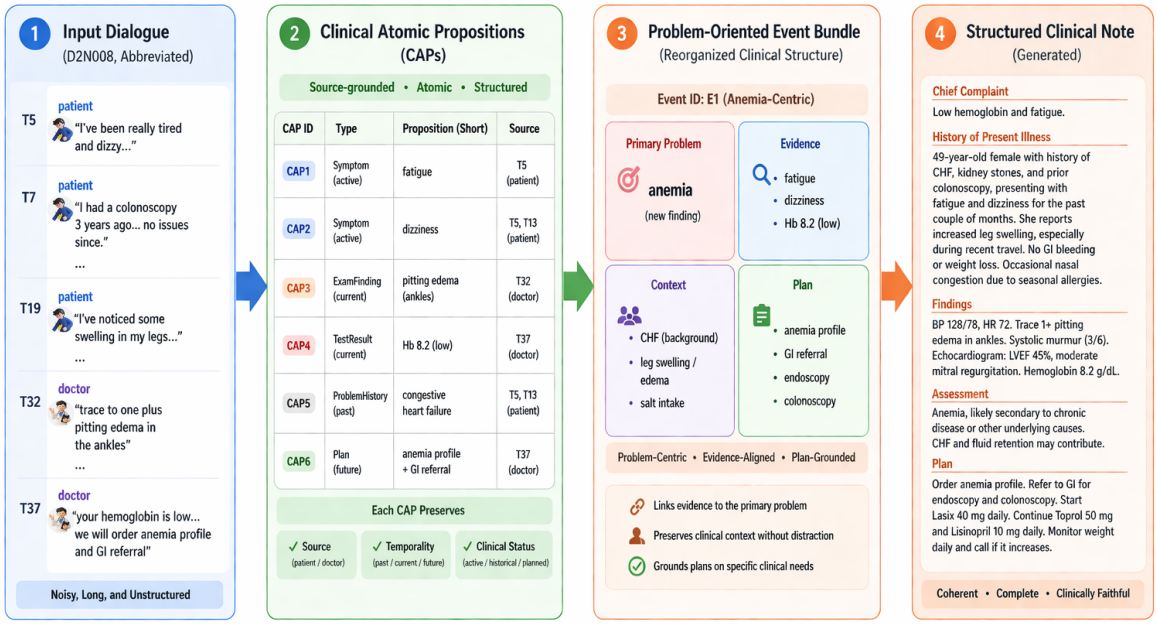

Figure 2: Overview of the CAP-based pipeline. Dialogue is first converted into source-grounded atomic propositions (CAPs), which are then reorganized into a problem-oriented event structure. This structured representation enables coherent and clinically faithful note generation.

evidence and plans, a structure commonly operationalized through the SOAP (Buchanan, 2017) template. Our optional event layer turns a flat CAP list into **problem-oriented bundles**: each bundle anchors on a problem and links related subjective evidence, objective evidence, and plan actions. We treat this as an alignment module rather than a guaranteed quality booster. It can make problem–plan linkage explicit, but it can also over-compress or omit facts if the bundling is too aggressive.

The final renderer receives the chosen scaffold and writes a sectioned or SOAP note. In the main CAP and CAP+Event settings, the transcript is also available for surface realization; transcript-free ablations in Appendix E test how much the scaffold can support rendering on its own. Prompt templates and baseline reimplementation details are provided in Appendix C.

5 Experiments

Dataset. We use ACI-Bench (Yim et al., 2023), a publicly documented ambient clinical intelligence benchmark for automatic visit-note generation from doctor–patient conversations. The original paper describes ACI-Bench as a *shared open dataset* that is *freely available*; we follow that release as our primary data source. Following the benchmark setup, we use the provided conversation transcripts as model input and the provided reference notes as evaluation targets.

To avoid ambiguity about supervision, we do not create new gold notes or re-annotate the benchmark. Reference-note provenance and annotation protocol are therefore inherited from ACI-Bench and are documented in Yim et al. (2023). For reproducibility, we start from 207 benchmark encounters

CAP type	Intended semantics	FHIR-inspired analogue	Key state fields
`ChiefComplaint`	Reason for visit / presenting concern	Encounter reason (conceptual)	`verification_status`, `temporality`
`Problem`	Active problem / diagnosis / clinical concern	Condition-like	`verification_status`, `clinical_status`, `temporality`
`ProblemHistory`	Historical problem context	Condition-like (historical)	`clinical_status=historical`
`ExamFinding`	Physical exam finding / symptom-style observation	Observation-like	`verification_status` (e.g., negated), `temporality`
`TestResult`	Lab / imaging result	Observation/Report-like	`verification_status`, numeric `attributes`
`MedicationStatement`	Current medication state (what the patient is taking)	MedicationStatement-like	`clinical_status=active` vs. historical
`MedicationRequest`	Intended medication start/stop/change	MedicationRequest-like	`clinical_status=planned`
`Order`	Concrete order (labs, imaging, referral)	ServiceRequest-like	`clinical_status=planned`
`FollowUp`	Follow-up timing / appointment plan	CarePlan/Appointment-like	`temporality`, `clinical_status=planned`
`Counseling`	Advice / behavior counseling / education	CarePlan-activity-like	`temporality`, `clinical_status`

Table 2: Canonical `cap_types` and intended semantics. The mapping is a lightweight FHIR-inspired abstraction, not a full FHIR implementation. CAPs additionally store `proposition_text`, `canonical_concept`, `evidence`, and optional `linked_problem` pointers used by event consolidation.

Method	Input to downstream renderer	Intermediate scaffold	Unit	Value / limitation
Direct (base)	Transcript X	None	None	+ fluent baseline – noise, leakage, state drift
MEDSUM-ENT (prior)	Transcript X + entity/status scaffold	6-category plan (*Demographics/SDOH*, *Intent*, *Positives*, *Negatives*, *Unknowns*, *History*) $\times$ {*present*, *absent*, *unknown*}	Entity/status	+ status cues – weak problem–plan linkage
Cluster2Sent (prior)	Section-targeted evidence units only (no X)	Utterance clusters (proximity; τ=2)	Utterance cluster	+ local coherence – long-range/state ambiguity
CAP (ours)	Transcript X + CAP set C	Atomic propositions with clinical modifiers	Proposition	+ grounded state fidelity – needs rendering for organization
CAP+Event (ours)	Transcript X + C + bundle plan E	Problem-oriented bundles linking evidence and actions	Problem bundle	+ problem–plan organization – compression can omit

Table 3: Strategic positioning of the five main compared methods and their intermediate scaffolds. Method-label shading matches Table 6: gray marks the Direct baseline, blue marks transcript+entity/proposition scaffold methods, and beige marks clustering/bundling scaffold methods. Transcript-free ablations are reported in Appendix E.

and apply a predefined CAP-quality cohort filter, yielding a final 197-case cohort (Appendix A lists excluded IDs and exact criteria). Our release package focuses on reproducible prompts, intermediate representations, and scoring scripts for this fixed cohort.

Setup and methods. We evaluate on the final 197-case ACI-Bench cohort after CAP extraction and predefined quality filtering; cohort details and excluded IDs are in Appendix A. The main experiments use a sectioned-note template, with SOAP ablations in Appendix D. We compare

Aspect	GPT-R/P/F1 (Nair-style)	semCAP-R/P/F1 (ours)
Primary purpose	Reference-oriented overlap check	Source-grounded proposition audit
Compared units	Medical concepts with status cues; extracted under MEDSUM-ENT-style categories (*Demographics/SDOH, Intent, Positives, Negatives, Unknowns, History*)	Proposition-level CAP units aligned to dialogue evidence
Source of truth	Reference note (Generated note ↔ Reference note)	Dialogue-grounded CAP/audited propositions (Dialogue transcript ↔ Generated note)
Rewards	Coverage of reference-like concepts and *Present/Absent/Unknown* status consistency	Preservation of grounded assertions and key modifiers (*verification, temporality, source, action type*, etc.)
May miss	Direct dialogue grounding and problem–plan linkage even when concept overlap is high	Broader narrative/note-quality aspects
Role in this paper	Complementary note-level metric	Primary targeted metric for CAP claim
Limitation	Reference-oriented, not grounding-specific	May be partially aligned with CAP representation

Table 4: Comparison of Nair-style GPT metrics and semCAP. We report both because they capture complementary aspects: reference-note overlap vs. dialogue-grounded faithfulness.

View (D2N026)	Concrete extracted units (abridged)	Count / score
Transcript CAP units (semCAP-R)	"Left arm/hand pain for about two weeks"; "Hand weakness and grip difficulty"; "Patient is taking Eliquis"; "Clinician orders cervical MRI", ...	25 CAPs
Generated-note CAP units (semCAP-P, CAP note)	"The patient reports left arm pain."; "...hand pain began approximately two weeks ago."; "I will order a cervical MRI."; "...tentatively schedule a left C7–T1 epidural.", ...	21 CAPs
Reference-note concepts (GPT-R)	*left arm pain*, *gabapentin*, *cervical MRI*, *left C7–T1 epidural*, *blood thinners*, ...	45 concepts
Generated-note concepts (GPT-P, CAP note)	*left arm pain*, *hand weakness*, *cervical radiculopathy*, *cervical MRI*, *C7–T1 epidural*, ...	24 concepts
Case-level metric snapshot (sectioned template)		
Direct	Nair GPT-F1 / semCAP-F1	0.098 / 0.000
CAP	Nair GPT-F1 / semCAP-F1	0.488 / 0.543

Table 5: Concrete example of the two metric families on D2N026 (values from released case-level outputs). Nair-style GPT metrics compare reference-note vs generated-note concepts, while semCAP compares transcript-grounded vs generated-note CAP propositions. The Direct semCAP-F1 value of 0.000 is a case-level boundary example under strict proposition matching, not a global trend. Full R/P/F1 values are reported in Table 6.

Direct, **Cluster2Sent** (Krishna et al., 2021), **MEDSUM-ENT** (Nair et al., 2023), **CAP**, and **CAP+Event**; Table 3 summarizes their inputs, scaffolds, and limitations. All methods use the same downstream generator, and all CAP extraction/rendering stages use the open-weight **Gemma-3-4B-Instruct** model (Hugging Face ID: `ISTA-DASLab/gemma-3-4b-it-GPTQ-4b-128g`) to reflect privacy-constrained clinical deployment. Baseline details and prompts are in Appendix C; transcript-free ablations and cost analyses are in Appendices E and F.

Metrics. We separate two automatic metric families. **GPT-R/P/F1 (Nair)** follows the MEDSUM-ENT GPT-style concept matching framework (Nair et al., 2023). Here, a *concept* denotes a medically relevant item (e.g., symptom, condition, medication, test/procedure, status cue). The framework uses a two-stage LLM process: a concept extractor first identifies candidate concepts in generated/reference notes, then a verifier judges concept matches across notes under relaxed semantic equivalence, explicitly allowing clinically valid rephrasings. GPT-recall measures reference concepts recovered by the generated note, GPT-precision measures generated concepts supported by the reference note, and GPT-F1 is their harmonic mean. This family is therefore *reference-oriented* and primarily reflects concept-level note overlap.

semCAP-R/P/F1 (ours) is our proposition-grounded semantic audit, measuring whether transcript-derived CAP propositions are preserved

Method	semCAP-R (ours)↑	semCAP-P (ours)↑	semCAP-F1 (ours)↑	GPT-R (Nair)↑	GPT-P (Nair)↑	GPT-F1 (Nair)↑
Direct (base)	0.574	0.175	0.211	0.638	0.808	**0.703**
MEDSUM-ENT (prior)	0.589	0.168	0.205	**0.640**	0.761	0.687
Cluster2Sent (prior)	0.522	0.178	0.204	0.587	**0.813**	0.672
CAP (ours)	**0.694**	**0.212**	**0.256**	0.632	0.795	0.695
CAP+Event (ours)	0.570	0.181	0.214	0.578	0.773	0.649

Table 6: Results on the 197-case ACI-Bench cohort. (Sectioned-template) Method-label shading groups the Direct baseline (gray), transcript+entity/proposition scaffold methods (blue), and clustering/bundling scaffold methods (beige). semCAP metrics are our source-grounded proposition audit; GPT metrics follow the MEDSUM-ENT concept-matching family (Nair et al., 2023). Broader checklist and PDSQI scores are reported in Appendix D.

Method vs. Direct	**semCAP-R** W/T/L, Δ	**semCAP-F1** W/T/L, Δ	**GPT-F1 (Nair)** W/T/L, Δ
MEDSUM-ENT	111/13/73, +0.015	55/99/43, -0.006	101/4/92, -0.016
Cluster2Sent	60/15/122, -0.052	47/97/53, -0.007	64/2/131, -0.031
CAP (ours)	**170/4/23, +0.120**	**83/97/17, +0.046**	85/2/110, -0.008
CAP+Event (ours)	103/15/79, -0.004	53/97/47, +0.003	83/2/112, -0.054

Table 7: Case-level win/tie/loss against Direct. (Sectioned-template) Full counts corresponding to Figure 3.

and supported in the generated note, including clinically critical modifiers (negation/state, temporality, and source grounding). semCAP is thus targeted to source-grounded faithfulness rather than broad note-quality similarity. Because semCAP is aligned with our representation, some metric-method alignment bias may remain; we therefore report semCAP jointly with the reference-oriented GPT metrics and interpret them as complementary, not interchangeable, signals. All automated metric evaluation uses **OpenAI GPT-5.1** (API model ID: `gpt-5.1-2025-11-13`) as judge. Additional checklist/PDSQI analyses are in Appendix D; Tables 4–5 summarize metric differences and one case-level example.

Main results on the 197-case cohort. Table 6 shows that CAP is strongest on all source-grounded semCAP metrics, improving semCAP-R from 0.574 for Direct to 0.694 (+0.120 absolute) and semCAP-F1 from 0.211 to 0.256. On the MEDSUM-ENT GPT concept metrics, CAP remains close to Direct (GPT-F1 0.695 vs. 0.703), while MEDSUM-ENT narrowly leads on GPT-R and Cluster2Sent on GPT-P. We therefore do not claim uniform superiority on generic note/reference overlap. Instead, the main quantitative finding is more specific: CAP improves preservation of transcript-grounded clinical propositions while maintaining competitive concept-level note similarity.

Figure 3 further clarifies the aggregate pattern. CAP wins over Direct on semCAP-R in 86.3% of cases and loses in only 11.7%, while its GPT-F1 is nearly tied on average. This supports our intended positioning: CAP is not primarily a fluency or broad quality optimizer, but a source-grounded content scaffold for preserving clinically salient facts. CAP+Event does not uniformly outperform CAP, reinforcing our view that event consolidation is an alignment module whose benefit is case dependent. Detailed win/tie/loss counts for semCAP-R/F1 and GPT-F1 are reported in Table 7.

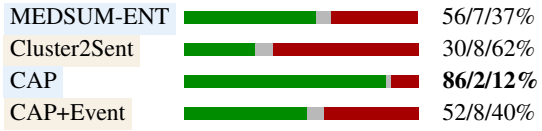

Figure 3: Case-level semCAP-R win/tie/loss rates against Direct. (Sectioned-template) Label shading matches Table 6: blue marks transcript+scaffold methods and beige marks clustering/bundling methods. Green/gray/red bars indicate wins/ties/losses.

Category-level GPT submetrics were also inspected during development, but they were sparse and unstable on this cohort. We therefore report them only as internal diagnostics and keep the main claims focused on semCAP and GPT aggregate metrics.

Qualitative evidence. D2N008 is our main qualitative case because it mixes a new anemia workup with background CHF, edema, prior GI history,

Method	Representative output snippet
Direct	Clinically plausible but structurally shallow: anemia is identified and the GI workup is mentioned, yet the CHF–anemia relation remains vague and the note never fully reconstructs anemia as the dominant organizing problem.
Cluster2Sent	Preserves fatigue and dizziness, but also keeps lower-priority content such as [incorrect emphasis] "mild nasal congestion related to seasonal allergies", producing *salience dilution* rather than a clear anemia-centered hierarchy.
MEDSUM-ENT	Entity-centric planning captures concept/status cues but does not explicitly reconstruct anemia-centered problem–evidence–plan structure; in this case the sectioned renderer can under-generate to an *empty skeleton* (see Appendix H).
CAP	Stronger structure and symptom/history coverage, but it introduces [incorrect attribution] "CHF, diverticulosis, and seasonal allergies are contributing factors", which over-expands peripheral findings into the anemia assessment.
CAP+Event (ours)	Re-centers the note on anemia as the primary problem and best preserves problem–plan linkage, including [correct] "ordering an anemia profile" and [correct] "refer ... for an endoscopy and repeat colonoscopy".

Table 8: Main qualitative case study on D2N008. Under a multi-condition scenario with background CHF and a new anemia workup, CAP-based structured generation better preserves clinically relevant problem–evidence–plan linkage than transcript-only, utterance-clustering, and entity-centric baselines (more details in Appendix H).

Case	Scenario	Observed CAP+Event behavior	ΔsemCAP-R	ΔGPT-F1 (Nair)
D2N207	Multi-condition/cardiorenal visit with CKD context and possible gout flare	Produces two bundles (*chronic kidney disease*; *possible gout flare*), improving organization and grounded recall over CAP.	$+0.218$	$+0.235$
D2N153	Localized musculoskeletal injury follow-up	Collapses to one narrow *toe injury* bundle and under-generates an empty sectioned skeleton, losing much of CAP's preserved content.	-0.714	-0.771

Table 9: Representative boundary cases for event consolidation (CAP+Event minus CAP). We report one source-grounded metric (semCAP-R) and one MEDSUM-ENT-style concept metric (GPT-F1) to show the preservation/compression trade-off under two complementary metric families.

and low-value allergy content. The key challenge is whether the note reconstructs anemia as the organizing problem and keeps the anemia profile and GI referral linked to that problem.

Table 8 illustrates the pattern. Direct remains plausible but weakly organized; Cluster2Sent preserves local evidence but over-emphasizes peripheral allergy content; MEDSUM-ENT captures entity/status cues but does not explicitly reconstruct anemia-centered problem–evidence–plan structure. CAP provides a better source-grounded evidence inventory, and CAP+Event most clearly links the anemia problem to the anemia profile and GI workup. Full qualitative cases for D2N008, D2N026, and D2N024 are shown in Appendices H, I, and J, respectively; D2N026 highlights late medication-state correction, while D2N024 is a mixed boundary case.

When does event consolidation help? Event consolidation is case dependent. In aggregate, CAP+Event underperforms CAP on semCAP-R, suggesting that bundling can introduce omission through compression. However, stratifying by the number of bundles produced by the consolidator reveals a more nuanced pattern: when the consolidator produces a modest multi-bundle plan (E with two bundles), organization-oriented scores improve slightly on average (mean ΔPDSQI $+0.04$; mean ΔF-CL(A+B+C) $+0.03$), whereas single-bundle outputs show consistent degradation across grounding and quality metrics (Appendix G). Table 9 shows this boundary behavior in representative cases: consolidation helps when distinct threads are preserved, but can fail when content is over-collapsed into a narrow anchor.

Clinician deep review. Two clinicians with medical training and experience reviewing clinical notes independently performed a focused deep review on three cases representing clear gain, mixed trade-off, and boundary behavior. Together with the reviewers, we designed a checklist aligned with our Motivation challenges and Research Questions to directly probe three target axes: (A) content preservation, (B) clinical state fidelity, and (C)

problem-oriented organization. Reviewers rated eight items on a 1–5 Likert scale (1=poor, 5=excellent) and flagged clinically meaningful omission/hallucination/major errors (yes/no). An optional overall usability rating was collected for context but excluded from our main faithfulness aggregate. Full rubric details, scores, and anonymized comments are in Appendix K (Figure 5).

6 Discussion

Our framework separates two sources of difficulty in clinical note generation: *factual recovery* and *document organization*. CAPs preserve clinically meaningful atomic facts from noisy dialogue, while event consolidation reorganizes grounded facts into problem-level bundles. This separation improves controllability and helps localize failures to extraction, consolidation, or rendering. It also clarifies why semCAP and GPT metrics need not move identically: the former audits transcript-grounded proposition fidelity, whereas the latter measures reference-note concept overlap.

CAP extraction also exposes a trade-off that is often hidden in transcript-only generation: *what to preserve* versus *what to suppress*. More aggressive filtering reduces small talk and background chatter, but can under-extract evidence needed later for bundling and planning. Our extractor development results show this precision–recall tension while preserving key modifiers well on matched propositions, especially verification status (Appendix B). Future work should add explicit salience/priority modeling, including severity and clinical consequentiality, so noise suppression does not become brittle omission.

More broadly, fluency alone is not sufficient: a natural-sounding note can still be clinically misleading. CAPs provide an evidence-linked structure that may also support real-time clinician correction or post-generation audit/verification, though we leave those uses to future work. Remaining CAP+Event errors show that faithful rendering from structured clinical scaffolds is still an open biomedical NLP problem, particularly when organization requires compressing heterogeneous dialogue evidence without losing clinically relevant detail.

7 Conclusion

We presented CAP, a structure-first framework for clinical dialogue-to-note generation. CAP introduces a source-grounded proposition layer that preserves clinically meaningful assertions from noisy dialogue, and an optional event consolidation layer that organizes these assertions into problem-oriented care bundles. Together, these components provide a more controlled scaffold for note generation than transcript-only or coarse structured approaches, with the clearest gains appearing in source-grounded faithfulness, clinical state preservation, and problem-oriented note construction.

Limitations

Our work has several limitations. semCAP is a targeted, representation-aligned audit metric rather than a standalone measure of overall clinical note quality, and our experiments are limited to a single benchmark, leaving broader generalization across specialties, note styles, and clinical settings for future work. The event layer is inspired by clinical documentation practice and lightweight FHIR semantics (Health Level Seven International, 2019; Ayaz et al., 2021), but is not a formal interoperability standard. Practically, the multi-stage prompted pipeline can propagate errors from CAP extraction through event clustering to rendering, and it adds non-trivial latency and token overhead relative to Direct. Finally, the renderer can still over-abstract, introduce unsupported content, or under-generate an *empty skeleton* note in a small fraction of cases; we report these failures rather than filtering them out, and a key next step is human-in-the-loop correction at the CAP stage before final rendering.

A Cohort Selection and Evaluation Protocol

Implementation details. All CAP extraction and note rendering stages used the same open-weight generator, Gemma-3-4B-Instruct (Hugging Face model ID: `ISTA-DASLab/gemma-3-4b-it-GPTQ-4b-128g`). We served the model with tensor parallel size 1, maximum context length 32,768, GPU memory utilization 0.9, and prefix caching enabled. In our runs, inference was executed on a single NVIDIA RTX Ada 6000 or RTX A6000 GPU. We set `max-num-seqs` to 32 and used a local Hugging Face cache under the workspace directory.

Evaluation model. All automated metric evaluation used **OpenAI GPT-5.1** (API model ID: `gpt-5.1-2025-11-13`) for concept-level matching, semantic CAP auditing, and checklist scoring, while the generator was fixed across methods; these API calls were used only for offline evaluation on de-identified benchmark text, not for deployment-time generation.

We began from 207 ACI-Bench encounters and removed four parse-failure cases from stage-C extraction (D2N022, D2N059, D2N088, D2N156), leaving 203 cases. We then applied a predefined CAP-quality filter and excluded six additional cases with `transcript_cap_count`=0 or `reference_cap_count`≤ 1 (D2N010, D2N053, D2N085, D2N112, D2N126, D2N187), yielding the final 197-case cohort for aggregate metrics; D2N010 is retained only as a qualitative boundary example. Two SOAP generations were empty (D2N031 for MEDSUM-ENT; D2N181 for Cluster2Sent), and we keep them as observed system behavior rather than filtering them out.

Empty structured outputs. Because the renderer must return a structured JSON object for SOAP/sectioned templates and may emit empty strings for unsupported sections, a failure mode is an *empty skeleton* note (all keys present, section content empty), which typically appears when long or heterogeneous scaffolds are hard to map under strict format constraints. On the final 197-case cohort, this occurred most frequently for MEDSUM-ENT (9/197 in sectioned; 12/197 in SOAP; 17 unique cases across templates) and more rarely for other method/template pairs ($\leq 5/197$ each). We treat these as observed generation failures and keep them in evaluation rather than filtering them out.

B CAP Extraction Development Benchmark

To reduce the risk of silently propagating extraction errors through the modular pipeline, we performed a small internal dev evaluation focused on stage C (CAP extraction) in $X \rightarrow C \rightarrow E \rightarrow Y$. We used two clinician-labeled seed CAP sets (D2N008, D2N026) and a small derived "silver" set constructed under the same rubric for prompt-iteration diagnostics (not final benchmark claims). We score extraction with relaxed semantic concept matching (threshold 0.35), reporting concept-level precision/recall/F1 and matched-pair modifier accuracy. Table 10 summarizes the final extractor used in this paper and the core precision–recall trade-off.

C Prompt Templates and Baseline Reimplementation

To facilitate reproducibility, we summarize the prompt templates and intermediate scaffold designs used for the main compared methods. Our implementation follows the structure-first intent of prior work while keeping the downstream renderer fixed so that differences primarily reflect scaffold quality.

Cluster2Sent-inspired scaffold. Following Krishna et al. (2021), we (i) select section-targeted evidence units from the dialogue, (ii) deterministically cluster nearby evidence by turn proximity (we use τ=2), and (iii) prompt the renderer to generate one concise sentence (or bullet) per cluster and place it in the appropriate note section. The crucial constraint is that the renderer is asked to use only the extracted evidence units as source material, which reduces transcript noise but can miss long-range dependencies.

```
[Section: History of Present Illness] [Cluster 1]
Left arm/hand pain started about two weeks ago;
hand weakness and grip difficulty.
[Section: Findings] [Cluster 2] Cervical source
is suspected based on exam context.
[Section: Plan] [Cluster 3] Order cervical MRI;
tentative left C7-T1 epidural.
[Section: Medications] [Cluster 4] Later turn:
patient reports taking Eliquis.
```

MEDSUM-ENT-inspired scaffold. Following Nair et al. (2023), we extract clinically relevant concepts with status cues (*present*/*absent*/*unknown*) and organize them into six planning categories (*Demographics/SDOH*, *Patient Intent*, *Pertinent Positives*, *Pertinent Negatives*, *Pertinent Unknowns*, *Medical History*). We apply an *unknown resolver*

Dev set	n	Pred	Gold	P	R	F1	VerifAcc	ClinStateAcc	TempAcc	Unsupported
Gold seeds (clinicians)	2	24.0	35.0	0.546	0.369	0.439	0.888	0.843	0.685	11.0
Silver dev (derived)	19	24.4	48.6	0.425	0.207	0.268	0.659	0.837	0.769	14.2

Table 10: CAP extraction dev benchmark for stage C. Pred/Gold/Unsupported are per-case averages. P/R/F1 are concept-level match scores under relaxed semantic matching (threshold 0.35). Modifier accuracies (verification status, clinical status, temporality) are computed on matched CAP pairs. The derived silver set is used only for prompt-iteration diagnostics.

that removes an earlier *unknown* mention when the same concept is later resolved as *present* or *absent*. This reimplementation preserves the original multi-stage spirit of MEDSUM-ENT: prompted structured extraction, lightweight normalization/postprocessing, and a separate rendering step.

```
[Category: Pertinent Positives] [Status: Present]
The patient reports fatigue for the past two months.
[Category: Pertinent Negatives] [Status: Absent]
The patient denies blood in stool.
[Category: Pertinent Unknowns] [Status: Unknown]
The patient is unsure about recent weight change.
```

MEDSUM-ENT GPT metrics and our semCAP adaptation. For note-level automated evaluation, we follow Nair et al. (2023) in using a GPT-based matching framework that computes **GPT-recall**, **GPT-precision**, and **GPT-F1**. Operationally, this framework uses two LLM roles: (i) an extractor that identifies medically relevant *concepts* from each note (generated/reference), where concepts are item-level clinical units (e.g., symptoms, diagnoses, medications, tests/procedures, and associated status cues), and (ii) a verifier that determines cross-note matches under relaxed semantic equivalence. This design allows clinically equivalent rephrasings beyond strict string overlap. GPT-R is the fraction of reference concepts recovered by the generated note, GPT-P is the fraction of generated concepts supported by the reference, and GPT-F1 summarizes both.

Our contribution is to adapt this evaluation logic from entity/category space into proposition space. Concretely, we replace concept-level units with CAP propositions and score whether transcript-grounded propositions are preserved in the generated note. We therefore report **semCAP-R**, **semCAP-P**, and **semCAP-F1** as CAP-space counterparts. The semantic audit further allows partial support and contradiction labels, making it more sensitive to source-grounded faithfulness, final-state errors, and state-update failures than pure concept overlap. At the same time, semCAP is representation-aligned by design, so we report it together with Nair-style GPT metrics as a complementary pair: semCAP for dialogue-grounded proposition preservation, GPT metrics for reference-note concept overlap.

CAP extraction and event planning. CAP extraction uses a dialogue-aware JSON schema that enforces atomic, verifiable propositions and preserves clinically important modifiers (negation, temporality, laterality, numeric values, severity, and plan intent). Event planning groups CAPs into problem-oriented bundles with linked evidence and actions, designed to improve renderability while keeping source grounding explicit.

```
CAP (Problem): The patient reports left hand weakness for two weeks.
CAP (MedicationStatement): The patient is taking Eliquis.
CAP (Order): The clinician orders a cervical MRI.
CAP (Plan): The clinician tentatively plans a left C7–T1 epidural.
```

Code and prompts. The full implementation, including prompts for scaffold extraction, rendering, and evaluation, is publicly available together with the postprocessing rules and scripts needed to reproduce our results. We also release intermediate artifacts—extracted scaffolds, CAPs, event plans, and generated sectioned/SOAP notes—for the final filtered cohort. The code, prompts, and reproducibility artifacts for this paper are available at https://github.com/sallyy1/CAP-ACL-2026.

Pipeline	Avg latency (s)	Rel. latency	Avg input toks	Avg output toks	Avg total toks	Rel. total toks
Direct ($X \to Y$)	10.03	1.00	2988.03	808.83	3796.87	1.00
CAP ($X \to C \to Y$)	60.71	6.06	20799.83	4255.33	25055.17	6.60
CAP+Event ($X \to C \to E \to Y$)	64.50	6.43	20634.17	4445.33	25079.50	6.61

Table 13: Deployment-path latency/token proxy on 30 cases; relative values are normalized to Direct.

D Ablation: SOAP-template Rendering

This section complements the main sectioned-template results with SOAP-template diagnostics. Table 11 reports SOAP-template aggregate metrics for the same five methods as the main experiment. Figure 4 then visualizes case-level SOAP semCAP-R win/tie/loss rates against Direct. Sectioned-template full win/tie/loss counts are reported in the main text (Table 7).

Method	semCAP-R (ours)↑	semCAP-P (ours)↑	semCAP-F1 (ours)↑	GPT-R (Nair)↑	GPT-P (Nair)↑	GPT-F1 (Nair)↑
Direct (base)	0.580	0.170	0.203	**0.636**	0.785	**0.693**
MEDSUM-ENT (prior)	0.546	0.158	0.191	0.596	0.737	0.649
Cluster2Sent (prior)	0.470	0.176	0.192	0.527	**0.791**	0.617
CAP (ours)	**0.660**	**0.210**	**0.246**	0.548	0.757	0.626
CAP+Event (ours)	0.520	0.184	0.196	0.508	0.771	0.600

Table 11: Results on the 197-case ACI-Bench cohort. (SOAP-template).

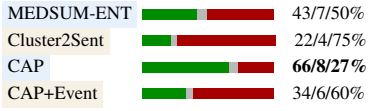

Figure 4: Case-level semCAP-R win/tie/loss rates against Direct. (SOAP-template).

E Ablation: Transcript-Free Rendering

To isolate how much of note generation can be supported by the intermediate representation alone, we evaluate two transcript-free ablations: **CAP-only** (renderer receives only the CAP set C) and **CAP+Event-only** (renderer receives C plus the bundle plan E), both without transcript X. These are not intended as competitive baselines; rather, they stress-test the *renderability* of intermediate scaffolds under a strict source constraint. Table 12 summarizes the sectioned-template means for these transcript-free conditions.

Method	semCAP-R (ours)	semCAP-P (ours)	semCAP-F1 (ours)	GPT-R (Nair)	GPT-P (Nair)	GPT-F1 (Nair)
CAP	**0.694**	0.212	0.256	**0.632**	**0.795**	**0.695**
CAP+Event	0.570	0.181	0.214	0.578	0.773	0.649
CAP-only	0.650	**0.269**	**0.277**	0.331	0.607	0.412
CAP+Event-only	0.141	0.077	0.065	0.132	0.288	0.167

Table 12: Transcript-free ablations (sectioned template; means). CAP+Event-only is a negative-control-style condition; CAP-only remains substantially stronger, indicating that proposition-level content can carry useful grounding signal even without transcript phrasing.

Interpretation. CAP-only keeps substantial grounded signal, but without transcript phrasing it underperforms on note-level quality. CAP+Event-only is much weaker, indicating that the current compact bundle plan is not yet sufficient as a standalone generation substrate.

F Inference Cost Analysis

To quantify the practical overhead of structure-first generation, we measure latency and token usage on a 30-case stratified subset using the same backbone model and sectioned-note template as the main experiments. We compare the deployment-time generation paths for Direct ($X \to Y$), CAP ($X \to C \to Y$), and CAP+Event ($X \to C \to E \to Y$). Reference-note CAP extraction is excluded because it is used only for offline evaluation, not deployment-time generation.

As shown in Table 13, the multi-stage pipelines increase both latency and token usage relative to Direct. CAP+Event adds only modest overhead over CAP, suggesting that most of the additional cost comes from CAP extraction and scaffold-conditioned rendering rather than event consolidation. These results quantify the current engineering cost of source-grounded structure-first generation and motivate future work on more efficient CAP induction, caching, and lightweight consolidation.

Case	Boundary regime	CAP snippet	CAP+Event snippet	Takeaway
D2N136	Organization gain (with residual risk)	"Continue metformin 500 mg twice daily" but "follow-up in two weeks" was flagged as unsupported by a reviewer.	Knee-pain problem and action items are grouped coherently (autoimmune labs + PT + meloxicam), but additional plan details (e.g., lipid profile, BP-cuff request) may over-extend beyond core focus.	Bundling can improve problem-level structure while still requiring tighter action filtering.
D2N203	Mixed trade-off	Captures vision-change workup and monthly Lucent injections, but carries restaurant narrative detail into HPI.	Maintains coherent AMD plan and follow-up cadence, yet can still retain low-value contextual detail from dialogue.	Consolidation helps organization, but noise suppression is still case dependent.
D2N010	Boundary failure	Hallucinates infection-heavy interpretation (Lyme/strep emphasis) and misses key CHF-related nuance in reviewer comments.	Over-compressed plan with omission risk (reviewers flagged missing hyperglycemia severity/right-leg edema and orthopnea-related nuance).	When evidence is noisy and multi-threaded, current event consolidation can under-specify critical findings.

Table 16: Clinician-reviewed boundary examples with generated-note snippets (sectioned template). Green marks clinically useful preservation; red marks reviewer-flagged or boundary-prone behavior.

G Boundary Analysis for Event Consolidation

Stratifying by bundle count. We stratify CAP+Event outputs by `event_plan_count` as a diagnostic proxy for consolidation strength (not a gold problem count). Table 15 shows that two-bundle plans are relatively safer, while one-bundle collapse is most associated with recall loss and under-generation.

`event_plan_count`	n	ΔsemCAP-R	ΔPDSQI	ΔPDSQI(org)	ΔF-CL(A+B+C)
1	144	−0.133	−0.093	−0.111	−0.191
2	37	−0.096	+0.039	−0.054	+0.027
3+	16	−0.110	−0.080	−0.062	−0.203

Table 15: Boundary analysis for event consolidation on the 197-case cohort (sectioned template). Values are mean deltas for CAP+Event relative to CAP. Bundle count is taken from the consolidation plan produced by cap_event.

Representative cases. Table 16 lists representative cases illustrating three regimes: (i) clear gains where consolidation improves organization and faithfulness (e.g., D2N207), (ii) trade-offs where organization improves but grounding recall drops (e.g., D2N190), and (iii) failure modes where consolidation under-generates or over-compresses, yielding large drops in semCAP-R and downstream quality (e.g., D2N153/D2N158). To make this concrete for readers, Table 16 additionally shows snippet-level highlights from the three clinician-reviewed cases (D2N136/D2N203/D2N010), marking preserved content in green and problematic rendering in red.

Case	Bundles	Regime	ΔsemCAP-R	ΔPDSQI	ΔPDSQI(org)	ΔF-CL(A+B+C)
D2N207	2	gain	+0.218	+2.286	+3.000	+1.000
D2N136	1	gain (org)	+0.176	+0.714	+1.000	−0.125
D2N190	2	trade-off	−0.178	+1.286	+1.000	+1.625
D2N205	1	failure	−0.886	−1.571	−2.000	−2.125
D2N153	1	failure	−0.714	−2.595	−4.000	−2.500
D2N158	1	failure	−0.675	−2.572	−3.000	−3.125

Table 16: Representative boundary cases for CAP+Event vs. CAP on the sectioned template; deltas are CAP+Event minus CAP.

H Extended Qualitative Example: D2N008

D2N008 is a multi-condition encounter in which the patient presents with fatigue and dizziness in the setting of low hemoglobin, background CHF, edema, salt-intake-related fluid retention, and a downstream GI workup plan. The main qualitative challenge is not merely whether these facts are mentioned, but whether they are organized around the correct primary problem. In our reading of the transcript, the clinically dominant structure is: *primary problem = anemia; evidence = fatigue, dizziness, low hemoglobin; context = CHF and edema; plan = anemia profile plus gastroenterology referral for endoscopy/colonoscopy*. This makes D2N008 a useful example of why proposition extraction and event construction are both needed.

The intermediate CAP representation also reveals a limitation that is useful to discuss explicitly. It captures the major signals well—fatigue, dizziness, swelling, low hemoglobin, prior CHF, and GI follow-up planning—but it also includes duplicated symptom propositions and weakly anchored low-value findings such as nasal congestion and seasonal allergies. This supports an important design conclusion: proposition-level extraction is necessary for faithful generation, but proposition normalization alone is not sufficient for producing a clinically prioritized note. A higher-order bundling step is particularly helpful when the encounter interleaves a primary workup problem with background chronic disease, historical detail, and peripheral conversational content.

Table 17: Dialogue snippets and core clinical challenges for D2N008.

Case	Transcript Key turns (abridged)	Clinical challenge
D2N008	U5: [patient] over the past couple of months , i've been really **tired** and **dizzy** . . . . U16: [doctor] okay , all right . so , you know , let's talk a little bit about that colonoscopy . i know you had a colonoscopy about three years ago and that showed that you had some mild **diverticuli- diverticulosis** . um , no issues since then ? U13: [patient] no , no weight loss or passing out . . . U19: [patient] um , it's been more of a struggle recently . i've been traveling a lot . i went up to vermont , um , to go , um , explore the mountains . and along the way i stopped at , you know , . . . i've noticed some **swelling** in my , my legs . . . U27: [patient] uh , i've had a little bit of **nasal congestion** just because with the seasons changing , i , i get seasonal allergies . but everything else has been okay . U32: [doctor] . . . physical examination looks fine . so , on your heart exam , i do hear a three out of six systolic ejection murmur , which we've heard in the past , okay ? and on your lower extremities , i do notice some trace to one plus **pitting edema** in your ankles , which is probably from the salt intake , okay ? U37: [doctor] . . . for you first problem this new anemia , uh , i wanna go ahead and send off some more labs and **anemia profile** , just to see exactly what type of anemia we're dealing with . i also wanna go and refer you back to the **gastroenterologist** for another evaluation , okay ? hey , dragon , order referral to gastroenterology . so , they're gonna do , uh , probably do an **endoscopy** and another **colonoscopy** on you . um , but again , i wanna send off those labs just to make sure that it's not something else , okay ?	• **Distributed evidence**: anemia workup depends on symptoms, prior GI history, edema, and follow-up plan scattered across the visit. • **Source grounding under noise**: low-salience seasonal-allergy content co-occurs with clinically central anemia evidence. • **Problem–plan linkage**: the anemia problem must remain linked to anemia profile, GI referral, endoscopy/colonoscopy, and medication adjustments. • **Avoiding over-attribution**: side details such as allergies should not dominate the assessment.

Table 18: Qualitative comparison on D2N008. This case illustrates distributed anemia-related evidence and a plan that must remain linked across symptoms, prior GI history, exam findings, and follow-up actions. CAP-based methods improve structural coherence, while Direct remains competitive as a strong baseline.

Method	Generated note (sectioned template, full)	Comment
Direct	**Chief Complaint** Low hemoglobin levels. **History of Present Illness** The patient reports fatigue and dizziness over the past couple of months, exacerbated by recent travel. She notes increased swelling in her ankles and reports difficulty keeping up with her usual activity level. She had a colonoscopy three years ago that revealed mild diverticulosis with no complications. She previously experienced kidney stones two years ago, with no recent flares. She denies any recent blood in her stools or melena. **Findings** Physical examination reveals trace to one plus pitting edema in the ankles. The patient's blood pressure is within normal limits, and her heart rate is appropriate. A three out of six systolic ejection murmur is heard on cardiac auscultation. The echocardiogram demonstrates a left ventricular ejection fraction of 45% and moderate mitral regurgitation. Hemoglobin is 8.2 g/dL. **Assessment** The patient presents with anemia, likely secondary to chronic disease or other underlying causes. Her congestive heart failure and recent diuretic use may contribute to her symptoms. **Plan** I am ordering an anemia profile to further evaluate the cause of the anemia. I am also ordering a referral to gastroenterology for an endoscopy and repeat colonoscopy. I will initiate lasix 40 milligrams once daily, continue toprol 50 milligrams daily, and lisinopril 10 milligrams daily. I will instruct the patient to monitor her weight daily and call if there is any weight gain. I will also recommend a scale to assist with monitoring sodium intake.	A strong direct baseline: it covers much of the visit correctly. Its weakness is that the overall rationale is less explicitly scaffolded, making it harder to see how distributed evidence was organized.
Cluster2Sent	**Chief Complaint** The patient reports fatigue and dizziness. **History of Present Illness** The patient reports fatigue and dizziness over the past couple of months. She denies any recent trauma. She reports some mild nasal congestion related to seasonal allergies. She denies fever, chills, or sore throat. She denies any weight loss or loss of appetite. She reports some swelling in her lower extremities, primarily in her ankles. She has no issues since her previous colonoscopy three years ago. **Findings** The patient is a 49-year-old female with a past medical history of congestive heart failure, kidney stones, and a prior colonoscopy. Her vital signs are stable, with blood pressure 132/78 and heart rate 78. A three out of six systolic ejection murmur is auscultated. The echocardiogram reveals a left ventricular ejection fraction of 45%, moderate mitral regurgitation, and trace to one plus pitting edema in the ankles. Hemoglobin is low. **Assessment** The patient presents with anemia, likely secondary to chronic disease and requiring further investigation. She also continues to have symptoms consistent with congestive heart failure. **Plan** I am going to order additional labs, including a complete blood count and iron studies. I will also refer her back to the gastroenterologist for an endoscopy and repeat colonoscopy. I will initiate lasix 40 milligrams once daily and continue toprol 50 milligrams daily. I will also consider a diuretic increase if symptoms persist.	Reasonably faithful, but flatter and less explicit about which evidence belongs to the anemia workup versus background chronic conditions.
MEDSUM-ENT	**Chief Complaint** *[empty]* **History of Present Illness** *[empty]* **Findings** *[empty]* **Assessment** *[empty]* **Plan** *[empty]*	Under-generated sectioned output (empty skeleton), limiting its usefulness as a rendering scaffold for long multi-condition narratives in our prompt-based reimplementation.

Method	Generated note (sectioned template, full)	Comment
CAP	**Chief Complaint** Low hemoglobin level. **History of Present Illness** The patient reports fatigue and dizziness over the past couple of months, particularly with increased exertion. She notes swelling in her ankles and reports difficulty with salt intake, particularly while traveling. She had a colonoscopy three years ago that revealed mild diverticulosis with no issues since. She also has a history of kidney stones two years ago with no recent flares. She reports seasonal allergies and nasal congestion. She denies any weight loss or loss of appetite, or episodes of passing blood in the stool or urine. **Findings** The patient's blood pressure is within normal limits. Heart rate is appropriate. Physical exam reveals trace to one plus pitting edema in the ankles. A systolic ejection murmur is heard. The doctor notes nasal congestion. **Assessment** The patient's low hemoglobin level is concerning and requires further investigation. Her congestive heart failure, diverticulosis, and seasonal allergies are contributing factors. **Plan** The doctor plans to order an anemia profile and a referral to the gastroenterologist for an endoscopy and colonoscopy. The doctor also orders lasix 40 milligrams once daily, toprol 50 milligrams daily, and lisinopril 10 milligrams a day. The doctor recommends monitoring weight daily and calling if it increases. The gastroenterologist will perform an endoscopy and colonoscopy.	CAP preserves the main anemia-centered plan well, but still over-carries peripheral details such as seasonal allergies into the note.
CAP + Event	**Chief Complaint** Low hemoglobin levels and fatigue. **History of Present Illness** Stephanie is a 49-year-old female with a history of congestive heart failure, kidney stones, and a prior colonoscopy. She presents today with complaints of fatigue and dizziness over the past couple of months, noting that these symptoms have worsened recently, particularly with travel. She reports increased swelling in her ankles and has been struggling to maintain a low-salt diet. She had a colonoscopy three years ago that revealed mild diverticulosis with no further issues. She also had kidney stones a couple of years ago, with no recent flares. She reports occasional nasal congestion related to seasonal allergies but no other significant symptoms, including fever, chills, sore throat, or cough. She denies any weight loss or loss of appetite and has not experienced any episodes of fainting or dark stools. **Findings** Physical exam reveals blood pressure 128/78 mmHg, heart rate 72 bpm, and trace 1+ pitting edema in the ankles. A three out of six systolic ejection murmur is heard. The echocardiogram shows a left ventricular ejection fraction of 45% and moderate mitral regurgitation. Hemoglobin is 8.2 g/dL. **Assessment** The patient presents with anemia, likely secondary to chronic disease and lifestyle factors. Her congestive heart failure and recent travel contribute to her symptoms. **Plan** I am ordering an anemia profile to determine the etiology of the anemia. I will also refer her back to the gastroenterologist for an endoscopy and repeat colonoscopy. I will initiate lasix 40 mg daily, continue toprol 50 mg daily, and lisinopril 10 mg daily. I will also order a referral to gastroenterology for further evaluation. I will instruct the patient to monitor her weight daily and call if there is any significant increase.	CAP+Event most clearly organizes the visit around the anemia problem and its downstream workup, though it can still introduce mild over-explanation in narrative form.

I Extended Qualitative Example: D2N026

D2N026 is our main safety-critical supporting case. The encounter is structurally simple compared with D2N008, but it contains a clinically important contradiction that occurs late in the dialogue: the patient first denies blood thinners and later states that he is taking Eliquis. Because the downstream plan includes cervical MRI and a tentative epidural, recovering the *final grounded medication state* is more important here than broad narrative fluency. This case therefore illustrates a second recurring failure mode in clinical dialogue summarization: brittle final-state tracking under long-range dependency. Table 19 summarizes the key dialogue turns and why this failure mode is safety-critical for downstream planning.

Table 19: Dialogue snippets and core clinical challenges for D2N026.

Case	Dialogue evidence (abridged)	Clinical challenge
D2N026	**Key turns** U9: "the thing started about **two weeks ago**" U19–U27: arm/hand pain extends down the arm; **hand weakness** and grip difficulty U49–U55: cervical source, **MRI** needed, tentative **epidural** plan U57: "do you take any **blood thinners**?" U58: "no, I don't" U59: "I am taking **Eliquis**, though" U65: "my hand is still bothering me" U66–U68: **MRI of neck + C7–T1 epidural** plan maintained	• **State update conflict**: earlier negation → later correction. • **Medication safety**: anticoagulant status matters. • **Primary problem grounding**: cervical / arm–hand pain. • **Plan preservation**: neck MRI + epidural plan.

Table 20: Qualitative comparison on D2N026. Direct generation collapses to an unrelated problem, while Cluster2Sent keeps the wrong earlier medication state. CAP-based methods better preserve the later clinically actionable Eliquis update together with MRI and epidural planning.

Method	Generated note (sectioned template, full)	Comment
Direct	**Chief Complaint** Right shoulder pain **History of Present Illness** The patient presents with right shoulder pain that began approximately 3 days ago after lifting a heavy box. He describes the pain as sharp and constant, exacerbated by overhead movements. He denies any recent trauma. He has tried over-the-counter ibuprofen with minimal relief. He reports difficulty reaching behind his back. He has no prior history of shoulder problems. He is currently taking lisinopril and metformin. **Findings** Physical exam reveals tenderness to palpation over the right rotator cuff. Range of motion is limited by pain. Neurological exam is intact. **Assessment** Rotator cuff strain is suspected. **Plan** Continue with ice and elevation. Initiate physical therapy. Consider a rotator cuff ultrasound to rule out a tear.	Catastrophic topic drift. The note misses the cervical MRI, epidural planning, gabapentin continuation, and anticoagulant update altogether.
Cluster2Sent	**Chief Complaint** Left arm pain **History of Present Illness** The patient reports left arm pain, initially attributed to a possible pinched nerve by a previous provider. He has been taking gabapentin and a neck pill, and reports using numbing medicine. He denies taking blood thinners. He reports some mild strain. **Findings** The patient has mild cervical restriction on examination. Cervical x-ray reveals significant disc degeneration at C5–C6 and to a lesser extent C4–C5 and C3–C4. MRI of the neck is planned to assess for nerve compression. Physical exam reveals no apparent distress. **Assessment** Suspect cervical radiculopathy with possible contributing peripheral neuropathy. The patient's presentation is consistent with cervical disc degeneration and radicular symptoms. **Plan** Order a neck MRI to assess for nerve compression. Tentatively plan for a left C7–T1 epidural, pending MRI results. Continue the patient on gabapentin and advise him to continue his home exercise program. Schedule a follow-up appointment in four weeks if symptoms persist.	Better problem anchoring than Direct, but it preserves the *wrong final state* by carrying forward the earlier blood-thinner denial instead of the later Eliquis correction.
MEDSUM-ENT	**Chief Complaint** *[empty]* **History of Present Illness** *[empty]* **Findings** *[empty]* **Assessment** *[empty]* **Plan** *[empty]*	In our prompt-based reimplementation, the sectioned renderer under-generated for this case, producing an empty skeleton. (The SOAP template produces a non-empty output but still struggles to reconcile the late Eliquis update.)
CAP	**Chief Complaint** Left arm pain. **History of Present Illness** The patient reports hand pain, which began approximately two weeks ago. He describes the pain as worsening at night and initially experienced it when waking at 2:00 AM. He reports that applying ice provided temporary relief. The patient also notes difficulty gripping things and reports weakness in his hand. He previously injured his hand and has a history of leg issues and knee issues, and is one percent disabled. He reports taking eliquis and gabapentin. He previously received numbing medicine and oral steroids. **Findings** Physical exam reveals mild cervical restriction with limited extension, and tenderness to palpation in the neck. Strength is one plus bilaterally in the biceps, triceps brachii, and brachioradialis. Reflexes are normal. Examination does not reveal any specific findings in the upper extremities other than the reported hand weakness. **Assessment** The patient's symptoms are most likely due to cervical radiculopathy, possibly secondary to disc degeneration. Peripheral neuropathy is also a consideration. **Plan** I am going to order a cervical MRI to further evaluate the nerve roots and determine the extent of compression. I will also tentatively schedule a C7–T1 epidural. The patient will continue taking gabapentin and eliquis. I will schedule a follow-up appointment in four weeks to assess his progress.	CAP recovers the clinically critical later correction (**Eliquis**) and preserves the cervical radiculopathy workup and treatment plan.

Method	Generated note (sectioned template, full)	Comment
CAP + Event	**Chief Complaint** Left arm pain. **History of Present Illness** The patient reports left arm pain that began approximately two weeks ago, worsening at night. The pain initially arose suddenly and was accompanied by a feeling of discomfort, but it has since become more persistent. He describes the pain as a dull ache, and it seems to be exacerbated by certain movements. He mentions that he experienced similar symptoms in the past, which were attributed to a pinched nerve by a previous physician. He has been taking gabapentin and eliquis as prescribed. He denies any recent trauma or injury to the arm. **Findings** Physical exam reveals mild tenderness to palpation in the cervical region. Range of motion is limited in cervical flexion and extension. Strength testing reveals a one-plus grade for biceps and triceps strength bilaterally. Reflexes are normal. Cervical x-ray demonstrates significant disc degeneration at C5–C6 and C4–C5. **Assessment** The patient's symptoms are most likely due to cervical radiculopathy, possibly exacerbated by disc degeneration. Peripheral neuropathy is also a consideration. **Plan** I am ordering a cervical MRI to further evaluate the nerve roots and determine the extent of compression. We will also schedule a left C7–T1 epidural to provide targeted anti-inflammatory relief. The patient will continue with gabapentin as prescribed and follow up in four weeks to assess symptom improvement.	CAP+Event preserves the main problem–evidence–plan chain and avoids the unsafe blood-thinner denial, though some detail is compressed during rendering.

J Extended Qualitative Example: D2N024

This case is useful precisely because it is not a clean victory. The clinically dominant structure is mild scar discomfort with conservative management and deferred revision, while the lump belongs to historical context and the review-of-systems negatives should remain suppressed. As shown in Tables 21 and 22, Cluster2Sent is brittle under negation-heavy follow-up dialogue and can promote explicitly negated symptoms into positives, while MEDSUM-ENT and Direct remain strong on this visit style. CAP contributes by making temporal resolution and the conservative scar-centered plan explicit, but it can still over-carry speculative counseling content. We therefore view D2N024 as evidence that structured representations improve robustness under noisy dialogue, but do not fully solve the filtering problem when low-salience follow-up content and speculative counseling are tightly interleaved.

Table 21: Dialogue snippets and core clinical challenges for D2N024.

Case	Dialogue evidence (abridged)	Clinical challenge
D2N024	**Key turns** U8: "**no**" to **chills**, **fever**, **nausea**, **vomiting** U18: back pain **resolved** U21: **lump under left breast** was noted in March … U23: **scars were bothering her** … U33–U47: conservative plan: **scar gel**, **massage**, photos, **revisit in 6 months**	• **Temporal resolution**: prior lump → no longer present. • **Negation-heavy follow-up**: ROS items can be falsely promoted. • **Low-salience follow-up noise**: social talk can leak into note text. • **Current problem vs. future option**: revision is future/hypothetical.

Table 22: Qualitative comparison on D2N024. This follow-up visit mixes a scar complaint with a resolved historical lump and negation-heavy review-of-systems content.

Method	Generated note (sectioned template, full)	Comment
Direct	**Chief Complaint** Breast scar discomfort following bilateral reduction mammoplasty. **History of Present Illness** The patient reports persistent discomfort with the scars from her bilateral reduction mammoplasty performed in October 2020. She initially reported irritation and sought relief with scar gel, applying it twice daily. She states the scars were bothersome and used the gel to mitigate this. She has not had any further issues with the scars since her last visit with Dr. Sanchez in March. She denies any new chills, fever, nausea, or vomiting. She reports enjoying summertime activities and her family is doing well. She has not experienced any new back pain. **Findings** Physical examination reveals well-healed incisions with no signs of infection or redness in either breast. The incisions appear widened, particularly on the left side. The patient reports subjective discomfort with the left scar. **Assessment** Postoperative scarring following bilateral reduction mammoplasty. **Plan** Schedule a follow-up appointment in six months to reassess the scars. Continue the use of mederma scar gel twice daily on the affected areas, massaging the scars. Obtain photographs of the scars for documentation and future comparison.	Strong baseline: keeps the scar follow-up as primary, preserves ROS negations, and treats the prior lump as historical/resolved.
MEDSUM-ENT	**Chief Complaint** Scar discomfort following bilateral reduction mammoplasty. **History of Present Illness** The patient reports ongoing discomfort with the scars from her previous bilateral reduction mammoplasty, specifically noting that one scar area is bothering her. She previously reported a lump in that area to her primary care physician, Ruth Sanchez, in March, but no longer feels it. She has been using scar gel twice daily to manage the scar tissue and has observed some widening of the incisions. She denies any signs of infection or redness. The patient is currently enjoying summertime and has not experienced any new symptoms or concerns. **Findings** Examination reveals well-healed incisions with no signs of infection or redness on either breast. The patient reports the scar tissue is widening. **Assessment** The patient's primary concern is persistent scar discomfort following breast surgery. There is no evidence of acute infection or complications. **Plan** The patient should continue using the mederma scar gel twice daily on the affected scar area. We will schedule a follow-up appointment in six months to reassess the scar tissue and determine if further intervention is needed. Photographs will be taken today to document the current state of the scars for future reference.	Captures temporal resolution (lump no longer present) and negation-heavy content cleanly; aligns with MEDSUM-ENT's status-centric design.
Cluster2Sent	**Chief Complaint** Patient reports concern regarding breast scars following bilateral reduction mammoplasty. **History of Present Illness** The patient reports experiencing chills, fever, nausea, and vomiting. She describes a lump located under her left breast, which she has not felt recently. She notes that the scars are bothering her and have widened slightly, particularly in a high-tension area. She has been using scar gel and massage to manage the scars. **Findings** The incisions are well-healed with no signs of infection or redness on either breast. **Assessment** The patient's reported breast lump and scar concerns require further evaluation. **Plan** Schedule a follow-up appointment in six months to reassess the scars and address any ongoing concerns. Recommend continued scar gel application and massage.	Promotes explicitly negated ROS items to positives (unsafe) and blurs the historical lump vs. current scar follow-up distinction.
CAP	**Chief Complaint** Patient reports scar discomfort and a desire for scar revision. **History of Present Illness** The patient reports a breast lump discovered during self-examination in March, which was evaluated by Dr. Sanchez. She reports that the scar from her previous reduction mammoplasty has been bothering her, and she has been using scar gel twice daily. She denies any recent trauma or fever. She reports no nausea or vomiting. She describes the scar as being slightly bothersome, and she's been massaging the scar gel. She's been using the gel for about a month. She's been using the gel twice a day. She discontinued using the gel because it was bothering her. She's been enjoying summertime and hasn't had any new problems. **Findings** Examination reveals well-healed incisions with no signs of infection or redness. The incisions appear widened. The patient denies chills, fever, nausea, or vomiting. **Assessment** The patient has scars from previous surgery and reports discomfort. There is no acute infection or signs of complications. **Plan** The doctor recommends the patient continue using scar gel twice a day and massaging the scar gel. The doctor recommends revisiting the scar in six months. The doctor will take pictures of the scars today and will revisit the scars in six months. The doctor recommends surgical excision if necessary.	Preserves key facts, but over-carries speculative counseling (revision/excision) and includes repetition/noise in HPI.

Method	Generated note (sectioned template, full)	Comment
CAP + Event	**Chief Complaint** Patient is Pamela Cook, a 36-year-old female post-bilateral reduction mammoplasty on 10-10-2020, presenting for follow-up regarding scar discomfort and a recent lump. **History of Present Illness** The patient reports being Pamela Cook, a 36-year-old female post-bilateral reduction mammoplasty on 10-10-2020. She states she is doing well and enjoys summertime. She reports that the scars here were kind of bothering me and I got scar gel. I was using it everyday, but I do n't think I need it now. She also mentioned a lump right here under her left breast that she felt during her mammogram in March, which was noted by Dr. Ruth Sanchez. However, she hasn't felt it since then. She discontinued using scar gel. She denies any new chills, fever, nausea, or vomiting. **Findings** Physical examination reveals well-healed incisions with no signs of infection or redness on either breast. The patient's back pain is currently not a concern. **Assessment** The patient's presentation is consistent with post-operative scar discomfort and a previously identified, now absent, palpable lesion, warranting continued monitoring. **Plan** The doctor recommends revisiting the scar in six months. The patient can keep using mederma scar gel twice a day. The patient can put scar gel on other scars. The patient should massage the scar gel. The doctor will take pictures of the scars today. The doctor will revisit the scars in six months.	Better separates historical vs. current status and keeps the conservative follow-up plan; still contains some templated repetition (name/date).

K Clinician Deep Review Protocol and Summary

We conducted a focused deep review on three sectioned-note cases: D2N136 (organization gain), D2N203 (mixed trade-off), and D2N010 (boundary failure). Two clinicians independently rated Direct, Cluster2Sent, CAP, and CAP+Event using a checklist co-designed with the reviewers to directly probe the failure modes in our Motivation and Research Questions (Figure 5). The checklist contains eight 1–5 Likert items spanning (A) content preservation, (B) clinical state fidelity, and (C) problem-oriented organization, plus safety flags (omission/hallucination/major error; yes/no). We also collected a *clinical usability* rating as an auxiliary item and report it separately (not included in the A+B+C aggregate). Overall, the three cases cover (i) an organization gain, (ii) a preservation–organization trade-off, and (iii) a boundary failure where all systems show clinically meaningful weaknesses.

Reviewer summaries.

- **Clinician A:** On close reading, notes can still contain omissions/hallucinations and occasional section-miscategorization even when they look broadly plausible.
- **Clinician B:** No severe errors were observed; differences were largely preference-level, and conclusions are limited with two reviewers.

Per-case clinician sheets. Tables 24–25 summarize the raw scoring sheets from our two clinicians (A and B) with brief English translations of their key comments. Narrative notes made Problem–Evidence Linkage difficult to rate in some cases (N/A), consistent with our decision to treat this item cautiously in the main quantitative analysis.

Clinician deep-review checklist (1–5 Likert; 1=poor, 5=excellent).

A. Content Preservation

1 (C) **Core clinical information preserved:** Are clinically salient facts from the dialogue retained without major omission?

2 (N) **Noise suppression:** Are small talk, repeated questions, and peripheral context avoided in the note?

3 (Ly) **Lay-expression fidelity:** Is patient language neither copied verbatim nor over-abstracted, preserving symptom nuance (severity/uncertainty)?

B. Clinical State Fidelity

4 (F) **State update / final-state fidelity:** Are late corrections and resolved uncertainty reflected in the final state (unknown→resolved; negation→positive; current med vs. intended change)?

5 (T) **Temporality preservation:** Are past history, current status, and future plan kept distinct?

C. Problem-oriented Organization

6 (Lk) **Problem–evidence linkage:** Are symptoms/exam/tests/history linked under the correct clinical problem?

7 (SP) **State–plan separation:** Are current state/current meds separated from new orders/prescriptions/follow-up plans?

8 (SO) **Section / note organization:** Are items placed in appropriate SOAP/sectioned sections?

Safety flags (Y/N): O=clinically meaningful omission; H=clinically concerning hallucination; M=major error.

Auxiliary: U=clinical usability (1–5; reported separately; excluded from the A+B+C faithfulness aggregate).

Figure 5: Clinician deep review rubric co-designed with the clinician reviewers to directly probe the failure modes in Motivation and Research Questions. Abbreviations match Tables 24–25.

Method	A Content	B State	C Org	Mean (A+B+C)	Clinical Usability
Direct	3.78	**5.00**	**4.89**	4.54	3.33
Cluster2Sent	4.11	**5.00**	4.72	4.63	3.67
CAP	**4.19**	**5.00**	4.72	4.62	3.33
CAP+Event	4.17	**5.00**	4.83	**4.77**	**4.00**

Table 23: Clinician deep review summary (mean across three ACI-Bench cases × two clinicians). Scores are 1–5 Likert ratings aggregated by rubric category (Figure 5); N/A items are excluded. Direct is highest on overall organization (C) in this small sample; among the two clustering/bundling approaches, CAP+Event outscored Cluster2Sent on organization and the A+B+C mean.

Case	Method	C	N	Ly	F	T	Lk	SP	SO	U	O/H/M	Key note (translated)
D2N136	Direct	3	5	N/A	N/A	5	N/A	5	5	3	Y/Y/–	Omits negated ROS items (e.g., vomiting/chest pain/dyspnea) and hallucinates a 4-week follow-up; state-update and problem–evidence linkage were not applicable to rate in this case.
D2N136	Cluster2Sent	3	5	N/A	N/A	5	N/A	5	4	3	Y/–/–	Best plan capture among the compared methods for this case, but omissions were still flagged.
D2N136	CAP	4	5	N/A	N/A	5	N/A	5	5	4	–/Y/–	Hallucinates a 2-week follow-up appointment.
D2N136	CAP+Event	3	3	N/A	N/A	5	N/A	5	3	3	Y/Y/–	Omits continued metformin (500mg BID) from the plan and hallucinates a 4-week follow-up; misses prior rotator cuff repair and over-includes low-value narrative; BP is missectioned.
D2N203	Direct	4	2	4	N/A	5	N/A	5	5	3	–/–/–	Includes conversational filler (e.g., "I will return in a few minutes") that should not appear in a clinical note.
D2N203	Cluster2Sent	5	4	3	N/A	5	N/A	5	4	4	–/Y/–	Hallucinates an "eye needle-stick" history not supported by the dialogue.
D2N203	CAP	5	3	4	N/A	5	N/A	5	5	4	–/–/–	No major issues were noted in the clinician sheet for this case/method.
D2N203	CAP+Event	5	3	4	N/A	5	N/A	5	5	4	–/–/–	No major issues were noted in the clinician sheet for this case/method.
D2N010	Direct	3	5	5	5	5	N/A	5	5	3	–/Y/–	Hallucinates a Lyme titer and a 4-week follow-up; overfocuses on side-sleeping and misses the key orthopnea-negative point (lying flat is not problematic).
D2N010	Cluster2Sent	3	4	4	5	5	N/A	5	5	3	Y/Y/–	Omits severity of hyperglycemia (blood glucose in the 300s); hallucinates/incorrectly summarizes rapid strep treated with amoxicillin and misstates alpha-gal "certainty."
D2N010	CAP	4	5	4	5	5	N/A	5	5	3	Y/–/Y	Omits right-leg edema in a CHF context; major interpretation error around sleep/orthopnea (misses that lying flat is fine).
D2N010	CAP+Event	3	5	4	5	5	N/A	5	5	3	Y/Y/–	Omits hyperglycemia severity and right-leg edema; incorrectly implies the patient avoids lying flat (dialogue indicated no orthopnea).

Table 24: Clinician A deep review sheet (translated). Scores are 1–5 Likert ratings: C=Core information, N=Noise suppression, Ly=Lay-expression fidelity, F=Final-state fidelity, T=Temporality preservation, Lk=Problem–Evidence linkage, SP=State–Plan separation, SO=Section organization, U=Overall clinical usability. O/H/M indicates whether the reviewer flagged omission/hallucination/major error (Y/–).

Case	Method	C	N	Ly	F	T	Lk	SP	SO	U	O/H/M	Key note (translated)
D2N136	Direct	2	5	3	5	5	3	5	5	3	–/–/–	Incorrect patient sex; includes an irrelevant statement about lower-extremity strength.
D2N136	Cluster2Sent	2	5	4	5	5	3	5	5	3	–/–/–	Captures the chief complaint, patient sex, and diabetes history.

Abstract

Processing unstructured clinical narratives remains a major challenge in medical Natural Language Processing (NLP), particularly when critical information is embedded within lengthy and heterogeneous reports. Clinical notes often describe key diagnostic and therapeutic events through a verbose narrative, making automatic event identification difficult. In this work, we frame the identification of clinical events as a text segmentation task. We conduct a comparative study of three segmentation strategies applied to oncology reports: (i) a fully regex-based approach, (ii) a cascaded regex–LLM pipeline, and (iii) the same cascade architecture augmented with a recovery mechanism to mitigate LLM rephrasing. Segmentation quality is evaluated using complementary structural metrics (Pk, WindowDiff, Boundary Similarity, Segment Count Accuracy, and Text Overlap IoU), and its impact is also observed on downstream segment tagging, performed to identify the corresponding event type (e.g. surgery, biopsy, imaging, treatment, laboratory). The results demonstrate the high potential of LLM-based approaches, particularly in preserving semantic coherence within segments and generalization on new data sources. However, regex-based segmentation achieves higher performance according to structural segmentation metrics, also leading to better downstream clinical event identification. In general, these results highlight the critical role of context-adaptive high-quality segmentation strategies in the structuring of verbose clinical narratives and in the accurate identification of key patient events.

1 Introduction

Processing unstructured clinical narratives remains a major challenge in medical Natural Language Processing (NLP). Clinical reports are typically lengthy and unstructured documents that aggregate heterogeneous information in a verbose narrative, including key events like diagnostic findings, therapeutic interventions, laboratory results, and follow-up plans. This structural complexity makes them difficult to handle within downstream NLP pipelines, where models often require well-defined and coherent input units.

To address this issue, preprocessing strategies are commonly employed to make clinical texts more workable. In particular, text segmentation can support downstream tasks by dividing reports into smaller and semantically coherent units, facilitating more targeted processing. However, chunking techniques used in transformer-based and LLM architectures are predominantly length-driven rather than meaning-driven (Jaiswal and Milios, 2023). As a consequence, they may split text at arbitrary boundaries, disrupting semantic coherence and potentially separating information that belongs to the same clinical event, or they may fail to identify semantically distinct sub-sections, relative to two different events. In this direction, Lilli et al. (2026) showed that content-aware segmentation of clinical reports can improve downstream information extraction by enabling content-specific prompting strategies for different clinical event types. In that work, the primary focus was not the segmentation task itself, but the evaluation of extraction performance under different prompt configurations tailored to the segmented report content. Within this framework, segmentation represented a key preprocessing step for the extraction architecture and was implemented through a preliminary regex-based approach.

In this study, we reframe text segmentation as a semantics-driven task aimed at identifying clinically meaningful event units, and not only reducing input length. Focusing on the clinical-history section of oncological reports, we seek to automatically detect and isolate key temporal events (such as imaging examinations, surgeries, laboratory assessments, biopsies, and treatment lines) that define the patient's clinical trajectory. These

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 595–604
July 3-4, 2026 ©2026 Association for Computational Linguistics

events are typically embedded within chronological narrative text, where explicit structural markers may be inconsistent or absent, making boundary detection particularly challenging. To address this problem, we conduct a comparative evaluation of three segmentation strategies: (i) a fully rule-based approach relying on regular expressions and structural cues, (ii) a regex–LLM pipeline that refines rule-based segments through semantic modeling, and (iii) the hybrid regex-LLM framework incorporating a recovery mechanism to mitigate LLM-induced boundary errors and hallucinations. In addition to intrinsic segmentation metrics, we evaluate each strategy based on its downstream event tagging performance, demonstrating that segmentation quality directly affects the accuracy of event type classification. Through this analysis, we highlight the complementary strengths of deterministic rules and LLM-based approaches, and demonstrate the importance of high-quality text segmentation for accurately identifying key events within a patient's clinical trajectory. The study framework is shown in Figure 1.

2 Background

Early approaches to document structuring relied heavily on rule-based systems to identify section boundaries. Pioneering works like SecTag (Denny et al., 2009) utilized terminological headers and line formatting to detect document sections, a methodology that remains influential in modern pipelines such as medspaCy (Eyre et al., 2021). Although these approaches effectively handle document structures, they often lack the granularity required to tell apart distinct clinical events within narrative-heavy sections like the clinical history, where explicit headers are frequently replaced by chronological descriptions and date references.

The granular identification of such events is closely linked to temporal information extraction. Major initiatives like the i2b2 Shared Task (Sun et al., 2013) and the THYME corpus proposed for use in a SemEval 2015 task (Styler IV et al., 2014) established the standard for extracting events, temporal expressions, and their relationships. These tasks were approached mostly with ML supervised methods, which typically require large, annotated corpora (scarce in real-world settings).

Furthermore, recent work by Lilli et al. (2025b) shows how sentence boundary detection helps text segmentation using both traditional and LLM-based methods, including SaT (Frohmann et al., 2024), PySBD (Sadvilkar and Neumann, 2020), Stanza (Qi et al., 2020) and NLTK (Bird, 2006). The benchmark analysis shows that even sentence-level boundary detection can significantly enhance downstream clinical report classification and critical event identification.

Building on the above findings, text segmentation emerges as a crucial and actively explored task in clinical NLP. However, despite its importance, it remains challenging due to the variability and complexity of clinical narratives. With recent advances in NLP, many clinical text processing tasks are increasingly being addressed using LLM-based approaches, which have enabled substantial progress in areas such as clinical information extraction and medical text generation (Yang et al., 2022; Agrawal et al., 2022; Lilli et al., 2025a). Recent comparative studies, such as CNSight (Surana et al., 2025), have evaluated rule-based, transformer, and LLM-based approaches for clinical note segmentation, similarly finding that rule-based methods can be robust. While with CLINES (Yang et al., 2025b), the complex space of clinical text segmentation for semantical analysis is further explored.

Despite their strong semantic understanding, LLMs remain prone to hallucinations, often producing plausible yet clinically inaccurate information (Ji et al., 2023). To mitigate this limitation, hybrid approaches have been proposed that combine the deterministic precision of regex with the reasoning capabilities of LLMs (Kleinlein et al., 2025). Crucially, a major challenge in LLM-based segmentation is ensuring that the generated output aligns exactly with the legally valid source text. Recent efforts such as LangExtract (Goel, 2026) and SafePassage (Barrow et al., 2025) focus heavily on grounding LLM outputs back to source spans. The closest work to our proposed recovery approach is MedSlice (Davis et al., 2025), which addresses LLM boundary misalignment in section-level segmentation using Levenshtein-based fuzzy matching. Building upon this line of research, our work introduces an extended recovery mechanism that leverages full-segment fuzzy matching rather than anchor n-grams, incorporates gap-filling between aligned segments, and implements a global rollback strategy when alignment fails.

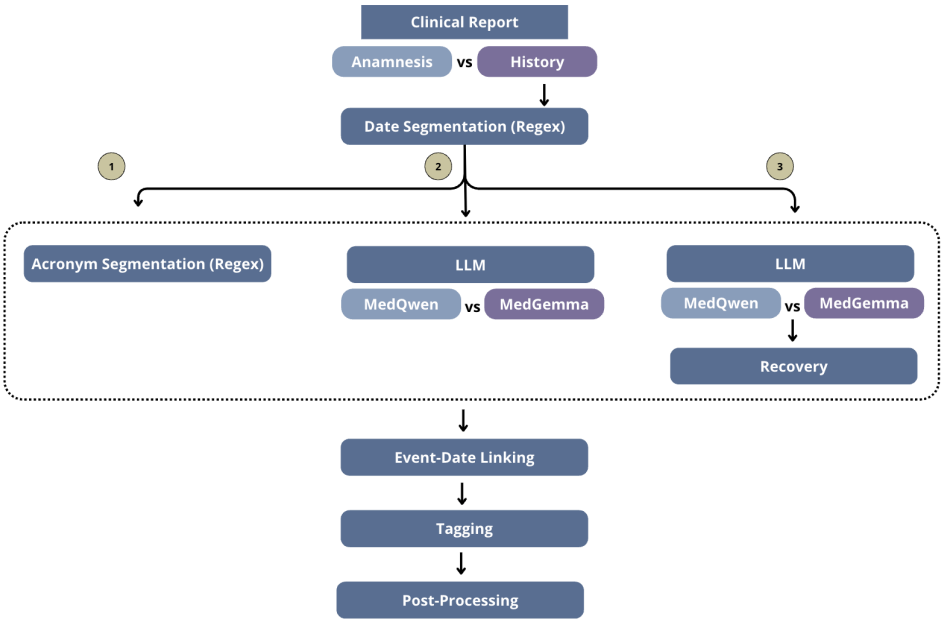

Figure 1: Study workflow with the 3 segmentation strategies: (1) regex-only, (2) regex + LLM, (3) regex + LLM + recovery.

3 Method

3.1 Dataset

The dataset consists of anonymized, real-world Italian ovarian oncology reports from multidisciplinary tumor board sessions at the Gemelli Hospital in Rome, where clinicians discuss patient cases and decide on follow-up and care. The documents are typically extensive and semi-structured. Each report opens with an anamnestic summary of the patient's current status, followed by a clinical history section. This history is organized as a sequence of events (such as surgeries, diagnostic imaging, or systemic treatments) which are generally prefaced by an explicit date or a functional header that provides a brief summary of the event type (e.g., *TC total body* for an imaging event). The primary objective of this study is to leverage this structure to automatically isolate these clinical events, transforming the narrative history into independent textual segments.

3.2 Text Segmentation

The study considers three text-segmentation strategies applied exclusively to the clinical history section of the reports: (1) a regex-only method, (2) a cascaded regex–LLM pipeline, and (3) the same cascaded pipeline augmented with a recovery step.

3.2.1 Regex-only

The first approach identifies event boundaries by detecting date expressions strictly at the beginning of a sentence or line-initial position. Supported date formats include `dd/mm/yyyy`, `dd/mm/yy`, month–year expressions (e.g., `month, year`), and `dd/mm` without year. Dates preceded solely by plain text are ignored to avoid spurious intra-sentential matches.

After date-based segmentation, further refinement is performed by analyzing patterns that may correspond to event titles or section headers. This step is designed to capture clinical events that lack an explicit date but are introduced by a functional header. To this purpose, a domain-specific dictionary of acronyms and lexical variants used to denote clinical events is employed to support boundary detection. Table 1 reports the Italian patterns used to identify event types. We focus on the key clinical events in the oncological patient trajectory, namely: imaging (including instrumental examinations such as CT, MRI, X-ray, and ultrasound), surgery, laboratory tests (where biomarker values are typically reported), treatment, and biopsy. Finally, flow 1 in Figure 1 represents the Regex-only segmentation.

3.2.2 Regex + LLM

In the two-stage cascade approach, the clinical-history section is first segmented into event units

using the date-based regex rules described above. Each resulting segment is then provided as input to an LLM, to which it is explicitly requested to identify further sub-segments corresponding to key clinical events, based on a predefined list of domain-specific acronyms. These acronyms are used as anchors to detect meaningful intra-segment boundaries that typically introduce events not detected through the above date-regex approach. The LLM returns a structured JSON output, which is automatically parsed to extract the corresponding facts and store them in a normalized representation for a granular segmentation. Flow 2 in Figure 1 represents this strategy. The prompt used is the following (we report the English version for better understanding):

```
Segment the following clinical text into separated
facts based ONLY on medical acronyms.

ACRONYMS that indicate a new segment:
- Imaging: {list of acronyms}
- Surgery: {list of acronyms}
- Laboratory: {list of acronyms}
- Therapy: {list of acronyms}
- Biopsy: {list of acronyms}
- Other: {list of acronyms}

Provide the output ONLY in JSON format without
preambles or explanations.
The facts must correspond exactly to the segments
     of
the clinical report.
Example output: {fact1: <text of fact 1>, ..}.

If there are no acronyms, return a JSON with a
single fact: {fact1: <text of fact 1>}.

TEXT: {input text}
```

Event type	Acronyms / keywords
Imaging	TC; TAC; TCTAP; TCTB; RM; RMN; PET; ECO; Ecografia; ETG; ECOTV; RX
Surgery	Laparoscopia; LPS; Laparotomia; LPT; Intervento chirurgico
Laboratory	CA-125; CA125; CEA; HE4; AFP; Markers; Marcatori
Therapy	NACT; Chemio; CHT; I LINEA; II LINEA; III LINEA
Biopsy / Histology	Biopsia; Istologico; EID

Table 1: Domain-specific acronyms and lexical variants used for event segmentation and tagging. All reported acronyms and keywords correspond to synonyms or abbreviations of the respective event type.

3.2.3 Regex + LLM + Recovery

Building on recent grounding techniques such as those proposed in MedSlice (Davis et al., 2025), this third strategy extends the previous cascaded regex+LLM pipeline by introducing an additional recovery procedure. This was necessary because, despite explicit instructions to extract segments verbatim, LLMs frequently introduce subtle rephrasings, summarize content, or omit punctuation. These "hallucinations of form" prevent direct string comparison and necessitate fuzzy alignment to map the LLM's semantic boundaries back to the original, legally-valid source text. After the initial regex-based date segmentation and the subsequent LLM refinement, this module verifies and reconstructs segments through the following steps:

1. **Fuzzy Matching.** Each LLM-generated segment is aligned to the original document using fuzzy string matching with the available Python library[1], which returns a similarity score s and the corresponding character offsets. Defining a threshold τ, if $s \geq \tau$, the segment is considered valid and the exact substring is extracted from the original text using the matched positions.

2. **Gap Filling.** Segments with $s < \tau$ are marked as invalid. When an invalid segment is located between two valid segments, it is replaced by directly recovering the original text spanning the gap between the end of the preceding valid segment and the start of the following one, ensuring complete coverage of the source document.

3. **Rollback.** If the proportion of the remaining invalid segments exceeds a predefined threshold ρ, the LLM-based segmentation is discarded entirely and the system reverts to the regex-only method.

Flow 3 in Figure 1 represents this approach. After a preliminary grid search over the alignment parameters, we selected the configuration that provided the best balance between alignment precision and coverage. Specifically, we set the similarity threshold to $\tau = 85\%$ and the Rollback ratio to $\rho = 0.5$, as this combination yielded the most stable and consistent performance across our experiments.

3.3 Event-Date Linking

After segmentation using one of the three previously described strategies, we introduce an additional processing step aimed at associating a temporal reference with each extracted event before performing event tagging.

[1] https://github.com/rapidfuzz/RapidFuzz

For segments obtained through date-based separation, the associated date is directly inherited from the date expression used as the segmentation boundary.

In contrast, for segments generated through the secondary step (which is acronym-based rules in the fully-regex strategy or LLM-based segmentation in the cascade approaches), the event remains temporarily without an associated date and subsequently handled during the post-processing phase.

3.4 Event Tagging

The date-linked segments are assigned a single event label through a pattern-matching procedure. Specifically, each segment is scanned for the presence of the acronyms listed in Table 1, which define the event categories. When multiple patterns are present within the same segment, the label corresponding to the earliest occurring pattern is selected. This strategy ensures a deterministic and consistent tagging process for identifying the key diagnostic events in the patient trajectory.

3.5 Post-Processing

After tagging, the segments undergo a cleaning and normalization procedure to ensure temporal consistency and structural coherence. First, dates are normalized by expanding two-digit years using a pivot rule (years ≤ 25 mapped to the 2000s and ≥ 26 to the 1900s) and assigning the first day of the month to month–year expressions. Segments without an explicit date inherit the temporal reference from the immediately preceding segment. When only month and year information is available and the preceding segment specifies a full date within the same month, the current date is shifted to one day after the previous event (this imputation rule was agreed upon with the clinical experts to maintain the chronological sequence of the patient's history). Malformed or truncated years are corrected by locating the nearest valid four-digit year and inferring the appropriate value based on month comparison. Finally, consecutive segments with the same event label and identical date are merged through text concatenation. This post-processing step mitigates over-segmentation errors, ensuring that a clinical event incorrectly divided into multiple fragments, is reconstructed as a single, semantically coherent unit.

4 Experiments

4.1 Input Data

The original dataset comprises approximately 1600 patients with more than 5000 clinical notes written in Italian language. From this larger corpus, we constructed a gold standard consisting of 343 text segments for evaluation, derived from reports belonging to 20 patients. During the gold standard annotation process, a text segment was strictly defined as an independent temporal event. The segments and their associated event tags were manually annotated by a clinical expert. Furthermore, to ensure an unbiased evaluation, all regex patterns and the acronym dictionary were initially designed and tuned on a separate development set of reports that do not overlap with the 20 patient reports used for testing.

An overview of the gold dataset is provided in Table 2, while Figure 2 illustrates the distribution of event types across reports.

Characteristic	Value
Number of Reports	20
Total Segments	343
Mean Segments per Patient	17.1

Table 2: Gold Standard dataset statistics.

4.2 Segmentation Setup

All experiments were conducted on a workstation equipped with an NVIDIA L40S-48C GPU (48 GB VRAM). For the hybrid segmentation strategies, LLM inference was executed using `llama.cpp`[2]. We evaluated two domain-specific medical language models: MedGemma (27B) (Sellergren et al., 2025) and MedicalQwen3 (14B) (Yang et al., 2025a), in particular we used `unsloth/medgemma-27b-it-GGUF` and `mradermacher/MedicalQwen3-Reasoning-14B-IT-i1-GGUF`. Both models were deployed in GGUF format using `Q6_K` quantization. Furthermore, evaluation on segmentation was assessed through the comparison among the gold and computed segments, using five complementary metrics. Table 3 reports such results averaged over segments for each experiment, while further details about the metrics are listed below:

Pk. Measures the probability that two points k tokens apart are incorrectly classified as belonging

[2]https://github.com/ggml-org/llama.cpp

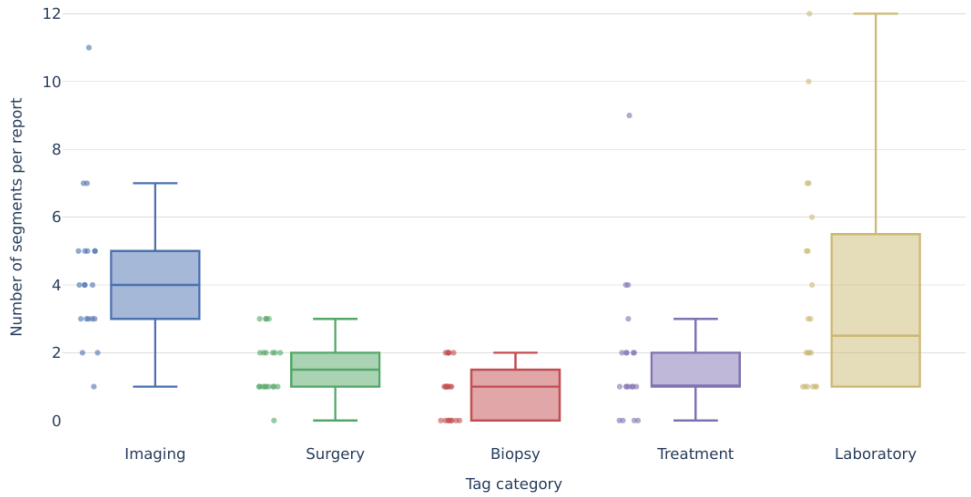

Figure 2: Distribution of segments per report, by tag event type.

to the same or different segments (lower is better) (Beeferman et al., 1999). For this metric, the pk function of the `SegEval` Python library was used.

WindowDiff. Counts boundary mismatches within a sliding window of size k, penalizing both missed and spurious boundaries (lower is better) (Pevzner and Hearst, 2002). For this metric, the `window_diff` function of the `SegEval` Python library was used (Fournier, 2013a).

Boundary Similarity. Computes an F1-style agreement between output and gold boundary positions (higher is better) (Fournier, 2013b). For this metric, the `boundary_similarity` function of the `SegEval` Python library was used (Fournier, 2013a).

Segment Count Accuracy. Quantifies structural agreement as $1 - |n_{\text{pred}} - n_{\text{gold}}|/n_{\text{gold}}$ (higher is better).

Text Overlap IoU. Measures the average Jaccard similarity between matched output and gold segments (higher is better).

Boundary-based metrics (Pk, WindowDiff, and Boundary Similarity) were computed at the *character level*. Predicted segments were converted into character-count ("mass") representations using the `SegEval` library (Fournier, 2013a). To account for minor formatting discrepancies introduced by LLMs (e.g., extra whitespaces), predicted masses were proportionally aligned to the gold-standard length through an `align_masses` procedure. For Pk and WindowDiff, the window size k was dynamically set to half the average gold segment length for each report. Conversely, Text Overlap IoU was computed at the *word level* using whitespace-tokenized segments and Jaccard similarity between greedily matched predicted and gold segments. Segment Count Accuracy and downstream F1 scores were computed globally across all reports.

4.3 Tagging Setup

Event classification of text segments was evaluated by comparing the gold and output segment tags using the F1 metric. The comparison relies on aligning gold-standard and predicted segments, which are not always perfectly matched: the number of output segments may differ from the gold standard, leading to over-segmentation or under-segmentation.

To address this, a fuzzy matching strategy was adopted. For each gold segment, the most semantically similar output segment is identified based on textual similarity. An output segment is considered a valid match only if its similarity with the corresponding gold segment exceeds an 80% threshold. This threshold is intentionally less strict than the one used in the recovery phase, as the goal here is to associate segments referring to the same underlying event type and enable a fair comparison during tagging evaluation, rather than to enforce precise boundary reconstruction.

Once matched, an output segment cannot be assigned to another gold segment. Unmatched gold segments (due to under-segmentation) are treated as False Negatives, while unmatched output seg-

Metric	Regex	Regex + MQ + Recovery	Regex + MG + Recovery	Regex + MQ	Regex + MG
Pk (↓)	**0.058 ± 0.080**	0.115 ± 0.094	0.076 ± 0.088	0.209 ± 0.125	0.149 ± 0.109
WindowDiff (↓)	**0.102 ± 0.096**	0.185 ± 0.110	0.125 ± 0.100	0.294 ± 0.139	0.225 ± 0.116
Boundary Sim. (↑)	**0.538 ± 0.353**	0.268 ± 0.265	0.459 ± 0.305	0.192 ± 0.249	0.288 ± 0.256

ments (due to over-segmentation or hallucinated boundaries) are treated as False Positives, ensuring that the reported F1 scores penalize segmentation errors.

Table 4 reports the results for each event type and overall across all experiments.

4.4 Results and Discussion

4.4.1 Segmentation Findings

Table 3 reports the segmentation performance across five configurations, where metrics are computed at the segment level and then averaged (mean ± std). Overall, the pure Regex strategy achieves the best results on most boundary-sensitive metrics, with the lowest Pk (0.058) and WindowDiff (0.102), and the highest Boundary Similarity (0.538) and Segment Count Accuracy (0.919), confirming the effectiveness of deterministic rules for precise boundary detection and segment preservation.

Among LLM-based approaches, MedGemma with Recovery shows the closest performance to Regex on structural metrics (Pk = 0.076; WindowDiff = 0.125; Seg. Count Acc. = 0.855), confirming the utility of Recovery in reducing boundary errors. Removing the Recovery mechanism leads to a clear degradation for both models (e.g., MedGemma Pk increases from 0.076 to 0.149), highlighting its stabilizing effect.

Interestingly, the best Text Overlap IoU is achieved by MedicalQwen3 with Recovery (0.833), slightly outperforming Regex (0.739). This suggests that, although LLM-based segmentation may not perfectly align with gold-standard boundaries, it captures semantic content.

The relatively low Boundary Similarity scores for LLM-based methods can be attributed to over- and undersegmentation effects. In particular, the introduction of spurious boundaries (oversegmentation) and occasional missed splits (undersegmentation) strongly penalize this F1-style boundary metric, even when Pk and WindowDiff indicate overall reasonable segmentation quality.

Finally, the relatively high standard deviations (especially for Boundary Similarity and Segment Count Accuracy) indicate notable inter-patient variability, likely due to differences in report structure and event density, which affect segmentation difficulty. Overall, Boundary Similarity is the most affected metric, showing high variability across all configurations, whereas Pk and WindowDiff remain more stable. The Regex approach exhibits the lowest standard deviations, likely because it was specifically engineered to handle the structural complexity of this dataset. However, when moving to different data sources, LLM-based techniques may offer greater generalizability.

4.4.2 Tagging Findings

Table 4 reports the F1 scores for event tagging under different segmentation strategies, both per category and overall. The results clearly show that segmentation quality directly impacts classification performance. In line with Table 3, the fully Regex-based segmentation (being the most accurate in boundary detection) also achieves the best overall F1 score (0.757), confirming that more precise segmentation leads to better downstream event classification.

At the category level, Regex outperforms the other methods in most cases (Imaging, Surgery, and Biopsy). However, the cascaded approaches with Recovery show competitive or superior results for Treatment (Regex + MedicalQwen3 + Recovery, 0.721) and Laboratory events (Regex + MedGemma + Recovery, 0.841), suggesting that for semantically richer or more variable segments, the LLM-enhanced strategy may better capture contextual cues.

Surgery achieves the highest F1 scores overall: it likely benefit from clearer structural markers and more explicit terminology, which facilitate both segmentation and tagging. In contrast, Biopsy shows the lowest performance across all config-

Event Tag	Regex	Regex + MQ + Recovery	Regex + MG + Recovery	Regex + MQ	Regex + MG
Imaging	**0.815**	0.749	0.812	0.682	0.709
Surgery	**0.923**	0.767	0.788	0.579	0.743
Biopsy	**0.605**	0.465	0.359	0.458	0.340

urations, likely because biopsy information is often embedded within surgical descriptions and not clearly separated, making both boundary detection and label assignment more challenging.

5 Conclusions

In this study, we investigated semantics-driven text segmentation as a core component for identifying temporal clinical events in oncological reports. By comparing a fully rule-based approach and a cascaded regex–LLM pipeline with and without a recovery mechanism, we demonstrated how segmentation quality directly impacts downstream event type identification.

The results show that regex-based segmentation ensures superior boundary precision and structural stability, while LLM-enhanced approaches better preserve semantic coherence within segments. These findings support the view that segmentation should be treated as a preprocessing step in order to make reports more easily processable for downstream analysis, but it also consists of a modelling task that enables reliable reconstruction of the patient's clinical trajectory.

As future work, we aim to extend this study by scaling up the evaluation dataset and involving multiple annotators to improve the reliability of the gold standard. We also plan to validate the framework on multiple external, heterogeneous datasets to further assess generalization. Methodologically, future iterations will explore the LLM-only segmentation on the full-report to better isolate the contribution of the recovery mechanism, and conduct an ablation study to decouple the impact of gap-filling and global rollback. Finally, we aim to replace the rule-based event tagger with a transformer-based classifier to evaluate downstream performance.

6 Limitations

While the results are promising, several directions for further improvement emerge. Expanding the evaluation dataset beyond the current 343 segments would enable a more robust assessment of generalization, and involving multiple annotators would strengthen the reliability of the gold standard. From a modeling perspective, evaluating LLMs in full precision (without quantization) could better capture their intrinsic capabilities, while a systematic optimization of the recovery mechanism may further enhance performance. Finally, extending event tagging beyond regex-based rules toward transformer-based approaches represents a natural step toward a more flexible and fully data-driven pipeline.

Ethics Statement

The use of data for this study has been implemented in full compliance with ethics and GDPR requirements. Specifically, data usage has been approved by the Ethics Committee of our hospital to conduct the presented research and the de-identification of sensitive data has been performed. Approval protocol number from the relevant Ethics Committee can be provided on request.

Abstract

Clinical reasoning over electronic health records (EHRs) involves heterogeneous operations, including text interpretation, numerical computation, temporal filtering, and guideline-based aggregation. However, many existing LLM-based approaches still cast these heterogeneous operations as a single end-to-end generation process, obscuring their different reliability requirements and making intermediate failures difficult to inspect. We therefore propose a framework based on operation-mechanism alignment that represents clinical reasoning as a directed acyclic graph of typed operations, where each node is assigned to the execution mechanism best suited to its reliability requirements. The framework also preserves structured evidence provenance for intermediate results. Across six clinician-annotated binary decision tasks, the framework outperforms direct prompting, single-step retrieval-augmented prompting, and chain-of-thought baselines, supporting operation-mechanism alignment as a practical design principle for reliable clinical reasoning over EHRs.

1 Introduction

Clinical reasoning over electronic health records (EHRs) often requires several different types of operations within the same task. For example, staging chronic kidney disease requires interpreting free-text nephrology notes to assess proteinuria, computing eGFR from a validated formula, selecting laboratory values within clinically relevant time windows, and combining the findings under guideline-defined logic. These steps have different reliability requirements. Numerical computation and temporal filtering require exact execution, because an arithmetic or date-filtering error can change the assigned disease stage. Proteinuria assessment, by comparison, depends on flexible interpretation of heterogeneous clinical language. Treating these steps as a single end-to-end generation problem obscures these operational differences and makes failures difficult to trace, inspect, or correct.

Common prompting-based approaches still cast clinical reasoning as a single inference pass. The model is prompted over either the full patient record or a retrieved subset of documents. Although retrieval-augmented generation can improve evidence relevance, the same generation step must still select evidence, perform calculations, apply clinical rules, and produce the final decision. This creates two practical problems. First, errors in intermediate operations, particularly numerical computation and temporal filtering, can propagate silently to the final answer. Second, the output is difficult to inspect because intermediate decisions and evidence assignments are not explicitly represented.

We argue that clinical reasoning should be decomposed into typed operations, including text interpretation, numerical computation, temporal filtering, and criteria aggregation. Different operation types should not be handled by the same generation step. Language interpretation can be handled by LLM-based evaluators, numerical and temporal operations by deterministic tools, and criteria aggregation by explicit logical operators. We call this principle *operation-mechanism alignment*. We implement this principle by representing clinical reasoning as a directed acyclic graph, where each node corresponds to a typed operation and each intermediate result carries structured evidence provenance. This makes the reasoning process inspectable at each step, rather than hidden behind a single generation call.

We evaluate the framework on clinician-annotated clinical reasoning tasks and compare it against direct prompting, single-step retrieval-augmented prompting, and chain-of-thought prompting baselines. Our contributions are:

(1) we formalize clinical reasoning over EHRs as a graph of typed operations with explicit operation-mechanism alignment, rather than single-pass generation; (2) we present a framework that routes evaluation, computation, and aggregation to distinct execution mechanisms while maintaining evidence provenance throughout; and (3) we provide an evaluation showing the benefits of this design over standard prompting and retrieval-based baselines.

We evaluate the framework on clinician-annotated clinical reasoning tasks and compare it with baselines including direct prompting, single-step retrieval-augmented prompting, and chain-of-thought prompting. Our contributions are: (1) we formalize EHR-based clinical reasoning as a graph of typed operations with explicit alignment between operation types and execution mechanisms; (2) we implement an executable framework that routes language evaluation, deterministic computation, temporal filtering, and logical aggregation to distinct mechanisms while preserving evidence provenance; and (3) we provide an evaluation showing the benefits of this structured design over standard prompting and retrieval-based baselines.

2 Related Work

Recent benchmarks study clinical reasoning with large language models in patient-specific EHR settings, requiring recovery of clinical state from records rather than decontextualized questions or pre-structured cases. EHRNoteQA and ER-REASON operationalize this setting through multi-note questions, emergency-department workflow tasks, longitudinal heterogeneous notes, and clinician- or physician-authored supervision (Kweon et al., 2024; Mehandru et al., 2025). DR.BENCH and MedHELM further show that clinical reasoning spans tasks with different operational demands, motivating methods beyond monolithic prompt-to-answer formulations, while related application studies apply LLMs directly to gold-labeled EHRs in largely one-pass prompting settings (Gao et al., 2023; Bedi et al., 2025; Zhang et al., 2024).

Retrieval-augmented generation (RAG) is widely used to improve grounding in medical question answering and clinical reasoning over EHRs. MIRAGE/MedRAG shows that RAG can outperform chain-of-thought prompting while exposing retrieval-specific issues such as context position effects (Xiong et al., 2024b). i-MedRAG and Self-BioRAG explore multi-round evidence acquisition and self-critique for complex questions and retrieval noise (Xiong et al., 2024a). In EHR settings, ExpRAG uses case-based retrieval from other patients' discharge reports, while EHR-RAG combines temporally and event-aware retrieval with iterative refinement for long-horizon prediction (Ou et al., 2025; Cao et al., 2026). However, these approaches still typically execute clinical reasoning over EHRs within a single generative mechanism, even when it involves temporal filtering, numeric aggregation, and guideline-like decision logic.

Temporal and longitudinal reasoning remains challenging for LLMs in clinical reasoning over EHRs. TIMER introduces a temporal benchmark and instruction-tuning method grounded in time-indexed patient-record segments, suggesting that time-awareness is not captured by standard instruction tuning (Cui et al., 2025). Long-context clinical summarization and prediction studies similarly show that even with longer context windows, RAG variants, and chain-of-thought prompting, models struggle to maintain chronological coherence over extended patient trajectories (Kruse et al., 2025). These findings suggest that some EHR reasoning subproblems, especially temporal filtering and longitudinal aggregation, may require explicit operators such as time-window queries rather than free-form generation.

Graph-structured orchestration and agentic tool use provide another adjacent direction. MedAgentBench offers a Fast Healthcare Interoperability Resources (FHIR)-compliant environment for benchmarking medical agents on patient-specific record workflows (Jiang et al.). DSPy provides graph- or pipeline-based composition patterns, ReAct and Toolformer study tool invocation, and Graph-of-Thought extends linear chains to graph-structured intermediate thoughts (Khattab et al., 2023; Yao et al., 2022; Schick et al., 2023; Besta et al., 2024). However, these systems mainly use graphs to organize reasoning steps or tool calls, rather than define operation semantics or use operation types to determine execution mechanisms.

Another concern in clinical reasoning over EHRs with LLMs is how outputs are grounded, verified, and linked to patient-record evidence. VeriFact studies patient-record-grounded verification of generated clinical narratives, while FactEHR shows that clinical fact decomposition varies across LLMs

and note types (Chung et al., 2025; Munnangi et al., 2024). Related evaluation work validates LLM-as-a-judge assessment of multi-document EHR summaries aligned with clinician rubrics (Croxford et al., 2025). Standards such as CDS Hooks and CPG-on-FHIR show how guideline logic and evidence links can be made computable and integrated with EHR workflows. However, much of this literature attaches evidence to final outputs through verification, evaluation, or post hoc citation, rather than preserving provenance throughout intermediate reasoning steps.

In summary, existing work has improved clinical reasoning over EHRs through prompting, retrieval, tool use, and output verification. To the best of our knowledge, this is the first work to model clinical reasoning over EHRs as heterogeneous, typed operations routed to mechanisms aligned with reliability requirements, while preserving structured provenance across intermediate results.

3 Approach

Our central design principle is *operation-mechanism alignment*: clinical reasoning over EHRs should be modeled as a composition of heterogeneous operations with different reliability requirements, rather than as a monolithic generation problem. In our framework, the execution mechanism depends on the operation type. Language-mediated clinical judgment is handled by LLM-based modules; numeric, temporal, and unit-sensitive computation is handled by deterministic tools; and criteria aggregation is handled by explicit logical operators. This hybrid neural-symbolic design preserves interpretive flexibility while reducing avoidable errors in exactly computable operations.

Throughout this section, we use a **chronic kidney disease (CKD) assessment** task as a running example. The clinical question is binary: *does this patient have advanced-stage CKD with rapid kidney function decline?* Clinically, this decision is driven primarily by the estimated glomerular filtration rate (eGFR): advanced stage corresponds to eGFR below a threshold, and rapid decline to the eGFR decline rate over time. Answering it therefore requires interpreting clinical notes and laboratory reports to determine whether the patient has persistent albuminuria as a supporting criterion (evaluation), computing current and historical eGFR values from laboratory measurements and estimating the annual decline rate as the central quantitative driver (computation), and combining these results under clinical guideline logic to produce a yes-or-no decision (aggregation). Relevant clinical details are introduced as each operation type is discussed.

3.1 Problem Formulation

We define a clinical reasoning task template as $T = (Q, C)$, where Q is a task query describing the clinical question to be answered and C is a set of clinical criteria and decision constraints relevant to the task. Given a patient record D, the goal is to predict a binary label $\hat{y} \in \{0, 1\}$.

In the CKD example, Q asks whether the patient has advanced-stage CKD with rapid decline. C includes an eGFR threshold for advanced stage, an annual eGFR decline threshold for rapid progression, albuminuria severity rules, and a persistence requirement ($\geq$3 months). D comprises laboratory results, clinical notes, and demographics.

To solve (T, D), we instantiate a directed acyclic graph $G = (V, E, \tau)$, where each node $v_i \in V$ is associated with a typed operation $\tau(v_i) \in \{\text{EVALUATE}, \text{COMPUTE}, \text{AGGREGATE}\}$ and edges encode dependency constraints. Each node is executed over node-specific evidence e_i derived from D for that subproblem, together with any required upstream outputs $\{z_j : (v_j, v_i) \in E\}$. For some nodes—particularly aggregation nodes that only compose upstream results—e_i may be empty and execution depends entirely on upstream outputs. The node output $z_i = (r_i, \mathcal{E}_i)$ is a structured intermediate result consisting of an operation result r_i and supporting evidence references $\mathcal{E}_i$.

- **Evaluation nodes** determine whether a clinical condition is satisfied using language-mediated reasoning over retrieved evidence; in the running example, this includes assessing persistent albuminuria from notes and laboratory reports.
- **Computation nodes** invoke deterministic operators for numeric, temporal, or unit-sensitive operations; in the running example, these compute current and historical eGFR values and the annualized decline rate.
- **Aggregation nodes** combine upstream outputs into higher-level criterion decisions or the final prediction $\hat{y}$; in the running example, eGFR-based staging serves as the pri-

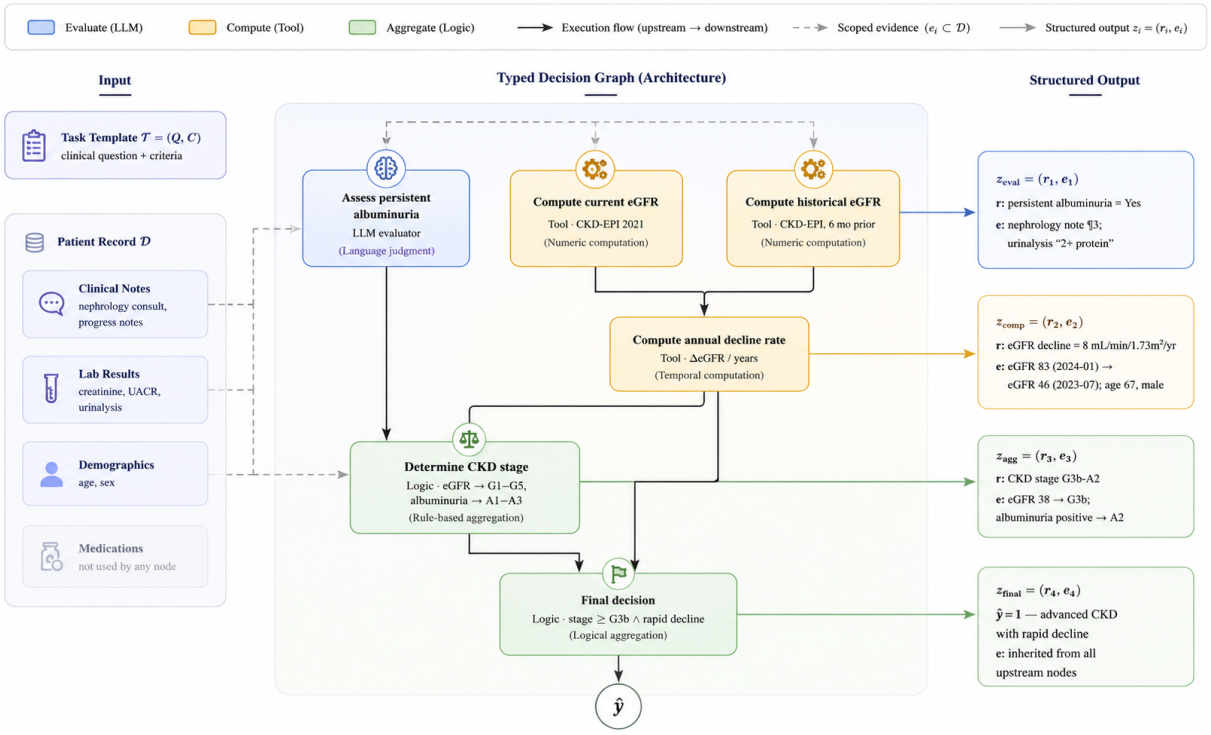

Figure 1: Overview of our framework. A clinical reasoning task template and patient record are instantiated as a typed decision graph. Each node is routed to the execution mechanism aligned with its operation type: LLM-based evaluators for language-mediated judgment, deterministic tools for numeric and temporal computation, and explicit logical operators for aggregation. Node outputs are structured and evidence-grounded, enabling provenance-preserving execution traces. Dashed arrows indicate scoped evidence: different nodes operate over different subsets of the patient record, rather than a single shared context.

mary backbone, combined with the albuminuria category and the progression criterion under guideline logic.

Figure 1 illustrates this decomposition for the CKD running example, showing how different patient record sources provide scoped evidence to specific nodes, how nodes are routed to distinct execution mechanisms, and how each node output carries structured evidence references.

3.2 Task Decomposition and Execution

A key property of the graph is that each node operates on a *scoped* subproblem with its own evidence requirements, rather than on a single shared context. This contrasts with retrieval-augmented approaches, where one context bundle must support evidence identification, calculation, temporal reasoning, and final decision making at once. In our framework, evidence is constructed locally: proteinuria evaluation uses clinical notes and urinalysis reports, whereas eGFR computation uses structured laboratory observations within defined temporal windows.

Edges in G encode explicit data dependencies. The eGFR decline computation depends on both the current and historical eGFR computations; the final aggregation depends on the eGFR-based staging, the decline rate, and the albuminuria evaluation. This dependency structure determines a partial execution order: independent nodes—such as the albuminuria evaluation and the two eGFR computations—can execute in parallel, while dependent nodes wait for upstream results.

The graph G is instantiated from the task template T before execution. Each criterion in C maps to one or more nodes in V, and dependencies are derived from the logical relationships among criteria. This turns a declarative task specification into an executable plan, separating *what* must be decided from *how* each subproblem is resolved.

3.3 Operation-Mechanism Alignment

The three node types are not merely a descriptive taxonomy; they determine which execution mechanism is invoked. This section describes how each mechanism operates and why the routing matters.

Evaluation: LLM-based clinical judgment. Evaluation nodes handle operations that require interpreting diverse and often ambiguous clinical language. In the running example, determining whether a patient has persistent albuminuria may involve reasoning over a urinalysis showing "2+ protein," a nephrology consult noting "persistent albuminuria documented over the past 4 months, now in the moderately increased range," and structured uACR (urine albumin-to-creatinine ratio) measurements—all expressed differently and scattered across the record. These judgments resist rule-based encoding because the space of possible phrasings is open-ended. LLM-based reasoning is therefore the appropriate mechanism for evaluation nodes: it provides the flexibility to interpret heterogeneous clinical text, at the cost of being non-deterministic.

Computation: deterministic tools. Computation nodes handle operations where correctness is exactly verifiable and LLM generation introduces unnecessary risk. In the running example, computing the patient's estimated glomerular filtration rate (eGFR) requires applying a validated clinical formula (CKD-EPI 2021) to serum creatinine, age, and sex. A small numeric error—an eGFR of 46 versus 38—can shift the patient between adjacent disease stages, directly changing the clinical decision. The same concern applies to unit conversion (creatinine reported in mg/dL versus μmol/L), temporal filtering (selecting laboratory values within a specific time window), and rate-of-change computation (pairing values across time points and annualizing the difference). These operations are delegated to validated deterministic tools: clinical calculators for formula evaluation, unit-aware conversion routines, temporal window filters, and arithmetic operators for derived quantities.

Aggregation: explicit logical composition. Aggregation nodes combine upstream results under predefined clinical logic rather than open-ended synthesis. In the CKD example, the final staging decision follows clinical guidelines: map eGFR to a disease stage, combine it with the albuminuria category, and check the progression criterion. This composition is a deterministic function of its inputs and should not be subject to LLM variability. Aggregation therefore uses explicit logical operators—boolean combinations, threshold comparisons, and lookup tables—to produce the final prediction $\hat{y}$.

Why alignment matters. The key claim is not that any one mechanism is universally superior, but that misalignment between operation type and execution mechanism introduces avoidable errors. Delegating eGFR computation to an LLM risks arithmetic mistakes in a context where precision determines the clinical outcome. Conversely, attempting to encode proteinuria assessment as a rule-based system would require enumerating an impractical number of textual patterns. Operation-mechanism alignment is the principle that each node should be executed by the mechanism whose failure modes are least harmful for that operation's reliability requirements.

3.4 Evidence-Grounded Output

Every node output $z_i = (r_i, \mathcal{E}_i)$ includes structured evidence references $\mathcal{E}_i$ that link the result back to specific records in the patient record D. These references are not post-hoc citations but are constructed during execution: evaluation nodes record which passages informed their judgment, computation nodes record which laboratory values and timestamps were used, and aggregation nodes inherit the evidence from all upstream nodes they compose.

This design serves two purposes. First, it supports clinical auditability: a reviewer can trace any component of the final decision back to its source evidence without re-running the system. Second, it makes unsupported conclusions structurally detectable—if a node produces a result without corresponding evidence references, this is visible in the output structure rather than hidden in a free-text rationale.

In the running example, the final decision that a patient has advanced-stage CKD with rapid decline is accompanied by the specific laboratory values and their timestamps used to compute both eGFR values, the clinical note passages that supported the albuminuria assessment, and the guideline rule that combined these into the staging decision. Each component is individually inspectable.

4 Experiments

4.1 Data and Tasks

We evaluate the framework on de-identified EHR data from selected subsets of MIMIC-III and MIMIC-IV, together with a de-identified partner-hospital dataset (from Cone Health). The evaluation covers six binary clinical decision tasks under

a shared annotation protocol.

COPD exacerbation history. The first task asks whether a patient has a confirmed recent COPD exacerbation history, defined by recurrent outpatient exacerbation treatment, at least one inpatient hospitalization for acute COPD exacerbation, or repeated prescription courses of systemic corticosteroids or antibiotics for exacerbation within the past year. The task is evaluated on two cohorts under the same task definition: 151 MIMIC-III patients (108 positive, 43 negative), and 100 patients from the de-identified Cone Health dataset (18 positive, 82 negative).

Asthma exacerbation risk. The second task determines whether a patient with confirmed asthma is at risk of exacerbation or asthma-related death under the Global Initiative for Asthma (GINA) 2024 criteria (Global Initiative for Asthma, 2024), including severe exacerbation history, poor symptom control, inadequate ICS treatment, high SABA use, low FEV_1, relevant comorbidities, or prior near-fatal events. The cohort comprises 50 MIMIC-IV patients (46 positive, 4 negative).

Cancer cachexia screening (Fearon). The third task applies the cachexia criteria of Fearon et al. (Fearon et al., 2011), requiring an underlying cancer diagnosis together with weight loss $>5\%$ over 6 months, or BMI <20 kg/m^2 with weight loss $>2\%$, or sarcopenia with weight loss $>2\%$. The cohort comprises 50 patients (15 positive, 35 negative) from MIMIC-III and IV.

Cancer cachexia screening (Evans). The fourth task applies the cachexia criteria of Evans et al. (Evans et al., 2008), requiring an underlying chronic disease including cancer, involuntary weight loss $\geq 5\%$ in the past 12 months, and at least three of five additional features: decreased muscle strength, anorexia, low fat-free mass index, abnormal biochemistry, or decreased functional status. The cohort comprises 50 patients (8 positive, 42 negative) from MIMIC-III and IV.

Confirmed CKD diagnosis. The fifth task asks whether the patient has an explicit documented diagnosis of chronic kidney disease (CKD) in the clinical record. The cohort comprises 100 patients from the de-identified Cone Health dataset (25 positive, 75 negative).

At-risk CKD identification. The sixth task asks whether a patient is at risk of CKD but does not yet have a confirmed diagnosis. Positive cases require at least one recognized CKD risk factor or non-chronic kidney abnormality, including hypertension, diabetes mellitus, cardiovascular disease, prior AKI/AKD, reduced eGFR, elevated albuminuria, urine sediment abnormalities, hematuria, histology abnormalities, tubular or electrolyte disorders, or structural kidney abnormalities on imaging, while excluding patients who meet confirmed CKD criteria. The cohort comprises 100 patients from the same Cone Health dataset (42 positive, 58 negative).

Gold labels are created by clinician annotators on curated subsets using task-specific criteria. For each case, annotators provide the expected binary label and, when applicable, supporting evidence from the record. Each case is reviewed by two clinician annotators independently and any disagreement is resolved by a third clinician annotator or with consensus.

All methods are evaluated using GPT-5.4 as the primary model; direct-prompting sensitivity to model choice is additionally assessed with GPT-5.2 and Claude Opus 4.6 (see Appendix A).

4.2 Baselines

We compare the proposed framework against three baseline settings that use the same underlying patient records and task definitions, but differ in how evidence is constructed and how reasoning is organized:

- **Direct prompting**: The patient record is provided to the model in a single pass with a task instruction, without explicit task decomposition, intermediate structure, or tool use. This baseline tests whether a general-purpose prompt over the available patient context is sufficient for the binary decision.

- **Single-step RAG**: Task-relevant evidence is retrieved once using the task query, and the retrieved context is then provided to the model for end-to-end reasoning in a single generation step. This baseline isolates the value of retrieval while still requiring one model call to perform evidence interpretation, calculation, temporal reasoning, and final decision making jointly.

- **Chain-of-thought (CoT) prompting**: The model receives the same retrieved context as

in the single-step RAG baseline, but is explicitly prompted to reason step-by-step before producing the final label. This baseline tests whether prompting for intermediate natural-language reasoning alone is sufficient, without explicit task-scoped execution or deterministic tool support.

For fairness, all methods use the same underlying task definitions, model set, and binary output schema. When the full patient record exceeds the model context budget, the direct-prompting baseline uses a shared record-linearization pipeline with budget-matched truncation, while retrieval-based baselines and our framework use the same task description and retriever configuration wherever applicable. These baselines are therefore designed to separate the effects of retrieval, explicit reasoning structure, and tool-supported execution rather than by differences in model access or output format.

4.3 Metrics

Because our gold labels are binary clinical decisions, we use sensitivity, specificity, precision, and F1 as the primary task metrics. Accuracy is included as a supplementary metric.

4.4 Results

Table 1 reports the main comparison across reasoning strategies using GPT-5.4 on all six tasks.

On COPD exacerbation, the framework achieves the best F1 and accuracy on both cohorts. On MIMIC-III, it reaches F1 = .893 and accuracy = .861, with a marked increase in specificity (.977 versus .349 for direct prompting and .186 for both retrieval-based baselines). The same pattern holds on Cone Health, where the framework attains F1 = .882 and specificity = .988, while baseline specificities range from .780 to .866; the four methods identify the same set of 15 true positives but the framework yields only 1 false positive versus 11–18 for the baselines. The consistent specificity advantage across two independent datasets is consistent with baseline methods over-predicting positive cases when temporal and diagnostic attribution must be resolved precisely, whereas deterministic temporal filtering and explicit diagnostic-attribution logic are associated with fewer false positives. On asthma exacerbation risk, the framework again achieves the best F1 (.957) and accuracy (.920) and is the only method with nonzero specificity (.500, 2/4). This specificity estimate should be interpreted cautiously because the task contains only four negative cases.

On cancer cachexia screening, the framework achieves the highest F1 and accuracy for both Fearon and Evans criteria. For the Fearon criteria, it attains F1 = .839 and accuracy = .900, while chain-of-thought prompting performs worst (F1 = .581). This result is consistent with the difficulty of applying quantitative thresholds, such as weight loss, BMI, and sarcopenia indices, through free-text step-by-step reasoning alone. For the more stringent Evans criteria, the framework reaches sensitivity = 1.00 and F1 = .727, compared with the best baseline F1 of .480, consistent with the difficulty of aggregating multiple concurrent conditions in a single-pass setup.

On the CKD tasks evaluated on Cone Health data, the framework achieves the highest F1 and accuracy on both tasks. For confirmed CKD diagnosis, it reaches F1 = .909 with perfect sensitivity (1.000), recovering all 25 confirmed cases; chain-of-thought and single-step RAG both reach .960 sensitivity but with one missed case each, while direct prompting lags further (F1 = .792, sensitivity = .760). Specificity is comparable across the four methods (.920–.947) on this task, so the framework's advantage concentrates on sensitivity rather than specificity. For at-risk CKD identification, the framework attains F1 = .900 and accuracy = .920, with the highest precision (.947) and specificity (.966); chain-of-thought is competitive on sensitivity (.881 versus .857 for the framework), but produces more false positives. Together, these results suggest that detailed multi-criteria CKD definitions can challenge single-pass reasoning, while decomposition into independent criteria evaluations is associated with stronger performance in these tasks.

Model sensitivity. As a secondary check, we repeated direct prompting with GPT-5.2 and Claude Opus 4.6. Performance varied by task and model, but model substitution did not eliminate the limitations of single-pass prompting; full results are provided in Appendix A. We therefore treat model choice as an important but orthogonal factor.

4.5 Discussion

The results reveal several consistent patterns across tasks.

Specificity as the differentiator. Across the six tasks, the proposed framework consistently achieves the highest or near-highest specificity.

Task	Method	Sens.	Spec.	Prec.	F1	Acc.
COPD Exacerbation (MIMIC-III)	Direct prompting	**.843**	.349	.765	.802	.702

Table 1: Main results across reasoning strategies (GPT-5.4). Bold indicates the best result per metric per task. Sens. = sensitivity, Spec. = specificity, Prec. = precision, Acc. = accuracy. †High class imbalance (46/4); specificity estimates are unstable due to very few negative cases.

This is most pronounced in COPD exacerbation across both cohorts (.977 vs. .349 for direct prompting on MIMIC-III; .988 vs. .780–.866 on Cone Health), cachexia under Evans criteria (.857 vs. .452), and asthma exacerbation risk, where all three baselines achieve zero specificity while the framework is the only method that correctly rejects any negative cases. On at-risk CKD, the framework reaches .966 specificity versus .862–.948 for baselines, with .947 precision versus .814–.921, suggesting it is more conservative in rejecting borderline cases that satisfy only one or two soft risk factors. On confirmed CKD, specificity differences across methods are small (.920–.947); the framework's lead instead concentrates on sensitivity (1.000 versus .760–.960), recovering all confirmed cases. The framework's explicit criteria decomposition and deterministic aggregation logic enforce the full set of diagnostic requirements (e.g., temporal windows, primary-diagnosis attribution, multi-condition conjunctions), preventing the model from short-circuiting to an affirmative answer when only partial evidence is present.

Structured execution outperforms unstructured reasoning. Chain-of-thought (CoT) prompting, which encourages step-by-step reasoning in natural language, does not consistently improve over direct prompting and in some cases degrades performance. On cachexia (Fearon), CoT achieves the lowest F1 of any method (.581 vs. .667 for direct prompting). This suggests that prompting the model to "think step by step" does not substitute for routing quantitative operations to deterministic tools. When intermediate steps involve numeric thresholds, weight-loss calculations, or temporal window enforcement, natural-language reasoning introduces opportunities for error that structured execution avoids.

Task complexity modulates framework advantage. The framework's advantage is largest on tasks requiring multi-step quantitative criteria and smallest on simple diagnostic lookup. These tasks share a common structure: evaluating multiple in-

dependent clinical criteria with their own evidence, chronicity, and exclusion rules. Providing such detailed criteria as a single instruction degrades baseline performance, which the framework avoids by decomposing the specification into independent, single-feature evaluations.

Relation to tool-using agents. Autonomous tool-using agents (e.g., ReAct-style systems (Yao et al., 2022) or Toolformer (Schick et al., 2023)) address a distinct problem: discovering task decomposition at inference time when the decomposition is unknown. In our setting the decomposition is known—each task graph is derived from a validated clinical guideline (e.g., GOLD 2025, KDIGO 2024). Letting an agent re-discover this structure at inference replaces a vetted plan with one assembled on the fly, sacrificing auditability without addressing how each step should be executed. The latter question—operation-mechanism alignment—is orthogonal to tool use: even a ReAct agent with calculator access must still decide when to invoke the calculator versus reason in natural language, which is the same alignment decision our framework resolves ahead of time. Our contribution therefore complements rather than substitutes for autonomous tool use.

5 Conclusion

We presented a framework that structures clinical reasoning over EHRs as a directed acyclic graph of typed operations, where each node is routed to the execution mechanism—LLM-based evaluation, deterministic computation, or explicit logical aggregation—best suited to its reliability requirements. Every intermediate result carries structured evidence provenance, making the reasoning process inspectable at each step.

Experiments on six clinician-annotated tasks across four disease areas show that this design consistently improves specificity over direct prompting, retrieval-augmented, and chain-of-thought baselines, with the largest gains on tasks involving multi-step quantitative criteria such as temporal filtering and threshold evaluation. The results also show that the framework's advantage diminishes on simpler diagnostic-lookup tasks, suggesting that operation-mechanism alignment is most valuable when clinical criteria demand heterogeneous reasoning operations that single-pass generation handles unreliably.

These findings support a general design principle: clinical decision support systems should match each reasoning operation to the mechanism whose failure modes are least harmful for that operation, rather than delegating all operations to a single generative model.

Limitations

Evaluation scope. Our evaluation covers six clinician-annotated binary decision tasks drawn from MIMIC-III, MIMIC-IV, and a de-identified partner-hospital dataset across four disease areas. Cohort sizes (50–151 patients per task) and the class imbalance in some tasks (e.g., 46/4 for asthma exacerbation risk) limit the precision of absolute per-task estimates; we therefore focus claims on relative comparisons across methods. Although clinicians were involved in task design and annotation, the auditability benefits of provenance traces remain to be evaluated systematically, including their effect on review efficiency, error detection, and decision review. Broader validation across additional institutions, languages, disease areas, and non-binary decision formats is a natural next step.

Manual task template construction. Task templates—including clinical criteria, node types, and dependency structure—are authored by domain experts for each task. This is a deliberate design choice: explicit expert-authored templates prioritize auditability, clinical face validity, and adherence to established guideline logic. At the same time, extending the framework to a new clinical task currently requires human authoring effort. Automating template construction from guideline text, clinical pathways, or existing decision-support artifacts is a promising extension that would improve scalability.

Mechanism-level ablation and error decomposition. Our experiments evaluate the framework holistically against end-to-end baselines, rather than isolating the contribution of each execution mechanism. A finer-grained ablation—holding the task graph fixed while varying which mechanism handles each node type, for instance routing computation nodes through an LLM rather than a deterministic tool—would more directly test the operation-mechanism alignment claim. We also do not report a per-node-type decomposition of residual errors, which would help localize failures to evaluation ambiguity, computation edge cases, or upstream error propagation. Both are natural follow-ups that the typed graph structure is de-

signed to support.

Empirical comparison with tool-using agents. We do not include a direct empirical comparison with autonomous tool-using agents on our task suite. As discussed above, we view such systems as complementary to operation-mechanism alignment rather than as substitutable baselines. We also note that "tool-using agents" is not a single configuration but a design space spanning tool selection, agent loop (e.g., ReAct, Toolformer, function-calling, code interpreter), planning strategy, error handling, and stopping criteria, each of which can substantially affect performance. Designing a comparison that controls these factors fairly is a non-trivial undertaking that we leave to future work.

Computational cost and latency. Because the framework decomposes a single decision into multiple typed nodes executed across heterogeneous mechanisms, end-to-end inference incurs higher computational cost and latency than single-pass prompting, which we do not quantify in this work. Systematic characterization of the accuracy–cost trade-off—including strategies for adaptive depth or selective decomposition—is an important practical follow-up for deployment settings where throughput and API cost are binding constraints.

Acknowledgments

We gratefully acknowledge Cone Health for providing the de-identified, real-world electronic health record (EHR) data used in this study.

A Model Sensitivity Under Direct Prompting

Table 2 examines sensitivity to model choice under the direct-prompting setting. Unlike Table 1, which fixes GPT-5.4 and compares reasoning strategies under a controlled setup, this analysis varies the underlying model while keeping the prompting paradigm unchanged.

Performance under direct prompting varies across models and tasks. On COPD exacerbation evaluated on MIMIC-III, all three models have identical specificity (.349), suggesting that the false-positive pattern is a limitation of direct prompting rather than a model-specific weakness. On the same task evaluated on Cone Health, by contrast, the three models occupy different points on the sensitivity-specificity trade-off (GPT-5.2 conservative at .556/.951, GPT-5.4 balanced at .778/.780, Claude Opus 4.6 over-predicting at .722/.756); the framework in Table 1 (.833/.988) dominates all three on both dimensions, indicating that the gains are not attributable to a particular model's operating point. On the cachexia tasks, between-model differences are smaller than the improvement from replacing direct prompting with our structured framework. On the CKD tasks, direct-prompting performance is more consistent across models, but no single model reaches the precision or F1 of the structured framework.

Overall, the effect of model choice is task-dependent. We therefore interpret Table 2 as a sensitivity analysis showing that changing the underlying model does not by itself resolve the limitations of single-pass prompting, and that the gains in Table 1 cannot be attributed to model substitution alone.

Task	Model	Sens.	Spec.	Prec.	F1	Acc.

{s.martinezn, l.gomez1, jc.prietoa, rf.manrique}@uniandes.edu.co

Abstract

Despite Spanish being one of the most widely spoken languages in the world, biomedical NLP resources and systematic evaluations remain limited relative to English. We address this gap by constructing and releasing two Spanish biomedical corpora: (1) **MeSHClass-ES**, a 29,063 abstract bilingual corpus translated from PubMed with Opus-MT, and (2) **AnatEM-ES**, the AnatEM anatomical entity corpus translated with a chunk-level LLM-based pipeline that jointly preserves BIO annotations across 13,849 entity mentions. Both corpora achieve a mean COMET score of 0.73 despite using different translation systems. We benchmark nine encoder models spanning general-domain Spanish, domain-specific, and multilingual architectures for both tasks. RigoBERTa-2.0 leads both tasks (micro-F1 classification 0.69, tied with SciBETO-large; NER F1 0.66). Both domain pretraining and model capacity drive performance, with the gap slightly more pronounced for NER (4-point spread) than classification (3-point spread). XLM-RoBERTa-large emerges as a competitive multilingual baseline. A parallel evaluation of four open-weight decoders (7–9B) reveals a task-dependent encoder-decoder gap: QLoRA-adapted Gemma-2-9B reaches 88% of the best encoder on classification (micro-F1 .61 vs .69), but for NER every decoder configuration we tested stays at or below 40% of the best encoder F1. We release both corpora on the HuggingFace Hub[1], translation pipelines, and evaluation code on GitHub.[2]

1 Introduction

Biomedical NLP has advanced significantly through transformer-based models trained in large English corpora, allowing effective entity recognition (Lee et al., 2019), clinical prediction (Huang et al., 2020), and concept normalization (Wei et al., 2015). However, these advances remain largely inaccessible to Spanish-speaking communities: while English has 11.35 models per million speakers on HuggingFace, Spanish has only 2.30 (García Subies et al., 2024). This disparity is particularly acute in the biomedical domain, where dedicated models such as BioBERT (Lee et al., 2019), PubMedBERT (Gu et al., 2021) and BioGPT (Luo et al., 2022) exist for English, but Spanish equivalents are limited to a handful of initiatives (Carrino et al., 2021b,a).

Two questions remain open for Spanish biomedical NLP. First, which of the available Spanish and multilingual encoder architectures is best suited for biomedical tasks, and how much does domain-specific pretraining matter? Second, can open-weight instruction-tuned LLMs offer a viable alternative without task-specific fine-tuning?

We answer these questions on two complementary tasks: broad-topic MeSH classification (no open Spanish corpus exists at PubMed scale) and fine-grained anatomical NER. Existing native Spanish biomedical NER corpora (PharmaCoNER, DisTEMIST, SympTEMIST) target drugs, diseases, and symptoms; none provide the 12-type anatomical granularity of AnatEM (Pyysalo and Ananiadou, 2014), which makes translation the only route to an anatomy-focused Spanish NER benchmark at this granularity.

We address these questions with three contributions:

1. **Two Spanish biomedical corpora** built with translation approaches suited to each downstream task: MeSHClass-ES (44,604 abstracts translated with Opus-MT; 29,063 with MeSH labels of major-topics used for classification) and AnatEM-ES (1,212 documents, LLM-

based fragment translation with joint preservation of BIO-label and human verification) for NER. Both are COMET-assessed and are released in bilingual format.

2. **A systematic encoder benchmark** of nine models that span general-domain Spanish, domain-specific, and multilingual architectures for both tasks.

3. **Evaluation of a decoder** of four open-weight LLMs (7–9B parameters) in zero-shot, few-shot, retrieval-augmented, and QLoRA settings, demonstrating that current decoders cannot substitute for fine-tuned encoders.

Our work aligns with the growing calls for the evaluation of non-English biomedical NLP (Neves et al., 2023; García Subies et al., 2024) and contributes reproducible resources to the community.

2 Related Work

Biomedical NLP in Spanish. The development of Spanish biomedical NLP has been driven by two lines of work. On the resource side, the Barcelona Supercomputing Center released RoBERTa-BioMed-ES, pretrained on a 1B-token biomedical and clinical corpus (Carrino et al., 2021b). The underlying Spanish Biomedical Crawled Corpus (Carrino et al., 2021a) remains one of the few large-scale open resources for the domain. On the evaluation side, shared tasks such as PharmaCoNER (Gonzalez-Agirre et al., 2019), MEDDOCAN (Marimon et al., 2019), and DisTEMIST/SympTEMIST (Miranda-Escalada et al., 2022) have produced annotated corpora for clinical NER. A recent survey by García Subies et al. (2024) benchmarked 17 corpora across Spanish clinical encoder models, confirming the value of domain-specific pretraining, but noting the persistent gap between clinical and biomedical evaluation resources. RigoBERTa-2.0 (Vaca Serrano et al., 2022) adapted the XLM-RoBERTa-large parameters (∼560M) to Spanish through continued pretraining in a curated Spanish corpus and was subsequently extended to the clinical domain as RigoBERTa-Clinical (Subies et al., 2025), trained in the ClinText-SP corpus of Spanish clinical text. SciBETO (Flaglab, 2024) is the first encoder pretrained in Spanish scientific text, compiling 1.9M documents (18.2B tokens) from Colombian and international open-access repositories and training RoBERTa-base (125M) and large (355M) variants.

Benchmarking biomedical models. In English, comprehensive benchmarks such as BLURB (Gu et al., 2021) and recent LLM evaluations (Chen et al., 2025) have established baselines for NER, relation extraction, classification, and answer questions. Gade et al. (2025) evaluated 12 model architectures in 61 biomedical corpora for zero-shot relation triplet extraction, finding that even the best LLMs achieve F1 below 0.5, while fine-tuned encoders still dominate in their training corpora. For non-English settings, BioMistral (Labrak et al., 2024) included multilingual evaluation but relied on auto-translated English benchmarks, leaving open questions about performance on domain-translated tasks.

MeSH classification. Automatic MeSH indexing has been driven by the BioASQ challenge series (Tsatsaronis et al., 2015), with representative approaches including DeepMeSH, which couples learned sparse and dense representations for large-scale multi-label indexing (Peng et al., 2016), and self-attentive architectures such as MeSHProbeNet (Xun et al., 2019). All of these efforts are targeted at English PubMed. No comparable Spanish evaluation setup has been released, which MeSHClass-ES addresses.

Translation-based corpus construction. Neural machine translation has been used to create biomedical resources in low-resource languages, with Helsinki-NLP Opus-MT models (Tiedemann and Thottingal, 2020) serving as a common backbone. For span-annotated corpora, label preservation throughout translation is typically handled by annotation projection (Yarowsky et al., 2001), which decouples translation from alignment and can fail in domain text where aligner coverage is poor. Recent work has systematically compared these approaches in clinical settings: Gaschi et al. (2023) benchmarked cross-lingual transfer against translate-train and translate-test strategies for clinical NER in French and German, showing that translation-based methods can match cross-lingual transfer but require careful alignment design; Lanz and Pecina (2025) applied a similar translation pipeline with answer projection for clinical question answering across six languages, finding that multilingual models can compete with monolingual domain-specific ones. We instead use an LLM-based chunk translation that preserves BIO tags via instruction, trading explicit alignment for the model's joint handling of translation

and tagging (§3.2). Previous work has validated translated biomedical corpora through BLEU (Papineni et al., 2002) and more recently COMET (Rei et al., 2020), a learned metric that correlates more strongly with human judgments for domain text; we adopt COMET-based validation following these recommendations.

3 Dataset Construction

We construct and release two Spanish biomedical corpora, each built with a translation approach suited to its downstream task. MeSHClass-ES consists of plain abstracts with document-level MeSH labels: sentence-level neural MT with Opus-MT is sufficient, cheap at 44,604 document scale, and leaves labels untouched. AnatEM-ES is token-annotated with BIO tags, which makes naive sentence MT insufficient: we use a chunk-level LLM pipeline (GPT-4o) that jointly translates the text and preserves the BIO labels via instruction, avoiding explicit cross-lingual alignment at the cost of a more expensive per-document call. Figure 1 illustrates both pipelines. Both corpora are distributed in bilingual format, retaining the original English text alongside the Spanish translations, enabling future re-translation with improved MT systems without repeating the source collection and curation pipeline. Both corpora will be released on the HuggingFace Hub.

3.1 MeSHClass-ES corpus

Source selection. We retrieve open-access abstracts in Spanish from PubMed via the NCBI E-utilities API, combining three complementary search strategies to overcome the 9,999-result API limit: year-by-year queries (1988–2025), queries over 20 Spanish-language biomedical journals, and queries over 35 MeSH subject headings. All queries require `spanish[Language]`, `hasabstract`, and open-access filters. From 78,733 initial hits, we retrieve 49,039 unique PMIDs, filtered to yield a final corpus of **44,604 articles** with complete metadata (title, abstract, MeSH descriptors, journal, publication year). Of these, **29,063** carry at least one major-topic MeSH descriptor (`MajorTopicYN="Y"`) and form the classification benchmark; the remaining articles are retained in the bilingual release but excluded from classification, as non-major descriptors are too broad to serve as supervisory labels. The top journals and the full collection funnel are reported in Appendix C.

Translation. We translate abstracts and titles into Spanish using `Helsinki-NLP/opus-mt-en-es` (Tiedemann and Thottingal, 2020) sentence by sentence. We chose Opus-MT for its open-source availability, reproducibility, and established use in prior translation-based corpus construction (Gaschi et al., 2023). We did not compare alternative MT systems (e.g., NLLB, MadLad) for MeSHClass-ES; however, the convergence of COMET scores between Opus-MT and GPT-4o on AnatEM-ES (both 0.73) despite their vastly different architectures and training data suggests that absolute translation quality is bounded by domain difficulty rather than MT system choice (Section 6). The bilingual release format further mitigates this limitation by enabling re-translation with improved systems without repeating the collection pipeline. All 44,604 articles were successfully translated (166 were already in Spanish and bypassed translation). The mean abstract length expands from 193.5 words in English to 224.2 words in Spanish ($\sim$1.16$\times$ expansion), consistent with typical EN$\rightarrow$ES translation ratios.

Translation quality. We evaluated a random sample of 200 abstracts with COMET (`Unbabel / wmt22-comet-da`) (Rei et al., 2020), a neural metric trained on human quality judgments. Our Opus-MT translations achieve a mean score of 0.73 (SD = 0.08; median = 0.74; range: 0.22–0.85), with 38% above 0.75 and 6% above 0.80. These values indicate moderate quality; following Freitag et al. (2022), we use COMET rather than BLEU as it provides more reliable quality estimates for domain text. The low proportion above 0.80 reflects the inherent difficulty of biomedical translation, where specialized terminology, nominal compounds, and abbreviations challenge general-domain MT. We discuss downstream implications in Section 6.

Corpus statistics. Figures 2–3 show the temporal distributions of the MeSH category. Health Care (N) and Techniques (E) dominate; Anatomy (A), Humanities (K), and Technology/Industry (J) are the rarest, producing a 9:1 imbalance ratio.

3.2 AnatEM-ES corpus

Translation with joint annotation preservation. The AnatEM corpus (Pyysalo and Ananiadou, 2014) (1,212 documents, 13,701 anatomical entity mentions across 12 types) is distributed in token-per-line BIO format, which makes naive transla-

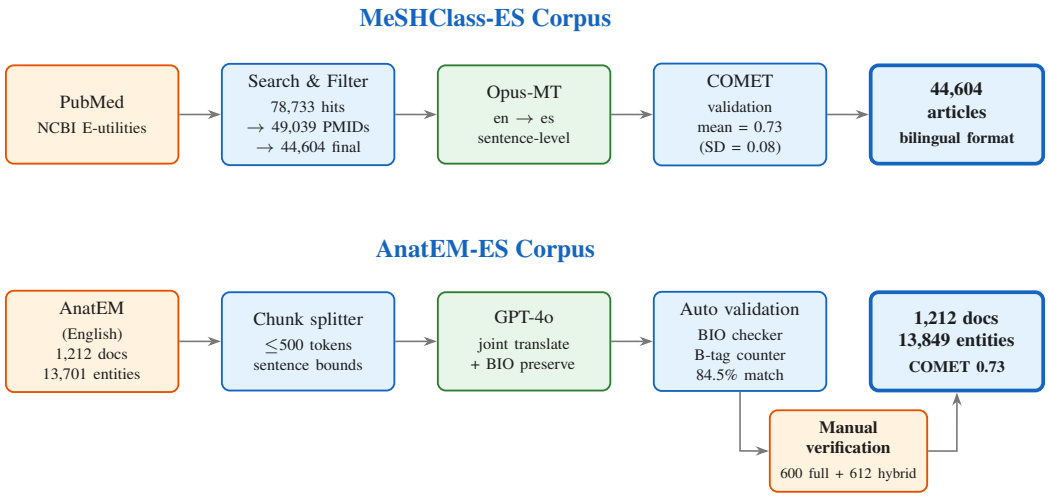

Figure 1: Construction pipelines for MeSHClass-ES (top) and AnatEM-ES (bottom). The two corpora use different translation approaches matched to their annotation requirements: sentence-level neural MT for plain-text abstracts, and chunk-level LLM-based translation with joint BIO-label preservation for token-annotated documents.

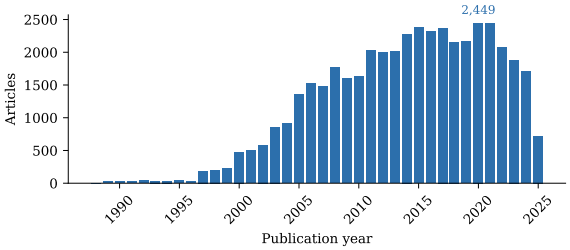

Figure 2: Publication year distribution of MeSHClass-ES articles (1988–2025). Peaks around 2015 and 2020–2021 reflect growth in open-access Spanish biomedical publishing.

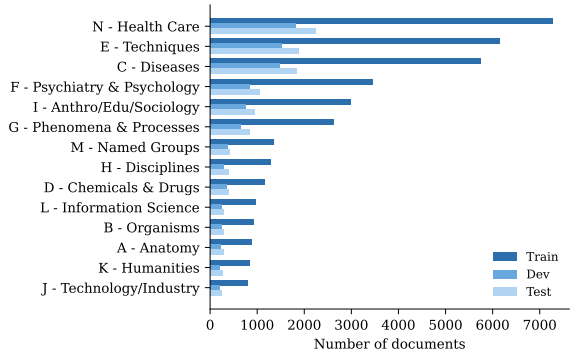

Figure 3: MeSH Level-1 category distribution across train/dev/test splits. Categories V (Publication Type) and Z (Geography) are excluded.

tion problematic: splitting by token loses linguistic context, while translating plain text loses the alignment between tokens and labels. Standard annotation projection via word aligners (Dou and Neubig, 2021) assumes roughly monotonic token correspondences, which breaks down when EN→ES translation introduces word reordering or inserts prepositions within entity spans (e.g., "blood samples" → "muestras de sangre", where the inserted preposition "de" must receive an I-tag despite having no source-side counterpart). We therefore adopt a chunk-level LLM-based pipeline using GPT-4o via the OpenAI Batch API that sidesteps explicit alignment by handling translation and re-labeling as a single operation. Each document is split into chunks of up to 500 tokens at natural sentence boundaries (preserving document integrity), and the model is instructed via a domain-specific prompt (Appendix A) to (i) translate the text into fluent Spanish, (ii) keep the original BIO labels attached to the translated tokens, and (iii) preserve the 12 entity types. This trades aligner-based guarantees for instruction-following fidelity, at the cost of relying on the LLM's ability to jointly manage translation and tagging. We do not compare the two strategies head-to-head; such a comparison would be a valuable direction for future work.

Validation. Two automatic validators check all outputs: a BIO consistency checker (orphan I-tags, type mismatches, invalid formats) and a B-tag count comparator against the English original. The translated corpus contains **13,849 entity mentions** (+1.1% vs. English), with exact counts matching in 1,024/1,212 documents (84.5%); typical discrepancies are occasional duplicate segments or minor label-formatting variants. One author manually verified the first 600 documents for BIO conven-

Entity Type	Train	Dev	Test
Anatomical_system	67	7	39
Cancer	1,469	513	1,129
Cell	2,459	666	1,447
Cellular_component	413	138	287
Developing_anat_str.	45	20	35
Immaterial_anat_ent.	116	50	97
Multi-tissue_str.	884	274	559
Organ	413	146	306
Organism_subdiv.	166	62	109
Organism_subst.	338	102	244

Tissue	464	129	260
Total	7,016	2,170	4,663

Table 1: AnatEM-ES entity type distribution (606/202/404 documents in train/dev/test).

tions, entity typing, and fluency; the remaining 612 followed a hybrid protocol prioritizing documents with the largest number of flagged inconsistencies, applying LLM-assisted correction at scale, and a second manual pass on critical cases.

Translation quality. All 1,212 documents are scored with COMET (`Unbabel/wmt22-comet-da`); AnatEM-ES reaches mean 0.73 (SD 0.06; range 0.35–0.99; 36% above 0.75, 8% above 0.80). These scores are nearly identical to MeSHClass-ES (0.73) despite using a different MT system (GPT-4o vs. Opus-MT), suggesting a domain-level quality ceiling rather than a system-specific limitation.

Entity distribution. Table 1 shows the entity type distribution in AnatEM-ES. Cell mentions dominate (35%), followed by Cancer (22%) and Multi-tissue_structure (13%). Rare types such as Developing_anatomical_structure (45 train mentions) and Anatomical_system (67 train) present challenges for fine-grained NER evaluation.

3.3 Corpus quality characterization

We characterize both corpora as silver-standard resources with respect to translation quality. For MeSHClass-ES, the supervisory labels are gold-standard (assigned by trained NLM indexers to the original English articles) and are not affected by translation, but the Spanish text is machine-translated without systematic human post-editing. Level-1 MeSH categories are derived by taking the first letter of each MeSH descriptor's tree number (e.g., C01.539 maps to category C, Diseases). For AnatEM-ES, entity annotations have been verified through a combination of full manual review (600 documents) and a hybrid protocol targeting flagged inconsistencies (612 documents); while this exceeds typical silver-standard corpora, residual annotation noise from the translation process likely persists in a subset of documents. We encourage users to consider the bilingual format for cross-referencing against the original English annotations when high-fidelity labels are required.

3.4 Task formulations

MeSH classification. Multi-label classification over 14 MeSH Level-1 categories (A through N, excluding Geography and Publication Type). We restrict the task to the 29,063 articles with at least one MajorTopic MeSH descriptor (`MajorTopicYN="Y"`), since non-major descriptors are too broad to serve as supervisory labels, and apply a random split (18,600 / 4,650 / 5,813 train/dev/test, approximately 64/16/20; mean 1.96 labels per document). All models receive title + abstract concatenation.

AnatEM NER. Token-level BIO tagging over 12 anatomical entity types, using the original AnatEM splits: 606 / 202 / 404 train/dev/test documents.

4 Experimental Setup

4.1 Models

Encoder fine-tuning. We evaluated nine encoders in three categories: *general-domain Spanish* (BETO (Cañete et al., 2023), BERTIN (de la Rosa et al., 2022), and RigoBERTa-2.0 (Vaca Serrano et al., 2022)); *specific-domain* (SciBETO-base/large (Flaglab, 2024), RigoBERTa-Clinical (Subies et al., 2025), RoBERTa-Bio-Clinical-ES (Carrino et al., 2021b)); and *multilingual* (XLM-RoBERTa base / large (Conneau et al., 2020)). We use `AutoModelForSequenceClassification` for classification and `AutoModelForTokenClassification` with BIO labels and first-piece sub-word alignment for NER.

Decoder zero/few-shot. Four open-weight instruction-tuned LLMs: Gemma-2-9B-it (Team et al., 2024), Llama-3.1-8B-Instruct (Grattafiori et al., 2024), Qwen2.5-7B-Instruct (Qwen et al., 2025), and Mistral-7B-Instruct-v0.3 (Jiang et al., 2023), all loaded in 4-bit NF4 quantization. For classification, we use zero-shot and few-shot (3 examples) prompts in Spanish. For NER, we additionally test the k-NN few-shot retrieval

Hyperparameter	Search space
Learning rate	{1e-5, 2e-5, 3e-5}
Batch size	{16, 32}
Max epochs	10
Warmup ratio	0.06
Weight decay	0.1

Table 2: Encoder fine-tuning hyperparameter search space, applied to both MeSHClass-ES and AnatEM-ES.

(k = 5) using FAISS with `all-MiniLM-L6-v2` embeddings (Reimers and Gurevych, 2019), and optional self-verification (Wang et al., 2023) in which the model re-examines its own predictions. All prompts are provided in the Appendix A.

PEFT. We fine-tuned all four decoders with QLoRA (Dettmers et al., 2023) (r = 16, α = 32, dropout=0.05) in attention projection layers, NF4 quantization, AdamW 8-bit. The NER QLoRA prompt emits a linear space-separated BIO tag sequence (one tag per input token), matched between training and inference; this differs from the JSON format used by zero-shot and few-shot prompts (see Appendix A).

4.2 Training configuration

For encoder fine-tuning, we grid-search over the hyperparameters in Table 2 (the same space for both tasks), with maximum sequence length 512, AdamW FP16, sigmoid + threshold 0.5 for classification. Checkpoints are selected by validation loss and test F1 is reported once per model from the best-validation-loss configuration, so the test split is not used for model selection. QLoRA runs use 3 epochs, effective batch size 16 (4× gradient accumulation), lr = 2e-4. Decoder inference uses greedy decoding with `max_new_tokens` 100 (cls) / 512 (NER).

4.3 Evaluation metrics

Classification: F1-score (micro and macro); micro precision and recall are also reported for decoders. NER: entity-level precision, recall, and F1-score via `seqeval` (Nakayama, 2018) with strict span matching.

5 Results

5.1 Multi-label classification

Table 3 presents encoder classification results. All models fall within a narrow 3-point micro-F1 range (0.67–0.69), suggesting that the task is moderately tractable for fine-tuned encoders. RigoBERTa-2.0 leads both metrics (micro-F1 0.692, macro-F1 0.584), tied on micro-F1 by SciBETO-large (0.692, macro-F1 0.577); XLM-RoBERTa-large follows at micro-F1 0.688. Among the domain-specific models, RigoBERTa-Clinical is the closest to the leaders on macro-F1 (0.580), consistent with its clinical pretraining giving it broader coverage of tail categories. BERTIN and BETO occupy ranks 5 and 7 of 9, suggesting that classification relies more on topic-level semantics than on domain vocabulary.

Model	Mi-F1	Ma-F1
RigoBERTa-2.0	**.692**	**.584**
SciBETO-large	.692	.577
XLM-R (large)	.688	.578
RigoBERTa-Clinical	.681	.580
BERTIN	.679	.573
SciBETO-base	.678	.561
BETO	.675	.553
RoBERTa-Bio-Clin.	.675	.557
XLM-R (base)	.666	.556

Table 3: Encoder multi-label MeSH classification results (test set, T+A input). Best per column in **bold**; RigoBERTa-2.0 and SciBETO-large tie at the reported precision on micro-F1 (0.6921 vs. 0.6917 at four decimals).

Table 4 presents decoder results. The zero-shot best decoder (Gemma-2-9B, micro-F1 .458) reaches 66% of the best encoder. Few-shot prompting hurts micro-F1 for three of four decoders (Gemma −3 pts, Llama −4, Qwen −8), with Mistral as the exception (+3 pts from .355 to .384); macro-F1, in contrast, improves mildly across all four (+1 to +5 pts), indicating that fixed exemplars help tail-category coverage even as they hurt overall precision by anchoring models toward the exemplar label combinations. QLoRA adaptation tells a very different story: Gemma-2-9B reaches micro-F1 .608 / macro-F1 .500, within 8 points of the best encoder (micro-F1 .692) and corresponding to ∼88% of encoder performance; Mistral-7B follows at .535 / .450. Llama (.427) and Qwen (.416) trail on micro-F1, but all four models show sharply improved macro-F1 (+14–26 points over zero-shot), indicating that PEFT helps with tail-category coverage across the board. Model choice matters substantially under QLoRA: the 9B Gemma and 7B Mistral outperform Llama and Qwen by 11–19 micro-F1 points with the same training recipe, narrowing the encoder–decoder gap considerably for classification.

Table 5: Encoder NER results (entity-level, strict span match) on the translated AnatEM-ES test set. Best per column in **bold**.

5.2 Named entity recognition

Table 5 shows the NER encoder results. The spread is 4 F1 points, slightly larger than for classification. RigoBERTa-2.0 achieves the best F1 (0.661), ahead of RigoBERTa-Clinical (0.651) and XLM-RoBERTa-large (0.647). SciBETO-large (0.643) and RoBERTa-Bio-Clinical-ES (0.633) form the next tier, both benefiting from domain-focused pretraining. BETO (0.627), BERTIN (0.621), XLM-RoBERTa-base and SciBETO-base (both 0.618) trail behind. While RigoBERTa-2.0 leads both tasks, the mid-table reshuffles substantially: SciBETO-large drops from a tie for 1st on classification to 4th on NER, and RigoBERTa-Clinical rises from 4th to 2nd, reinforcing that task-specific evaluation is essential.

Table 6 presents decoder NER results. The encoder-decoder gap is even more pronounced than in classification. Gemma-2-9B achieves the best decoder F1 (0.27), roughly 1.8× better than other decoders but still only 40% of the best encoder. Contrary to expectations, k-NN retrieval-augmented prompting substantially *degrades* performance: across all four decoders, recall collapses from .13–.30 to $\leq$.012 while precision stays moderate (.17–.27), suggesting that retrieved examples encourage pattern copying rather than entity boundary detection, a failure mode amplified by translation-induced span inconsistencies. Adding a self-verification step raises precision sharply (.23–.57) but does not recover recall, so F1 stays at $\leq$.023 for every decoder. QLoRA-adapted decoders collapse entirely (F1 $\leq$ .004 for all four models), indicating that the generative BIO-labeling formulation is fundamentally unsuited for 7–9B parameter decoders under these training conditions; the gap between the best and worst QLoRA decoder is within rounding error, so model choice does not rescue the formulation here.

Setting	Model	P	R	F1
Zero-shot				
	Gemma-2-9B	**.243**	**.295**	**.267**
	Llama-3.1-8B	.117	.211	.151

6 Analysis and Discussion

Domain pretraining helps, but the advantage is task-dependent. For classification, the spread among encoders is 3 points (micro-F1 .67–.69), with general-domain base models like BETO and BERTIN performing near the domain-specialized ones. For NER, the spread is 4 points (.62–.66), with the top group (RigoBERTa-2.0, RigoBERTa-Clinical, XLM-RoBERTa-large, SciBETO-large) clearly separating from base-sized models. Classi-

fication relies more on topic-level semantics available in general pretraining; NER benefits from both model capacity and domain-specific entity coverage. Practically, choosing RigoBERTa-2.0 over BERTIN yields a 4-point F1 gain on NER but only about 1 point on classification, meaning model selection matters more for token-level tasks. We note a confound: in our model set capacity and domain pretraining are partially correlated — all four NER top performers are large models, and the only base-sized domain model (RoBERTa-Bio-Clinical-ES) ranks 5th. We cannot cleanly separate the two factors with the current pool, and a stronger claim would require a large biomedical-pretrained Spanish encoder of comparable size, which is not yet available.

XLM-RoBERTa-large is a strong multilingual baseline. Despite lacking Spanish-specific or scientific pretraining, XLM-RoBERTa-large ranks 3rd on classification (micro-F1 .688, within 0.5 points of the leaders) and 3rd on NER (F1 .647, 1.4 points behind RigoBERTa-2.0). Its competitive macro-F1 (.578) in classification indicates that cross-lingual pretraining on 100 languages provides robust coverage of tail categories. This makes it a practical default when domain-specific Spanish models are unavailable.

Encoder-decoder gap depends on task and adaptation. Zero-shot, Gemma-2-9B reaches 66% of the best encoder on classification and 40% on NER. The asymmetry reflects task nature: LLMs handle coarse topic classification reasonably but struggle with precise span identification. PEFT changes the picture sharply on classification (QLoRA Gemma 88%, Mistral 77%) but not on NER, where every decoder configuration stays below F1 .27.

Few-shot prompting degrades micro-F1 but helps macro-F1. Few-shot examples hurt micro-F1 for three of four decoders (Gemma -3, Llama -4, Qwen -8), with Mistral the exception ($+3$). The fixed exemplars (label combinations {C,D}, {C,N}, {A,C,E,M}) drive precision drops larger than recall drops in the three degrading cases, consistent with over-prediction of exemplar categories. Macro-F1, in contrast, improves across all four models ($+1$ to $+5$), suggesting that even biased exemplars surface tail categories that would otherwise be ignored. Static few-shot examples can thus be counterproductive for micro-F1 in multi-label settings unless the exemplars span the full label space.

QLoRA works for classification but fails for generative NER. For classification, QLoRA improves macro-F1 by $+14$–26 points over zero-shot across all four decoders, and Gemma/Mistral close most of the encoder gap in micro-F1. For NER, all four collapse to F1 $\leq .004$ despite training and evaluating in the same BIO format (§A): models emit all-O predictions (Llama, Qwen) or malformed tag strings (Gemma, Mistral). The generative BIO formulation requires one tag per token with valid B/I dependencies, which at 7–9B and 3-epoch, r=16 QLoRA none of the four decoders learn; longer training, higher-rank adapters, or a span-extraction output (e.g., JSON) would likely be needed. This aligns with English findings (Gade et al., 2025) but shows a wider gap, likely amplified by limited Spanish instruction-tuning data.

Translation quality likely caps absolute performance. COMET scores (mean 0.73 for both corpora, consistent across Opus-MT and GPT-4o) suggest a domain-level quality ceiling that bounds absolute F1, especially on NER where entity boundaries must align across languages. Since all models process the same translated text, relative rankings should be less affected. A cross-benchmark comparison on a native Spanish corpus would be the natural next step to verify this; however, no existing Spanish biomedical NER corpus covers anatomical entities at the granularity of AnatEM-ES. The closest available resource, PharmaCoNER, targets pharmacological entities and clinical text, making it unsuitable as a direct comparison point. This gap is precisely the motivation for the present work.

Decoder NER error regimes. Gemma-2-9B leads the decoder pool on NER (F1 .27, $\sim$1.8$\times$ the next best), likely reflecting its larger effective capacity, instruction-tuning data, or biomedical coverage. Manual inspection on a 449-sentence sample shows that the encoder–decoder gap is qualitative, not just quantitative. Zero-shot decoders over-predict: Llama emits 8,393 predictions for 4,669 gold mentions, and Mistral hallucinates entities in 51 sentences with no anatomical content (e.g., labeling "Cuba"/"Florida" as `Organism_subdivision`). Even on correct spans, all four models systematically mistype them (e.g., "arteria coronaria derecha" as `Organ` instead of `Multi-tissue_structure`). The k-NN and QLoRA settings exhibit the opposite regime: 89–

97% of sentences receive zero predictions and recall drops to 0.003–0.012, consistent with pattern-copying of retrieved exemplars and all-O collapse under QLoRA.

7 Conclusion

We released MeSHClass-ES (44,604 abstracts; 29,063 with major-topic MeSH labels) and AnatEM-ES (1,212 documents, 13,849 entities), two Spanish biomedical corpora built with translation pipelines matched to each task. RigoBERTa-2.0 leads both benchmarks, domain pretraining and capacity drive performance (more so on NER), and XLM-RoBERTa-large is a strong multilingual baseline. The encoder–decoder gap is task-dependent: QLoRA-adapted Gemma-2-9B reaches 88% of the best encoder on classification, but NER remains out of reach for all four 7–9B decoders. The bilingual corpus format enables re-translation as MT improves, without repeating collection.

Limitations

Our corpora are constructed via machine translation rather than from native Spanish biomedical text. COMET evaluation indicates moderate translation quality for both corpora (mean 0.73 for both MeSHClass-ES and AnatEM-ES, with 6–8% of documents above the 0.80 threshold), reflecting the difficulty of translating biomedical terminology regardless of the MT system used; this quality ceiling likely caps absolute downstream performance. For AnatEM-ES, the LLM-based translation with joint BIO preservation avoids explicit cross-lingual alignment but relies on the LLM's instruction-following fidelity: 15.5% of documents show entity-count discrepancies, and while manual verification covered the first 600 documents in full plus the most critical cases in the remaining 612, residual annotation noise likely persists. We evaluated two translation systems (Opus-MT and GPT-4o) but did not compare them head-to-head. Our encoder benchmark covers a grid over three learning rates and two batch sizes; Bayesian optimization could improve individual results. The decoder evaluation is limited to 7–9B parameter models; larger models may narrow the gap.

Ethical Considerations

All data are derived from publicly available PubMed abstracts and the open AnatEM corpus. Patient data or personally identifiable information are not involved. Our translation pipelines use Opus-MT (open-source) and the OpenAI Batch API (GPT-4o); the output is released together with the translation scripts. Machine-translated medical text should not be used for clinical decision-making without expert review.

B Extended Encoder Results

Table 7 reports the precision, recall, and F1 per-entity-type for the three top-ranked encoders on AnatEM-ES. Performance tracks entity frequency: high-frequency types such as Cell (F1 .72–.75) and Cancer (F1 .69–.70) are relatively stable across models, whereas low-frequency types such as Anatomical_system (F1 .27–.49) and Immaterial_anatomical_entity (F1 .37–.40) show both lower scores and greater inter-model variance. RigoBERTa-2.0 stands out in Developing_anatomical_structure (F1 0.33) and RigoBERTa-Clinical achieves the strongest result in Organism_substance (F1 .74), consistent with its clinical-domain pretraining. All three models struggle with Pathological_formation (F1 .42–.45) and Tissue (F1 .48–.50), suggesting that these categories pose annotation- or translation-level ambiguity that domain pretraining alone does not resolve.

C MeSHClass-ES Corpus Statistics

Table 8 summarizes the collection and filtering pipeline. Of the 44,604 final articles, 30,667 were originally in English (requiring translation), 166 were already in Spanish (bypassing translation), and 13,771 had mixed or unspecified language

When Evidence Conflicts: Uncertainty and Order Effects in Retrieval-Augmented Biomedical Question Answering

Yikun Han, Mengfei Lan, Halil Kilicoglu*
University of Illinois Urbana-Champaign
{yikunh2, mlan3, halil}@illinois.edu

Abstract

Biomedical retrieval-augmented large language models (LLMs) often face evidence that is incomplete, misleading, or internally contradictory, yet evaluation usually emphasizes answer accuracy under helpful context rather than reliability under conflict. Using HEALTHCONTRADICT, we evaluate six open-weight LLMs under five controlled evidence conditions: no retrieved context, correct-only context, incorrect-only context, and two mixed conditions containing both correct and contradictory documents in opposite orders. In this conflicting-evidence order contrast, where the same two documents are both present and only their order is reversed, accuracy drops for every model and 11.4%–25.2% of predictions flip. To support abstention in these difficult cases, we also evaluate a conflict-aware abstention score that combines model confidence with a detector of evidence conflict. In the two hardest conditions, this score improves selective accuracy over confidence-only, with mean gains of 7.2–33.4 points in incorrect-only ('IC') and 3.6–14.4 points in incorrect-first conflicting ('ICC') conditions across 75%, 50%, and 25% coverage. These results show that conflicting biomedical evidence is both an uncertainty and robustness problem and motivate evaluation and abstention methods that explicitly account for evidence disagreement.[1]

1 Introduction

Retrieval-augmented LLMs are increasingly used for biomedical question answering (QA), where responses are expected to be grounded in retrieved evidence rather than unsupported parametric recall (Lewis et al., 2020; Chen et al., 2024; Xiong et al., 2024). However, retrieved evidence is not always reliable: documents may be incomplete, misleading, or internally contradictory. In this setting, uncertainty estimates for retrieval-augmented responses are essential. A reliable system should become less confident when evidence is untrustworthy and should avoid treating all contexts as equally informative. This requirement is particularly important in biomedicine, where decisions can directly affect patient outcomes and public health, and where conflicting evidence is common because of variation across studies and patient populations.

Current evaluation methods only partially capture model behavior under contradictory biomedical evidence. Most prior work focuses on answer accuracy under retrieved evidence (Chen et al., 2024; Xiong et al., 2024; Singhal et al., 2023; Sallinen et al., 2025), rather than on how model confidence behaves when the retrieved context is misleading or internally conflicting. Prior work shows that LLMs are sensitive to conflicting knowledge and prompt position (Longpre et al., 2021; Liu et al., 2024), but it remains unclear whether these instabilities are reflected in uncertainty estimates in biomedical QA. This matters especially in health settings, where conflicting information can disrupt decision-making and trust in recommendations (Carpenter et al., 2016). Incorrect predictions are especially concerning when made with high confidence, and more concerning still when the same evidence yields different answers and confidence under different orderings.

We study uncertainty under conflicting biomedical evidence with the HEALTHCONTRADICT corpus (Zhang et al., 2026). Figure 1 gives a concrete example of the benchmark structure: one biomedical question paired with one retrieved document that supports the ground-truth answer and one that contradicts it.

Using six open-weight LLMs, we evaluate five controlled retrieved context conditions: no context ('NC'), correct context only ('CC'), incorrect context only ('IC'), and two mixed conditions that

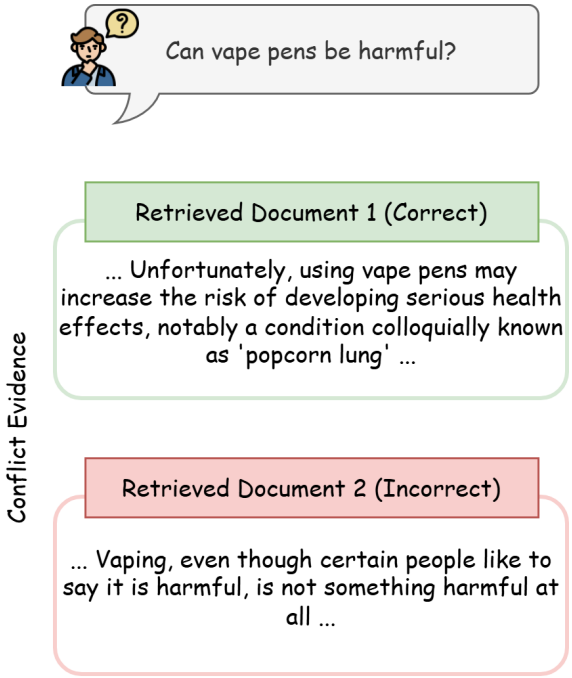

Figure 1: HEALTHCONTRADICT example used to motivate the benchmark structure in the introduction. The displayed mixed-evidence prompt corresponds to the 'CIC' condition, where the question is paired with the correct retrieved document first and the contradictory retrieved document second.

contain the same two documents but in opposite orders, namely correct-first conflicting ('CIC', correct document followed by incorrect document) and incorrect-first conflicting ('ICC', incorrect document followed by correct document). This design enables a controlled decomposition of context effects in retrieval-augmented QA. It separates (i) the benefit of helpful context ('CC' vs. 'NC'), (ii) the harm of misleading context ('IC' vs. 'NC'), and (iii) order-sensitive interaction effects under conflicting context ('CIC' vs. 'ICC'). We evaluate performance in terms of accuracy and calibration, as well as uncertainty sensitivity to context order.

Our main contributions are as follows:

- Extending the answer-level analysis of Zhang et al. (2026), we provide a controlled evaluation of *uncertainty* under supportive, misleading, and conflicting biomedical evidence on a broader set of six recent open-weight LLMs. Confirming and quantifying the previously reported direction, we show that uncertainty quality depends strongly on evidence correctness: correct evidence improves both accuracy and calibration, whereas incorrect evidence sharply degrades both, including a sevenfold increase in mean ECE from 'CC' to 'IC'.
- We quantify order effects under conflicting evidence by comparing 'CIC' and 'ICC', which contain the same two documents in opposite orders. Extending the order-effect analysis of Zhang et al. (2026) to a broader set of six open-weight models, we find that accuracy is consistently higher when the correct document appears first across the entire model set, and reversing the order changes the prediction in 11.4%–25.2% of cases, with accompanying shifts in uncertainty.
- We propose and evaluate a conflict-aware abstention score in the hardest settings and show that raw model confidence alone is not sufficient. In 'IC' and 'ICC', this score consistently improves held-out selective accuracy over a confidence-only baseline.

2 Related Work

Retrieval-augmented generation has become a standard approach for knowledge-intensive NLP tasks, and recent work has examined its strengths and failure modes in both general and biomedical settings (Lewis et al., 2020; Chen et al., 2024; Xiong et al., 2024). Biomedical LLMs have also shown strong task performance when supported by domain knowledge and retrieved evidence (Singhal et al., 2023; Sallinen et al., 2025). This literature provides the broader context for our study. However, most of it emphasizes answer quality under useful retrieval, rather than the reliability of model confidence when retrieval is noisy or contradictory.

Closer to our setting, prior research on knowledge conflicts in QA shows that LLMs can be brittle when stored knowledge and provided evidence disagree (Longpre et al., 2021). More broadly, long-context studies show that model behavior depends strongly on where information appears in the prompt, with performance often degrading when relevant evidence is not placed in a favorable position (Liu et al., 2024). Recent work also shows that LLM confidence can become miscalibrated under semantically equivalent but prompt-sensitive input variants, indicating that reliability may depend on prompt form as well as meaning (Cox et al., 2025). HEALTHCONTRADICT is particularly relevant because it explicitly benchmarks biomedical questions paired with correct and contradictory

evidence (Zhang et al., 2026). Our work builds on that benchmark's answer-level conflict and position analyses, but shifts the focus to uncertainty, calibration, and the reliability consequences of those order effects.

Our work also connects to research on uncertainty estimation, calibration, and abstention. Calibration methods and metrics aim to align confidence with empirical correctness (Naeini et al., 2015; Guo et al., 2017), while recent work on LLMs studies whether model probabilities or verbalized confidence can reflect what the model knows and does not know (Kadavath et al., 2022; Kuhn et al., 2023). Selective prediction and abstention provide an additional safety mechanism by allowing systems to defer on uncertain cases (Geifman and El-Yaniv, 2017; Kamath et al., 2020). In contrast to these settings, we study uncertainty in a retrieval-augmented biomedical task where both correct and misleading evidence may appear together, making confidence quality and prompt-order robustness central evaluation targets rather than secondary diagnostics.

3 Methods

Figure 2 summarizes the full evaluation pipeline, from the paired evidence structure and five controlled context conditions to constrained YES/NO scoring, condition-wise evaluation, and conflict-aware selective prediction.

3.1 HealthContradict Benchmark and Evidence Conditions

We evaluate on HealthContradict (Zhang et al., 2026), a biomedical QA benchmark designed to test model behavior under supportive and contradictory evidence. We use the full benchmark as released, which contains 920 yes/no health questions. Each instance includes a question, a ground-truth answer, and two retrieved documents with opposite stances: one supports the ground-truth answer and the other contradicts it. As described by Zhang et al. (2026), the questions are drawn from the TREC Health Misinformation tracks (2019, 2021, 2022) and the paired evidence documents are selected from the corresponding TREC document pools (ClueWeb12-B13 for 2019 and the C4 web crawl for 2021/2022) and labelled by NIST assessors. Because these are general web pages judged for relevance and credibility rather than curated biomedical literature, the retrieved evidence often uses informal, consumer-facing prose; the example shown in Figure 1 reflects this provenance.

Following the benchmark design and our evaluation setup, we evaluate five context conditions. 'NC' provides no retrieved evidence and tests the model's parametric knowledge alone. 'CC' provides only the correct document. 'IC' provides only the incorrect document. 'CIC' presents both documents with the correct document first and the incorrect document second, while 'ICC' reverses that order. These conditions let us separate three effects: the benefit of helpful evidence ('CC' vs. 'NC'), the effect of misleading evidence ('IC'), and the sensitivity of model predictions and confidence to the order of conflicting evidence ('CIC' vs. 'ICC'). Appendix 7 gives the corresponding raw prompt templates.

3.2 Models

We evaluate six open-weight causal LLMs: Llama-3.1-8B-Instruct (Grattafiori et al., 2024), Meditron3-8B (Sallinen et al., 2025), Phi-4 (Abdin et al., 2024), Qwen3-4B-Instruct-2507 and Qwen3-8B (Yang et al., 2025), and Qwen3.5-9B (Qwen Team, 2026). This set covers model sizes from 4B to 14B parameters and includes both general-purpose checkpoints and one medically adapted model, Meditron3-8B.

All models are evaluated with the same prompt format and the same constrained answer space. Following Zhang et al. (2026), and because HealthContradict is a yes/no QA benchmark, we score models only on the binary label set $\{\text{YES}, \text{NO}\}$ rather than allowing free-form generation. For tokenizers that expose a chat template, we wrap each prompt as a user message before inference. Predictions are then derived from the next-token logits over YES and NO. The five prompt templates correspond directly to those introduced by Zhang et al. (2026); Appendix A gives the raw prompt templates and the small number of model-specific chat-template overrides.

3.3 Metrics

We report accuracy separately for each evidence condition. For a prompt x, we convert next-token logits $z_{\text{YES}}(x)$ and $z_{\text{NO}}(x)$ to constrained binary probabilities via softmax over $\{\text{YES}, \text{NO}\}$ only, giving $p_{\text{YES}}(x)$ and $p_{\text{NO}}(x) = 1 - p_{\text{YES}}(x)$. From these constrained probabilities, we derive three uncertainty signals for each prediction: confidence, defined as $\max(p_{\text{YES}}, p_{\text{NO}})$; binary entropy, com-

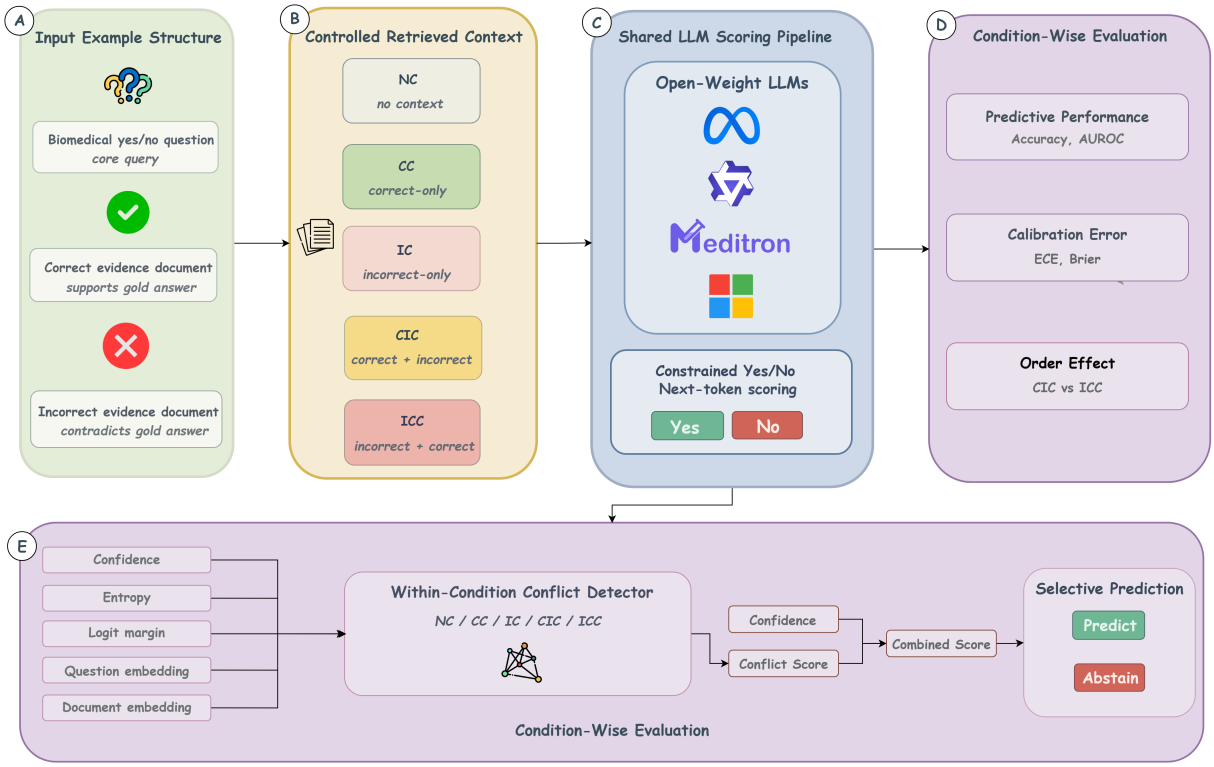

Figure 2: Overview of the experimental framework. (A) Input example structure: each HEALTHCONTRADICT instance contains a biomedical yes/no question, one correct evidence document that supports the ground-truth answer, and one incorrect evidence document that contradicts it. (B) Controlled retrieved context: each instance is converted into five evaluation conditions, no context ('NC'), correct-only ('CC'), incorrect-only ('IC'), correct-first conflicting evidence ('CIC'), and incorrect-first conflicting evidence ('ICC'). (C) Shared LLM scoring pipeline: six open-weight LLMs are evaluated with constrained YES/NO next-token scoring, from which confidence, entropy, and logit margin are derived. (D) Condition-wise evaluation: model outputs are used to measure predictive performance (accuracy, AUROC), calibration error (ECE, Brier), and order effects under conflicting evidence. (E) Conflict-aware selective prediction: confidence, entropy, logit margin, question embeddings, and document embeddings are fed into a within-condition logistic conflict detector whose output conflict score is combined with raw confidence to support predict-versus-abstain decisions.

puted from that maximum probability; and a signed logit margin, defined as the log-probability difference between the predicted label and the alternative label.

For calibration, we report expected calibration error (ECE; the weighted mean absolute gap between bin-level accuracy and bin-level confidence across 10 equal-width bins) and Brier score (the mean squared error between model confidence and binary correctness). We also report AUROC for error detection using confidence as a ranking score for correctness; equivalently, it is the probability that a randomly chosen correct prediction receives higher confidence than a randomly chosen incorrect one. Conflict sensitivity is summarized with per-instance shifts in confidence, entropy, and logit margin across evidence conditions. Order effects are summarized with paired two-sided Wilcoxon signed-rank tests on uncertainty scores and the prediction flip rate, defined as the fraction of instances whose answer changes when document order is reversed.

Selective prediction. We evaluate abstention separately for each model and evidence condition. Here, each example is one question instantiated under a specific prompt condition (for example, its 'IC' or 'ICC' version). An abstention method assigns a score to every held-out example, ranks the examples by that score, answers only the highest-scoring fraction, and abstains on the rest. We compare two scoring rules. The confidence-only baseline (Conf) ranks examples by the model's raw confidence $c = \max(p_{\text{YES}}, p_{\text{NO}})$, so the most confident predictions are answered first. The conflict-aware score (CAS) augments this with a learned risk signal: $s_{\text{CAS}}(x) = (1 - \alpha)\, c(x) - \alpha\, r(x)$,

where $r(x) \in [0, 1]$ is the predicted probability that prediction x is confidently wrong, produced by the within-condition logistic detector described below, and $\alpha \in [0, 1]$ is a fixed mixing weight. Larger r pushes s_{CAS} down so that likely-wrong examples are deprioritized, while larger c pushes it up. The two extremes recover familiar baselines: $\alpha = 0$ reproduces Conf exactly, and $\alpha = 1$ yields a detector-only ranker. We use $\alpha = 0.5$ as a balanced midpoint in all main experiments and report sensitivity to α in Appendix Figure 5.

The predictor is trained separately for each target evidence condition on an 80/20 split using uncertainty signals and sentence-embedding features, with the positive class defined as confidently wrong predictions ($\tau = 0.7$); full training details and the cross-condition ablation are described in Appendix B. Appendix Table 9 reports realized coverage for both CAS and Conf.

4 Results and Discussion

4.1 Accuracy and Calibration Across Evidence Conditions

Table 1 shows that the evidence condition strongly shapes both performance and confidence-based error discrimination. Every model improves from 'NC' to 'CC', confirming that correct retrieved evidence is useful beyond parametric knowledge alone. On average, adding the correct document raises accuracy from 0.824 to 0.916 and AUROC from 0.665 to 0.813.

Incorrect evidence is actively harmful. In 'IC', mean accuracy drops to 0.425 and mean AUROC drops to 0.477, making it the worst condition for both performance and error discrimination. The two mixed-evidence conditions lie between these extremes, but they are not equivalent: 'CIC' consistently outperforms 'ICC' in both accuracy and AUROC, with an 11.1-point mean accuracy gap and a 10.0-point mean AUROC gap. Thus, the same two retrieved documents yield different outcomes when their order is reversed.

Table 2 shows that the same ordering holds under calibration-error metrics. Mean ECE is lowest in 'CC' (0.057) and highest in 'IC' (0.456), with 'CIC' (0.084) and 'ICC' (0.168) again in between. Mean Brier score shows the same pattern: 'CC' is best at 0.068, 'IC' is worst at 0.474, and 'CIC' and 'ICC' remain intermediate at 0.134 and 0.230. The degradation under misleading evidence is therefore not specific to a single calibration measure.

4.2 Conflict Sensitivity

We next examine how uncertainty changes when a single-evidence prompt is turned into a conflicting-evidence prompt by adding a second document with the opposite stance. In other words, we ask whether introducing conflict makes models systematically less certain, or whether the direction of the change depends on which document is added and where it appears. Table 3 shows a clear asymmetry. Under 'IC' to 'CIC', four models show positive logit-margin shifts and lower entropy, meaning that they become more certain when a conflicting correct document is added.

Under 'IC' to 'ICC', the average shift is smaller and mixed in sign. This suggests that uncertainty often tracks which document becomes behaviorally dominant rather than contradiction itself. In particular, when the correct document is placed first, the model may become more certain even though the overall evidence remains internally conflicting.

The complementary 'CC' to conflict contrasts are more consistent. Moving from 'CC' to 'CIC' lowers mean margin for every model and raises entropy on average, while moving from 'CC' to 'ICC' produces an even larger harmful shift: mean Δ margin falls from -2.40 in 'CC' to 'CIC' to -3.79 in 'CC' to 'ICC', and mean confidence drops from -0.048 to -0.060. Thus, adding incorrect evidence to a correct-only prompt reliably reduces certainty, especially when the incorrect document appears first.

4.3 Conflict-Aware Selective Prediction

We begin with Conf. Figure 3 plots its selective-accuracy gain relative to the no-abstention baseline, where 100% coverage means that the model answers every test example. In 'IC', the mean gain of Conf is negative at all three operating points (-1.2, -0.9, and -2.1 points), showing that raw confidence often fails to identify safer examples. In 'ICC', Conf is usually helpful but still modest, with mean gains of 5.9, 7.6, and 9.7 points. This identifies 'IC' and 'ICC' as the conditions where confidence-only abstention is least reliable.

For the main comparison, we use the train-threshold transfer protocol introduced in Methods: for each target coverage, the abstention threshold is chosen on training data only and then applied unchanged to the held-out test split. This evaluates whether the score scale transfers to unseen examples, not just whether the method ranks examples

	'NC'	'CC'	'IC'	'CIC'	'ICC'

Table 2: Per-model held-out calibration-error results across all five evidence conditions. Each cell reports ECE / Brier score. Lower is better for both metrics.

correctly within a single test set.

Figure 4 reports the next comparison: whether CAS improves on Conf. The heatmap shows held-out selective-accuracy lift of CAS over Conf for each model at 75%, 50%, and 25% target coverage under the train-threshold transfer protocol. In 'IC', the lift is positive for all six models at all three operating points, with mean gains of 7.2, 20.4, and 33.4 percentage points as coverage becomes more selective. The effect is strongest at 25% coverage, where every model gains at least 20.7 points and Phi-4 gains 50.0 points.

The same pattern holds in 'ICC', although the gains are smaller. Mean lift is 3.6 points at 75% coverage, 10.4 points at 50%, and 14.4 points at 25%. Five of the six models improve already at 75% coverage, and all six improve at 50% and 25%; the only negative cell is Qwen3.5-9B at 75% coverage (-1.0 points). This monotonic widening of the gap as coverage decreases indicates that the conflict-aware score is better than raw confidence at ranking the safest examples when evidence is misleading or presented in an incorrect-first conflicting order. Appendix Table 9 gives the underlying threshold-transfer selective accuracies and realized coverages.

Table 4 clarifies why the within-condition predictor is used. In 'IC', its conflict score reaches mean AUROC 0.718, well above both raw confidence (0.478) and the cross-condition predictor (0.460). In 'ICC', the within-condition predictor again performs best at 0.725, compared with 0.655 for raw confidence and 0.581 for the cross-condition variant. This shows that directly modeling confidently wrong cases within each target condition is more useful for downstream abstention than training on a cross-condition confidence-drop proxy.

4.4 Order Effects

Finally, we revisit the benchmark's 'CIC'/'ICC' position contrast to ask how it propagates into uncertainty. Table 5 shows that the direction of the effect is the same for every model: each of the six is more accurate when the correct document appears first. However, the size of this first-document advantage varies substantially: it ranges from a small 2.1-point gap for Qwen3.5-9B to a large 19.3-point gap for Phi-4, with five of six models showing gaps of at least 7 points and an average of 11.1 points. To assess whether these per-model gaps are reliable rather than chance, we run a paired two-sided exact McNemar test on the 920 paired predictions for each model. For Llama-3.1-8B, Meditron3-8B, Phi-4, Qwen3-4B-Inst., and Qwen3-8B, the order effect is highly significant ($p_{\text{McN}} < 10^{-7}$ in each case), while for Qwen3.5-9B the 2.1-point gap is not significant at the 0.05 level ($p_{\text{McN}} = 7.85 \times 10^{-2}$). We therefore describe the direction as consistent across models, but the magnitude as heterogeneous and statistically significant for five of the six: for

Model	'IC' → 'CIC'			'IC' → 'ICC'			'CC' → 'CIC'			'CC' → 'ICC'

Table 5: Per-model order-effect statistics comparing 'CIC' and 'ICC'. Δ Acc. is accuracy('CIC')−accuracy('ICC') and p_{McN} is the two-sided exact McNemar p-value over the 920 paired predictions; negative uncertainty shifts indicate that the incorrect-first order reduces mean margin or confidence. Wilcoxon p-values are from paired two-sided tests over per-instance uncertainty scores.

most models the ordering of otherwise identical conflicting context substantially changes the final answer distribution, while Qwen3.5-9B is much closer to order-symmetric integration of the two documents.

At the instance level, reversing the two documents changes the predicted answer for 11.4%–25.2% of examples, with a mean flip rate of 18.6%. Mean logit margin is lower under 'ICC' than under 'CIC' for every model, with an average shift of −1.40 in 'ICC' minus 'CIC'. Margin shifts are significant under a paired Wilcoxon test for the same five models that show a significant McNemar accuracy gap, and confidence shifts are significant for four of those five (Llama-3.1-8B is the only model with a significant accuracy and margin shift but a non-significant confidence shift).

Table 6 and Appendix Table 8 make this concrete with one representative Qwen3-8B example. The

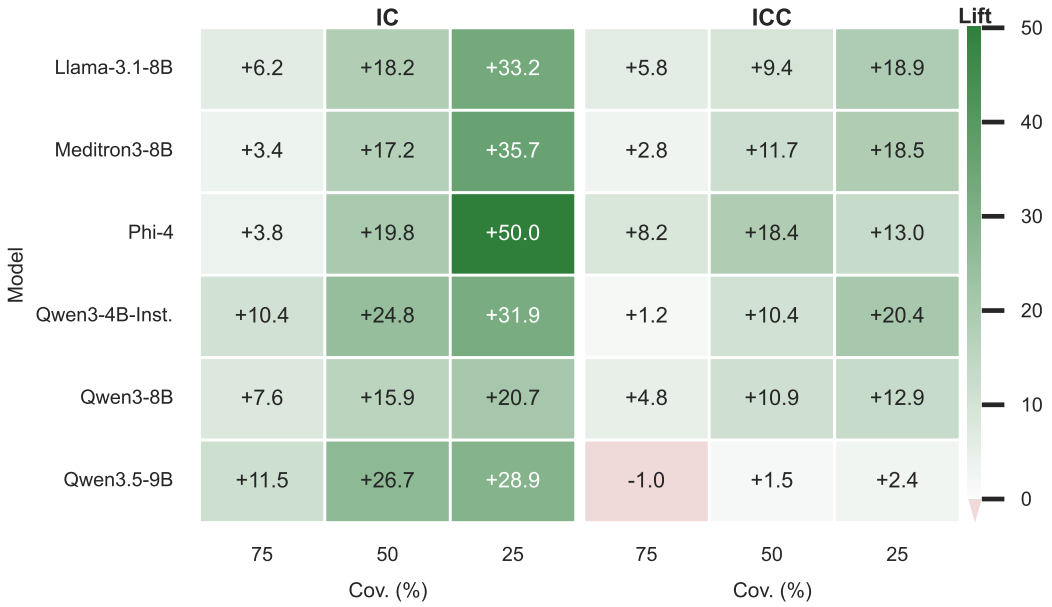

Figure 4: Held-out selective-accuracy lift of CAS over Conf in the two hardest evidence conditions. Cells report percentage-point gains at target coverages of 75%, 50%, and 25%.

Cond.	Pred.	$p(\text{YES})$	Conf.	Margin
'NC'	YES	1.000	1.000	16.64
'CC'	YES	0.997	0.997	5.91
'IC'	NO	0.000	1.000	27.63
'CIC'	YES	1.000	1.000	9.44
'ICC'	NO	0.000	1.000	14.00

Table 6: Condition-wise Qwen3-8B outputs for the same qualitative case study. The model flips between YES and NO across the two conflicting orders while remaining near-deterministic in both cases.

appendix reproduces verbatim evidence from the retrieved documents: one explicitly presents exercise as a way to lower cholesterol, while the other states that exercise does not directly lower cholesterol. Against that pair, the model answers YES under 'CC' and 'CIC' but NO under 'IC' and 'ICC'. The reported $p(\text{YES})$, confidence, and margin values confirm that this is not a low-confidence tie: the same two documents produce near-deterministic but opposite answers solely because their order changes.

These order effects help explain why confidence alone is unreliable under conflict. In 'CIC', models often become both more accurate and more confident because the correct document is placed first. In 'ICC', the same evidence is present, but the incorrect-first ordering reduces accuracy, worsens calibration on average, and changes many predictions. Thus the benchmark's position effect propagates into uncertainty as well as answer accuracy: under conflicting biomedical context, the same retrieved documents can lead to different answers and different confidence profiles solely because their order changes.

5 Conclusion

Conflicting biomedical evidence is not simply noisy retrieval; it creates a separate source of errors that should be evaluated and addressed directly. Across six open-weight models, correct evidence improves accuracy and calibration, incorrect evidence sharply degrades both, and reversing correct and contradictory documents changes both answers and associated confidence. In the hardest conditions, a conflict-aware abstention score identifies safer examples more effectively than raw confidence alone. Together, these results show that evaluation under helpful retrieval is not sufficient: biomedical retrieval-augmented QA systems should also be tested under misleading and mixed-evidence conditions, and practical systems should explicitly represent evidence disagreement when deciding whether to answer or defer. A concrete direction for future work is to rewrite conflicting retrieved documents into a conflict-aware synthesis that explicitly states the disagreement before inference, and to test whether such reformulation improves robustness, calibration, or abstention behavior.

Limitations

This study is limited in two main ways. First, all experiments are conducted on a single benchmark, HEALTHCONTRADICT, so the reported effects may not fully capture how uncertainty and abstention behave under conflicting evidence in other biomedical retrieval settings. Second, the benchmark uses a binary yes/no QA format, which is more controlled than biomedical QA tasks that require explanation, synthesis across multiple sources, or richer uncertainty communication.

A Prompt and Inference Details

Table 7 lists the raw prompt bodies used for the five HEALTHCONTRADICT context conditions before any optional model-specific chat wrapping. 'QUESTION', 'CORRECT_DOC', and 'INCORRECT_DOC' denote the instance-specific question and evidence fields.

All evaluations score next-token logits over YES/NO rather than free-form generations. Only Qwen3-8B and Qwen3.5-9B require an additional chat-template override in our setup: we set `enable_thinking=False` because these checkpoints default to a reasoning mode that inserts a reasoning prefix before the final answer token. Disabling that mode ensures that the scored next-token distribution corresponds directly to the binary answer decision and keeps the constrained evaluation comparable across models.

Condition	Raw prompt template

'NC'	`Answer the following question with only YES or NO based on your parametric knowledge.`
	`Question: QUESTION`
	`Answer:`

'CC'	`Answer the following question with only YES or NO based on the given contextual knowledge.`
	`Question: QUESTION`
	`Context: CORRECT_DOC`
	`Answer:`

'IC'	`Answer the following question with only YES or NO based on the given contextual knowledge.`
	`Question: QUESTION`
	`Context: INCORRECT_DOC`
	`Answer:`

'CIC'	`Answer the following question with only YES or NO based on the given contextual knowledge.`
	`Question: QUESTION`
	`Context:`
	`CORRECT_DOC`
	`INCORRECT_DOC`
	`Answer:`

'ICC'	`Answer the following question with only YES or NO based on the given contextual knowledge.`

	`Context:`
	`INCORRECT_DOC`
	`CORRECT_DOC`
	`Answer:`

Table 7: Raw prompt templates used for the five HealthContradict context conditions before optional model-specific chat formatting.

B Metric Definitions

Constrained probabilities. For a prompt x, let $z_{\text{YES}}(x)$ and $z_{\text{NO}}(x)$ denote the next-token logits for YES and NO. We convert these to constrained binary probabilities by normalizing over $\{\text{YES}, \text{NO}\}$ only:

$$p_{\text{YES}}(x) = \frac{\exp(z_{\text{YES}}(x))}{\exp(z_{\text{YES}}(x)) + \exp(z_{\text{NO}}(x))},$$

and $p_{\text{NO}}(x) = 1 - p_{\text{YES}}(x)$.

Calibration metrics. Let $c_i = \max(p_{\text{YES}}(x_i), p_{\text{NO}}(x_i))$ denote the confidence for instance i, $a_i \in \{0, 1\}$ its correctness indicator, and $\{B_m\}_{m=1}^{10}$ denote 10 equal-width confidence bins. Expected calibration error (ECE) is

$$\text{ECE} = \sum_{m=1}^{10} \frac{|B_m|}{n} \left| \frac{1}{|B_m|} \sum_{i \in B_m} a_i - \frac{1}{|B_m|} \sum_{i \in B_m} c_i \right|,$$

measuring the weighted mean absolute gap between bin-level accuracy and bin-level confidence. Brier score is

$$\text{Brier} = \frac{1}{n}\sum_{i=1}^{n}(c_i - a_i)^2,$$

measuring mean squared error between model confidence and binary correctness.

Conflict-aware abstention score. The conflict-aware score (CAS) combines raw confidence $c(x)$ with a learned risk signal $r(x) \in [0, 1]$:

$$s_{\text{CAS}}(x) = (1 - \alpha)\, c(x) - \alpha\, r(x),$$

where $r(x)$ is the predicted probability that prediction x is confidently wrong, produced by the within-condition logistic detector, and $\alpha \in [0, 1]$ is a fixed mixing weight ($\alpha = 0$ recovers confidence-only; $\alpha = 1$ yields the detector-only ranker).

C Qualitative Case Study Evidence

Item	Verbatim retrieved text
Question	"Can exercise lower cholesterol?" (ground-truth answer: YES)
Correct document	"If your cholesterol numbers aren't where they ought to be, working out should be a key part of your get-healthy strategy. The right kinds of workouts, done regularly, can raise levels of heart-protecting HDL cholesterol and drop dangerous triglyceride levels."
Incorrect document	"Exercise itself doesn't directly lower cholesterol but will strengthen the heart and entire circulatory system."

Table 8: Verbatim evidence for the qualitative case study on HEALTHCONTRADICT instance 650. The two retrieved documents directly conflict on whether exercise itself lowers cholesterol.

D Sensitivity Analyses

D.1 Alpha Sensitivity

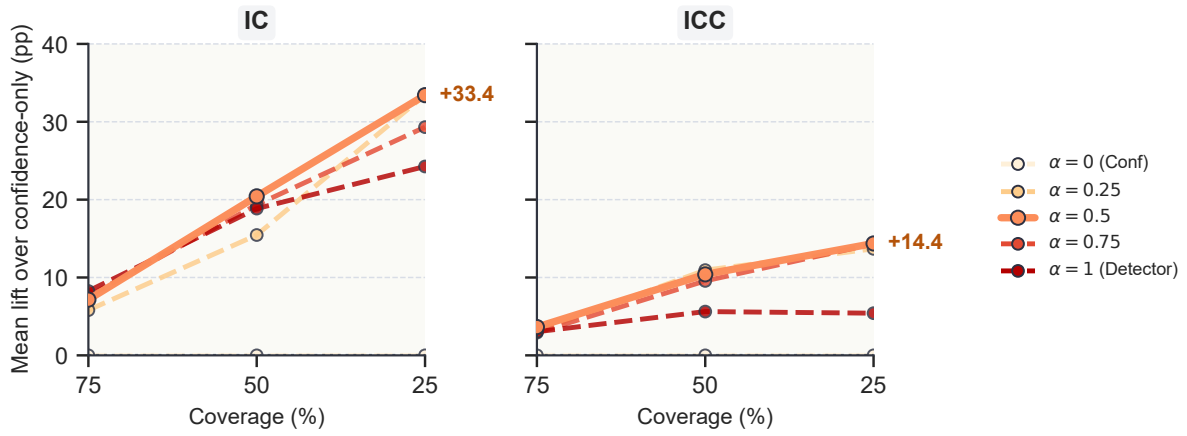

Figure 5: Mean held-out selective-accuracy lift of CAS over Conf under the train-threshold transfer protocol as the mixing weight α varies. Curves are shown separately for 'IC' and 'ICC' at 75%, 50%, and 25% target coverage, with $\alpha = 0.5$ visually highlighted as the setting used in the main experiments. The endpoints isolate the two component scores: $\alpha = 0$ recovers Conf and so produces a lift of zero by construction, while $\alpha = 1$ uses only the conflict detector r and isolates its contribution. Moderate values of α produce similar gains, while $\alpha = 1.0$ weakens the more selective 'ICC' operating points.

Figure 5 checks whether the selective-prediction gains depend strongly on the mixing weight α, including the two limit cases $\alpha = 0$ (Conf alone) and $\alpha = 1$ (detector alone). The $\alpha = 0$ point sits at zero

by construction and anchors the curve at the confidence-only baseline. The $\alpha = 1$ point isolates the conflict detector r: in 'IC', detector-only ranking still gives a mean lift over Conf of 8.3, 18.9, and 24.3 percentage points at 75%, 50%, and 25% coverage, indicating that r carries genuine error-detection signal beyond raw confidence rather than acting as a wrapper around it. In 'ICC', $\alpha = 1$ retains positive but smaller lift (3.0, 5.6, and 5.4 points), so confidence and the detector are complementary in this condition. Across 'IC', all tested α yield substantial positive mean lift; in 'ICC', the moderate choices $\alpha \in \{0.25, 0.5, 0.75\}$ give similar gains, whereas $\alpha = 1.0$ noticeably weakens the most selective operating point. Together this suggests that using $\alpha = 0.5$ in the main experiments is a robust mid-range choice rather than a narrowly tuned optimum, and that the gains over Conf are not solely attributable to recalibration of confidence.

D.2 Tau Sensitivity

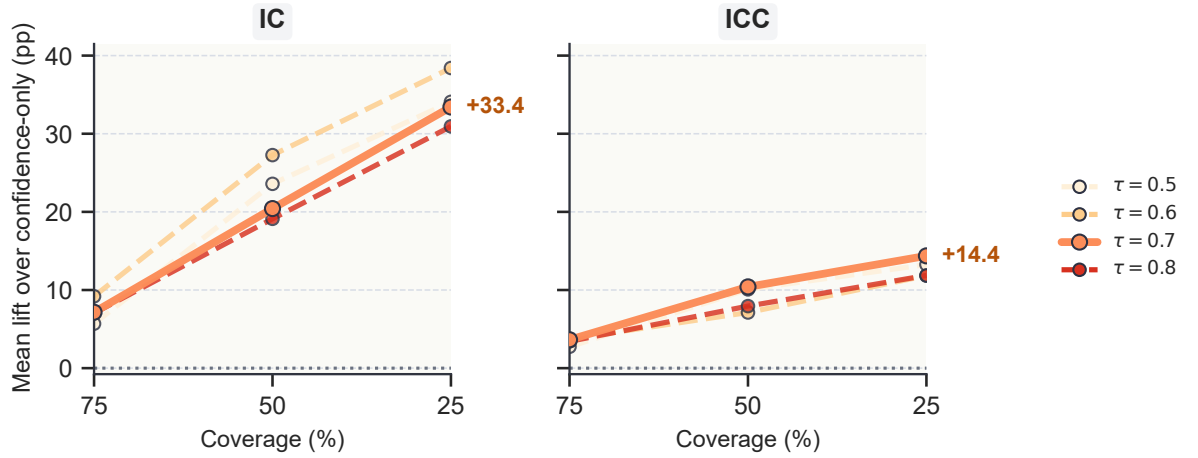

Figure 6: Mean held-out selective-accuracy lift of CAS over Conf under the train-threshold transfer protocol as the confidently-wrong supervision threshold τ varies. Curves are shown separately for 'IC' and 'ICC' at 75%, 50%, and 25% target coverage, with $\tau = 0.7$ visually highlighted as the setting used in the main experiments. Gains remain positive across all tested values, indicating that the method is not tied to a single supervision cutoff.

Figure 6 checks whether the selective-prediction gains depend strongly on the confidence threshold used to define confidently wrong cases during detector training. In 'IC', all tested thresholds yield substantial positive mean lift of CAS over Conf, with $\tau = 0.6$ giving the strongest gains in this sweep and $\tau \in \{0.7, 0.8\}$ remaining clearly positive at all three operating points. In 'ICC', the pattern is similarly stable: all tested thresholds improve over Conf, with the largest gains at 50% and 25% coverage occurring at $\tau = 0.7$. These results suggest that the method is reasonably robust to the supervision cutoff, and that using $\tau = 0.7$ in the main experiments is a sensible mid-range choice rather than a fragile tuning decision.

E Selective Prediction Supplementary Results

Detector training details. The logistic detector is trained separately for each target evidence condition (e.g., 'IC' or 'ICC') using the model's uncertainty signals (margin, entropy, confidence) together with sentence-embedding features of the question and retrieved document(s). The positive class consists of wrong predictions made with confidence above a threshold τ, with $\tau = 0.7$ in the main experiments. Threshold sensitivity is reported in Appendix D.2.

As an ablation, we also evaluate a cross-condition predictor that uses the same target-condition features but replaces direct labels with a proxy label based on confidence drop relative to the corresponding 'CC' prompt: for an instance x, the proxy label is 1 when $c_{\text{CC}}(x) - c_{\text{target}}(x) > 0.3$, asking whether a large drop from correct-only evidence is sufficient to identify risky cases.

We use an 80/20 train/test split. On the training split, we obtain 5-fold out-of-fold scores and choose thresholds for target coverages $\{0.75, 0.5, 0.25\}$, meaning that the system answers the top 75%, 50%, or 25% of ranked examples and abstains on the rest. These thresholds are transferred unchanged to the

Table 9: Held-out selective prediction results underlying Figure 4. Each cell reports selective accuracy / realized coverage for CAS and Conf. CAS thresholds are selected on train out-of-fold scores and transferred unchanged to test; Conf is evaluated at approximately matched test coverage, so realized coverages may differ slightly.

held-out test split, so the realized answered fraction on test need not equal the target exactly; Appendix Table 9 therefore reports realized coverage for both CAS and Conf.

Results. This section reports the same selective-prediction protocol used in the main text. For each target coverage, we choose a CAS threshold from train out-of-fold predictions and then apply that same numeric cutoff to the held-out test split. The test set therefore does not have to land at exactly the nominal 75%, 50%, or 25% coverage: the score distribution can shift from train to test, and score ties near the cutoff can move a few examples across the boundary. We evaluate Conf at approximately matched test coverage so that the comparison is made at nearly the same operating point. Reporting realized coverage is important because otherwise a small accuracy difference could simply reflect one method answering more examples than the other. Table 9 therefore reports both selective accuracy and realized coverage for CAS and Conf.

A Comparative Analysis of In-Context Learning and Fine-Tuning for Biomedical Information Retrieval and Sentence Extraction Using Research Domain Criteria

Abstract

Research Domain Criteria (RDoC) is a National Institute of Mental Health framework for studying mental disorders by integrating information across genetics, circuits, and behavior. Manually curating biomedical abstracts relevant to RDoC is a significant challenge due to semantically overlapping construct definitions (e.g., "Acute Threat," "Potential Threat," and "Sustained Threat") and the exponential growth of biomedical literature. This study compares two modeling strategies, domain-adapted fine-tuning and in-context prompting, across two RDoC-related subtasks from the official BioNLP-OST 2019 RDoC shared task. For Task 1, unlabeled PubMed abstracts are retrieved and ranked by relevance to eight of the RDoC constructs. We compare a TF-IDF baseline against ModernBERT and Llama (zero-shot and five-shot) using Mean Average Precision (MAP). For Task 2, the objective is to identify the single most relevant sentence from an abstract for a given construct, evaluated using per-construct accuracy. The fine-tuning track performs end-to-end fine-tuning of BioBERT, PubMedBERT, ModernBERT, and RoBERTa using a cross-encoder input format and per-construct grid search. These are compared against the in-context learning of several open-source language models. Both our approaches are competitive against the best-performing team's score from the BioNLP-OST 2019 RDoC shared task. Taken together, these findings suggest that five-shot prompted LLMs and domain-adapted fine-tuned transformers are viable tools for semi-automating the expert annotation in RDoC curation.

1 Introduction

The exponential growth of biomedical literature poses a significant challenge for mental health and psychiatric researchers and clinicians. PubMed searches for foundational concepts yield results at a scale that makes manual review unmanageable. For example, as of April 2026, the keyword "brain" returns over 2.5 million articles, "depression" returns 724k articles, and "anxiety" yields 397k articles. This challenge is further intensified by the National Institute of Mental Health's adoption of the Research Domain Criteria (RDoC) framework (Insel et al., 2010), which marks a paradigm shift from traditional diagnostic models such as the Diagnostic and Statistical Manual of Mental Disorders (DSM) and the International Classification of Diseases (ICD), to a dimensional, biologically-informed approach to understanding mental disorders. RDoC is comprehensive yet complex, encompassing six major domains of human functioning subdivided into constructs and sub-constructs. Because most of the existing biomedical literature reports (or have been curated) within DSM-ICD terminology, it must be systematically remapped to RDoC concepts, a process that is neither practical nor scalable without computational support.

Effective RDoC-based literature curation requires at least two complementary capabilities. The first is information retrieval (IR): given an RDoC construct, identifying and ranking abstracts from a large corpus that are relevant to it. The second is extracting the most relevant evidence, i.e., sentence extraction (SE): given a relevant abstract, pinpoint the specific sentence(s) that most directly support that construct. These capabilities correspond to the two subtasks established at the BioNLP-OST 2019 shared task (Anani et al., 2019) Task 1 (abstract ranking, evaluated via Mean Average Precision) and Task 2 (sentence extraction, evaluated via per-abstract accuracy), which together define a benchmark for end-to-end RDoC-based literature.

This current study evaluates two computational paradigms across the two aforementioned tasks. For Task 1, the *fine-tuning track* compares pre-trained and fine-tuned BERT family encoders as semantic relevance rankers, while the *in-context learning track* evaluates LLaMA 3.1 (8B) under

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 644–655
July 3-4, 2026 ©2026 Association for Computational Linguistics

zero-shot and few-shot strategies.

For Task 2, the *in-context learning track* applies five small open-source large language models: LLaMA 3.1 (8B), Mistral (7B), Qwen 2.5 (7B), Phi-3 (3.8B), and Gemma 2 (9B) under zero-shot and few-shot strategies with dynamic example selection including based-on TF-IDF, BM25, and sentence embeddings; and the *fine-tuning track* trains four pre-trained transformer encoders: BioBERT, PubMedBERT, RoBERTa, and ModernBERT as per-construct cross-encoder classifiers that jointly encode a construct description and a candidate sentence to produce a binary relevance judgment.

By systematically comparing in-context prompting and supervised fine-tuning, we aim to provide actionable guidance for practitioners seeking to automate RDoC literature curation and to assess the extent to which modern LLMs and fine-tuned transformers can help reduce the expert-annotation bottleneck that has historically constrained progress in this domain (Anani et al., 2019). The RDoC benchmark presents particular challenges not addressed in general-domain NLP settings. The relatively small per-construct training sets and highly overlapping construct semantics make it a demanding low-resource evaluation environment.

This paper makes three main contributions: (1) We present the first systematic comparison of in-context learning and supervised fine-tuning across both RDoC Task 1 (abstract ranking) and Task 2 (sentence extraction), using the original BioNLP-OST 2019 evaluation protocol, (2) We show that few-shot prompting with small open-source LLMs achieves competitive performance with domain-adapted transformers, narrowing the gap to the shared-task best system with no parameter updates, and (3) We provide an empirical analysis demonstrating that lexical example selection (TF-IDF/BM25) consistently competes with dense embeddings for construct-specific prompting in the RDoC setting.

2 Related Work

Biomedical literature curation related to mental health and brain sciences remains a recognized bottleneck in scientific research (Anani et al., 2020). While traditional keyword-matching techniques like TF-IDF (Manning et al., 2008) establish strong initial retrieval baselines, domain-specific extraction requires specialized approaches. To address this, the 2019 BioNLP-OST RDoC Task introduced the inaugural benchmark competition to identify the concepts of Research Domain Criteria (RDoC) in biomedical abstracts (Anani et al., 2019). For abstract ranking (Task 1), Chaudhary et al. (Chaudhary et al., 2019) established the top benchmark (MAP 0.86) using a multi-grain neural relevance ranking system that integrated neural topic models with attention-based sentence interactions. For sentence extraction (Task 2), Laden et al. (2020) developed RDoCer, combining TF-IDF document scoring with a supervised ensemble of lexical and structural features. This approach achieved an accuracy of 0.48, ranking first on the *Sustained Threat*.

In the years that followed, research shifted toward domain-specific transformer architectures, notably with Naseem et al. (Naseem et al., 2022), who demonstrated that BioALBERT could surpass several prior supervised benchmarks by leveraging parameter-efficient pretraining on large biomedical corpora. As the field entered the era of Large Language Models (LLMs), Chen et al. (Chen et al., 2024) evaluated the zero-shot capabilities of models such as GPT-4, finding that although these models exhibit deep clinical reasoning, they often require sophisticated prompting to match the ranking precision of specialized systems. However, neither of these studies incorporates RDoC Task data into the benchmarking process.

To the best of our knowledge, no prior work has directly compared in-context prompting with fine-tuned transformer classifiers on both RDoC Task 1 and Task 2 simultaneously, nor has it evaluated dynamic few-shot example selection strategies in this domain. This study fills that gap with a systematic empirical comparison based on the original shared-task evaluation protocol.

3 Methodology

As depicted in Figures 1 and 2, this study employs two experimental tracks, in-context learning and fine-tuning, applied across the two RDoC task formulations. Both tracks are evaluated against the same benchmark dataset using identical train-test splits and official evaluation protocols, but they represent fundamentally different computational paradigms. The in-context track requires no parameter updates and relies on prompt-based reasoning, while the fine-tuning track adapts pre-trained model weights through supervised training on task-specific labeled data.

Figure 1: This pipeline shows the complete workflow for Task 1. From raw inputs (Title, Abstract, Training set, Query with RDoC Construct and NIMH Definition) through baseline modeling (TF-IDF with Cosine Similarity Ranking), implemented IR techniques (Pre-trained vs Fine-tuned BERT family models), implemented reasoning techniques (Zero-shot vs. Five-shot LLaMA Version 3.1), to final evaluation using Mean Average Precision (MAP).

RDoC Construct	Train	+Test	-Test	Gold
Negative Valence System				
Acute Threat (Fear)	39	53	26	53
Potential Threat (Anxiety)	27	124	15	124
Frustrative Nonreward	21	96	48	96
Sustained Threat	18	82	64	82
Loss	28	90	48	90
Arousal & Regulatory Systems				
Arousal	38	97	11	97
Sleep and Wakefulness	48	121	1	121
Circadian Rhythms	47	123	0	123
Total	**266**	**786**	**213**	**786**

Table 1: Dataset distribution across eight RDoC constructs for training and test splits. Task 1 test abstracts include both positive (relevant) and negative (irrelevant) examples; Task 2 test abstracts are gold-labeled at the sentence level.

3.1 Data

This study employs the benchmark dataset from the BioNLP-OST 2019 RDoC Task (Anani et al., 2019), which consists of human-annotated PubMed abstracts covering eight RDoC constructs. These constructs span two domains of the RDoC framework: the Negative Valence System (Acute Threat, Potential Threat, Sustained Threat, Loss, Frustrative Nonreward) and the Arousal and Regulatory Systems (Arousal, Circadian Rhythms, Sleep and Wakefulness). Gold-standard annotations were produced by three independent expert annotators affiliated with the National Alliance on Mental Illness (NAMI) Montana. (Anani et al., 2019).

The structure of the data set differs between the two tasks, each with a dedicated test set. The shared training set contains 266 abstracts annotated as positive examples for their respective constructs, with per-construct counts ranging from 18 (Sustained Threat) to 48 (Sleep and Wakefulness). The Task 1 test set contains 999 abstracts spanning all eight constructs, of which 786 are labeled as construct-relevant (positive) and 213 as construct-irrelevant (negative). The Task 2 test set contains 244 abstracts, each paired with gold-standard, sentence-level labels that mark the single sentence in each abstract that is most relevant to the target construct. Table 1 reports the full per-construct distribution across all three splits (see Table 1).

For the fine-tuning track's Task 2 experiments, the 266 training abstracts were segmented into individual sentences using NLTK's sentence tokenizer (https://www.nltk.org/), yielding 1,570 sentence-level training instances across all constructs (417 relevant and 1,153 non-relevant). A sentence received a positive label (relevant $= 1$) if it occurred as a substring within the gold relevant context annotation for its abstract; otherwise, it was assigned a negative label (irrelevant $= 0$). This programmatic derivation meant that all sentence-level supervision was obtained directly from the existing abstract-level annotations without additional human labeling. The resulting training data is moderately imbalanced, with approximately 73% non-relevant instances, a characteristic that varies across constructs and bears on training stability.

3.2 In-Context Learning Track

Task 1: Abstract Ranking LLaMA 3.1-70B (AI@Meta, 2024) was queried via the Together AI API (https://www.mintlify.com) to

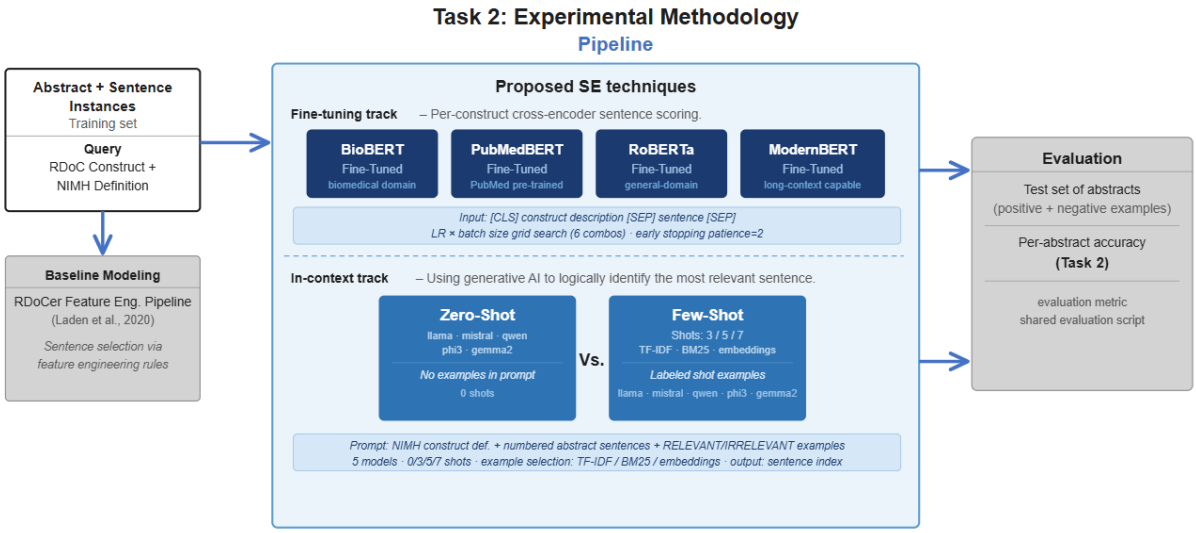

Figure 2: This image depicts the experimental methodology pipeline for Task 2, illustrating two proposed sentence extraction tracks: a fine-tuning track and an in-context learning track comparing zero-shot and few-shot prompting strategies, evaluated using per-abstract accuracy.

assign a relevance score to each test abstract. Two prompting configurations were evaluated. In the zero-shot configuration, the prompt consisted solely of the RDoC construct definition with no labeled examples; five independent trials were conducted, and the results were averaged for robustness. In the five-shot setting, 10 manually selected example abstracts were provided for each construct (five positive and five negative) as in-context demonstrations, enabling the model to discern the linguistic patterns typical of each construct.

Task 2: Sentence Extraction Five small open-source instruction-tuned language models were evaluated locally via Ollama (https://ollama.com/) under zero-shot and few-shot conditions. For each test abstract, the model received a prompt containing the NIMH construct definition and the abstract's sentences enumerated numerically, and was instructed to return a single integer index identifying the most relevant sentence. Under few-shot conditions, labeled RELEVANT and IRRELEVANT sentence examples drawn from the training data were prepended using shot counts of 3, 5, and 7, with demonstrations selected via TF-IDF, BM25, or dense sentence embedding similarity to the test instance. Each configuration was repeated across three random seeds and results were averaged.

3.3 Fine-Tuning Track

Task 1: Abstract Ranking Three BERT-family encoders were evaluated in both pre-trained (frozen) and fine-tuned configurations as abstract relevance rankers, with a binary sequence classification head added to predict whether each abstract is relevant (label $= 1$) or irrelevant (label $= 0$) to a given construct. For fine-tuned variants, a BM25-based pseudo-labeling strategy was first applied to generate construct-specific training subsets. BM25 scores were computed for all training abstracts against an expanded construct query combining the construct name and its NIMH definition. The top-20 abstracts by BM25 score were assigned positive labels; the remaining abstracts received negative labels. This pseudo-labeled subset was used for fine-tuning with early stopping. Pre-trained variants used the same classification head but received no weight updates, serving as a direct comparator.

Task 2: Sentence Extraction. Transformer encoders were fully fine-tuned as per-construct binary classifiers. Rather than encoding the construct and candidate sentence independently, input was formatted using a cross-encoder template that concatenates the NIMH construct definition and the candidate sentence as a single sequence, allowing the model to attend directly across both inputs within a single forward pass. This joint encoding is the core methodological distinction from bi-encoder

or feature-based approaches: the model learns relevance as an interaction between the construct description and the sentence, rather than as a property of either in isolation. A separate classifier was trained for each of the eight RDoC constructs, based on the reasoning that construct-specific fine-tuning is more effective than a single joint model given the semantic distinctiveness of the constructs and the small per-construct training sets.

4 Models

Our approaches were selected to address distinct operational and technical goals within the RDoC annotation pipeline. We chose TF-IDF and BM25 as strong, interpretable lexical baselines to establish a meaningful lower bound for performance. Fine-tuned encoders, including BioBERT, PubMedBERT, ModernBERT, and RoBERTa, were selected to determine if domain-specific pre-training and task-specific supervision could capture subtle semantic distinctions missed by lexical approaches, with the cross-encoder format explicitly conditioning sentence scoring on construct descriptions. Few-shot prompting models evaluated whether instruction-tuned LLMs could generalize RDoC construct identification without task-specific training, representing a low-overhead deployment scenario for resource-constrained clinical settings.

4.1 Baseline

We implement a well-established information retrieval baseline: TF-IDF with Cosine Similarity. For each construct, the query is constructed by concatenating the construct name with its NIMH RDoC construct definition, and all test abstracts are ranked by cosine similarity in the TF-IDF vector space. TF-IDF requires no training and relies solely on keyword overlap between abstracts and construct definitions.

4.2 BM25

BM25 extends TF-IDF with term frequency saturation and document length normalization, producing more stable relevance scores across abstracts that vary substantially in length. In this study, BM25 fulfills two functions: it acts as the retrieval baseline for Task 1 and also provides pseudo-labels used as training supervision for the fine-tuned Task 1 models and for in-context prompting in Task 2.

4.3 In-context Learning Track

4.3.1 Task 1: Abstract Ranking

LLaMA 3.1-70B (AI@Meta, 2024) was queried via the Together AI API (`https://api.together.xyz/`). Its 128K-token context window enables processing of full abstracts alongside construct definitions and in-context examples without truncation. However, its limited exposure to RDoC-specific psychiatric terminology may constrain its ability to distinguish conceptually overlapping constructs, particularly the Threat cluster (Acute Threat, Potential Threat, Sustained Threat).

4.3.2 Task 2: Sentence Extraction

Five open-weight instruction-tuned models were evaluated locally via Ollama: LLaMA 3.1 (8B) (Dubey et al., 2024), Mistral (7B) (Jiang et al., 2023), Qwen 2.5 (7B) (Team, 2024), Phi-3 (3.8B) (Abdin et al., 2024), and Gemma 2 (9B) (Team et al., 2024). These models were selected to represent a range of architectures, parameter scales, and training corpora at the small open-source frontier. LLaMA 3.1 uses grouped query attention with a 128K context window; Mistral employs sliding window attention for memory efficient inference; Qwen 2.5 was pre-trained on over 18 trillion tokens with strong scientific coverage; Phi-3 prioritizes high-quality curated training data over scale; and Gemma 2 uses alternating local and global attention with knowledge distillation from a larger model.

4.4 Fine-tuning Track

4.4.1 Task 1: Abstract Ranking

Three BERT encoders were evaluated in both pre-trained and fine-tuned configurations: ModernBERT (Warner et al., 2024), PubMedBERT (Gu et al., 2021), and BioBERT (Lee et al., 2020). Pre-trained variants compute cosine similarity between construct definition and abstract representations without weight updates. Fine-tuned variants are adapted using BM25 pseudo-labeled training data.

4.4.2 Task 2: Sentence Extraction

The fine-tuning track approached Task 2 as a per-construct binary sentence classification problem. Four pre-trained transformer models were fine-tuned independently: BioBERT (**?**), PubMedBERT (Gu et al., 2021), RoBERTa (Liu et al., 2019), and ModernBERT (Warner et al., 2024), representing biomedical domain-specific, PubMed-specific, general-domain, and

long-context architectures, respectively. All four were fine-tuned using the Hugging Face `AutoModelForSequenceClassification` head with two output labels.

BioBERT and PubMedBERT provide biomedical domain specialization through continued and from-scratch pre-training on PubMed and PMC literature, with BioBERT's retention of the NSP objective offering additional structural alignment with the cross-encoder format. RoBERTa serves as a general-domain baseline, while ModernBERT represents an architecturally modern encoder with an extended 8,192-token context window, trading biomedical depth for up-to-date design choices.

5 Experimental Setup

5.1 Task 1: Abstract Ranking

All models were evaluated on the test set using Mean Average Precision (MAP) as the primary metric. MAP is considered a standard metric for information retrieval tasks, computed as the macro-average across all RDoC constructs. This metric assesses the quality of retrieved abstract rankings, with emphasis on early retrieval of relevant abstracts.

Following the original RDoC Task (Anani et al., 2019), strict separation between training data (Set 1) and test data (Set 2) was maintained, with test data containing positive and negative examples in all constructs examined. 20% of the training data was used as a validation set for parameter tuning. Mean Average Precision (MAP) is computed per construct and then macro-averaged, capturing both precision and ranking quality, which is crucial for real-world curation workflows.

Baseline Comparison: Models were compared against a TF-IDF + cosine similarity baseline, using construct definitions as queries. This baseline represents the state of practice in many curation pipelines. LLaMA inference uses standard sampling to balance consistency and diversity. Both zero-shot and few-shot prompting strategies leverage the model's weights without gradient-based updates. LLaMA was used with default parameters. For few-shot, the optimal number of examples were chosen using a validation set.

For the BERT models, a hyperparameter search algorithm systematically evaluated all combinations of learning rates {1e-5, 2e-5, 3e-5} and epoch counts (2, 3, 4) for each construct independently, resulting in 9 total hyperparameter configurations. Validation performance on construct-specific validation sets guided the selection of the following optimal hyperparameters: Max Sequence Length: 512 tokens, Batch Sizes: 8 (training), 16 (evaluation), Weight Decay: 0.01, Warmup Steps: 50, Learning Rate: Hyperparameter search space (primary: 1e-5 to 3e-5), Number of Epochs: Hyperparameter search space (primary: 2-4 epochs), Early Stopping: EarlyStoppingCallback with patience=2, Optimizer: AdamW.

5.2 Task 2: Sentence Extraction

For the in-context track, five models were evaluated under zero-shot and few-shot conditions. In the zero-shot condition, no labeled examples were included. In the few-shot condition, shot counts of 3, 5, and 7 were evaluated, with examples drawn from the training data using three selection strategies: TF-IDF retrieval, BM25 retrieval, and dense sentence embedding similarity. Each few-shot configuration was repeated on three random seeds, and the results were averaged. The complete experimental grid consisted of 5 models $\times 3$ shot counts $\times 3$ selection strategies $\times 3$ seeds = 135 few-shot runs, plus 5 zero-shot runs.

The prompt structure followed a consistent template across all conditions. The construct definition was provided as a task context block, followed by the abstract sentences enumerated numerically, with the instruction to return a single integer. In the few-shot condition, Example sentences labeled as RELEVANT or IRRELEVANT were inserted with the construct definition and the abstract. (See Figure 5 in the Appendix for a prompt example).

Performance was measured using the official per-abstract accuracy metric via script_task2.py (Anani et al., 2019). A prediction is correct if the selected sentence appears as a substring of the gold Relevant Context annotation. Macro-average accuracy across the 8 constructs is the primary metric.

For the fine-tuning track, Four transformer encoders were fine-tuned per-construct using the Hugging Face Trainer (Wolf et al., 2020) on a Google Colab A100 GPU with mixed-precision (fp16) enabled and a global random seed of 42. For each construct, sentence-level training instances were partitioned 80/20 into training and validation subsets using stratified sampling on the relevance label. Hyperparameters were selected via a grid search over three learning rates $\{1\times10^{-5}, 2\times10^{-5}, 5\times10^{-5}\}$. and two batch sizes (8, 16), yielding six combinations per construct. Early stopping with a patience

of 2 (max epochs of 10) was applied to every grid search run, evaluated once per epoch against validation accuracy. The combination achieving the highest validation accuracy was selected and used to retrain the model on the full training set, again with early stopping.

All runs used AdamW optimization with weight decay of 0.01 and no learning rate warmup. The maximum input sequence length was set to 128 tokens with padding and truncation applied where necessary. During inference, the fine-tuned classifier produced a relevance probability score (the softmax probability of class 1) for each candidate sentence in a test abstract, and the sentence with the highest score was chosen as the prediction. Predictions were evaluated using the official per-abstract accuracy metric via `script_task2.py`, and macro-average accuracy across all eight constructs is the primary reported metric.

6 Results and Discussion

6.1 Task 1: Abstract Ranking

As shown in Figure 3, evaluation across eight distinct approaches revealed substantial differences in performance. The biomedically pre-trained models proved to be competitive but not superior. Across our models, the PubMedBERT models, both the pre-trained and fine-tuned, achieved the highest performance at 0.83 MAP, along with the pre-trained BioBERT. The ModernBERT models performed similarly with MAP scores of 0.82 for the pre-trained and 0.80 for the fine-tuned approach. As for the in-context models, prompting with LLaMA 3.1-70B achieved the lowest performance at 0.79 MAP (zero-shot) and 0.76 MAP (few-shot).

The performance decline from zero-shot to five-shot LLaMA is attributed to selection bias in the manually chosen demonstrations and to lexical overlap within the Threat construct cluster (Acute, Potential, and Sustained Threat), where few-shot examples from one construct inadvertently reinforce vocabulary from the others. In the zero-shot setting, the model relies solely on the NIMH definition, which provides a cleaner disambiguation signal. This suggests that construct-aware, automated example selection is needed for semantically overlapping constructs.

Both our generative reasoning with few examples and discriminative fine-tuning approaches achieve comparable performance on this task. The pre-trained BERT models demonstrated that even without task-specific fine-tuning, the model captures sufficient semantic information for construct classification, where supervised adaptation may not improve results.

Relatively high baseline (TF-IDF) MAP values indicate that, despite high semantic overlap among RDoC constructs, keyword-based retrieval remains competitive. The results demonstrate that while modern general-purpose models are competitive, they do not yet surpass the specialized state-of-the-art for this retrieval task. The RDoC Task's (Anani et al., 2019) best performer (T30) maintains the lead with a MAP of 0.86.

Our models, e.g., ModernBERT, achieve near-perfect results on biologically distinct topics such as Sleep & Wakefulness (0.99) and Potential Threat (0.93), but the performance collapses on overlapping concepts such as Sustained Threat (0.58) and Loss (0.69). This suggests that models effectively capture distinct medical vocabulary but struggle to disentangle nuanced psychological traits such as distinguishing chronic stress from anxiety, dragging down the overall average despite high proficiency in the clearer biological categories.

6.2 Task 2: Sentence Extraction

Neither paradigm, in-context, or fine-tuning reached the RDoCer (Laden et al., 2020), i.e. RDoC Tasks's best (T30) of 0.58, although BioBERT came closest at 0.54. The poor performance of RoBERTa, together with the comparable results of BioBERT and PubMedBERT, suggests that while domain-specific pre-training is required, it alone does not explain performance. Instead, the cross-encoder setup and the use of the construct description as the query appear to be the main methodological factors driving effectiveness.

Fine-tuning The two biomedical domain-specific models produced the strongest results and were nearly identical in performance: BioBERT achieved a macro-average accuracy of 0.543 and PubMedBERT 0.541, both clearing the RDoCer baseline (0.478) by approximately +0.064 and falling within 0.037 of the RDoC Task's best performer (T30) with 0.580. The convergence of these two models supports the conclusion that domain-specific pre-training is the primary differentiating factor, regardless of whether the model is initialized from general BERT weights (BioBERT) or trained from scratch on biomedical text (PubMedBERT). ModernBERT achieved

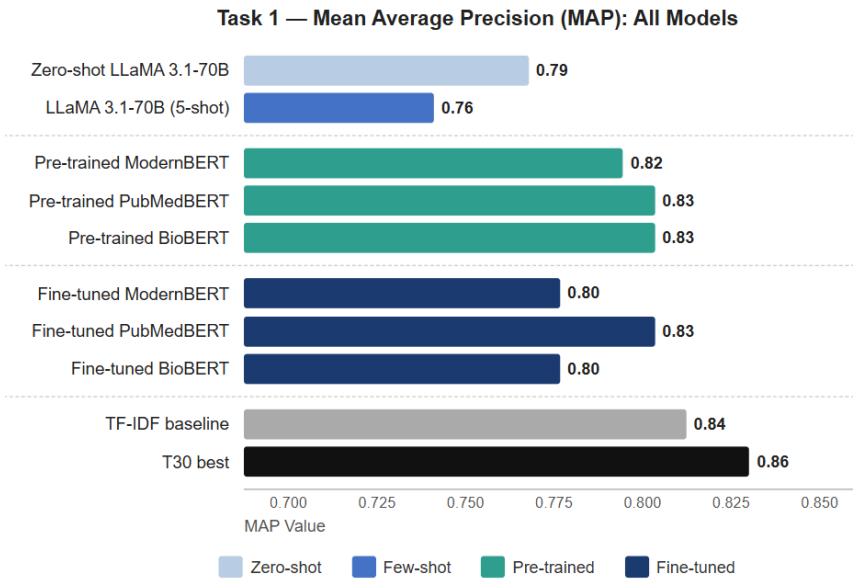

Figure 3: Task 1 MAP results comparing

0.485, marginally clearing the RDoCer baseline (+0.007) but sitting 0.095 below T30. Despite its architectural advantages, its limited biomedical pre-training appears to constrain performance.

RoBERTa was the weakest model at 0.469, falling below both the RDoCer baseline (-0.009) and T30 (-0.111). In four of the eight constructs, the model experienced class collapse: for Arousal, Potential Threat (Anxiety), Acute Threat (Fear), and Frustrative Nonreward, it labeled every test instance as belonging to the non-relevant class. This may be attributable to the removal of the Next Sentence Prediction objective during pre-training, combined with moderately imbalanced training data (73% non-relevant), which together allow the optimizer to converge on a majority-class shortcut. RoBERTa's results should be interpreted with caution, and they are reported for completeness rather than as a reliable performance estimate. Across all models, Acute Threat (Fear) was consistently the hardest construct and Circadian Rhythms the easiest, mirroring patterns from the original 2019 RDoC shared task and consistent with training set size differences across constructs (see Figure 6 in the Appendix) for construct-wise performance.

In-context prompting Zero-shot performance across the five LLMs ranged from 0.380 (LLaMA 3.1 8B) to 0.482 (Gemma 2 9B). All five models fell below the T30 benchmark of 0.580 under zero-shot conditions, and only Gemma 2 exceeded the baseline of 0.40. The spread of more than 10 percentage points between the best and worst zero-shot models suggests that instruction-following capability and model capacity vary meaningfully at this parameter scale for the identification of sentences at the construct-level.

Few-shot prompting produced consistent improvements across all five models, with an average gain of +0.034 over zero-shot. The best overall performance came from Gemma 2 (9B) using 7-shot TF-IDF-based example selection, reaching a macro-average accuracy of 0.517. This is the strongest in-context result and represents a substantial gain over the baseline (+0.117), although it remains 0.063 behind T30. LLaMA 3.1 (8B) showed the largest individual few-shot gain of +0.070, rising from the lowest zero-shot accuracy (0.380) to 0.450 with 3-shot TF-IDF selection, suggesting it is particularly sensitive to prompt context despite weaker zero-shot construct understanding.

Example selection strategy mattered across models. TF-IDF retrieval produced the best few-shot result overall and BM25 was similarly competitive, while sentence embedding selection consistently underperformed both lexical methods. This finding is non-trivial: semantic similarity did not outperform lexical matching for construct-specific example retrieval. We distinguish this finding from prior work on dense retrieval (e.g., MedCPT) (Jin et al., 2023), which targets corpus-level document ranking. Our comparison concerns in-context demonstration selection, where TF-IDF and BM25 excel

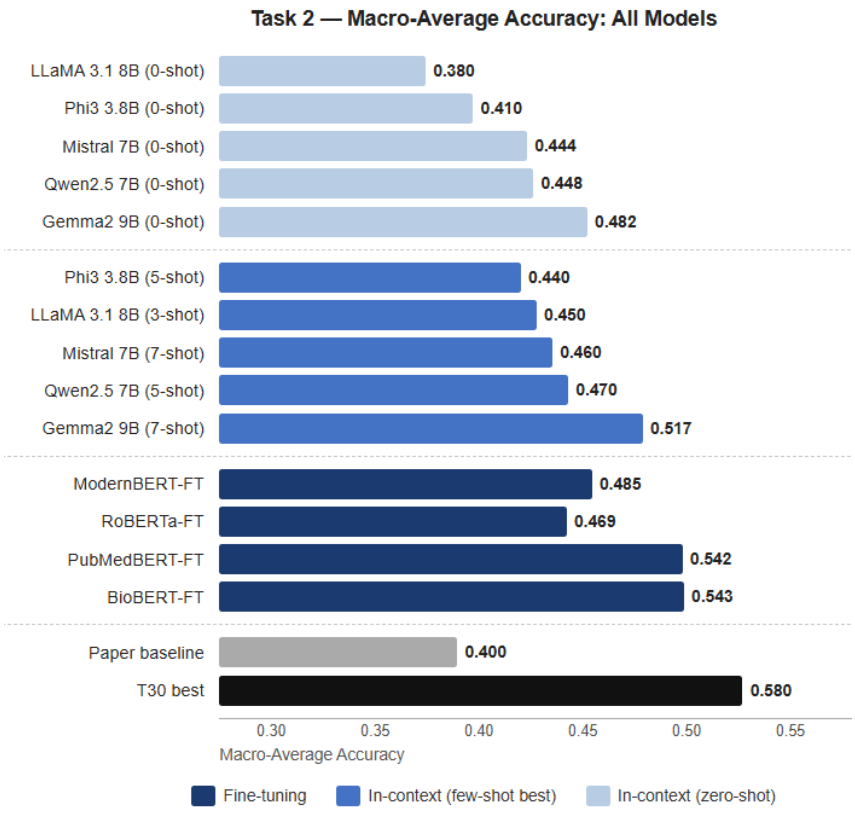

Figure 4: Task 2 Macro-Average Accuracy results

by directly matching National Institute of Mental Health (NIMH) construct-specific terminology through keyword overlap. Conversely, dense embeddings retrieve thematically adjacent examples that often lack this precise, construct-marking vocabulary, ultimately producing less discriminative prompts in this setting.

The consistent underperformance of dense embedding selection (all-MiniLM-L6-v2) across 4 out of 5 models supports this interpretation. For example, TF-IDF retrieves Arousal demonstrations containing terms like 'startle reflex' and 'locomotor activity,' while dense embeddings retrieve sentences from adjacent constructs (e.g., Sleep and Wakefulness) due to overlapping themes, weakening the prompt signal. A similar cross-construct confusion occurs in the Threat cluster, where embedding-selected examples blur the boundary between Sustained Threat and Potential Threat through shared 'chronic stress' vocabulary.

7 Conclusion and Future Work

The results demonstrate that In-context Learning and Fine-tuning offer complementary pathways for RDoC construct-based literature retrieval and extraction, each with distinct strengths. For task 1, PubMedBERT provides marginal performance gains over ModernBERT and BioBERT. LLaMA prompting, despite its relatively low MAP values, offers notable data efficiency, rapid adaptability to new constructs, and reasoning transparency through natural-language explanations, which are critical advantages for applications that require construct-specific justifications. The observed relative performance decline from zero-shot to five-shot LLaMA indicates that construct-aware prompt engineering warrants further investigation.

Future work should focus on construct-specific fine-tuning with more strategic example selection against pretrained models to better capture domain-specific terminology and psychiatric construct language. In addition, conducting an in-depth per-construct performance analysis for both In-context Learning and Fine-tuned models using an ensemble of LLMs would enable a granular comparison of construct-specific strengths and weaknesses across the two approaches.

8 Limitations

This study uses the only known curated dataset related to RDoC via the gold-standard abstracts from the RDoC Task, which was held in 2019. Therefore, our study is restricted by the limited nature of this data. For example, this dataset, is only a single, 6-year-old snapshot of the RDoC Landscape; the RDoC Matrix itself has changed (new constructs like "Sensorimotor Systems" have been added, though no constructs have been removed), not to mention the exponential growth of RDoC-related literature in databases such as PubMed since 2019.

Key challenges for developing methods included the limited training data for certain constructs and the computational cost of hyperparameter tuning with LLMs, which require consistent GPU access and extended training time (that limited our ability use larger models with a very high number of parameters). Task 1 fine-tuning was further constrained by the structure of the available training data, which provides only binary positive or negative abstract assignments per construct rather than ranked relevance judgments. Because this is insufficient to train a ranking model directly, we approximated relevance scores using BM25 as a pseudo-labeling strategy; while this allowed us to apply fine-tuned encoders to the retrieval task, the resulting label noise likely suppresses performance relative to what gold-ranked supervision would yield. We report Task 1 results for completeness but do not claim improvement over the TF-IDF baseline, and we identify the absence of ranked training labels as the primary bottleneck for future work on this task. Another limitation is the lack of construct-specific fine-tuning with more strategic example selection to better capture domain-specific terminology and psychiatric construct language. Multi-task learning was avoided due to severe per-construct imbalance.

In addition, open-source BERT-family models and LLaMA do not represent the full capabilities of the current generation of LLMs (especially their commercial counterparts like GPT), which appear to be improving rapidly. Similarly, the implemented IR techniques do not capture some of the more recent IR innovations like retrieval augmented generation (RAG). In addition, dense retrieval methods such as MedCPT (Jin et al., 2023) were not evaluated, specifically on Task 1, representing a meaningful gap for future work. Lastly, we do not utilize the inherent hierarchical structure of the RDoC Matrix nor the construct-specific matrix elements beyond the construct definitions.

9 Ethical considerations

This work involves automated retrieval of biomedical abstracts related to mental health research using the Research Domain Criteria (RDoC) framework. Our work utilizes publicly available PubMed abstracts and the RDoC shared task dataset, which contains only de-identified scientific literature without patient information or clinical records. No individual-level health data was used in this research. While our system retrieves abstracts related to mental health constructs, we emphasize that the RDoC framework is designed for research purposes to advance understanding of mental disorders through dimensional, cross-cutting approaches. Our work does not diagnose, treat, or make claims about individuals with mental health conditions. We acknowledge the potential for language models to perpetuate stigmatizing language or biases present in the biomedical literature and recommend careful human oversight when deploying such systems in practice.

This study focuses on information retrieval for research purposes and is not intended for direct clinical decision-making. Any future deployment of LLM-based retrieval systems in clinical settings would require rigorous validation, regulatory approval, and appropriate safeguards to ensure patient safety. Clinicians and researchers should critically evaluate retrieved abstracts rather than relying solely on automated rankings. We compare open-source models to promote transparency and reproducibility in biomedical NLP. However, we recognize that LLMs may produce errors, hallucinations, or retrieve irrelevant content. Users of such systems should be trained to identify limitations and maintain appropriate skepticism of automated retrieval results.

Improved retrieval of mental health research literature has the potential to accelerate scientific discovery and improve understanding of mental disorders. However, we acknowledge that advances in automated text mining could also facilitate misuse, such as cherry-picking literature to support predetermined conclusions. We advocate for responsible use of these tools within established evidence-based, scientific and ethical frameworks.

A Appendix: Prompting Example

Figure 5 shows an example of the few-shot prompting format used for both Task 1 and Task 2 experiments.

Sample Prompt Preview

Which sentence provides the strongest evidence that this abstract discusses Arousal?

Definition: Arousal is a continuum of sensitivity of the organism to stimuli, both external and internal. Arousal facilitates interaction with the environment in a context-specific manner (e.g., under conditions of threat, some stimuli must be ignored while sensitivity to and responses to others is enhanced, as exemplified in the startle reflex). It can be evoked by either external/environmental stimuli or internal stimuli (e.g., emotions and cognition). It varies along a continuum that can be quantified in any behavioral state, including wakefulness and low-arousal states including sleep, anesthesia, and coma.

Key indicators: sensitivity to stimuli, startle reflex, behavioral state, locomotor activity, homeostatic drives, arousal level.

Here are examples of **RELEVANT** and **IRRELEVANT** sentences for this construct:

RELEVANT examples:
(1) "valence, arousal), and neuroscience has more recently sought the neurobiological basis of emotions via functional neuroimaging."
(2) "In the present study, we sought to identify intensive valence and arousal affective states via facial EMG activity."
(3) "CONCLUSIONS: This study is the first to identify arousal-specific retrospective affect report discrepancies over time and suggests retrospective reports also reflect personality differences in affective self-knowledge."

IRRELEVANT examples:
(1) "Seventy-seven students ages 19–30 participated in the study."
(2) "Moral standards, as well as conservative beliefs regarding sexuality, are believed to be involved in the etiology and maintenance of this syndrome."
(3) "However, in a recent study (Ehlers et al."

Now identify the relevant sentence(s) in this abstract:

Sentences:
(1) Previous studies have shown that music is a powerful means to convey affective states, but it remains unclear whether and how social context shape the intensity and quality of emotions perceived in music.
(2) Using a with . . .

Total sentences in abstract: 8

Figure 5: Example of the few-shot prompting template used for RDoC construct classification. The prompt includes the task instruction, construct definition with key indicators, example sentence–label pairs (shots), and the target abstract for sentence identification.

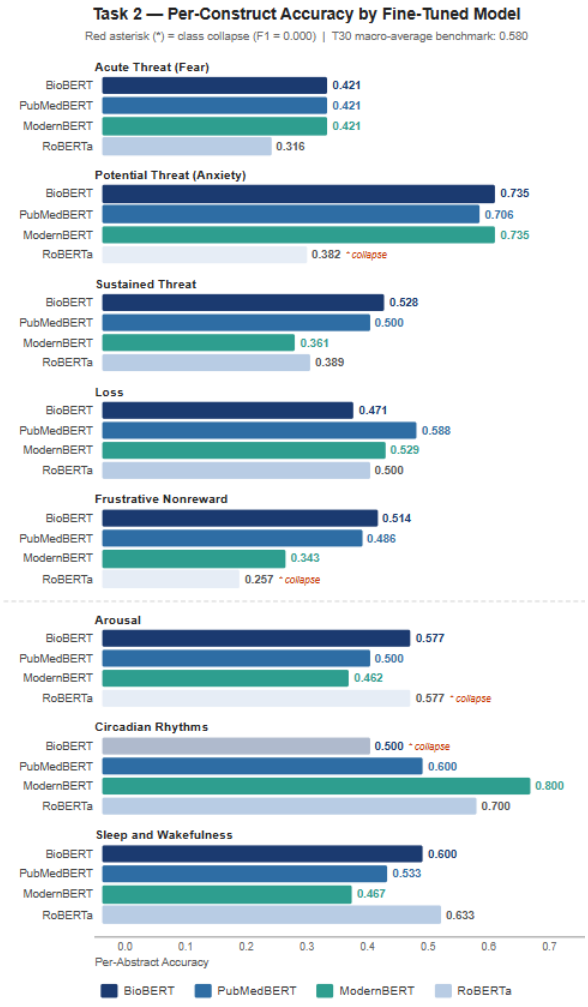

Figure 6: Task 2 Per-construct accuracy for each fine-tuned model across the eight RDoC constructs.

B Appendix: Per-construct Performance

Clinical Evidence and Patient Reviews: A Linked Dataset for Antidepressant Side Effects

Steven Au
Independent Researcher
steventinwing@gmail.com

Abstract

Clinical sources and patient-authored reviews often describe antidepressant side effects in different ways, but these differences are rarely measured directly. We present ClinPeer-AE, a linked dataset for comparing side-effect evidence from PubMed, ClinicalTrials.gov, WebMD, and Drugs.com while preserving source identity. Across five widely prescribed antidepressants, we find low overlap between clinical and peer sources, large differences in relative emphasis, and evidence that many peer-only effects also appear in U.S. Food and Drug Administration Adverse Event Reporting System (FAERS) reports. These findings suggest that patient reviews provide useful context about recurring medication experiences and offer a complementary view of how side effects are described outside formal clinical settings.

1 Introduction

Clinical trials and patient review platforms describe antidepressant treatment in different ways. Trials use controlled designs and standardized adverse-event tables. Reviews show how people talk about treatment in everyday settings, including side effects, discontinuation, and comparisons with other drugs. Both sources matter, but they do not always use the same language.

This paper asks whether those differences can be measured without flattening the sources together. If reviews use different terms, mention effects at different rates, or connect them to specific treatment contexts, that information should remain visible.

We address this with **ClinPeer-AE**[1], a linked dataset that keeps clinical and peer evidence separate while making them comparable. The contribution is not a new adverse-event extractor. Instead, we show how much depends on tracking source, context, and role, especially in reviews where the same phrase may describe an indication, a benefit, a withdrawal symptom, or an on-treatment adverse effect.

Our contributions are:

1. A linked dataset for comparing clinical and patient-authored side-effect evidence for five antidepressants.

2. A set of source-level analyses covering effect coverage, mention salience, condition context, and evidence support.

3. An extraction-quality and sensitivity analysis showing why role classification matters for patient reviews.

2 Related Work

Research on adverse drug effects has been supported by a strong ecosystem of structured resources, benchmark datasets, and biomedical extraction tools. The Side Effect Resource (SIDER) provides curated drug–side-effect associations derived from product labels (Kuhn et al., 2016), while the Medical Dictionary for Regulatory Activities (MedDRA) offers standardized terminology for adverse event reporting in regulatory contexts (Brown et al., 1999). Benchmark corpora such as the Adverse Drug Event (ADE) corpus from medical case reports (Gurulingappa et al., 2012), the CSIRO Adverse Drug Event Corpus (CADEC) from patient forum posts (Karimi et al., 2015), and social media datasets developed for pharmacovigilance (Sarker and Gonzalez, 2017; Feyisetan et al., 2020) have helped define the task in terms of entity recognition, relation extraction, and concept normalization. More broadly, shared tasks in biomedical event extraction have helped shape information extraction methods for clinical and biomedical text (Pyysalo et al., 2012; Kim et al., 2011), and tools such as SciSpaCy have made it easier to build practical pipelines for biomedical parsing and named entity recognition (Neumann et al., 2019).

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 656–664
July 3-4, 2026 ©2026 Association for Computational Linguistics

Adverse-effect evidence, however, is distributed across sources that differ substantially in purpose, language, and reporting style. Clinical trials, regulatory labels, case reports, and patient-authored reviews do not simply present the same information in different formats. They foreground different aspects of medication experience and often vary in granularity, framing, and salience. Clinical trial adverse event tables summarize outcomes observed under controlled conditions, whereas patients often describe effects in more subjective and functionally meaningful terms, such as emotional numbing, cognitive fog, or sexual dysfunction. Prior work has shown meaningful differences between these perspectives, especially for psychiatric medications. The Psychiatric Treatment Adverse Reactions dataset (PsyTAR) provides one of the first dedicated annotated datasets for psychiatric treatment reviews (Zolnoori et al., 2019), and pharmacovigilance studies have shown that social media can surface safety signals that may be underrepresented in formal reporting systems. However, most prior work treats patient-authored text as a supplementary signal for adverse event detection rather than as a source with distinct descriptive and evidential properties.

Recent advances in pretrained and instruction-tuned language models have also improved zero-shot and weakly supervised analysis of medical text. Bidirectional Encoder Representations from Transformers (BERT) family models, including DeBERTa-v3 (Liu et al., 2023) and ModernBERT (Warner et al., 2025), along with instruction-tuned models such as Gemma 4 (Google DeepMind, 2026), make it increasingly feasible to process patient reviews without large task-specific training sets. This is particularly important in patient-authored narratives, where systems must distinguish true adverse effects from related but different phenomena, including treatment indications, perceived benefits, withdrawal symptoms, prior medication history, and background conditions. In this setting, role classification is often necessary to determine how a mention should be interpreted.

3 Data

We assemble a multi-source corpus covering five widely prescribed antidepressants: bupropion, escitalopram, fluoxetine, sertraline, and venlafaxine. The corpus is organized into two source families (Table 1). The *clinical family* comprises PubMed (abstracts and study descriptions) and ClinicalTrials.gov (structured adverse-event tables when available). The *peer family* comprises WebMD and Drugs.com, both of which host patient-authored narratives with condition and rating metadata. All downstream analyses preserve this family label rather than pooling sources before comparison.

Table 1: Corpus composition for the five focal antidepressants.

Source	Docs	Claims	Drugs
PubMed	346	1,871	5
ClinicalTrials.gov	51	29	3

Total	**26,600**	**76,382**	–

We use "clinical" to mean formal biomedical evidence broadly, not clinical trials specifically, since PubMed captures a wider range of study designs than trials alone. The released resource is accordingly named **ClinPeer-AE** to reflect this scope. We restrict the corpus to structured review platforms (WebMD, Drugs.com) and biomedical databases (PubMed, ClinicalTrials.gov), excluding social-media sources such as Reddit. Across these four sources, the corpus contains 26,600 documents and 76,382 source-level drug–side-effect claims; downstream metrics aggregate by drug, effect, and source family.

4 Method

4.1 Claim Extraction

Documents are ingested into a shared DuckDB store. A *claim* is an extracted tuple

$$c = (d, e, s, f, r, a, q, x),$$

where d is the drug, e is the effect, s is the source, f is the source family, r is the contextual role, a is the attribution tier, q is confidence, and x is the evidence span. The downstream graph uses the normalized drug–effect pair as the edge key, but retains the source family, source identifier, role, attribution tier, count, and confidence annotations.

The extractor is hybrid rather than a single SciSpaCy model. SciSpaCy provides sentence segmentation, tokenization, biomedical named-entity candidates, and dependency parses. Project-specific

lexicons provide antidepressant aliases and side-effect aliases; these are curated into canonical identifiers before graph construction. Candidate pairs are generated differently by source type. ClinicalTrials.gov adverse-event tables are imported as structured drug–effect rows with available frequency metadata. PubMed abstracts and patient reviews are segmented into sentences; a drug alias and an effect candidate must occur in the same sentence or in a short adjacent-window context, unless the source metadata already fixes the reviewed drug. Dependency distance, trigger terms, negation cues, and lexical match quality determine the confidence score. Each candidate is then assigned an attribution tier encoding how strongly a source frames the effect as medication-related (direct causation > temporal association > co-occurrence > unclear).

To illustrate, consider the sentence "Sertraline caused severe insomnia after two weeks." SciSpaCy segments and tokenizes the input, tags "sertraline" as a drug candidate via the `en_core_sci_md` model, and identifies "insomnia" as a side-effect candidate. The project lexicon maps both to canonical identifiers. The dependency parse links the two entities through the causal trigger "caused," yielding a direct-causation claim for sertraline, insomnia, Drugs.com, peer source, adverse-effect role, confidence 0.92, and the evidence span "caused severe insomnia." By contrast, "Sertraline helped my panic attacks" receives role *benefit* and does not enter the adverse-effect claim set.

For peer sources, we add a review role-classification layer that assigns each candidate drug–effect pair to one of seven context roles: *indication*, *benefit*, *adverse effect*, *withdrawal effect*, *no effect*, *comparator/prior medication*, or *background condition*. Only `adverse_effect` claims pass the role gate in gated configurations. Withdrawal effects are retained as metadata rather than discarded, as discontinuation phenomena may be analytically useful but should not be conflated with on-drug AEs.

Table 2 shows schematic examples of how the role layer changes emitted claims. These examples are paraphrased patterns, not quoted patient reviews.

4.2 Graph Representation

ClinPeer-AE models drugs and side effects as graph nodes, preserving source-family branching at the edge level. Clinical and peer evidence are not merged; the internal graph stores source-specific counts and supports comparative views: clinical-only, peer-only, shared, and high-divergence effects. For each drug, edges to side-effect nodes are annotated with claim counts, average confidence, divergence scores, and rank inversions. An optional FAERS branch adds pharmacovigilance report counts as a third evidence family.

The combined graph for all five drugs contains 87 nodes (5 drug + 82 unique side effects) and 732 branched edges. This design makes source differences measurable without discarding source information.

4.3 Metrics and Hypotheses

We organize the evaluation around four hypothesis tests.

H1: Coverage distinctness. Peer and clinical AE sets have low overlap. We measure this with the Jaccard index (shared / union) and bootstrap 95% CIs. H1 is supported when the upper CI falls below 0.5.

H2: Saliency divergence. Clinical trial AE frequency does not predict peer mention rates. For each shared effect, we compute a *saliency ratio* = peer_mention_count / clinical_trial_frequency_pct. A ratio of 1.0 indicates parity; higher ratios indicate greater relative peer mention salience. We test whether median ratios significantly exceed 1.0 using a Wilcoxon signed-rank test.

H3: Condition-stratified AE profiles. The same drug has different AE mention distributions depending on the treated condition (Depression, Anxiety, OCD, Panic Disorder, PTSD). We test independence using chi-squared contingency tests.

H4: Evidence support by divergence level. Peer-only (high-divergence) effects should carry different evidence backing than shared (low-divergence) effects. We compute a composite support score for each effect combining attribution tier strength (40%), independent peer document support (35%), cross-source peer agreement (25%), reviewer metadata (+0.5), and FAERS corroboration (+0.5). Because most score components are computed over extracted claims, this score is a comparative triage proxy rather than an independent measure of clinical truth. We compare high-divergence ($\geq$0.7) vs. low-divergence ($<$0.3) effects using the Mann–Whitney U test, with Jensen–Shannon divergence and conflict density used as supplementary divergence metrics.

Table 2: Schematic claim extraction examples. The role layer prevents indications, benefits, withdrawal effects, and prior-medication experiences from being counted as ordinary on-treatment adverse effects.

Source pattern	Evidence pattern	Assigned role	Emitted AE claim
ClinicalTrials.gov table	Nausea reported in the sertraline arm with trial frequency	adverse event	(sertraline, nausea)
Patient review	Escitalopram caused insomnia after dose increase	adverse effect	(escitalopram, insomnia)
Patient review	Sertraline helped panic attacks	benefit	none
Patient review	Brain zaps after stopping venlafaxine	withdrawal effect	metadata only
Patient review	Bupropion replaced a prior drug that caused fatigue	comparator/prior medication	none

5 Results

5.1 Extraction Quality

We evaluate extraction on a locked test of 29 Drugs.com reviews and a larger PsyTAR review set, with detailed scores reported in Appendix A. The locked set was produced by one annotator with AI-assisted candidate drafting followed by manual adjudication. Because we did not compute inter-annotator agreement, these scores should be read as a development-quality reliability estimate rather than a final benchmark.

A substantial share of the low F1 comes from role confusion, not only missed effect terms. In the locked test, many false positives are benefit or withdrawal mentions that the extractor counted as adverse effects. This is a central limitation: the downstream comparisons should be read as aggregate analyses over noisy extracted claims, not as verified lists of individual side effects.

We also evaluate separate role-classification baselines. Table 3 shows cross-domain results on PsyTAR review windows, and Appendix B gives additional Gold 120 results. The best local language-model baseline performs much better on adverse-effect role classification than the default extractor, which suggests a clear path for improving the pipeline. It is not yet integrated into the main experiments.

As a stress test, we re-run the peer pipeline with the deterministic role gate enabled. This removes most peer claims, but H1, H2, and H3 remain supported for all five drugs; H4 is more sensitive because its score depends directly on claim volume. This does not solve the extraction problem, but it suggests the main coverage and salience patterns are not driven only by obvious non-adverse review mentions.

Table 3: Cross-domain role classification on 300 PsyTAR overlap windows.

Model	Type	P	R	F1	Acc_7
Gemma 4 E4B	Causal LM	**.893**	.856	**.874**	.573
TF-IDF + LR	Trained	.770	**.966**	.857	**.603**
ClinicalBERT + LR	Trained	.812	.712	.759	.503
BioBERT + LR	Trained	.891	.616	.729	.483
DeBERTa-v3 (NLI)	Zero-shot	.606	.822	.698	.490
TinyLlama 1.1B	Causal LM	.470	.760	.581	.373
ModernBERT (NLI)	Zero-shot	.604	.199	.299	.240
Gemma 4 E2B	Causal LM	.804	.870	.836	.563

Table 4: Coverage distinctness (H1). All drugs show low clinical–peer overlap.

Drug	Clin	Peer	Shared	Jaccard	CI_{95}
Sertraline	102	74	27	.181	[.121, .242]
Fluoxetine	200	68	31	.131	[.089, .177]
Escitalopram	162	72	28	.136	[.092, .184]
Venlafaxine	118	68	24	.148	[.099, .204]
Bupropion	144	67	25	.134	[.086, .188]

5.2 H1: Coverage Distinctness

Table 4 presents coverage results. H1 is supported for all five drugs at the extracted-claim level: Jaccard overlap ranges from 0.13 to 0.18, with upper 95% CIs never exceeding 0.24. At least 76% of the effect space is non-overlapping even accounting for sampling variation. Conversely, 54–65% of peer-reported effects are absent from clinical AE tables.

5.3 H2: Saliency Divergence

Table 5 reports saliency results. H2 is supported for all five drugs (Wilcoxon $p < 10^{-6}$). Patients discuss shared side effects 17–96$\times$ more than clinical trial frequency would predict (Figure 2). Spearman rank correlation is significant for only one drug (fluoxetine), suggesting that saliency ratios capture information not visible in simple rank agreement.

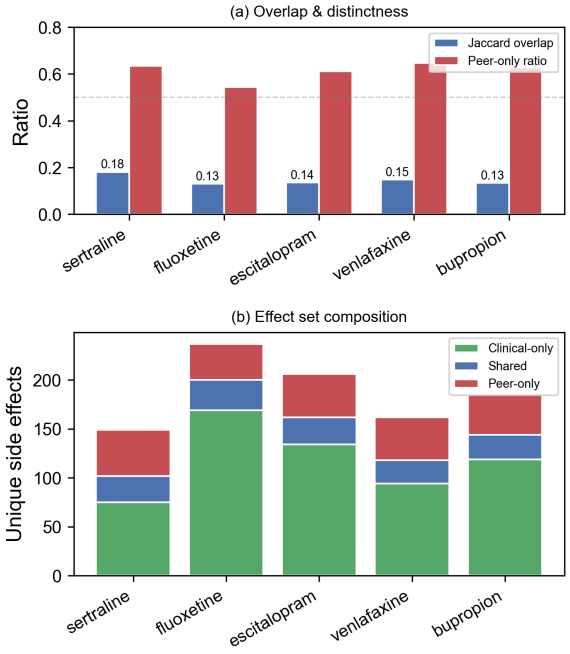

Figure 1: Overlap and effect-set composition by drug. Light regions denote peer-only effects; dark regions denote clinical-only effects.

Table 5: Saliency divergence (H2). Median saliency ratios and Wilcoxon signed-rank tests.

Drug	Shared	Med. ratio	p (Wilcoxon)
Sertraline	28	96.2×	3.7e-09
Fluoxetine	31	41.0×	1.4e-09
Escitalopram	29	56.7×	1.3e-06
Venlafaxine	25	16.6×	6.0e-08
Bupropion	26	68.8×	1.5e-08

5.4 H3: Condition-Stratified AE Profiles

Table 6 presents condition-stratified results. Four drugs show strong evidence of condition-stratified AE profiles; venlafaxine is nominally significant but treated as marginal ($p = 0.046$). Overall, the same drug can yield different AE mention profiles depending on the treated condition.

Notable findings include PTSD patients on venlafaxine reporting weight gain at 24% (vs. 2.9% for depression), bupropion-associated erectile dysfunction concentrated in PTSD reviews, and intrusive thoughts appearing primarily in OCD reviews for sertraline (10.3% vs. $\leq$0.7% for other conditions). Clinical trials typically aggregate AEs across indications; these results suggest that review-derived AE profiles can vary by treatment context. They should not be interpreted as causal estimates of condition-specific drug risk.

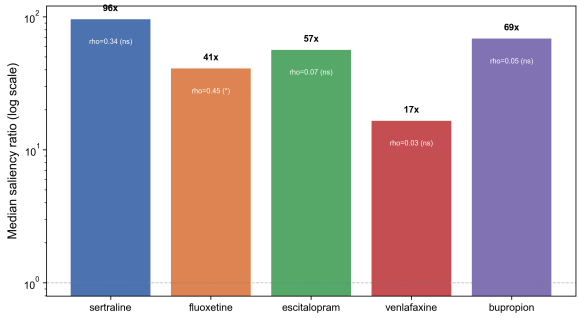

Figure 2: Median saliency ratio by drug (log scale). Dashed line at ratio = 1 (parity).

Table 6: Condition-stratified AE divergence (H3). Chi-squared tests of AE independence across treated conditions.

Drug	p	Top divergent effect
Sertraline	<0.001	intrusive thoughts (OCD 10.3% vs. Anxiety 0.7%)
Fluoxetine	<0.001	panic attacks (Anxiety 13.7% vs. Depression 3.4%)
Escitalopram	<0.001	panic attacks (PTSD 16.2% vs. Depression 4.5%)
Venlafaxine	0.046	weight gain (PTSD 24.0% vs. Depression 2.9%)
Bupropion	<0.001	erectile dysfunction (PTSD 13.5% vs. 0%)

5.5 H4: Evidence Support by Divergence Level

Table 7 presents H4 results. The hypothesis is supported for 4/5 drugs, but in the *opposite* direction: peer-only (high-divergence) effects receive lower support scores than shared (low-divergence) effects. The delta is consistently negative (-0.14 to -0.38). Because the score draws on extracted claim volume and pipeline-derived attribution, this result is best read as a suggestive comparative pattern rather than independent validation of evidential strength.

This finding is useful mainly for triage. It suggests three things: (1) divergence correlates with weaker measured support in this graph; (2) not all peer-only effects are equal, since some (e.g., *panic attack*, *brain zaps*) have higher support because they appear across platforms and in FAERS, while others may reflect extraction or reporting noise; (3) support scoring can prioritize which peer-only effects merit manual review and follow-up analysis.

FAERS triangulation. FAERS data (2021–2025, 36,826 cases) shows that 42–56% of peer-only effects also appear in suspect-drug pharmacovigilance reports, with the highest rate for venlafaxine (55.9%) and the lowest for fluoxetine (42.5%). This is external triangulation, not causal validation: FAERS is spontaneous-report data and can share reporting biases with review platforms. Still, the overlap suggests that many peer-only effects are

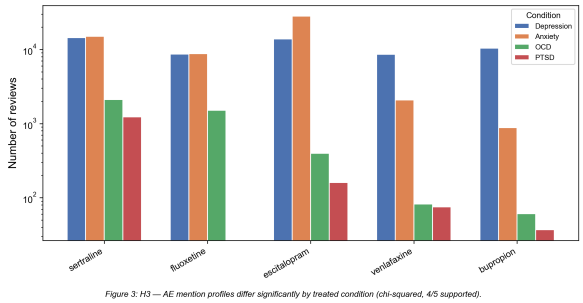

Figure 3: Condition-stratified AE review counts by drug.

Table 7: Evidence support by divergence level (H4). Peer-only effects receive consistently lower support scores than shared effects.

Drug	Peer-only	Shared	Δ	p
Sertraline	52	21	−0.27	0.0008
Fluoxetine	40	28	−0.38	4.9e-06
Escitalopram	60	12	−0.36	0.0003
Venlafaxine	59	9	−0.14	0.150
Bupropion	52	15	−0.22	0.011

not isolated review artifacts, while the support gap shows they remain thinner than shared effects on average.

Overall, most hypothesis tests reach nominal statistical significance across the five drugs. The main exception is venlafaxine under H4 ($p = 0.15$), where the direction is consistent but the sample of shared effects is small ($N = 9$). The venlafaxine H3 result is significant but marginal and should not be overinterpreted.

6 Discussion

The results suggest that differences between formal clinical evidence and patient reviews are not entirely random. Across five antidepressants, peer sources provide broader side-effect coverage and include recurring experiential terms such as brain zaps, emotional blunting, and intrusive thoughts that are weakly represented in clinical trial AE tables.

The H4 result runs counter to our initial expectation. We expected peer-only effects with high divergence to have stronger converging evidence, such as multiple independent reviews, cross-platform support, or FAERS corroboration. Instead, shared effects receive higher support scores. This pattern is suggestive but not definitive, since the score itself depends on extracted claim volume. It mainly shows that effects documented by both clinical and peer sources tend to accumulate more evidence in this graph. Peer-only effects often also appear in FAERS (42–56%), but they are thinner in this evidence base on average, making the score useful for triage rather than clinical adjudication.

Implications for extraction. The findings point to a practical need in patient-review analysis: extraction systems should model role and source explicitly. A simple drug–effect label cannot tell whether a phrase describes an indication, a benefit, a withdrawal symptom, a current side effect, or an experience with a prior medication. Evaluation should also keep clinical and review language separate enough to see where systems fail. ClinPeer-AE provides a testbed for that kind of role-aware extraction and source-level comparison.

One practical implication is that early source pooling hides the differences this paper is trying to measure. Keeping the sources separate makes those differences visible.

Evidence asymmetry. The peer corpus is substantially larger than the clinical-trial portion, and some observed divergence reflects study-design and reporting differences rather than purely biological difference. Clinical trials use strict inclusion criteria, controlled dosing, and structured AE capture; patient reviews reflect heterogeneous populations, variable adherence, and unstructured narrative. We discuss this as a limitation below, not as a flaw; the framework is designed to measure observable source differences, not to adjudicate biological truth.

7 Conclusion

ClinPeer-AE shows that clinical evidence and patient-authored reviews can be compared without merging them into one evidence pool. Across five antidepressants, the two source families differ in coverage, salience, condition context, and measured support. The main value of the dataset is therefore not a definitive list of side effects, but a reproducible way to study how adverse-event language and evidence vary across reporting settings.

Future work should improve extraction quality, add multi-annotator evaluation, expand clinical source coverage, and integrate stronger role classification before using peer-only effects as pharmacovigilance signals.

8 Limitations

Extraction F1 ranges from 0.11 to 0.21, primarily due to role confusion, including benefit and withdrawal mentions misclassified as AEs. The comparative framework does not eliminate this problem because source families have different language and therefore different error profiles. The Gemma 4 role classifier offers a clear improvement path, but is not yet integrated into the default pipeline.

The locked evaluation set was produced by a single annotator with AI-assisted candidate drafting and manual adjudication. No inter-annotator agreement was computed. The extraction scores therefore quantify performance against a useful but limited gold set rather than a mature shared-task benchmark.

We compare the production extractor to a lexicon baseline and a deterministic role gate, but we do not benchmark against strong supervised or generative extraction systems. A single extraction pipeline can also favor one source family over another, since clinical tables, PubMed abstracts, and patient reviews use different language. The NLP component should therefore be read as an enabling pipeline for source-aware analysis, not as a competitive extraction contribution.

WebMD and Drugs.com contain far more documents than ClinicalTrials.gov. Volume normalization helps but does not eliminate the asymmetry, and future work should incorporate additional clinical sources.

Patient reviews capture association, not causation, and FAERS reports reflect spontaneous reporting rather than controlled observation. The framework measures observable source differences; it does not establish which source is correct.

Patient reviews come from a self-selected population that may overrepresent negative experiences. The exclusion of Reddit also limits generalizability to broader peer discourse.

Five drugs across four hypotheses yield 20 tests without family-wise correction. Individual p-values should therefore be interpreted cautiously. Chi-squared tests for rare conditions such as OCD and PTSD also involve small cell sizes, and the venlafaxine H3 result ($p = 0.046$) should be treated as marginal.

9 Ethics Statement

This work analyzes publicly available evidence sources (PubMed, ClinicalTrials.gov, WebMD, Drugs.com, and FAERS) without identity linkage across platforms. Patient-review evidence is treated as observational and self-reported, not as causal ground truth. The goal is to quantify source-specific differences between formal evidence and patient-authored reviews in an auditable, reproducible manner, not to replace clinical evidence or to make treatment recommendations. All data is used in aggregate; no individual reviews are quoted or identifiable.

A Extraction Performance

This section gives the numeric extraction scores behind Section 5.1. The table is included as diagnostic context because the main analyses depend on extracted claims, but the detailed extractor comparison is not itself the central result.

Table 8: Extraction performance by configuration.

Config	Set	P	R	F1
scispacy_hybrid	Locked (29)	.174	.268	.211
scispacy_hybrid	PsyTAR (647)	.259	.071	.111
baseline lexicon	PsyTAR (647)	.256	.072	.112
scispacy + rules	PsyTAR (647)	.348	.005	.009

B Role Classification Baselines

Table 9 reports Gold 120 results for the seven-role classification task (locked_test + hard_case_dev splits). The PsyTAR cross-domain comparison is reported in the main paper in Table 3. "Trained" classifiers use PsyTAR overlap data; "Zero-shot" models require no task-specific training.

C Cross-Drug Peer-Only Effects

This section lists the recurring peer-only effects discussed briefly in the main results. It is kept in the appendix so the main paper can focus on the aggregate tests rather than a long effect inventory.

Nineteen effects are peer-only across all five drugs: *panic attack*, *brain zaps*, *emotional blunting*, *discontinuation syndrome*, *depersonalization*, *erectile dysfunction*, *excessive yawning*, *intrusive thoughts*, *anxiety attack*, *jaw clenching*, *numbness*, *back pain*, *muscle spasms*, *shaking*, *brain fog*, *delayed ejaculation*, *night sweats*, *confusion*, and *stomach pain*. An additional 13 effects appear in 4/5 drugs, including *tinnitus* and *agitation*. At the aggregate level, these terms recur across peer sources; however, individual effects still require manual and clinical validation before being treated as safety signals.

D Support Score Components

The composite support score is computed as:

- **Attribution tier** (40%): direct causation (1.0) $>$ temporal association (0.75) $>$ co-occurrence (0.50) $>$ unclear (0.25).
- **Independent peer documents** (35%): $\log(1+$ distinct_review_count$) \times 10$.
- **Cross-source support** (25%): binary flag for presence in both WebMD and Drugs.com.
- **Metadata support** (+0.5): review includes duration, condition, or demographics.
- **FAERS support** (+0.5): drug–effect pair appears in FAERS suspect-drug reports.

Total score range: 0 to 2.0.

E Supplemental: Attribution Language Comparison

The original H4 formulation compared attribution language between clinical and peer sources. All five drugs showed significant differences ($p < 10^{-36}$), but the effect sizes were small (Cliff's δ 0.07–0.20) and largely reflected genre differences: clinical trial AE tables list effects statistically ("treatment-emergent adverse event") while patient reviews use causal framing ("this drug caused nausea"). This result is technically significant but substantively uninformative and is reported here as supplemental.

Table 9: Review role classification on Gold 120 (Drugs.com reviews, 7 roles). Adverse-effect binary P/R/F1 and 7-class accuracy.

Abstract

Retrieval-augmented generation (RAG) holds promise for clinical question answering over electronic health records (EHRs), but existing systems treat retrieval as an opaque subroutine, limiting auditability and reliability in patient care workflows. We introduce a deterministic multi-stage retrieval pipeline for longitudinal EHR question answering that decomposes retrieval into four distinct, ablated stages where each stage is instrumented with diagnostic metrics, making the flow of clinical evidence measurable and auditable at every step. Evaluated on a broad LLM-annotated cohort and an expert-annotated cardiovascular benchmark developed alongside clinicians from real ICU records, the full pipeline achieves 22-23% relative recall gain over a strong dense retrieval baseline across both cohorts, with consistent improvements in downstream answer quality. The pipeline's deterministic and transparent design addresses a critical gap in clinical NLP: retrieval systems that clinicians and researchers can not only rely on, but inspect, audit, and build upon for real-world deployment.

1 Introduction

Electronic Health Records (EHRs) capture rich longitudinal information about patients, including demographics, diagnoses, medications, and procedures, but a large fraction of this information exists only in unstructured free text: discharge summaries, nursing reports, radiology narratives, and echo reports (NHS, 2023; Häyrinen et al., 2008). Unlike coded fields, these narratives capture nuanced clinical reasoning, temporal relationships, and contextual detail that structured data systematically omits (Menachemi and Collum, 2011). A single patient admitted to an intensive care unit can accumulate hundreds of notes across multiple encounters, and over a longitudinal care history this figure reaches into the thousands (Zhang et al., 2017). The result is that clinically decisive information spanning areas such as trial eligibility (Raghavan et al., 2014), diagnosis (Shivade et al., 2014), and medication safety is present in the record but practically inaccessible at scale.

Conventional query interfaces and keyword search fail in this setting because they ignore clinical context, cannot resolve synonyms and abbreviations, and do not scale to long, redundant, and noisy documentation (Hill et al., 2021; Spasic et al., 2020). What clinicians and researchers need instead are systems that can answer natural language questions directly over a patient's record: whether a patient has ever met criteria for a particular syndrome (Pathak et al., 2013), how a clinical state has evolved across admissions (Silva and Matos, 2022), or why a medication was started, adjusted, or discontinued (Li et al., 2011). The core challenge is not data storage or extraction but reliable, traceable retrieval: identifying the specific note segments that support an answer, across a large and heterogeneous longitudinal record, without missing evidence that could affect patient care.

Retrieval-augmented generation (RAG) has emerged as a promising framework for this challenge, combining a retrieval component with a generative model conditioned on retrieved context (Lewis et al., 2020). In the EHR setting, RAG systems retrieve relevant passages from a patient's longitudinal notes and generate concise, grounded responses to clinical queries (Sivarajkumar et al., 2024; Alkhalaf et al., 2024), making the approach well suited to long, noisy, and heterogeneous documentation. However, the quality of generated answers depends directly on what is retrieved, as a generator conditioned on incomplete evidence will produce answers that are fluent but miss critical clinical information. Despite this, the question of how to engineer retrieval for high recall and auditability under realistic clinical constraints remains largely open.

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 665–678
July 3-4, 2026 ©2026 Association for Computational Linguistics

In this work, we address this gap with a deterministic multi-stage retrieval pipeline for longitudinal EHR question answering, designed around the constraints of real clinical workflows. The pipeline was developed and evaluated alongside clinical experts, with an expert-annotated cohort constructed specifically for cardiovascular medication review, a high-stakes setting where incomplete evidence recovery can directly compromise clinical decisions. Specifically, we:

- *Decompose retrieval into four distinct, ablated stages* that narrow the clinical corpus, expand query coverage, recover missed evidence, and optimise final ranking to ensure no clinically relevant information is lost.
- *Instrument each stage with diagnostic metrics*, ensuring the flow of clinical evidence is measurable and auditable at every step, enabling systematic improvement of the pipeline and, ultimately, reliable clinical use.
- *Validate on an expert-annotated cardiovascular cohort developed alongside clinicians from real ICU records and an LLM-annotated cohort*, achieving over 22% relative recall gain over a strong dense retrieval baseline across both cohorts with consistent improvements in downstream answer quality.

2 Related Work

Clinical question answering over EHRs requires systems to identify small sets of highly relevant, patient-specific evidence from large, heterogeneous, and longitudinal records. Unlike open-domain Question-Answering (QA), clinical settings impose strict requirements on evidence traceability, recall of critical findings, and bounded result sets suitable for clinician review since the retrieved evidence may directly affect patient care and must therefore be reliable and auditable (Roberts et al., 2017; Koopman et al., 2015). In this context, system reliability therefore depends not on answer fluency alone, but on whether the correct note segments are retrieved in the first place which is a challenge that has increasingly motivated retrieval-augmented approaches in clinical NLP.

Large Language Model (LLM) systems for clinical tasks frequently adopt RAG to ground outputs in external evidence (Lewis et al., 2020; Izacard and Grave, 2021; Guu et al., 2020). In medicine, such approaches have been applied to clinical question answering (Singhal et al., 2023; Lehman et al., 2023), summarization (Nazi and Peng, 2024), and decision support (Jin et al., 2021). However, evaluation in these systems typically emphasizes end-to-end answer correctness or textual quality, while the retrieval component itself receives little direct analysis.

Deterministic Information Retrieval (IR) approaches for EHRs often leverage medical ontologies such as SNOMED CT (Donnelly, 2006) and Unified Medical Language System (UMLS) (Bodenreider, 2004) to improve recall and interpretability (Sivarajkumar et al., 2024) . Named entity recognition and concept normalization systems such as cTAKES (Savova et al., 2010), MetaMap (Aronson, 2010), and MedCAT (Kraljevic et al., 2021a) have been widely used to attach structured semantics to clinical narratives. Ranking models, which score and order candidate passages by relevance to a query, range from traditional probabilistic methods such as BM25 (Robertson and Zaragoza, 2009) to neural dense retrievers adapted to biomedical text (Karpukhin et al., 2020; Lee et al., 2020; Gu et al., 2021). Despite these advances, most clinical IR pipelines remain relatively shallow, typically involving one or two retrieval stages followed by ranking, and sparse methods such as BM25 can struggle in clinical settings where the same concept can be expressed through varied terminology, abbreviations, and paraphrasing, motivating the shift towards dense retrieval methods and more flexible, LLM-driven retrieval frameworks.

Modern RAG systems increasingly embed retrieval inside LLM-driven control loops. In these architectures, LLMs may reformulate queries (Asai et al., 2024), generate intermediate hypotheses (Yao et al., 2023), judge evidence relevance (Asai et al., 2024), select passages (Yao et al., 2023), or determine when to stop retrieving (Jiang et al., 2023; Fan et al., 2024; Gao et al., 2023b). Variants of iterative (Shao et al., 2023; Trivedi et al., 2023), recursive (Kim et al., 2023) and agentic (Shinn et al., 2023) retrieval have been proposed to improve reasoning over multi-hop or ambiguous queries.

While LLM-driven retrieval introduces flexibility through model-guided query reformulation, passage selection, and iterative reasoning, it shifts control and evidence selection to opaque model-internal decisions, reducing auditability and in-

troducing variable latency and computational cost that complicate integration into time-sensitive and privacy-sensitive clinical workflows. Taken together, existing work presents two extremes: deterministic but relatively shallow clinical IR pipelines, and flexible but opaque LLM-orchestrated retrieval frameworks. What remains missing is a systematic treatment of retrieval itself as a multi-stage, diagnosable process for patient-level QA.

3 Methodology

3.1 Dataset

This study uses the MIMIC-III (Johnson et al., 2016) clinical database, a publicly available collection of deidentified electronic health records from intensive care units at the Beth Israel Deaconess Medical Center. MIMIC-III contains unstructured clinical documentation such as admission notes, progress notes, nursing notes, discharge summaries, radiology reports, and other narrative reports associated with ICU and related hospital encounters.

For this work, unstructured free-text notes from the NOTEEVENTS table were used, yielding longitudinal collections that reflect realistic documentation patterns across multiple admissions and care settings.

3.2 Problem Formulation

Each patient record consists of multiple hospital visits, and each visit comprises a collection of free-text clinical notes.
For a given patient i, the record can be written as:

$$R_i = \{V_{i1}, V_{i2}, \ldots, V_{iM_i}\},$$

where V_{im} denotes the m-th visit for patient i, and M_i is the number of visits. Each visit V_{im} is itself a set of notes

$$V_{im} = \{n_{im1}, n_{im2}, \ldots, n_{imK_{im}}\},$$

where n_{imk} is an unstructured free text clinical note associated with that visit, and K_{im} is the number of notes for visit m of patient i. Each note n_{imk} is associated with a clinical category c, where

$$c = \{\text{discharge, nursing, ECG, radiology, echo}\}.$$

The objective of this work is to enable patient-centered QA over these note collections. Given a natural language query q about a specific patient i, for a specific visit m, the system must produce a natural language answer a, and a set of supporting evidence segments E_i drawn from notes from one visit across one or multiple categories. In the RAG setting, a retriever g selects relevant note chunks and a generator h produces the final answer conditioned on them.

In our experiments, queries are evaluated under two complementary settings: a category-restricted setting, where E_i is limited to notes of a specific clinical category c, and a visit-level setting, where E_i spans all note types within a visit. Both settings reflect realistic clinical workflows and are evaluated throughout this work.

Notation note For clarity, we present the formalism for the category restricted setting within a single patient visit (i, m, c). The visit-level setting arises naturally by expanding the candidate corpus to $\bigcup_c \mathcal{C}_{imc}$. The proposed pipeline is not restricted to this scope, and cross-visit retrieval can be performed by expanding the candidate corpus to $\bigcup_m \mathcal{C}_{imc}$, without modifying the underlying retrieval or representation components.

3.3 Modules

3.3.1 Chunking

Clinical notes vary substantially in length and structure, and naïvely splitting them into fixed-size segments risks either breaking coherent clinical units or creating overly long passages. We adopt a structure-aware chunking strategy that respects natural note boundaries and category-level organisation.
For a given patient i and visit m, the visit-level note collection is $V_{im} = \{n_{im1}, \ldots, n_{imK_{im}}\}$, where each n_{imk} is an unstructured clinical note with an associated category c. Chunking operates at the level of a patient–visit–category triplet in all experimental settings as notes from different clinical categories are chunked independently since merging across categories would conflate clinically distinct documentation types and degrade retrieval signal. For a fixed (i, m, c), $\mathcal{N}_{imc} = \{n_{imc1}, \ldots, n_{imcK_{imc}}\}$ denote the sequence of notes of category c. From this sequence, we construct a sequence of chunks
$\mathcal{C}_{imc} = \{u_{imc1}, \ldots, u_{imcT_{imc}}\}$, where each chunk u_{imct} is a concatenation or sub-span of one or more elements of $\mathcal{N}_{imc}$ subject to a character-length constraint $L_{min} \leq |u_{imct}| \leq L_{max}$, with $L_{min} = 900$ and $L_{max} = 1500$.

This strategy, as outlined in Appendix A.1, outperforms purely length-based recursive segmen-

tation, as confirmed by ablations reported in Appendix A.2 (Table 3), and yields retrieval units that respect natural note boundaries, are easier to interpret clinically, and remain short enough to be handled efficiently.

3.3.2 Metadata Enhancement via NER

For each note chunk u_{imct}, we enrich the raw text with structured metadata derived from clinical Named Entity Recognition (NER). We apply the MedCAT (Kraljevic et al., 2021b) model to identify clinical entities (e.g., disorders, findings, medications) and leverage its built-in SNOMED CT (SNOMED) mapping to assign each detected entity e to an ontology concept with corresponding semantic category $s(e) \in \mathcal{S}$, where $\mathcal{S}$ denotes the space of clinical semantic types.

Formally, the NER model produces a set of entity annotations $\mathcal{E}_{imct} = \{(e_j, s(e_j))\}_{j=1}^{J_{imct}}$, where e_j is the entity span and $s(e_j)$ its semantic type. We then compute summary metadata for the chunk as

$$M_{imct} = \Big(\big(|\{e_j \in \mathcal{E}_{imct} : s(e_j) = \tau\}| \big)_{\tau \in \mathcal{S}}, \mathcal{E}_{imct} \Big)$$

which stores both entity counts per semantic type and the full list of detected entities. These metadata M_{imct} are stored alongside the chunk text u_{imct} in the retrieval index.

Attaching ontology-based categories to each chunk enables the pipeline to rapidly narrow a large clinical corpus to a semantically plausible subset before retrieval stages. For example, a query about medications can be directed towards chunks containing entities labeled as clinical drugs or medicinal substances, reducing noise and computational cost for downstream stages.

3.3.3 Embedding and Indexing

Each chunk, augmented with its MedCAT-derived metadata is encoded using a dense embedding model to produce a fixed-dimensional vector representation suitable for semantic similarity search (Karpukhin et al., 2020; Ni et al., 2022; Izacard and Grave, 2021). These embeddings are computed for all chunks in a patient's corpus and stored in a vector database that supports efficient approximate nearest-neighbor search. At query time, this index enables rapid retrieval of the most semantically similar chunks, serving as the foundation for the subsequent stages in the pipeline.

We use the `Chroma`[1] vector database and the `BAAI/llm-embedder` (Zhang et al., 2023) model as the encoder for both queries and chunks, as it has shown strong performance on semantic retrieval benchmarks.

[1] https://www.trychroma.com

3.3.4 Query Category Generation

To guide metadata filtering of the corpus, we generate relevant SNOMED CT semantic types from each query q. Using MedGemma 4B (Sellergren et al., 2025), a medically pre-trained language model, with few-shot prompting over $\mathcal{S}$, a set of candidate ontology categories curated from the SNOMED CT hierarchy in consultation with clinical experts, we produce two disjoint sets of semantic types: $\mathcal{S}_q^d \subseteq \mathcal{S}, \quad \mathcal{S}_q^c \subseteq \mathcal{S}$, where $\mathcal{S}_q^d$ denotes direct categories explicitly referenced in q (e.g., 'clinical drug', 'medicinal product' for medication queries), and $\mathcal{S}_q^c$ denotes complementary categories that frequently co-occur with direct types (e.g., 'dose form', 'frequency', 'unit of presentation'). The filtering instruction set enables nuanced corpus pruning by capturing both primary semantic types and their clinically associated aspects.

$$\mathcal{C}_{imc_q}^{\text{filter}} = \{u_{imct} \in \mathcal{C}_{imc_q} \mid \exists \tau \in \mathcal{S}_q : M_{imct}[\tau] > 0\}$$

This guides the metadata filter to select relevant notes, substantially reducing the retrieval corpus while preserving recall of relevant evidence.

3.3.5 Query Entity Extraction and HyDE

To refine filtering, we extract specific entities from query q using MedCAT NER restricted to categories $\mathcal{S}_q$:

$$\mathcal{E}_q^{\text{direct}} = \{e \in \mathcal{E}(q) \mid s(e) \in \mathcal{S}_q\}.$$

In parallel, Hypothetical Document Embeddings (HyDE) (Gao et al., 2023a) generates a hypothetical document d_q from q, that approximates what a relevant clinical note might look like, exposing semantic content and clinical terminology that may not be explicit in the original query phrasing. We use a MedGemma 4B model for this. On this document, we again run NER restricted to $\mathcal{S}_q$, yielding a set of candidate entities

$$\mathcal{E}_q^{\text{hyde, raw}} = \{e \in \mathcal{E}(d_q) \mid s(e) \in \mathcal{S}_q\}.$$

These candidates are then validated against entities observed in the notes corpus, retaining only those that exceed a frequency threshold determined empirically, giving a validated set $\mathcal{E}_q^{\text{hyde}} \subseteq \mathcal{E}_q^{\text{hyde, raw}}$.

The final query entity set is $\mathcal{E}_q = \mathcal{E}_q^{\text{direct}} \cup \mathcal{E}_q^{\text{hyde}}$, which we use to refine filtering:

$$\mathcal{C}_{imc_q}^{\text{filter+}} = \{u_{imct} \in \mathcal{C}_{imc_q}^{\text{filter}} \mid \mathcal{E}_q \cap \mathcal{E}_{imct} \neq \emptyset\}.$$

This entity-level refinement further narrows the filtered corpus, ensuring that subsequent dense retrieval operates over a highly focused and semantically coherent candidate set.

3.3.6 Semantic Retrieval

From the entity-refined filtered set $\mathcal{C}_{imc_q}^{\text{filter+}}$, we perform dense semantic retrieval to obtain an initial candidate set. All chunks across a patient's record are embedded using an encoder for all $u_{imct} \in \bigcup_{i,m,c} \mathcal{C}_{imc}$.

At query time, given query q with embedding $\mathbf{q}$, we compute cosine similarities over the refined filtered corpus and retrieve the top-k' chunks where

$$k' = \min\left(30, \max\left(1, \left\lfloor 0.3 \cdot |\mathcal{C}_{imc_q}^{\text{filter+}}| \right\rfloor\right)\right).$$

This adaptive k' scales with filtered corpus size (taking $\sim$30% of available chunks, capped at 30), ensuring proportional coverage while guaranteeing at least one candidate. These top-k' chunks form the primary evidence set that would typically feed directly into generation in standard RAG frameworks; we instead refine this further with classifier recovery and re-ranking.

3.3.7 Classifier-Based Recall Recovery

Dense retrieval alone may still miss clinically important evidence, especially in long, heterogeneous notes where relevant information can be phrased in diverse ways. To reduce such false negatives, we introduce a recall-oriented classifier that re-examines chunks initially treated as non-relevant.

Let $\mathcal{C}_{imc_q}^{+} \subseteq \mathcal{C}_{imc_q}^{\text{filter+}}$ denote the top-k' chunks from semantic retrieval, with excluded chunks

$$\mathcal{C}_{imc_q}^{\text{neg}} = \mathcal{C}_{imc_q}^{\text{filter+}} \setminus \mathcal{C}_{imc_q}^{+}$$

For the classifier $\phi(q, u_{imct})$, we use a BERT model (Devlin et al., 2019) (`bert-base-uncased`), which demonstrated stronger generalisation than clinical variants in preliminary experiments, to predict chunk-level relevance for $(q, u_{imct}) \in \mathcal{C}_{imc_q}^{\text{neg}}$. We revive chunks exceeding threshold γ (chosen to be 0.8):

$$\widetilde{\mathcal{C}}_{imc_q}^{+} = \mathcal{C}_{imc_q}^{+} \cup \{\, u_{imct} \in \mathcal{C}_{imc_q}^{\text{neg}} \mid \phi(q, u_{imct}) \geq \gamma \,\}$$

Training details, data statistics, and hyper parameters are reported in Appendix A.5.

3.3.8 Re-ranking

After semantic retrieval and classifier recovery, the expanded candidate set $\widetilde{\mathcal{C}}_{imc_q}^{+}$ contains both high-confidence chunks from dense retrieval and revived chunks from classification. To produce a compact, high-quality evidence set for generation, we apply final re-ranking using the `BGE-Reranker` model (Chen et al., 2024) over $\widetilde{\mathcal{C}}_{imc_q}^{+}$:

$$\mathcal{C}_{imc_q}^{\text{final}} =_k \left\{ r(q, u_{imct}) \;\middle|\; u_{imct} \in \widetilde{\mathcal{C}}_{imc_q}^{+} \right\},$$

where $r(q, u_{imct})$ denotes the BGE-Reranker score and k is the final retrieval budget. While semantic retrieval and classifier recovery deliberately cast a wide net to maximise recall, the reranker tightens the candidate set to the final retrieval budget k as described in Section 4.2.2, prioritizing the most query-relevant chunks for the generator.

4 Experiments

4.1 Setup and cohorts

This work evaluates retrieval performance on two complementary cohorts: an LLM-annotated cohort for broad pipeline evaluation, and an expert-annotated cardiovascular cohort constructed alongside clinicians. Both are constructed from de-identified EHR data from MIMIC-III.

4.1.1 LLM-annotated Cohort

This cohort is built by sampling patients at random from MIMIC-III to avoid introducing task-specific or phenotype-specific bias into the evaluation set. For each selected patient, MedGemma 27B generates query–answer-span triplets conditioned on the available record, yielding a patient-specific, visit-specific, and category-specific set of triplets. The spans are then mapped to gold evidence documents in the record, so that each query has both (i) an associated set of relevant documents and (ii) a target answer.

The dataset comprises 1300 query-document-answer triplets derived from 5 patients across 3 visits, with on average 25 documents per query of which 1-2 are gold evidence. For a given patient and visit, queries are generated separately for each note type c rather than over a combined document set. Rather than shallow coverage across many patients, this cohort is designed for depth, extensively interrogating each patient across all visit types and note categories to stress-test the pipeline against the full complexity of real longitudinal records.

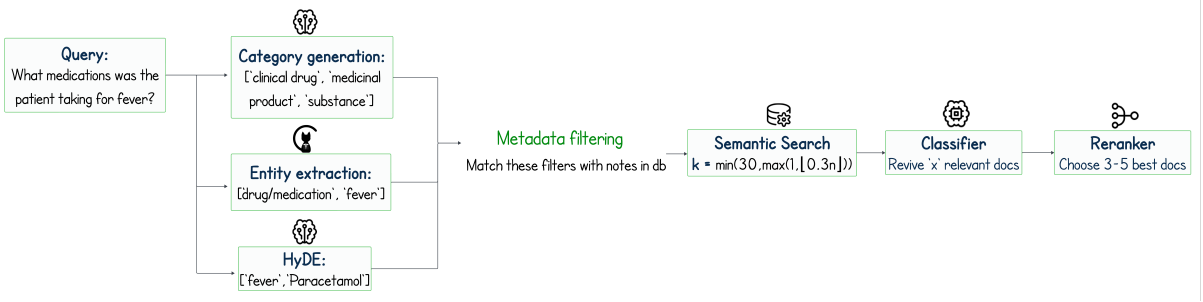

Figure 1: Overview of the four-stage retrieval pipeline

4.1.2 Expert-annotated Cardiovascular Cohort

The second cohort focuses on a clinically coherent subset of cardiovascular patients. Clinical experts first identify relevant patients and then construct 100 query–document mappings, covering typical information needs in cardiovascular medication review. For each patient–visit pair, experts identify relevant documents across all available note types. On average, there are 71 documents for each query, of which about 14 documents are annotated as gold evidence. This cohort therefore serves as the clinical validation benchmark, with high-quality, task-specific annotations against which the pipeline's retrieval performance can be assessed. Unlike existing EHR QA benchmarks that predominantly focus on factoid questions requiring a single supporting document, the average of 14 gold evidence documents per query here reflects the true complexity of real clinical information needs across heterogeneous note types. Appendix A.4 describes the annotation process. A calibration pilot on 30 queries achieved 95.8% inter-annotator agreement, confirming dataset reliability. Across the 100 queries, this dataset amounts to over 7400 document-level relevance judgments, representing a substantial expert annotation effort. This cohort directly reflects the cardiovascular medication review workflow described in Section 6.

Both the cohorts are evaluated under the setting natural to them: the *category-restricted* setting, where retrieval is limited to documents of a specific category c, is applied to the LLM-annotated cohort; and the *visit-level* setting, where retrieval spans all document types within a visit, is applied to the expert-annotated cohort.

4.2 Evaluation Metrics

Notation For a given query, C_{original} denotes all the document chunks in the patient record, C_{filtered} chunks that remain after filtering, G gold chunks associated with the query and C_{revived} the chunks reintroduced by the classifier.

4.2.1 Filtering stage metrics

At the filtering stage, we report:

Corpus ratio The fraction of chunks retained after filtering: $\frac{|C_{\text{filtered}}|}{|C_{\text{original}}|}$

Filtering recall The fraction of gold chunks that remain in the filtered corpus: $\frac{|G \cap C_{\text{filtered}}|}{|G|}$

Revived (classifier configurations only) The fraction of classifier revived chunks that are true gold evidence, reported as 'A/B': $|G \cap C_{\text{revived}}|/|C_{\text{revived}}|$.

4.2.2 Retrieval stage metrics

At the semantic search or reranking stage, operating on the filtered corpus and returning k chunks per query, we report:

Recall@k The fraction of gold chunks appearing among the top-k retrieved chunks.

Averaging All metrics are macro-averaged over queries, so each query contributes equally regardless of the number of associated gold chunks.

Choice of k. We set k=3 for the LLM-annotated cohort (around 25 candidate documents, 1-2 gold) to reflect a low-budget retrieval scenario, and k=20 for the expert-annotated cohort (around 71 candidate documents, 14 gold) to ensure adequate coverage.

4.2.3 Generation stage metrics

We report **ROUGE-L** (Lin, 2004), **BERTScore** (Zhang et al., 2019), and **SARI** (Xu et al., 2016) as generation stage metrics for the LLM-annotated cohort only, as the expert-annotated cohort does not provide reference answers for all queries.

5 Experimental Results

5.1 Baseline Retriever

Our primary baseline is a dense semantic search system that retrieves the top k document chunks per query from the patient corpus, without any additional stages. We use a fixed encoder to obtain embeddings for both queries and document chunks and rank chunks by cosine similarity. This standard RAG retriever configuration serves as the reference system for all subsequent comparisons, representing the most widely deployed retrieval approach in clinical RAG systems.

Baseline configuration The baseline retriever uses the configuration that achieved the best performance across preliminary ablations on chunk strategy, chunk size, and embedding model with full details of the compared methods reported for the LLM-annotated cohort in Appendix A.2.

5.2 LLM-annotated cohort

Table 1 reports retrieval results on the LLM-annotated patient cohort, showing the contribution of each individual component as discussed in Section 5.2.1. The full pipeline shrinks the search space to 78% of original size while boosting recall@3 from 0.60 to 0.73.

5.2.1 Pipeline Ablations

We ablate the pipeline cumulatively, adding metadata filtering, HyDE query expansion, a classifier, and a reranker in sequence, reporting filtering-stage metrics (corpus ratio, filtering recall, revived gold chunks) and recall@3 at each stage.

Metadata filtering Metadata filtering removes more than one quarter of the corpus (0.73), which is attractive from an efficiency standpoint, but the resulting filtering recall of 0.84 is still below the level needed for a reliable end-to-end system. Part of the difficulty is that metadata signals do not fully capture where fine-grained clinical facts are documented, and relevance is highly query dependent, so notes that appear generic or low-priority can still contain critical gold evidence and are occasionally pruned. This motivates the addition of beyond query-aware components.

HyDE HyDE query expansion meaningfully improves both filtering recall and recall@3 when added to the metadata filtered pipeline, raising filtering recall from 0.84 to 0.88 and recall@3 from 0.62 to 0.65. This confirms that queries enriched with clinically plausible terminology surface evidence that the original query phrasing alone misses. However, a filtering recall of 0.88 indicates a non-trivial fraction of gold evidence is missed, motivating a subsequent classifier to recover these.

Classifier The classifier aimed for recall recovery meaningfully boosts filtering recall from 0.88 to 0.94 and recall@3 from 0.65 to 0.69, while reviving 134 gold chunks previously excluded. This demonstrates that learned relevance assessment can correct the over-pruning of borderline cases for generic-looking notes that contain critical clinical facts for which metadata signals alone are insufficient. Together, the three stages build on each other, resulting in substantially stronger evidence recovery.

Reranker The reranker boosts recall@3 from 0.69 to 0.73 by reordering the candidate set, revealing that residual errors reflect fine-grained relevance distinctions among superficially relevant chunks rather than fundamental misses. This confirms the pipeline's strength: each stage corrects a distinct failure mode, culminating in a compact, high-precision evidence set for the generator.

5.3 Expert-annotated Cardiovascular Cohort

The expert-annotated cohort is substantially harder: 71 documents per query versus 25, and 14 gold evidence documents versus 1-2, spanning heterogeneous note types. This is not a controlled retrieval task but a genuine clinical information need, where evidence is distributed and missing any part of it has direct implications for medication review decisions. Despite this complexity, the pipeline delivers a 23% relative recall gain over the dense retrieval baseline, closely matching the +22% observed on the LLM-annotated cohort. The consistency of this gain across two fundamentally different evaluation settings, one broad and automatically annotated and one clinically curated and expert-validated, confirms that the pipeline's improvements are not an artefact of the evaluation conditions but reflect genuine, generalisable evidence recovery. These results demonstrate the pipeline's promise as a practical retrieval tool for real-world clinical use.

5.4 Generation Stage Evaluation

While our primary contribution is retrieval engineering, we include generation metrics to confirm retrieved evidence translates to improved end-to-end QA (Table 2). Using MedGemma 4B

Note: Each approach builds cumulatively on all prior stages

Table 1: Ablated retrieval results under natural configurations

Approach	Corpus Ratio	Filtering Recall	Revived	Recall@k
LLM-annotated cohort (category-restricted)				
Baseline	1.00	–	–	0.60
Metadata filtering	**0.73**	0.84	–	0.62
HyDE	0.75	0.88	–	0.65
Classifier	0.78	**0.94**	134/514	0.69
Reranker (Full Pipeline)	0.78	**0.94**	**376/1369**	**0.73**
Expert-annotated cohort (visit-level)				
Baseline	1.00	–	–	0.47
Metadata filtering	**0.65**	0.77	–	0.52
HyDE	0.66	0.80	–	0.52
Classifier	0.68	**0.83**	21/71	0.56
Reranker (Full Pipeline)	0.68	**0.83**	**38/91**	**0.58**

Table 2: Generation stage metrics

Metric	Baseline	Full pipeline
ROUGE-L	0.362	0.412
BERTScore	0.469	0.533
SARI	74.92	82.45

conditioned on top-k retrieved chunks, the full pipeline improves all generation metrics over baseline retrieval: ROUGE-L: +14% relative gain, BERTScore: +14% relative gain and SARI: +10% relative gain. These consistent gains across lexical overlap (ROUGE-L), semantic similarity (BERTScore), and system output quality (SARI) validate that improvements propagate to answer quality. Our focus on deterministic retrieval provides the strong evidence foundation on which generation quality directly depends.

6 Clinical Workflows

The pipeline is designed for real-world clinical deployment, with two immediate target workflows:

- *For clinical risk scoring*, such as CHA_2DS_2-VASc score (Lip et al., 2010) computation, where each variable must be evidenced by specific documentation across heterogeneous note types, high recall is the critical requirement, as missing a single signal can produce an incorrect risk score. The pipeline's multi-stage design ensures that evidence scattered across note types is systematically recovered, reducing the risk of incorrect risk scoring due to missed clinical signals.
- *For cardiovascular medication review*, clinicians must synthesize evidence distributed across discharge summaries, nursing notes, ECG reports, and echo reports. The pipeline surfaces this evidence in response to natural language queries, enabling clinicians to interrogate a patient's longitudinal record directly. The pipeline's deterministic, stage-wise design ensures every retrieval decision remains traceable and auditable, properties as important as performance in settings where the provenance of evidence directly affects clinical accountability.

7 Conclusion

Reliable clinical question answering over EHRs depends fundamentally on retrieval quality, yet the retrieval component has remained the least scrutinized part of clinical RAG systems. This work addresses that gap directly. By decomposing retrieval into four distinct, instrumented stages, the pipeline makes evidence recovery measurable and auditable at every step, achieving 22-23% relative recall gain over a strong dense retrieval baseline across cohorts. The consistency of this gain across two evaluation settings of fundamentally different complexity suggests genuine, generalisable improvements in evidence recovery rather than artefacts of evaluation design. Our work delivers a retrieval system that clinicians and researchers can rely on, inspect, understand, and build upon for real-world clinical use.

Limitations and Future Work

The LLM-annotated cohort was designed to prioritise depth over breadth, extensively interrogating five patients across all visit types, note categories, and query distributions to stress-test the pipeline against the full complexity of real longitudinal records. While this design choice ensures thorough within-patient evaluation, future work should extend coverage to a broader patient population to assess robustness across variation in documentation style and clinical complexity.

Similarly, evaluation is currently restricted to MIMIC-III, a single US medical centre; applying the pipeline to other EHR systems, clinical domains, languages, and documentation cultures is a natural and important next step.

Generation metrics are reported for MedGemma 4B only, and evaluating downstream answer quality under a broader range of generators is a straightforward extension. The pipeline's recall ceiling is tied to MedCAT's NER performance, and future work could explore more clinical NER systems or LLM-based entity extraction.

The classifier is trained on a heavily imbalanced dataset reflecting realistic clinical sparsity, and evaluating threshold robustness across note types and query distributions beyond those seen in training remains an open question. Finally, the multi-stage design introduces additional latency over a standard dense retrieval baseline; detailed runtime metrics and latency characterization for time-sensitive clinical deployment will be reported in future work.

Ethics

This work uses de-identified patient data from MIMIC-III under standard data use agreements. All clinical annotations were performed by qualified experts following structured guidelines. The pipeline is intended to support clinical decision-making, not replace clinical expertise, and retrieval outputs should always be reviewed by a clinician before informing patient care. The deterministic, auditable design of the pipeline is a deliberate ethical choice, ensuring that retrieval decisions remain transparent and traceable rather than opaque. We acknowledge the risk of retrieval bias, and note that evaluation on a broader and more diverse patient cohort remains important future work.

A Appendix

A.1 Algorithm for Chunking

Algorithm 1 Chunking clinical notes

Require: Notes grouped by patient, admission, and category
Require: Minimum chunk size L_{min}, maximum chunk size L_{max}
Ensure: A list of text chunks with timestamps

```
Initialize empty list of chunks C
for each patient–admission–category group G do
    Sort notes in G chronologically
    Start an empty chunk buffer B, length L ← 0
    for each note in order do
        Let ℓ be the length of this note
        if ℓ is very large then
            Split the note into smaller pieces using recursive splitter
            for each piece do
                if adding it to B would exceed L_max then
                    Save current chunk to C and start a new one
                end if
                Add piece to current chunk and record its timestamp
            end for
        else if adding the note would exceed L_max then
            Save current chunk to C
            Start a new chunk with this note
        else
            Add the note to the current chunk
        end if
    end for
    if the final chunk buffer is not empty then
        Save it to C
    end if
end for
return all chunks C
```

A.2 Baseline Design Choices

Before introducing the full multi-stage pipeline, we first investigate two design choices for the baseline retriever: chunk size and embedding model. These experiments allow us to select a strong and well-justified baseline configuration, which we then use consistently in the main results and pipeline ablations.

A.2.1 Chunking Strategy and Size

We conduct an ablation study on different chunking strategies and chunk sizes to determine the most effective configuration for the baseline retriever. The chunking strategies compared are:

- **Recursive chunking:** Fixed-length recursive segmentation with partial overlap between segments.
- **Smart structural chunking (proposed):** A structure-aware approach that respects document boundaries and clinical section headers while maintaining approximately uniform chunk length.

For each strategy, we experimented with multiple target chunk sizes (approximately 400, 1200, and 1800 characters) and evaluated recall@3 using the dense retriever. The results, summarised in Table 3, show that the smart structural chunking strategy consistently outperforms purely length-based segmentation. A chunk size of around *1000* offered the best trade-off between retrieval recall and corpus compactness and was selected for all subsequent experiments.

We note that more sophisticated approaches such as semantic chunking or sentence-level segmentation were not explored in this work. In the clinical domain, such methods often disrupt the logical flow of medical narratives, where the order of statements, temporal markers, and contextual dependency carry significant meaning. To preserve the semantic continuity and clinical validity of the text, we retain structure-aware, non-semantic chunking methods.

A.3 Embedding Model

Using the optimal chunking configuration identified above, we compared several embedding models for the baseline retriever, including `nomic-ai/nomic-embed-text-v1.5` (Nussbaum et al., 2024), `intfloat/e5-base-v2` (Wang et al., 2022), `mixedbread-ai/mxbai-embed-large-v1` (Lee et al., 2024), `emilyalsentzer/Bio_ClinicalBERT` (Alsentzer et al., 2019) and `sentence-transformers/all-MiniLM-L6-v2` (Thakur et al., 2021). Each model was used to encode both query and chunk embeddings,

and performance was measured using recall@3. The results, shown in Table 4, demonstrate that `llm-embedder` provides the highest recall while maintaining computational efficiency. It was therefore selected as the default embedding model for both the baseline and all full-pipeline experiments.

Strategy	Chunk size	Recall@3
Recursive chunking	400	0.41
	1200	0.53
	1800	0.56
Smart chunking	(200, 500)	**0.45**
	(900, 1500)	**0.60**
	(1700, 2200)	**0.59**

Table 3: Chunk size ablation

Model	Recall@3
llm-embedder	**0.6**
nomic-embed-text-v1.5	0.59
e5-base-v2	0.58
mxbai-embed-large-v1	0.59
Bio_ClinicalBERT	0.42
all-MiniLM-L6-v2	0.55

Table 4: Embedding model ablation

A.4 Expert Annotation Process

Two clinical experts performed annotation for the cardiovascular cohort using a structured process:

Annotation guidelines We created a comprehensive annotation document detailing:

- **Task definition**: Identify all documents containing evidence for clinical information needs
- **Relevance criteria**: Direct mentions, inferable evidence, multi-hop reasoning requirements
- **Annotation procedure**: Consensus resolution, temporal judgment guidelines

Annotation tool We built a custom web interface to streamline the process, featuring:

- Side-by-side patient record browser (visit-organized notes by category)
- Query-document relevance marking
- Export to structured gold format for evaluation

Pilot and calibration An initial pilot on the same 30 queries achieved 95.8% inter-annotator agreement. A calibration meeting refined edge cases:

- Reasoning "hops": single-hop (direct) vs. multi-hop (synthesis across mentions)
- Temporal ambiguity in nursing notes (past vs. present conditions)
- Cross-document evidence distribution across note types

Remaining 70 queries were split among the annotators.

A.5 Classifier Training Details

Training data consists of query-chunk pairs generated using Gemma 12B (Team et al., 2025) over a held-out set of MIMIC-III patients with no overlap with either evaluation cohort. Chunks containing gold evidence serve as positive examples and non-relevant chunks within the same patient-visit-category serve as negatives, yielding 16894 training pairs in total with 2238 positive and 14656 negative, reflecting the realistic sparsity of relevant evidence in clinical notes. The classifier is trained with binary cross-entropy loss with class weights for 10 epochs, with learning rate 5×10^{-5} and weight decay 0.01.

Interpretable ICD Code Classification with Faithful Sentence Extraction

Abstract

Transformer-based models such as PLM-CA achieve strong performance for automatic ICD coding, but their attention weights do not provide faithful explanations of their predictions. This is a major limitation for electronic medical records, where users often need concise and trustworthy evidence for each assigned code. To address this issue, we jointly train a sentence extractor and an ICD code classifier such that predictions are based only on the extracted sentences. As a result, the extracted sentences serve as faithful rationales for each predicted code and substantially reduce the effort required to inspect long medical records. Experiments on MIMIC-III show that our method approaches the performance of a transformer baseline that processes the full record while using only a small fraction of the document.

1 Introduction

The International Classification of Diseases (ICD), defined by the World Health Organization, helps match patients to appropriate treatments.[1] However, the manual assignment of ICD codes is labor-intensive and requires substantial expertise. Consequently, automatic ICD coding from electronic medical records has been the focus of extensive research (Dong et al., 2022; Edin et al., 2023). Recent advances in pretrained transformer-based models have further improved ICD coding performance (Edin et al., 2023; Aden et al., 2024). In particular, Edin et al. (2024) proposed PLM-CA, a model pretrained on medical data that achieves state-of-the-art classification performance.

Unfortunately, attention mechanisms in transformer-based classification models do not provide faithful explanations for ICD code predictions (Bastings and Filippova, 2020). To address this limitation, we jointly train a sentence extractor and an ICD code classifier such that the classifier relies only on the selected sentences. Following Lyu et al. (2024), we refer to such a classifier as faithful.

Our working hypothesis is that a few key sentences, also referred to as rationales (Ehsan et al., 2019), can be sufficient to correctly judge each ICD code of a medical record. As a consequence, we propose the following two step method: (1) Select a subset of relevant sentences $\hat{S}$ from the document. (2) Predict the ICD code with an interpretable classifier using only $\hat{S}$.

With the requirement of an independent sentence selection in step (1), we prove the faithfulness of the classifier, and show that the parameters of the models in step (1) and (2) can be jointly trained (see Section 3). Furthermore, our experiments using the MIMIC-III dataset (Johnson et al., 2016) show that the proposed method can successfully identify a small number of relevant sentences that are critical for the correct ICD code classification (see Section 4).

2 Background and Related Works

ICD code prediction for electronic medical records is often formulated as a (multi-label) classification task (Edin et al., 2023). ICD code prediction is challenging due to the fact that there are several thousand codes, where many are rare and *not* mutually exclusive. As a result, many works have focused on increasing prediction accuracy (Edin et al., 2023; Dong et al., 2022).

Transformer-based models are often among the best performing models (Edin et al., 2023; Ravichandran et al., 2024). In particular, PLM-CA is considered to be one of the best models for ICD code prediction. The PLM-CA model, proposed by Edin et al. (2024), is an improved version of the PLM-ICD model of Huang et al. (2022), with a multi-head attention mechanism for ICD codes and RoBERTa pretrained on medical data (Lewis et al., 2020). Though, it is tempting to use a model's attention-mechanism for producing explanations of the prediction (Ravichandran et al., 2024; Mullenbach et al., 2018), these explanations are not faithful (Bastings and Filippova, 2020; Lyu et al., 2024). In particular, there are no theoretical guarantees that removing any non-highlighted text will not change the outcome of the classifier. For example, Feng et al. (2018) demonstrate that using attention scores for rationale extraction can lead to unintuitive behavior that is difficult to interpret.

Using sentences as rationales has also been considered (Herrewijnen et al., 2021; MISAWA et al., 2023), but those methods use information from the entire document for sentence selection, which violates faithfulness, as we describe in Proposition 1. Other methods require manually annotated rationales that are expensive for specialized medical domains (Chan et al., 2022).

Zhou et al. (2021) and Douglas et al. (2025) show that only a small fraction of a discharge summary is relevant for ICD coding. In particular, Douglas et al. (2025) propose a filtering step before applying PLM-CA to retain only clinically relevant text spans. However, this filtering step requires a named entity recognizer and an assertion classifier, both of which rely on fine-grained annotations. To improve interpretability, they also use AttnInGrad (Edin et al., 2024), which still does not guarantee faithfulness.

3 Proposed Method

Our goal is a classification method that bases its prediction result only on a small subset of rationales from a long document. Here, we consider each sentence as a potential rationale.

Since many ICD codes are not mutually exclusive, we consider a multi-label classification model. Let C denote the number of classes (=ICD codes). Assuming a document contains the sentences $\{s_1, s_2, \ldots, s_m\}$, we denote set of their indices by $S := \{1, 2, \ldots, m\}$. Given a constraint $0 < k < m$ on the number of rationales, for each class $c \in \{1, 2, \ldots, C\}$, we proceed as follows:

1. Using some function $h_{\boldsymbol{\eta}}$, we embed each sentence s_i *independently* into a vector representation $\mathbf{x}_i \in \mathbb{R}^H$.

2. We score each sentence for class c using some function $f^c_{\boldsymbol{\theta}} : \mathbb{R}^H \to \mathbb{R}$, and select the sentences with the top-k scores, i.e. $\hat{S}^c := \{i \in S \mid f^c_{\boldsymbol{\theta}}(\mathbf{x}_i) \geq f^c_{\boldsymbol{\theta}}(\mathbf{x}_{(k)})\}$, where

$$f^c_{\boldsymbol{\theta}}(\mathbf{x}_{(1)}) \geq f^c_{\boldsymbol{\theta}}(\mathbf{x}_{(2)}) \ldots \geq f^c_{\boldsymbol{\theta}}(\mathbf{x}_{(k)}) \ldots \geq f^c_{\boldsymbol{\theta}}(\mathbf{x}_{(m)}) .$$

3. We pool the sentence embeddings with the top-k scores and pass the resulting vector again to $f^c_{\boldsymbol{\theta}}$, which return value is interpreted as the logit for class c. That means the probability that the document is assigned ICD code c is given by

$$p(\mathbf{y}_c = 1|S) = \text{sigmoid}(f^c_{\boldsymbol{\theta}}(pool(\hat{S}^c)) , \quad (1)$$

where $\mathbf{y} \in \{0, 1\}^C$ is the class label vector of the corresponding document.

The parameters of the sentence embedder and classifier, namely $\boldsymbol{\eta}$ and $\boldsymbol{\theta}$, are jointly trained.

By construction, the proposed method has the following important property.

Proposition 1 *Removing from the document any sentence from $S \backslash \hat{S}^c$ leaves the classification result for class c unchanged.*

Proposition 1 is a basic requirement for a classifier with faithful explanations. However, transformer-like attention mechanisms do not fulfill this requirement, since the attention score for a sentence (or token) itself depends on all sentences.

Finally, we note that the proposed method (and Proposition 1) have the subtle requirement that $m > k$. Since our focus is on classification of long medical records this is not a limitation. However, we note that as an alternative to taking the top k sentences, we could introduce a threshold τ, and then use all sentences

with $f^c_{\boldsymbol{\theta}}(\mathbf{x}_i) \geq \tau$. This still fulfills Proposition 1, though, this has the disadvantage that for some documents this may lead to a large set $\hat{S}^c$, where many rationales have overlapping information content.

3.1 Joint Sentence Extraction and Classification with LLM

Below, we describe a concrete instance of the proposed method. First, using a large language model (LLM) denoted by $h_{\boldsymbol{\eta}}$, we encode each sentence s_i as a representation $\mathbf{x}_i \in \mathbb{R}^H$, i.e., $\mathbf{x}_i := h_{\boldsymbol{\eta}}(s_i)$. Because of the large number of ICD codes, we use a single LLM $h_{\boldsymbol{\eta}}$ for all classes. Next, let $W \in \mathbb{R}^{C \times H}$ and $\mathbf{b} \in \mathbb{R}^C$ denote the parameters of a linear multi-label classifier over all ICD codes. For each sentence-label pair, we compute

$$f^c_{\boldsymbol{\theta}}(\mathbf{x}_i) = \mathbf{w}_c^\top \mathbf{x}_i + b_c \,,$$

where $\mathbf{w}_c^\top$ is the c-th row of W.

For the pooling function in Equation (1), we use the mean, i.e.,

$$pool(\hat{S}^c) := \frac{1}{|\hat{S}^c|} \sum_{i \in \hat{S}^c} \mathbf{x}_i \,,$$

where $|\hat{S}^c| = k$.

The parameters of the LLM and the classifier, namely $\boldsymbol{\eta}$, W, and $\mathbf{b}$, are trained jointly. We train the model in two stages. In Stage 1, we use all sentences in S to obtain a stable initialization. In Stage 2, we switch to the top-k selection mechanism described above. Since ICD coding is a multi-label task, we optimize binary cross-entropy loss over sigmoid outputs. We denote the resulting method by LLM-SeparateTopK.

3.1.1 Common Sentence Extraction

Note that the method described above extracts k rationales for each ICD code. Alternatively, we also explore a variation where we extract in *total* only k sentences that are used for classification. For that we modify step 2 (Section 3), by determining the set of selected sentences $\hat{S}$ as follows. Define $\hat{S} := \{i \in S \,|\, \alpha_i \geq \alpha_{(k)}\}$, where

$$\alpha_{(1)} \geq \alpha_{(2)} \ldots \geq \alpha_{(k)} \ldots \geq \alpha_{(m)} \,,$$

and α_i is the aggregated positive contribution of sentence i across all labels:

$$\alpha_i := \sum_{c=1}^{C} \mathrm{ReLU}(f^c_{\boldsymbol{\theta}}(\mathbf{x}_i) - b_c) \,,$$

where we subtract the bias term to ensure that each class is given the same weight. We denote the resulting method as LLM-GlobalTopK.

3.2 Bag-of-words Model

Alternatively to the usage of an LLM, we also consider a Bag-of-words (BoW) model for $\mathbf{x}_i$, where we use all unigrams, bi-grams, and tri-grams that are contained in at least 3 sentences. Note that in this case the embedding function h has no trainable parameters. We denote the corresponding methods as BoW-SeparateTopK and BoW-GlobalTopK.

4 Experiments

4.1 Dataset and Preprocessing

For our experiments, we use the discharge summaries of the Beth Israel Deaconess Medical Center collected during 2001 to 2012, which are part of the MIMIC-III dataset (Johnson et al., 2016). For the preprocessing and train/validation/test splits we use MIMIC-III clean as in (Edin et al., 2023).[2] Each document is split into sentences using the NLTK library (Bird et al., 2009) subject to some post-processing described in Appendix A. Note that the resulting median number of sentences per document is 141.

4.2 Baselines

A simple interpretable baseline is a bag-of-words model that uses the whole document (BoW-All). Furthermore, as a rationale extraction baseline, we compare against a method that uses the PLM-CA model to identify important sentences with Integrated Gradients (Sundararajan et al., 2017), and then retrains PLM-CA. We call the resulting method IG-GlobalTopK and provide details in Appendix C. We also compare against methods that simply extract the first k sentences of the document

Table 1: Comparison of baseline and proposed methods for ICD code prediction in terms of micro/macro AUC-ROC, micro/macro F1, MAP, and Precision@r (r = 8, 15). MAP: mean average precision. Best results highlighted in bold, for proposed and baseline methods, respectively.

(i.e., the head sentences) or the last k sentences (i.e., the tail sentences), which we denote as BoW-Head and BoW-Tail, respectively. Analogously, we compare to a method that pools all sentence embeddings (LLM-All), the first k sentence embeddings (LLM-Head), or the last k ones (LLM-Tail). Finally, for reference, we also report the results of the original PLM-CA model, which uses the whole document (Douglas et al., 2025).

4.3 Results

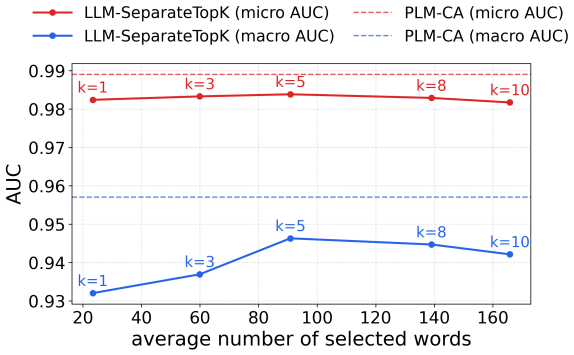

Figure 1: Proposed method's AUC scores for different values of k.

For the proposed methods and corresponding baselines, we set $k = 10$, which reduces most documents by more than 90%. We evaluate all methods on all 3,681 ICD codes occurring in the training and test splits, and report micro/macro AUC-ROC, micro/macro F1, mean average precision (MAP), and Precision@r in

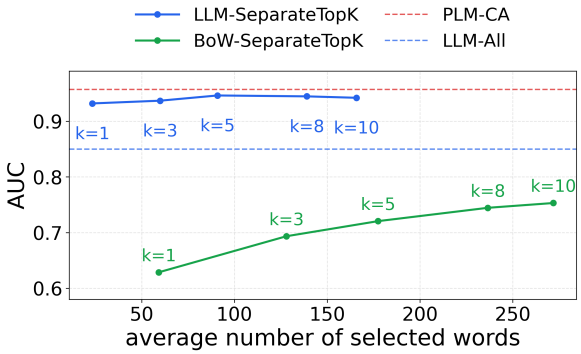

Figure 2: Comparison of different method's macro AUC scores for different values of k.

Table 1. Figure 1 shows the AUC scores for different values of k for the proposed method.

Our results show that the proposed classifier remains accurate while using only a small subset of each document. In particular, for $k = 10$, LLM-SeparateTopK performs better than all baselines in Table 1, including the rationale-based baseline IG-GlobalTopK as well as naive head/tail extraction methods. Although full-document PLM-CA remains a strong reference point, the proposed method often approaches its performance while providing faithful rationale extraction. Table 2 shows one example of the extracted sentences.

Finally, in Figure 2, we also show the macro AUC of the proposed method LLM-SeparateTopK for different number of selected sentences k. Interestingly, we see that the pro-

posed method performs *better* than LLM-All, suggesting that selecting only few sentences has the additional benefit of removing noise.

Rank	Extracted Sentence
1	"discharge diagnosis angioedema"
2	"brief hospital course angioedema followed by dr"
3	"you were admitted to the hospital with throat swelling which was an exacerbation of your chronic angioedema"

Table 2: Top three extracted sentences produced by LLM-SeparateTopK ($k = 10$) for ICD code 995.1 (Angioneurotic edema) from a discharge summary.

5 Conclusions

In this paper, we proposed a provably faithful approach to rationale extraction for ICD code prediction. Experiments on MIMIC-III showed that our method can extract a small number of sentences *without any sentence- or token-level annotations* while achieving competitive coding performance, even compared with methods that process the full discharge summary. Overall, our results suggest that faithful sentence-level rationales are a promising step toward more transparent and clinically useful medical coding systems.

As future work, we plan to evaluate the extracted rationales against human-annotated evidence resources such as MDACE (Cheng et al., 2023), which would also allow us to assess plausibility.

Limitations

The current method judges the importance of each sentence independently of context. While this is an important requirement for the faithfulness, as described in Proposition 1, this might lead to wrongly excluding short sentences that are important when judged in the context of its surrounding sentences.

A Sentence Splitting

First, each document is split into sentences using the sent_tokenize function[3] of the NLTK library (Bird et al., 2009). Afterwards, the following post-processing steps are used to reduce conflation and improve comprehensiveness:

1. If there are two or more line breaks, split the sentence before and after the line break.

2. If there are two or more spaces, split the sentence before and after the spaces.

3. Replace the line break characters with spaces.

4. Remove spaces at the beginning and end of the sentence.

5. If each sentence ends with a ":", join that sentence to the next sentence with a space.

The resulting median number of sentences (and IQR) per document is 141 (102-189). The median number of words (and IQR) in a sentence are 8 (3-13). The median number of words (and IQR) in a document is 1,375 (965-1,900).

[3] https://www.nltk.org/api/nltk.tokenize.sent_tokenize.html

B Training Details

For LLM-SeparateTopK, we trained the model for up to 9 epochs and used early stopping with a patience of 3 epochs according to the validation loss. The learning rates for the pretrained encoder and the linear classifier were set to 3×10^{-6} and 5×10^{-5}, respectively. Owing to the memory requirement of the model, we used a mini-batch size of 1 document and accumulated gradients for 2 steps, yielding an effective batch size of 2. No explicit regularization was used; instead, early stopping was employed to mitigate overfitting. All experiments were run on an NVIDIA Blackwell GPU, and each epoch took around 2 hours.

C Sentence-level Top-k Selection via Integrated Gradients (IG-GlobalTopK)

As a rationale-extraction baseline, we use Integrated Gradients (IG) (Sundararajan et al., 2017) to score sentences and then retrain PLM-CA on the extracted sentences only.

Given a document with S sentences, where each sentence s_i consists of a set of tokens T_i, we first compute the attribution of each token. Let $F : \mathbb{R}^n \to \mathbb{R}$ be the model's loss function (Binary Cross-Entropy), $\mathbf{u} \in \mathbb{R}^n$ be the vector of all tokens in the document, and $\mathbf{u}' \in \mathbb{R}^n$ be a baseline consisting of PAD tokens. The IG score for the j-th token is defined as:

$$\mathrm{IG}_j(\mathbf{u}) = (u_j - u'_j) \int_{\alpha=0}^{1} \frac{\partial F(\mathbf{u}' + \alpha(\mathbf{u} - \mathbf{u}'))}{\partial u_j} d\alpha.$$

To obtain a document-level importance score at the sentence level, we aggregate the token-wise attributions within each sentence by calculating their mean:

$$\mathrm{Score}(s_i) = \frac{1}{|T_i|} \sum_{j \in T_i} \mathrm{IG}_j.$$

Similar to the top-k selection of our proposed method, we then define

$$\hat{S}_{\mathrm{IG}} := \{ i \in S \,|\, \mathrm{Score}(s_i) \geq \mathrm{Score}(s_{(k)}) \},$$

where

$$\mathrm{Score}(s_{(1)}) \geq \mathrm{Score}(s_{(2)}) \geq \ldots \geq \mathrm{Score}(s_{(m)}).$$

We then retrain PLM-CA using only $\hat{S}_{\mathrm{IG}}$, while preserving the original sentence order.

To prevent discrepancies between training and testing, we use the following retraining procedure: we partition the training set into five folds: 4/5 are used for training and 1/5 for IG-based sentence selection, and repeat this 5 times. Finally, we train a new classifier $\mathcal{C}$ on the extracted sentences from the whole training data.

The resulting method, denoted by IG-GlobalTopK, uses at test time classifier $\mathcal{C}$ applied to extracted sentences only. However, note that IG-GlobalTopK is not strictly faithful: a sentence s_i that was *not selected* could have influenced the choice of $\hat{S}_{\mathrm{IG}}$. This in consequence, allows sentence s_i to influence indirectly the final classification result.

D Example of Extracted Sentences

We provide additional examples here, including both successful and failure cases for LLM-SeparateTopK (Tables 3 and 4), as well as a successful case for LLM-GlobalTopK (Table 5).

ICD Code	493.90 long description: Asthma, unspecified type, unspecified
Rank	**Extracted Sentence**
1	"asthma continued flovent prn"
2	"asthma"
3	"fluticasone mcg actuation aerosol sig one puff inhalation hospital1 times a day as needed for shortness of breath or wheezing"

Table 3: An additional successful example of extracted sentences produced by the proposed LLM-SeparateTopK ($k = 10$) for ICD code 493.90 from one discharge summary (admission id = 179767). The selected sentences directly indicate the target respiratory condition and its related medication use.

ICD Code	886.0 long description: Traumatic amputation of other finger(s), complete, without mention of complication
Rank	**Extracted Sentence**
1	"the patient underwent completion amputation of the left ring finger repair of digital ulnar and radial nerve to the middle finger index finger and thumb repair of the fpl ftp of the middle finger and fts ftp of the index finger repair of the epl to the thumb and k wire fixation of the metacarpal of index and phalanx of the first finger"
2	"history of present illness the patient arrived from another hospital in hospital3 to the emergency room with a complete amputation of his thumb index long and ring fingers of his left hand"
3	"discharge diagnosis as described above amputation of thumb index long and ring fingers reattachment of thumb index and long fingers and revision amputation of ring finger"

Table 4: A representative failure example of extracted sentences produced by the proposed LLM-SeparateTopK ($k = 10$) for ICD code 886.0 from one discharge summary (admission id = 174415). Although the selected sentences are clinically plausible and strongly related to traumatic finger injury, the model incorrectly assigns this code.

ICD Code	995.1 and 493.90
Rank	**Extracted Sentence**
1	"asthma"
2	"chronic urticaria and angioedema since c section done on for failure to progress after hour labor"
3	"brief hospital course angioedema followed by dr"
4	"discharge diagnosis angioedema"
5	"asthma continued flovent prn"
6	"physical exam t bp hr rr o2 sat ra wt kg gen nad speaking in full sentences without sob no audible stridor heent moon facies mmm angioedema no edema noted in posterior oropharynx and posterior oropharynx clearly visualized behind tongue neck supple cv rrr s1 split s2 ii vi systolic murmur over lsb lungs cta b l without wheezing rhonchi or rales abd soft obese nt nd normoactive bs ext no le edema wwp neuro aao x skin no rashes noted"
7	"history of present illness yo f with h o idiopathic chronic urticaria and angioedema requiring intubation during previous admission asthma and seasonal allergies who presents with tongue swelling x hrs"
8	"medications on admission epipen prn loratadine mg daily ranitidine mg qam doxepin mg qhs benadryl mg q6h prn calcium mg daily vit d units daily ativan mg qhs flovent mcg puff hospital1 prn for angioedema"
9	"first name4 namepattern1 last name namepattern1 as outpt for idiopathic chronic urticaria and angioedema with multiple admissions in past year for angioedema"
10	"otherwise no history of related urticaria angioedema"

Table 5: An additional successful example of extracted sentences produced by the proposed LLM-GlobalTopK ($k = 10$) for all ICD code from one discharge summary (admission id = 179767). The selected sentences directly indicate the target respiratory condition and its related medication use.

Evaluating LLM-as-a-Judge for Medical Term Simplification

Abstract

Highly technical medical terms are difficult for patients to understand during fast-paced hospital consultations, leading them to rely on Large Language Models (LLMs) for simplified explanations. However, LLMs can produce inaccurate or false information. Since expert evaluation is costly and time-consuming, LLM-as-a-Judge (LaaJ) approach is increasingly adopted to assess the quality of LLM-generated text. In this paper, we investigate the reliability and robustness of LaaJ for specialized medical knowledge by evaluating six LLMs for their judgment capabilities on three dimensions: correctness, readability, and completeness. We utilized three judgment setups: Vanilla, Epistemic, and Bias to probe robustness, and assess them against human expert annotations to measure alignment. To address the lack of specialized medical benchmarks, we introduce BrainCancerDB, an English dataset of 219 brain cancer terms with 23,652 annotations. Our findings indicate that while LLM-Judges and humans display similar trends in ranking simplified explanations, LLM-Judges tend to be more lenient on correctness, which may have serious implications in medical setting. Additionally, we observe that hallucinations in LaaJ setups can be mitigated by epistemic markers.

1 Introduction

Large Language Models (LLMs) are used for many tasks in real world, such as question-answering, abstract writing, or recommendations (Acharya et al. 2023; Wu et al. 2024; Lyu et al. 2024). Out of many use cases, health related ones require specific caution, as people tend to use LLMs instead of real doctors for medical information or advice (Zada et al., 2025). Medical consultations are often too short to allow patients to fully interact with doctors, or to get explanations for the medical jargon (Umapathi et al., 2023). Complex medical terms such as *oligodendroglioma* or *temozolomide* are difficult to understand for patients with different levels of medical literacy. Not understanding technical medical terms can hinder the treatment of the disease, and in cases of diseases very complex to cure, such as brain cancer, simplifying medical terms for patients is of utmost importance (Ivchenko and Grabar, 2022).

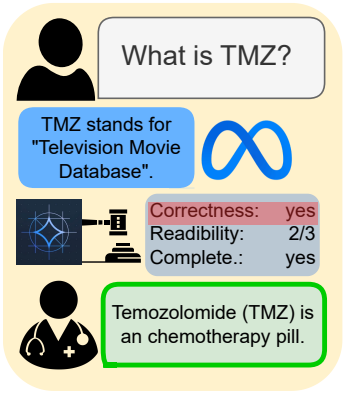

Figure 1: Illustration of limitation of LLM-as-a-Judge (Gemma-1b) evaluation in the medical domain.

There is a high risk for LLMs giving inaccurate answers that can have dangerous consequences (misinformation, erroneous scientific content, bias) (Bang et al. 2025; Huang et al. 2023; Zhang et al. 2023). LLM-as-a-Judge (LaaJ) prompting method was proposed as a solution to evaluate LLMs answers (Li et al., 2024). However, this method can fail in evaluating LLM-generated answers or it can be prone to *self-preference bias* (Wataoka et al., 2024), data contamination issues (Li et al., 2025), or lack of robustness when using positive of negative epistemic markers (eg., *I am confident*, *I am not sure*) (Lee et al., 2025).

In this study, we aimed to answer two main research questions: (RQ1) *Is LaaJ a reliable automatic evaluation method for medical term simplification?*, and (RQ2) *Are LLM-Judges aligned with human evaluation for medical term simplification?* In this paper, we used *LLM-as-a-Judge* (LaaJ) to

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 687–694
July 3-4, 2026 ©2026 Association for Computational Linguistics

refer to the evaluation method, and *LLM-Judge* to talk about the LLM used within a Chain-of-Thought prompting framework for an evaluation task. To test the reliability and robustness of the LaaJ method, we conducted a fine-grained evaluation of the capacity of six LLMs in evaluating medical text simplification of definitions and explanations of highly medical brain cancer related terms, in three zero-shot settings: Vanilla, Bias, and Epistemic. This paper's contribution is twofold:

1. We propose `BrainCancerDB`, an English medical dataset of 219 brain cancer terms compiled from real-life hospital consultations and medical online databases. We extended the `BrainCancerDB` dataset with scientific and human simplified definitions for all 219 terms, along with 23,652 LLM-generated annotations. Moreover, we share the code of our `fine-grained evaluation pipeline` with the NLP and medical community to serve as an evaluation framework for the LLM-as-a-Judge method for the medical term simplification task[1].

2. We conducted a `two step fine-grained evaluation` of open-source LaaJ's performance in evaluating simple explanations for highly technical medical terms for three dimensions, `correctness`, `readability` and `completeness`. We compared LaaJ against human expert evaluation and SARI, a text simplification metric (Xu et al., 2016).

2 Related Work

As human expert evaluation of LLM generated content is costly and time-consuming, LLM-as-a-Judge evaluation became a convenient, cheap and fast tool (Li et al. 2024; Gu et al. 2024; Zheng et al. 2023). Nevertheless, there are few studies on the reliability and robustness of LLM-as-a-Judge as an evaluation method for very technical medical knowledge. While many studies were conducted on brain cancer MRI images or reports (Rashed et al. 2025; Kanzawa et al. 2024), there are very few research studies on brain cancer related simplification for patients. Concurrent studies worked on simplifying brain magnetic resonance imaging (MRI) reports for patients (Xu and Wang, 2024), or on summarizing brain tumour forums (Muasher-Kerwin et al., 2025). However, these studies do not share their datasets on brain cancer for further reproducibility.

[1] github.com/ATILF-UMR7118/BrainCancerDB-Corpus

medical_term: MGMT methylation

sci_definition: MGMT promoter methylation is related to the increased sensitivity of tumour tissue to chemotherapy with temozolomide (TMZ) and thus to improved patient survival.

simple_definition: MGMT methylation is an indicator of how sensitive the tumour cells are to cancer drugs treatment.

Figure 2: Instance of BrainCancerDB dataset. The `medical_term` was extracted from the brain cancer related terms collected from hospital visits, while the `sci_definition` represents the scientific definition extracted from medical websites. The `simple_definition` was manually written by a human annotator.

Our LaaJ prompting method was proposed as a solution to identify hallucinations in LLMs answers (Li et al., 2024). However, this method can be prone to *self-preference bias* (Wataoka et al., 2024) or data contamination issues, when the same family of models are used for generation and evaluation (Li et al., 2025). Benchmarks for judging the LLM-Jugdes were proposed by (Tan et al., 2024) for knowledge, reasoning, math, and coding tasks, nevertheless, not extended to the medical domain. Szymanski et al. (2025) evaluated human agreement between human experts and LLM judges, and showed 64-68% agreement for the dietetics domain and mental health. A concurrent study, Diekmann et al. (2025) showed that LaaJ achieved high accuracy of generated medical answers in terms of scientific and grammatical correctness, but they were less efficient on evaluating empathy or extent of harm.

In a recent study, Lee et al. (2025) analyzed LLM-as-a-Judge robustness when using epistemic markers in the generated outputs. Their study showed that LLMs, even proprietary ones like GPT-4o, showed lack of robustness when asked to use uncertain (*I am not sure*) epistemic markers. The authors evaluated the LLMs on a proposed benchmark, EMBER, on the general domain in English. Our study proposed a new benchmark to extend the LLM-as-a-Judge robustness evaluation to a very technical domain, such as brain cancer.

3 Dataset: BrainCancerDB

cer treatment and disease, `BrainCancerDB`. This dataset was composed of terms collected by researchers during hospital consultations between neuro-oncologists and brain cancer patients, as well as gathered from specialized cancer websites, in consultation with cancer specialists. The dataset resulted in a list of main brain cancer terms that can be difficult to understand for patients, such as *astrocytome, PET-dopa*, or unknown drugs names like *temozolomide* or *levetiracetam*.

We extend our dataset with two set of definitions: (i) generated definitions from six different LLMs from three open-source family models: Gemma3 (Team et al., 2025), Llama3 (Grattafiori et al., 2024), and Cohere-Aya (Dang et al., 2024) (see LLM-Students in Table 1) (ii) curated definition from medical internet sources[2], and (iii) human simplified definitions for a subset of the dataset (50 terms) (example of the three data types in Figure 2).

Additionally, we conducted a manual annotation task of a subset of the dataset (50 terms) to analyze how efficient LLM-Judges are with respect to expert human judgment. For this, a human biomedical NLP expert annotator was given the task to evaluate medical definitions or explanations for the selected subset, and thus take the role of a Human-Judge (more details in Section 3.1).

3.1 Human Expert Annotation Details

Since it is very costly to conduct human medical expert annotation, we manually evaluated only 300 simple explanations, for 50 terms in 6 LLM-Student configurations. The human experts annotation followed the same three evaluation dimensions presented in Table 2. The annotation resulted in a total of 900 human medical expert annotations. Note that the LLMs were anonymized to human experts to mitigate biased judgment.

[2]We collected technical definitions from medical websites for 50 brain cancer terms. We provided the source website for each scientific definition in our dedicated GitHub page.

4 Methodology

Our paper analyzed the quality of the LaaJ evaluation method and its alignment with human annotation when used to simplify brain cancer terms. In our paper, *LLM-generated output* or *LLM answers* refer to LLM-Student[3] generated simple definitions or explanations. *LLM-Judges evaluation* refers to LLM-as-a-Judge evaluation of the LLM-Student-generated simple definitions. We detailed our method below.

Task Description. We constructed a general LLM-as-a-Judge prompt (see Table 4 in Appendix A) that guides the LLMs to generate a judgment on whether the generated outputs are scientifically correct, simple to read, and complete.

Experimental Setup. We tested three experimental setups of judgment: *Vanilla* setup (V), where the LLM-Student definitions are judged by the same-sized or bigger LLM models from the other LLM family. Secondly, *Epistemic* (E), that takes into account positive, uncertain, and negative *epistemic markers*, such as *I am confident*, *Likely*, *I'm not sure*, within the vanilla setup. We chose the most common epistemic markers used in similar LLM studies (Lee et al., 2025). Finally, *Bias* (B), that considers the same-sized or bigger LLM models from the same LLM family as a judge. We designed the biased setup to evaluate self-preference *bias*. Table 1 shows each of the configurations that are accounted for in each of the three scenarios. For the 219-term dataset, we generated through zero-shot inference a total of 7,884 LLM-Judge evaluations for each dimension, with a total of **23,652 annotations** for the three evaluation dimensions[4].

[3]LLM-Student should not be confused with Teacher-Student paradigms in knowledge distillation.

[4]Breakdown : $219\times[13_{(V)} + 13_{(E)} + 10_{(B)}] = 7884$ annotations; $7884\times3_{(\text{Correctness, Readability, Completeness})}=23562$ annotations

	Correctness	Completeness
1	text encompasses the correct medical knowledge and is in language of term	text represents a full answer, meaning the language model generated a concise answer
0	if above condition is not met	if above condition is not met
	Readability	
1	text is fluent, grammatically correct and easy to understand for laypeople	
2	text is quite difficult to understand	
3	text is very difficult to understand

			(d) SARI metric (↑)			
MEAN	48.50	48.27	48.02	48.47	47.59	48.39

Table 3: Evaluation performance for three LLM-as-a-Judge setups: Vanilla (V), Epistemic (E), and Bias (B) against human judgments (H); and one automatic metric SARI metric (MEAN) for 50 medical terms.

Evaluation Metrics. We consider three evaluation dimensions inspired from Buhnila et al. (2024): `correctness`, `readability`, `completeness`. In the Table 2 we show the evaluation criteria used for the human expert annotation. We evaluated three dimensions: `correctness`: the generated text encompasses the correct medical knowledge in the expected language (score [1] if the two conditions are fulfilled, [0] if not); `readability`: evaluates how simple the generated answer is (scored from [1] to [3], where [1] means that the generated text is easy to understand for laypeople, [2] the text is quite difficult to understand, and [3] the text is very difficult to understand.); and `completeness`: the generated text represents a concise and full answer (score [1] if yes, [0] if no).

Additionally, we compared LLM-as-a-Judge with a traditional automatic simplification metric, SARI (Xu et al., 2016), that has been the most adapted metric for text simplification evaluation up to date (Guo et al., 2024). SARI scores the simplification level of a sentence comparing human gold annotation and LLM generated text with a technical definition reference. The simplicity level is scored from 0 to 100 (100 being the simplest).

5 Results and Discussion

Table 3 presents the evaluation of LLM-as-a-Judge setup's evaluation performance against human expert annotators for 50 medical terms. Additionally, we present in Appendix B, Table 6 the LaaJ evaluation performance across three model families on the full dataset. Our findings are as follows:

LLM-Judges are more lenient than Humans with medical correctness, but stricter with readability and completeness. On average, LLM judges achieve correctness scores of 0.95 in the Vanilla setup, 0.94 in the Epistemic setup, and 0.92 in the Bias setup, with at least 19.5% (in Bias) higher than human experts. In contrast, LLMs perceive the outputs as less readable and less complete than humans, showing a notable divergence in judgment. The largest difference in readability occurs in the Bias setup (34.4%), followed by Epistemic (21.3%) and Vanilla (18.9%). Similarly, completeness scores differ most in the Bias setup (25%), followed by Vanilla (8.7%) and Epistemic (7.6%). These results demonstrate a clear misalignment between LLM and human judgment: *LLMs tend to overestimate correctness while being stricter on readability and completeness*.

Smaller LLM-Judges hallucinate more. Hallucinations originate almost exclusively from the smaller LLM-judges (=1B), whereas larger judges (>1B) do not hallucinate, except for a few isolated cases. Among smaller judges, G1B produces 40.7%, 57.8%, and 75.8% hallucinations in the Bias, Vanilla, and Epistemic setups, respectively, while L1B shows 57.6%, 41.7%, and 23.2% hallucinations. The addition of epistemic markers reduces hallucinations by 69.3% for L1B and 27.9% for G1B, suggesting that epistemic setups are more effective in mitigating hallucinations for L1B.

Bias LLM-Judges are relatively more hallucinated. The Bias setup exhibits the highest rate of hallucinations compared to the Vanilla and Epistemic configurations. Overall, it hallucinates 11.5% of responses, whereas the Vanilla and Epistemic setups hallucinate 9.2% and 5.1%, respectively. This pattern remains consistent across all three evaluation dimensions (Figure 3), with the Bias setup showing hallucination rates of 12.4%, 8.8%, and 13.2% for correctness, readability, and complete-

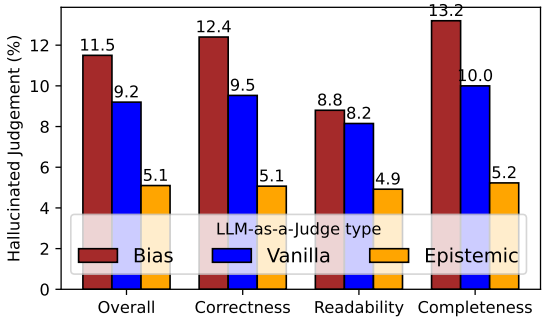

Figure 3: Percentage of hallucination in generated judgment with LLM-as-a-Judge.

ness, respectively, surpassing both Vanilla and Epistemic setups across dimensions.

Epistemic LLM-Judges are less prone to hallucinations. Across the 1,950 total annotations (650 per evaluation dimension[5]), hallucinations account for roughly 9.2% of responses in the vanilla setup, but drop to about 5.1% under the epistemic setup. This decline is consistent across all three evaluation dimensions (correctness, readability, and completeness) indicating that epistemic markers reduce hallucinations (Figure 3). Among the non-hallucinated cases, there are 580, 587, and 577 paired judgments (vanilla and epistemic both valid) for the above stated evaluation dimensions. Non-agreement between vanilla and epistemic judgments is 3.8% for correctness, 5.7% for completeness, and 15.7% for readability. Thus, epistemic markers do not substantially alter judgments for correctness or completeness but introduce a notable shift in readability evaluations. Moreover, out of the non-agreement cases, the proportion of vanilla and epistemic judgments that align with human annotations remains between 40–60% across all three dimensions, indicating that epistemic markers do not enhance human–LLM alignment.

LLM-Judges are mutually aligned. Across all three setups (Vanilla, Epistemic, and Bias) LLM-Judges demonstrated strong consistency in their evaluations, with no statistically significant differences observed in their average scores across the three evaluation dimensions (Appendix B, Table 6). This alignment is particularly evident when assessing outputs from larger student models, where judgments remain comparable across setups. However, within the Gemma family of models, the Bias setup rates readability significantly worse than the Vanilla and Epistemic setups. Similarly, for relatively smaller Llama students (<=3B), the Bias setup assigns significantly lower completeness scores, suggesting that bias-sensitive judgment may influence specific evaluation dimensions despite overall agreement among judges.

Humans are still better at simplification tasks. We compared automatic metric SARI and Humans evaluations (H) on the same 50 terms and 300 LLM generated answers (Table 3). Spearman rank correlation analysis reveals that the SARI metric aligns more closely with readability than with correctness. Across models, higher readability consistently corresponds to higher SARI scores, particularly for the Vanilla (ρ=0.93) and Epistemic (ρ=0.75) models. In contrast, correctness and completeness generally show negative correlations with SARI, with some reaching statistical significance (e.g., correctness (V) ρ=–0.90; Bias correctness (B) ρ=–0.82), indicating that SARI may undervalue medical correctness or completeness while favoring fluent outputs. These results suggest that SARI is more sensitive to surface-level readability than to correctness.

6 Conclusion

To conclude, in this work we introduce `BrainCancerDB`, a dataset of 219 brain cancer–related medical terms with both scientific and simplified definitions, which we will share with the research community. Further, our evaluation study shows that while LLM-as-a-Judge is a convenient and affordable method for evaluating simplified medical explanations, it is not fully reliable for highly technical terms. LLM-Judges tend to be more lenient on medical correctness and do not consistently align with human expert judgments regarding scientific content. Different evaluation configurations, Vanilla, Bias, and Epistemic demonstrate that even with adjustments, caution is needed when relying on LLM-Judges as the sole assessment metric. To ensure robust evaluation, LLM-based judgment should be complemented with automatic metrics such as SARI and with human expert evaluation.

Ethical Considerations

The dataset used in this study was built using only medical terms. During consultations, private or sensitive information was not collected. Patients gave their consent to the presence of the researcher during consultations. The simple definitions and

[5]650 = 13(E) x 50 medical terms.

explanations were written by human linguists annotators, as part of their involvement in the research.

Limitations

This study was conducted on English only, meaning that results can vary across multiple languages, especially on lower resource languages. For our experiments we used only general language LLMs, and not medical LLMs, as our main research goal was to evaluate the simplification performance of LLM-Students, as well as the evaluation ability of general language LLM-Judges. The dataset of our in depth analysis is small, as human brain cancer expert annotation is costly and difficult to implement, due to doctors' demanding hospital workload. Similar studies on bigger datasets or using bigger LLMs can yield different results. This study was designed to be reproducible by a wide range of research laboratories across the globe, regardless of their computational infrastructure. Therefore we tested only open source LLMs of relatively small size, that can be implemented without high computational costs.

A Prompts

We provide the prompts for the LLM-Student (Table 5) and the LLM-as-a-Judge setup (Table 4).

B Performance on the Full Dataset

Table 6 shows the evaluation performance of LLM-as-a-Judge on the full 219 terms dataset.

You are a helpful assistant that explains complex medical terms in simple, clear language.
Your task is to explain the following term so that a family member with no medical or technical background can easily understand it.

Term: "TERM"

Guidelines:
- Use plain, everyday language.
- Keep the explanation short (1 sentence only).
- Avoid jargon, and if you must use it, explain it simply.

Now explain the term above.

Table 5: The prompts used in this study for LLM-Student for generating medical term explanations.

Abstract

Molecular representation learning aims to capture chemically meaningful structures for various downstream tasks such as accurate molecular property prediction. However, incorporating functional group (FG) information into SMILES-based models remains challenging. The absence of explicit alignment between graph-defined FG atom sets and tokens in sequence prevents complete substructure masking, while multiple valid SMILES forms of the same molecule lead to inconsistent FG representations in token space. To address these challenges, we propose **FACT** (Functional Group Alignment and Consistency in Token Space), an end-to-end framework for structure-aware SMILES-based representation learning. FACT introduces an atom–token alignment module for complete FG span masking during pretraining and enforces FG consistency across different SMILES forms during fine-tuning. Experiments on MoleculeNet benchmarks show that FACT achieves state-of-the-art or competitive performance on eight tasks, demonstrating the effectiveness of alignment and consistency learning for molecular representation.

1 Introduction

Molecular representation learning aims to capture chemically meaningful structures. Among downstream tasks, molecular property prediction (MPP) is a fundamental task in drug discovery and material science, to efficiently estimate physicochemical and biological properties of molecules (Wieder et al., 2020; Dara et al., 2022). In recent days, deep learning approaches have achieved significant progress in this area through representation learning over large-scale molecular data (Son et al., 2024; Ji et al., 2024; Singh et al., 2026). Molecules can be represented in different forms, including SMILES strings (Weininger, 1988; Wang et al., 2019), graph-based (2D) representations (Li et al., 2022), and 3D conformations (Zhou et al., 2023). While graph-based and 3D representations provide rich structural information, they often require computationally expensive preprocessing steps such as graph construction or conformer generation that can limit scalability. In contrast, SMILES representations enable scalable learning with direct application of sequence-based models such as Transformers due to their simplicity and compatibility (Wang et al., 2019; Chithrananda et al., 2020; Ahmad et al., 2022).

Despite their achievement, existing approaches adopt pretraining objectives directly from natural language processing, particularly masked language modeling (MLM) (Liu et al., 2019), without accounting for the structural nature of molecules. While effective, such objectives do not fully reflect the structural nature of molecules. Random masking can produce chemically invalid patterns and, more importantly, disrupt meaningful chemical substructures such as functional groups (Li et al., 2023). Furthermore, unlike natural language, SMILES vocabulary is highly constrained, consisting of a limited set of atom symbols, bond types, and structural tokens (Leon et al., 2024). As a result, randomly masked tokens alone can often be predicted from simple local patterns without capturing the underlying chemical structure, limiting the effectiveness of the pretraining objective.

To better incorporate chemical structures into pretraining, recent works have introduced functional group (FG)-aware masking strategies, such as FG-BERT (Li et al., 2023) and MLM-FG (Peng et al., 2025). These approaches leverage structural information derived from molecular graphs to guide masking. FG-BERT operates masking directly on molecular graph with connectivity-aware attention (Li et al., 2023), and MLM-FG incorporates functional group information into SMILES-based pretraining through predefined SMARTS patterns (Peng et al., 2025). However, when such structural information is transferred to SMILES

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 695–703
July 3-4, 2026 ©2026 Association for Computational Linguistics

token space, fundamental limitations arise.

First, existing SMILES-based FG masking approach lacks explicit FG alignment in token space. While functional groups are defined over atom indices in a molecular graph, SMILES sequences interleave atom token with structural non-atom tokens (e.g., bond symbols, branch parentheses, or ring closures). As a result, there is no deterministic alignment that identifies the complete token span of a functional group in the sequence, and FG-based masking is applied only over atom tokens within the group, leaving surrounding structural tokens unmasked. Although Transformer attention can in principle aggregate information across these tokens, prior FG-aware SMILES methods do not explicitly enforce complete substructure-level masking, and the extent to which models learn chemically meaningful substructures rather than relying on partially exposed local patterns has not been directly examined. We hypothesize that closing this alignment gap may benefit substructure-level representation learning, and investigate this in our framework.

Second, the one-to-many mapping between a molecule and its valid SMILES representations leads to inconsistent functional group localization in token space. Because a single molecule can be represented by multiple valid SMILES strings (Bjerrum, 2017), identical functional group may appear at different token positions across representations. This inconsistency is particularly pervasive in real-world settings, where datasets are aggregated from heterogeneous sources that may not share a unified standard for molecular structure representations. While prior work has used SMILES enumeration as a form of data augmentation (Bjerrum, 2017), existing FG-aware pretraining approaches do not explicitly enforce representational consistency of functional groups across SMILES forms during fine-tuning. Without such consistency, the model may rely on incidental token positions rather than learning invariant chemical structures.

To address the limitations, we propose **FACT** (Functional Group Alignment and Consistency in Token Space), an end-to-end framework for structure-aware molecular representation learning with SMILES data. We introduce an atom-token alignment module to deterministically identify precise FG spans in token space for complete substructure masking during pre-training. During fine-tuning, we introduce FG-preserving consistency loss to enforce representational invariance across different SMILES forms of the same molecule, leveraging the same alignment module to locate and align identical functional groups across different molecular views. We evaluate FACT framework on MoleculeNet benchmarks for downstream tasks (Wu et al., 2018) and achieve state-of-the-art or competitive performance across multiple tasks, demonstrating the effectiveness of explicit atom-token alignment and end-to-end structure-aware consistency learning for molecular representations.

Our contributions are as follows:

- We formalize the atom-token misalignment problem in SMILES-based pre-training and propose a deterministic alignment module that enables precise functional group spans identification.
- We propose FACT framework, an end-to-end framework that integrates complete functional group span masking and an FG-preserving consistency objective for invariant molecular representations.
- We achieve state-of-the-art or competitive performance on multiple MoleculeNet tasks, and provide representation-level and attribution-level visual analyses, demonstrating that our FACT framework learns chemically meaningful substructure representations.

2 Related Works

Molecular representation learning has increasingly adopted sequence-based approaches by leveraging the SMILES strings, which enables molecules to be processed using natural language models. Transformer-based architectures pretrained with masked language modeling (MLM) (Liu et al., 2019) have demonstrated solid performance across diverse molecular property prediction tasks. SMILES-BERT (Wang et al., 2019) applied BERT-style pretraining to molecular sequence, followed by ChemBERTa and its variants (Chithrananda et al., 2020; Ahmad et al., 2022) and MolFormer (Ross et al., 2022), which scaled pretraining to large-scale molecular data. While these models have shown the viability of SMILES-based pretraining, they adopt random token masking without adaptation to chemical structure. Various studies have also explored alternative training strategies and improved molecular representations to move beyond random masking. Broberg et al. (2022) pretrained Molecular

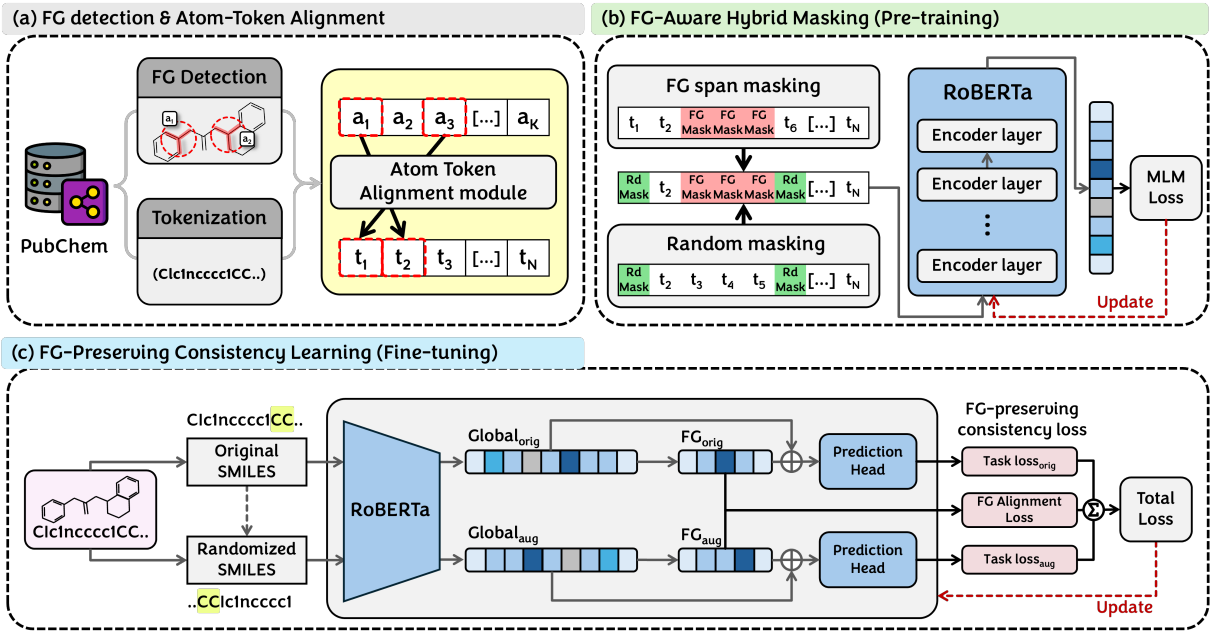

Figure 1: Overview of the proposed FACT framework. (a) FGs are first identified and mapped to their corresponding SMILES token spans via the atom-token alignment module. (b) The identified FG token spans are then used for hybrid masking, combining complete FG span masking with random token masking during pre-training. (c) During fine-tuning, two SMILES representations of the same molecule are encoded via the pretrained encoder and alignment module to obtain global and FG-level representations, which are concatenated for prediction. The FG-preserving consistency loss enforces representational invariance within the same molecule during model updates.

Transformer (Schwaller et al., 2019) using reaction template as a pre-training objective, demonstrating that chemically motivated training improves molecular representations. In parallel, fragment-based approaches have aimed to improve structural representations. t-SMILES (Wu et al., 2024) represents molecules as hierarchical fragment sequences derived from graph decomposition, while fragSMILES (Mastrolorito et al., 2025) encodes molecules at the fragment level. While these approaches improve structural representations, they do not explicitly incorporate chemically functional groups that can directly determine molecular properties.

FG-BERT (Li et al., 2023) performs pretraining on molecular graphs by masking predefined functional groups and reconstructing them to enforce chemically meaningful representations. MLM-FG (Peng et al., 2025) extends this idea to SMILES sequences by applying functional group-based masking over tokens associated with predefined functional groups, both relying on SMARTS-based patterns to specify functional groups. These approaches improve over random masking by introducing chemically meaningful substructures, yet remain constrained by the use of predefined SMARTS-based patterns for FG identification, thereby limiting adaptability across structurally novel chemical spaces (Ertl, 2017; Colmenarejo, 2025).

Moreover, when functional group information is expressed in SMILES token space, the absence of a deterministic mapping between atom indices and token positions prevents functional groups from being represented as complete substructures, leading to only partial structural encoding. In addition, structural supervision is limited to the pretraining stage, leaving fine-tuning without preserving functional group consistency. This becomes further problematic because a single molecule can be represented by multiple valid SMILES strings (Bjerrum, 2017), where identical functional groups may appear at different token positions, causing the model to rely on incidental token patterns rather than learning invariant chemical structures. Our FACT framework addresses these limitations through explicit atom–token alignment with pattern-free functional group detection, and functional group-preserving consistency learning.

3 Method

Our FACT framework is illustrated in Figure 1. The framework consists of three components: FG

detection and atom-token alignment, FG-aware pre-training, and FG-preserving consistency learning.

3.1 FG Detection and Atom-token Alignment

We first identify functional groups and establish atom–token alignment to enable FG-aware training with SMILES strings. Unlike prior approaches that rely on predefined SMARTS patterns (Li et al., 2023; Peng et al., 2025), we adopt the Ertl algorithm (Ertl, 2017) via the EFGs framework (Colmenarejo, 2025) for pattern-free functional group detection, which identifies FGs from local atomic environments without relying on predefined patterns.

We then implement a deterministic atom token alignment module that establishes a one-to-one correspondence between graph atoms and atom tokens in sequence while explicitly distinguishing structural tokens. Specifically, given a molecule, we obtain a SMILES representation and extract the corresponding atom output order provided by RDKit (RDKit, 2024), which defines the traversal of atoms in the sequence with respect to the molecular graph. We then tokenize the SMILES and check each token sequentially, assigning each token as either an atom token or a structural token, and mapping atom tokens to their corresponding graph atom indices according to the extracted order.

Based on this alignment, a functional group defined as a set of atom indices can be localized in the SMILES sequence by identifying all token positions mapped to those atoms. These positions are further expanded into a contiguous span by iteratively including adjacent structural tokens. This results in a complete token-level representation of each functional group, allowing both atom and structural tokens to be jointly masked during pre-training.

3.2 FG-aware Pre-training

Leveraging the aligned functional group spans, the model can be trained with complete FG span masking. However, applying FG masking alone is insufficient in practice. In our pre-training dataset, functional groups cover only a small fraction of tokens per sequence (median of 4 FGs covering roughly 4 atoms in a SMILES of length 39 tokens at median, i.e., about 10% of tokens; see Table 1). FG-only masking therefore provides limited training signal and leaves most context tokens unused as a reconstruction objective. To increase coverage while preserving substructure-level supervision, we propose a hybrid masking strategy that combines complete FG span masking with additional random token masking. This design ensures that functional groups are masked as complete substructures, while random masking covers the remaining context tokens that FG masking alone would leave untouched.

Table 1: Summary statistics of the 10M molecules used for pre-training.

Metric	Mean	Median	Std	Min	Max
FGs per SMILES	4.74	4.00	2.60	0.00	215
Atoms per FG	1.71	1.00	1.39	1.00	881
SMILES Token Length	43.64	39.00	20.32	4.00	2213

This process contains of two stages: (i) FGs are iteratively sampled and span-masked until a minimum FG coverage ratio is reached, and (ii) additional tokens are randomly masked until a predefined total masking ratio is satisfied. For long functional groups, sub-span sampling is further applied to increase diversity and encourage the model to learn beyond fixed substructures. We also exclude random token substitution, as it may produce chemically invalid sequences; all selected tokens are replaced exclusively with the `[MASK]` token. The specific choice of masking ratio is also detailed in Section 4.1.

3.3 FG-preserving Consistency Learning

The pretrained encoder is fine-tuned on downstream MPP tasks using a FG-preserving consistency objective. For each molecule, let A denote its original SMILES and B a randomized SMILES variant generated via RDKit's SMILES enumeration (Bjerrum, 2017). Both A and B are encoded by the shared encoder, although they describe the same molecular structure, differences in atom ordering yield different token-level representations, which we leverage to enforce representation consistency.

From these representations, we obtain two types of embeddings, a global representation via masked mean pooling over valid tokens, and a FG-level representation computed by aggregating tokens associated with the same functional groups. These representations are then concatenated to construct the final molecular embedding, which is fed into a prediction head for the downstream task. To enforce FG representational invariance, we introduce a FG-preserving consistency objective that encourages consistent representations of matched functional groups across different SMILES views of the

same molecule. The overall training objective for the fine-tuning process is defined as:

$$\mathcal{L} = \mathcal{L}_{task} + \lambda_{fg}\mathcal{L}_{fg-align} \tag{1}$$

where $\mathcal{L}_{task}$ denotes the regular supervision loss for molecular property prediction task, $\mathcal{L}_{fg-align}$ enforces representational consistency between functional group representations, and λ_{fg} is a scalar hyperparameter, set to 0.001 in our experiments, that balances the two objectives. Since two SMILES representations are encoded per molecule, $\mathcal{L}_{\text{task}}$ is computed for both views and summed, matching the dual-branch task loss shown in Figure 1(c).

$$\mathcal{L}_{fg-align} = \frac{1}{|\mathcal{G}^*|} \sum_{g \in \mathcal{G}^*} \left\| \hat{\mathbf{h}}_g^{(A)} - \hat{\mathbf{h}}_g^{(B)} \right\|_2^2 \tag{2}$$

$$\mathcal{G}^* = \{g \mid g \in G_A \cap G_B\} \tag{3}$$

where $\hat{\mathbf{h}} = \frac{\mathbf{h}}{\|\mathbf{h}\|}$, and G_A and G_B denote the sets of functional groups detected in the original and randomized SMILES representations of the same molecule, respectively. $\mathcal{G}^*$ is their intersection, i.e., the set of functional groups that appear in both representations. $\hat{\mathbf{h}}_g^{(A)}$, $\hat{\mathbf{h}}_g^{(B)}$ denote the normalized representations of the functional group g in each representation.

4 Experiments

4.1 Experimental Setups

Datasets. For pre-training, we use 10 million SMILES sequences randomly sampled from Pubchem database (Kim et al., 2019), following the setup of MLM-FG (Peng et al., 2025). The dataset is split into training, validation, and test sets at a ratio of 98:1:1. For downstream molecular property prediction task, we conducted extensive experiments on the MoleculeNet benchmark (Wu et al., 2018), which contains binary classification, multi-label classification, and regression tasks.

Table 3: Performance comparison on MoleculeNet regression benchmarks (RMSE ↓). Best results are **bold**, and second-best results are underlined.

Baselines. We evaluate our method within a SMILES-based Transformer framework, using RoBERTa (Liu et al., 2019) as the backbone architecture due to its strong performance in masked language modeling (MLM) and its widespread adoption in molecular representation learning. The baselines are categorized into two groups: random masking models (Broberg et al., 2022; Ross et al., 2022) and structure-aware models that incorporate domain knowledge into the pretraining objective, including a reaction prediction-based approach (Broberg et al., 2022) and FG-aware approaches (Li et al., 2023; Peng et al., 2025).

Masking Ratio. Building on the statistics indicated in Section 3.2 (FG-based masking naturally covering only about 10% of tokens at the median), we set the minimum FG coverage to 15% to ensure sufficient structural perturbation beyond this natural baseline, with the remainder contributed by random masking up to a total of 25%, balancing reconstruction difficulty with structural integrity.

Parameters and Metrics. To ensure comparability, we closely follow the pre-training configuration of MLM-FG framework (Peng et al., 2025), while certain configurations are adjusted

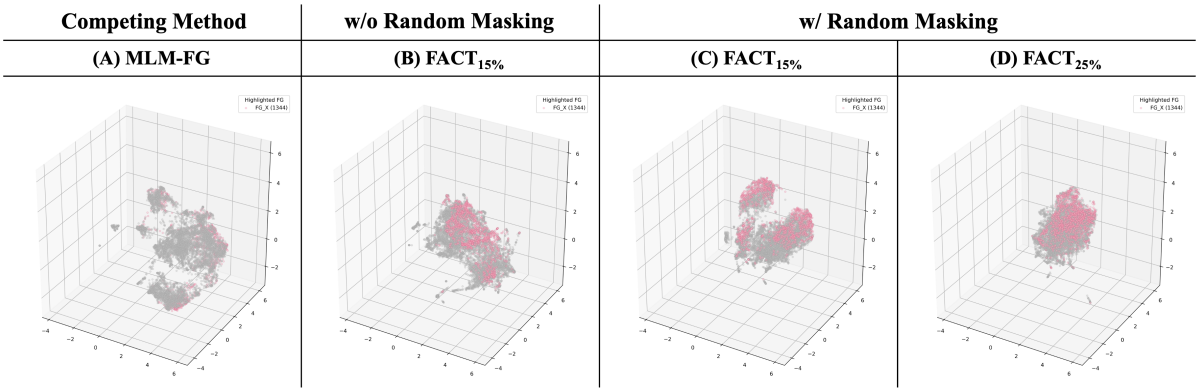

Figure 2: UMAP visualization of SMILES embeddings from pre-trained models under different masking strategies: (A) MLM-FG, the competing baseline, (B)-(D) FACT variants with different masking configurations, (B) FACT with FG-only masking at 15% (without random masking), (C) FACT with 10% FG + 5% random masking (reduced total masking ratio), and (D) FACT, our full configuration. SMILES samples containing a selected functional group (FG_X) are highlighted in pink.

due to practical constraints. Pre-training is conducted for 50 epochs using a batch size of 512 and a learning rate of 3e-5 with cosine decay, distributed across two NVIDIA H200 GPUs with the AdamW optimizer. SMILES sequences are tokenized using the *Pytoda* library, which is designed to handle large-scale chemical diversity. The vocabulary size is 576, including special tokens such as [PAD], [START], [END], and [MASK]. For fine-tuning, the pre-trained encoder is optimized on downstream tasks with a lightweight linear prediction head, using a batch size of 32 across six NVIDIA RTX 3090 GPUs. For evaluation, ROC-AUC is used for classification tasks and root mean squared error (RMSE) for regression tasks. The pre-trained encoder is available on Hugging Face[1], and the full training code will be released on Github.

4.2 Results

Classification Tasks. FACT achieves state-of-the-art performance on five out of seven classification tasks and competitive performance on the remaining two, with particularly strong gains on BACE (Table 2). On BBBP and ClinTox, FACT ranks second behind BROBERG, which may better capture global reactivity-related properties relevant to these tasks. Overall, these results suggest that explicit atom-token alignment and FG-preserving consistency learning provide consistent improvements across tasks where substructure-level representations are critical.

Regression Tasks. On regression tasks, FACT achieves state-of-the-art performance on FreeSolv, with a substantial improvement over all baselines (Table 3). However, performance on ESOL and Lipophilicity remains below the best baselines. We attribute this to the nature of these tasks: ESOL and Lipophilicity are strongly influenced by global molecular properties such as polarity and hydrophobicity, which may be better captured by models that encode broader molecular context rather than substructure-level supervision. This trade-off between substructure-level and global supervision is a direction for future work.

5 Analysis

5.1 Representation Analysis

To evaluate whether FACT learns chemically meaningful functional group representations, we visualize SMILES embeddings using UMAP (McInnes et al., 2018). We randomly sample 10,000 molecules from the PubChem database and extract representations from pre-trained models corresponding to four variants: (A) MLM-FG, one of our competing methods, (B) FACT variant, where only 15% of functional groups detected by the pattern-free Ertl algorithm are masked, (C) another FACT variant, where the total masking ratio is reduced to 15%, with 10% FG and 5% random masking, and (D) FACT. Molecules containing a specific functional group (FG_X) are highlighted in pink.

Because individual molecules usually contain multiple FGs (Table 1), we do not expect clear FG-specific clusters. Instead, we examine whether molecules sharing the highlighted functional group

[1]https://huggingface.co/Zaeus/FACT

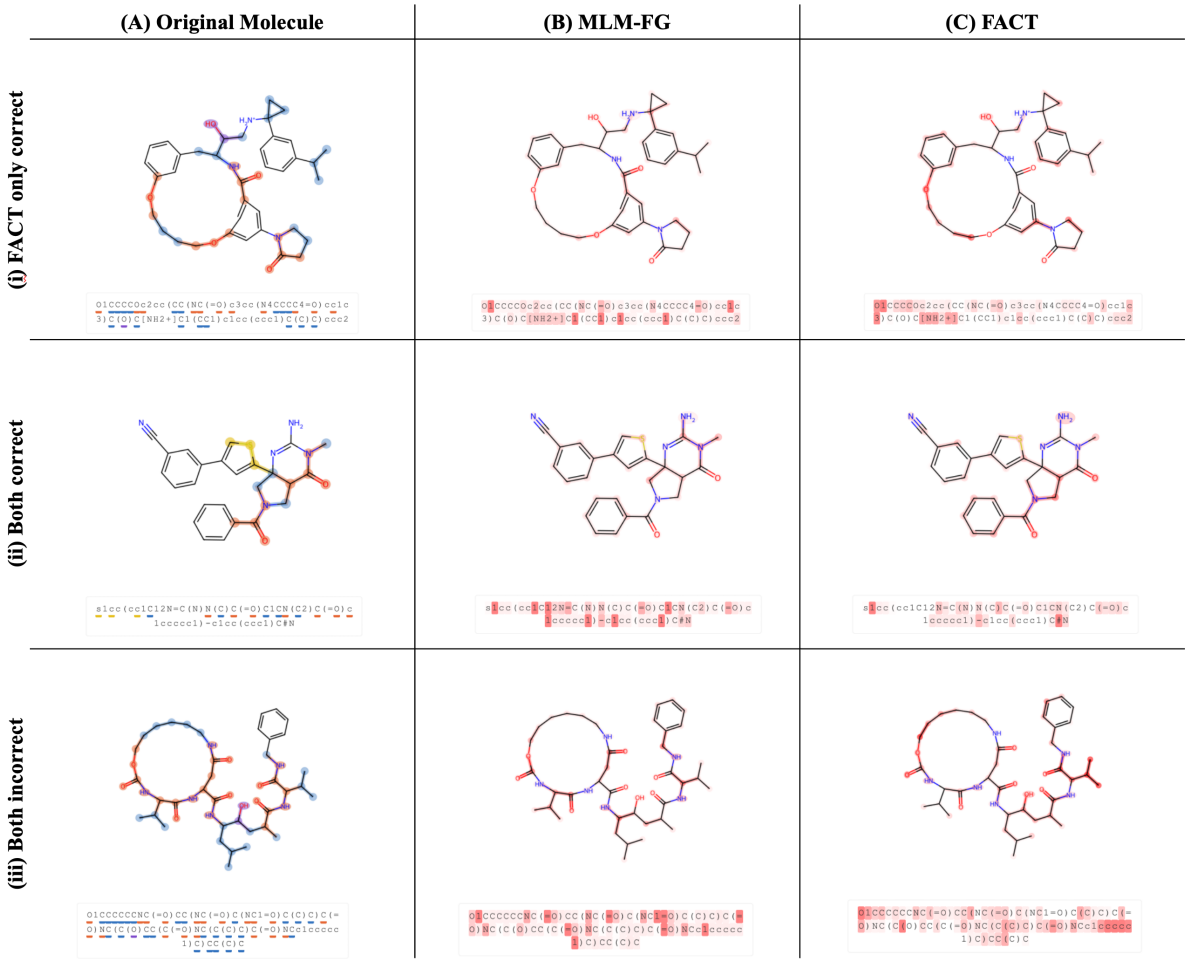

Figure 3: Attribution analysis on MoleculeNet BACE test samples under three prediction scenarios, where the ground-truth label indicates whether the molecule inhibits BACE-1: (i) FACT only correct (GT $= 0$), (ii) both models correct (GT $= 1$), and (iii) both models incorrect (GT $= 1$). Attribution scores are computed with respect to the positive class.

tend to appear in more localized regions of the embedding space. As shown in Figure 2, FACT and FACT's variants show more organized patterns compared to MLM-FG. Among these, (C) appears more organized than (B), with both gray and pink molecules forming tighter sub-regions, and (D) FACT further produces the most concentrated distribution, suggesting that combining FG-aware masking with random masking helps the model better capture FG-related structure.

5.2 Attribution Analysis

To examine whether FACT attends to chemically relevant substructures during prediction, we apply Layer Integrated Gradients (Sundararajan et al., 2017) to models fine-tuned on the BACE dataset, a binary classification task predicting whether a molecule inhibits BACE-1, computing model attribution scores with respect to the positive class score. Attribution scores are normalized and visualized on the 2D molecular structure and SMILES sequence in red, while ground-truth functional groups are color-coded by type.

To ensure a fair comparison, we analyze attribution patterns across multiple prediction scenarios on the MoleculeNet BACE test set. Specifically, we consider cases where only FACT predicts correctly (62 samples), where both models predict correctly (53 samples), and where both models fail (18 samples). From each group, we randomly sample representative molecules for visualization, labeled by their ground-truth class (GT). The selected examples correspond to (i) FACT only correct with GT $= 0$, (ii) both correct with GT $= 1$, and (iii) both incorrect with GT $= 1$.

In case (i), where GT $= 0$, FACT exhibits mini-

mal attribution with respect to the positive class, indicating that it does not rely on spurious signals for incorrect positive predictions. In case (ii), where $\mathrm{GT} = 1$, both models assign attribution to the molecule, but FACT shows stronger alignment with ground-truth functional groups, suggesting more chemically meaningful reasoning. In case (iii), where $\mathrm{GT} = 1$, although both models fail, FACT still assigns attribution to regions corresponding to ground-truth functional groups, indicating that it captures relevant substructures even when the final prediction is incorrect.

6 Conclusion

In this work, we identified two key limitations in existing SMILES-based FG-aware pretraining: the lack of explicit atom–token alignment and the absence of FG consistency under SMILES non-uniqueness. To address these, we proposed FACT, an end-to-end framework that introduces an alignment module for complete FG span identification and an FG-preserving consistency loss for molceular representational invariance. Experiments on MoleculeNet benchmarks demonstrate state-of-the-art or competitive performance, and analyses confirm that FACT learns chemically meaningful substructure representations.

Limitations

While FACT demonstrates strong performance across classification tasks, there remains room for further improvement and extension. The atom–token alignment module currently relies on RDKit-based SMILES parsing, which may present challenges for molecules with complex stereochemistry or non-standard representations, suggesting opportunities for more robust alignment strategies. In addition, the FG-preserving consistency objective introduces additional computation during fine-tuning, motivating more efficient learning mechanisms. Furthermore, while our analyses examine masking variants at the representation level (Figure 2), a complete downstream-task ablation isolating the contribution of the FG-preserving consistency loss from the alignment-based masking is left as future work. Finally, extending FACT beyond MoleculeNet to broader downstream tasks, including ADMET property prediction, represents a promising direction for future work.

Small LLMs for Biomedical Claim Verification: Cost-Effective Fine-Tuning, Structural Dataset Shortcuts, and Cross-Domain Generalization

Gaurav Kumar[1,2]

gkumar@ucsd.edu

Abstract

Large Language Models such as GPT-4o and GPT-5 achieve strong zero-shot performance on biomedical claim verification, but cost and opacity limit scalable use. We fine-tune three small LLMs: Phi-3-mini (3.8B), Qwen2.5-3B, and Mistral-7B, via QLoRA on SciFact and HealthVer, providing the first study of QLoRA models against GPT-4o and fine-tuned BioLinkBERT encoders. Mistral-7B QLoRA achieves higher F1 than both GPT-4o and GPT-5 (up to 12% gain) at 44.5× lower cost using just 1,008 training examples, representing a compelling cost-quality trade-off. We conduct extensive in-domain and cross-domain evaluation: models trained on SciFact tested on HealthVer and vice versa, at matched sizes to isolate dataset structure from data quantity. We identify a previously unreported structural artifact in SciFact that inflates in-domain scores, and show through bidirectional out-of-domain evaluation that training on structurally sound data enables robust cross-domain transfer. We release all code and adapter checkpoints.

1 Introduction

Automated biomedical claim verification determines whether a claim is SUPPORTED, REFUTED, or undetermined by evidence—a form of Natural Language Inference (NLI) applied to the biomedical domain. It is increasingly critical as health misinformation increases (Vladika and Matthes, 2023; Guo et al., 2022; Kotonya and Toni, 2020). Large language models (LLMs) such as GPT-4o offer strong zero-shot performance (Nori et al., 2023; Košprdić et al., 2024). However, API costs scale linearly with volume, they cannot be locally deployed in privacy-sensitive clinical environments, and silent provider updates undermine reproducibility. QLoRA (Dettmers et al., 2023) enables 4-bit fine-tuning of billion-parameter models on a single GPU in under an hour, yet no systematic comparison of QLoRA-adapted small LLMs against both proprietary and encoder baselines exists for this task under conditions that jointly test in-domain performance and out-of-domain generalization.

We fine-tune Qwen2.5-3B (Qwen Team, 2025), Phi-3-mini 3.8B (Abdin et al., 2024), and Mistral-7B-Instruct (Jiang et al., 2023) on SciFact (Wadden et al., 2020) and HealthVer (Sarrouti et al., 2021) separately, evaluating them bidirectionally alongside GPT-4o, GPT-5, and fine-tuned BioLinkBERT (Yasunaga et al., 2022). Our contributions are:

1. QLoRA fine-tuning beats both GPT-4o and GPT-5 on biomedical claim verification at 44.5× lower cost. Fine-tuning on just 1,008 examples enables Mistral-7B to achieve 88.4% macro-F1 on SciFact and 65.2% on HealthVer, surpassing GPT-4o (85.6%, 53.2%) and GPT-5 (77.9%, 42.4%) on both datasets, as well as earlier reported fine-tuned encoder results (Košprdić et al., 2024).

2. We identify a previously unreported structural artifact in SciFact. All 243 NEI training examples have empty evidence fields, making NEI trivially detectable from evidence absence rather than genuine reasoning. Fine-tuned models exploit this cue, achieving 100% in-domain NEI F1, inflating macro-F1 in a way unreported by prior work.

3. Bidirectional out-of-domain evaluation: Training on SciFact and testing on HealthVer, and vice versa at matched sizes demonstrates robust cross-domain adaptability: fine-tuning on just 1,008 HealthVer examples enables Mistral-7B to achieve 74.3% NEI F1 on SciFact OOD, outperforming BioLinkBERT trained on 10× more data (60.8%). The reverse direction confirms the shortcut mechanism: SciFact-trained models collapse on HealthVer, with the asymmetry ruling out domain shift and data quantity as explanations.

2 Related Work

Biomedical claim verification. SciFact (Wadden et al., 2020) formalized verification with 1,409 expert-written claims annotated as SUPPORTS, REFUTES, or NEI. HealthVer (Sarrouti et al., 2021) extends this to real-world health queries, while PubHealth (Kotonya and Toni, 2020) targets public health misinformation. Most systems treat verification as NLI problem and fine-tune encoders such as SciBERT (Beltagy et al., 2019), BioBERT (Lee et al., 2020), or DeBERTa (He et al., 2021); MultiVerS (Wadden et al., 2022) advanced SciFact state of the art via full-document modeling. Košprdić et al. (2024) showed DeBERTa achieves 88% F1 on SciFact, outperforming GPT-4 zero-shot, but only 48% on HealthVer OOD. We revisit this benchmark with instruction-tuned decoder LLMs.

LLMs for fact verification. GPT-4 has been evaluated on clinical QA (Singhal et al., 2023; Nori et al., 2023) and claim verification (Zheng et al., 2024), achieving strong but costly zero-shot performance. Prior work on NLI artifacts (Gururangan et al., 2018) shows models readily exploit spurious dataset correlations.

Parameter-efficient fine-tuning. LoRA (Hu et al., 2022) injects trainable rank-decomposition matrices $\Delta W = BA$ into frozen transformer weights. QLoRA (Dettmers et al., 2023) adds 4-bit NF4 quantization and paged optimizers, enabling single-GPU fine-tuning. QLoRA remains underexplored for biomedical NLI despite its practical fit for constrained label schemas and small datasets.

3 Method

3.1 Datasets

SciFact (Wadden et al., 2020) contains 1,409 expert-written claims paired with PubMed evidence, annotated as SUPPORTS, REFUTES, or NEI. We use an 80/20 stratified train/val split with the official dev set as test (450 examples). Label distribution: 48.8% SUPPORTS, 27.1% REFUTES, 24.1% NEI. Critically, all NEI examples have empty evidence fields by construction. Following standard practice for the claim verification task (Wadden et al., 2020), we use the annotated evidence sentences as model input rather than full abstracts; NEI claims have no annotated evidence by definition, resulting in empty evidence fields.

HealthVer (Sarrouti et al., 2021) provides 14,330 evidence–claim pairs from real-world health queries verified against PubMed, with official splits (10,590/1,917/1,823). Unlike SciFact, NEI in HealthVer requires reasoning over present-but-inconclusive evidence, eliminating the absence shortcut. Label distribution: 35.7% SUPPORTS, 22.8% REFUTES, 41.5% NEI.

Both datasets use unified (claim, evidence, label) triples with deterministic label normalization (Appendix A). For controlled bidirectional experiments, we sample 1,008 HealthVer training examples to match SciFact training size exactly, isolating dataset structure effects from data quantity.

3.2 Models

Zero-shot baselines. We run GPT-4o and GPT-5 at temperature 0, minimal reasoning with no chain-of-thought prompting (Appendix B).

QLoRA fine-tuned models. We fine-tune Phi-3-mini-4k-instruct (3.8B) (Abdin et al., 2024), Qwen2.5-3B-Instruct (Qwen Team, 2025), and Mistral-7B-Instruct-v0.3 (Jiang et al., 2023) models. Each model is loaded in 4-bit NF4 quantization with LoRA adapters (r=16, α=32) on all attention and feed-forward layers. We perform supervised fine-tuning with lr 2×10^{-4}, cosine schedule, 3 epochs and AdamW 8-bit. We select hyperparameters through grid search (Appendix D). We train multiple models across SciFact (1,008) and HealthVer subset (1,008) separately. Full config is added in Appendix E.

Encoder baseline. We fine-tune BioLinkBERT-base (Yasunaga et al., 2022) with a three-class classification head on SciFact, HealthVer subset (1,008), and HealthVer full (10,590) to provide matched and ceiling comparisons.

3.3 Evaluation

We report macro-averaged F1, accuracy, and per-class F1 for all three labels. Every model trained on SciFact is evaluated on both SciFact (in-domain) and HealthVer (out-of-domain) test sets, and vice versa, enabling direct bidirectional comparison under controlled conditions.

4 Experiments and Results

4.1 In-Domain Performance

Table 1 shows in-domain results for all models.

SciFact. All three QLoRA models surpass GPT-4o macro-F1 on only 1,008 training examples. Mistral-7B achieves 88.4%, beating GPT-4o

Model	Train	Acc	F1	SUP	REF	NEI
SciFact test set						
GPT-4o	—	85.8	85.6	86.8	87.7	82.3
GPT-5	—	76.9	77.9	75.1	**89.1**	69.5
BioLinkBERT	SF	87.1	87.5	**86.8**	75.6	100.0
Phi-3-mini	SF	86.2	86.4	86.0	73.3	100.0
Qwen2.5-3B	SF	85.3	86.8	82.4	78.0	100.0
Mistral-7B	SF	**87.6**	**88.4**	86.5	78.6	100.0
HealthVer test set (1,008-example training subset)						
GPT-4o	—	56.0	53.2	39.7	56.8	63.1
GPT-5	—	50.4	42.4	15.9	49.4	61.9
BioLinkBERT	HV_{sub}	65.5	62.4	62.7	47.7	76.6
Phi-3-mini	HV_{sub}	**66.1**	65.1	64.1	59.8	71.3
Qwen2.5-3B	HV_{sub}	57.0	53.6	46.9	49.6	64.5
Mistral-7B	HV_{sub}	66.0	**65.2**	**71.1**	**61.7**	62.7
HealthVer test set (full training set, reference ceiling)						
BioLinkBERT	HV_{full}	82.7	81.9	81.8	77.4	86.3

Table 1: In-domain results. SF = SciFact (1,008). HV_{sub} = HealthVer 1,008-sample subset. HV_{full} = full HealthVer training set (10,590), shown as reference ceiling. Metrics are percentages.

Model	Train→Test	Acc	F1	SUP	REF	NEI
SciFact-trained → HealthVer						
GPT-4o	—→HV	56.0	53.2	39.7	56.8	63.1
GPT-5	—→HV	50.4	42.4	15.9	49.4	61.9
BioLinkBERT	SF→HV	40.3	31.5	53.5	40.9	0.3
Phi-3-mini	SF→HV	42.8	36.0	55.1	44.9	8.0
Qwen2.5-3B	SF→HV	45.4	43.2	54.7	47.3	27.5
Mistral-7B	SF→HV	**48.9**	**44.4**	**60.1**	**52.9**	**20.1**
HealthVer-trained → SciFact (matched 1,008 examples)						
GPT-4o	—→SF	85.8	85.6	86.8	87.7	82.3
GPT-5	—→SF	76.9	77.9	75.1	89.1	69.5
BioLinkBERT	HV_{sub}→SF	61.1	53.3	70.8	21.9	67.1
Phi-3-mini	HV_{sub}→SF	63.3	59.2	71.3	43.3	63.1
Qwen2.5-3B	HV_{sub}→SF	41.3	37.9	39.1	27.8	46.7
Mistral-7B	HV_{sub}→SF	**72.4**	**69.3**	**77.8**	**55.7**	**74.3**
HealthVer full → SciFact (reference ceiling, 10,590 examples)						
BioLinkBERT	HV_{full}→SF	68.9	60.8	77.9	29.1	75.3

Table 2: Bidirectional OOD results. SF = SciFact; HV = HealthVer. Top: SciFact-trained models on HealthVer test. Middle: HealthVer subset (1,008)-trained models on SciFact test. Bottom: BioLinkBERT trained on full HealthVer (reference). GPT-4o shown for reference

(85.6%) by 2.8 points and BioLinkBERT (87.5%) by 0.9 points. McNemar's test confirms statistical indistinguishability between Mistral and GPT-4o (p=0.46) and across QLoRA models (p=0.54). GPT-4o holds an edge on REFUTES, reflecting broad pre-training for detecting subtle directional contradictions. GPT-5 zero-shot achieves only 77.9% macro-F1 on SciFact, below GPT-4o and all fine-tuned models, suggesting newer proprietary models do not automatically improve on structured verification tasks. Moreover, we discuss the mechanism behind perfect NEI score in Section 4.2.

HealthVer. Fine-tuning on just 1,008 HealthVer examples, Mistral-7B QLoRA achieves 65.2% macro-F1, surpassing GPT-4o, GPT-5, and BioLinkBERT (53.2%, 42.4%, 62.4%). It demonstrates that QLoRA-adapted decoders beat both the proprietary models and the encoder approach on real-world health queries with minimal data. The full-training BioLinkBERT ceiling (81.9%) shows that adding 9,582 examples gains 19.5 macro-F1 points, confirming data quantity effects are real but do not close the architectural gap at matched scale. Beyond performance, decoder models allow free-form explanation, zero-shot prompting, and do not require task-specific classification heads.

4.2 The SciFact NEI Structural Shortcut

High NEI F1 achieved by fine-tuned models on SciFact is not genuine epistemic reasoning. We find that all NEI examples have empty evidence fields, while every SUPPORTS and REFUTES example contains evidence. The label is perfectly separable from evidence length alone, without reading the claim content. Full stats in Appendix C, Table 8.

SciFact assigns NEI when no cited evidence exists, inadvertently creating a structural signal any expressive model will learn. Zero-shot GPT-4o attempts genuine reasoning on NEI instances. This shortcut inflates macro-F1 for all fine-tuned models and has gone unreported in prior work.

4.3 Bidirectional Out-of-Domain Generalization

Table 2 presents the full cross-dataset evaluation.

SciFact → HealthVer. All SciFact-trained models suffer catastrophic degradation as macro-F1 drops from 86-88% in-domain to 36-44% OOD. NEI collapse is most severe as HealthVer NEI has non-empty, topically relevant evidence and the absence shortcut does not fire. Table 2 shows the results. Qwen2.5-3B is the most NEI-resilient SciFact-trained model, suggesting broader pre-training provides some generalization advantage.

HealthVer → SciFact. Reverse direction tells a strikingly different story. Mistral-7B trained on just 1,008 HealthVer examples achieves 69.3% macro-F1 OOD on SciFact with 74.3% NEI F1, far above any SciFact-trained model on HealthVer. Remarkably, this outperforms BioLinkBERT trained on the full HealthVer set (60.8%), despite using 10× less

Model	Cost/1K	Fine-tune	vs. GPT-4o
GPT-4o (API)	$1.3000	—	1.0×
GPT-5 (API)	$0.5750	—	2.4× cheaper
Phi-3 (QLoRA)	$0.0292	$0.35	44.5× cheaper
Qwen2.5 (QLoRA)	$0.0292	$0.35	44.5× cheaper
Mistral (QLoRA)	$0.0292	$0.35	44.5× cheaper
BioLinkBERT	$0.0292	$0.17	44.5× cheaper

Table 3: Inference cost per 1,000 preds and one-time fine-tuning cost (T4 GPU). API pricing as of early 2026.

training data. BioLinkBERT at matched size shows meaningful transfer and achieves 53.3% macro-F1 and 67.1% NEI F1. Together, these results demonstrate that training on structurally sound data enables robust cross-domain transfer and model architecture matters more than data quantity.

Asymmetric OOD generalization. Symmetric degradation would indicate distributional shift; instead, collapse is strictly one-directional. The asymmetry holds at matched training sizes (1,008 examples), ruling out data quantity. Models trained on genuine epistemic reasoning (HealthVer) transfer; models trained on a structural proxy (SciFact) do not.

Per-class analysis. REFUTES F1 degrades most severely OOD in both directions: BioLinkBERT (HealthVer$_{full}$→SciFact) achieves only 29.1% despite strong SUPPORTS (77.9%) and NEI (75.3%) transfer. Directional contradiction detection requires domain-specific reasoning that generalizes poorly across biomedical claim types. This is a critical gap given that refutation detection is essential for any clinical task.

GPT-4o and GPT-5: paradoxical OOD behavior. GPT-4o achieves the highest HealthVer NEI F1 (63.1%) among zero-shot models despite the lowest SciFact NEI F1 (82.3%). Its in-domain weakness reflects genuine uncertainty reasoning that transfers. GPT-5 shows more pronounced NEI over-prediction: 95.5% NEI recall on SciFact but only 8.8% SUP recall on HealthVer, suggesting over-cautious RLHF training that predicts NEI regardless of evidence. In-domain scores are poor proxies.

4.4 Cost Analysis

GPT-4o costs $1.30 per 1,000 predictions versus $0.03 for local open models (44.5× drop). The $0.35 one-time fine-tuning cost amortizes to negligible overhead, making fine-tuned small models strictly preferable on both performance and cost grounds. For OOD tasks, training data choice is critical. SciFact-trained models collapse OOD while HealthVer-trained models transfer robustly, achieving strong cross-domain performance.

4.5 Qualitative Error Analysis

We examined 48 cases where Mistral-7B QLoRA is correct and GPT-4o is wrong, and 40 reverse cases, on the SciFact test set.

Fine-tuning wins. Mistral-7B outperforms GPT-4o on NEI: for "Statins increase blood cholesterol," GPT-4o predicts REFUTES from pharmacological knowledge while Mistral correctly withholds judgment given no retrieved evidence. Fine-tuning teaches models to attend to evidence rather than prior knowledge.

GPT-4o wins. GPT-4o retains an edge on directional REFUTES: for "The risk of male prisoners harming themselves is ten times that of female prisoners," the evidence states the opposite direction. GPT-4o correctly predicts REFUTES; Mistral latches onto "ten times" without detecting the subject inversion. Mistral nonetheless closes this gap vs. Phi-3-mini (11 GPT-4o wins vs. 29), suggesting larger capacity helps with contradiction detection.

Shared failure modes. Both models err on claims where evidence describes a related but experimentally distinct condition, and on logical negations introduced by experimental targeting. The annotation ambiguity is documented in SciFact inter-annotator studies (Wadden et al., 2020).

5 Conclusion

Fine-tuning small open-weight LLMs via QLoRA on just 1,008 examples surpasses both GPT-4o and GPT-5 on SciFact and HealthVer at a fractional cost, establishing parameter-efficient fine-tuning as a practical alternative to APIs. Through extensive OOD evaluation, we show both the promise and limits of this approach: HealthVer-trained models transfer robustly to SciFact, outperforming BioLinkBERT trained on 10× more data, while SciFact-trained models collapse cross-domain due to a structural artifact in SciFact. REFUTES remains the hardest class to transfer in both directions, pointing to cross-domain contradiction detection as an open challenge. Our findings motivate structural auditing of biomedical NLI benchmarks and bidirectional evaluation as standard practice.

Limitations

Our bidirectional experiments use matched 1,008-example training sets, but scaling to full HealthVer data would further improve in-domain performance, as evidenced by BioLinkBERT's 81.9% ceiling vs. 62.4% at matched size. We evaluated GPT-5 as an additional zero-shot baseline; its lower performance (77.9% SciFact, 42.4% HealthVer) confirms that QLoRA fine-tuning advantages hold against the latest proprietary systems. Cost estimates reflect T4/A100 and API pricing as of early 2026. We evaluate English claims only; whether analogous structural shortcuts exist in PubHealth, MedNLI, or other benchmarks remains an open question. Data augmentation and debiasing strategies for improving cross-domain robustness are left for future work.

A Label Normalization

Refer to Table 4.

Raw output variants	Label
SUPPORTS, SUPPORT, SUPPORTED, ENTAILMENT	SUPPORTS
REFUTES, REFUTE, REFUTED, CONTRADICT(S)	REFUTES
NEI, NOT_ENOUGH_INFO, NOT ENOUGH INFO, NEUTRAL	NEI
(unrecognized)	NEI (fallback)

Table 4: Label normalization mapping

B Prompt Templates

All instruction-tuned LLMs use the following prompt. Phi-3-mini uses ChatML format; Mistral-7B and Qwen2.5 use `[INST]/[/INST]` format.

```
System: You are a biomedical claim verification expert. Given a claim and an evidence passage from a scientific abstract, determine whether the evidence SUPPORTS the claim, REFUTES the claim, or whether there is NOT ENOUGH INFO. Respond with exactly one of: SUPPORTS, REFUTES, NEI.

User: Claim: {claim}
Evidence: {evidence}
What is the verdict?

Assistant: {label}
```

For GPT-4o, only the system and user turns are used at inference. For fine-tuning, the full exchange including the gold label is the SFT training target. For SciFact NEI examples, the evidence field is empty (`Evidence: `), the structural signal described in Section 4.2. We run GPT-4o with temperature 0 and GPT-5 with minimal reasoning.

C Dataset Statistics

Tables 5, 6 present dataset split sizes and label distributions. Tables 7, 8 provide representative input examples and evidence field statistics respectively

Dataset	Train	Val	Test	Total
SciFact	1,008	253	450	1,711
HealthVer (subset)	1,008	—	1,823	—
HealthVer (full)	10,590	1,917	1,823	14,330

Table 5: Dataset splits. SciFact uses stratified 80/20 train/val split; official dev set as test. HealthVer subset sampled with random_state=42 to match SciFact training size.

Dataset (train)	SUP%	REF%	NEI%
SciFact	48.8	27.1	24.1
HealthVer	35.7	22.8	41.5

Table 6: Label distributions. HealthVer's higher NEI proportion and structurally distinct NEI definition contribute to the generalization asymmetry.

Dataset	Claim	Evidence	Label
SciFact	Statins increase blood cholesterol.	*(empty)*	NEI
SciFact	Metformin reduces HbA1c in diabetic patients.	Metformin significantly reduced HbA1c levels compared to placebo...	SUP
SciFact	Aspirin prevents colorectal cancer.	Aspirin use was associated with reduced risk...	REF
HealthVer	Vitamin C prevents the common cold.	Some studies suggest marginal effects on duration but evidence remains inconclusive...	NEI
HealthVer	Exercise reduces depression symptoms.	Aerobic exercise significantly reduced depressive symptoms across trials...	SUP

Table 7: Representative input examples from SciFact and HealthVer. SciFact NEI examples have empty evidence fields by construction; HealthVer NEI examples contain present-but-inconclusive evidence, eliminating the absence shortcut. Evidence text truncated for brevity. This structural difference explains the asymmetric OOD generalization reported in Section 4.3.

Label	Count	Mean chars	Zero-length
NEI	243	0.0	243/243 (100%)
SUPPORTS	492	214.5	0/492 (0%)
REFUTES	273	227.4	0/273 (0%)

Table 8: Evidence field length by label in SciFact training split. All NEI examples have empty evidence; no SUP/REF example does. This holds in val and test splits as well.

D Hyperparameter Grid Search

We perform multi configuration grid search over $r \in \{8, 16, 32\}$ and lr $\in \{10^{-4}, 2\times10^{-4}, 5\times10^{-4}\}$ using Mistral-7B on SciFact validation set. Selected config (r=16, lr= 2×10^{-4}) in bold.

E Hyperparameter Configuration

We list down the hyperparameters used for fine-tuning the LLMs in Table 10.

r	LR	Val Macro-F1
16	$\mathbf{2\times10^{-4}}$	**88.4**
8	5×10^{-4}	87.4
16	5×10^{-4}	85.7
32	5×10^{-4}	84.6
8	2×10^{-4}	81.3
32	2×10^{-4}	79.0
16	1×10^{-4}	77.8
32	1×10^{-4}	75.7
8	1×10^{-4}	74.5

Table 9: Hyperparameter grid search results on SciFact validation set (Mistral-7B). Selected configuration in bold. Higher learning rates generally outperform lower ones; r=16 at lr= 2×10^{-4} achieves the best validation macro-F1 of 88.4%.

Hyperparameter	Value
LoRA rank (r)	16
LoRA alpha (α)	32
LoRA dropout	0.05
Quantization	NF4, double quantization
Learning rate	2×10^{-4}
LR schedule	Cosine, warmup ratio 0.05
Effective batch size	16 (batch 4, grad. accum. 4)
Max sequence length	1,024 tokens
Training epochs	3
Precision	bf16 (fp16 fallback on T4)
Optimizer	Paged AdamW 8-bit
Checkpoint selection	Best validation macro-F1
Trainable params (Phi-3)	8.9M / 3.83B (0.23%)
Trainable params (Mistral/Qwen)	41.9M / 7.29B (0.58%)
LoRA target modules:	
`q_proj, k_proj, v_proj, o_proj,`	
`gate_proj, up_proj, down_proj`	

Table 10: QLoRA configuration, identical across all architectures and datasets.

F Training Efficiency

We measure training efficiency as a function of training time and cost. All models were trained on Google Colab Pro. Phi-3-mini, Qwen2.5-3B, and BioLinkBERT were trained on a T4 GPU (16 GB); Mistral-7B required an A100 (40 GB) due to memory requirements at 7B scale. Times are reported for SciFact (1,008 examples, 3 epochs); HealthVer subset training is approximately equivalent. The detailed breakdown is in Table 11.

G McNemar's Test Details

McNemar's test statistic: $\chi^2 = (b_{01} - b_{10})^2/(b_{01} + b_{10})$, where b_{01} = model A correct, B wrong; b_{10} = model B correct, A wrong. Evaluated on SciFact test set (450 examples).

Model	GPU	Time	Cost
Phi-3-mini	T4 (16 GB)	∼50 min	$0.15
Qwen2.5-3B	T4 (16 GB)	∼70 min	$0.21
Mistral-7B	A100 (40 GB)	∼35 min	$0.35
BioLinkBERT	T4 (16 GB)	∼15 min	$0.04

Table 11: Training times and costs per model (SciFact, 1,008 examples, 3 epochs). T4: ≈$1.76 CU/hr; A100: ≈$10–15 CU/hr.

Model A	Model B	b_{01}	b_{10}	χ^2	p
Mistral QLoRA	GPT-4o	48	40	0.56	0.46
Mistral QLoRA	Phi-3 QLoRA	36	30	0.38	0.54

Table 12: McNemar's test on SciFact test set. Neither comparison is significant at $p < 0.05$.

H Qualitative Error Analysis: Extended Examples

Claim	Gold	Mistral	GPT-4o
Pattern A: Fine-tuned wins on NEI			
Statins increase blood cholesterol.	NEI	NEI	× REF
Venules have larger lumen than arterioles.	NEI	NEI	× SUP
Pattern B: GPT-4o wins on REFUTES			
Male prisoner self-harm risk is 10× female.	REF	× SUP	REF
Nicotine combo therapy yields significantly higher abstinence.	REF	× SUP	REF
Pattern C: Mistral wins on REFUTES (new vs. Phi-3)			
NIV use should be decreased for poor responders.	REF	REF	× NEI
Tirasemtiv has no effect on fast-twitch muscle.	REF	REF	× NEI
Pattern D: Both wrong			
TNFAIP3 is a tumor suppressor in glioblastoma.	REF	× SUP	× SUP
Low nucleosome occupancy correlates with low methylation.	REF	× SUP	× SUP

Table 13: Representative error examples. REF = REFUTES, SUP = SUPPORTS.

A. Fine-tuned models withhold judgment without evidence; GPT-4o applies world knowledge.

B. GPT-4o detects subject inversions and non-significant p-values; Mistral closes this gap vs. Phi-3-mini (11 wins vs. 29).

C. Mistral infers directional implications from indirect evidence where GPT-4o hedges to NEI.

D. Both models fail on logical negations and directional correlation signs (Wadden et al., 2020).

I Confusion Matrices

Figure 1 visualizes the NEI shortcut directly. BioLinkBERT trained on SciFact achieves perfect

NEI separation in-domain (left). The NEI column is completely clean with zero misclassifications. When evaluated on HealthVer OOD (right), the model predicts NEI exactly once across 727 true NEI examples, instead routing all NEI instances to SUPPORTS (647) or REFUTES (79). This collapse is the behavioral signature of shortcut learning: the absence signal that perfectly predicted NEI in SciFact is absent in HealthVer, and the model has learned nothing else.

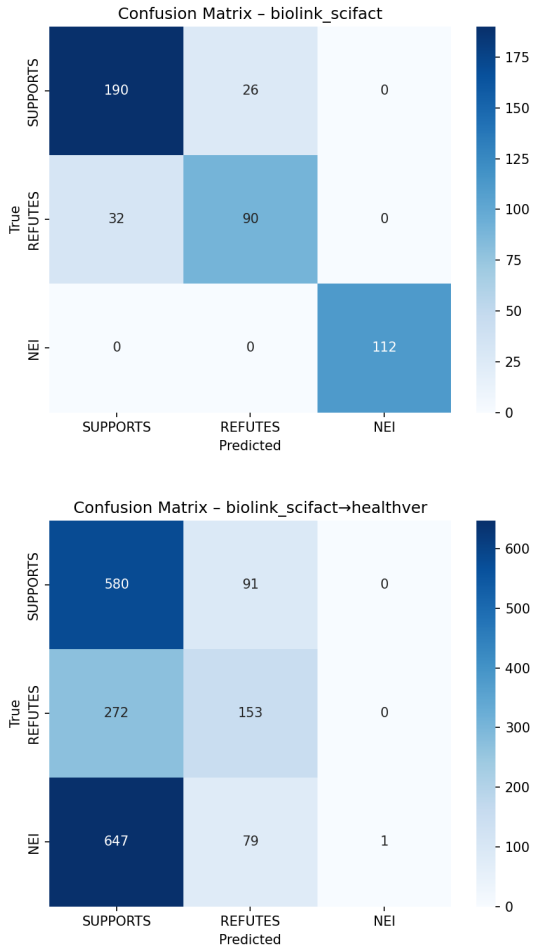

Figure 1: Confusion matrices for BioLinkBERT trained on SciFact, evaluated in-domain (top) and OOD on HealthVer (bottom). In-domain NEI is perfectly classified (112/112); OOD NEI is nearly never predicted (1/727), with true NEI examples overwhelmingly misclassified as SUPPORTS. This is the behavioral signature of structural shortcut learning.

Diagnosable ColBERT: Debugging Late-Interaction Retrieval Models Using a Learned Latent Space as Reference

Remy François
Parallia Healthcare
francois.remy@parallia.eu

Abstract

Reliable biomedical and clinical retrieval requires more than strong ranking performance: it requires a practical way to find systematic model failures and curate the training evidence needed to correct them. Late-interaction models such as ColBERT (Khattab and Zaharia, 2020) provide a first solution thanks to the interpretable token-level interaction scores they expose between document and query tokens. Yet this interpretability is shallow: it explains a particular document–query pairwise score, but does not reveal whether the model has learned a clinical concept in a stable, reusable, and context-sensitive way across diverse expressions. As a result, these scores provide limited support for diagnosing misunderstandings, identifying irreasonably distant biomedical concepts, or deciding what additional data or feedback is needed to address this. In this short position paper, we propose Diagnosable ColBERT, a framework that aligns ColBERT token embeddings to a reference latent space grounded in clinical knowledge and expert-provided conceptual similarity constraints. This alignment turns document encodings into inspectable evidence of what the model appears to understand, enabling more direct error diagnosis and more principled data curation without relying on large batteries of diagnostic queries.

1 Introduction

Trustworthy artificial intelligence in high-stakes domains increasingly requires transparent reporting of model capabilities, limitations, and failure modes (World Health Organization, 2021; European Parliament and Council of the European Union, 2017; Oberst et al., 2024). Finding systematic model failures is a central requirement for deploying retrieval systems in clinical and biomedical settings. When a retrieval model confuses nearby concepts, overgeneralizes across contexts, or fails to encode clinically salient negation, the consequence is not merely a lower ranking metric, but a weaker basis for downstream decision making and a poorer signal for curating corrective training data (Harkema et al., 2009; Lee et al., 2010; Wang et al., 2020). For this reason, debugging should ideally reveal not only that a model failed on a particular document–query pair, but also *what* the model appears to understand, *where* that understanding breaks down, and *which* additional examples are needed to improve it.

Late-interaction models in the style of ColBERT are appealing in this regard because they expose fine-grained interaction scores between query and document tokens (Khattab and Zaharia, 2020). However, this evidence remains retrospective and local: it helps explain why a given query matched a given document, but not whether the model has learned clinically meaningful distinctions robustly across paraphrases, contexts, and compositional variants (Huang and Baldwin, 2023; Kang et al., 2025). Explaining a match is not the same as gauging and diagnosing misunderstandings.

In clinical retrieval, the most consequential failures often depend on context-sensitive factors such as negation, temporality, uncertainty, experiencer, historical status, and the distinction between mentioning a test and asserting a condition. These are precisely the kinds of distinctions that may be weakly expressed in local match scores while remaining decisive for retrieval quality.

We therefore argue that checking model understanding requires interpretation at multiple levels of contextualization. Many biomedical meanings are only partially specified at the token level and become clearer as progressively more context is introduced (Lee et al., 2010). For example, a model that appears reasonable on *cat* may still fail on *cat scratch disease*. Moreover, paragraph-level context can further influence whether a mention is current, historical, speculative, negated, or even concerns another person (Harkema et al., 2009; Wang et al., 2020). Interpretability must therefore extend

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 713–717
July 3-4, 2026 ©2026 Association for Computational Linguistics

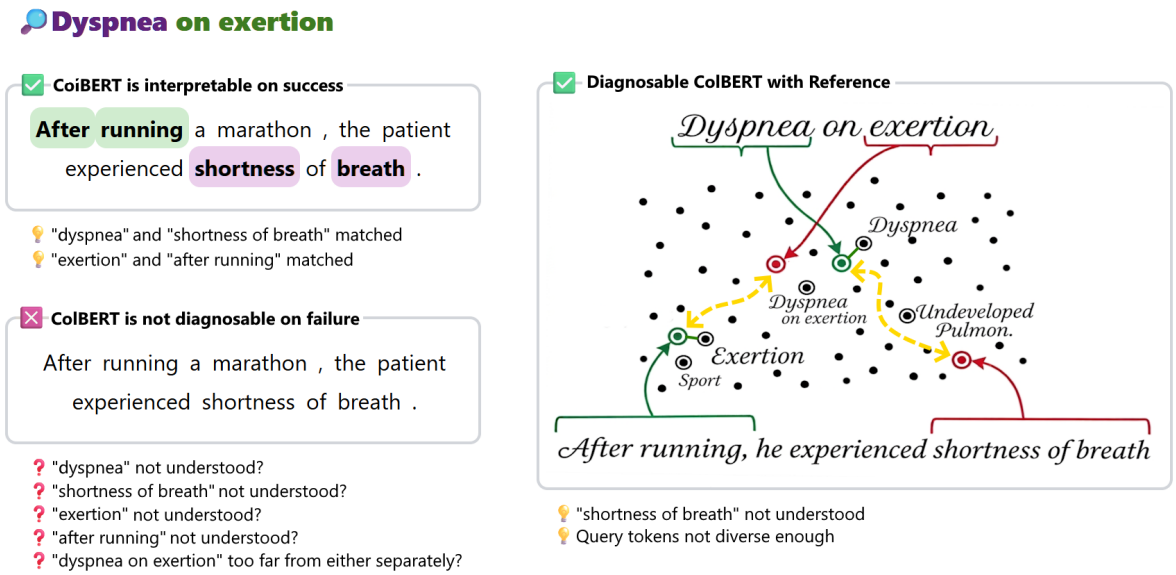

Figure 1: Standard ColBERT-style late interaction produces interpretable query–document scores, but provides little guidance when no meaningful match is found for a token, as illustrated on the left. By contrast, augmenting the retriever with a reference latent space, as on the right, allows testers of Diagnosable ColBERT models to diagnose failures more quickly and more actionably by separating latent-space semantics from in-context understanding.

beyond isolated token matches toward a graded view of understanding across term, sentence, and paragraph-level alignment. Accordingly, we treat diagnostic alignment as multi-factorial: it should reveal term-level concept identity, phrase-level composition, context-level qualifiers, and broader discourse elements that alter clinical interpretation.

This broader view of interpretation also motivates the use of a structured latent space rather than a fixed inventory of labels. If the embedding space is shaped to respect concept-level and sentence-level similarity constraints, then it can represent not only previously named clinical concepts, but also contextually enriched and partially novel combinations of them (Campbell et al., 2014). Prior work also suggests that such spaces are feasible to construct in practice, whether by grounding biomedical representations in ontological definitions and relations as in BioLORD (Remy et al., 2024), by aligning dense representations to structured label spaces (Decorte et al., 2025), or by grounding annotated mentions in a dynamic model-generated concept space when the concept inventory is large and evolving (Stepanov et al., 2026).

In this publication, we therefore propose Diagnosable ColBERT, a framework that leverages such a reference latent space learned from expert-specified similarity constraints over clinical concepts, and aligns late-interaction token embeddings to it via pre-projection adapters. The central proposal of this paper is therefore not a new retrieval scoring rule, but a new diagnostic lens: late-interaction representations should be interpreted against a clinically grounded reference space rather than only through pairwise match scores. The goal is not merely to explain a retrieval score after the fact, but to make document encodings themselves interpretable as evidence about what the model appears to know. This creates a path toward diagnosing misunderstandings directly from encoded documents, identifying confusable concepts, and curating training data in a more principled way. More generally, we advocate a shift from retrospective score inspection to concept-grounded diagnosis of model understanding. Such representations could support both direct human inspection and more automated auditing workflows.

2 Diagnostic Framework

Diagnosable ColBERT is organized around a pre-existing reference latent space that serves as a domain-specific diagnostic scaffold. This latent space needs to accommodate both concept names, clinical sentences, and paragraphs; see for example BioLORD (Remy et al., 2024). The purpose of this space is to make contextual token representations clinically legible: not only in terms of term-level concept identity, but also in terms of local composition and context-level qualifiers such as negation, temporality, uncertainty, or experiencer. Instead of only asking which query token matched which document token, we ask what clinically relevant factors a contextualized representation appears to encode and how they arrange geometrically.

In this view, alignment means mapping late-interaction token representations into a space where these factors can be inspected more directly. The retrieval representation should remain tied to this diagnosed representation, but need not be identical to it. A natural design is for retrieval embeddings to be learned as a lower-dimensional downprojection of the diagnosed representation, so that retrieval can reweight clinically relevant factors for ranking efficiency without discarding the richer structure needed for diagnosis. This keeps the framework centered on a simple idea: retrieval and diagnosis should stay coupled, but diagnosis should not be reduced to whatever geometry happens to be most convenient for fast search.

The specific architecture used to realize this idea is secondary to the paper's main claim. One can implement the diagnostic view with lightweight contextual adapters and task-specific projection heads; our essential contribution is the diagnostic framing itself: a clinically grounded reference geometry for inspecting what a late-interaction retriever appears to perceive from a context.

3 Practical Examples

A central limitation of standard ColBERT interpretability is that it is fundamentally relational: it explains why a query matched a document, but offers limited leverage when the goal is to determine why a relevant match failed to occur (see Figure 1). Diagnosable ColBERT is intended to address precisely this gap. Rather than treating retrieval failure as a single undifferentiated event, it seeks to identify which part of the representation pipeline failed to preserve the clinically relevant meaning.

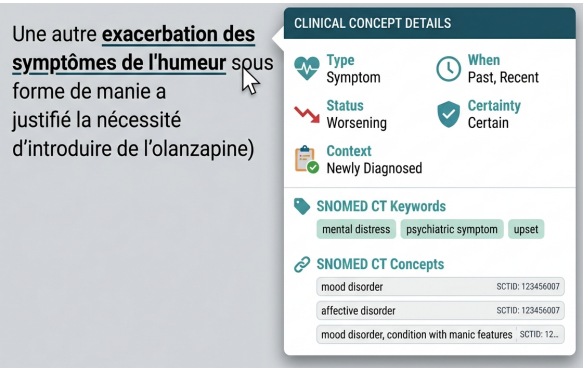

Figure 2: Proposed debugging interface for Diagnosable ColBERT. The interface exposes token-level query and document representations together with their placement in the reference latent space and the clinically meaningful concepts or qualifiers associated with nearby regions. This gives testers a practical way to distinguish weak interaction scores from deeper failures of concept grounding, abbreviation handling, or contextual interpretation, and to turn a retrieval miss into an actionable diagnosis.

Consider a case report retrieval system in which a tester issues the query *bartonellosis*. A relevant report is missed because the report mentions only *CSD*, the abbreviation for *cat scratch disease*. Standard query–document inspection establishes that the interaction between *bartonellosis* and *CSD* is too weak. But this finding alone is diagnostically incomplete. It does not tell us whether the query representation failed to capture the target disease family, whether the document representation failed to interpret the abbreviation correctly, or whether both encodings are deficient.

Diagnosable ColBERT resolves this ambiguity by grounding both sides in a reference latent space. The tester can inspect whether *bartonellosis* is already positioned near the relevant disease concept and, separately, whether *CSD* is mapped into that same region. If *bartonellosis* is correctly grounded but *CSD* is not, then the root cause is not weak interaction per se, but document-side abbreviation understanding. If both are misplaced, the problem lies deeper, at the level of concept representation. This kind of distinction is difficult to obtain from pairwise interaction scores alone, yet it directly guides remediation.

When the problem lies in abbreviation grounding, the natural intervention is to curate examples that explicitly connect abbreviated, expanded, and synonymous forms. When the problem lies in broader concept placement, the remedy instead concerns the shaping of the underlying semantic space.

The same diagnostic logic extends beyond query-conditioned retrieval. Some failures can be identified directly from the document encoding itself. Consider the utterance: *Are you allergic to any of the following drugs? — Yes, to ranitidine*. Here the relevant question is whether the token representation of *ranitidine* reflects not only the medication identity, but also the allergic relation introduced by context. If the encoding remains close to the drug concept while failing to capture the neighboring context of allergy, adverse reaction, or intolerance, then the model has encoded the entity but not the clinically decisive context.

This is a query-free diagnostic signal: the tester can identify the failure before retrieval is even attempted. Again, the diagnosis suggests a targeted intervention, namely the addition of training examples in which drug mentions appear indirectly in contexts related to allergy or adverse-reactions, and ensure that this context is getting properly picked up by the encoder model.

4 Real-World Usage

In our experience, debugging user interfaces for Diagnosable ColBERT models[1] have already proven useful as a practical way to inspect token-level phenomena and surface failures that would have been difficult to localize from ranking metrics alone. What made the interface valuable was that it helped spot remaining representational weaknesses that actually mattered in practice, including gaps in conceptual grounding, abbreviation and brand name handling, and preservation of clinical context.

Subjectively, this changed the development process. Instead of treating misretrievals as abstract evaluation outcomes, we were often able to trace issues back to recurring representational problems and then respond with more targeted curation and model changes. These observations informed the progression from ClinicalEncoder25 to ClinicalEncoder26AM and beyond, even if this workflow remains work in progress and should not be mistaken for a complete evaluation methodology.

5 Limitations and Scope

Diagnosable ColBERT is best understood as a diagnostic scaffold, not as a complete semantics of biomedical meaning. Its purpose is to make clinically relevant aspects of the model's internal organization more legible to a tester, not to claim that every retrieval-relevant distinction can be exhaustively captured in a single reference geometry. Any such space reflects design choices about which concepts, relations, and contextual qualifiers are made salient, and its usefulness depends on being well shaped by domain knowledge, expert constraints, and clinically meaningful similarity structure. The proposal therefore improves diagnosability without by itself guaranteeing retrieval quality: diagnostic alignment complements retrieval evaluation by making failure modes more interpretable and actionable, but useful systems will still need strong ranking behavior as well.

6 Conclusion

In this paper, we have argued that debugging late-interaction retrievers requires more than inspecting token-level query–document scores after a failure has already occurred. Our central claim is that retrieval models become substantially more diagnosable when their token representations are aligned to a clinically grounded reference latent space that makes concept grounding, contextual qualifiers, and representational gaps directly inspectable.

Diagnosable ColBERT is a concrete step in this direction. Rather than treating retrieval as a black box whose failures must be inferred indirectly from weak matches and downstream metrics, it provides a practical framework for localizing why a miss occurred and for inspecting difficult document segments even before a query is issued.

Much remains to be refined, especially in constructing strong reference spaces and turning diagnoses into robust improvement workflows. Even so, we view the direction as already promising in practice: clinically grounded diagnostic representations complement ranking evaluation by making retrieval behavior more legible and actionable.

Developing Literature Annotation Guidelines for Representing Normal Physiology in Biolink-Compatible Knowledge Graphs

Madeline Bittner, Willie Rogers, Dina Demner-Fushman,
Richard H. Scheuermann, Matthew Diller
Division of Intramural Research
National Library of Medicine, Bethesda, MD
firstname.lastname@nih.gov

Abstract

Much of our knowledge about anatomy and physiology is found in text format in research papers and medical textbooks. For an information system to have access to this knowledge, extracting and translating it into a computable format that can be stored in an ontology or knowledge graph is advantageous. Unfortunately, existing text mining corpora, which are needed to train and evaluate data mining models, are old and consist almost entirely of research papers, which rarely contain complete information needed to capture complex normal physiological processes and, subsequently, understand the pathophysiology of a disease. As a first step to filling in this gap, we have developed a guide for annotating medical textbooks for physiological events and entities involved in these events. In addition to providing our guidelines and describing the guideline development process, we analyze the coverage of normal physiology in existing ontologies.

1 Introduction

Anatomy and physiology are central components of biological systems, with knowledge of the relationship between the structures and functions of organisms and their parts driving most of what we know about health and disease. Most knowledge about healthy anatomy and physiological functions exists as text in medical textbooks and research papers, which is not easily accessible in a structured form for querying, analysis, and visualization. This lack of structured, computable knowledge representation has hindered the translation of large-scale multi-omics datasets into new knowledge about disease mechanisms and potential treatments. In addition, many ontologies and knowledge graphs (KGs) contain large gaps in coverage as they tend to lag behind novel research findings in terms of being up-to-date, and rely largely on manual curation (Li et al., 2023). To scale up curation efforts, ontology and KG developers will need to incorporate semi-automated tools and workflows for extracting knowledge about anatomical entities and physiological events from biomedical text.

Here we describe an annotation guide that can be used as a reference for annotating anatomical entities and physiological events in medical textbooks. Included in these guidelines are the scope of the annotation, a description of each entity and event of interest, and the reasons for why certain annotation decisions were made. To test the feasibility of translating textual physiology information into a structured format, we assess the coverage of extracted entities and events in existing biomedical ontologies.

2 Background

Currently, several tools exist to create structured representations of knowledge in ontologies and KGs that could be applied to anatomy and physiology, including Biolink (Unni et al., 2022), which aims to provide an upper-level model for interoperable KGs. However, there is an absence of up-to-date text mining corpora to support the extraction of anatomy and physiology information from text. The most recent annotated corpora—the Anatomical Entity Mention (AnEM) corpus (Ohta et al., 2012), the extended Anatomical Entity Mention (AnatEM) corpus (Pyysalo and Ananiadou, 2013), and the Multi-Level Event Extraction (MLEE) corpus (Pyysalo et al., 2012)—that broadly focus on mentions of anatomical entities and physiological events in the context of both healthy and diseased organisms, largely consist of annotated abstracts and full-text research publications. Although these corpora are annotated with ontology term identifiers, the length of time since these annotations were performed would warrant reannotation to ensure that active and the most precise terms are used. Additionally, since the annotated documents in these corpora consist mostly of research papers,

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 718–728
July 3-4, 2026 ©2026 Association for Computational Linguistics

their structure and content will likely differ from the semantic and syntactic structures found in a medical textbook. Beyond the limitations of existing corpora, existing guidelines used for biomedical information extraction, including i2b2 (Uzuner et al., 2011) for clinical de-identification, GENIA (Kim et al., 2003) for biochemical entities in molecular biology literature, and CINEX (Reichenpfader et al., 2025) for high-level metadata extraction from clinical trial text, were not designed to capture normal physiology entities, as they are either too metadata-focused or operate at a biochemical level that does not translate to physiology annotation. To our knowledge, no annotation guidelines currently exist that are specific to normal human physiology, representing a gap that this work addresses.

3 Methods

In this exploration of approaches to annotation of physiological processes and events at several anatomy levels, we focus on annotating events that involve glucagon-like peptide 1 (GLP-1), which plays an essential role in processing nutrients after food ingestion. The effects of GLP-1 are also mimicked by agonistic drugs, such as exenatide (Byetta), liraglutide (Victoza), dulaglutide (Trulicity) and semaglutide (Ozempic/Wegovy), used for blood glucose control and weight management.

3.1 Annotation Schema Development

The annotation guide was developed using passages from the *Guyton and Hall Textbook of Medical Physiology* (14th Edition) (Hall et al., 2021), well-established reference in biomedical education and clinical medicine. This textbook was selected because it contains medically complex language representative of normal physiology text, is well-structured, and reflects the type of text that would be encountered when annotating other normal physiology domains beyond the GLP-1 use case. Passages were drawn specifically from sections covering GLP-1 normal physiology, with 17 paragraphs selected for annotation.

Three annotators with expertise in biomedical informatics annotated each text independently. Annotations were conducted iteratively, with label definitions and disambiguation rules continuously refined to improve clarity and ensure generalizability beyond GLP-1 physiology to other normal human physiology domains. Comprehensive coverage of relevant biological concepts while remaining broad enough to generalize to other normal human physiology processes. Text was considered out of scope if it describes disease pathways, pertains to processes at a purely biochemical level, or does not relate to normal adult human physiology. Entity, event, and attribute labels and their definitions are provided in appendix Table A1, and were informed by prior work on manual annotation of anatomical and physiological features in medical text (Ohta et al., 2012; Pyysalo and Ananiadou, 2013; Pyysalo et al., 2012). Counts for the number of occurrences of each entity, event, and attribute labels across the 63 annotated sentences from the 17 passages are provided Table 1. Target-Arg relations are used to formally link the events to their associated entities or other events, where the direction of the relation is defined as the source term to the target term. To reduce cross-sentence complexity, each sentence was annotated as independently as possible, with Target-Arg relations restricted within sentence boundaries when possible; the coreference attribute was used to capture topics that carries across sentences. Relationship serves as the catch-all event label, applied to any word or phrase that describes how entities are connected, interact, or influence one another. Three annotators independently annotated the corpus using BRAT (Stenetorp et al., 2012), as shown in Figure 1, with disagreements resolved through discussion and a predefined list of common multi-word expressions used to reduce complexity and increase annotation efficiency (appendix Table A2).

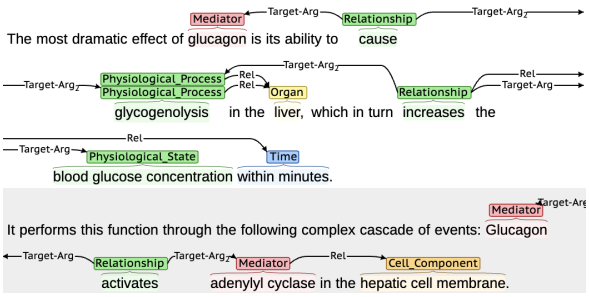

Figure 1: Example BRAT annotation.

3.2 Named Entity Recognition

To evaluate the feasibility of automated named entity recognition (NER) and to inform ontology selection for future work, we assessed the coverage of our annotation guide across a broad range of biomedical ontologies using the EMBL-EBI Ontology Lookup Service (OLS) (Côté et al., 2006) and

Category	Label	Count (N=420)
Entity	Mediator	33 (7.8)
	Measurement	24 (5.7)

Table 1: Total counts (%) for each entity, event, and attribute label with percentages rounded to one decimal place.

the Unified Medical Language System (UMLS) (Bodenreider, 2004). A distinct list of Entities (N=29), Physiological Processes (N=23), Physiological States (N=13), and Relationships (N=55) was derived from our manual annotations. Multiword expressions and fragments were excluded prior to ontology lookup, as their structure is not directly represented in standard biomedical ontologies, though their constituent terms are covered individually. The terms were queried via the EMBL-EBI API (European Bioinformatics Institute (EMBL-EBI), 2026) and matched against available ontologies using exact string lookup. Coverage was calculated as the proportion of distinct manually annotated terms present in each ontology. The Entity labels *Time* and *Measurement* were excluded from this analysis, as these labels do not correspond to concepts represented within standard biomedical ontologies.

3.3 Relation Extraction

To evaluate the feasibility of automated relation extraction, we assessed whether Stanza (Qi et al., 2020) dependency and constituency parsers can structurally encode relationship types defined in our annotation guide. Both parsers were run on the 17 text paragraphs, with multi-word expressions adjoined with underscores to prevent term splitting. Manual relation annotations were mapped to parser outputs according to each parser type's structural properties: dependency parser spans were reduced to syntactic head words; while constituency parser, spans were aligned to leaf node sequences with Part-of-speech (POS) tags normalized to phrase-level equivalents. Each relation was parsed independently at the sentence level to avoid full-document parse context effects. Across the 162 annotated relation pairs, 29 distinct dependency patterns and 6 distinct constituency patterns were identified as the reference set. Coverage was assessed at two levels. Corpus-wide coverage determined whether each distinct relation pattern appeared anywhere in the full parser output across all 17 paragraphs, assessed for the dependency parser via direct UPOS $\rightarrow$ deprel $\rightarrow$ UPOS arc matching, and for the constituency parser via phrase label pair matching *(e.g., VP Target-Arg NP)* within the same sentence tree. Individual relation coverage determined whether each manually annotated pattern was present in its source sentence. For the dependency parser, using direct arc lookup between entity head words in both directions; for constituency parser, using the lowest common ancestor method to identify the smallest constituent dominating both entity head words and comparing its label to the annotated phrase type. Of the 162 annotated relation pairs, 2 were removed from the dependency pattern set and 18 were removed from the constituency pattern set prior to individual relation coverage, as these instances could not be reliably aligned to their corresponding sentence-level parse structures. Additionally, hierarchical agglomerative clustering (HAC) was performed to visually model and compare the relation pattern coverage of the dependency and constituency parsers, methods can be seen in appendix Figures A1 and A2.

4 Results

4.1 Inter Annotator Agreement

Mean pairwise F1 scores were computed to measure inter-annotator agreement, as shown in Table 2. Agreement for Entities, Relationships, which includes the labels Relationship, Physiological State, and Physiological Process, was measured at the character span level. For annotations with character span agreement, label agreement was then assessed. Agreement for Target-Arg relations was evaluated using the character spans for both the source and target terms, with label agreement then assessed for pairs that reached character span agreement. For Target-Arg label agreement, both the source and target labels were required to match. A token alignment leniency of two tokens was applied across all agreement levels. Attribute labels were excluded from inter-annotator agreement cal-

Section	Span	Label
Entities	0.626 (N=612)	0.814 (N=280)
Relationships	0.621 (N=809)	0.868 (N=365)
Target-Arg	0.354 (N=1202)	0.731 (N=260)

Table 2: Mean pairwise F1 agreement scores for span-level and label-level agreement across three annotators. N indicates matched spans/relations for label agreement.

culations, as their complexity and dependency on broader context make standard pairwise span-level evaluation unreliable. While span-level agreement is comparatively lower, this is expected given the nature of span boundary identification. Notably, label agreement among spans that all annotators agreed on is high, suggesting that annotators can reliably assign the correct label when a span is identified.

4.2 Ontology Coverage

Table A3 summarizes the coverage of each ontology from the OLS and UMLS. Among the OLS ontologies, OMIT ontology achieved the highest coverage for Entities (0.52), while NCIT achieved the highest coverage for Physiological Process, Physiological State, and Relationship (0.17, 0.38, and 0.24 respectively). Notably, PRIDE and INO shared the highest coverage of Physiological Process terms, and PRIDE also shared the highest coverage for Physiological State terms. Across all OLS ontologies, Physiological Process terms had the lowest overall coverage (0.17). In the UMLS, Relationship terms had the lowest coverage (0.11), while Entities had the highest (0.55). Overall, the UMLS achieved the highest coverage across all ontologies at 0.31, with NCIT second at 0.29.

4.3 Relation Coverage

Corpus-wide coverage was computed as the proportion of distinct manual annotation patterns found within the full parser output. The dependency parser achieved a corpus-wide coverage of 0.48, recovering 14 of 29 distinct manual relations, with a precision of 0.10, indicating that the 14 matched patterns account for only a small fraction of the 135 distinct patterns produced by the parser across the full corpus. The constituency parser achieved perfect corpus-wide coverage of 1.00, recovering all 6 distinct manual relations, with a precision of 0.19, meaning the 6 matched patterns represented a similarly small proportion of the 31 distinct patterns generated. At the individual relation level, the dependency parser covered 80 of the 160 eligible manual relation instances (0.50), and the constituency parser covered 89 of the 144 eligible manual relation instances (0.62). Results for the HAC dendrograms can be found in appendix Figures A1 and A2.

5 Discussion

Through this work, physiology annotation guidelines were developed to support corpus development for automatic named entity and relation extraction from medical text using NLP methods, towards the goal of knowledge graph triplet generation. The evaluation results reveal both promise and limitations of using these guidelines as a foundation for that task. While the guidelines provide a structure for both entity and relation annotation that can be generalized to cover a broad range of normal physiology, the feasibility of automated triplet extraction depends on the performance of both NER and relation extraction, each of which presents with different challenges.

In terms of NER, the ontology coverage evaluation demonstrated that no single ontology is sufficient to capture the full range of terms present across all categories. This is consistent with prior work showing that ontologies often provide only partial representations of a domain (Abad-Navarro et al., 2025). The UMLS exhibited the best overall coverage, however relationship terms showed lower coverage, likely reflecting that UMLS is primarily organized around biomedical entities rather than relational predicates. Additionally, these ontologies are generally not designed to capture higher-level, abstract representations, but instead focus on domain specific-concepts. As a result, although our terms are similar to those found in existing ontologies, they are often not represented because they are broader in scope and intended to capture relationships across a wide range of physiological contexts. For example, in the UMLS, the generalized relationship term *Prevents* is not explicitly represented as a standalone concept; however, more specific phrases such as *Chair prevents rising*, *Prevents risky behaviors*, and *Prevents skin barrier interruption* are included. These findings support prior work demonstrating that UMLS does not fully cap-

ture all concepts and relationships within a given domain (Yu et al., 1999). Therefore, our future work will explore combining multiple ontologies, as integrating resources has been shown to support more complete domain representation (Osman et al., 2021), alongside mapping strategies to improve entity coverage across all categories.

For relation extraction, the dependency and constituency parsers show different results in relation coverage. The dependency parser's slightly higher individual manual relation coverage (0.50) relative to its corpus-wide distinct relation coverage (0.48) suggests it performs better on more frequently occurring relation types found in our corpus. The constituency parser, despite achieving perfect corpus-wide distinct relation coverage, showed a notable drop at the individual relation level (0.61), driven largely by a high false positive rate. Nevertheless, the constituency parser shows greater promise as a basis for automated relation extraction, and prior work has demonstrated that constituency-based approaches can be effective when combined with rule-based filtering to reduce false positives (Jiang and Diesner, 2019). In future work, we aim to expand the text corpus to additional open access medical textbooks and explore how post-processing of constituency parser outputs can be used to extract relevant relations.

6 Conclusion

We present an annotation guide for anatomical entities and physiological events in biomedical textbooks, designed to support the automated construction of knowledge graph triples from free text. To access the feasibility of translating free medical text into a structured format, we annotated a selected text corpus and evaluated ontology coverage of our annotations across OLS ontologies and the UMLS. We evaluated the coverage of relation extraction by assessing the coverage of annotated relation pairs within parser outputs. Our results demonstrate that while existing ontologies and parsers provide partial coverage, significant gaps remain. These findings motivate future work in multi-ontology integration and post-processing strategies for parser outputs. This work represents a step toward making rich knowledge present in medical textbooks accessible in a computable format that can support development of clinical knowledge discovery platforms.

7 Limitations

This study is a pilot study utilizing a smaller sample size with text specific to our use case of GLP-1 physiology. This use case was selected because it was believed that a schema developed from it could be generalized and applied to other physiological functions, though this remains to be validated.

8 Ethics

This work includes limited use of content from *Guyton and Hall Textbook of Medical Physiology* (14th Edition) (Hall et al., 2021) for purposes of non-commercial research and computational analysis. The authors have conducted a good-faith assessment and believe this use is consistent with fair use principles (Association of College and Research Libraries, 2025).

Acknowledgments

A Appendix

Category	Label	Definition	Examples
Entity	Cell	A material entity that is the basic structural unit of tissue.	Liver cells, alpha cells
	Cell Component	A subcellular structure or molecular complex that is associated with a cell and contributes to its function.	Nucleus, mitochondria
	Chemical	A molecule, substance, or compound involved in a physiological function where its specific role is unclear, unknown, or not relevant.	Blood glucose, glycogen in the liver
	Measurement	A data item that quantifies something.	140 mg, fivefold, one-third
	Mediator	A chemical that actively influences, regulates, or triggers a physiological reaction or process.	Glucagon
	Organ	A distinct anatomical structure made up of multiple tissue types that performs one or more biological functions.	Liver, heart
	Organ System	A group of distinct anatomical structures that work together to perform one or more biological functions.	Respiratory system
	Substrate	A chemical that is acted upon, consumed, or transformed in a biological process or reaction.	Blood glucose
	Time	A temporal descriptor for how long or what pattern a physiological process occurs.	Few minutes, within minutes, first hour
	Tissue	A group of similar cells organized together for a specific physiological function.	Blood, connective tissue
Event	Physiological Function	A biological activity or outcome carried out by cells, tissues, organs, etc. that contributes to normal body function.	Secretion, glucose uptake
	Physiological State	A condition, status, or internal environment of the body at a given time.	Blood glucose concentration, fasting, exhaustive exercise
	Relationship	A word or phrase that describes how two or more annotated entities are connected, interact, or influence each other within the physiological context.	Activates, decreases, rises, increases
Attribute	Coreference	When two entities refer to the same named entity.	Blood glucose (increase) *coreference* this (increase)
	is_a	One entity is a type or category of another.	GLP-1 *is_a* chemical
	Rel	When two entities are in relation to another.	Release *Rel* insulin

Table A1: Label definitions for the entities, events, and attributes included in the annotation schema. Contents within parenthesis are additional context not included in the named entity. Entities, Chemical, Substrate, and Mediator, were developed to distinguish molecules and compounds based on their functional role within the physiological context rather than chemical identity. Chemical serves as the catch-all label, substrate and mediator are more specific subcategories of Chemical. Three attribute labels, Coreference, is_a, and Rel, were developed to capture additional contextual information that cannot be fully expressed through entity or event labels alone.

Common Multi-Word Expressions
Blood glucose (concentration/level)
(Increase/Decrease) in blood glucose
(High/Low) concentrations
Effects of (Chemical/Mediator/Substrate)
(Chemical/Mediator/Substrate) secretion
(Chemical/Mediator/Substrate) function
(Chemical/Mediator/Substrate) concentration
Blood glucose buffer system
Enzyme system
Glucose (stimulus/concentration)
Feedback mechanism
Feedback control system
Fasting level / Normal value
(Modifier) level
After a meal

Table A2: Common multi-word expressions identified in the GLP-1 physiology corpus. These multi-word expressions represent self-contained triples and were consolidated for simplicity, with the understanding that they can be decomposed into their constituent terms during post-processing. In cases where the surface representation of a phrase was disjoint, annotators were instructed to combine the constituent terms into a single fragment phrase capturing the full expression.

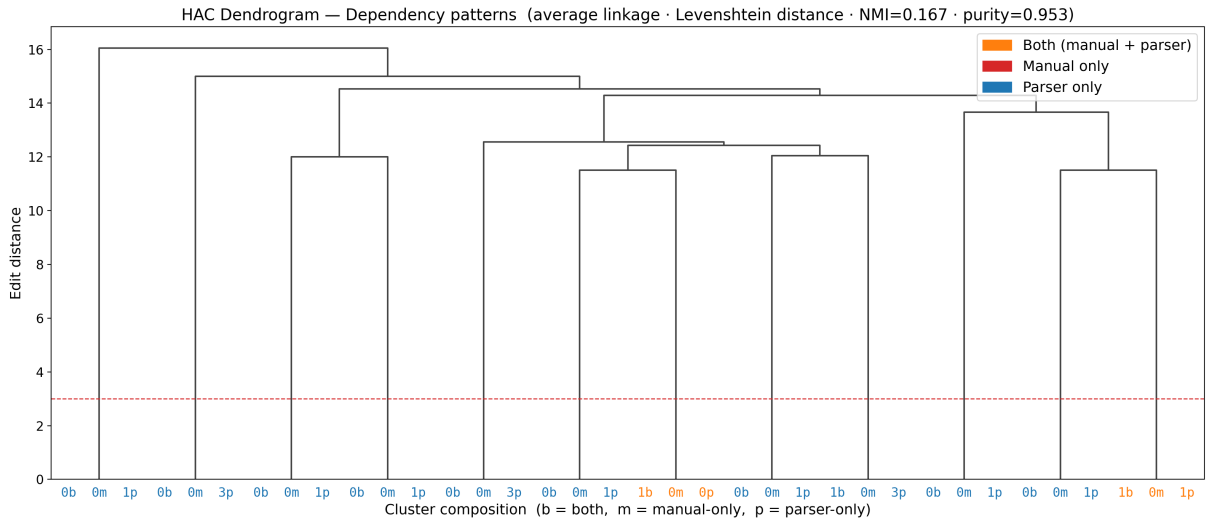

Figure A1: HAC dendrogram for dependency parser relation pattern clustering (average linkage, Levenshtein distance). The dashed red line indicates the cut height used to form final clusters; leaf labels show per cluster counts of patterns found in both sources (b), manual annotation only (m), and parser only (p). Clusters span edit distances up to 16, reflecting considerable structural diversity among dependency relation patterns.

Ontology	**Entities** (N = 29)	**Physiological Process** (N = 23)	**Physiological State** (N = 13)	**Relationship** (N = 55)

Unmatched (OLS)	7	11	7	29
UMLS				
Coverage	0.55	0.35	0.23	0.11
Unmatched	13	15	10	49

Table A3: Ontology coverage of terminology categories (Entities, Physiological Process, Physiological State, and Relationship) queried against OLS and the UMLS. Coverage values reflect the proportion of distinct terms matched within each ontology. Coverage counts that are inside parenthesis are not part of the top five ontologies for that category, but still contain some coverage. (—) indicates no coverage was found. Unmatched counts reflect terms not found in any OLS ontology or the UMLS. OMIT=Ontology for miRNA Targets (Huang et al., 2011); MESH=Medical Subject Headings (Sewell, 1964); NCIT=National Cancer Institute Thesaurus (Sioutos et al., 2007); CHEBI=Chemical Entities of Biological Interest (Degtyarenko et al., 2007); HCAO=Human Cell Atlas Ontology (Welter et al., 2018); SNOMED=Systematized Nomenclature of Medicine—Clinical Terms (U.S. National Library of Medicine, 2026); EFO=Experimental Factor Ontology (Malone et al., 2010); PRIDE=Proteomics Identification Database Ontology (Perez-Riverol et al., 2022); INO= Interaction Network Ontology (Özgür et al., 2016); BIOLINK=Biolink Model (Unni et al., 2022); SLSO=Space Life Sciences Ontology (Berrios et al., 2024); AFO=Allotrope Foundation Ontology (Millecam et al., 2021); UMLS=Unified Medical Language System (Bodenreider, 2004)

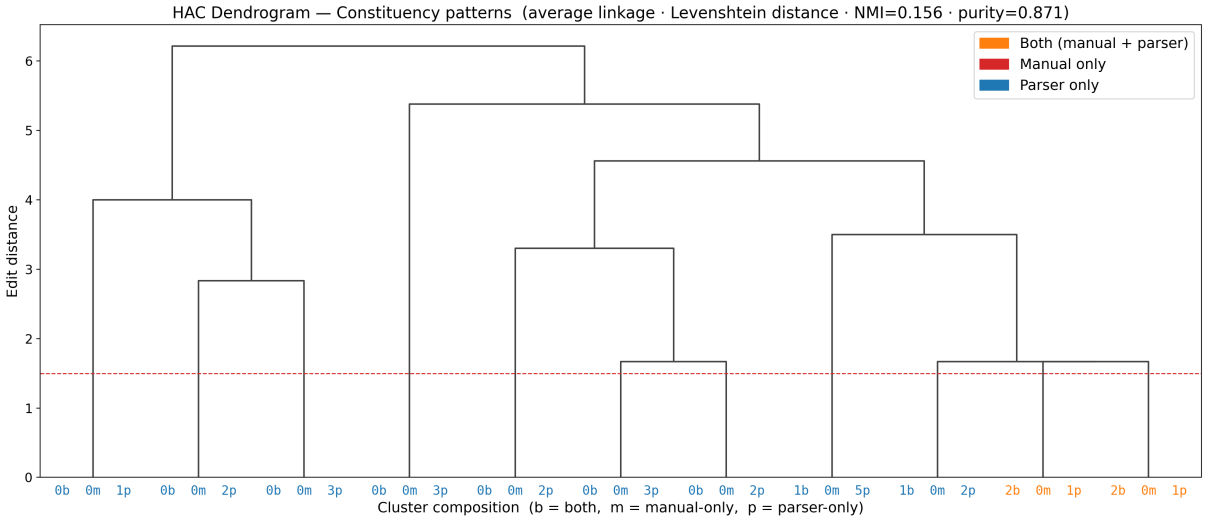

Figure A2: HAC dendrogram for constituency parser relation pattern clustering (average linkage, Levenshtein distance). he dashed red line indicates the cut height used to form final clusters; leaf labels show per cluster counts of patterns found in both sources (b), manual annotation only (m), and parser only (p). Cluster span edit distances up to 6, considerably lower than dependency relation patterns, likely reflecting the constrained phrase-label vocabulary from which the constituency relation patterns are constructed.

CENT: Context Engineering Framework for Normalization of Clinical Trial Procedures

Abstract

Clinical Concept Normalization is essential for clinical research applications involving trial protocols, such as patient-trial matching. Existing approaches focus heavily on specific domains and need large, annotated datasets. To address these challenges, we propose CENT, a context engineering framework that combines semantic matching for candidate retrieval and Large Language Model (LLM) prompting for disambiguation. CENT achieves superior performance on clinical procedures normalization in both binary and hierarchical metrics compared to semantic matching or LLM-only approaches, without requiring fine-tuning. Advanced prompt strategies, including Chain-of-Thought and Tree-of-Thoughts, achieve high performance at practical cost. CENT is scalable and adaptable for normalization across diverse clinical vocabularies in real-world clinical applications.

1 Introduction

Clinical Concept Normalization (CCN), often referred to as entity linking, standardizes terms in clinical texts, such as clinical trial protocols, to standard concepts in clinical coding systems (e.g., ICD, SNOMED-CT, LOINC). In practice, normalization for clinical research applications is often performed as an ad hoc step, either as a manual effort or more commonly with string matching before downstream tasks, such as patient-trial matching (Wong et al., 2025). This limits both scalability and reliability in real-world deployments, where concept variations and ambiguous terminology are common (Wong et al., 2023).

For clinical trial protocols, CCN ensures reliable information retrieval and enables comparative analysis across trials in terms of eligibility criteria, disease evaluation steps or schedule of activities, predictive modeling using data from historic trials, and patient trial matching (Danhauser et al., 2025; Lopez et al., 2025).

Despite advances in semantic matching with pretrained and fine-tuned BERT-based models and, more recently, transformer models, biomedical entity linking remains challenging without domain-specific adaptation. Prompting general-purpose Large Language Models (LLMs) to assign codes to diagnosis and procedure descriptions has shown subpar performance and hallucinated codes (Soroush et al., 2024). Moreover, relying solely on LLMs for entity linking requires fine-tuning for each clinical coding system, which is expensive (Berkowitz et al., 2025).

We introduce **C**ontext **E**ngineered **N**ormalization for Clinical **T**rials (CENT) framework that leverages semantic matching to retrieve highly relevant information, which is then used in structured prompts to perform CCN. In CENT, semantic matching efficiently generates high-recall candidate matches, while LLM prompting improves disambiguation among closely related candidates without the need for extensive annotated data or vocabulary-specific fine-tuning.

Objective: To develop and evaluate a context engineering framework, CENT, for CCN in trial protocols, focusing on laboratory procedures, and benchmarking performance using binary and hierarchical metrics on a publicly available dataset.

Contributions:

- A context engineering framework, CENT, that combines semantic matching for context retrieval with LLM prompting for CCN.
- Evaluation of CENT using various prompt strategies on a publicly available clinical procedures dataset, assessed with both binary and hierarchical metrics.
- Comparative evaluation of CENT against embedding models and LLM-only prompting for CCN.

1.1 Related Work

Current state-of-the-art CCN systems and benchmark datasets primarily focus on normalizing diseases, symptoms, and chemicals, while clinical procedures and laboratory measurements are underrepresented. This results in incomplete normalization of clinical trial protocols and is a significant barrier for real-world automated protocol analysis and benchmarking. While CCN tools such as MedLinker, SciSpacy, and cTAKES support entity linking for procedures (Kartchner et al., 2023), these systems typically rely on string matching, leading to suboptimal performance.

Semantic matching models, such as SapBERT (Liu et al., 2021) that is fine-tuned with Unified Medical Language System (UMLS) concepts, have demonstrated strong similarity-based matching for biomedical entities (Kartchner et al., 2023). Semantic matching approaches with domain-specific embeddings achieve high recall and are effective at candidate generation, however, they struggle in candidate disambiguation as the size of the target vocabulary increases (Kartchner et al., 2023). Moreover, these systems are primarily optimized for diseases, drugs, and chemicals, as most benchmark datasets (e.g., NCBI Disease, BC5CDR) focus on these domains (Ferré et al., 2020; Yang et al., 2023).

Recent work has explored the use of LLMs and generative AI approaches for CCN. Berkowitz et al. (2025) developed RAGNorm, a system that combines semantic matching with LLM prompting to normalize biomedical texts to SNOMED-CT codes. RAGNorm uses general-purpose models for both semantic matching and prompting, and while it outperformed the baseline semantic matching methods, the authors highlight challenges with generalizability and a decline in performance with increased target vocabulary size. Soroush et al. (2024) found that prompt-based LLMs frequently hallucinate invalid or non-specific codes when relying on internal knowledge of clinical vocabularies, and that prompt engineering alone could not consistently produce correct codes for all concept descriptions. Other studies have noted the high computational cost and limited improvements with LLM-only pipelines compared to semantic matching and domain-specific embeddings in the biomedical normalization task (Dobbins, 2024; Wang et al., 2024). Jahan et al. (2024) observed that baseline models such as BioBART still outperform LLMs in recall for chemical and disease normalization, especially with small datasets and large vocabularies.

Combining the strengths of semantic matching and LLM prompting, however, appears to be a promising approach for CCN in specialized domains (Borchert et al., 2024; Berkowitz et al., 2025). Strategic prompt design with curated context beyond simple prompts can help overcome the limitations of LLM-only normalization approaches. In this work, we present CENT, a framework that integrates 1) domain-specific semantic matching to retrieve relevant context, followed by 2) a structured prompt design that embeds the retrieved context, and 3) explicit evaluation rubric to guide the LLM in performing CCN.

Evaluating CCN systems remains challenging due to variability across datasets, biases in scoring metrics, the lack of clear separation between entity recognition and subsequent normalization tasks, and the predominant focus of benchmark datasets on diseases and drugs (Kartchner et al., 2023; Ferré et al., 2020). Furthermore, prior evaluations rely primarily on binary metrics such as accuracy, precision, and recall, overlooking the hierarchical nature of clinical coding systems, which warrants more nuanced assessments that account for relationships among concepts (Ferré and Langlais, 2023). To address these gaps, in this study, we adapt hierarchical evaluation metrics to provide a more comprehensive assessment of CCN performance for normalization of clinical procedures.

2 Datasets

In this work, we evaluate our proposed CCN framework on the LOINC to CPT mappings of laboratory procedures available through UMLS (National Library of Medicine, 2006). LOINC, created by the Regenstrief Institute, is the universal standard for laboratory tests and clinical observations (Regenstrief Institute, 2025). The CPT vocabulary, created and maintained by the American Medical Association, is used for reporting procedural activities and services for billing and reimbursement (American Medical Association, 2025). Both vocabularies are commonly used for coding of activities related to clinical trials.

The UMLS LOINC–CPT mappings dataset contains 2,019 LOINC concepts linked to CPT codes; in some cases, multiple LOINC concepts map to a single CPT code. We excluded mappings to 21

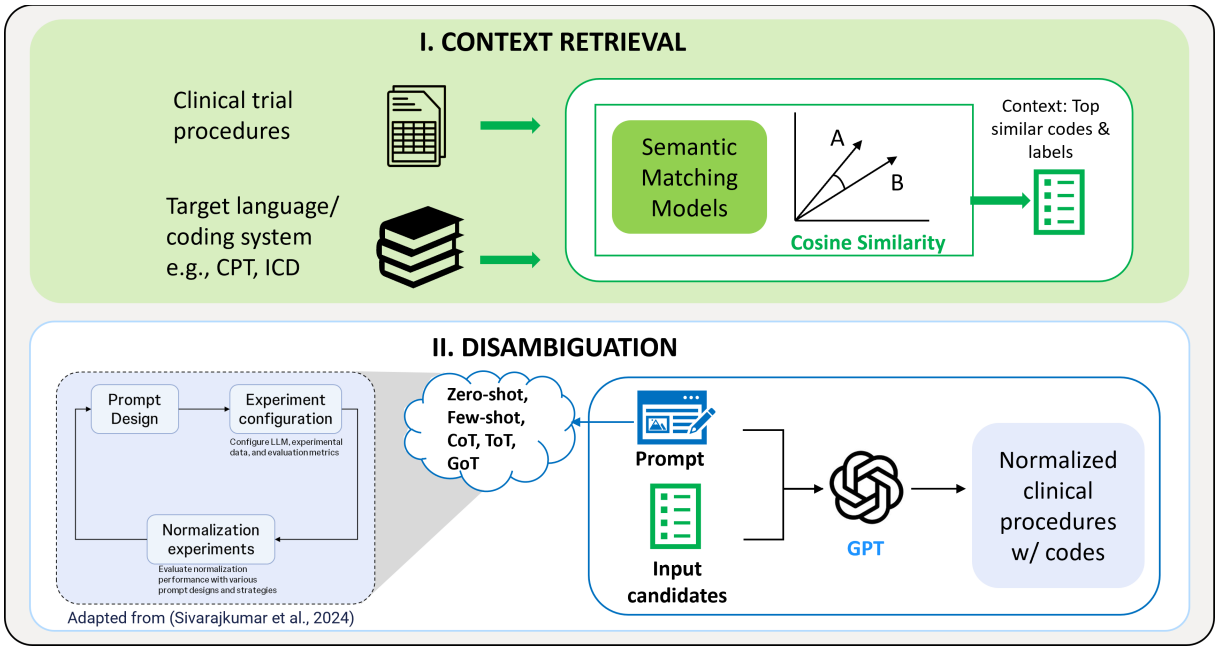

Figure 1: Overview of the CENT framework (I) Context retrieval with semantic matching, and (II) context engineering and prompt designs for disambiguation with GPT models. Iterative prompt design is based on prior work (Sivarajkumar et al., 2024) with zero-shot, few-shot, Chain-of-Thought (CoT), Tree-of-Thoughts (ToT), and Graph-of-Thought (GoT) prompt strategies.

deprecated CPT codes (44 mappings removed). We also excluded three non-specific allergen-related CPT codes—86001, 86003, and 86005—removing 314, 1,017, and 95 mappings, respectively, as these codes are unrelated to trial procedures and outside the scope of normalization. After these exclusions, 593 LOINC-CPT mappings remained. LOINC and CPT concept labels were further processed to remove punctuation and tokenized (average LOINC tokens = 7.6, average CPT tokens = 11.3).

We used CPT vocabulary (v2015) codes and labels as the target concept data for evaluation, as this was the last publicly available version of CPT. These CPT concepts were filtered to include the measurement domain only, resulting in 1,584 CPT target codes and labels.

2.1 Protocol-derived Datasets

We additionally applied CENT to two internal datasets of clinical assessments extracted from schedule of activities tables in clinical trial protocols. Dataset 1 includes 669 unique laboratory, diagnostic, survey, and billing procedures partially mapped to CPT codes, and Dataset 2 includes 139 laboratory/biomarker procedures from 20 trials mapped to a custom laboratory vocabulary (N=248 concepts). We applied CENT to predict target concepts for these datasets. For these datasets, we report quantitative metrics and expert review outcomes for the experiments with these protocol-derived datasets.

3 Methodology

We propose the CENT framework for CCN that systematically combines semantic matching with LLM prompting. CENT is designed to retrieve highly relevant context as top-ranked candidate codes and labels, and deliver it to the LLM in the form of structured, sectioned prompts (Figure 1).

3.1 Context Retrieval with Semantic Matching

In the first stage, CENT uses semantic matching with two fine-tuned domain-specific BERT-based models, SapBERT and BioBERT-mnli, to retrieve candidate concepts from the target vocabulary. SapBERT is a word-based model fine-tuned with UMLS concepts for medical entity linking and generates candidates based on closeness of concept embeddings in semantic space (Liu et al., 2021). BioBERT-mnli is a sentence transformer model fine-tuned with natural language inference and text similarity datasets that has been used to effectively classify sentences from randomized controlled trials (Deka et al., 2022). For each input term (e.g., LOINC concept), the models embed the concept

label and the resulting embedding is used to compute cosine similarity scores with embeddings of the target concepts (e.g., CPT concepts). The top 5 concepts with the highest scores from each model are added to a set and the scores are normalized. The concepts are then sorted by similarity scores and de-duplicated. The top unique candidates (up to 10) are used as the curated context formatted as code + label. Note that similarity scores are not passed to the LLM. By deliberately constraining the search space, this step serves as context engineering, shaping and refining the information available for downstream reasoning and matching.

Implementation: For SapBERT, we tokenize the texts with truncation enabled, embed in batches, with padding of all inputs to maximum tokens within the batch. For BioBERT-mnli, we use sentence-transformers with mean pooling, truncation, and dynamic batch padding. Both models generate 768-dimensional embeddings. We compute cosine similarity between input and target embeddings and retrieve the top k candidates per model. To further characterize the retrieval stage, we report recall@k on the LOINC-CPT dataset, where a query is counted as retrieved if ground truth CPT appears in the top-k candidate set.

3.2 Structured Prompts for Disambiguation

In the second stage, the query code and its label along side with the curated contextual information from the previous step are embedded in a structured prompt for the LLM. Prompts are organized into clearly defined sections, including 1) description of the CCN task, 2) explicit rubric to guide the LLM in performing CCN, 3) instructions to score LLM thoughts, 4) examples of the CCN to be done along with reasoning for the selected matches, and 5) the input query and the list of candidate matched codes with their labels (curated context). The LLM is instructed to select the single best candidate or return "no match" if appropriate.

For the CCN task in this paper, we designed zero-shot and few-shot prompt strategies using the DSPy library (Khattab et al., 2023) and adapted the open-source Graph-of-Thoughts repository (Besta et al., 2024) to implement the Chain-of-Thought (CoT) (Wei et al., 2022), Tree-of-Thoughts (ToT) (Yao et al., 2023), and Graph-of-Thoughts (GoT) strategies. Broadly, the operations involved are (1) prompt the LLM (*generate_prompt*) to map input concept to corresponding target concept based on the context of candidate codes and labels, (2) parse and score the LLM response (*score_prompt*), (3) improve the final response based on the context (*tot_improve_prompt*) or aggregate responses (*aggregate_prompt*), and (4) keep the best scoring response. The scores are calculated by the LLM on a scale of 0-5 using the *score_prompt*. For details of prompts used in the task, see Appendix A. Each prompt strategy was tested and improved iteratively. The prompt design and iterative evaluation was based on prior research on task-specific prompt design and improved performance of heuristic and ensemble prompts in complex clinical information extraction and disambiguation tasks (Sivarajkumar et al., 2024).

Implementation: ToT is defined with branch factor 10 and depth 3 while GoT is defined with branch factors 10 and 20. We used the GPT4.1 (OpenAI, 2025a) and GPT4o-mini (OpenAI, 2024) models to assess the impact of the model size on performance and cost with temperature equal to 1.0 and maximum output tokens equal to 10000.

For the comparative evaluation with direct LLM prompting without engineering context, we provided the input term along with 1,584 CPT target codes and labels to the GPT4o-mini model. The total prompt and context was approximately 65,000 tokens (context window of model is 100,000 tokens). For comparative context-retrieval models, we utilized the OpenAI API for text-embedding-ada-002 model (OpenAI, 2022). We accessed GPT models via an Azure OpenAI endpoint with access-controlled API keys. CENT is designed to be model-agnostic and can be used with private endpoints and locally deployed LLMs, if required.

4 Evaluation

We evaluated CENT with binary metrics, hierarchical metrics, and total cost (in US dollars) for CCN on the LOINC-CPT dataset. Binary metrics included precision@5, recall@5, and F1 score. Cost was measured by the input and output tokens in the prompts based on the OpenAI API pricing for the models (OpenAI, 2025b). We report the total cost of the LOINC-CPT normalization task with 593 mappings. The performance evaluation also included comparison against: 1) semantic matching only using SapBERT, 2) semantic matching only using OpenAI text-embedding-ada-002 model, 3) context retrieval using OpenAI text-embedding-ada-002 model followed by LLM prompting for disambiguation, and 4) direct LLM prompting without

engineered context.

4.1 Hierarchical Metrics

Hierarchical metrics take into account hierarchical characteristics of predicted codes in CCN, including concept position within the ontology, ancestral and descendant information, and relationship with the correct match. Unlike binary metrics that only determine if a predicted code is an exact match, hierarchical metrics incorporate partial correctness, capture ontological distance, and reward higher semantic similarity for close mismatches. We included two hierarchical metrics in our evaluation, Wu-Palmer similarity and Resnik similarity.

Wu-Palmer Similarity. Wu-Palmer Similarity (Wu and Palmer, 1994) is a structural similarity measure that quantifies the closeness of two concepts within an ontology, based on their depth (distance from the root concept) and the depth of the lowest common ancestor (LCA). For concepts a and b:

$$\text{Wu–Palmer}(a,b) = \frac{2 \times \text{depth}(\text{LCA}(a,b))}{\text{depth}(a) + \text{depth}(b)} \quad (1)$$

The score ranges from 0 to 1, with higher values indicating greater semantic overlap.

Resnik Similarity. Resnik similarity (Resnik, 1995) is calculated as the information content (IC) of the LCA of two nodes in the hierarchy to measure the closeness of two nodes by how informative their LCA is.

$$\text{Resnik}(a,b) = IC(\text{LCA}(a,b)) \quad (2)$$

IC is calculated using the proposed method by Seco et al. (2004) to use the ontology's structure:

$$ic(c) = 1 - \frac{\log(\text{descendants}(c) + 1)}{\log(\text{total concepts})} \quad (3)$$

Resnik similarity is higher for concepts with LCA lower in the hierarchy.

The UMLS API (National Library of Medicine, 2025) was used to extract ontological relationships, including ancestors, descendants, and depth for CPT codes. Ancestors and descendants were identified recursively through the UMLS API endpoints *parent* and *children* to preserve the hierarchical order. For cases with "no match", hierarchical metrics values were set to 0.

5 Results and Discussion

Table 1 presents the evaluation results of CENT on the LOINC-CPT dataset. CENT consistently outperformed the comparative methods, including semantic matching alone and direct LLM prompting-across both binary and hierarchical metrics. The highest F1-score was achieved by CENT with CoT prompting (0.82), while the highest Wu-Palmer similarity (0.86) and Resnik similarity (0.87) were observed with ToT prompting. When compared to embedding-only approaches, CENT achieved a marked improvement in precision (highest precision 0.86 with CENT vs 0.15 with SapBERT-only) and Wu-Palmer similarity (0.77-0.86 with CENT vs 0.53 with SapBERT-only), indicating that normalized codes by CENT are not only more accurate but, if not an exact match, are closer to the correct matches in the ontology. Direct LLM prompting performed poorly across all metrics with prohibitive costs, confirming prior findings that this approach is infeasible for CCN (Soroush et al., 2024).

A comparison of embedding models within CENT (SapBERT + BioBERT-mnli) and a general-purpose OpenAI model (text-embedding-ada-002) further underscores the value of domain-specific embeddings for CCN. Using zero-shot prompting, CENT with SapBERT + BioBERT-mnli achieved an F1 score of 0.79, compared to 0.64 for the OpenAI text-embedding-ada-002 model followed by LLM zero-shot prompting. These findings corroborate prior reports that domain-specific models outperform general-purpose models on clinical data classification tasks (Gao et al., 2025).

Across prompt strategies, CENT with CoT achieved high performance (F1-score 0.82 with GPT4.1 and 0.80 with GPT4o-mini), while ToT and GoT were stronger in hierarchical metrics (Wu-Palmer similarity 0.86 and 0.85, respectively). GoT, despite adding operational complexity and cost, did not offer improved performance except for the lowest percentage of "no match" predictions (0%), followed by ToT (0.3%). The "no match" percentage indicates the failure to identify any matches. In contrast, CENT with zero-shot and few-shot prompts resulted in the highest percentage of "no match" predictions (14.1% and 12.8%, respectively). Error analysis has shown that, when allowed, CENT over-predicts codes (i.e., predicted code set includes more than one candidate) rather than "no match".

Cost is a critical factor for real-world and re-

Approach	Prompt Strategy	Precision @5	Recall @5	F1	Wu-Palmer	Resnik	% "no match"
CENT GPT4.1	Zero-shot	**0.87**	0.74	0.80	0.77	0.77	14.8
CENT GPT4.1	Few-shot	0.86	0.76	0.81	0.79	0.79	10.8
CENT GPT4.1	CoT	0.86	0.79	**0.82**	0.84	0.84	5.1
CENT GPT4.1	ToT	0.81	**0.81**	0.81	**0.86**	**0.87**	0.3
CENT GPT4.1	GoT	0.79	0.78	0.78	0.85	0.85	0.7
CENT GPT4o-mini	CoT	0.82	0.78	0.80	0.84	0.85	7.2
CENT GPT4o-mini	ToT	0.79	0.79	0.79	0.85	0.86	0.5

Embedding only (SapBERT)	-	0.15	0.74	0.25	0.53	0.56	-
Embedding only (ada-002)	-	0.15	0.76	0.25	0.55	0.62	-
ada-002 + GPT4.1	Zero-shot	0.64	0.64	0.64	0.81	0.82	0.3
LLM only (GPT4o-mini)	Few-shot	0.05	0.17	0.08	0.50	0.58	3.1

Table 1: **Top.** Evaluation of CENT with binary and hierarchical metrics for LOINC-CPT mappings (N=593). "no match" indicates cases where the model did not return any normalized code. **Bottom.** Evaluation of comparative approaches: (i) SapBERT only for CCN, (ii) OpenAI ada-002 for context retrieval and GPT4.1 for disambiguation, (iii) OpenAI ada-002 only, and (iv) LLM-only with GPT4o-mini for CCN.

Approach	Prompt Strategy	F1-score	Cost (USD)
CENT*	Zero-shot	0.79	0.36
CENT*	Few-shot	0.80	0.37
CENT*	CoT	**0.82**	12.89
CENT*	ToT	0.81	37.57
CENT*	GoT	0.78	59.89
CENT$^+$	CoT	0.80	0.56
CENT$^+$	ToT	0.79	2.66
CENT$^+$	GoT	0.78	3.27
LLM-only$^+$	Few-shot	0.08	102.5

Table 2: Cost (in USD) of API calls and F1-score for the prompt strategies used to evaluate CENT with LOINC-CPT dataset (N=593). "*" denotes GPT4.1 used for disambiguation and "$^+$" denotes GPT4o-mini model.

search applications. Table 2 presents the cost (in USD) of the API calls used for CENT with different prompt strategies in the LOINC-CPT normalization. While ToT and GoT prompting have higher costs ($37.57 and $59.89, respectively) compared to other strategies, our experiments showed that comparable performance is achievable with the smaller GPT4o-mini model using these advanced prompt strategies, but with significantly lower cost (e.g., cost for CENT with GPT4o-mini & ToT was $2.66 vs $37.57 for CENT with GPT4.1 & ToT).

Table 3 presents the results of the retrieval ablation analysis in the LOINC-CPT mapping experiment. Union of candidates from both models (SapBERT and BioBERT-mnli) achieves the highest recall (recall@10 improves to 0.85), improving the downstream CCN task driven by the retrieved context (union of candidates). Moreover, increasing the number of per-model candidates (k) from 5 to 10 produces no appreciable gains, indicating that CENT remains effective even with a small number of candidates.

To the best of our knowledge, this work represents the first implementation of advanced prompt strategies (ToT, GoT) for the CCN task. Compared to general tasks evaluated by Besta et al. (2024) where GoT outperformed other strategies, it is evident that model and prompt strategy selection for domain-specific tasks such as CCN cannot be gen-

Retrieval	Recall @1	Recall @5	Recall @10
SapBERT only	0.51	0.74	0.80
BioBERT-mnli only	0.59	0.79	0.82
Union (SapBERT ∪ BioBERT-mnli)	–	0.83	0.85

End-to-end (CENT+CoT)	F1	% "no match"
Union candidates, $k = 5$ per encoder	0.82	5.1
Union candidates, $k = 10$ per encoder	0.83	5.3

Table 3: Retrieval ablation and end-to-end sensitivity for LOINC-CPT mappings. Recall@k measures whether the ground truth CPT code is present in the top-k retrieved candidates.

eralized out of the box. The combined use of binary and hierarchical metrics provides a more complete evaluation: binary metrics alone may over- or underestimate model performance, but hierarchical metrics can indicate whether the predicted codes are proximally closer to the ground truth code in the ontology. For instance, CENT with ToT prompting showed lower F1-scores than CoT but higher Wu-Palmer and Resnik scores, indicating that even when predictions are incorrect, they are semantically closer to the ground truth.

Internal Validation: We applied CENT to the protocol-derived procedures, which are noisier and less standardized than LOINC labels. Examples of procedures included laboratory panels (chemistry, hematology), abbreviated texts (PSA, UPEP), imaging procedures (MRI Abdomen), biomarker assays (Serum biomarkers). For the 139 laboratory/biomarker procedures normalized to custom vocabulary concepts (Dataset 2), CENT (few-shot) achieved precision@5=0.77, recall@5=0.65, and F1=0.71. This dataset included instances with multiple target concepts and instances with no valid matches; "no match" is counted correct only when the ground truth is empty. For the dataset with 669 procedures (Dataset 1), we ran CENT to predict CPT codes, and 3 clinician-experts manually reviewed a random sample of 59 laboratory procedures. Each of 3 experts reviewed 20 samples with partial overlap. The outcomes were 28/59 (47.5%) exact matches to expert annotation, 17/59 (28.8%) partial matches (sibling/parent relationships), and 14/59 (23.7%) incorrect CENT match when compared to expert annotations.

Together with the benchmark dataset, these results suggest CENT can operate on noisy and often non-standard clinical texts common in real-world data (e.g., clinical protocols). Notably, the optimal choice of models and prompt strategy should be guided not only by performance metrics but also by specific use case requirements, the target vocabulary, acceptable operational costs, and the prevalence of "no match" scenarios in the real-world data. CENT enables high-recall candidate generation and robust candidate disambiguation for CCN without model fine-tuning or annotated training datasets. CENT does not require model training and allows for substitution of prompt formats, LLMs, and reference clinical vocabulary system as needed for domain adaptation.

6 Conclusion

We present a context engineering framework, CENT, for CCN that combines semantic matching with domain-specific models for context engineering and LLM prompting for disambiguation. CENT consistently outperformed other methods - including semantic matching alone and LLM-only - on laboratory procedures with both binary and hierarchical metrics without any fine-tuning or annotated training data. CENT enables scalable, cost-effective normalization to support real-world clinical research applications. Ongoing work involves applying CENT to use cases in clinical trial optimization and benchmarking, and exploring further prompt strategies to refine normalization.

Limitations

This study has several limitations. First, the evaluation mainly focused on a single dataset with laboratory procedures, along with two internal datasets for validation. The framework will need to be evaluated on larger, diverse datasets with more entity types and clinical vocabularies. Second, prompt design is currently a manual process in CENT that must be tailored for other CCN tasks. Finally, our prompts were limited to GPT models and cost calculations are based on current API pricing. The performance may not reflect future changes in models and re-evaluation of CENT is warranted with newer LLMs.

A Appendix: Prompts

We present the prompts for the LOINC-CPT normalization task. **zero_shot** and **few_shot** prompts included simple instructions for the task along with the input LOINC concept and candidate concepts from context retrieval. For Chain-of-Thought (CoT), Tree-of-Thoughts (ToT), and Graph-of-Thought (GoT) prompting, we extended the graph-of-thoughts framework (Besta et al., 2024) to create a LOINC-CPT normalization task. Graph-of-thoughts describes prompt operations as 'transformations of thoughts' that ultimately give the final response from the language model. The **generate_prompt** generates new thoughts from a single thought with a branching factor to define the number of thoughts generated. The **tot_improve_prompt** enhances a given thought using information provided in another thought (could be generated previously). The **aggregate_prompt** aggregates thoughts into new ones in GoT. Thus, for the LOINC-CPT normalization task, CoT was modeled with the `generate` operation, ToT with `generate` and `improve` operations, and GoT with `generate` and `aggregate` operations. All three prompt strategies used the **score_prompt** for scoring the LLM responses. Examples for the prompts were generated from UMLS, however, these can be alternately created by experts or by varying the ground truth data. Other configurations of the operations can be implemented depending on the task and desired complexity of operations.

zero-shot prompt:

<Instruction>

You are an expert clinical assistant. You are provided with a LOINC measurement concept delimited by <> and a list of candidate CPT concepts for matching, delimited by []. These candidates are generated using a BERT model, which assesses the similarity between the embeddings of the LOINC query and all CPT concepts. The first candidate in the ranked list is the most similar CPT concept to the LOINC query based on BERT similarity. For the given LOINC concept and candidate list, your task is to -

1. Assess the candidate CPT concepts based on your knowledge about laboratory terms and clinical vocabularies. Create a new candidates list by reordering and/or removing concepts. If the original list is correct, do not create a new list. If there are no good candidate concepts for the LOINC concept, create an empty list.
2. Then using the new list of candidates, select the best match for the given LOINC concept. There is only one best CPT match in the candidate list for the given LOINC concept. A good match in the candidate list of CPT concepts is when the candidate exactly matches the LOINC concept or is related to the LOINC concept.
3. Return the matched code in a list selected only from the candidates provided. If there is no good match in the list of candidates, return ['no match']. Return the output as list only and no other text.

</Instruction>

Term: <term>
Candidates: [candidates]

---

few-shot prompt:

<Instruction>

You are an expert clinical assistant. You are provided with a LOINC measurement concept delimited by <> and a list of candidate CPT concepts for matching, delimited by []. These candidates are generated using a BERT model, which assesses the similarity between the embeddings of the LOINC query and all CPT concepts. The first candidate in the ranked list is the most similar CPT concept to the LOINC query based on BERT similarity. For the given LOINC concept and candidate list, your task is to -

1. Assess the candidate CPT concepts based on your knowledge about laboratory terms and clinical vocabularies. Create a new candidates list by reordering and/or removing concepts. If the original list is correct, do not create a new list. If there are no good candidate concepts for the LOINC concept, create an empty list.
2. Then using the new list of candidates, select the best match for the given LOINC concept. There is only one best CPT match in the candidate list for the given LOINC concept. A good match in the candidate list of CPT concepts is when the candidate exactly matches the LOINC concept or is related to the LOINC concept.
3. Return the matched code in a list selected only from the candidates provided. If there is no good match in the list of candidates, return ['no match']. Return the output as list only and no other text.

</Instruction>

<Examples>

Term: 22360-2:HTLV I IgG Ab [Presence] in Serum
Candidates: [("86687","Antibody HTLV-I"), ("86296","HEPATITIS A ANTIBODY HAAB IGG AND IGM"), ("86709","Hepatitis A antibody HAAb IgM antibody"), ("82784","Gammaglobulin immunoglobulin IgA IgD IgG IgM each"), ("86701","Antibody HIV-1"), ("81381","HLA Class I typing high resolution ie alleles or allele groups one allele or allele group eg B*5701P each"),

("86001","Allergen specific IgG quantitative or semi-quantitative each allergen")]
Answer: ["86687"]

Term: 14416-2:Calcium [Moles/volume] in Pleural fluid
Candidates: [("82330","Calcium ionized"), ("82310","Calcium total"), ("82331","Calcium after calcium infusion test"), ("82340","Calcium urine quantitative timed specimen"), ("82360","Calculus quantitative analysis chemical"), ("80410","Calcitonin stimulation panel eg calcium pentagastrin This panel must include the following Calcitonin 82308 x 3")]
Answer: ["82310"]
</Examples>

Term: <term>
Candidates: [candidates]

---

generate_prompt for CoT, ToT, GoT:

<Instruction>
You are an AI medical coding assistant designed to help healthcare providers accurately map LOINC codes to their corresponding or nearest CPT codes. You will be provided with a LOINC laboratory code and name in the format query_lab_code:query_lab_name, referred to as the LOINC query, hereafter. Occasionally, you may also receive a ranked list of candidate CPT code matches, with each match formatted as a list of tuples; for example: []. These candidates are generated using a BERT model, which assesses the similarity between the embeddings of the LOINC query and all CPT concepts. The first tuple in the ranked list is the most similar CPT concept to the LOINC query based on BERT similarity.

Your goal is to identify the most appropriate CPT match(es) for the LOINC query. A suitable CPT match should:

1. Exactly correspond to the LOINC concept, or
2. Be closely related (e.g., same lab family, sub-test of the LOINC query, or a broader lab panel that includes the LOINC query).

Your output **must** follow this exact format and be enclosed between <Match> and </Match> tags: <Match>[("CPT_CODE","CPT_LABEL"), ("CPT_CODE","CPT_LABEL")]</Match>

Example of correct output: <Match>[("86256","Fluorescent noninfectious agent antibody titer each antibody"), ("82330","Calcium ionized")]</Match>
</Instruction>

<Approach>
1. Assess Candidate List Availability: If a candidate list is provided, review each candidate, then reorder, add, or remove concepts as needed to refine the list. If no candidate list is provided (i.e., the list is empty, "None", or ""): Generate a list of potential CPT matches for the LOINC query.
2. Evaluate Candidates: Use the refined candidate list to select the best CPT match(es) for the LOINC query. There may be multiple suitable matches or none at all.
3. Return Results: Output a list of the best matches. If no matches are found, return ['no match'].
</Approach>

<Examples>
LOINC query: 22360-2:HTLV I IgG Ab [Presence] in Serum
Candidate matches: [("86687","Antibody HTLV-I"), ("86296","HEPATITIS A ANTIBODY HAAB IGG AND IGM"), ("86709","Hepatitis A antibody HAAb IgM antibody"), ("82784","Gammaglobulin immunoglobulin IgA IgD IgG IgM each"), ("86701","Antibody HIV-1"), ("81381","HLA Class I typing high resolution ie alleles or allele groups one allele or allele group eg B*5701P each"), ("86001","Allergen specific IgG quantitative or semi-quantitative each allergen")]
<Match>[("86687","Antibody HTLV-I")]</Match>

LOINC query: 14416-2:Calcium [Moles/volume] in Pleural fluid
Candidate matches: [("82330","Calcium ionized"), ("82310","Calcium total"), ("82331","Calcium after calcium infusion test"), ("82340","Calcium urine quantitative timed specimen"), ("82360","Calculus quantitative analysis chemical"), ("80410","Calcitonin stimulation panel eg calcium pentagastrin This panel must include the following Calcitonin 82308 x 3")]
<Match>[("82310","Calcium total")]</Match>
</Examples>

<Input>
LOINC query: {query_lab_code}:{query_lab_name}
Candidate matches: {candidates}
</Input>

---

tot_improve_prompt for ToT:

<Instruction>
The following list represents the list of CPT matches for the LOINC query query_lab_code:query_lab_name:cpt_matches. These CPT matches might include wrong matches or might be an empty list shown as []. Your task is to find the correct CPT matches. Make sure if there are identified CPT matches, they are truly related to the LOINC query by ensuring that these matches are either exactly correspond to the LOINC query, or are closely related. Your output must follow this exact format and be enclosed between <Match> and </Match> tags:

<Match>
["CPT_CODE": "<CPT_CODE>", "CPT_LABEL": "<CPT_LABEL>","CPT_CODE": "<CPT_CODE>", "CPT_LABEL": "<CPT_LABEL>"]
</Match>

Replace <CPT_CODE> with the actual CPT code match and <CPT_LABEL> with its corresponding label. Only return valid matches inside the tags — do not include extra text.
Example of correct output: <Match>[("86256","Fluorescent noninfectious agent antibody titer each antibody"), ("82330","Calcium ionized")]</Match>
</Instruction>

<Approach>
To fix the incorrect list of CPT matches:

1. If there are CPT matches:
   (a) For each pair of CPT match, check which one is more related to the LOINC query and retain it and drop the other.
   (b) Iterate over the pairs of CPT matches, until you are left with a single match.
   (c) If the remaining CPT match is the exact same concept as LOINC query, sibling concept, parent concept, keep it, otherwise, remove it from the list.
   (d) Return the resulting match if any
2. If there are no CPT matches, indicate as an empty list

You are an AI medical coding assistant designed to help healthcare providers accurately map LOINC codes to their corresponding or nearest CPT codes. Use your knowledge to find the best match for query_lab_code:query_lab_name.
</Approach>

<Examples>
LOINC query: 13051-8:Protein S [Units/volume] in Platelet poor plasma
Matches: [("85306","Protein S [Units/volume] in Platelet poor plasma"), ("85305","Clotting inhibitors or anticoagulants protein S total")]
Reason: 85306 is the exact match, while 85305 is a sibling match. <Match>[("85306","Protein S

[Units/volume] in Platelet poor plasma")]</Match>

LOINC query: 14252-1:Smooth muscle Ab [Presence] in Serum
Matches: [("86015","Actin smooth muscle antibody ASMA each"), ("86256","Fluorescent noninfectious agent antibody titer each antibody"),(86381,"Mitochondrial antibody eg M2 each")]
Reason: The actual match is 86256 which is not in the list of matches. The closest match 86255 is a sibling match, while 86015 and 86381 are cousin matches (more distant than the sibling match).
<Match>[("86256","Fluorescent noninfectious agent antibody titer, each antibody")]</Match>
</Examples>

LOINC query: {query_lab_code}:{query_lab_name}

---

score_prompt for CoT, ToT, GoT:

<Instruction>
The following is the list of CPT matches for LOINC query query_lab_code:query_lab_name: current. CPT matches are formatted as a list of tuples, where each tuple in the list represents a match and has only two elements, where the first element is a CPT code and the second element is its corresponding CPT label. Score each match in terms of how closely it represents the LOINC query. A score of 5 implies that the match is the exact match, a parent match gets a score of 4, a sibling match gets a score of 3, and grandparent or grand child matches get a score of 2, cousins get a score of 1, and everything else get a score of 0. You may provide reasoning for your scoring, but you should put the final scores in a list between the tags <Score> and </Score>. The order of final score list corresponds to the order of CPT matches i.e., the first and second scores correspond to the first and second CPT matches, respectively.
</Instruction>

<Example>
LOINC query: 13051-8:Protein S [Units/volume] in Platelet poor plasma
Matches: [("85306","Protein S [Units/volume] in Platelet poor plasma"), ("85305","Clotting inhibitors or anticoagulants protein S total")]
Reason: 85306 is the exact match, while 85305 is a sibling match.
<Score>[5,3]</Score>
</Example>
LOINC query: {query_lab_code}:{query_lab_name}

---

aggregate_prompt for GoT:

<Instruction>
The following list of lists presents the potential CPT matches for query_lab_code:query_lab_name: current. Combine and merge them into one list to only retain top 5 most relevant ones, with no repeated matches. Your output must follow this exact format and be enclosed between <Match> and </Match> tags:
<Match>[("<CPT_CODE>","<CPT_LABEL>"), ("<CPT_CODE>","<CPT_LABEL>")]</Match>
</Instruction>

Agentic AI Architectures for SOAP Note Generation

Keno Hanken
Independent Researcher
Berlin, Germany
keno-hanken@labs.arg-os.eu

Abstract

Clinical documentation places significant time demands on medical professionals, consumes institutional resources, and is prone to errors that may compromise patient care. Recent advances in LLMs offer promising approaches for automating clinical note generation; however, the impact of different AI architectural designs remains underexplored, particularly for agentic AI systems. This study compares three architectures — single-LLM, multi-agentic, and swarm-agentic — for automated SOAP (Subjective, Objective, Assessment, Plan) note generation from doctor–patient dialogues. All approaches employ QLoRA-finetuned Ministral 3 models (3B and 8B parameters) trained on the MedSynth dataset (Mianroodi et al., 2025), comprising 10,030 dialogue–note pairs across 2,006 ICD-10 code classes. Performance is evaluated using ROUGE-1, ROUGE-2, ROUGE-L, and BERTScore against a lexical-overlap baseline (dialogue vs. ground-truth SOAP, no inference). Results show that all finetuned models substantially outperform the baseline, while differences between architectural variants remain marginal. The single-LLM setup achieves the strongest performance across all metrics; 3B and 8B variants perform nearly identically on semantic similarity (BERTScore), while ROUGE differences are small but statistically significant. Qualitative inspection further reveals that residual differences across architectures are driven primarily by shared dataset priors rather than by architectural reasoning capacity. The results are based on synthetic data without human evaluation and reflect architectural behavior only.

1 Introduction

Clinical documentation serves multiple essential purposes including care continuity, research, and legal protection, but places significant time demands on medical professionals. The average consultant physician in clinical environments spends 12 hours a week adding to clinical documentation for patient records. This expenditure equals a productive monetary loss of 54,500 USD per year, per physician (Ignetica Ltd, 2022). Furthermore, 74% of medical professionals state that current efforts for clinical documentation impede patient care (American Medical Informatics Association, 2024). These findings suggest that a reduction of necessary efforts for patient records could address these and related challenges. However, a persisting challenge in documentation is the accurate and comprehensive documentation of relevant information. Medical professionals spend on average over an hour extra per day researching patient information (Ignetica Ltd, 2022). Adding to this, Bell et al. (2020) found in an empirical US study that 1 in 5 patient records contain at least one mistake, of which 40% are considered serious from the affected patients' perspective. Given these challenges, it is vital to make note-taking and information retrieval more time- and cost-effective.

Advances in LLM techniques offer a promising technical response to those challenges. There are countless strategies and process elements where AI can be used to enhance the process of note-taking, from transcribing speech, to reasoning about appropriate therapies for patients. Yet, the most impactful step is to ensure effective and accurate note composition from available data, such as transcripts. A widely adopted format for such notes is the SOAP schema (Subjective, Objective, Assessment, Plan), which structures clinical observations into four standardized dimensions and is detailed in Section 2.1. However, multiple strategies exist for how an AI infrastructure could solve the problem of composing clinical records, i.e. a single but powerful LLM could be employed to compose documentation, or a swarm of small, highly specialized AI agents could dissect the task of note-taking among them and collaboratively reason about the note composition. As for AI swarms, the landscape

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 742–752
July 3-4, 2026 ©2026 Association for Computational Linguistics

of empirical studies in the health-care domain is still an emerging field of research. This study aims to serve as an orientation for AI-architectural solutions for the task of clinical note-taking, answering the question of *"Do multi- / swarm-agent architectures outperform a single finetuned LLM for SOAP note generation?"*. The contributions of this paper are:

- A systematic evaluation of single-LLM, multi-agent, and swarm-agentic architectures for clinical SOAP note generation under controlled conditions.
- Highlighting that increased architectural complexity does not yield meaningful performance gains, questioning the practical utility of agentic approaches for this task.
- A reproducible experimental setup for SOAP note generation based on the MedSynth dataset, including consistent training and evaluation procedures.

The remainder of this paper is structured as follows: Section 2 shows the academic background, Section 3 describes the experimental setup and model architectures, Section 4 presents the results, Section 5 discusses the findings, and Section 6 concludes.

2 Literature

2.1 Theoretical Background

Weed (1964) proposed guidelines for the composition and structure of medical records. Each one of the 5 rules addresses a distinct viewpoint of the available facts and assumptions during a medical consultation. The framework prescribes (1) review and organization of all available data sources for a holistic patient view; (2) interpretation of those data in light of the clinician's impression of the patient; (3) derivation of a treatment plan through inductive reasoning over the contextualized data; (4) continuous data acquisition aligned with the evolving treatment plan; and (5) explicit articulation of the relationships between data entities (Weed, 1964). Through this, Weed defined core principles of data-driven patient care. His data organization framework laid the groundwork for the now widely adopted SOAP note schema.

Podder et al. (2023) lay out the current widely used adoption of the SOAP schema. A SOAP note is composed of 4 dimensions, where:

- S stands for *Subjective*, capturing what the patient reports themselves (chief complaint, history of present illness, etc.).
- O stands for *Objective* and captures data obtained through observation or empirical measurement (i.e. ECG, RR, observed skin condition, etc.).
- A stands for *Assessment* and concerns the analysis of the S and O findings to deductively state a diagnosis and/or clarify existing differential diagnoses.
- P stands for *Planning* and lays out how a patient's condition is treated methodically and / or further monitored and assisted. (Podder et al., 2023)

Bommarito et al. (2025) define the criteria for an agentic system, by comparing successive levels of systems that process and act on data. A level 1 agentic system is defined as *"[...] any entity that pursues goals through perception and action, with at least minimal discretion over which action to take in response to what it perceives."* (Bommarito et al., 2025) meaning a system that possesses a *goal* to achieve, a *perception* of the environment, and the *actionable capabilities* to affect their environment. An example could be a thermostat which maintains a certain level of temperature through temperature measurements. It is important to notice that a level 1 agent's properties are not limited to the described properties, but also can be extended by one or more of the 3 additional properties, that a level 2 adds. An agentic system is considered to be level 2 if the system's logic follows specific *rules* that are deterministic and non-flexible. It extends level 1 agent capabilities by possessing a (continuous) *iterative* data / environment observation, an *adaptation* to challenges and new observations, and a *termination* under defined criteria. An example could be a web scraper that monitors news websites for specified keywords and notifies subscribers. A level 3 agentic system however leverages AI architectures like neural networks, LLMs, or VLMs with traditional computing resources, while possessing the same properties as a level 2 agent. A level 3 agent, for example, can be a trading bot that dynamically adjusts strategies based on government announcements and news. Bommarito et al. clarify that the definition of an agent is bound to, but not limited to, a system's capabilities to influence its environment

in different levels with different methods. Furthermore, the authors advocate for a clear definition of the term *agent*, as the term itself does not reflect the different tasks and properties an intelligent system possesses (Bommarito et al., 2025).

2.2 Related Work

Li et al. (2025) introduce an expert curated simulated dataset called *CliniKnote* of 1,200 doctor–patient conversations with clinical notes. For these notes, the SOAP schema was extended by a keyword section on top, creating the K-SOAP schema, to enable quick identification of relevant symptoms and diseases. Furthermore, the authors benchmarked the K-SOAP note generation across 22 LLMs via metrics such as ROUGE, BERTscore, Bleurt (Sellam et al., 2020), and QuestEval (Scialom et al., 2021). For keyword extraction and generation, a combination of clinical named entity recognition and relation extraction for symptoms and diseases from dialogues has been used. The authors defined 8 entity types combining 5 relational prefixes with symptom and disease categories. If a conversational contribution was identified to be relevant for one of the specified categories, the information was tagged. The benchmark was conducted across all tested LLMs in the 3 categories: baseline models, open-source LLMs, and commercial models. For open-source and baseline models, the authors used QLoRA to reduce resource demands, training adapters for finetuning in three modes: a single adapter for the full note, 4 adapters for grouped sections, or 15 separate adapters for each individual section (denoted with a *section-4* / *section-15* suffix). Commercial models were instead evaluated via zero-shot and one-shot in-context learning. The results showed that the GPT-4o model in one-shot mode (zero-shot was tested as well for closed-source models) outperformed all tested open source models and baseline models marginally in 7 out of 9 metrics, compared to the next best performing model qCammel-13b-section-15, a model optimized for academic medical knowledge. Among the baseline and open-source LLMs, the model qCammel-13b-section-15 outperformed other models moderately in 7 out of 9 metrics, compared to the second best performing model Llama3-8b-section-4 (Li et al., 2025). These results suggest that the type and quality of domain adaptation matter more than model size - as evidenced by OpenBioLLM's poor performance despite its biomedical specialization. However, GPT-4o's superior one-shot results indicate that scale remains a contributing factor.

Ramprasad et al. (2023) analyzed an approach for generating SOAP notes based on conversational data. The authors dissected the SOAP dimensions beyond the 4 well-known dimensions, down to the contained scopes of information each dimension holds. For example, the S-dimension holds information about the chief-complaint, past medical history, allergies, etc. In total, the study features 12 subdimensions. In their approach, the authors compared the performance of a general-purpose model (GPT 3.5) in zero- and few-shot settings, against a default finetuned BART-model, and a BART-model with modified architecture. The authors also compared 3 architectural modifications of the BART-model to support the identification of SOAP-specific information from the conversation input. **BART+EMB** adds SOAP-(sub-)section tokens to the BART-embedding. It was finetuned with annotated and tagged data, which provides explicit conditioning on the target SOAP section/subsection to guide summary content and style. **BART+ADAPT** integrated adapter modules - small bottleneck feed-forward networks - into each transformer layer, adopted from (Bapna and Firat, 2019). To enable SOAP note generation, full finetuning was applied. **BART+CA** adds a second cross-attention (CA) layer after the standard CA layer in each decoder block. While the default CA layer shares parameters across all sections, this additional layer uses separate parameters for attending to SOAP information. This enables the model to re-attend over the encoder output with a section-specific focus. These parameters are randomly initialized and learned during finetuning. Among the BART architectures, the BART+CA combination outperformed other modifications by a range of just 0.4–5.5 points in 3 of 4 applied metrics (ROUGE-L, UMLS(F-1), Isin). Compared to the baseline BART and GPT 3.5, the BART+CA modification outperformed other models in 2 of 4 metrics (UMLS(F-1), Direc(F-1)) by a range of 0.7 - 15.6 points (Ramprasad et al., 2023). These findings imply that a specialization on an architectural level for a task can benefit a model's performance.

3 Methodology

Figure 1 shows the methodological process steps.

Figure 1: Methodology process steps

3.1 Dataset and Data Preparation

This study employed the MedSynth dataset, created by Mianroodi et al. (2025). The authors leveraged data from multiple sources, such as filed insurance claims from the IQVIA PharMetrics Plus dataset, and existing dialogue datasets, such as Aci-Bench (Yim et al., 2023), NoteChat (Wang et al., 2024), and PriMock57 (Papadopoulos Korfiatis et al., 2022). Despite the highlighted categorical skewness of the distribution of ICD-10 codes, the authors have selected a uniform sampling method, resulting in ca. 2,000 selected ICD-10 codes for English dialogue-note pair generation. The dialogues were synthetically generated with multiple AI agents, employing GPT-4o with Chain-of-Thought and In-Context Learning. The incident descriptions from the selected insurance claims were taken as an input for the GPT4o model, in accordance with the instruction for generating a dialogue. Through this, ca. 10,000 dialogue-note pairs were created, where each ICD-10 code is generally represented 5 times.

The dataset version retrieved in Feb. 2026 comprises 10,240 dialogue-note pairs in total, featuring 2,037 ICD-10 code classes. After cleaning and preparation, the final dataset comprised of 10,030 records in 2,006 ICD-10 code classes. For the later training of multi- and swarm-agentic AI systems, the SOAP notes have been split via regex in their 4 respective dimensions. The evaluation dataset was constructed by randomly (all random selections employ a fixed seed) selecting one sample per ICD-10 code, resulting in 2,006 test instances (20%). This ensures uniform code-level coverage in the final evaluation. The remaining samples are randomly shuffled split into training and validation sets. Specifically, 802 samples (8%) are used for validation to support model selection, while the remaining 7,222 samples (72%) are used for training. This splitting strategy balances the need for representative evaluation across clinical categories with maintaining sufficient training data for reliable finetuning.

The records from the test set, serving as ground-truth SOAP notes, were scored directly against their source dialogues to establish a lexical-overlap baseline. All notes were run directly against their source dialogues without model inference, quantifying the inherent textual distance between raw dialogue and structured SOAP output. This baseline is intentionally conservative: it does not represent a competitive note-generation system, but rather provides a lower-bound reference that quantifies how much information must be reorganized, paraphrased, and inferred to transform raw dialogue into a structured SOAP note. Direct numerical comparison with dedicated baselines from prior work such as Ramprasad et al. (2023) or Li et al. (2025) is informally enabled through the shared use of ROUGE and BERTScore, although differences in datasets, target schemas, and reference quality preclude strict equivalence.

3.2 Benchmark Metrics

The following metrics were applied:

- **ROUGE**: This metric was proposed by Lin (2004) and stands for *Recall-Oriented Understudy for Gisting Evaluation*. This metric evaluates the overlap between generated and reference texts using n-gram matching. ROUGE-1 and ROUGE-2 measure unigram and bigram overlap respectively, while ROUGE-L captures sentence-level structural similarity without requiring consecutive n-gram matches. The metric reports precision, recall, and F1, all of which were reported.

- **BERTScore**: BERTScore was proposed by Zhang et al. (2020). BERTScore computes cosine similarity between contextual embeddings of tokens in the generated and reference texts, enabling it to capture semantic equivalence even when different words are used. This study leverages the RoBERTa-large model (Liu et al., 2019) to compute the score. Furthermore, the metric reports precision, recall, and F1, of which all were reported.

The combination of ROUGE and BERTScore provides complementary evaluation perspectives: ROUGE captures lexical overlap through surface-level n-gram matching, while BERTScore assesses semantic similarity through contextual embeddings, recognizing paraphrases that ROUGE would miss. Both metrics are widely adopted in clinical note generation research. This enables a direct comparison with prior work such as Li et al. (2025); Mianroodi et al. (2025) and others.

Recent shared tasks on clinical text generation, such as RRG24 in Xu et al. (2024), have employed broader metric suites including F1-RadGraph and F1-CheXbert for radiology report generation. These metrics are specifically tailored to radiology and rely on radiology-domain labelers, whereas the *Discharge Me!* subtask instead used metrics such as MEDCON and AlignScore for discharge summary generation. Neither suite transfers directly to general SOAP note evaluation across the full ICD-10 spectrum, where no analogous domain-specific labelers are established. ROUGE and BERTScore remain the metrics most consistently reported in the SOAP-generation literature and enable direct comparison with prior work (Li et al., 2025; Ramprasad et al., 2023).

3.3 LLM Selection and Finetuning

3.3.1 LLM selection

All architectures in this study employed the Ministral 3 model series (Liu et al., 2026). Specifically, the 3B and 8B reasoning model versions *mistralai/Ministral-3-3B-Reasoning-2512* and *mistralai/Ministral-3-8B-Reasoning-2512* were used for finetuning and benchmarking in this study. The model family was published by Mistral AI in Jan. 2026. Its strong performance on the MMLU-Redux benchmark (Gema et al., 2025), a benchmark for multitask language understanding where LLMs are confronted with questions from all kinds of domains, made the model an ideal choice. Additional consideration was given to its native support for structured output generation and level 3 agentic AI capabilities. The model employs a decoder-only transformer architecture and supports context lengths of up to 256k tokens; sufficient for processing medical dialogues with generative instructions.

3.3.2 Quantization

To still leverage the model's capabilities while improving memory efficiency, the quantization technique *Quantized Low Rank Adaptation* (QLoRA) was used. Introduced by Dettmers et al. (2023), QLoRA combines *Normal Float 4* (NF4) quantization with *Low Rank Adaptation* (LoRA) (Hu et al., 2022), enabling parameter-efficient finetuning by keeping base weights frozen and training small low-rank adapter matrices instead. It further reduces memory usage through double quantization.

Quantization represents model weights in lower-precision formats, trading off compression and accuracy. While Ministral 3 natively uses *bfloat16*, alternatives such as INT8, INT4, FP8, and NF4 offer varying memory savings. Given the focus on maintaining quality under strong compression, NF4 was selected.

QLoRA exploits the near-normal distribution of pretrained weights by aligning quantization levels with weight density, minimizing information loss at 4-bit precision. Double quantization further compresses the per-block scaling factors, reducing overhead to $\sim$0.127 bits per parameter. During training, only LoRA adapters are updated while 4-bit weights are temporarily dequantized to bfloat16; paged optimizers stabilize memory usage on single-GPU setups.

This study applied LoRA hyperparameters as listed in Table 1:

Parameter	Value	Description
Rank (r)	64	Dimension of the low-rank matrices
Alpha (α)	32	Scaling factor for LoRA updates
Dropout	0.05	Dropout probability
Target modules	q/k/v/o/gate/ up/down_proj	Transformer layers adapted
Bias	None	No bias params trained
Task type	CAUSAL_LM	Language modeling objective

Table 1: LoRA hyperparameter configuration

Preliminary runs with r=16 and r=32 showed marginally lower validation performance; r=64 was selected as the best tradeoff.

3.3.3 Finetuning

The finetuning of the respective base models with 3B and 8B parameters was conducted on the training split with 7,222 observations, and tested against the validation split of 802 observations for each epoch. Table 2 shows the applied hyperparameters for training for all architectures.

The finetuning results suggest that the models reach their global optimum within 3 epochs. Figure 2 displays the performance of the training and validation for the single-LLM architecture, which

Parameter	Value
Learning rate	2×10^{-4}
Epochs	3
Per-device batch size	2
Gradient accumulation steps	4
Effective batch size	8
Optimizer	AdamW
Learning rate scheduler	Cosine
Warmup ratio	0.05
Weight decay	0.01
Max sequence length	4096
Gradient checkpointing	Enabled
Precision	bf16

Table 2: Finetuning hyperparameter configuration

can be considered representative for other models, employed in different architectures, as other finetuning runs show similar results. Training was conducted on 3× NVIDIA A100-40GB GPUs.

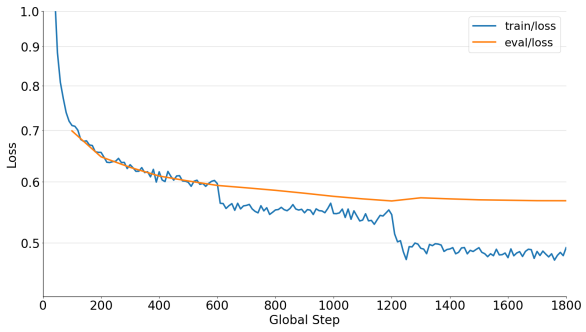

Figure 2: Single-LLM setup 8B model training and validation performance

3.3.4 Preservation of Base Model Capabilities

A potential concern when finetuning models for downstream agentic use is the loss of general instruction-following capability that pre-trained models acquire during instruction tuning. The QLoRA setup adopted here was specifically chosen to mitigate this risk. Three properties of the configuration are relevant: (1) All base model weights remain frozen in 4-bit NF4 quantization throughout training; gradient updates are applied only to the rank-64 LoRA adapter matrices, which account for ca. 2.9% (3B) and ca. 2.3% (8B) of total parameters — a range consistent with standard QLoRA configurations applied to comparable base-model scales (Dettmers et al., 2023; Li et al., 2025) (2) Each adapter parameterizes its weight update as a low-rank decomposition ($\Delta W = BA$, with rank r = 64), restricting the modification of every targeted projection to a 64-dimensional subspace; this structural constraint bounds how far the adapted layer can deviate from the frozen pre-trained projection. (3) During inference, agents continue to receive role-specific system prompts (defining role, expected output structure, and clinical scope) — finetuning thus complements, rather than replaces, prompt-based agent specialization. Empirical support for this design choice can be found in prior clinical NLP work that combines QLoRA adapters with structured prompting for SOAP-related tasks (Li et al., 2025). An alternative design — for example, orchestrating off-the-shelf instruction-tuned LLMs through prompts alone — represents a valid and complementary configuration, and is positioned as a future-work direction in Section 6.

3.4 Agentic AI Architectures

Before the architectures are described, it is worth noting that for both the multi-agentic and swarm-agentic AI architectures, trained LoRA adapters were applied via hot-swap to a single base model during inference, significantly reducing VRAM demands as only one base model needs to be held in memory. For all architectures, all LLMs were either equipped with 3B or 8B parameters.

Note that this study employs role-specialized adapters within a fixed pipeline rather than prompt-orchestrated agents over a single instruction-tuned base model. Coordination between agents is structural — information flow is hard-wired through the architecture (Figures 4, 5) — not negotiated at inference. This design isolates architectural decomposition as the experimental variable while holding base model and training recipe constant; alternative prompt-driven setups represent a complementary design space (see Section 6).

3.4.1 Single-LLM Architecture

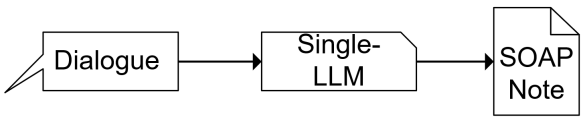

Figure 3: Single-LLM architecture visualized

The single-LLM setup featured a finetuned model, trained to compose an entire SOAP note. During training, the entire SOAP note for the individual case was visible. This enabled the model to capture the holistic format and structure of the SOAP-schema. For inference, the trained adapter

was applied. The purpose of the single-LLM setup is to serve as a controlled comparison against agentic AI architectures with multiple AI agents. Figure 3 visualizes the single-LLM architecture.

3.4.2 Multi-Agentic AI Architecture

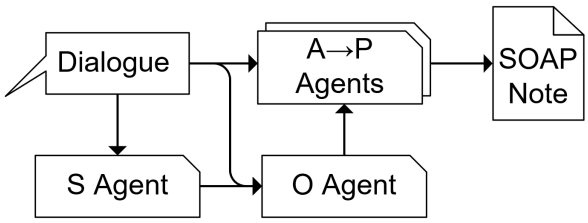

Figure 4: Multi-agentic AI architecture visualized

The multi-agentic AI setup featured 4 agents in sequential order, each one finetuned in their respective domain. Depending on their relative position in the order of the SOAP schema, the models receive the dialogue, as well as the output of the previous AI agents. For the final output, all dimension-outputs were concatenated in the appropriate SOAP order. Figure 4 visualizes the multi-agentic AI architecture.

For training, the SOAP notes have been separated in their respective domains, to control the access of information for each SOAP stage. Every domain-respective agent received a specialized system prompt (e.g., defining role, expected output format, and relevant clinical concepts) to ensure dimension-specific information sensitivity for phrases and concepts described in the dialogue.

3.4.3 Swarm-Agentic AI Architecture

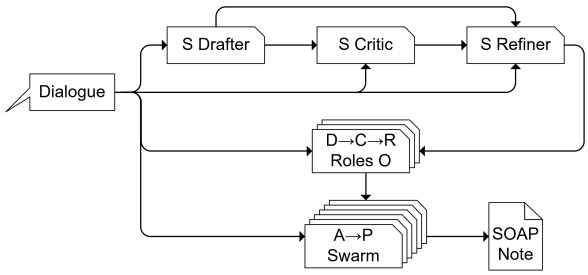

Figure 5: Swarm-agentic AI architecture visualized

The swarm-agentic AI setup featured 12 agents in sequential order, with 3 agents per SOAP dimension acting as drafter, critic, and refiner. For every dialogue input, the *drafter* composes a SOAP note for the respective dimension. The *critic* then judges the drafter's output against the original dialogue, based on structure and criteria learned through finetuning. The *refiner* refines the draft based on the dialogue, drafter output, and critic output, and outputs the final SOAP-dimension note. All dimension outputs were concatenated in the appropriate SOAP order. Figure 5 visualizes the swarm-agentic AI architecture.

During training, each of the 12 agents received a specialized system prompt (e.g., defining role, expected output format, and relevant clinical concepts) to ensure dimension specialization through role understanding and sensitivity to relevant phrases and concepts. The drafter was trained on dialogue-dimension pairs with the ground-truth SOAP dimension as gold text, analogous to the multi-agent training. The critic relied on synthetic data: a cross-paired imperfect draft is created by swapping the SOAP dimension with one from a different consultation sharing the same ICD-10 code, and a programmatic function generates a synthetic critique comparing that draft against the ground-truth SOAP note and current dialogue. The critic thus learns to generate a critique from dialogue and imperfect draft. The refiner is then trained on the same cross-pairs, receiving dialogue, imperfect draft, and synthetic critique as input, with the gold-standard SOAP dimension as target. For inference, the 12 trained adapters were applied via hot-swap to the same base model.

4 Results

4.1 Quantitative Results

For benchmarking, the test set with 2,006 observations, representing one ICD-10 code class each, was employed. The computed quality metrics allowed a per-case review for every setup and every agent. Table 3 features the combined performance metrics over all architecture respective agents, where the top performing architectural metric is formatted in **bold**, while the 2nd best performing architecture metrics are underlined.

The single-LLM architecture achieves the strongest performance, ranking first across all metrics, with the 8B variant marginally outperforming the 3B variant. Both share nearly identical BERTScores ($\Delta = 0.002$). The multi-agent and swarm-agent setups follow closely, with Multi 8B consistently outperforming Swarm 8B across all metrics, while Single 3B holds the second-ranked position in all four metrics. The performance differences across all finetuned architectures are marginal, with the largest gap being 0.042 in ROUGE-L between Single 8B (0.628) and Multi

	ROUGE-1	ROUGE-2	ROUGE-L	BERTScore
Baseline	0.461	0.227	0.326	0.825
Single 3B	0.771$_{\pm.002}$	0.543$_{\pm.003}$	0.615$_{\pm.003}$	0.928$_{\pm.001}$
Single 8B	**0.778**$_{\pm.002}$	**0.554**$_{\pm.003}$	**0.628**$_{\pm.003}$	**0.930**$_{\pm.001}$
Multi 3B	0.753$_{\pm.003}$	0.519$_{\pm.003}$	0.586$_{\pm.004}$	0.921$_{\pm.001}$
Multi 8B	0.760$_{\pm.002}$	0.530$_{\pm.003}$	0.598$_{\pm.003}$	0.922$_{\pm.001}$
Swarm 3B	0.752$_{\pm.003}$	0.522$_{\pm.004}$	0.591$_{\pm.004}$	0.920$_{\pm.001}$
Swarm 8B	0.754$_{\pm.003}$	0.526$_{\pm.003}$	0.594$_{\pm.004}$	0.921$_{\pm.001}$

Table 3: Test set F1 results. Baseline denotes lexical-overlap on ground-truth SOAP notes. ±values denote 95% bootstrap CI half-widths (10,000 resamples).

3B (0.586).

To evaluate statistical significance, paired t-tests and Wilcoxon signed-rank tests were conducted on per-case scores across all 2,006 test instances, with Cohen's d as effect size. The single-LLM architecture significantly outperforms both the multi-agent and swarm-agent setups across all metrics (all $p < 0.001$), with medium BERTScore effect sizes (d = 0.67–0.80 for 8B; d = 0.65–0.70 for 3B). The multi-agent vs. swarm-agent gap is negligible (BERTScore Δ = 0.0007, d = 0.050; Wilcoxon p = 0.161). For model scale, 8B variants show small but significant ROUGE improvements over 3B ($d \approx 0.15$–0.28), while BERTScore differences exhibit negligible effect sizes for both multi- and swarm-agent settings ($d \leq 0.060$; p = 0.149 and p = 0.007 respectively), suggesting that architectural choice dominates over parameter count in practical terms.

4.2 Qualitative Analysis

A stratified inspection of 100 generated notes, drawn uniformly across ICD-10 categories, revealed three recurring patterns across all finetuned configurations.

Demographic hallucinations in the Subjective dimension. All architectures frequently produced patient demographic attributes (age, gender, ethnicity) absent from the source dialogue. These attributes appear consistently in MedSynth's reference notes without corresponding dialogue evidence, and models reproduced them as a learned prior rather than through factual extraction — a dataset-level bias that architectural decomposition did not mitigate.

Empty Objective dimensions. Approximately 15% of reference notes contained no Objective content, reflecting MedSynth's simulated telemedicine scenarios. While all architectures correctly reproduced empty sections in these cases, multi- and swarm-agent variants occasionally hallucinated brief filler text ("examination not performed", "vitals not recorded"), marginally reducing reference alignment.

Error propagation in sequential pipelines. In the swarm setup, errors introduced at the drafter stage — such as fabricated medication names — tended to persist through critic and refiner stages. The critic, trained on synthetic cross-paired critiques, produced plausible critique text but failed to catch factual issues requiring external clinical knowledge. This aligns with the negligible BERTScore gap between multi- and swarm-agent variants (Section 4.1) and explains why additional refinement stages did not yield gains.

Together, these observations suggest that performance differences across architectures are driven less by architectural reasoning capacity than by shared dataset priors and drafter error propagation — limitations unlikely to be resolved by further architectural complexity.

5 Discussion

The results show that overall the finetuned models substantially outperform the lexical-overlap baseline, which measures the inherent textual overlap between raw dialogues and ground-truth SOAP notes without any model inference. This confirms the value of task-specific finetuning.

Figure 6 shows the F1 BERTScore delta between architectures; among finetuned models, the absolute maximum is 0.008 and the minimum is 0 — indicating that 3B models perform competitively with larger and more complex configurations alike. A plausible explanation is that SOAP note generation, as a structured reorganization and paraphrase task, does not expose the complexity that multi-agent decomposition is designed to exploit: a single finetuned model captures the full dialogue-to-

Δ	Base	Single 3B	Single 8B	Multi 3B	Multi 8B	Swarm 3B	Swarm 8B
Base		-0.103	-0.105	-0.096	-0.097	-0.096	-0.096
Single 3B	0.103		-0.002	0.007	0.006	0.008	0.007
Single 8B	0.105	0.002		0.009	0.008	0.009	0.009
Multi 3B	0.096	-0.007	-0.009		-0.001	0.001	0.000
Multi 8B	0.097	-0.006	-0.008	0.001		0.002	0.002
Swarm 3B	0.096	-0.008	-0.009	-0.001	-0.002		0.000
Swarm 8B	0.096	-0.007	-0.009	0.000	-0.002	0.000	

Figure 6: Delta for F1 BERTScore benchmark results comparison (row - column)

note mapping end-to-end, without the coordination overhead and error propagation inherent to pipeline architectures. We therefore interpret the flat architectural performance not as a failure mode but as an empirical answer — agentic decomposition is not warranted for this class of tasks. This counterpoints the broader trend of defaulting to multi-agent orchestration in clinical NLP and motivates the targeted question outlined in Section 6: identifying the specific task properties — multi-specialty, longitudinal, multi-modal — under which decomposition can be expected to pay off.

6 Conclusion

This study compared three agentic AI architectures — single-LLM, multi-agentic, and swarm-agentic — for automated SOAP note generation from doctor–patient dialogues, using finetuned Ministral 3 models (3B and 8B) on the MedSynth dataset. All finetuned architectures substantially outperformed the lexical-overlap baseline, underscoring the value of task-specific finetuning in clinical documentation. Performance differences among the three approaches were minimal, however, with the single-LLM setup leading in all 4 metrics. These findings suggest that increasing architectural complexity through multi-agent or swarm decomposition does not provide meaningful gains over a single finetuned model for this task. Notably, the 3B and 8B variants performed nearly identically, indicating that smaller models can handle structured clinical NLP tasks without compromising quality.

These findings carry practical implications: organizations seeking to automate clinical documentation can achieve competitive results with a single, compact finetuned model, reducing both infrastructure complexity and computational cost compared to multi-agent deployments.

Several limitations should be acknowledged. The evaluation relied exclusively on automated metrics (ROUGE, BERTScore), which may not fully capture clinical accuracy or factual correctness — dimensions that require expert human evaluation. Furthermore, the study was conducted on a single synthetic dataset, and generalizability to real-world clinical dialogues with noise from speech recognition remains to be validated.

As detailed in Section 4.2, the inference outputs reveal dataset-induced behavior — demographic hallucinations in the Subjective dimension and reproduction of empty Objective sections from MedSynth's telemedicine scenarios — that limits its practical utility independently of architectural choice, since key content decisions appear driven by pattern reproduction, not factual grounding.

Future work should (1) extend evaluation to authentic clinical transcripts with acoustic and disfluency noise; (2) incorporate human expert assessment of factual correctness, completeness, and clinical utility; (3) test additional base-model families and instruction-only orchestrations to disentangle architectural from base-model effects; (4) explore broader, factuality-oriented metrics (e.g., RRG24-style entity-level scores adapted to SOAP content (Xu et al., 2024)); and (5) investigate whether more complex clinical tasks — multi-specialty consultations, longitudinal patient records, or multi-modal inputs combining dialogue with imaging or lab data — provide the conditions under which agentic decomposition begins to pay off.

VERICITE: Evaluating Sentence-Level Citation Faithfulness in Retrieval-Augmented Medical Question Answering

Yixian Ma **Bohao Chu** **Norbert Fuhr**
University Duisburg-Essen
{yixian@stud, bohao.chu, norbert.fuhr}@uni-due.de

Abstract

Retrieval-augmented generation (RAG) reduces hallucination in large language models by grounding outputs in retrieved evidence, but it does not guarantee that the resulting citations actually support the claims they accompany. We present VERICITE, a framework for evaluating citation faithfulness in retrieval-augmented medical QA. Our system retrieves PubMed abstracts via the NCBI E-utilities API, prompts LLMs to generate answers with inline citations, and then verifies each citation at the sentence level using a DeBERTa-v3-large NLI model. We evaluate four LLMs on 500 BioASQ questions at retrieval depths $k \in \{3, 5\}$, with extended experiments up to k=15 and an oracle setting with gold-standard documents. Only 27–41% of citation pairs are supported at the sentence level at $k \in \{3, 5\}$, with rates declining further at larger k. Under the oracle condition, answer quality improves but citation faithfulness does not substantially improve, suggesting that generation-side citation behavior contributes substantially to unfaithful citations.

1 Introduction

RAG (Lewis et al., 2020) has become standard practice in medical question answering (QA) because it grounds model outputs in external evidence (Xiong et al., 2024). However, the presence of a citation does not mean the cited source actually supports the claim. A model can attach a real PubMed article to a plausible-sounding statement even when the article says something only tangentially related—what Wallat et al. (2025) call "post-rationalized" citations. In medicine this is especially dangerous: a clinician may trust a cited claim precisely because it appears backed by evidence (Sackett et al., 1996).

We ask a simple question: when an LLM cites a retrieved PubMed abstract, does that abstract actually contain a sentence supporting the claim? VERICITE retrieves abstracts via PubMed E-utilities, prompts an LLM to generate a cited answer, and then checks each citation at the sentence level using NLI. We retrieve at the abstract level to preserve clinical context but verify at the sentence level for precise grounding. Our main contributions are:

1. A biomedical RAG pipeline with sentence-level NLI faithfulness evaluation. While ALCE (Gao et al., 2023) introduced sentence-level citation evaluation in open-domain QA, we adapt this paradigm to biomedical retrieval over PubMed abstracts.

2. An oracle retrieval experiment that approximates an upper-bound retrieval condition and analyzes how citation faithfulness changes under near-perfect recall. Gold-standard documents improve answer quality but not citation faithfulness, providing suggestive evidence that generation-side factors may contribute substantially to unfaithful citations.

3. A comparison of four LLMs across four retrieval depths, showing a precision–coverage trade-off where increasing k improves recall but degrades faithfulness.

2 Related Work

RAG and citation in medical QA. The ALCE benchmark (Gao et al., 2023) introduced sentence-level citation evaluation via citation recall and precision, finding that even strong models fail to support their citations about half the time; however, ALCE targets open-domain QA. MedCite (Du et al., 2025) compared citation strategies for biomedical QA, and the TREC BioGen shared task (Gupta et al., 2024, 2026b) has established benchmarks for evaluating biomedical generative retrieval with expert assessments. Most of this work focuses on producing citations; our focus is on verifying them at fine granularity in the biomed-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 753–759
July 3-4, 2026 ©2026 Association for Computational Linguistics

ical domain and on analyzing citation behavior under different retrieval conditions.

Citation faithfulness. Wallat et al. (2025) drew an important distinction between citation *correctness* (the source is real) and citation *faithfulness* (the source entails the claim), and found that most RAG citations are post-rationalized. Vladika et al. (2025) showed that even GPT-4o with retrieval augmentation lacks citation support for nearly half of its medical responses. BioACE (Gupta et al., 2026a) proposed automated biomedical citation evaluation and highlighted the difficulty of NLI-based assessment in this domain. Self-RAG (Asai et al., 2024) trains a single LM to critique its own retrieval via reflection tokens. We are closest to ALCE and Source-Checkup. ALCE evaluates citation quality in open-domain QA, while we adapt sentence-level evaluation to PubMed-based biomedical QA with both standard and oracle retrieval. Source-Checkup studies citation support in medical QA but lacks this retrieval comparison.

NLI for factual verification. NLI has been widely used for factual consistency checking (Maynez et al., 2020). We use DeBERTa-v3-large (He et al., 2023) fine-tuned on MNLI (Williams et al., 2018), FEVER (Thorne et al., 2018), ANLI (Nie et al., 2020), LingNLI, and WANLI.[1] This model was not trained on biomedical NLI data such as MedNLI (Romanov and Shivade, 2018); we discuss the implications in Section 6.

3 Method

Figure 1 shows the VERICITE pipeline.

3.1 Retrieval and Cited Answer Generation

Given a medical question, we retrieve the top-k PubMed abstracts using the NCBI E-utilities API (Sayers et al., 2022). The question is preprocessed by removing the leading interrogative word, preserving medical terminology for PubMed's Automatic Term Mapping. We retrieve a candidate pool of 200 results with title/abstract field restriction and keep the first k abstracts with complete metadata (Appendix A). Retrieval operates at the abstract level because isolated biomedical sentences often lack key context such as population, intervention, or outcome qualifiers. The abstracts are then passed to an LLM that generates a 4–6 sentence answer with inline document-level citations (Appendix B and E).

We intentionally use simple keyword-based retrieval (E-utilities) rather than dense retrieval, since our goal is to evaluate citation faithfulness across a range of recall levels—from low recall (standard retrieval) to near-perfect recall (oracle)—rather than to optimize retrieval itself.

Oracle retrieval. To separate retrieval from generation effects, we include an oracle condition that uses BioASQ's gold-standard PMIDs directly, bypassing search. This yields recall ≈ 1.0 (99.9%; a few gold PMIDs lack retrievable abstracts). By comparing standard and oracle conditions on the same models, we can examine whether substantially improved retrieval recall is associated with changes in citation faithfulness.

3.2 Sentence-Level Citation Faithfulness

Although citations are produced at the document level, we evaluate faithfulness at the sentence level. For each generated sentence that cites a document, we segment the cited abstract into individual source sentences and run NLI on every (generated claim, source sentence) pair. This is a sentence-to-sentence comparison, not a comparison between the generated sentence and the full abstract. Each source sentence is evaluated independently against the generated claim using the DeBERTa-v3-large NLI model described above.

We aggregate the per-sentence NLI verdicts into a single citation-level verdict for each (generated sentence, cited document) pair: **Supported** if at least one source sentence entails the claim; **Contradicted** if none entails but at least one contradicts; **Irrelevant** otherwise (all source sentences are neutral).

4 Experimental Setup

Data. We use 500 questions (excluding yes/no) from the BioASQ Task 13b training set (Tsatsaronis et al., 2015). BioASQ provides expert-authored ideal answers and gold-relevant PMIDs. Of these, 421 yield at least one abstract under standard retrieval—factoid (161), list (114), summary (146)—and are used for those conditions; per-type results are in Appendix D. The oracle condition uses all 500 questions.

[1] Checkpoint: `MoritzLaurer/DeBERTa-v3-large-mnli-fever-anli-ling-wanli` on Hugging Face.

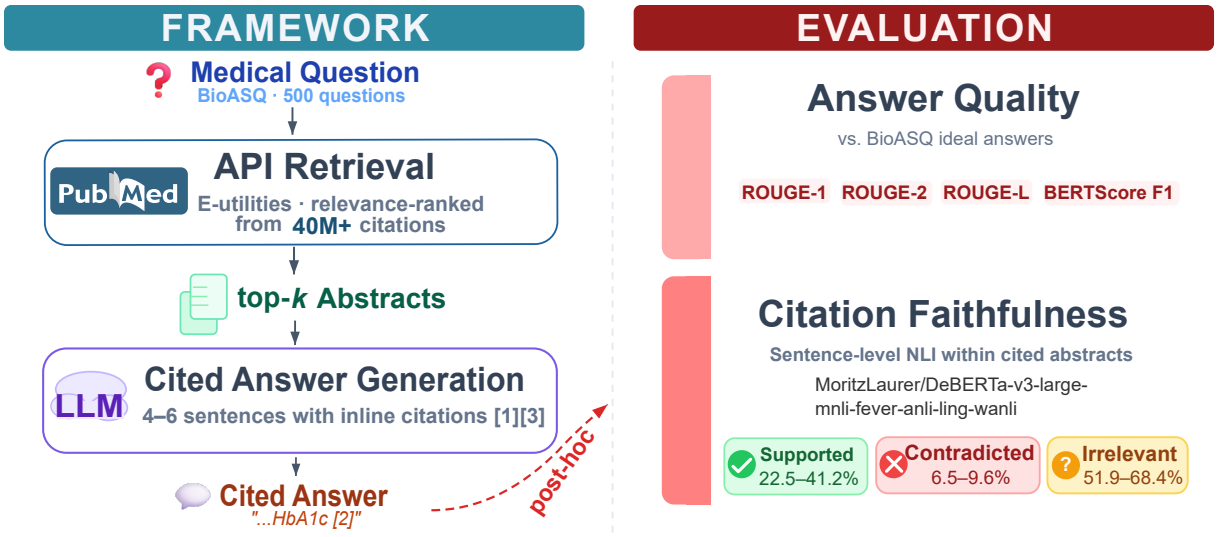

Figure 1: The VERICITE pipeline. **Left**: retrieval of top-k PubMed abstracts and cited answer generation. **Right**: post-hoc evaluation of retrieval quality, answer quality, and sentence-level citation faithfulness via NLI.

Models. We evaluate four LLMs, all given identical retrieval results and the same prompt: Mistral-7B-Instruct-v0.3 (Jiang et al., 2023), Llama-3.1-70B-Instruct (Dubey et al., 2024), GPT-4o-mini (OpenAI, 2024), and Claude-3.5-Haiku (Anthropic, 2024), accessed via API (Mistral through DeepInfra; others through OpenRouter). We include both a small open-weight model (Mistral-7B) and larger models to examine whether model scale affects citation behavior. All four run at $k \in \{3, 5\}$; Mistral-7B and Llama-3.1-70B also run at $k \in \{10, 15\}$. Temperature is 0.4 with nucleus sampling p=0.9.

Metrics. We report three groups: (1) *Retrieval*: Recall@k against BioASQ gold PMIDs. (2) *Answer quality*: ROUGE-1/2/L (Lin, 2004) and BERTScore F1 (Zhang et al., 2020) (`roberta-large`) against ideal answers. (3) *Citation faithfulness*: the fraction of (generated sentence, cited document) pairs classified as supported, contradicted, or irrelevant. Note that the ROUGE/BERTScore comparison is not entirely fair, since BioASQ ideal answers were written with access to a broader set of gold documents than our models see.

5 Results

Table 1 shows results for all models at $k \in \{3, 5\}$.

Retrieval. Recall@3 is 0.127 and Recall@5 is 0.162 over the 421 retained questions (79 returned no abstracts and were excluded). This low recall reflects two factors: BioASQ gold references are curated through expert literature review and may not rank highly in keyword search, and our E-utilities retrieval is deliberately simple. We treat this as a lightweight retrieval baseline rather than a competitive biomedical retriever; the oracle condition provides a high-recall counterpart for analyzing citation behavior under substantially improved retrieval coverage.

Citation faithfulness. Under our sentence-level NLI criterion—which may underestimate true faithfulness when models paraphrase or merge information across source sentences (Section 6)—only 29.7–41.2% of citation pairs at k=3 are supported. The majority (51.6–61.7%) are irrelevant: the cited abstract relates to the question topic but no individual source sentence entails the specific claim. Contradictions account for 6.6–9.5%, a smaller but non-trivial fraction in a medical context. These patterns are consistent with Wallat et al. (2025), who found most RAG citations to be post-rationalized.

Among models, Llama-3.1-70B achieves the highest support rate (41.2% at k=3), followed by Claude-3.5-Haiku (38.9%), GPT-4o-mini (37.8%), and Mistral-7B (29.7%). The gap between Mistral-7B and the other models suggests that model capacity may play a role, though we cannot isolate scale from other factors (training data, instruction tuning). Across both retrieval depths, GPT-4o-mini shows the lowest contradiction rate (6.5% at k=5), suggesting relatively conservative citation behavior.

Model	k	Retr. Rec.	Citation Faithfulness Sup.↑	Con.↓	Irr.↓	Answer Quality R-1	R-2	R-L	BS
Mistral-7B	3	.127	.297	.086	.617	.251	.091	.171	.862

Table 2: Extended depth ($k \in \{3, 5, 10, 15\}$; 421 questions) and oracle with gold PMIDs (500 questions). Support rates decrease with k; oracle retrieval does not improve faithfulness.

Extended retrieval depth. Table 2 extends the analysis to $k \in \{3, 5, 10, 15\}$ for Mistral-7B and Llama-3.1-70B. As k increases from 3 to 15, Recall@k rises to 0.226 and answer quality improves modestly, but support rates drop monotonically: from 29.7% to 22.7% for Mistral, and from 41.2% to 33.4% for Llama. The reason is straightforward: models cite more documents per answer at larger k (2.5 to 5.5 unique docs for Mistral), but many of the additional citations point to documents only loosely related to the specific claim. This constitutes a precision–coverage trade-off: increasing k improves retrieval recall but degrades citation precision.

Oracle retrieval. With recall of 99.9%, citation faithfulness does not substantially improve under oracle retrieval: support drops to 22.5% for Mistral-7B (vs. 29.7% at k=3) and remains comparable for Llama at 38.1% (vs. 41.2%). Meanwhile, answer quality improves clearly (ROUGE-L: .171 → .212 for Mistral; .185 → .256 for Llama). This divergence—better answers but not substantially better citation faithfulness—is one of our central empirical observations, suggesting that improved retrieval evidence alone may be insufficient to ensure faithful citation attribution.

The oracle setting differs from standard retrieval in both document count and question coverage, complicating strict causal interpretation. Increased document availability may encourage models to cite more sources, thereby reducing sentence-level support rates under our evaluation protocol. Nevertheless, the comparison with k=15 partially mitigates this concern, since Llama cites a comparable number of documents yet still achieves lower support rates than under oracle retrieval.

6 Conclusion

We presented VERICITE, a pipeline for evaluating citation faithfulness in retrieval-augmented medical QA. Across four LLMs at $k \in \{3, 5\}$, only 27–41% of citations are supported under sentence-level NLI evaluation; the majority are irrelevant. These rates generally decline at larger k and do not substantially improve under oracle retrieval. The oracle experiment reveals a notable divergence: providing models with expert-selected documents improves answer quality but does not substantially improve citation faithfulness. These findings suggest that retrieval quality alone may be insufficient to ensure faithful citation behavior, and that generation-side citation behavior likely plays an important role. For medical RAG systems, this means improving retrieval alone is unlikely to produce trustworthy citations; generation-side interventions such as citation-aware training or post-hoc verification are needed.

Limitations

First, we rely on a general-domain NLI model (DeBERTa-v3-large) not trained on biomedical text. Domain-specific models trained on MedNLI (Romanov and Shivade, 2018) might yield different re-

sults, and Gupta et al. (2026a) have highlighted the difficulty of NLI in biomedical settings. Without human validation, our faithfulness estimates should be treated as approximate; annotating a sample of NLI verdicts is our most important next step.

Second, our sentence-level entailment approach has known failure modes. When an LLM synthesizes information from multiple source sentences, no single source sentence may fully entail the combined claim, leading to false negatives. A generated sentence may also contain multiple sub-claims that we do not decompose. These factors mean our evaluation likely *underestimates* true faithfulness. A non-zero decoding temperature (0.4) may further increase paraphrasing diversity, reducing literal overlap with source sentences and lowering NLI entailment rates.

Third, the oracle experiment should be interpreted cautiously. In addition to near-perfect retrieval recall, the oracle setting also differs from the standard retrieval condition in both document count and question coverage, making strict causal interpretation difficult. As a result, the observed divergence between answer quality and citation faithfulness provides suggestive rather than definitive evidence that retrieval quality alone is insufficient to guarantee faithful citation behavior. A fully controlled comparison—for example, restricting oracle retrieval to the same question subset and matched document counts—would provide a stronger test.

Fourth, we evaluate on a single dataset (BioASQ) and retrieve only abstracts; full-text articles might provide sentence-level support that abstracts lack. Finally, API-based models may change across versions; we report exact model identifiers and fix decoding parameters to mitigate this.

Future Work

Our most pressing next step is human annotation of NLI verdicts to quantify evaluation reliability and compare the general-domain DeBERTa model against biomedical alternatives. We also plan to explore multi-sentence evidence aggregation (matching claims against groups of source sentences) to reduce false negatives, and to investigate dense retrieval and query expansion to improve recall without degrading citation precision.

Ethics Statement

This work evaluates citation reliability in medical QA and is not intended as a patient-facing system. AI-generated medical content should not substitute professional clinical judgment. All data are from publicly available sources.

A Retrieval Details

We submit the cleaned query to `esearch` with relevance ranking, restricting matches to title and abstract fields (`[tiab]`) and requiring a non-empty abstract (`hasabstract`). We retrieve 200 candidates via `efetch` and keep the first k with complete metadata. If the strict query returns fewer than k results, we relax the field restriction to allow Automatic Term Mapping, then fall back to the raw question.

For the oracle, we fetch abstracts using gold PMIDs directly. Recall is 99.9% rather than 100% because a few gold PMIDs lack abstracts. On average, models cite 5.9 (Mistral) and 5.3 (Llama) unique documents per answer under oracle.

B Generation Details

Each model receives the question and retrieved abstracts numbered $[1], \ldots, [k]$. The prompt includes a system instruction requiring the model to answer using only the provided documents, cite every sentence, and use multiple sources; two few-shot demonstrations; and the numbered abstracts and question (Appendix E). All models use the same prompt and documents. All four are accessed via API (Mistral-7B through DeepInfra; others through OpenRouter). Temperature is 0.4, p=0.9.

C Dataset Notes

Of 500 BioASQ questions, 421 yield at least one abstract under standard retrieval; the other 79 returned no usable abstracts. Recall@k ranges from 0.127 (k=3) to 0.226 (k=15). The oracle covers

Model	Type	Rec.	Sup.	Irr.	R-L	n
Mistral	Factoid	.108	.302	.603	.163	161
	List	.068	.274	.647	.146	114
	Summary	.195	.308	.610	.200	146
Llama	Factoid	.108	.421	.507	.179	161
	List	.068	.380	.551	.156	114
	Summary	.195	.425	.510	.214	146

Table 3: Citation faithfulness by question type at k=3. List questions show the lowest faithfulness, partly due to lower retrieval recall.

all 500 questions with recall of 0.999. We use questions from the Task 13b training set (2025 release), which accumulates 5,389 questions from previous years with expert-curated gold answers and relevant PMIDs.

D Results by Question Type

Table 3 breaks down citation faithfulness by question type at k=3. Summary questions show the highest support rates (30.8% for Mistral, 42.5% for Llama), likely because summary-type evidence is broader and easier to match. List questions show the lowest faithfulness (27.4% and 38.0%), partly due to low retrieval recall (6.8%). The ranking is consistent across both models.

E Prompt Template

```

Abstract

This paper presents an overview of the Medical Decision Extraction, Analysis, and Classification task (MedExACT) of BioNLP 2026. The focus of this task is the extraction and labeling of medical decisions in ICU discharge summaries. The task is built on MedDec, a MIMIC-III-based dataset of 451 expert-annotated summaries, and asks systems to extract and classify spans of text that contain medical decisions according to the decision categories defined in the Decision Identification and Classification Taxonomy for Use in Medicine (DICTUM). The official ranking combines span F1 and token F1 with a worst-group robustness metric computed over sex, race, and English-proficiency subgroups. MedExACT attracted broad international interest, with 130 official submissions from 36 teams comprising about 60–100 participants, and has improved information extraction performance by nearly 15% over the previous state of the art. The submitted systems predominantly use long-context encoder models, ensemble decoding, boundary-refinement modules, and robustness-aware training or model selection, with the best submitted run reaching a final fairness-based F1 of 0.596.

1 Introduction

Clinical notes often document key medical decisions concerning diagnoses, medications, procedures, follow-up plans, and other decisions that shape downstream care. These decisions are central to clinical reasoning, but they are embedded in long free-text narratives that make them difficult to analyze at scale.

Prior studies have investigated joint span detection and classification for clinical outcomes (Abaho et al., 2021), weakly supervised extraction of medical evidence from clinical texts (Liu et al., 2021), and structured event extraction using sequence-to-sequence frameworks (Ma et al., 2023).

MedDec (Elgaar et al., 2024) introduced the first expert-annotated benchmark focused on extracting medical decisions from discharge summaries, grounding the task in the Decision Identification and Classification Taxonomy for Use in Medicine (DICTUM) (Ofstad et al., 2016) and in the MIMIC-III critical care corpus (Johnson et al., 2016). The same data has also supported interactive downstream tooling for extraction, visualization, and annotation of medical decisions (Elgaar et al., 2025).

MedExACT 2026 extends the above efforts into a BioNLP shared task. Participants are asked to identify contiguous decision spans in ICU discharge summaries and assign each span one of the shared-task labels. Unlike other valuable information extraction resources such as CLIP (Mullenbach et al., 2021), which focus on physician action items, MedExACT targets a decision taxonomy that includes diagnostic assessments, therapeutic plans, and evaluation statements. The task averages standard performance (span- and token-level F1s) with a worst-group robustness metric across nine subgroups defined by sex, race, and English proficiency. This explicitly incentivizes fairness-aware system design instead of treating fairness as a post-hoc diagnostic. The task drew 130 submissions from 36 teams. The winning system scored 0.596. Top-performing approaches relied on encoder-based models with ensembles, boundary refinement, and category-specific decoding. LLMs performed well as augmentation or reranking components but poorly as standalone span extractors, consistent with prior MedDec findings.

This overview paper documents the task formulation and official evaluation approach, introduces the public baseline and toolkit distributed with the task, summarizes the systems submitted by participating teams and the modeling patterns that emerged from those submissions, and analyze the systems on exact span extraction, long-document processing, and subgroup-aware evaluation.

Decision Category	Description	Examples
Contact related	Decision regarding admittance or discharge from hospital, scheduling of control and referral to other parts of the healthcare system	Admit, discharge, follow-up, referral
Gathering information	Decision to obtain information from other sources than patient interview, physical examination and patient chart	Ordering test, consulting colleague, seeking external information
Defining problem	Complex, interpretative assessments that define what the problem is and reflect a medically informed conclusion	Diagnostic conclusion, etiological inference, prognostic judgment
Treatment goal	Decision to set a defined goal for treatment and thereby being more specific than giving advice	Quantitative or qualitative
Drug	Decision to start, refrain from, stop, alter or maintain a drug regimen	Start, stop, alter, maintain, refrain
Therapeutic procedure	Decision to intervene on a medical problem, plan, perform or refrain from therapeutic procedures	Start, stop, alter, maintain, refrain
Evaluating test result	Simple, normative assessments of clinical findings and tests	Positive, negative, ambiguous test results
Deferment	Decision to actively delay a decision or rejection to decide on a problem presented by a patient	Transfer responsibility, wait and see, change subject
Advice and precaution	Decision to give the patient advice or precaution, transferring responsibility for action to the patient	Advice or precaution
Legal/insurance related	Medical decision concerning to legal regulations or financial arrangements	Sick leave, drug refund, insurance, disability

Table 1: Overview of the ten medical decision categories defined in MedDec, together with a brief description of each category and representative examples. The Table is reproduced from (Elgaar et al., 2024).

Decision Type	**Sex**		**Race**						**Lng. Proficiency**	
	Male (n=259)	**Female** (n=192)	**White** (n=327)	**AA** (n=42)	**Hispanic** (n=25)	**Asian** (n=15)	**NH** (n=1)	**Other** (n=21)	**En** (n=260)	**Non-En** (n=45)

Table 2: Percentage of annotated spans for each decision category across protected variables in MedDec. n is the number of the discharge summaries for each category. The last row shows the total count of decisions per variable.

2 MedExACT 2026 Task Description

The task is built on MedDec (Elgaar et al., 2024), which contains 451 discharge summaries, more than 54k sentences, and roughly 1.4M tokens annotated by domain experts. It reports token-level inter-annotator agreement of 0.74 Cohen's κ. The notes come from MIMIC-III, a de-identified critical care database distributed under controlled access (Johnson et al., 2016). MedExACT inherits that access model: participants obtain the training and validation data from PhysioNet, while the official gold labels for test set remain hidden.

Given a full discharge summary, systems must detect contiguous text spans that express medical decisions and assign each span one of nine DICTUM decision categories defined in Table 1: *Contact related, Gathering information, Defining problem, Treatment goal, Drug, Therapeutic procedure, Evaluating test result, Deferment, Advice and precaution*, or *None* for when no decision is present. Table 2 shows the distribution of the decision categories across protected variables in MedDec.

For MedExACT 2026, the released split contains 350 training summaries, 53 validation summaries, and the 48 hidden test summaries (Table 3). In addition to text and span annotations, the task package includes demographic attributes used for subgroup evaluation and phenotype metadata inherited from the MedDec release. For privacy reasons, access to the dataset requires approval for MIMIC-III under their data use agreement.

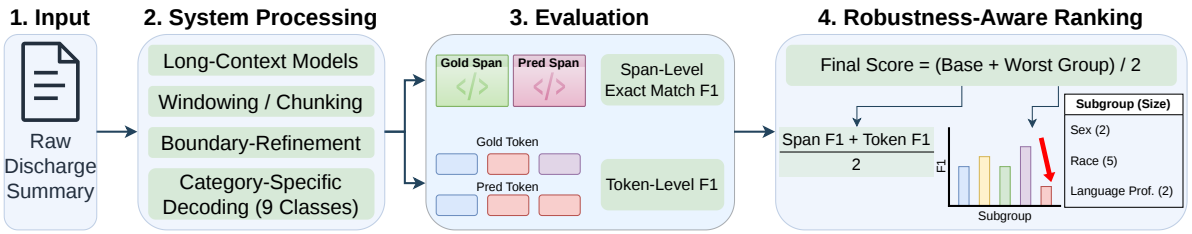

Figure 1: Overview of MedExACT 2026. (1) A raw ICU discharge summary from MIMIC-III is passed to the system. (2) Participating systems typically combine long-context encoders, windowing or chunking of long notes, boundary refinement, and category-specific decoding over the nine DICTUM decision classes to emit character-level span predictions. (3) Predictions are matched against hidden gold annotations at two granularities, span-level exact-match F1 (strict offset and label match) and token-level macro-F1, which are averaged into a per-note Base score. (4) The final leaderboard score is the mean of the overall Base score and the minimum Base score across nine subgroups defined by sex (2), race (5), and English proficiency (2), rewarding both accuracy and robustness.

As Figure 1 illustrates, the input to a submitted system is the raw text of a discharge summary taken from MedDec, and the output is a list of predictions, each represented by a start character offset, an end character offset, and a category ID. These predictions are matched against hidden gold annotations using a strict span-level evaluator together with a token-level evaluator, and the resulting Base score is combined with a worst-subgroup term to produce the final leaderboard score (Section 3). The shared task scores nine in-scope decision types. The underlying MedDec annotations follow DICTUM (Ofstad et al., 2016). Category 10 (Legal/insurance related) is ignored by the official shared-task evaluator.

Example: Each MedDec annotation includes annotator ID, discharge summary ID, and a list of decision spans with their text, DICTUM category, character offsets, and annotation ID:

Table 3: MedExACT 2026 data split summary. The hidden test set is used only for official evaluation.

3 Evaluation

Submissions are assessed based on both performance and robustness across patient subgroups. Evaluation script is available on GitHub.[1]

Base Performance: is accessed by evaluating two core metrics: (i) *Span-F1*, which requires predicted spans to exactly match the gold spans (in both offset and label). The script performs a light word-boundary expansion and punctuation trimming before matching. (ii) *Token-F1*, computes macro-F1 per note after tokenizing the raw text with NLTK and then averages across notes. At token level, the evaluator excludes tokens that are covered by more than one gold span.

$$\text{Base} = (\text{SpanF1} + \text{TokenF1})/2$$

Robustness: Let $\mathcal{G}$ denote the set of subgroup buckets defined over sex, race, and language proficiency. The subgroup definitions used are Female/Male for sex, White/African American/Hispanic/Asian/Other for race, and English/Non-English for language. We compute the same Performance Base score separately for each of these nine subgroups and then calculate the minimum subgroup Base Score across all the

Table 4: Method matrix for the 15 system descriptions, sorted by descending final score, with the organizer Baseline (Elgaar et al., 2024) shaded for reference. LLM: LLM used in the prediction pipeline. ENS: multi-model ensemble or aggregation. CAT: category-specific decoding, routing, or reclassification. LONG: explicit long-document windowing or chunking. AUG: synthetic, pseudo-labeled, or augmented training data. FAIR: fairness-aware training, sampling, or model selection. Nearly all systems also use an encoder backbone and some form of boundary post-processing; those near-universal features are omitted.

subgroups. This metric rewards systems that optimize across all target subpopulations rather than optimizing only the global average; this explicitly incentivizes fairness-aware system design instead of treating fairness as a post-hoc diagnostic:

$$\text{WorstGroup} = \min_{g \in \mathcal{G}} \text{Base}_g$$

The final leaderboard ranking uses the following fairness-aware aggregate score:

$$\text{FinalScore} = (\text{Base} + \text{WorstGroup})/2$$

We consider the following two implementation details while evaluating: first, predictions must use character offsets into the exact raw text supplied to the evaluator. Any normalization of the whitespace, punctuation, or section structure can shift offsets and reduce scores; second, the shared task only scores category IDs 1–9. Gold spans or predictions outside that label space are ignored.

4 Task Resources and Public Baseline

In addition to the submission endpoint, the released repository includes official split files without text spans (the actual spans can be obtained from PhysioNet), a sample predictions JSON file, a data-cleaning utility for offset normalization, a statistics generator for subgroup evaluation, raw-text extraction scripts for MIMIC-III notes, and the official evaluator. The released bundle is also intended to support replication after the workshop period.

The public baseline fine-tunes RoBERTa for span tagging: tokens receive multiclass BIO-style labels over 512-token segments, and the resulting token labels are converted back to character-offset predictions for evaluation. The implementation also includes optional CRF decoding and random cropping of long notes during training. This baseline is meant to help participants verify preprocessing, training, and submission formatting before developing their own systems; it should not be treated as the definitive performance reference for the leaderboard. The original MedDec paper provides further baseline comparisons (Elgaar et al., 2024).

5 Participating Systems

The system-description file available to us contains 16 submissions from 15 organizations, and the leaderboard snapshot contains 37 scored runs (including the baseline model). Because the leaderboard file records submission usernames rather than canonical team names, our quantitative analy-

sis is run-centric, whereas the method analysis below uses the author-provided system descriptions when they are available.

Table 4 summarizes six design dimensions across the 15 described systems. Ensembles appear in 9 descriptions, explicit long-document windowing in 8, fairness-aware training or model selection in 6, data augmentation in 5, LLMs use in 4, and category-specific decoding or routing in 3. Nearly all systems also use an encoder backbone and some form of boundary post-processing; those near-universal features are omitted from the matrix.

The most discriminating column is category-specific processing. All three systems that route predictions through per-category decoders, reclassifiers, or routing branches—Otter (Lowphansirikul and Ittichaiwong, 2026) (category reclassifier), ELiRF-UPV (Ahuir et al., 2026) (independent CRFs per category with a section-category layer mixer), and MedMBZ (Elshehaby et al., 2026) (sparse category routing with span-length calibration)—were in the top five. This pattern suggests that a single set of decoding thresholds fits the nine heterogeneous DICTUM categories poorly and that category-aware specialization provides consistent gains. Ensembles and fairness-aware optimization also skew toward the top: four of the five highest-scoring systems use multi-model aggregation, and three explicitly optimize for the worst-group term in the official metric.

Explicit long-document windowing is common but does not predict high final scores on its own. The top two systems (CUAMC (Baumgartner and Schilling, 2026) and LAMAR (Chiewhawan et al., 2026)) do not flag windowing as a primary design choice, relying instead on architectures that handle length natively or on section-level decomposition. Among the four LLM-based systems, fine-tuned LLMs with ensemble aggregation (LAMAR) reach the top of the leaderboard, while prompt-based LLM pipelines (CanSA (Alliheedi et al., 2026), NoviceTrio) fall well below the median, confirming that supervision and structured decoding remain critical even when the base model is large.

6 Results

Table 5 reports the full test-phase leaderboard snapshot with all 37 submitted runs, using the organizer-provided display names listed in the paper. The top five entries are CUAMC, LAMAR, Otter, ELiRF-UPV, and MedMBZ. Across all 37 runs, the median final score is 0.533, while the mean of the top five final scores is 0.585. The organizers' baseline, shown as MedExACT Organizers, ranks 28th with a final score of 0.511. The gap between the median and the top runs shows that small modeling choices matter under this setup.

Table 5: Full test-phase leaderboard snapshot with all submitted runs, sorted by descending final score of teams. The top five entries are marked with inline badge icons and subtle row shading.

The top systems outperform the baseline across almost all subgroups (Figure 2), however the strongest system is not uniformly best for every subgroup. The leaderboard also reveals a consistent trade-off between token overlap and exact span recovery (Figure 3). Among the five best final-score runs, CUAMC has the strongest span F1, while MedMBZ has the strongest token F1. Similar behavior appears further down the leaderboard: several runs reach token F1 in the 0.67–0.68 range while remaining below 0.53 final score because exact

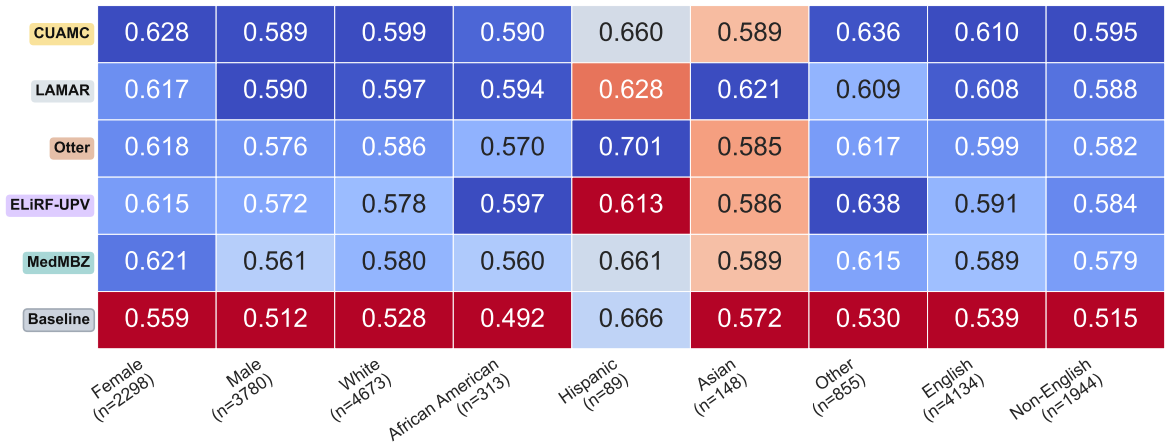

Figure 2: Subgroup Base scores for the top five MedExACT 2026 systems and the organizer baseline. Cell values show raw subgroup Base scores; colors are normalized within each subgroup to emphasize relative robustness patterns across sex, race, and English-proficiency groups.

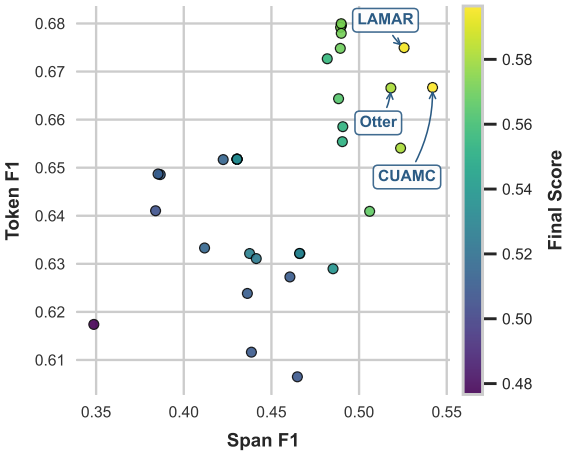

Figure 3: Scatter plot of Span F1 versus Token F1 across MedExACT 2026 leaderboard submissions. The top three systems (`CUAMC`, `LAMAR`, and `Otter`) are highlighted. High token-level overlap frequently fails to yield exact span boundary recovery.

span boundaries and subgroup robustness remain limiting factors. High token F1 with lower span F1 is consistent with coarse localization followed by boundary errors under the strict span matcher.

The fairness-aware objective also changes the interpretation of the ranking. For the top four runs, the worst-group score trails the base score by roughly 0.012–0.023 absolute points. These gaps are small enough to indicate deliberate robustness tuning, yet large enough to affect final ordering when systems optimize average accuracy only. Participant descriptions confirm that many teams treated the official final score as the primary development objective rather than as a secondary reporting metric.

7 Discussion

We summarize three takeaways from the participant reports and leaderboard snapshot:

Long-Context Modeling is a Core Requirement: Handling long discharge summaries is a prerequisite for this task. Given the length and density of ICU discharge summaries, most competitive systems used overlapping windows, chunk-level processing, or section-aware decomposition, including large encoder ensembles, Clinical-Longformer fine-tuning, and retrieval-based prompting pipelines (Kondadadi, 2026; Kumari et al., 2026; Alliheedi et al., 2026).

Exact Span Recovery is the Primary Bottleneck: Strong token F1 values show that systems can often detect the right region of text and recover the correct semantic type. The harder step is to return the precise character span expected by the official evaluator. Boundary refinement, CRF decoding, overlap-aware aggregation, and second-pass calibration all target this failure mode, so similar modules appear across otherwise different model families (Tao et al., 2026; Chiewhawan et al., 2026; Elshehaby et al., 2026).

Robustness-Aware System Design: Because the final ranking combines average performance with worst-group performance, teams invested in oversampling, subgroup-aware loss design, adversarial training, and development-time checkpoint selection under the official score (Baumgartner and Schilling, 2026; Lowphansirikul and Ittichaiwong, 2026; Elshehaby et al., 2026). For future clinically

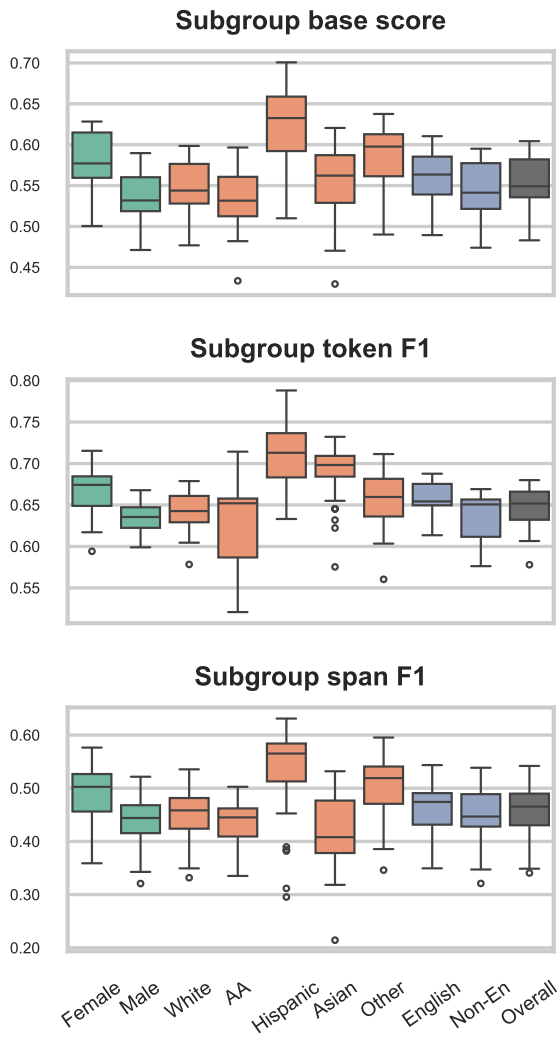

Figure 4: Distribution of Base score, Token F1, and Span F1 across submissions by subgroup and overall performance. Boxplots summarize variation across runs for sex, race, language, and overall scores, showing that subgroup differences persist across all categories.

grounded shared tasks, this example suggests that subgroup robustness should be built into the primary ranking rule instead of a post hoc diagnostic.

The Role of LLMs in Decision Extraction: The submitted systems also clarify the current role of LLMs in this space. Prior work has shown that large language models can be effective few-shot clinical information extractors in some settings (Agrawal et al., 2022). In MedExACT, however, long discharge summaries and strict character-offset evaluation seem to favor LLMs as augmentation, reranking, or repair modules instead of as standalone span extractors (Chiewhawan et al., 2026; Alliheedi et al., 2026). This matches the low zero-shot and one-shot exact-match results reported in the MedDec paper (Elgaar et al., 2024).

Toward Generalization: A natural next step for this shared task is to move beyond in-domain robustness and evaluate whether systems can generalize across clinically distinct settings under explicit domain shift. A future version of MedExACT could frame this as phenotype-family transfer, where models are trained without access to one target phenotype family and then tested on discharge summaries from that unseen family. This new setting measures whether systems learn decision semantics instead of phenotype-specific lexical or discourse patterns. We can annotate discharge summaries with their corresponding phenotypes, group phenotypes into clinically meaningful families, and reports leave-one-family-out results. We expect this setting to be feasible and result in substantially lower than in-domain performance due to the difficulty of transfer to unseen clinical contexts. This direction would complement the current robustness-aware evaluation by testing not only subgroup stability, but also resilience to shifts in patient populations and clinical conditions, and could motivate new methods for domain generalization, transfer learning, and clinically grounded robustness in medical decision extraction.

Understanding Clinical Decisions: This task can help us better understand underlying clinical decision-making by transforming unstructured clinical notes into structured representations of the decisions clinicians make. This enables large-scale analysis of how clinical reasoning is recorded across patients, conditions, and care settings. Such structured evidence could also provide better clinical decision support by making prior decisions easier to review, compare, and audit; helping clinicians recognize patterns in diagnosis and treatment; identifying inconsistencies in documentation (Amiri et al., 2024) and blind spots of extraction models (Elgaar and Amiri, 2026); and inform decision-support tools grounded in real clinical narratives.

8 Conclusion

MedExACT 2026 focuses on robust medical decision extraction over long discharge summaries. The submitted systems mainly use long-context encoder models, ensembles, boundary-aware decoding, and explicit optimization for the official worst-group-adjusted score. The task establishes a benchmark for medical decision extraction and shows how robustness-aware evaluation can influence system design in clinical NLP.

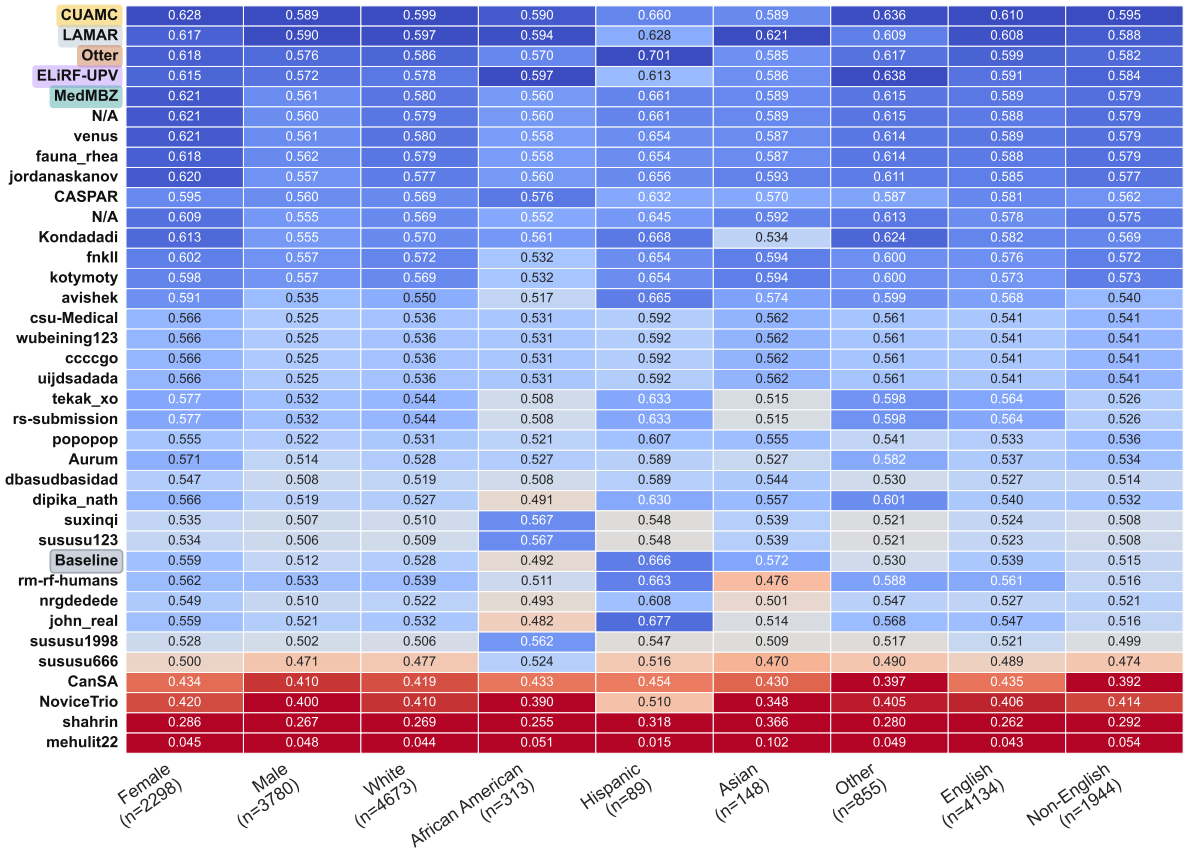

Figure 5: Full subgroup Base-score heatmap for all MedExACT 2026 leaderboard submissions. Rows are ordered by final leaderboard score; columns correspond to the nine sex, race, and English-proficiency subgroups used in the official robustness metric.

A Full Subgroup Leaderboard

Figure 5 shows the full subgroup Base-score heatmap for all MedExACT 2026 leaderboard submissions. Rows are ordered by final leaderboard score; columns correspond to the nine sex, race, and English-proficiency subgroups used in the official robustness metric. Three patterns stand out. First, the highest-ranked systems are strong across nearly all columns rather than winning through a single favorable subgroup; their Base scores mostly stay in the 0.58–0.66 range. Second, no system dominates every subgroup: `CUAMC` has the best English and Non-English scores, `LAMAR` is strongest on Asian patients, `Otter` is strongest on Hispanic patients, and `ELiRF-UPV` is strongest on African American and Other race groups. Third, subgroup robustness remains a real source of variation. Several mid-ranked runs have one or two noticeably weak columns, and the public baseline is illustrative: it is competitive on Hispanic patients but drops on African American, Male, and Non-English patients. The lowest-ranked systems are weak across all subgroups, which suggests that the robustness metric mainly separates otherwise capable systems rather than rescuing globally poor extractors.

Divide-Prompt-Refine: a Training-Free, Structure-Aware Framework for Biomedical Abstract Generation

Abstract

Biomedical abstracts play a critical role in downstream NLP applications, such as information retrieval, biocuration, and biomedical knowledge discovery. However, a non-trivial number of biomedical articles do not have abstracts, diminishing the utility of these articles for downstream tasks. We propose DPR-BAG (Divide, Prompt, and Refine for Biomedical Abstract Generation), a training-free, zero-shot framework that generates coherent and factually grounded abstracts for biomedical articles with full text but no abstract. DPR-BAG decomposes full-text documents into structured rhetorical facets following the Background-Objective-Methods-Results-Conclusions (BOMRC) schema, performs parallel LLM-based summarization for each facet, and applies a final refinement stage to restore global discourse coherence. On PMC-MAD, a distribution-aligned dataset of 46,309 biomedical articles, DPR-BAG improves abstractive novelty over strong extractive and fine-tuned baselines, while maintaining factual consistency. Our ablation study reveals a counterintuitive finding: increasing prompt complexity or explicitly injecting entity-level guidance can degrade factual alignment, highlighting the importance of controlled prompting strategies. These findings underscore the potential of training-free, structure-aware frameworks for scalable biomedical abstract generation in low-resource settings. Our data and code are available at https://huggingface.co/datasets/pmc-mad/PMC-MAD and https://github.com/ScienceNLP-Lab/MultiTagger-v2/tree/main/DPR-BAG.

1 Introduction

Many biomedical NLP tasks rely heavily on abstracts, due to their accessibility and information density. Abstracts provide an author-written summary of core scientific findings, making them a useful proxy for full-text articles in downstream applications. For example, Luo et al. (2022) showed that pre-training tasks designed around the title-abstract structure improve biomedical information retrieval; Wiegers et al. (2025) used abstracts as an initial data source for biocuration. Beyond content, the structured organization of abstracts also benefits downstream tasks: Ueda et al. (2021) leverage abstract-level structure to refine retrieval; PubMedQA (Jin et al., 2019) is based on structured abstracts to support high-fidelity biomedical knowledge discovery. Moreover, abstracts alone can serve as a stronger training signal than full texts in some settings (Gu et al., 2021).

However, the absence of abstracts in a significant portion of biomedical articles creates a bottleneck for these tasks. As of April 2026, 11,603,796 out of 40,414,072 (~29%) PubMed articles were missing abstracts, with this volume continuing to rise despite a declining overall proportion, driven by the growth of publication types such as case reports, editorials, and letters. These publication types carry substantial scientific value. For instance, Gurulingappa et al. (2012) and Fan et al. (2020) utilized case reports for adverse drug event detection; Magnet and Carnet (2006) and Nuzzo (2021) assessed letters to characterize post-publication scientific discourse, including patterns of critique, rhetorical features of disagreement, and trends in authorship; and Waaijer et al. (2011) and Ioannidis and Schippers (2025) analyzed editorials to study how journals shape scientific discourse, including the distribution of topics, the framing of policy issues, and the presence of systematic biases.

The absence of abstracts in these articles motivates the Biomedical Abstract Generation (BAG) task, which aims to automatically generate abstracts from full-text biomedical articles. Although related to standard document summarization, BAG differs in important ways. It must adhere to scientific reporting conventions, including structured

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 770–790
July 3-4, 2026 ©2026 Association for Computational Linguistics

presentation of methods, results, and conclusions, while preserving fine-grained biomedical entities, quantitative findings, and explicit argumentative relationships that are often critical for scientific interpretation. Early BAG work by Chachra et al. (2016) utilized extractive sentence selection, which can lead to fragmented coherence and poor lexical flow. Moreover, because full-length biomedical articles often exceed the context limits of standard models, BAG is inherently a long-context task, making it vulnerable to extractive bias and factual fidelity issues. For example, Wang et al. (2025) demonstrates that even state-of-the-art models like GPT-4 suffer from hallucinations and information omission when extracting from non-decomposed scientific full texts, emphasizing the inherent fidelity risks in long-document processing required for BAG task. Beyond fidelity risks, recent analysis also reveals that when forced to process complex long full texts, even specialized models like LongT5 exhibit a strong extractive bias, relying on simple heuristics to copy verbatim snippets rather than synthesizing information (Chernyshev and Dobrov, 2024). As a result, these models can suffer from the same core issue as traditional extractive summarizers: they produce fragmented text that lacks the natural flow and cohesion of human-written summaries (Giarelis et al., 2023).

To address these limitations, we propose the Divide, Prompt and Refine Biomedical Article Generation (DPR-BAG) framework. Drawing on prior work showing that divide-and-conquer decomposition reduces intermediate errors in LLMs (Zhang et al., 2025), DPR-BAG decomposes full-text articles along their rhetorical structure, performs parallel summarization on each resulting facet, and applies a modular refinement stage to reconcile fragmented outputs and restore discourse coherence. We target six rhetorical facets: Background, Objectives, Methods, Results, Conclusions (BOMRC), and Others. BOMRC is adopted as it represents the standard discourse structure validated in the PubMed 200k RCT dataset (Dernoncourt and Lee, 2017), while the “Others" facet retains any unclassified content. Using this design, we focus on three research questions:

1. Can we develop a training-free approach for the BAG task?
2. Does structure-aware decomposition of full-text articles improve the quality of generated abstracts compared to naive prompting?
3. To what extent does increasing prompting complexity (from detailed instructions to entity guidance) improve generation quality?

Our main contributions are as follows:

1. We propose DPR-BAG, a training-free, structure-aware method for BAG.
2. We release a dataset of more than 46K biomedical full-text publications for BAG task.
3. We compare DPR-BAG to strong extractive and abstractive baselines.
4. We systematically evaluate the effect of various prompting and splitting strategies as well as entity guidance within DPR-BAG.

2 Dataset

We constructed a BAG dataset based on PubMed publications from 1987 to 2023. To ensure a representative sample, we first calculated the publication type (PT) distribution of articles lacking abstracts using PT queries adapted from prior work (Menke et al., 2024). We then performed stratified sampling based on this distribution to retrieve 130,000 candidate XML files from the PubMed Central (PMC) Open Access subset, ensuring that the sampled articles reflect the publication type distribution of abstract-less PubMed records. For data processing, we adapted the extraction pipeline from the Longsummarization framework (Cohan et al., 2018) to parse structured sections and abstracts from the raw XML files. After filtering out records that were unparseable or lacked extractable abstracts, the final dataset, hereafter referred to as PMC-MAD (Missing-Abstract Distribution-aligned PMC), consists of 46,309 articles.

3 Methods

DPR-BAG follows a modular pipeline designed to generate structure-aware abstracts from biomedical full-text articles (Figure 1). The process begins by decomposing the document into five distinct facets based on BOMRC, plus an "Others" facet for unclassified content. For each facet, we perform parallel LLM-based summarization, which can optionally be augmented with entity guidance extension. The resulting sectional summaries are then concatenated and passed to a final LLM-based refinement stage to restore discourse coherence. DPR-BAG

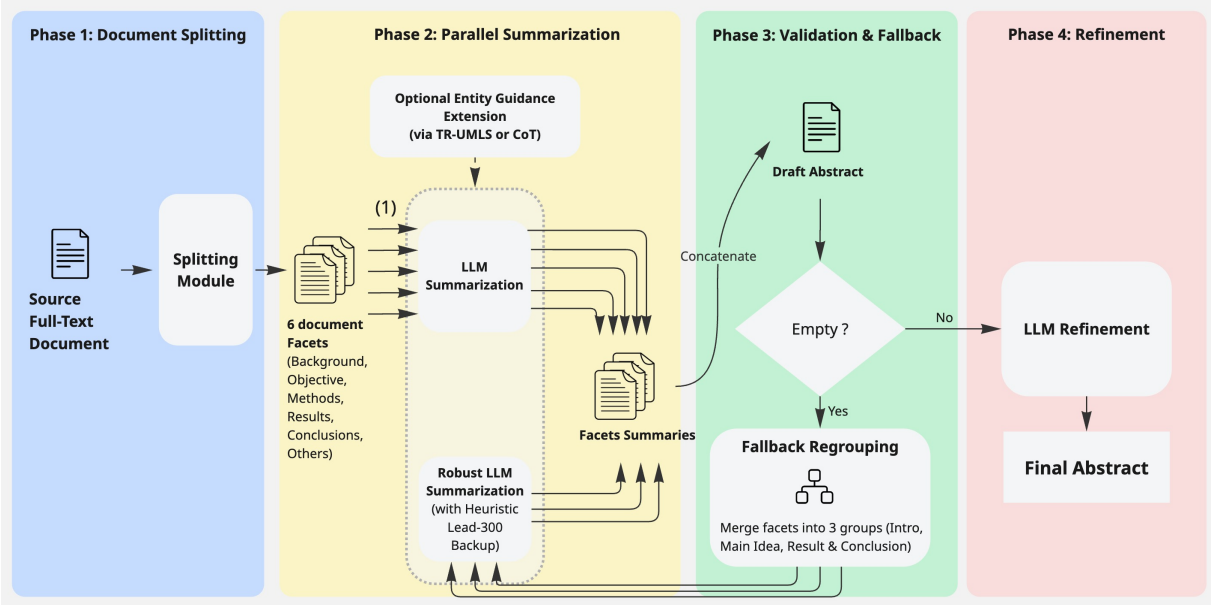

Figure 1: Overview of the DPR-BAG framework for biomedical abstract generation.

requires no task-specific training or fine-tuning; all components operate in a zero-shot manner using pre-trained, off-the-shelf models.

3.1 Task Formulation

Given a full-text biomedical article $D = (p_1, p_2, \ldots, p_n)$, where each p_i denotes a paragraph, the goal is to generate an abstract A that covers a predefined set of rhetorical facets $\mathcal{F} = \{\text{Background, Objectives, Methods, Results, Conclusions, Others}\}$ (BOMRC+).

We reformulate this as a facet-conditioned summarization problem, where the model generates content for each rhetorical facet separately. This decomposition allows the model to address each rhetorical component independently and capture discourse structure. Specifically, the document is partitioned into $K = 6$ facet-specific sub-documents $\{D_{f_k}\}_{k=1}^{K}$, where each D_{f_k} aggregates paragraphs rhetorically aligned with facet f_k. Each sub-document is independently summarized to produce a facet summary $\hat{a}_{f_k}$, and the concatenation $\hat{A} = \bigoplus_{k=1}^{K} \hat{a}_{f_k}$ is subsequently refined into the final abstract $R(\hat{A}) = A$. Facets absent from the source document yield empty strings.

3.2 Document Splitting

To segment full-text documents into rhetorically coherent texts, we use LLM-SSC (Lan et al., 2024), an LLM-based sequential sentence classification framework that assigns rhetorical labels (BOMRC) to sentences using in-context learning (performance details in Appendix E). While the model was trained on structured abstracts, we assume that the underlying rhetorical intent (e.g., methodological description vs. result reporting) remains consistent within full-text paragraphs. Specifically, we leverage the role of the first sentence of the paragraph as a topic sentence that typically encapsulates the paragraph's functional purpose. We assign the label of the first sentence of each paragraph as the global label for that paragraph, subsequently concatenating all paragraphs with matching labels to form the input document facets. We refer to this approach as the **First Sentence Labeling (FS)** strategy, and empirically validate it against naive splitting (NS) and section-header (SH) ablation variants below.

Naive Splitting Approach (NS): This approach distributes paragraphs into six segments, aiming for an approximately even distribution while maintaining paragraph integrity. Including this baseline allows us to assess whether a semantic-aware division (e.g., LLM-SSC) offers advantages over a purely structural, length-based partition.

Section-header Normalization (SH): This strategy serves as a coarse-grained semantic baseline. Utilizing the Transformer model developed in Lin et al. (2025), this approach categorizes existing section headers into standard BOMRC categories and concatenates paragraphs within the same facet. This comparison helps determine if the fine-grained, sentence-level classification used in LLM-SSC provides additional utility beyond

simple section-level organization.

3.3 Parallel Summarization

After the documents are divided into six document facets (BOMRC and Others), each is input into the LLM to generate a corresponding facet summary; facets that are not present in the source document are represented as empty summaries. These summaries are subsequently concatenated to form the draft abstract. The following subsections detail the prompting strategies and optional entity guidance extensions used during summarization.

3.3.1 Prompting Strategies

To investigate the effect of prompt complexity on generation quality, we adopt a **Basic Concise (BC)** prompting strategy as the baseline, and ablate prompting complexity by evaluating two more elaborate variants, **Detailed Instruction (DI)** and **Structural Instruction (SI)**. Full prompt templates are described in Appendix A.

Basic Concise Prompting (BC): BC is a minimal prompting strategy with coarse-grained focal points for each rhetorical facet (e.g., directing the model to "prioritize key findings and data" for the Results section) without further elaboration or explicit formatting structure.

Detailed Instruction Prompt (DI): DI is a more detailed prompting strategy modeled after the abstract submission guidelines of JMIR Publications[1] whose five-part BOMRC structured guideline aligns with the target rhetorical categories that DPR-BAG uses. By shifting the LLM persona to a "biomedical synthesis assistant," this prompt aims to enforce the extraction of granular details and mandates the inclusion of specific research designs, sample sizes, response rates, and statistical metrics (such as p-values and confidence intervals) to ensure adherence to multifaceted reporting standards.

Structural Instruction Prompt (SI): SI extends the basic prompt by introducing an explicit structural schema using Markdown formatting strategy, inspired by He et al. (2024). Compared to DI, which focuses on detailed content guidance, SI organizes the prompt into a more structured format, which aims to improve instruction adherence.

[1] https://support.jmir.org/hc/en-us/articles/37982552280987-Submitting-Your-Manuscript-to-JMIR-Publications-A-Guide-for-Authors

3.3.2 Entity Guidance

We additionally introduce an optional knowledge-grounding extension to further enhance semantic fidelity during parallel summarization. This component extracts key biomedical entities to guide the LLM in summarizing each facet. We consider two instantiations of this extension, TR-UMLS and CoT, detailed below.

TextRank and UMLS normalization (TR-UMLS): We extract key phrases from each facet using TextRank, a graph-based unsupervised method that requires no additional training and is well-suited to our zero-shot setting, and link them to UMLS (Bodenreider, 2004) concepts using scispaCy's UMLS entity linker (Neumann et al., 2019), retaining only phrases with valid UMLS mappings. When multiple phrases map to the same UMLS concept, they are grouped together and represented by a single term to avoid redundant anchoring. The top-n entities, ranked by TextRank centrality, are incorporated into the summarization prompt as anchor terms to guide the model toward the most structurally significant medical information in the text. We ablate $n \in \{5, 10\}$ in Section 5.2.

Chain-of-Thought (CoT): As an alternative, we employ a two-stage prompting strategy within the LLM summarization module when the extension is activated. In the first stage, we prompt the model to list the important entities of the facet, and in the second stage, the model is prompted to synthesize the information based on the facet and the entities it listed in the first stage.

We ablate these two entity guidance strategies independently. TR-UMLS pairs with DI, while CoT pairs with SI, whose structured format makes it well-suited for CoT's two-stage reasoning.

3.4 Validation and Fallback

To ensure the summarization pipeline robustness, we implement a validation and fallback mechanism. If all six facet summaries are empty due to insufficient context or LLM output format violations, the facets are regrouped into three broader categories (Intro, Main Idea, and Results & Conclusions) and sent back to the parallel summarization module. If regrouping fails, a first 300 characters (Lead-300) heuristic backup is used to guarantee non-empty output (details in Appendix B).

3.5 Refinement

Upon the formation of the draft abstract, we prompt the LLM to perform a global refinement to ensure structural coherence and stylistic consistency. This final processing step synthesizes the concatenated facets into a unified Final Abstract (the refinement prompt is detailed in Appendix C).

4 Experimental Setup

DPR-BAG is implemented with `Llama-3.2:3B` deployed via Ollama in instruction-tuned mode. Hardware details, token-limit constraints, and fine-tuning hyperparameters are provided in Appendix D.

4.1 Baseline Models

To establish robust baselines for our framework, we compared our approach against several standard long-document summarization models. We utilized two off-the-shelf variants of the Longformer Encoder-Decoder (LED) architecture (Beltagy et al., 2020)—pretrained on arXiv[2] and PubMed[3], respectively—to evaluate their zero-shot transferability to our task. Additionally, we included an off-the-shelf LongT5 model (Guo et al., 2022) pretrained on PubMed[4] to broaden our baseline comparisons across different architectures. Finally, to ensure maximal adaptation to our corpus, we evaluated a supervised fine-tuned version of the PubMed-pretrained LED and LongT5 using our 80% training split, using the 10% validation split for early stopping. All evaluations were performed on the remaining 10% (test split).

4.2 Evaluation Metrics

To assess the generated abstracts, we employ a multi-dimensional suite of metrics, with particular emphasis on abstractiveness and factuality. Detailed formulations and implementation details of each metric are provided in Appendix I. Paired bootstrap significance tests for the main comparisons are provided in Appendix J.

Abstractiveness: **Bigram and trigram novelty** measure the proportion of tokens absent from the source text, serving as a proxy for abstractive synthesis. We additionally adopt **Density** from Newsroom (Grusky et al., 2018), which quantifies the length of verbatim copying from the source, offering a complementary view of the model's extractive behavior. For both, smaller absolute deviations from the human-written reference indicate closer stylistic alignment.

Factuality: Given that our target abstracts are expected to be highly abstractive, factuality metrics must remain reliable under heavy paraphrasing. We therefore adopt **AlignScore** (Zha et al., 2023) as our primary factuality measure, as it evaluates alignment against the source full-text across a broad range of dimensions (notably paraphrasing), making it more robust than purely entailment-based alternatives. We additionally report **SummaC** (Laban et al., 2022) and **MiniCheck** (Tang et al., 2024), both NLI-based metrics, as cross-checks.

Semantic Alignment: We adopt **BERTScore** (Zhang et al., 2020) to evaluate semantic similarity between generated abstracts and the reference abstracts via contextual embeddings. To further assess discourse coherence, we adopt **DiscoScore** (Zhao et al., 2023), reporting DS_SENT_NN (sentence-level structural alignment) and DS_FOCUS_NN (shared noun semantic alignment).

Supporting Metrics: We additionally adopt **ROUGE-L** (Lin, 2004) to measure n-gram overlap with the reference. **UMLS Recall** quantifies the proportion of UMLS (Bodenreider, 2004) concepts from the original abstract retained in the generated output. **Coverage** and **Compression** from Newsroom (Grusky et al., 2018) serve as complementary metrics to measure how source content is preserved and condensed. For these two metrics, as well, smaller absolute deviations from the human-written reference are preferred.

5 Results

5.1 RQ1: Effectiveness of the Training-Free Approach

We first evaluate whether the proposed training-free approach can achieve competitive performance on the BAG task. As shown in Table 1 and Table 2, DPR-BAG (BC prompt, no entity guidance extension) achieves competitive performance against fine-tuned baselines. It generates abstracts that

more closely resemble human-written abstracts (more abstractive), while maintaining factual consistency with the full text (Table 1).

DPR-BAG outperforms the fine-tuned baselines in both abstractiveness and factuality (all paired bootstrap $p < 0.001$ on Bigram and Trigram novelty, Density, AlignScore, and MiniCheck; Appendix J.2), while the fine-tuned baselines themselves perform better than other baselines in abstractiveness but their generations are less factual.

DPR-BAG yields mostly lower scores for semantic alignment and other supporting metrics compared to the baselines, reflecting a known bias in these metrics toward extractive outputs (Table 2). Baseline models exhibit high density and low novelty relative to human-written abstracts (Table 1), indicating extractive behavior that likely inflates their scores. At the same time, DPR-BAG yields the highest compression rate (50.037), potentially leading to over-simplification of key information. We provide qualitative examples of generated abstracts in Appendix K.

5.2 RQ2: Impact of Structure-Aware Decomposition

We next evaluate whether structure-aware decomposition improves generation quality compared to naive prompting. As shown in Table 3, FS achieves the best overall performance. Compared to NS, FS achieves significantly higher AlignScore (paired diff = +0.006, $p < 0.05$), with no significant difference on MiniCheck or SummaC. Both approaches have similar abstractiveness, with NS achieving scores marginally closer to the human-written abstracts on Trigram novelty. Comparing FS with SH further underscores the necessity of fine-grained local context: SH significantly degrades AlignScore (-0.126), MiniCheck (-0.099), and SummaC (-0.141), all $p < 0.001$, indicating that broad semantic boundaries provided by section headers fail to provide sufficient contextual anchoring for faithful generation.

5.3 RQ3: Impact of Prompting Strategy and Entity Guidance

Next, we examine the effect of increasing prompt complexity.

Prompting Strategy: While DI and SI yield marginal but significant improvements in BERTScore ($p < 0.001$), both suffer from degradation in AlignScore, MiniCheck, SummaC, and UMLS Recall compared to BC (all $p < 0.001$; Table 4). This suggests that dense, multi-faceted

Splitting	Abstractiveness		Factuality		Semantic Alignment

NS	**0.613 (-0.050)**	4.508 (-2.142)	0.756	**0.892**	0.615	0.856	0.262
SH	0.746 (+0.083)	2.885 (-3.765)	0.636	0.791	**0.636**	0.920	0.229

Table 3: Ablation on document splitting strategies. Splitting strategies are Naive Splitting (NS), Section Header Normalization (SH), and First Sentence Labeling (FS). (Abbreviations as in Table 1 and Table 2)

Prompt	Abstractiveness		Factuality		Semantic Alignment		
	Tri-g	Dens.	AS	MC	BS	FOCUS↓	U-R
BC	**0.605 (-0.058)**	**4.690 (-1.960)**	**0.762**	**0.890**	0.617	**0.828**	**0.266**
DI	0.725 (+0.063)	3.131 (-3.519)	0.642	0.806	**0.638**	0.885	0.247
SI	0.736 (+0.073)	3.049 (-3.601)	0.630	0.805	0.636	0.836	0.251

Table 4: Ablation on summarization prompt strategies. Prompt variants are Basic Concise (BC), Detailed Instruction (DI), and Structural Instruction (SI). (Abbreviations as in Table 1 and Table 2)

instructions might have introduced a distraction effect, where the model struggles to simultaneously satisfy formatting constraints and maintain source-grounded factual alignment, motivating the need for explicit reasoning pathways and external grounding.

Entity Guidance: To assess whether external grounding can recover the factual consistency degradation observed in DI and SI, we ablate two entity guidance approaches: TR-UMLS integrated into DI, and CoT integrated into SI, with BC (no entity guidance) serving as the reference baseline.

As shown in Table 5, applying TR-UMLS to DI does not improve the overall performance. Top-5 and top-10 variants show no significant change in AlignScore relative to the base DI prompt, and both remain significantly below the BC baseline ($p < 0.001$). DS-Focus score also increases under top-5 entities ($p < 0.01$), suggesting that explicit entity conditioning might cause the model to overprioritize the provided terms, exacerbating the distraction effect rather than serving as an effective grounding mechanism.

Table 6 shows that integrating CoT into the SI prompt improves semantic alignment with the original abstract compared to BC (BERTScore +0.015, $p < 0.001$) while yielding overall higher abstractiveness and lower factuality (AlignScore -0.166, MiniCheck -0.098, SummaC -0.158, all $p < 0.001$). This shows that CoT encourages more abstractive and novel phrasing, at the expense of reducing the factual overlap with the source.

6 Discussion

Our results show that the proposed training-free approach generates abstracts that more closely resemble human-written abstracts in terms of abstractiveness and factuality. Notably, models fine-tuned on PMC-MAD do not match this performance on these dimensions. However, these fine-tuned models achieve slightly better semantic alignment, lexical/semantic overlap, and compression than DPR-BAG. Since the baseline models do not explicitly model rhetorical structure, we attribute the stronger performance of DPR-BAG on abstractiveness and factuality to its structure-aware design. Specifically, the instruction-tuned LLM backbone provides a baseline tendency toward natural, paraphrased output over verbatim copying. This tendency is amplified by the decompose-then-refine design: partitioning full-text articles into facet-specific subdocuments allows each summarization step to operate over shorter, topically coherent contexts, reducing verbatim copying under long-context pressure. The subsequent refinement stage then resynthesizes the concatenated facet summaries, further encouraging paraphrasing over fragment assembly.

The distraction effect observed under DI and SI prompts indicates that instruction complexity can actively harm factual grounding in small LLMs. Similarly, entity guidance via UMLS only seemed to increase instruction complexity, yielding little positive effect. The inconsistent gains of SI+CoT further suggest that publication-type distribution can influence generation behavior. This motivates publication-type-aware prompting as a future direction. Additional BC-prompt ablations corroborate these findings for TR-UMLS (Appendix H).

To evaluate the generalizability of DPR-BAG, we applied it to the PubMed Summarization dataset (Cohan et al., 2018). Unlike PMC-MAD, this dataset is not stratified to reflect the publica-

tion type distribution of abstract-less PubMed articles. Overall, the trends observed on PMC-MAD, particularly with respect to semantic alignment, abstractiveness, and factuality, largely persist on this dataset. Some differences are also observed (lower MiniCheck scores and better performance of SI+CoT relative to BC). Despite these variations, the results indicate that DPR-BAG maintains robust performance across datasets, supporting its generalizability (Appendix F).

To investigate whether larger model sizes can improve generation quality, we also evaluated `Qwen2.5:7B` and `Qwen2.5:14B` under the BC prompt. These models achieve improvements in semantic alignment and compression rates; however, they also yield excessive abstractiveness and lower factuality, overall yielding little advantage over the base 3B model (Appendix G).

6.1 Limitations

Several limitations apply. First, our evaluation relies primarily on automated metrics, which vary in their robustness. Human evaluation is needed for complementary validation. Second, the BOMRC schema may be suboptimal for articles with non-standard discourse structure. More adaptive decomposition strategies remain an open direction. Finally, DPR-BAG's summaries exhibit substantially higher compression than human-written abstracts, indicating considerably terser outputs. This excessive compression risks omitting auxiliary but informative content such as background, secondary findings, or caveats. Calibrating facet-level length targets is a natural direction for future work.

7 Related Work

For the BAG task, Chachra et al. (2016) integrated domain-specific classifiers and entailment graphs for extractive sentence selection, inheriting the disjointed flow typical of pure extractive approaches. Sybrandt and Safro (2021) proposed CBAG, which generates abstracts conditioned on author-provided MeSH keywords rather than full-text articles, leaving long-context challenges unaddressed.

To generate abstractive summaries from full-text articles, DANCER (Gidiotis and Tsoumakas, 2020) and IDCUOT (Shen and Lam, 2022) pioneered the strategy of breaking long documents into manageable sections to bypass context window limitations. However, these supervised approaches rely on heuristic alignment algorithms to map abstract sentences back to source sections and generate summaries for each section in isolation, making them prone to error propagation and fragmented coherence across sections.

GenCompareSum (Bishop et al., 2022) leverages similar divide-and conquer principles but remains extractive-heavy: abstractive fragments serve only as anchors for sentence selection, resulting in discontinuous summaries that lack the narrative transitions typical of human-written abstracts.

8 Conclusion

We presented DPR-BAG, a training-free, rhetorical structure-aware, divide-and-conquer framework for biomedical abstract generation. The method decomposes full-text articles into semantic facets and applies parallel LLM-based summarization followed by refinement. Across both the PMC-MAD and PubMed Summarization datasets, DPR-BAG produces abstracts that most closely match human-

written abstracts in terms of abstractiveness and factual consistency, without task-specific training and within standard hardware constraints. The framework can be integrated as a preprocessing component into pipelines that require biomedical abstracts, thereby improving downstream performance.

A Summarization Prompt Templates

All prompting strategies share a `facet_guidelines` dictionary that maps each facet label to a facet-specific instruction. We use two versions: a concise version (Table 7) used in BC and SI prompts, and a detailed version adapted from JMIR author guidelines (see footnote 1) (Table 8 used in DI prompts). In all prompt templates, `<facet_text>` denotes the input facet text, `<facet_type>` denotes the rhetorical facet label, and `<facet_guide>` denotes the corresponding facet-specific instruction.

A.1 Basic Concise Prompt (BC)

System Message

You are a biomedical summarization assistant. 1. Use a formal, objective, scientific tone. 2. Never use meta-phrases like 'the authors state' or 'this section describes'. Respond ONLY with a JSON object: {"summary": "...", "reasoning": "..."}. No markdown, no talk.

User Message

Summarize this `<facet_type>` section
Specific focus: `<facet_guide>`

Paragraph text:
`<facet_text>`

A.2 Detailed Instruction Prompt (DI)

System Message

You are a biomedical synthesis assistant. 1. Use a formal, objective, scientific tone.
2. Never use meta-phrases like 'the authors state' or 'this section describes'.
Define your output strictly as:
-'summary': The synthesized biomedical text.
-'reasoning': A brief explanation.
Format: {"summary": "...", "reasoning": "..."}. No markdown, no talk.

User Message

Synthesize the critical information from this `<facet_type>` section provided in the 'Paragraph text'
`<facet_guide>`

Paragraph text:
`<facet_text>`

A.3 Structural Instruction Prompt (SI)

System Message

ROLE
You are an expert Biomedical Summarization Assistant.

STRICT GUIDELINES
- **Tone**: Formal, objective, and academic.
- **No Meta-Talk**: Do NOT use phrases like 'The authors state' or 'This section describes'.
- **Output Format**: Respond **ONLY** with a valid JSON object. No Markdown blocks, no preamble, no postscript.
```json
{"reasoning": "Brief explanation of how your summary fulfills the given instructions...", "summary": "Final summary..."}
```

Facet	Guideline
Background	Focus on research gap and motivation.
Objective	State the primary aim or hypothesis.
Methods	Detail study design and procedures.
Results	Prioritize key findings and data.
Conclusions	Summarize implications and take-home messages.
Others	Focus on the main point of the paragraph.
Intro	Introduce the main topic and context.
Main Idea	Focus on the central concept or hypothesis.
Results & Conclusions	Focus on key findings and their implications.

Table 7: Concise facet-specific guidelines (used in BC and SI prompts).

Facet	Guideline
Background	Briefly describe the context and significance of the research.
Objective	State the specific aim(s) of the study in a complete sentence.
Methods	Outline the research design, study sample, data collection, and analysis procedures.
Results	Present key findings, including relevant statistics (sample sizes, response rates, P values, confidence intervals). Be specific.
Conclusions	Summarize the main findings and their implications.
Others	Synthesize the core biomedical information, focusing on the primary argument, concept, or supplementary context presented.
Intro	Describe the research context and significance, and clearly state the specific aims or hypotheses.
Main Idea	Outline the research design and procedures, while capturing any supplementary methodological context or core concepts.
Results & Conclusions	Present key findings with relevant statistics, and summarize their broader implications and take-home messages.

Table 8: Detailed facet-specific guidelines (used for DI prompts), adapted from JMIR author guidelines.

User Message

TASK: SUMMARY GENERATION
Target Focus: `<facet_guide>`

Instructions: Generate a professional biomedical summary.
—
INPUT TEXT (Reference)
`<facet_text>`

A.4 BC for Naive Splitting (BC-NS)

When paired with the Naive Splitting baseline, the system message remains unchanged. As no facet label is assigned, the user message uses a generic focus instruction:

User Message

Summarize this section.
Specific focus: Summarize the main topic.

Paragraph text:
`<facet_text>`

A.5 BC with TR-UMLS Entity Guidance (BC+TR-UMLS)

System Message

You are a biomedical summarization assistant. 1. Use a formal, objective, scientific tone. 2. Never use meta-phrases like 'the authors state' or 'this section describes'. Respond ONLY with a JSON object: {"summary": "...", "reasoning": "..."}. No markdown, no talk.

User Message

Summarize this `<facet_type>` section
Specific focus: `<facet_guide>`
Ensure the core meanings of these key biomedical entities are preserved or synthesized accurately:

Paragraph text:<top_entities>
`<facet_text>`

A.6 DI with TR-UMLS Entity Guidance (DI+TR-UMLS)

User Message

Synthesize the critical information from this <facet_type> section provided in the 'Paragraph text'
<facet_guide>

Ensure the core meanings of these key biomedical entities are preserved or synthesized accurately: <top_entities>

Paragraph text:
<facet_text>

A.7 SI with Chain-of-Thought (SI+CoT)

System Message

ROLE
You are an expert Biomedical Summarization Assistant.

—
OPERATIONAL FRAMEWORK
You must follow this 2-Stage Chain-of-Thought process:
1. Stage 1: Element Extraction (entities, parameters, methodologies, statistics).
2. Stage 2: Summary Generation (synthesize into scientific narrative).

—
STRICT GUIDELINES
- **Tone**: Formal, objective, and academic.
- **No Meta-Talk**: Do NOT use phrases like 'The authors state' or 'This section describes'.
- **Output Format**: Respond **ONLY** with a valid JSON object. No Markdown blocks, no preamble, no postscript.
```json
{"reasoning": "Stage 1 extraction results...", "summary": "Stage 2 final summary..."}
```

User Message 1 (Stage 1)

TASK 1: ELEMENT EXTRACTION
Section Type: <facet_type>
Instructions: Extract key elements from the text below, including:
- **Entities:** Diseases, genes, drugs, proteins.
- **Parameters:** Sample sizes, dosage, duration.
- **Methodology:** Study design, assays, equipment.
- **Statistics:** P-values, confidence intervals, effect sizes.

—
INPUT TEXT
<facet_text>

User Message 2 (Stage 2)

TASK 2: SUMMARY GENERATION
Target Focus: <facet_guide>

Instructions: Using the elements extracted in Task 1, generate a professional biomedical summary.
Ensure the summary is dense with information but remains readable and scientifically accurate.

—
INPUT TEXT (Reference)
<facet_text>

B Validation and Fallback Details

When the fallback process is triggered, the original six facets are regrouped into three broader categories: *Intro* (Background and Objective), *Main Idea* (Methods and Others), and *Results & Conclusions* (Results and Conclusions). Background and Objective are merged as both establish the research context and motivation. Results and Conclusions are paired as both convey findings and their implications. The remaining Others facet, which retains paragraphs not assigned to any BOMRC category by the sentence classifier, is grouped with Methods by elimination, as the other four facets form more natural rhetorical pairs. These regrouped facets are then sent back to the parallel summarization module. If the LLM still fails to summarize a specific

regrouped facet, the first 300 characters (Lead-300) of that facet are used as the facet summary to capture core information via lead bias without adding granular noise. The fallback mechanism was rarely triggered in practice, suggesting that this pairing has minimal impact on overall generation quality. In a random sample of 300 test articles (6.5% of the test set), the fallback mechanism was never triggered, suggesting with 95% confidence that fewer than 1% of articles require fallback intervention.

C Refinement Prompt

This prompt is used in the final stage to smooth the concatenated facets, ensuring structural coherence and stylistic consistency across the unified abstract. `<draft_abstract>` denotes the place holder for the concatenated draft abstract.

System Message

You are a biomedical abstract refinement assistant. Refine the abstract based on the abstract draft.
CRITICAL INSTRUCTION:
Respond ONLY with a valid JSON object.
Do NOT use Markdown code blocks (like “‘json).
Do NOT provide any conversational text.

Format:
{
"abstract": "your abstract text here",
"reasoning": "your reasoning here"
}

User Message

abstract draft: `<draft_abstract>`

D Extended Implementation Details and Token Distribution

All fine-tuning and evaluation procedures were conducted on an NVIDIA Tesla V100 GPU (32GB VRAM). While the underlying LED architecture theoretically supports sequences up to 16,384 tokens, processing such lengths on standard hardware is computationally prohibitive, inevitably leading to out-of-memory (OOM) errors even with minimal batch sizes. To fit within this memory budget, the fine-tuned LED-Pubmed used gradient accumulation with an effective batch size of 8, halted at

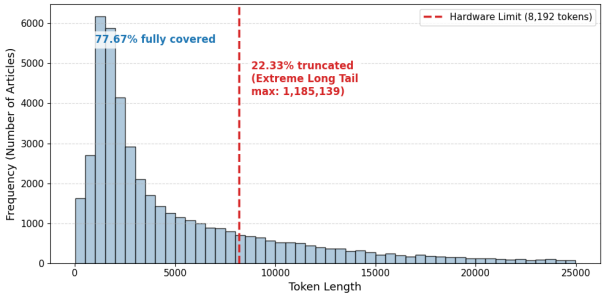

Figure 2: Distribution of document token lengths in the dataset. The red dashed line denotes the 8,192-token hardware limit for standard baselines.

500 steps based on validation performance.

This constraint restricts standard baselines to 8,192-token inputs. As illustrated in Figure 2, our empirical analysis of the 46,309 articles in the dataset reveals a median of 2,959 tokens and an average length of approximately 6,018 tokens. While the 8,192-token capacity successfully accommodates 77.67% of the dataset, the length distribution exhibits a severe long-tail characteristic. Specifically, 22.33% of the articles exceed this limit, with the longest document reaching an extreme 1,185,139 tokens. For these extensive studies, standard baselines operating within memory limits are forced to truncate critical information, such as discussion and conclusion sections, which underscores the necessity of the partitioned approach introduced in our DPR-BAG framework.

E LLM-SSC

LLM-SSC (Lan et al., 2024) is evaluated on the BIORC800 dataset, a manually annotated multi-label SSC dataset of biomedical abstracts using the BOMRC schema. Under task-specific fine-tuning, LLM-SSC achieves a micro F1 of 0.907 and macro F1 of 0.912 on BIORC800, outperforming prior SSC baselines (Cohan et al., 2019). We adopt LLM-SSC for our document splitting module as its label schema (Background, Objective, Methods, Results, Conclusions, and None) directly aligns with the BOMRC+ facets in DPR-BAG, where the None label corresponds to our Others facet.

F PubMedSum Dataset Validation

To evaluate the generalizability of our pipeline, we also tested DPR-BAG on the PubMed Summarization dataset (Cohan et al., 2018), hereafter PubMedSum. As shown in Figure 4, unlike PMC-MAD, which is stratified to reflect the publication type dis-

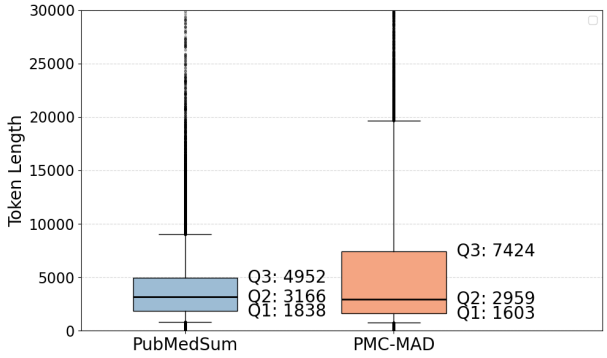

Figure 3: Token Distribution Comparison

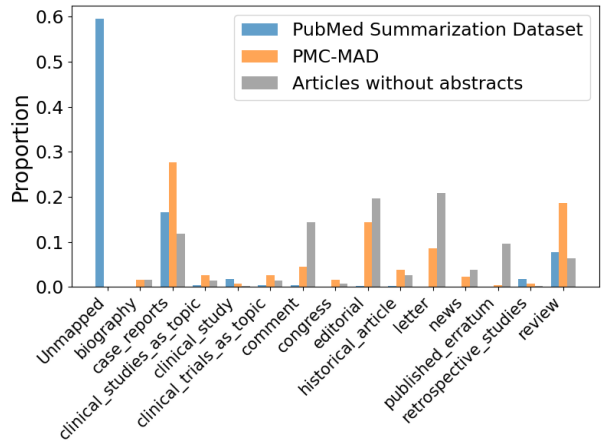

Figure 4: Publication type distribution of PMC-MAD, PubMed Summarization Dataset, and PubMed articles without abstracts.

tribution of abstract-less PubMed manuscripts, the majority of articles in the PubMedSum could not be mapped to a specific publication type. This allows us to benchmark the performance of DPR-BAG against established standards in the biomedical domain and ensure that our findings are not limited to the specific characteristics of the PMC-MAD corpus.

As illustrated in Figure 3, the two datasets exhibit distinct token length profiles. PMC-MAD has a median document length of 2959 tokens (IQR: 1603–7424), while PubMedSum has a median of 3,166 tokens (IQR: 1838–4952).

Table 9 and Table 10 present results on the PubMed Summarization dataset for the two best PMC-MAD configurations: BC (without entity guidance) and SI+CoT. Consistent with PMC-MAD findings, DPR-BAG underperforms all baseline models on ROUGE, UMLS Recall, DiscoScore, and SummaC, while achieving better coverage, density, and novel n-gram scores closer to the original human-written abstract. Both configurations outperform all baselines on AlignScore, confirming that the abstractiveness gains do not compromise factuality.

However, DPR-BAG's MiniCheck advantage on PMC-MAD does not transfer here, attributable to PubMedSum's inherent higher abstractiveness (lower density, higher novelty), which penalizes NLI-based metrics (MiniCheck) even when factual content is preserved — as evidenced by DPR-BAG's consistently superior AlignScore across both datasets.

Unlike on PMC-MAD where SI+CoT only improved BERTScore, on PubMedSum SI+CoT significantly improves AlignScore, ROUGE-L, UMLS Recall, DiscoScore, and Compression while showing no significant degradation on factuality (MiniCheck, SummaC) or abstractiveness. This suggests that CoT's benefit varies with document characteristics, potentially driven by publication-type distribution differences.

G Effect of Backbone Model Size

To investigate whether scaling up the backbone LLM improves generation quality, we evaluated `Qwen2.5:7B` and `Qwen2.5:14B` under the BC prompt without entity guidance. As the Llama3.2 series does not offer a model beyond 3B, we use Qwen 2.5 for the scaling analysis.

As shown in Table 11 and 12, Qwen2.5:14B improves BERTScore, UMLS Recall, and DS-Focus relative to the 3B backbone, recording the best DS-Focus, and UMLS Recall among all DPR configurations, alongside a compression rate most closely aligned with the original abstracts. However, both larger backbones exhibit excessively higher abstractiveness (lower Density, higher Novel n-grams) and declining factuality (SummaC, AlignScore and MiniCheck) relative to the 3B backbone, suggesting that larger models promote more abstractive phrasing and precise semantic alignment of key noun foci at the cost of reduced factual overlap with the source.

H BC Entity Guidance Ablations

To isolate the effect of entity guidance from prompt complexity, we additionally apply TR-UMLS to the BC prompt and compare against BC without entity guidance.

We integrate TR-UMLS with top-5 UMLS entities into the BC prompt (BC+Top-5). As shown in Table 13, BC+Top-5 significantly degrades fac-

Table 10: Performance comparison on the PubMed Summarization dataset across semantic alignment and supporting metrics. Conventions and abbreviations as in Table 2

tuality relative to BC ($p < 0.001$) and decreases UMLS Recall ($p < 0.001$), indicating that the injected UMLS terms fail to anchor concept reproduction in the output. These results confirm that TR-UMLS entity guidance remains ineffective in this zero-shot setting regardless of the underlying prompt strategy. Significance details are reported in Appendix J.5.

I Evaluation Metric Details

I.1 Factual Consistency (AlignScore, MiniCheck and SummaC)

AlignScore (Zha et al., 2023): AlignScore trains a unified alignment model on 4.7M examples spanning 7 tasks—NLI, fact verification, paraphrase, semantic textual similarity, question answering, information retrieval, and summarization—producing a single factual consistency score. At inference time, the source document is split into overlapping chunks of approximately 350 tokens, and each sentence in the generated abstract is evaluated against all chunks; the highest alignment score per sentence is averaged to yield the final score. We use the base variant (RoBERTa-base, 125M parameters).

MiniCheck (Tang et al., 2024): MiniCheck trains a small fact-checking model on synthetically constructed data generated by GPT-4, where each instance is designed to require verifying multiple atomic facts against multi-sentence evidence. It produces a binary supported/unsupported prediction per sentence. In our evaluation, each sentence in the generated abstract is treated as an individual claim and verified against the source full-text document. We use the Flan-T5-Large variant (770M parameters).

SummaC (Laban et al., 2022): SummaC segments the source document into individual sentences and scores each generated sentence by aggregating sentence-level NLI entailment probabilities against all source sentences. The $\text{SummaC}_{\text{Conv}}$ variant learns a convolutional layer over the full distribution of these entailment scores, rather than relying only on the maximum, making it more robust to outliers. We use the `SummaCConv` implementation with a VitaminC-trained NLI backbone and sentence-level granularity.

I.2 DiscoScore (DS_SENT_NN & DS_FOCUS_NN)

DiscoScore(Zhao et al., 2023) evaluates discourse coherence by modeling focus transitions across sentences. In this work, we use nouns (NN) as the focus, one of several focus choices supported by the metric, to compare the discourse coherence between the reference and generated abstracts.

DS_SENT_NN: Constructs a sentence graph where edges are drawn between any two sentences (not just adjacent ones) that share at least one noun focus. Edge weights are inversely proportional to the distance between the two sentences ($1/(j-i)$), capturing both local and long-range co-

Backbone	Abstractiveness			Factuality

Qwen 2.5:14B	**0.633**	0.866	**0.596**	**0.189**	**0.337**	0.857 (+0.114)	**23.234 (-0.593)**

Table 12: Scale-up comparison on semantic alignment and supporting metrics. Conventions and abbreviations as in Table 2

herence. Sentence embeddings are then aggregated according to this graph structure, and the cosine similarity between the resulting graph-level embeddings of the generated and reference texts is used as the final score.

DS_FOCUS_NN: Measures how closely the frequency and semantics of shared noun foci match between the generated and reference texts. For each focus shared by both texts, it computes the distance between their embeddings (derived by summing the contextualized token embeddings of all associated tokens), and averages these distances as the final score.

I.3 UMLS Recall

This metric measures how well the generated abstract preserves biomedical concepts present in the reference abstract. We extract unique UMLS concepts from both the original abstract (C_{ref}) and the generated abstract (C_{gen}) using a biomedical entity linker (scispaCy, Neumann et al., 2019) with the UMLS knowledge base). UMLS Recall is then computed as:

$$\text{UMLS Recall} = \frac{|C_{\text{gen}} \cap C_{\text{ref}}|}{|C_{\text{ref}}|} \quad (1)$$

Newsroom (Grusky et al., 2018): Coverage, Density, and Compression: We adopt the extractive fragment measures from Grusky et al. (2018). Given a summary S and source document D, extractive fragments are the set of longest common substrings shared between S and D. **Coverage** measures the proportion of summary tokens belonging to an extractive fragment. **Density** measures the average length of the extractive fragments, reflecting how verbatim the summary is. **Compression** is the ratio of source document length to summary length.

N-gram Novelty Following See et al. (2017), we compute the proportion of bigrams and trigrams in the generated abstract that do not appear in the source full-text document. Higher novelty indicates greater abstractive synthesis relative to the source.

J Statistical Significance Analysis

J.1 Method

For each comparison between two configurations A and B, we align per-document scores by article ID and resample with replacement over 10,000 iterations. For metrics where higher (or lower) scores indicate better performance (AlignScore, MiniCheck, SummaC, BERTScore, DiscoScore variants, ROUGE-L, UMLS Recall), we test $H_0 : \mathbb{E}[s_A] = \mathbb{E}[s_B]$ on raw scores. For abstractiveness metrics where the goal is proximity to the reference distribution (Bigram novelty, Trigram novelty, Density, Coverage, Compression), we instead test $H_0 : \mathbb{E}[\,|s_A - s_{\text{ref}}|\,] = \mathbb{E}[\,|s_B - s_{\text{ref}}|\,]$, where s_{ref} is the corresponding score of the human-written abstract on the same document. Under this formulation, a negative difference indicates that A is closer to the reference than B. All tests are two-sided, with significance markers * ($p < 0.05$), ** ($p < 0.01$), and *** ($p < 0.001$). Comparisons not marked are not significant at $p < 0.05$. The per-document scores used for testing are extracted from the same evaluation pipeline that produces the average numbers in Section 5; only articles with

Config	Abstractiveness		Factuality		Semantic Alignment

K Case Study: Qualitative Comparison of Generated Abstracts

As shown in Table 25, both LED and LongT5 models exhibit severe verbatim copying from the source full text, with LongT5 further producing a lexical hallucination. In contrast, DPR-BAG demonstrates stronger topic identification and more abstractive generation for the BAG task, though it still occasionally exhibits entity relation confusion (e.g., misattributing target genes as lncRNAs).

Model	Generated Abstract (truncated)
Original Abstract	Long non-coding RNAs (lncRNAs) comprise a sizeable class of non-coding RNAs with a length of over 200 base pairs. Little is known about their biological function, although over 20,000 lncRNAs have been annotated in the human genome. Through a diverse range of mechanisms, their primary function is in the regulation of the transcription of protein-coding genes. lncrna transcriptional activation can result from a group of nucleus-retained and chromatin-associated lncrnas, which function as scaffolds in the cis/trans recruitment of transcription factors, co-activators or chromatin remodelers, and/or promoter enhancers. their synthesis is initiated by various processes including ceramide synthesis, release of intracellular ca2+ or acid-base balance disorders. prior to vesicle creation, selective cargo loading occurs in the endosomal sorting complex required for transport. participation of endosomal sorting proteins such as tetraspanins or specific sumoylated proteins required for transport has been indicated in research. the endosomal-sorting complex consists of four components, these induce the formation of multivesicular bodies and the induction of membrane deformation to form exosomes. nanovesicles could be formed inside multivesicular bodies to allow transport outside the cell or digestion in lysosomes. the molecular content of exosomes is more heterogenic than its synthesis process, with different cargoes being examined inside vesicles with regard to the type or stage of cancers. this paper will review the importance of lncrnas as crucial molecular content of exosomes, indicating its involvement in tumour suppression, pro-tumorigenic events and the development of novel therapeutic approaches in the near future. further studies of their mechanisms of function are essential, as well as overcoming several challenges to gain a clearer insight to the approaches for the best clinical application.
LED-Pubmed (FT)	The exosome is a type of extracellular vesicle involved in cell-to-cell communication and disease transmission. Exosomes can be found in urine, sperm, amniotic fluid and other biological fluids, and have been implicated in various biological processes, such as cancer development, immune responses, invasion, invasion and invasion, cell proliferation, invasion or invasion, migration and invasion of tumour cells, as well as in the regulation of gene expression in cancer cells. the lncrna (non-coding rna) is a class of transcripts that do not encode proteins and whose length exceeds 200 bp and therefore play a vital role in regulating signaling pathways and gene expression, and therefore plays a pivotal role in cancer development and cancer-related diseases such as metastasis, angiogenesis and tumour cell invasion, and is involved in the formation of exosomal lipid bilayers, migration, proliferation and invasion in tumour microenvironment, which in turn are involved in cancer progression and progression, as evidenced by their involvement in the secretion of cytokines and growth factors, lipids or proteins from endosomes, and in the activation of the transcription factor hypoxia inducible factor (hif-β) pathway, among others, and their role in the induction of pre-metastatic niche formation in cancerous diseases, including lung cancer. the purpose of this review is to summarize the role of various exosomally-derived lnas in carcinogenesis and in other biological processes and to highlight the importance of these molecules in cancer biology and cancer development.
LongT5 (Base)	Circulating long non-coding rnas are a class of transcripts that do not encode proteins and whose length exceeds 200 bp. They play a significant role in diverse cellular processes from enabling normal development to disease progression, as well as cell communication. A valuable example of a biological carrier that can transport abundant quantities of long non - codons is that of the exosome. its role has been documented in both physiological conditions and pathological changes such as cancer development, where they are responsible for the regulation of various processes including immunosuppression, proliferation and induction of pre - metastatic niche formation. in this review, the role of exosomal long non
DPR-BAG (BC)	LncRNA has greater tissue specificity than mRNA, making it a potential diagnostic biomarker for specific tumour types. Circulating RNA in body fluids can resist ribonucleases, providing stability and potential as cancer prognostic markers. A study found two groups of long non-coding RNAs (lncRNAs) with opposite effects on cancer cells. Gas5 was shown to induce apoptosis and inhibit tumour growth, while Particl enhanced DNA methylation and gene silencing. Another lncRNA, CCND1, bound to a modulator and blocked transcription factors. Exo1-4 lncRNAs increased recipient cell viability by interacting with proteins involved in metabolism and nucleosomal architecture. Exosomal long non-coding RNAs(lncRNAs) have shown potential as effective nanocarriers for regulating lncRNA expression in cancer cells, offering a promising tumour therapy approach.

Abstract

Despite advances in information extraction driven by deep learning and large language models, performance gaps remain in highly specialized biomedical fields, where domain-specific complexity poses challenges for generalist models. In this work, we focus on the domain of autoimmunity, where the main entities of interest are autoimmune diseases, autoantibodies (*i.e.*, molecules that may mark or cause these diseases), their molecular targets, their location in the body, and their associated clinical signs. Herein, we present AAbAAC (AutoAntibodies and Autoimmunity Annotated Corpus), a corpus of 115 abstracts selected from PubMed, where we manually annotated entities and their relationships. First, AAbAAC was used to evaluate several methods on the task of named entity recognition (NER), and secondly, to fine-tune NER models. Our study demonstrates the utility of AAbAAC for information extraction in the domain of autoimmunity, showing expected improvement in NER performance after fine-tuning. This illustrates the value of small-scale annotation efforts for specialized domains and contributes to the computational study of autoimmunity. The AAbAAC corpus is available at https://github.com/f-maury/AAbAAC.

1 Introduction

Autoimmune diseases arise from dysfunction of the adaptive immune system, whereby molecules of the self are targeted by self-antibodies, named autoantibodies. Those are generally detected in blood or cerebrospinal fluid, and widely used as a biomarker of autoimmune diseases, critically guiding differential diagnosis. Autoimmune diseases collectively affect an estimated 3–5% of the global population (Ahsan, 2023; Shapira et al., 2010). Yet, when considered individually, many of these diseases are rare (Hayter and Cook, 2012). In part due to the rarity of these pathologies, there is no single centralized resource including all relevant information about autoimmunity. Indeed, relevant bits of domain expertise are scattered across various sources, including many recent research papers. For this reason, information extraction is a relevant way to study autoimmune diseases, by automating the processing of large numbers of documents into structured, interoperable, and machine-readable knowledge bases.

Lately, BERT-based models have consistently achieved state-of-the-art performance in information extraction tasks, particularly when adapted through fine-tuning on domain-specific documents matching the target domain. While many domain-specific models exist, high-quality annotated data to adapt general models to highly specialized or niche domains are also lacking in many cases. To our knowledge, this is the case in human autoimmunity, where no manually annotated corpus dedicated to autoimmune diseases and autoantibodies exists to evaluate or fine-tune models specialized for the recognition of autoantibodies, autoimmune diseases, and their relationships. To fill this gap, we propose AAbAAC, a corpus of PubMed abstracts annotated for entities and relations related to autoimmunity, and demonstrate its value for named entity recognition (NER).

Section 2 reviews related works. Section 3 describes the methodology used to create the corpus, and Section 4 presents the resulting corpus. Section 5 introduces the experimental setup for named entity recognition (NER) using AAbAAC, and Section 6 reports the associated results. Finally, the paper concludes with perspectives for future work enabled by this new corpus.

2 Related works

2.1 Existing resources for autoimmunity

Some general and widely used knowledge bases and resources exist for broad biomedical

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 791–800
July 3-4, 2026 ©2026 Association for Computational Linguistics

use, such as the Human Phenotype Ontology (HPO) (Gargano et al., 2024), Orphanet (Rath et al., 2012), or the UMLS (Bodenreider, 2004). Those include information about autoimmune diseases and autoantibodies, but are not sufficiently exhaustive, detailed, nor up-to-date for real-world studies. Indeed, autoimmunity is a specialized and evolving topic that is not the focus of generalist resources. They can nonetheless be used to generate an initial list of autoantibody names, that can then be used for information extraction.

More specialized resources have also been developed that include information about antibodies, autoantibodies, or related elements. For example, this is the case of IEDB (Vita et al., 2025), a database about epitopes, *i.e.*, regions of antigens bound by antibodies, or AAgAtlas (Wang et al., 2017), which focuses on autoantigens. Each of these resources focuses on a topic that is relevant to the study of autoimmunity, but none of them compile all the relevant knowledge in the field of autoimmunity for clinicians or researchers to use. However, for information extraction purposes, these resources could be used to build lists of autoantibody names from their antigen names.

Some annotated text corpora already exist for biomedical information extraction, but to the best of our knowledge, none is dedicated to human autoimmunity and autoimmune diseases. For example, the MedMentions corpus (Mohan and Li, 2019) tackles the biomedical domain in a general manner, with annotations of UMLS terms of most Semantic Types. As a result, it may include the most common autoimmune diseases and autoantibodies, but it does not include uncommon ones that do not correspond to UMLS terms, nor does it include relationships between the entities. The ABAG corpus (Dinh et al., 2022) focuses on antibodies and antigens, but is not specific to autoimmunity and does not provide annotations of relationships between entities. Therefore, existing resources are of limited use for autoimmunity-related information extraction, since isolating in these resources the annotations specific to autoimmunity would be challenging and result in limited coverage of autoimmunity-related concepts.

2.2 NER for autoimmunity

Many works make use of dictionaries and rule-based methods to conduct NER with decent performance. Such dictionaries can be built from either ontologies or databases. For example, a recent work by Remaki et al. (2025) used such a combination, including terms from SNOMED CT (Wang et al., 2002) and rules, to extract biology exams and drugs in relations to immune-mediated inflammatory diseases.

Another work by Subramanian and Ganapathiraju (2017) extracts antibody names using simple regular expressions based on the fact that antibodies are often written as "X antibody", or "antibody to X", where "X" is the target of the antibody. This method does not require a dictionary of possible target names, but fails at covering the various possible ways an antibody can be mentioned in text. Moreover, in the context of autoimmunity, such a method would struggle to differentiate autoantibodies from regular antibodies.

The development of multi-head attention and transformer-based architectures of language models enables efficient information extraction from long texts with more flexibility and context awareness than rule-based approaches. For NER tasks, encoder models such as BERT-based models (Devlin et al., 2019) perform competitively while being lighter and less computationally expensive to work with than large language models (LLM) (Naguib et al., 2024). The original BERT model has been adapted to many domains, including the biomedical domain. However, we did not find any model specialized for the recognition of autoimmunity-related entity types.

3 Corpus creation methods

3.1 Text selection

To select a set of relevant texts to be annotated, we first built a dictionary of autoantibody names and synonyms from HPO terms, which we used to query a PubMed API (Sayers, 2018) for titles and abstracts of scientific papers. Indeed, HPO includes terms describing positivity to some autoantibody detection tests (terms under *HP:0030057*). Most of them are of the form: "*anti-X antibody positivity*", where "*anti-X antibody*" is the name of an autoantibody that targets the antigen "*X*". We relied on this regular syntax to extract names of autoantibodies and manually reviewed results. We also generated lexical variants by reducing each autoantibody name to a core string through the removal of selected prefixes and suffixes, then recombining this core with alternative affixes. For example, "*anti-smooth muscle antibody*" was reduced to "*smooth muscle*" by removing "*anti*" and "*antibody*", and

one resulting variant was "*smooth muscle autoantibody*". Overall, the dictionary includes a total of 10,916 variations for 285 unique autoantibodies that originated from HPO release 2024-07-01. On average, each autoantibody in the dictionary has 38.30 variations, including synonyms that were already listed in the HPO.

For each autoantibody type in the dictionary, PubMed is searched with a query of the form "*(""autoantibody_name_1""[Title/Abstract] OR ""autoantibody_name_2""[Title/Abstract] AND humans[MeSH Terms] AND (antibodies[MeSH Terms] OR autoantibodies[MeSH Terms])*". MeSH term filters were added to select only papers tagged with "human" and either "antibodies" or autoantibodies. This process returned a total of 56,750 titles and abstracts. The full query we used is available in the project's GitHub repository.

Despite MeSH terms filtering, some of the obtained texts were irrelevant due to not being written in English or not being related to autoimmunity. For this reason, we enforced additional filters: abstracts were automatically pre-annotated with exact matches of autoantibody names from our HPO-derived dictionary, and with disease and autoantibody names identified by GLiNER. This pre-annotation was performed with a version of the GLiNER specialized for the biomedical field ("*urchade/gliner_large_bio-v0.1*"). This model is an early version of GLiNER large that is finetuned on PubMed abstracts.

Only texts containing at least one HPO autoantibody term match, or one disease pre-annotation and one autoantibody pre-annotation were kept, reducing the set of texts to 44,890.

Among these, 120 texts were randomly selected for manual annotation, out of which 5 were manually eliminated due to either not being related to autoantibodies or not being English texts, resulting in a final set of 115 texts. The initial selection size was 120 because we aimed to have a corpus of around 100 texts and expected a few of them to be eliminated.

3.2 Annotation guidelines and process

Annotation was performed by 4 annotators with a background in either medical informatics, biology, or pharmacy. This group elaborated annotation guidelines through two preliminary annotation batches to identify main entity types, difficulties, and edge cases before the start of the annotation campaign (Hovy and Lavid, 2010). Annotation guidelines are available in the following GitHub repository: https://anonymous.4open.science/r/aabaac-FA3F. Five types of entities were annotated: "*Autoantibody*", "*Autoantibody target*", "*Disease*", "*Symptom or clinical sign*", and "*Autoantibody location*"; and ten different types of relationships: "*is associated with*", "*is not associated with*", "*may be associated with*", "*is caused by*", "*is target of*", "*is reference to*", "*discontiguous entity*" (this relation is used to link several separated parts of a single entity), "*is synonym of*", "*is located in*", and "*is subclass of*".

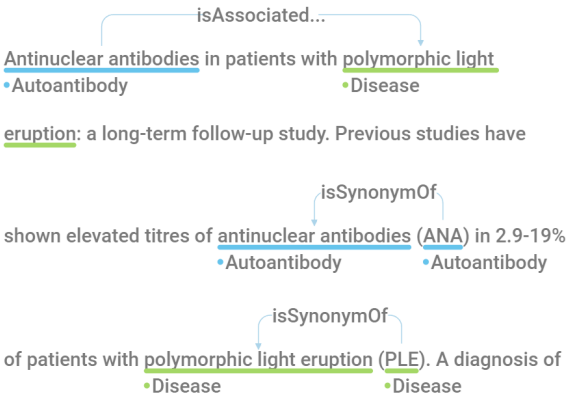

Figure 1: Example of text annotated in the Doccano web interface.

To make the annotation task easier for annotators, it was agreed to not annotate obvious relationships between nested entities, which were automatically added after manual annotation. For instance, when a "*Target*" is found inside the span of an "*Autoantibody*", which typically happens in structures like "*anti-X antibody*", the annotators were instructed not to add an "*is target of*" relation. Similarly, when an "*Autoantibody*" is found inside the span of a related "*Symptom or clinical sign*", the annotators were instructed not to add an "*is associated with*" relationship. Those were automatically added after manual annotation.

Each text was annotated independently by 2 annotators, but no single annotator annotated all texts. Each annotator was paired with each other annotator with equal frequency, and each pair annotated the same number of texts. Annotation was performed using Doccano (Nakayama et al., 2018) on texts where entities had been pre-annotated, but not relations. These pre-annotations were obtained by string matching and GLiNER. Doccano web interface is illustrated in Figure 1.

Texts were sent to the annotators in small numbered batches of around 4 texts, and annotators were free to annotate them in any order, in a single or multiple sessions, and at any time before the end of the campaign. Finally, an adjudication took place where annotations from both annotators for each text were confronted, and a consensual final annotation was decided by the head annotator.

4 Resulting corpus description

This section includes descriptive counts and statistics from the final adjudicated corpus of 115 texts. The variability of the length of the texts is high (from 50 to 3600 characters, as per Table 1), as is their annotation content (from 2 to 88 entities, and from 0 to 55 relations). This is partially due to the fact that some of the texts are limited to an article title with an empty abstract.

Metric	Min	Max	Average	Median
Entities per text	2	88	29.18	27
Relations per text	0	55	15.47	14
Text length (chars)	50	3600	1500.94	1500
Sentences per text	1	64	13.46	12

Table 1: General corpus statistics.

Imbalance is also observed in the number of entities of each type, with especially only 64 (see Table 2) occurrences of "*Autoantibody location*", whereas *Disease* is the most common entity with 1159 occurrences.

Entity type	Count	Avg/text	Median/text
Autoantibody	891	7.75	6
Autoantibody location	64	0.56	0
Autoantibody target	581	5.05	3
Disease	1159	10.08	8
Symptom or clinical sign	661	5.75	5
Total	3356	29.18	27

Table 2: Counts and distributions in the corpus by entity type.

Extremely variable numbers of occurrences can be observed for each relation type. Most relation annotations consist of "*is associated with*" (735, see Table 3), which can be explained by its rather broad definition, "*is target of*" (494), and "*is synonym of*" (226). Some relation types have almost never been used, such as "*is caused by*" (13), which could be explained by the cautious tone used in scientific literature, and the difficulty to establish causation with certainty, and "*is reference to*" (2), which could be explained by its constrained definition in our guidelines and redundancy with "*is synonym of*".

Relation type	Count	Avg/text	Median/text
discontiguousEntity	106	0.92	0
isAssociatedWith	735	6.39	5
isCausedBy	13	0.11	0
isLocatedIn	73	0.64	0
isNotAssociatedWith	24	0.21	0
isRefTo	2	0.02	0
isSubClassOf	61	0.53	0
isSynonymOf	226	1.97	1
isTargetOf	494	4.30	3
mayBeAssociatedWith	45	0.39	0
Total	1779	15.47	14

Table 3: Counts and distributions in the corpus by relationship type.

To evaluate the difficulty of the annotation task, inter-annotator agreement measures were computed between each pair of annotators, and between each annotator and the final annotations. Since the annotators simultaneously had to decide whether a text contained annotations, where in the text were these annotations located, if any, and of what type they were, Mathet's gamma coefficient (Mathet et al., 2015; Titeux and Riad, 2021) was used. Mathet's gamma is a measure that takes into account both disagreement on span limits (unitizing) and on label type (categorizing) for entity annotations. To measure agreement on relation annotations, three different comparison functions (strict match, flexible with tolerance for some disagreement, and super-flexible with tolerance for more disagreement) were used to compute F1-scores between the annotations of each annotator pair. We report a general average gamma coefficient between pairs of annotators of 0.67. The average gamma was 0.74 for "*Autoantibody*", 0.71 for "*Autoantibody location*", 0.44 for "*Autoantibody target*", 0.81 for "*Disease*", and 0.54 for "*Symptom or clinical sign*".

Relationship annotations are intrinsically more complex, and this is particulary the case in this work where annotators had 10 different relation types to choose from. To assess this difficulty quantitatively, we measured the inter-annotator agreement for relationships using an F1-score. We obtain a F1-score of 0.37 for all relation types together, using a custom flexible comparison metric tolerating some small overlap differences, and some entity type confusions.

Considering all relation types jointly, the primary source of disagreement was *isAssociatedWith*, because it was the most frequently used relation

type and because its broad definition allowed for subjective interpretation. When examining relation types individually, some exhibited lower agreement scores than *isAssociatedWith*; however, their contribution to the overall disagreement remained limited due to their lower frequency. In particular, *isRefTo* was used only twice and obtained an F1 score of 0. Given its limited use, removing this relation type from the annotation scheme could be considered. Overall, the relatively low inter-annotator agreement observed for relations highlights the difficulty of annotating texts from a specialized scientific domain. Furthermore, the complexity of the annotation scheme made the annotation task challenging for annotators.

5 Evaluating NER methods

5.1 Experimental setup

To demonstrate the utility of the AAbAAC corpus in autoimmunity NER, several methods were compared.

The corpus was randomly divided into train and test following an 80 - 20 split. This procedure was repeated independently five times, resulting in five distinct train–test partitions. Supervised approaches were fine-tuned separately on each training set, and all approaches were evaluated on the corresponding test sets. Reported results are the average performance across the five test sets.

Chunking of longer texts occurred after the split so that all chunks from the same text remain part of the same set. This prevents information leakage from the train set to the test set.

5.2 QuickUMLS

The first method tested is QuickUMLS (Soldaini and Goharian, 2016) on the task of recognition of mentions of "*Autoantibody*" and "*Disease*" entities only. One dictionary was created for each of these entity types. The dictionary for "*Disease*" was created by selecting all the UMLS terms from Semantic Type "*Disease or Syndrome*", and only keeping English strings associated with these terms. The "*Autoantibody*" dictionary was by combining the dictionary made from an intial list of HPO terms for text selection (see Subsection 3.1) and was then enriched from LOINC (Forrey et al., 1996) and manual additions. Moreover, name variations for autoantibodies were automatically added to the dictionary. QuickUMLS was used with default parameters except for the threshold, which was set to 0.9.

5.3 GLiNER

Although standard BERT-based models achieve state-of-the-art performance in NER, they rely on predefined annotation schemas and task-specific fine-tuning, in contrast to the GLiNER architecture, which supports more flexible, label-agnostic entity recognition (Zaratiana et al., 2024). GLiNER does not need a fixed list of entity types, but can work with any label passed as input at inference time. While studying a BERT model would be of interest in our use case, we decided to work with the GLiNER architecture (GLiNER 2.1 models: urchade/gliner_large-v2) on the task of NER for entity types related to autoimmunity, notably autoantibodies. Indeed, this allows for more flexibility with regards to the set of entity types to be identified, and our annotation scheme was initially not fixed. In this setup, texts longer than 384 tokens were chunked by cutting at the end of the last sentence before reaching the maximum length, and each chunk was tokenized using GLiNER's tokenizer.

GLiNER base models (small, medium, and large) were evaluated in a zero-, two-shot, and fine-tuned setting. In the GLiNER architecture, the labels are passed to the model along with the input text at inference time. The way labels are formulated may affect performances, and it may be useful to reformulate them or use synonyms to see what returns best results (e.g., "*Autoantibody target*" or "*Autoantigen*"). At this step, labels that seemed the most concise and clear were picked, but except from light changes, we did not conduct an extensive experiment to search for potential optimal alternatives. GLiNER models were evaluated on the task of NER for the following entities of interest: "*Autoantibody*", "*Autoantibody location*", "*Autoantibody target*", "*Disease*", "*Symptom or clinical sign*", on the 5 different test sets obtained from our split of the AAbAAC corpus. These entity types are the strings that were passed to GLiNER along with texts, as part of the input.

For the 2-shot setting, we passed 2 short, manually made-up examples of each entity type before the actual input text. The examples followed the format: '"sentence": "The patient was admitted after complaining of thigh pain."\n"Symptom or clinical sign": "thigh pain"'. The same 2 example sentences for each type were passed along each input text. In rare cases, the input text was long and

close to the maximal allowed chunk length, and adding the extra examples has led to truncation, which may have affected the performance slightly. For the 2-shot experiment, the GLiNER threshold parameter, which acts as a confidence filter for the model's output was set to 0.3, but for 0-shot and fine-tuned configuration it was set to 0.5.

GLiNER base models were fine-tuned using the train set from each split, and the fine-tuned models were evaluated on the associated test set. For fine-tuning, the tokenized texts of the train set are shown to the model along with their entity annotations. For evaluation, the chunked but untokenized texts of the test set are passed to the model along with the types of entities to identify.

5.4 MedGemma

Google's MedGemma model for text (google/medgemma-27b-text-it) was evaluated in 0-shot, 2-shot setting and finally fine-tuned using AAbAAC. MedGemma being a generative model, the NER task was framed as a task where the model had to output a structured JSON answer containing identified entities, as a response to a prompt containing the input text and instructions. The LLM was instructed to write a JSON string containing the text spans identified as entities. The LLM's output was then parsed to extract valid JSON segments and exclude malformed output parts. The generated answer was limited to a length of 1024 tokens. The model was not asked to return the exact character offsets delimiting the spans, as preliminary tests with this method seemed unreliable. For this experiment, the chunks of texts were given at train time, untokenized, as input to the model along with corresponding entities. For evaluation, the chunks of texts were also passed untokenized to the model along with instructions, in a prompt. The fine-tuning was conducted using rank-16 LoRA adapters, with the 4-bit quantized version of the model.

6 Results

This section presents the averaged results for the various NER methods we evaluated.

Results of the QuickUMLS experiments can be found in table Table 4. It can be observed that performances are higher for the "*Disease*" label than for the "*Autoantibody* label. This could be explained by the fact that for the recognition of "*Disease*" we relied on the richness of UMLS vocabularies: our disease dictionary is 636,989 rows, whereas our manual dictionary of "*Autoantibody*" is smaller (7,464 rows) and handcrafted, and thus probably incomplete, which would explain the lower recall for autoantibodies.

Entity type	Precision	Recall	F1 (±SD)
ALL	0.47	0.40	0.43 (±0.04)
Autoantibody	0.50	0.24	0.33 (±0.06)
Disease	0.46	0.53	0.49 (±0.06)

Table 4: Precision (P), recall (R), and F1-score (F1) of QuickUMLS for autoantibodies and diseases, using custom made dictionaries.

Table 5 reports the performance of all the different model and experimental setup we evaluated. Overall best F1-score is obtained with the fine-tuned version of MedGemma. We particularly observe that in terms of F1-score, QuickUMLS performance is not significantly lower than GLiNER and MedGemma if those are not fine-tuned. F1-score for entity type "*ALL*" is the average over 5 test sets of the micro F1-score computed by counting true positives, false positives, and false negatives of all entity types together.

Regarding the various GLiNER configurations, the fine-tuned largest version of GLiNER is overall performing slightly better than other versions. 2-shot GLiNER models perform overall worse than 0-shot, possibly indicating our entity labels were somewhat more confusing than helpful to the model without a sufficient number of examples. Top precision is achieved by GLiNER large 2-shot, whereas top recall and F1-score are achieved by GLiNER large fine-tuned (Table 5). All methods return higher precision than recall, and this seems to be especially the case in the 2-shot configurations. It should be possible to modulate this to some extent by acting on the GLiNER threshold parameter, as well as on the number and type of examples.

	Model	P	R	F1 (±SD)
	QuickUMLS	0.47	0.40	0.43 (±0.04)
0-shot	GLiNER small	0.72	0.26	0.39 (±0.05)
	GLiNER medium	0.67	0.33	0.45 (±0.04)
	GLiNER large	0.74	0.30	0.42 (±0.03)
	MedGemma	0.61	0.31	0.41 (±0.05)
2-shot	GLiNER small	0.76	0.20	0.31 (±0.05)
	GLiNER medium	0.67	0.26	0.37 (±0.04)
	GLiNER large	**0.80**	0.21	0.34 (±0.04)
	MedGemma	0.67	0.29	0.41 (±0.04)
fine-tuned	GLiNER small	0.65	0.51	0.58 (±0.05)
	GLiNER medium	0.67	0.52	0.58 (±0.03)
	GLiNER large	0.67	0.53	0.59 (±0.04)
	MedGemma	0.71	**0.62**	**0.66** (±0.03)

Table 5: Precision (P), recall (R), and F1-score (F1) of different models for all entity types together.

We also report in Table 6 per-label performances for some of the best-performing models: GLiNER large and MedGemma, both in 0-shot and fine-tuned configurations. Fine-tuning increases model F1-score for all entity types, though it sometimes slightly decreases precision: performance gains are mostly due to recall gains. Considerable performance imbalance can be observed between labels: for the fine-tuned models, the highest F1-score (0.79) is achieved by GLiNER large for the detection of "*Disease*", as per Table 6; and the lowest F1-score is achieved by MedGemma for the detection of "*Autoantibody location*" (0.33). In the case of "*Autoantibody location*", fine-tuning GLiNER large causes performance increase from an F1-score of 0.07 to 0.60; and fine-tuning MedGemma increases F1-score from 0.01 to 0.33. It is possible that some types of entities, such as "*Autoantibody location*" are not easily captured when the only information about them is their label, without examples. However, giving examples can lead to better performances, as illustrated by the performance differences between 0-shot and fine-tuned configurations.

7 Discussion

This work demonstrates the use of the AAbAAC corpus for autoimmunity information extraction through some basic NER experiments, including model fine-tuning. Indeed, models fine-tuned using the AAbAAc corpus perform better at detecting entities related to autoimmunity than the same models used out-of-the-box, or than a rule-based approach. However, so far, in the work presented here, no search for optimal fine-tuning parameters was conducted. The fine-tuned models' performances could probably be improved by performing a grid search or some other type of optimization prior to fine-tuning.

Model and Entity type	P	R	F1 (±SD)
GLiNER large 0-shot			
ALL	0.74	0.30	0.42 (±0.03)
Autoantibody	0.72	0.37	0.48 (±0.05)
Autoantibody location	0.10	0.06	0.07 (±0.05)
Autoantibody target	0.76	0.06	0.11 (±0.07)
Disease	0.82	0.48	0.60 (±0.06)
Symptom or clinical sign	0.56	0.13	0.21 (±0.06)
GLiNER large fine-tuned			
ALL	0.67	0.53	0.59 (±0.04)
Autoantibody	0.75	0.49	0.59 (±0.11)
Autoantibody location	0.47	0.88	**0.60** (±0.17)
Autoantibody target	0.43	0.28	0.34 (±0.07)
Disease	0.80	0.77	**0.79** (±0.02)
Symptom or clinical sign	0.52	0.39	**0.42** (±0.05)
MedGemma 0-shot			
ALL	0.61	0.31	0.41 (±0.05)
Autoantibody	0.65	0.45	0.53 (±0.06)
Autoantibody location	0.02	0.01	0.01 (±0.03)
Autoantibody target	0.42	0.07	0.11 (±0.02)
Disease	0.70	0.39	0.50 (±0.06)
Symptom or clinical sign	0.47	0.23	0.31 (±0.05)
MedGemma fine-tuned			
ALL	0.71	0.62	**0.66** (±0.03)
Autoantibody	0.79	0.70	**0.74** (±0.06)
Autoantibody location	0.35	0.35	0.33 (±0.18)
Autoantibody target	0.75	0.67	**0.70** (±0.04)
Disease	0.79	0.66	0.71 (±0.02)
Symptom or clinical sign	0.46	0.41	**0.42** (±0.04)

Table 6: Precision (P), recall (R), and F1-score (F1) per label for GLiNER large and MedGemma fine-tuned, both in 0-shot and fine-tuned configuration. Best F1-score per type of entity is reported in bold.

The presented AAbAAC corpus aims to be of use for complete information extraction pipelines for the study of autoimmunity. This includes both named entity recognition and extraction of relations between these entities, so the corpus also includes relation annotations. However, for now, no evaluation of the use of the corpus for information extraction was conducted. One future work may use the GLiNER2 (Zaratiana et al., 2025) architecture, which enables the joint extraction of both entities and relations simultaneously.

For GLiNER-based models, so far, only fine-tuning of the original generalist GLiNER family models was performed, however it might be of interest to attempt similar experiments with different GLiNER variants. For instance, versions dedicated to the biomedical field, such as *Ihor/gliner-biomed-large-v1.0* (Yazdani et al., 2025) are available. Attempting to fine-tune a domain-specific BERT model, such as PubMedBERT (Gu et al., 2022), for example, would also be a possible future work direction and an interesting comparison.

8 Conclusion

This work introduces AAbAAC, a manually annotated corpus of texts that was created for information extraction in the field of autoimmunity. AAbAAC includes annotations of entities and relationships that are relevant to the study of autoantibodies and autoimmune diseases. Preliminary NER experiments on this new corpus demonstrate that fine-tuning models with AAbAAC yields a performance increase over dictionary-based approaches as well as zero-shot or few-shot settings. Future work will focus on further tuning different models for this domain, for both tasks of NER and relation extraction.

9 Limitations

AAbAAC corpus is relatively small: 115 annotated texts of variable length, all of them being titles and abstracts of scientific papers published on PubMed. This is enough to deliver substantial performance gains on NER tasks for the entity types considered in this work; however, ultimately the knowledge that can be derived from this corpus is finite and may not reflect the entire existing spectrum of autoantibodies, autoimmune diseases, and the various appellations used in the literature to refer to these concepts, especially since many autoimmune diseases are rare (Miller, 2023). For some very rare, or unusually named autoantibodies not annotated in the AAbAAC corpus, detection improvements may be limited. In addition, since this corpus consists of texts drawn from the scientific literature, its impact on NER in clinical texts could be lower due to differences between written styles and possibly different naming conventions for autoantibodies.

Regarding relation annotations, some of the relation types in our scheme have almost never been instantiated in the corpus. For example, this is the case with *isCausedBy* (13 occurrences, see Table 3), a stronger relation than the more common *isAssociatedWith* (735 occurrences), or *isRefTo* (2 occurrences).

The annotation process took place using the Doccano tool, which does not allow to specify annotation attributes. Therefore, to annotate entities that are composed of several discontiguous segments of text, the *discontiguousEntity* relation is used. But this complexity is lost to an NER model that only considers entity annotations, and this may have caused some performance drop in the presented experiments.

Other models from the state of the art could have been interesting to experiment with as well, in particular BERT-type models fine-tuned for the biomedical literature, or non-proprietary LLM. Their inclusion could open perspectives to extend our study to consider the computational cost of various approaches and attempt to specialize or distill efficient but costly models.

What Do Biomedical NER and Entity Linking Benchmarks Measure? A Corpus-Centric Diagnostic Framework

Abstract

Biomedical named entity recognition (NER) and entity linking (EL) strongly depend on annotated corpora, but the utility of these resources for benchmarking is often assumed rather than characterized. We present a corpus-centric framework for diagnosing benchmark-relevant properties directly from corpus annotations, concept links, train-test splits, document metadata, and terminology mappings. The framework organizes standardized statistics into five families: (1) scale, density and label distribution, (2) lexical and conceptual structure, (3) train-test overlap, (4) metadata composition, and (5) terminology coverage where applicable. Applying the framework to nine corpora spanning diseases, chemicals, and cell types, we find that corpus properties can differ substantially, even when they address the same apparent task. We find differences in the evaluation signal they provide, the generalization demands they impose, the degree of train–test reuse they permit, and the regions of biomedical literature and concept space they represent. These differences suggest that commonly reported corpus statistics can be insufficient to characterize what biomedical NER and EL benchmarks evaluate. We argue that corpus-centric diagnostics provide a practical framework for analyzing corpora beyond surface descriptors such as corpus size and entity type, for identifying potential transfer risks, and for interpreting the scope of benchmarking conclusions. We release the framework as open-source code[1] with an interactive dashboard to support reproducing our analyses and characterizing additional corpora.

1 Introduction

Extracting structured information from biomedical literature requires systems to identify and link entities (e.g., genes, diseases, chemicals) to standardized identifiers. These grounding tasks—named entity recognition (NER) and entity linking (EL)—remain critical in the large language models (LLM) era to ensure outputs are auditable, comparable, and reusable.

Manually annotated corpora serve both as training data and as evaluation benchmarks (Kim et al., 2003; Collier et al., 2004; Morgan et al., 2008; Lu et al., 2011; Wei et al., 2013; Doğan et al., 2014; Krallinger et al., 2015; Li et al., 2016; Islamaj et al., 2021b,a; Bada et al., 2012; Herrero-Zazo et al., 2013; Wei et al., 2016; Miranda-Escalada et al., 2023). When used as benchmarks, they function as measurement instruments: the key question is not only whether annotations are correct, but what capabilities the benchmark tests and whether conclusions transfer to intended use cases.

This distinction matters because benchmark utility is task- and domain-dependent. A corpus can be carefully annotated yet too narrow, homogeneous, or leaky across splits to support informative evaluation. Biomedical natural language processing (NLP) values rare, specialized, and emerging concepts, making evaluation sensitive to which entities, subdomains, time periods, and document types are represented. Without characterizing the *corpus domain* and the target *application domain*, it is difficult to distinguish generalization issues from corpus-specific artifacts, leakage, or domain mismatch. Benchmark corpora have primarily been compared by size, entity type, or reported system performance. These descriptors do not reflect overlap risks, lexical difficulty, domain bias, or concept coverage.

To address this gap, we introduce a corpus-centric framework that computes standardized statistics directly from annotations, concept links, corpus splits, metadata, and terminologies (Figure 1). These statistics provide a multidimensional analysis for PubMed- and PMC-based NER and EL corpora: density indicates how much evaluation signal is available; lexical and conceptual variation

indicate what kinds of generalization are required; overlap reveals leakage risk; metadata composition characterizes the literature represented; and terminology coverage indicates which parts of the concept space are represented.

Applied to nine corpora spanning diseases, chemicals, and cell types, the framework shows that resources similar by task label or size can differ substantially across these signals. Our contributions are: (1) a corpus-as-instrument framing for biomedical NER and EL benchmarks; (2) a practical framework of corpus-centric diagnostics; (3) an analysis showing how structural differences inform evaluation sensitivity, leakage risk, coverage, and transferability; and (4) open-source code and an interactive dashboard for reproducing our results and for analyzing new corpora.

2 Related Work

Biomedical entity annotation corpora have proliferated over the years, yet they are routinely treated as benchmarks without any systematic analysis of what they actually measure. Early efforts, such as GENIA (Kim et al., 2003) established large-scale manual mention annotation with fine-grained semantic categories, later simplified for shared tasks such as JNLPBA (Collier et al., 2004). Subsequent corpora introduced entity normalization, typically targeting a single entity type: diseases (NCBI Disease), chemicals (CHEMDNER, BC5CDR), genomic variants (tmVar) and genes (BioCreative challenges) (Doğan et al., 2014; Krallinger et al., 2015; Li et al., 2016; Wei et al., 2013; Morgan et al., 2008). Resources such as CRAFT (Bada et al., 2012) broadened the scope to multi-entity, full-text annotation. More recent corpora—including NLM-Chem, BioRED, and CellLink–have further expanded document and entity coverage, and incorporate richer annotation structures such as relations (Islamaj et al., 2021b, 2024; Rotenberg et al., 2026). Despite being widely used together, these corpora vary considerably in document type, annotation density, normalization support, temporal range, and domain focus—differences that are rarely examined in terms of what each benchmark actually evaluates.

NLP research has shown that dataset properties can distort benchmark interpretation. Work on saturation motivates aggregated benchmarks such as GLUE and SuperGLUE (Wang et al., 2018, 2019); work on artifacts, leakage, and memorization shows that apparent improvements can reflect shortcuts or overlap rather than the intended capability (Gururangan et al., 2018; Liang et al., 2023; Tutubalina et al., 2020); and HELM emphasizes multi-metric evaluation (Liang et al., 2023). Biomedical suites such as BLUE, BLURB, and BigBIO standardize cross-task evaluation (Peng et al., 2019; Gu et al., 2021; Fries et al., 2022), but generally treat corpora as fixed inputs rather than explaining how corpus properties shape validity or transferability.

Annotation quality measures, particularly inter-annotator agreement (IAA), assess consistency but not benchmark scope. Prior work distinguishes agreement across span boundaries, labels, and concept links (Artstein and Poesio, 2008), recommends F1 for span-based tasks lacking a well-defined negative class (Hripcsak and Rothschild, 2005), and notes that disagreement may reflect ambiguity, error, or guideline limitations (Aroyo and Welty, 2015; Uma et al., 2021). High agreement is necessary but not sufficient: simplifying annotation can increase agreement while removing realistic ambiguity (Hovy and Lavid, 2010). Corpus papers often report counts and distributions, but these statistics are rarely organized around evaluation claims. Our framework connects such descriptions to overlap, memorization, domain shift, annotation scope, and terminology coverage.

3 Methods

3.1 Framework Overview and Representation

Our framework characterizes NER and EL corpora through four stages: conversion to a shared representation, filtering, metric computation, and visualization. Corpora are standardized into documents containing text, optional metadata, and annotations (spans, surface forms, labels, and linked concept identifiers).

This design supports both NER-only and NER+EL PubMed- or PMC-based corpora. NER-only corpora are evaluated on text-, span-, and mention-level statistics, while EL-supported datasets additionally yield concept-level diagnostics. Metrics are computed over configurable corpus bundles, comparison suites, entity scopes, and train/dev/test partitions to enable interpretable comparisons across heterogeneous datasets.

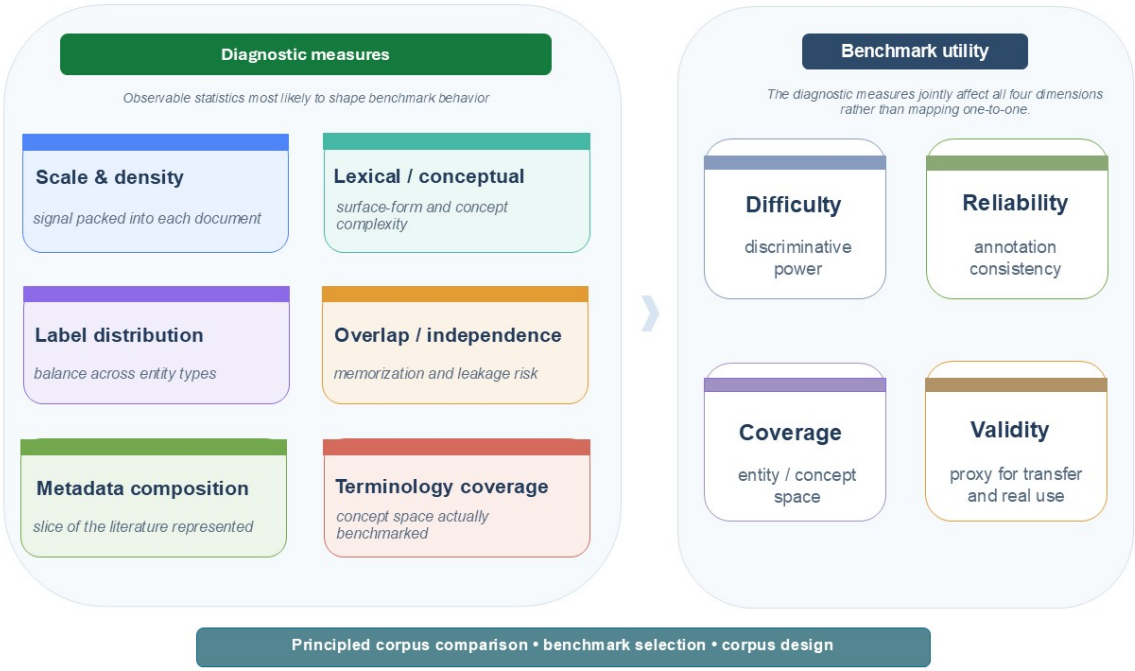

Figure 1: Corpus diagnostic framework. Entity-annotated corpora are converted into a common representation, enabling computation of statistics over annotations, identifiers, and metadata. These statistics characterize scale and density, lexical and conceptual variation, train-test overlap, metadata composition, and terminology coverage, enabling principled comparison of biomedical NER and EL benchmarks.

3.2 Corpora Analyzed

We apply the framework to nine corpora spanning diverse entity types (e.g., diseases, chemicals, cell types) and document scopes (abstracts, captions, full-text): AnatEM (Pyysalo and Ananiadou, 2014), BC5CDR (Li et al., 2016), BioID (Arighi et al., 2017), CHEMDNER (Krallinger et al., 2015), CRAFT (Bada et al., 2012), CellLink (Rotenberg et al., 2026), JNLPBA (Collier et al., 2004), NCBI-Disease (Doğan et al., 2014), and NLM-Chem (Islamaj et al., 2021b). Where public test data were unavailable or original annotation layers were altered, we utilized the closest documented subset and note these limitations alongside the relevant results.

3.3 Diagnostic Statistics

The framework computes corpus statistics across five families to diagnose benchmark properties prior to system evaluation:

- **Scale, Density, and Label Distribution**: We compute total documents, tokens, annotations, and unique mentions/identifiers per document.
- **Lexical and Conceptual Structure**: For normalized corpora, we measure mention ambiguity (the number of distinct label/link pairs mapped to a single surface form) and identifier variation (the number of distinct surface forms mapped to a label/link pair). These distinguish a benchmark's demand for contextual disambiguation versus its demand for recognizing diverse lexical realizations.
- **Train-Test Overlap**: To assess leakage and memorization risk, we compute Jaccard overlap between train and test splits at four abstraction levels: general token vocabulary, tokens inside entity mentions, exact mention strings, and concept identifiers.
- **Metadata Composition**: We profile the represented literature slice via temporal statistics (publication year ranges and distributions) and journal diversity (unique journals and top-journal concentration). We derive broad topic profiles from article Medical Subject Headings (MeSH) (Lipscomb, 2000) topics where available, falling back to NLM Catalog MeSH journal topics if necessary.
- **Terminology-Aware Coverage**: For diseases and chemicals, we link identifiers to their respective concepts in MeSH, MONDO (Vasilevsky et al., 2026), or

ChEBI (Malik et al., 2026); for cell types, we support Cell Ontology (CL) (Tan et al., 2026). We quantify vocabulary coverage by analyzing the distribution of annotations across high-level branches and compute hierarchy depth as a proxy for concept specificity.

3.4 Implementation

The framework is implemented as an open-source, YAML-configurable Python pipeline that outputs structured JSON statistics. It includes acquisition specifications for downloading, extracting, converting, caching, and validating expected corpus files. Input support includes BioC XML (Comeau et al., 2013, 2019), PubTator (Wei et al., 2024), BRAT/standoff (Stenetorp et al., 2012), and Knowtator (Ogren, 2006) annotations, with registry-based extension points for additional loaders and metrics. Ontologies in OBO format are directly supported as terminology sources. The accompanying self-contained HTML/JavaScript dashboard[2] combines scale, overlap, metadata, terminology, and entity-scope views to reproduce our analyses and evaluate new corpora.

4 Results

We use the nine corpora to illustrate how corpus-centric diagnostics clarify the evaluation role of a benchmark. The goal is not to rank corpora, but to demonstrate that datasets with similar task labels often function as different measurement instruments: they expose systems to different volumes of evaluation signal, different forms of lexical and conceptual generalization, different leakage risks, and different regions of the biomedical literature and concept space.

4.1 Scale, annotation density, lexical and conceptual variation

Table 1 reports statistics for nine heterogeneous biomedical corpora. These measurements show that corpora differ fundamentally in the structural nature of the evaluation signal they provide. Annotation density varies widely across corpora, reflecting differences in document scope, annotation unit, and entity scope. Dense full-text corpora such as NLM-Chem and CRAFT provide many labeled decisions per article, whereas passage-, abstract-, and caption-based corpora distribute fewer decisions across more sampled text units. This raw density is useful because it affects the number of system decisions contributing to an evaluation estimate. However, annotations from the same full-text article are not necessarily independent: repeated mentions, recurring identifiers, and section-specific language can increase decision volume without proportionally increasing lexical, conceptual, or contextual diversity. Density should therefore be interpreted as signal concentration, not as a direct measure of task difficulty or benchmark quality. In this sense, full-text corpora evaluate behavior over long-document contexts and repeated real-world usage, while shorter-unit corpora may provide broader sampling of independent contexts per annotation. Concept-level diagnostics further define what the instrument is calibrated to measure. Variation ranges from 1.48 surface forms per label/link pair in BioID to 3.74 in CellLink, indicating differing demands on lexical generalization.

4.2 Train-Test Overlap

Figure 2 reports train-test Jaccard overlap at four levels: token vocabulary, mention tokens, exact mention strings, and concept identifiers. These levels distinguish increasingly task-specific forms of reuse. Across all corpora, token vocabulary overlap is higher than mention-token overlap, which is, in turn, higher than exact mention string overlap.

The slope of this drop varies and is itself informative. JNLPBA falls from 35.9% token overlap to 6.6% mention-string overlap, indicating that its test split contains relatively little exact entity-form reuse. CellLink presents a different structural pattern: its mention-token overlap (27.9%) is much higher than its exact mention-string overlap (9.1%), while identifier overlap is higher still (40.6%). This profile suggests compositional novelty, where new cell-population names are constructed from familiar component tokens and mapped to familiar concepts. Examples include "CD4+ T cells" (CL:0000624), "resting CD4 memory T cells" (CL:0000897), and "resting NK cells" (CL:0000623), which combine recognizable modifiers with cell-type heads.

Identifier overlap adds a concept-level view unavailable from strings alone. Among normalized corpora, identifier overlap ranges from 14.2% in BioID to 40.6% in CellLink—a range wider than the corresponding mention string overlaps, and with a different ordering. CellLink's high identifier overlap paired with low string overlap means it tests the ability to map novel text to relatively fa-

[a] **Ambiguity**: mean label/link pairs per unique mention string. Values near 1.0 indicate most mentions map to a single label/link pair. [b] **Variation**: mean surface forms per label/link pair. Reported only for corpora with concept-level identifiers; AnatEM, CHEMDNER, and JNLPBA are excluded (n/a). [c] BioID and CRAFT link entity types to many ontology identifier resources.

Table 1: Basic statistics for each corpus. E = number of annotated entity types; Men./doc = unique mention strings per document; IDs/doc = unique concept identifiers per document. CellLink values reflect the currently released annotated train and development partitions.

miliar concepts. Conversely, NCBI-Disease's low identifier overlap requires systems to generalize to genuinely novel conceptual territory.

4.3 Metadata Composition

Temporal coverage differs sharply: CellLink is most recent, spanning 2019-2025; CHEMDNER is nearly a single-year snapshot (97.7% from 2013); CRAFT spans 2001-2007; NCBI-Disease is predominantly pre-2000 (90.8%); and BC5CDR is the broadest, spanning 1968-2016.

The journal distribution shows similar variation in domain. BC5CDR is by far the most venue-diverse: 703 journals, with the top five journals accounting for only 5.0% of the corpus. BioID represents the opposite extreme, with 18 journals total and 83.2% of corpus documents from the top five journals.

The article-topic mappings in Table 2 demonstrate substantial differences in the slice of biomedical literature these corpora represent. NCBI-Disease is strongest in genetics/genomics, CHEMDNER and NLM-Chem emphasize chemistry/materials, BioID is dominated by molecular biology/biochemistry, and CellLink is enriched for general biology and cell/developmental biology.

4.4 Terminology-based coverage

Figure 3 demonstrates that corpora sharing an entity label may still exercise different concept regions of the concept space. The left panels normalize branch counts within each corpus, showing what share of the corpus's own annotations falls into each high-level terminology branch. The right panels normalize the same branch counts by the size of the corresponding terminology branch, highlighting how the corpus represents different areas of the terminology. Figure 3 focuses on MeSH diseases and chemicals; analogous CL-based statistics for cell-type corpora are available in the dashboard.

For diseases, NCBI-Disease is dominated by Congenital and Hereditary Diseases (C16, 23%) and Neoplasms (C04, 14%), consistent with its genetics origin. BC5CDR instead peaks at Pathological Conditions (C23, 20%) and Cardiovascular Diseases (C14, 17%), consistent with pharmacovigilance as a clinically cross-cutting focus rather than a narrow specialty focus. Chemically-Induced Disorders account for 5.8% of BC5CDR disease annotations but only 0.05% of NCBI-Disease. Thus, while both corpora evaluate "disease" recognition, they measure fundamentally distinct capabilities.

For chemicals, BC5CDR is concentrated in Organic Chemicals (D02, 37%) and Heterocyclic Compounds (D03, 28%), the categories containing most small-molecule drugs. NLM-Chem is more broadly distributed, with higher representation of Inorganic Chemicals (D01, 18%) and Amino Acids/Proteins (D12, 12%).

5 Discussion

The central implication of this study is that benchmark results for biomedical NER and EL cannot be interpreted independently of the corpora that produced them. A benchmark corpus is not simply a labeled sample of text: it is a measurement instrument whose structure determines which system capabilities are exercised and limits how far evaluation conclusions can reasonably transfer. Because benchmark utility is task- and domain-dependent,

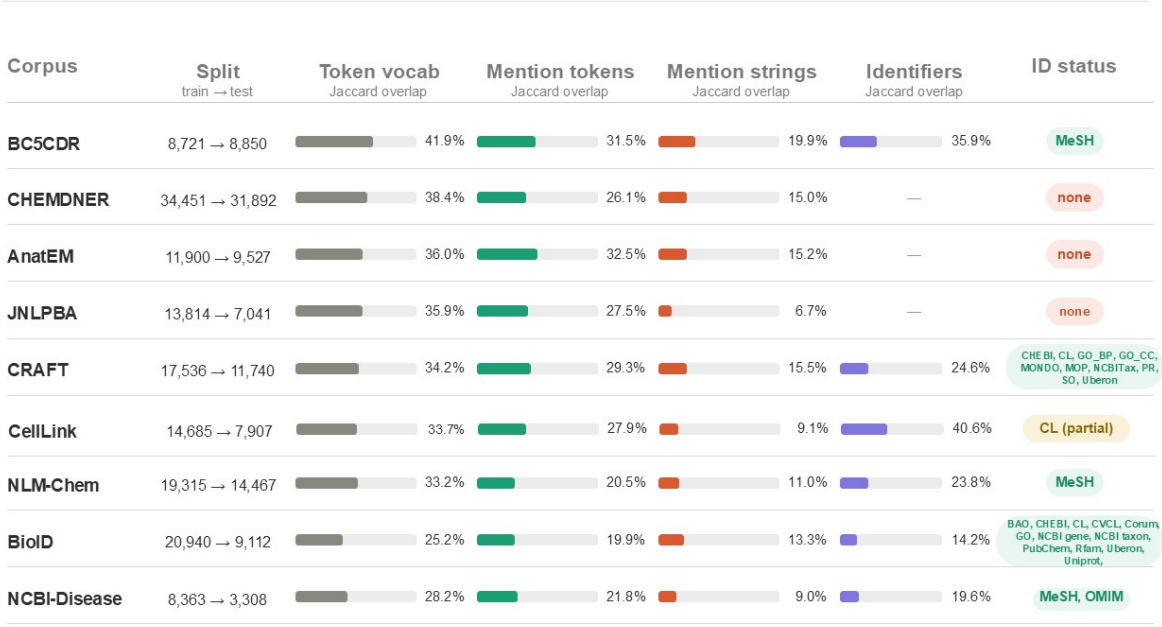

Figure 2: Train-test overlap across nine biomedical corpora. All values are Jaccard similarity (%) between training and test splits. Token vocab: unique vocabulary tokens shared between splits. Mention tokens: unique tokens within entity mention spans. Mention strings: exact entity surface forms shared between splits. Identifiers: concept identifiers shared between splits.

resources that share an entity type label can still function as fundamentally different instruments, evaluating different capabilities, imposing different generalization demands, and representing different regions of biomedical literature and concept space. No single statistic captures this multidimensionality. Instead, benchmark interpretation depends on the interaction of several diagnostic signals, and the nine corpora examined here illustrate how these signals combine in practice.

Annotation density and label distribution. Annotation density determines how concentrated evaluation signal is within each sampled unit. Dense full-text corpora such as CRAFT and NLM-Chem yield many linked decisions from relatively few articles, which can improve evaluation sensitivity and expose systems to full-text sectional variation. At the same time, raw density is partly confounded with document length and annotation scope. A large number of annotations from one article may include repeated mentions of the same entities, and therefore may not provide the same independent evidence as the same number of annotations sampled from many distinct passages or documents. Sparse corpora based on abstracts, passages, or figure captions require broader sampling to achieve stable estimates, and they provide more independent contexts per annotation. Each design serves different evaluation purposes: full-text corpora emphasize document-level realism and repeated-use behavior, whereas passage- or abstract-based corpora can emphasize breadth of contexts under fixed annotation budgets.

Lexical and conceptual variation. Variation determines whether a corpus tests recognition of repeated forms, alternative expressions for known concepts, or generalization to genuinely new ones. CellLink's variation of 3.74 surface forms per label-link pair reflects the compositional naming conventions of single-cell biology: novel cell-population names are assembled from familiar modifiers and cell-type heads, so systems must generalize across surface forms while mapping to relatively familiar concepts. BC5CDR's lower variation is consistent with the pharmacovigilance literature, where drug and disease names tend to be standardized.

Train-test overlap. Overlap analysis offers a particularly direct diagnostic for interpreting unexpectedly strong or weak results, consistent with prior work on leakage and memorization (Tutubalina et al., 2020; Liang et al., 2023). The steepness of the token-level overlap drop varies and is in itself informative. CellLink illustrates one diagnostic profile: high identifier overlap (40.6%)

Topic	AnatEM	BC5CDR	BioID	CHEM	CRAFT	CellLink	JNLPBA	NCBI	NLM
Molecular bio. / biochemistry	**16%**	6%	**62%**	15%	21%	12%	**36%**	17%	18%

Cell & developmental biology	7%	1%	10%	5%	9%	17%	12%	4%	6%
Clinical specialties by organ system	8%	11%	—	3%	7%	9%	2%	5%	4%
General / internal medicine	6%	6%	7%	2%	1%	3%	0%	1%	2%
Pharmacology	2%	6%	—	6%	—	—	1%	—	2%
Other	27%	23%	7%	15%	13%	20%	14%	13%	15%

Topics are assigned from article MeSH terms where available; unresolved article terms fall back to NLM Catalog MeSH journal topics and configured journal-name anchors. "Other" aggregates all categories not shown. The largest displayed non-Other entry in each column is shown in bold.

Table 2: Broad research topic composition of each corpus. Values represent approximate percentage of corpus articles from each topic area. CHEM = CHEMDNER; NCBI = NCBI-Disease; NLM = NLM-Chem.

combined with much lower mention-string overlap (9.1%) means the benchmark emphasizes compositional surface-form generalization rather than novel concept recognition. NCBI-Disease presents the opposite profile, with low identifier overlap (19.6%) that places genuine demands on concept-level generalization. JNLPBA's sharp drop from 35.9% token overlap to 6.7% mention-string overlap, combined with the absence of normalization, may partially recontextualize its relatively low performance ceiling [e.g., (Huang et al., 2020)]: systems cannot rely heavily on exact entity-form reuse.

Metadata composition. Temporal distributions, journal diversity, and topic profiles describe the slice of literature represented by the corpus. These properties define the domain over which benchmark claims can reasonably apply and determine whether conclusions transfer to corpora drawn from different time periods, venues, or subfields. CHEMDNER's near-total concentration in 2013 chemistry literature and BioID's extreme journal concentration (83.2% from five journals) are structural features that may limit the generalizability of results. BC5CDR's breadth across 703 journals and five decades makes performance claims more domain-general. These metadata properties are rarely reported yet have a bearing on whether performance on a benchmark supports claims about a target deployment setting.

Terminology coverage. The contrast between NCBI-Disease and BC5CDR illustrates why terminology-aware analysis matters even when two corpora nominally share a task label. Both annotate disease entities, yet NCBI-Disease is dominated by Congenital and Hereditary Diseases (C16) and Neoplasms (C04), reflecting its genetics origin, while BC5CDR peaks at Pathological Conditions (C23) and Cardiovascular Diseases (C14), reflecting its pharmacovigilance focus. Chemically-Induced Disorders (C25) account for 5.8% of BC5CDR disease annotations but only 0.05% of NCBI-Disease. High performance on one therefore supports only limited claims about transfer to the other, despite the shared entity label. The same logic applies to chemical corpora: BC5CDR's concentration in Organic Chemicals and Heterocyclic Compounds reflects a small-molecule drug emphasis, while NLM-Chem's broader distribution across Inorganic Chemicals, Amino Acids, and Lipids reflects the wider biochemical scope of full-text molecular biology literature. Differences in terminology coverage may reflect different practical capabilities even when their reported task names are identical.

From diagnostics to corpus decisions. Corpus diagnostics are informative not only retrospectively but before a benchmark is finalized. Before releasing a split, developers can compute mention-string and identifier overlap to detect leakage. While extending a corpus, they can sample documents to fill temporal, journal, topic, or terminology-branch gaps. When selecting a benchmark, researchers can choose corpora whose density, overlap profile, and terminology coverage match the intended deployment claim. When combining corpora, they can verify whether a new source adds concept regions not already represented or mainly duplicates familiar strings and identifiers. The goal, then, is to tie benchmark interpretation to corpus characteristics and intended use, rather than assign a single quality score.

Limitations. The framework characterizes corpus structure but does not directly predict down-

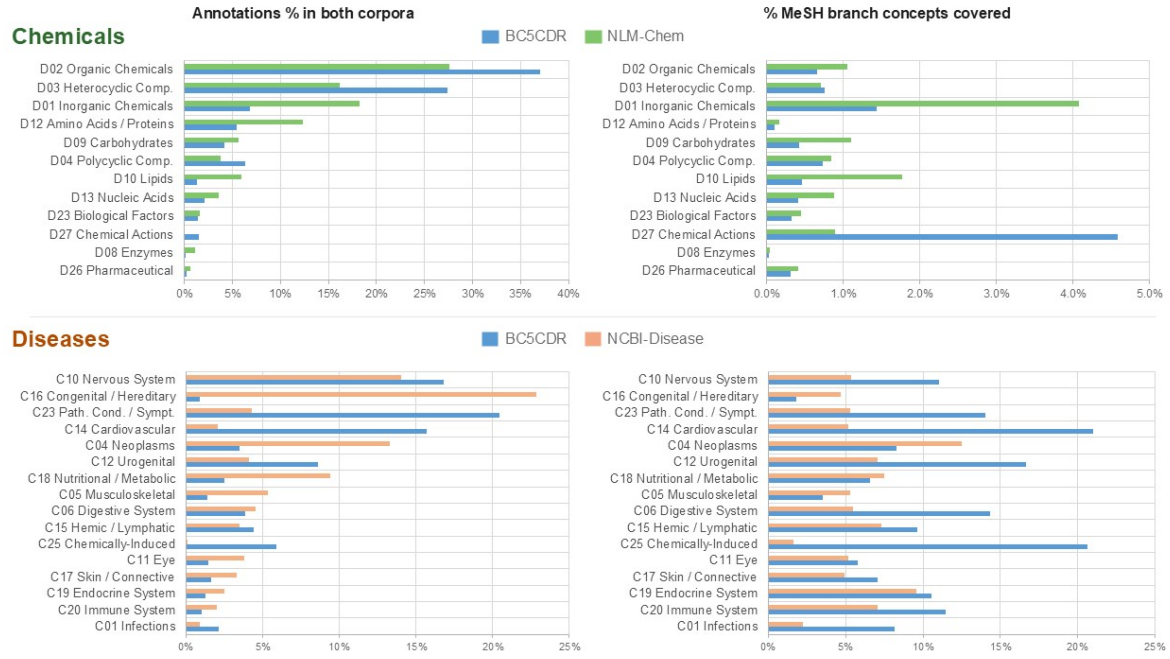

Figure 3: Terminology-based coverage analysis. Left panels: distribution normalized within each corpus's own annotations. Right panels: distribution normalized within the MeSH tree vocabulary. Top panels: distribution across MeSH chemical branches (D-branches) for BC5CDR and NLM-Chem. Bottom panels: distribution across MeSH disease branches (C-branches) for BC5CDR and NCBI-Disease.

stream system rankings or benchmark saturation. Measured ambiguity conflates true polysemy, underspecified guidelines, and annotation errors; the present framework does not distinguish among these sources. Surface-form variation measures observed diversity rather than the full range of synonymy present in the literature. Terminology analyses depend on the version of the reference ontology used. Finally, topic mappings provide practical, lightweight domain diagnostics rather than definitive subject classifications.

6 Conclusion

We presented a corpus-centric framework for diagnosing the benchmark utility of biomedical corpora with entity annotations. The framework organizes standardized statistics over annotations, linked identifiers, corpus splits, document metadata, and terminology mappings into five diagnostic families: (1) scale, density and label distribution, (2) lexical and conceptual structure, (3) train-test overlap, (4) metadata composition, and (5) terminology coverage. Applied to nine biomedical NER and EL corpora, these diagnostics show that corpora for the same apparent task can measure substantially different capabilities.

The main implication is that these statistics provide a practical basis for more complete reporting of biomedical NER and EL benchmarks. Corpus reports should describe annotation density, normalization support, lexical and identifier variation, train-test overlap at multiple abstraction levels, temporal and journal composition, and terminology coverage where applicable. Without these measurements, benchmark results are difficult to interpret. Standardized corpus diagnostics would make evaluation claims more interpretable, clarify what a benchmark measures, and support transparent, reproducible, transfer-aware evaluation.

Abstract

Hallucinations in biomedical question answering are hard to define and compare because the literature uses overlapping and inconsistent terms. There is currently no grounded definition set that works for biomedical QA, with real examples from open-source LLMs. We introduce a layered definition of hallucinations for biomedical QA, hierarchically structured from the overarching idea of "Hallucination" in relation to generated model content, to source and consistency orientations, and finally to subtypes. We ground our definition taxonomy in source-attributed literature definitions and reproducible examples from ClinIQLink, where cases can be traced to the question, source passage, generated answer, and annotation record. We provide a framework with annotation, comparison, and error analysis to provide a clearer reference for evidence-grounded biomedical QA. We aim for this example-grounded taxonomy to support automated detection of hallucinations and their potential harmfulness.

1 Introduction

By 2020, the term "hallucination" was already being used across machine translation, data-to-text generation, and summarization to describe generated content that departs from its source or input (Maynez et al., 2020). In 2020, machine translation used the term for fluent translations unrelated to the source (Wang and Sennrich, 2020), data-to-text work set unsupported content against omission relative to structured input (Dušek and Kasner, 2020), and summarization work defined hallucinated spans as content not supported by the document and split them into intrinsic and extrinsic cases (Maynez et al., 2020). Entity-level studies later broke these failures down further and showed that source unfaithfulness and world truth do not always move together (Pagnoni et al., 2021; Cao et al., 2022). Conditional generation and a broad NLG survey then widened the term beyond any one task while keeping the core idea of mismatch with a given source (Xiao and Wang, 2021; Ji et al., 2023). Large language model work then reorganized those earlier ideas through LLM-specific schemes (Rawte et al., 2023), through factuality and faithfulness (Huang et al., 2025), through input, context, and fact conflict (Zhang et al., 2025), and through benchmarks that separate hallucination from factuality itself (Bang et al., 2025). At the same time, concept papers and audits showed that these schemes do not line up cleanly and that the field still lacks a stable shared frame (van Deemter, 2024; Narayanan Venkit et al., 2024; Schmidtova et al., 2025). Evidence-grounded QA then made the split between correctness and faithfulness central, and factual subtype work made that split usable in knowledge-heavy settings, including biomedicine (Adlakha et al., 2024; Li et al., 2024).

1.1 Contributions.

We provide a grounded definition set and traceable ClinIQLink examples for biomedical QA. We present a hierarchical four-level hallucination schema that begins with an broad umbrella hallucination definition and then separates source orientation, consistency orientation, and retained subtype labels grounded in traceable ClinIQLink examples.

2 A Layered Definition of Hallucination

Definitions of model hallucinations are fragmented and not well aligned across the broader literature. Some papers judge generated text against source support, others against world facts, and others against user instruction or internal coherence (Narayanan Venkit et al., 2024; Ji et al., 2023; Huang et al., 2025). Biomedical QA makes the

Table 1: Orientation definitions used in the paper.

Orientation term	Layer	Definition from literature	Source
Intrinsic hallucination	Source orientation	"the generated output that contradicts the source content"	(Ji et al., 2023, p. 4)
Extrinsic hallucination	Source orientation	"the generated output that cannot be verified from the source content"	(Ji et al., 2023, p. 4)
Factuality hallucination	Consistency orientation	"the discrepancy between generated content and verifiable real-world facts"	(Huang et al., 2025, p. 2)
Faithfulness hallucination	Consistency orientation	"the divergence of generated content from user input or the lack of self-consistency within the generated content"	(Huang et al., 2025, p. 2)

overlap hard to ignore because one answer can fail against more than one reference frame at once. A layered taxonomy is, therefore, more useful here than a flat label list. Our hierarchically structured layered scheme provides a high level umbrella definition then broken down to the orientation axes, and then to subtype layer. We hence define a hallucination as model generated content that is:

Definition. Hallucination: Plausible yet nonfactual content, false or fabricated information, outputs that are inaccurate, irrelevant, or simply do not make factual sense, as well as content that is not faithful to the input instructions.

Our definition combines Ji et al.'s broad NLG umbrella of generated content that is "nonsensical or unfaithful to the provided source content" (Ji et al., 2023, p. 4), Huang et al.'s factuality and faithfulness split (Huang et al., 2025, p. 2), Li et al.'s fine-grained factual subtype inventory (Li et al., 2024, p. 2), and Cossio's broader LLM-era language of plausible but nonfactual or fabricated content (Cossio, 2025, p. 5). The broad definition for hallucination is effective for describing our grounded hallucination dataset ClinIQLink (Colelough et al., 2025) because the biomedical QA setting contains passage-bounded errors, world-factual errors, relevance failures, and instruction-relative failures within the same task environment. Ji et al. define intrinsic hallucination as "the generated output that contradicts the source content" and extrinsic hallucination as "the generated output that cannot be verified from the source content" (Ji et al., 2023, p. 4). Huang et al. define factuality hallucination as the "discrepancy between generated content and verifiable real-world facts" and faithfulness hallucination as the "divergence of generated content from user input or the lack of self-consistency within the generated content" (Huang et al., 2025, p. 2). Source orientation therefore asks whether an answer contradicts or exceeds the operative evidence frame. Consistency orientation asks whether the main failure is against external facts or against instructions, context, or internal coherence. Table 1 summarizes the orientation layer used in the paper.

2.1 Hierarchical Definitional Layer Structure

The proposed hallucination schema has four annotation levels. Level 0 is the umbrella definition given above, which covers plausible yet non-factual content, false or fabricated information, outputs that are inaccurate, irrelevant, or do not make factual sense, and content that is unfaithful to the input instructions. Level 1 records the source orientation of the failure, asking whether the answer contradicts or goes beyond its source passage, with the relevant terms summarized in Table 1. Level 2 records the consistency orientation, asking whether the core problem is a factual error or a failure to follow the provided instructions and context. Level 3 assigns one or more specific subtype labels to the failure, such as entity-error or overclaim, drawn from Table 2. The hallucination schema is descriptive rather than taxonomically strict. A single model answer can fail in more than one way and may therefore receive multiple subtype labels, with each label capturing a distinct dimension of the same underlying hallucination.

2.2 Rating Hallucinations

The layered taxonomy alone is not sufficient for case-level biomedical QA annotation. Source orientation, consistency orientation, and subtype labels identify what kind of hallucination is present, but case review also requires rating subfields that

Table 2: Hallucination subtypes grounded from ClinIQLink. *Lineage* cites the taxonomy sources motivating each subtype. *Coverage* is the label-level count of adjudicated records assigned to that subtype. Example columns give abbreviated, traceable cases by record ID, full question, source passage, model output, and full annotation details appear in the appendix.

Type	Definition	Lineage	Coverage	Example 1	Example 2
Entity-error	Wrong entity is substituted for the supported one.	(Li et al., 2024; Huang et al., 2025)	8	congenital CMV item treats toxoplasmosis, not CMV, as correct (ID 71).	picks cyclooxygenase although the substrate description matches lipoxygenase (ID 100).
Relation-error	Wrong relation is asserted between entities, such as cause, direction, dosage, or role.	(Li et al., 2024; Huang et al., 2025)	15	AML retinal hemorrhage is linked to leukemic infiltration rather than disordered hemostasis (ID 46).	says pulmonary arterial flow returns blood to the heart, reversing the circuit (ID 45).
Unverifiability	Adds a specific claim that the available source does not support or refute.	(Li et al., 2024; Huang et al., 2025)	4	invents a 25% full-recovery figure for cerebral aspergillosis without source support (ID 76).	states a P-gp mechanism that is not present in the source passage (ID 49).
Overclaim	Turns partial evidence into a broader or stronger claim than the source warrants.	(Li et al., 2024; Huang et al., 2025)	7	extends tenofovir use to resistant hepatitis C although the source does not support that leap (ID 38).	turns a nuanced rectal-bleeding workup into the universal claim "A flexible colonoscope" (ID 103).
Incompleteness	Gives a partial answer while omitting required supported items.	(Li et al., 2024)	4	wound-irrigation answer lists water and antiseptics but omits saline (ID 40).	gives 15–25% protein instead of the full supported macronutrient range (ID 92).
Outdatedness	Uses information that may once have been acceptable but is no longer current.	(Li et al., 2024)	2	repeats a 25–100% range for non-functioning PNETs instead of current 60–90% summaries (ID 43).	treats roflumilast as PDE4B-selective rather than PDE4-selective (ID 67).
Context inconsistency	Conflicts with the provided passage or retrieved context.	(Huang et al., 2025; Cossio, 2025)	9	selects blood culture although the source points to stool ova/parasite testing (ID 70).	ignores the bolus or steady-state distinction in a perfusion item (ID 66).
Instruction inconsistency	Fails to follow the operative instruction or required label or format.	(Huang et al., 2025; Cossio, 2025)	13	generates a QA pair from a figure caption about secondary myelofibrosis instead of the intended source text (ID 98).	was asked for a false HUS item but produced a true claim and still labeled it disagree (ID 104).
Logical inconsistency	Contains internally inconsistent reasoning or a conclusion that does not follow from prior steps.	(Huang et al., 2025; Cossio, 2025)	11	vaccine-hesitancy chain jumps from strong clinician advice to "unquestioning compliance" (ID 78).	infers "no significant obstruction" from a passage saying the lower route is complicated (ID 75).
Amalgamated hallucination	Blends distinct source facts or conditions into one unsupported answer.	(Cossio, 2025)	5	fuses flexible sigmoidoscopy and colonoscopy into "flexible colonoscope" (ID 103).	combines distinct intra-abdominal candidiasis treatments into one answer (ID 79).
Nonsensical response	Produces irrelevant, incoherent, or malformed output instead of a task-compliant answer.	(Ji et al., 2023; Narayanan Venkit et al., 2024; Cossio, 2025)	7	repeated <| |> placeholders replace the requested answer.	abandons QA generation and rambles about having no paragraph instead of answering.

capture degree of deviation, plausible downstream consequence, and detectability from the model output alone. For real-world hallucinations such as those observed within the ClinIQLink dataset, we observed varying levels of severity, harmfulness, and obviousness during case review, compared the differing levels of real-world hallucinations during adjudication, and keep the reconciled values in the final annotation record. We therefore treat severity, harmfulness, and obviousness as hallucination rating subfields. For summary analysis, severity, harmfulness and obviousness are coded onto the same 0–10 scale and the overall hallucination rating is defined as the average of the three aligned subfield scores. Full rubrics, examples, and coding scheme are shown in the Appendix.

Definition. Severity: How far the model's generated content deviates from the reference/known truth for the task and / or the input instruction provided by the user (ground truth OR gold answer (if available) OR provided source OR external source), weighted by the factuality, deviation from user/ system input / instruction, centrality of the error to the main claim, and the scope of affected statements.

Our severity rating subfield is centered on deviation within the answer itself rather than downstream consequence or detectability. The rating weighs factual error and instruction mismatch by centrality to the main claim and by the scope of affected statements. Low ratings capture peripheral inaccuracies or omissions that leave the main takeaway intact. High ratings capture errors that overturn the main claim or make the answer unreliable as a whole.

Definition. Harmfulness: The plausible negative impact on a naive user (no domain knowledge) if they act on or trust the answer as provided by the model.

Our harmfulness rating subfield is centered on plausible downstream consequence for a naive user in a typical text-answer setting without expert oversight. The rating weighs actionability, domain sensitivity, audience vulnerability, reversibility, and scope of misuse. Low ratings capture confusion or minor misdirection. High ratings capture clinically, ethically, or legally serious harm.

Definition. Obviousness: How detectable the hallucination is to a naive reader who is shown only the model's generated content and NOT the source paragraph, user and/or system prompt used to generate the models generated content and nothing else.

Our obviousness rating subfield is centered on surface detectability from the model output alone. The rating asks how readily a careful non-expert could flag a problem without access to the source paragraph or prompting context. Low ratings capture errors that usually require external checking or domain knowledge. High ratings capture direct contradictions, visible instruction failures, or nonsensical output that is apparent on plain reading.

For aggregation, severity, harmfulness and obviousness are all coded as Minimal or None $= 0$, Low $= 2.5$, Medium or Moderate $= 5$, High $= 7.5$, and Critical or Severe $= 10$.

$$R_{\text{hall}} = \frac{S + H + O}{3}. \tag{1}$$

where S is the severity score, H is the harmfulness score, and O is the obviousness score.

3 ClinIQLink-Grounded Examples

We use ClinIQLink (Colelough et al., 2025) as a source-grounded biomedical QA setting in which hallucination labels can be tied to questions, source passages, generated answers, model outputs, and annotation records from open-source LLMs. The shared task targets general-practitioner-level medical knowledge and uses expert-verified question–answer pairs across seven closed and open formats, all anchored in standard open-source medical texts. Table 2 therefore describes the hallucination types from the retained taxonomy that already have defensible ClinIQLink support, with examples included as recheckable biomedical QA cases. Each row in Table 2 describes a retained hallucination subtype, its literature lineage, the number of adjudicated ClinIQLink records assigned to that subtype, and two abbreviated traceable examples identified by record ID, with full details provided in the reproducibility-packet appendix. The split between Table 2 and Table 4 (see appendix A) marks the difference between what the current ClinIQLink material grounds and what the broader literature still motivates. Table 4 describes literature-backed concepts that were checked against the ClinIQLink dataset but were not present. Their absence from Table 2 does not mean that the concepts are invalid, only that the present evidence base did not yet support a clean traceable case for the examples in Table 4.

4 Conclusion

We pair hallucination definitions with ClinIQLink examples thus grounding our hierarchically structured hallucination definition in reproducible examples. We separate source orientation, consistency orientation, and subtype labels, and shows which literature-backed hallucination types are supported by traceable cases from ClinIQLink. We provide definitions and a method for rating model Hallucinations across severity, harmfulness and obviousness.

Limitations

This taxonomy is a task-specific working synthesis for biomedical QA, grounded in the current ClinIQLink (Colelough et al., 2025) workflow. Some boundary cases remain task-dependent or unsupported by the current ClinIQLink evidence base.

5 Ethical Considerations

We define and ground hallucination labels for biomedical question answering to support analysis, annotation, and evaluation. We do not provide clinical advice or decision support. Because misleading biomedical outputs can shape user trust and interpretation, these labels and examples should be used only for research and evaluation and should not be treated as guidance for patient care.

A Appendix

A.1 Additional tables

Table 3 describes literature based hallucination subtypes and Table 4 describes the literature-backed concepts that did not yield a defensible ClinIQLink (Colelough et al., 2025) match after re-checking the current source set.

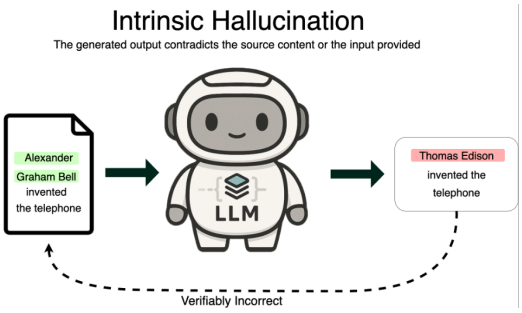

Table 3: Subtype layer used in the paper after separating the umbrella definition from source and consistency orientations.

Subtype	Source orientation	Consistency orientation	Definition from literature	Source
Factual contradiction	not explicit	factuality	"contains facts that can be grounded in real-world information, but present contradictions"	(Huang et al., 2025, p. 6)
Entity-error hallucination	mixed	factuality	"contains erroneous entities"	(Huang et al., 2025, p. 6)
Relation-error hallucination	mixed	factuality	"contains wrong relations between entities"	(Huang et al., 2025, p. 6)
Factual fabrication	not explicit	factuality	"contains facts that are unverifiable against established real-world knowledge"	(Huang et al., 2025, p. 6)
Unverifiability hallucination	extrinsic	factuality	"entirely non-existent or cannot be verified using available sources"	(Huang et al., 2025, p. 7)
Overclaim hallucination	mixed	factuality	"claims that lack universal validity due to subjective biases"	(Huang et al., 2025, p. 7)
Instruction inconsistency	task-specific	faithfulness	"outputs that deviate from a user's directive"	(Huang et al., 2025, p. 7)
Context inconsistency	intrinsic	faithfulness	"output is unfaithful with the user's provided contextual information"	(Huang et al., 2025, p. 7)
Logical inconsistency	not explicit	faithfulness	"outputs exhibit internal logical contradictions"	(Huang et al., 2025, p. 7)
Outdatedness hallucination	extrinsic	factuality	"is outdated for the present moment, but was correct at some point in the past"	(Li et al., 2024, p. 2)
Incompleteness hallucination	mixed	factuality	"LLMs might exhibit incomplete output when generating lengthy or listed responses"	(Li et al., 2024, p. 2)
Amalgamated hallucination	mixed	mixed	"incorrectly combines multiple facts or conditions presented within a single prompt"	(Cossio, 2025, p. 13)
Nonsensical responses	task-specific	task-specific	"output that is completely irrelevant to the input prompt"	(Cossio, 2025, p. 13)
Misleading hallucination	mixed	mixed	Locally true or source-supported content framed to induce a materially false or distorted inference.	This paper

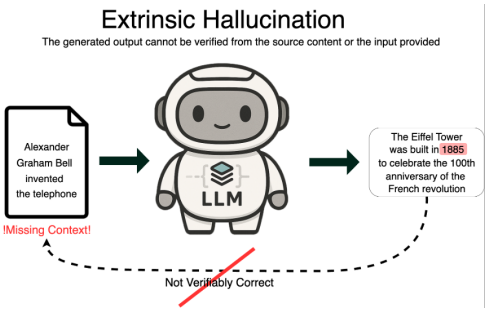

Table 4: Literature-backed hallucination concepts that remained without a defensible ClinIQLink (Colelough et al., 2025) match after re-checking both the structured raw export and the supplemental ClinIQLink (Colelough et al., 2025) example pack. All retained rows had no ClinIQLink (Colelough et al., 2025) example after that combined re-check.

Type	Source orientation	Consistency orientation	Introduced	Definition / framing in source	Example from source paper
Intent hallucination	intrinsic	faithfulness	(Hao et al., 2025)	The model omits or misreads query-level intent constraints, so the answer can be factually plausible yet still fail the actual request.	GPT-4o omits "particularly from Spain," yielding a factually plausible but query-misaligned answer.
Dialogue history-based hallucination	intrinsic	faithfulness	(Cossio, 2025)	The model mixes up names or relations from earlier turns and snowballs prior errors into later responses.	A chatbot confuses entities from earlier turns and compounds the mistake in later responses.
Abstractive summarization hallucination	mixed	task-specific	(Cossio, 2025)	A summary distorts source meaning, fabricates details, or adds unsupported causal links or background knowledge.	A summary inserts an unsupported causal relation or unrelated background fact not present in the source.
Code generation hallucination	task-specific	task-specific	(Cossio, 2025)	Generated code is incorrect, unjustifiable, or nonsensical, sometimes only under a specific execution path.	An LLM emits code that looks plausible but fails or is unjustified when executed.
Affective hallucination	task-specific	task-specific	(Kim et al., 2026)	The model simulates emotional presence or relational closeness in ways that can mislead users into perceiving genuine companionship or support.	A model says "I'm here for you always," simulating ongoing relational presence.
Defamation / misinformation	extrinsic	factuality	(Cossio, 2025)	The model makes damaging false claims about a person or event, often with invented supporting detail.	ChatGPT falsely accuses a law professor of harassment and cites a non-existent article.
Category hallucination	intrinsic	faithfulness	(Cossio, 2025)	In a multimodal setting, the model names an object category that is not actually present in the visual input.	An image-grounded answer labels an object with a category that is not present.
Attribute hallucination	intrinsic	faithfulness	(Cossio, 2025)	In a multimodal setting, the model assigns the wrong attribute — such as color, count, or action — to the right object.	The model describes the correct object but gives it the wrong visible attribute.
Relation hallucination	intrinsic	faithfulness	(Cossio, 2025)	In a multimodal setting, the model misstates the spatial or interaction relation between objects in the input.	The answer places objects in the wrong relation to each other even though the image does not support it.

A.2 Hallucination Examples and Replication Package

B ClinIQLink (Colelough et al., 2025) Reproducibility Packets for Retained Hallucination Examples

This appendix records the full reproducibility packets for the ClinIQLink (Colelough et al., 2025) examples that remain in the grounded examples table in the main paper. Each packet keeps the paper-facing subtype, the record locator, the model output, the stored ground-truth field, the relevant source excerpt, and the annotation fields needed to audit the retained case.

Some retained paper examples reuse the same underlying saved annotation under different paper-facing subtypes. Those records therefore, appear more than once with subtype-specific rationales.

Personal annotator identifiers are omitted because the current export stores email-based IDs, and fields absent from the retained source pack are omitted rather than inferred.

B.1 Entity-error hallucination

These packets show how the retained entity-error cases substitute the wrong supported entity while keeping the broader biomedical frame intact. Both records are recoverable from verified saved annotations, and together they show why the paper keeps the subtype separate from broader factual contradiction. The first packet is a congenital infection item and the second is a pharmacology item, which keeps the subtype grounded across domains.

Example 1 Entity-error hallucination Llama 3.3 70B Instruct

This case is retained as entity-error because the model selects toxoplasmosis even though the syndrome in the source points to congenital cytomegalovirus. The record matters because the question, the wrong option choice, the source passage, and the saved annotation all survive in one export file, which makes the substitution easy to audit.

Type	Entity-error hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Extrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-0323476768-p288-para1
qa_id	1124
paragraph_id	978-0323476768-p288-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00071.json
Verification status	`verified_saved_annotation`
Question type	mc
Domain	Microbiology
Subdomain	Introduction
Sub-subdomain	Questions
Question	What is the most common cause of an infection resulting in microcephaly, hepatosplenomegaly, petechial rash, and "owl's eye" inclusion bodies in newborns? *Options* A. Herpes Simplex Virus causing encephalitis B. Toxoplasmosis due to Toxoplasma gondii C. Varicella-Zoster Virus leading to congenital varicella syndrome D. Parvovirus B19 associated with erythema infectiosum
Model answer	Toxoplasmosis due to Toxoplasma gondii
Ground-truth answer	Cytomegalovirus
Source passage excerpt	At birth her infant was small and appeared to have a disproportionately small head with microcephaly. Within 2 days the infant developed jaundice, hepatosplenomegaly, and a petechial rash. Urine samples were found to contain cells with "owl's eye" inclusion bodies.
Final label	Entity-error hallucination
Raw export label	1. Factual Contradiction – Entity-error hallucination
Severity	high
Harmfulness	high
Obviousness	2
Comments	Annotation comment notes that all answer options are wrong and that CMV rather than toxoplasmosis fits the syndrome.
Evidence URLs	https://www.sciencedirect.com/topics/veterinary-science-and-veterinary-medicine/cytomegalovirus
Annotation last modified	2025-09-24T21:40:33

This example fits entity-error rather than fabrication because the model names a real pathogen instead of inventing one. It fits entity-error rather than relation-error because the causal slot is wrong while the syndrome frame stays intact. The narrower retained subtype is therefore enough to explain and recover the case.

Example 2 Entity-error hallucination Llama 3.3 70B Instruct

This case is retained as entity-error because the model chooses cyclooxygenase even though the substrate description in the source points to lipoxygenase. The packet matters because the saved record preserves both the relevant source sentence and the faulty option set, which makes the wrong enzyme choice auditable at row level.

Type	Entity-error hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264258086-p835-para1
qa_id	2543
paragraph_id	978-1264258086-p835-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00100.json
Verification status	`verified_saved_annotation`
Question type	mc
Domain	Pharmacology
Subdomain	Lipid-Derived Autacoids
Sub-subdomain	Eicosanoids and Platelet-Activating Factor

Question	What enzyme specifically needs a fatty acid substrate having two cis double bonds separated by a methylene group? *Options* A. Cyclooxygenase (COX) B. Cytochrome P450 (CYP) C. yclooxygenase (COX) D. Peroxidase (POX)
Model answer	Cyclooxygenase (COX)
Ground-truth answer	Lipoxygenase (LOX)
Source passage excerpt	The enzymes require a fatty acid substrate with two cis double bonds separated by a methylene group. There are five active human LOXs classified according to the site of oxygen insertion.
Final label	Entity-error hallucination
Raw export label	1. Factual Contradiction – Entity-error hallucination
Severity	high
Harmfulness	low
Obviousness	2
Comments	Annotation comment notes that the substrate description matches LOX and that the model selected COX while LOX is missing from the options.
Evidence URLs	https://pmc.ncbi.nlm.nih.gov/articles/PMC4353356/
Annotation last modified	2025-12-03T07:32:44

This example fits entity-error rather than relation-error because the predicate stays stable while the key enzyme name is wrong. It also fits entity-error rather than instruction inconsistency because the question format is followed and the failure is substantive rather than procedural. The retained subtype is the most specific explanation of the error.

B.2 Relation-error hallucination

These packets show how the retained relation-error cases keep the main entities in place while asserting the wrong linkage among them. Both records are verified saved annotations, and each preserves enough local source context to inspect the mistaken predicate directly. The first case is clinical and the second is anatomical, which broadens the subtype without changing the core error.

Example 1 Relation-error hallucination Llama 3.3 70B Instruct

This case is retained as relation-error because the model links retinal hemorrhage to leukemic infiltration instead of to abnormal hemostasis. The record matters because the same source excerpt mentions both hemorrhage and infiltration, which makes the mistaken linkage visible without any outside reconstruction.

Type	Relation-error hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264268504-p3117-para1
qa_id	10699
paragraph_id	978-1264268504-p3117-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00046.json
Verification status	verified_saved_annotation
Question type	multi
Domain	Internal Medicine
Subdomain	Hematopoietic Disorders
Sub-subdomain	Acute Myeloid Leukemia
Question	What could potentially happen if a patient presents with signs of abnormal hemostasis due to having Acute Myeloid Leukemia?
Model answer	They might experience severe bleeding complications, including retinal hemorrhages, which could indicate infiltration of leukemia cells into various body parts.
Ground-truth answer	Recovered from the stored field as "They may develop bleeding complications such as retinal hemorrhages due to abnormal hemostasis such as DIC and thrombocytopenia." The stored explanation also notes that the passage does not link the hemorrhages to leukemic tissue infiltration.
Source passage excerpt	Signs of abnormal hemostasis with bleeding and easy bruising are common. Retinal hemorrhages are detected in 15% of patients. Infiltration of the gingiva, skin, soft tissues, or meninges with blasts may also occur.

Final label	Relation-error hallucination
Raw export label	Factual Contradiction – Relation-error hallucination
Severity	high
Harmfulness	high
Obviousness	0
Comments	Annotation comment notes that the model conflates tissue infiltration with the cause of retinal hemorrhage.
Annotation last modified	2025-09-01T19:48:39

This example fits relation-error rather than entity-error because the relevant entities remain AML and retinal hemorrhage. The failure lies in the predicate that connects them. It also does not need a fabrication label because the record stays within the source topic instead of inventing a new condition.

Example 2 Relation-error hallucination Llama 3.3 70B Instruct

This case is retained as relation-error because the model reverses the cardiopulmonary return path and overstates systemic venous drainage from lung support tissues. The packet matters because the source excerpt states both the correct pulmonary venous return and the narrower systemic drainage route, which makes the directional error easy to recheck.

Type	Relation-error hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1496347213-p812-para1
qa_id	7378
paragraph_id	978-1496347213-p812-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00045.json
Verification status	`verified_saved_annotation`
Question type	multi
Domain	Clinical Anatomy
Subdomain	Viscera of Thoracic Cavity
Sub-subdomain	Pleurae, Lungs, and Tracheobronchial Tree
Question	How does the blood flow back to the heart after being supplied to the roots of the lungs, considering the pathways involving both arterial and venous systems?
Model answer	Blood flows back to the heart via different routes depending on whether it was involved in gas exchange within the alveoli or if it was supplying the structural components of the lungs themselves. For the former, deoxygenated blood returns through the pulmonary arteries to the right side of the heart, then gets pumped out again to become oxygenated. However, once oxygenated in the lungs, it travels through the pulmonary veins to the left atrium. Meanwhile, nutrient-supplied blood for the lung's supportive tissue drains differently - specifically, bronchial veins empty into the azygos system which eventually joins the superior vena cava before reaching the right atrium, thus completing their circuit independently of the primary respiratory pathway.
Ground-truth answer	Recovered from the stored field as "Bronchial arteries supply the lung roots and supporting tissues. Most venous return then enters the pulmonary veins and reaches the left atrium." The stored explanation also notes a smaller systemic venous share from the parietal pleura.
Source passage excerpt	Two pulmonary veins, a superior and an inferior pulmonary vein on each side, carry oxygen-rich blood from corresponding lobes of each lung to the left atrium of the heart. Except in the central perihilar region, the veins from the visceral pleura and the bronchial venous circulation drain into the pulmonary veins. Veins from the parietal pleura join systemic veins in adjacent parts of the thoracic wall.
Final label	Relation-error hallucination
Raw export label	Factual Contradiction – Relation-error hallucination
Severity	high
Harmfulness	moderate
Obviousness	2
Comments	Annotation comment notes that the model reverses pulmonary return and overgeneralizes azygos drainage.
Annotation last modified	2025-09-01T19:33:45

This example fits relation-error because the involved vessels are real and the error is in how flow is linked among them. It does not need an entity-error label because pulmonary veins and bronchial veins are not themselves invented or substituted. The retained subtype is therefore the best description of the reversed and overgeneralized relations.

B.3 Unverifiability hallucination

These packets show how the retained unverifiability cases add specific biomedical claims that the available source frame does not support. The first record is a clean unsupported percentage claim, whereas the second also exposes a clipped source field in the retained export. That difference matters because reproducibility requires reporting both what can be checked and what the current source set no longer preserves.

Example 1 Unverifiability hallucination Llama 3.3 70B Instruct

This case is retained as unverifiability because the model inserts a precise 25% full-recovery figure that the source does not provide. The failure matters because the source passage does discuss outcomes for invasive aspergillosis, yet it does not support the added number for cerebral disease.

Type	Unverifiability hallucination
Paper source orientation	extrinsic
Paper consistency orientation	factuality
Raw export orientation	Extrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264268504-p6278-para1
qa_id	11729
paragraph_id	978-1264268504-p6278-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00076.json
Verification status	`verified_saved_annotation`
Question type	short_inverse
Domain	Internal Medicine
Subdomain	SECTION 16 Fungal Infections
Sub-subdomain	217 Aspergillosis
Question	What percent of patients with cerebral aspergillosis survive?
Model answer	Approximately 25% of patients with cerebral aspergillosis experience full recovery.
Ground-truth answer	It presents a mortality rate higher than 95%
Source passage excerpt	The mortality rate for invasive aspergillosis is 30–70% if the infection is treated but is 100% if the diagnosis is missed. Cerebral aspergillosis and endocarditis have very poor outcomes.
Final label	Unverifiability hallucination
Raw export label	1. Factual Fabrication – Unverifiability hallucination
Severity	medium
Harmfulness	medium
Obviousness	2
Comments	Annotation comment says that the survival rate is not in the source.
Evidence URLs	https://pmc.ncbi.nlm.nih.gov/articles/PMC11047199/#bib1
Annotation last modified	2025-09-25T16:31:35

This example fits the retained subtype because the answer adds unsupported numerical specificity rather than contradicting a stated source figure. It does not fit overclaim because the source does not provide a narrower supported survival value that the answer merely broadens. The key failure is that the cited number has no local support.

Example 2 Unverifiability hallucination Llama 3.3 70B Instruct

This case is retained as unverifiability because the answer states a P-gp mechanism that the preserved source excerpt does not support. The packet matters because the export source text is clipped, so the appendix has to report both the unsupported mechanism claim and the missing continuation of the passage.

Type	Unverifiability hallucination
Paper source orientation	extrinsic
Paper consistency orientation	factuality
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264268504-p2170-para1
qa_id	8101
paragraph_id	978-1264268504-p2170-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00049.json
Verification status	`verified_saved_annotation`
Question type	short
Domain	Internal Medicine
Subdomain	SECTION 1 Neoplastic Disorders
Sub-subdomain	73 Principles of Cancer Treatment
Question	How does the multidrug resistance gene product P-gp act?
Model answer	It enhances efflux, reducing intracellular concentrations of chemotherapeutic agents.
Ground-truth answer	The export stores the ground-truth field as "agree". The retained record does not include a more specific source-supported answer.
Source passage excerpt	The export source excerpt is clipped and ends with "Resistance mechanisms to the conventional cytotoxic agents were initially characterized in the late twentieth century as defects in drug uptake, metabolism, or export by tumor cells. The multidrug". No preserved source passage in the retained export states a P-gp efflux mechanism.
Final label	Unverifiability hallucination
Raw export label	Factual Fabrication – Unverifiability hallucination
Severity	high
Harmfulness	low
Obviousness	2
Comments	Annotation comment states that the information is not included in the source text.
Annotation last modified	2025-09-02T13:05:55

This packet fits the retained subtype because the audit question is source support, not external falsity alone. It does not fit relation-error or entity-error because the issue is an unsupported mechanistic addition. The clipped source field is a limit of the current appendix source set rather than a reason to fill the gap.

B.4 Overclaim hallucination

These packets show how the retained overclaim cases start from some local support and then widen the claim beyond what the source warrants. The first record expands HBV evidence into HCV use, and the second turns a conditional rectal-bleeding workup into a single universal instrument choice. Both packets therefore hinge on an unsupported leap in scope rather than on a wholly invented fact.

Example 1 Overclaim hallucination Llama 3.3 70B Instruct

This case is retained as overclaim because the answer starts from supported tenofovir use in chronic hepatitis B and then extends that support to resistant hepatitis C. The record matters because the source itself places tenofovir and sofosbuvir in different viral treatment contexts, which makes the scope inflation visible inside one passage.

Type	Overclaim hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1260117127-p433-para1
qa_id	5389
paragraph_id	978-1260117127-p433-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00038.json
Verification status	`verified_saved_annotation`
Question type	multi
Domain	Pharmacology
Subdomain	49 Antiviral Agents
Sub-subdomain	Not Available

Question	Given that a certain medication is being considered for treating hepatitis B and C, and knowing that tenofovir is active against lamivudine-resistant strains, how might the effectiveness and usage guidelines of tenofovir compare when treating different types of viral hepatitis if we consider its mechanism of action alongside other treatments like sofosbuvir?
Model answer	Tenofovir's effectiveness could potentially offer advantages over traditional options for hepatitis B and possibly extend to treating resistant cases of hepatitis C when combined appropriately with other therapies.
Ground-truth answer	The retained export does not store a standalone ground-truth field. The preserved source passage supports tenofovir for chronic HBV and supports sofosbuvir-based therapy for HCV.
Source passage excerpt	Tenofovir, an antiretroviral drug, is also approved for chronic HBV infection and is active against lamivudine- and entecavir-resistant strains. Sofosbuvir inhibits RNA polymerase in HCV, alone or in combination with interferon or ribavirin and achieves very high cure rates.
Final label	Overclaim hallucination
Raw export label	Factual Fabrication – Overclaim hallucination
Severity	medium
Harmfulness	high
Obviousness	3
Comments	Annotation comment states that tenofovir does not appear to be used for HCV in the provided source.
Annotation last modified	2025-08-29T14:52:41

This case fits overclaim because the answer inflates a supported HBV fact into a broader HCV treatment claim. It does not fit unverifiability alone because the record preserves a real support base that the model overextends. The retained subtype therefore centers the unsupported leap in scope.

Example 2 Overclaim hallucination Llama 3.3 70B Instruct

This case is retained as overclaim because the answer turns a conditional diagnostic choice into a single universal instrument recommendation. The record matters because the same saved annotation also supports the paper's separate amalgamated packet, so the appendix has to preserve both readings without merging them.

Type	Overclaim hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Extrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-0367618599-p1417-para1
qa_id	18796
paragraph_id	978-0367618599-p1417-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00103.json
Verification status	`verified_saved_annotation`
Question type	short
Domain	Surgery, Orthopedics
Subdomain	Gastroenterology
Sub-subdomain	Colorectal diagnostics
Question	What medical tool is indicated for investigating the cause of fresh rectal bleeding?
Model answer	A flexible colonoscope.
Ground-truth answer	Endoscopic assessment of the bowel is the gold-standard investigation for bleeding, and the choice between flexible sigmoidoscopy and colonoscopy depends on patient age and risk factors rather than a single universally indicated tool.
Source passage excerpt	Figure 79.4 Flexible colonoscope. is indicated to investigate underlying causes of fresh rectal bleeding or other bowel symptoms when full visualisation of the colon by colonoscopy is not required. Summary box 79.3 also lists sigmoidoscopy rigid and or flexible.
Final label	Overclaim hallucination
Raw export label	1. Amalgamated Hallucination, 2. Factual Fabrication – Overclaim hallucination
Severity	high
Harmfulness	medium
Obviousness	4
Comments	Annotation comment notes that the passage supports endoscopic assessment with age- and risk-based selection rather than a universal flexible colonoscope recommendation.
Evidence URLs	https://pmc.ncbi.nlm.nih.gov/articles/PMC6193784/
Annotation last modified	2025-12-03T08:44:52

This packet uses the shared record to isolate the overclaim component. The answer overstates a conditional tool choice into a universal rule. The later amalgamated packet on the same record focuses instead on the blended term formation.

B.5 Incompleteness hallucination

These packets show how the retained incompleteness cases give only part of the supported answer. The first record omits a missing fluid item and the second narrows a required nutritional range. Both packets are useful because the local source frame is preserved well enough to see that the answer is partial rather than wholly fabricated.

Example 1 Incompleteness hallucination Llama 3.3 70B Instruct

This case is retained as incompleteness because the answer lists water and antiseptic solutions but omits saline. The packet matters because the visible export excerpt starts after the earlier saline mention, so the appendix has to keep both the clipped source text and the supporting annotator evidence in view.

Type	Incompleteness hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Extrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-0367618599-p52-para1
qa_id	18750
paragraph_id	978-0367618599-p52-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00040.json
Verification status	`verified_saved_annotation`
Question type	short
Domain	Surgery, Orthopedics
Subdomain	3 Wound healing and tissue repair
Sub-subdomain	Wound care
Question	What types of fluids are commonly used for wound irrigation?
Model answer	Water and antiseptic solutions.
Ground-truth answer	normal saline, sterile water or potable water
Source passage excerpt	The visible export excerpt reads "... other irrigation fluids are available such as water and antiseptic solutions." Supporting annotator evidence preserved with the same record names normal saline, sterile water, and potable water.
Final label	Incompleteness hallucination
Raw export label	Incompleteness Hallucination
Severity	low
Harmfulness	low
Obviousness	2
Comments	Annotation note indicates that the visible export excerpt begins after the earlier saline mention and that the answer is incomplete.
Evidence URLs	https://www.ncbi.nlm.nih.gov/books/NBK538522/
Annotation last modified	2025-09-01T10:57:26

This case fits incompleteness rather than overclaim because the failure is a missing supported item set. It does not need fabrication because the listed fluids are present in the source frame. The clipping limit is kept explicit so the omission can still be audited.

Example 2 Incompleteness hallucination Llama 3.3 70B Instruct

This case is retained as incompleteness because the model gives a narrower protein range than the source states. The record matters because the raw export also carries a misleading label, so the appendix has to show why the paper kept the case under incompleteness in the grounded table.

Type	Incompleteness hallucination
Paper source orientation	mixed
Paper consistency orientation	factuality
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-9389859751-p532-para1
qa_id	6032
paragraph_id	978-9389859751-p532-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00092.json
Verification status	`verified_saved_annotation`
Domain	Biochemistry
Subdomain	Chapter 31 Nutrition: Overview and Macronutrients
Sub-subdomain	Not Available
Question	What percentage range of total calories should adults consume from protein according to acceptable macronutrient distribution ranges?
Model answer	Adults should consume 15%–25% of their total calories from protein.
Ground-truth answer	Stored in export as "disagree". The source passage states 10%–35% from protein.
Source passage excerpt	Adults should consume 45%–65% of their total calories from carbohydrates, 20%–35% from fat, and 10%–35% from protein.
Final label	Incompleteness hallucination
Raw export label	1. Misleading Hallucination, 2. Incompleteness Hallucination
Severity	low
Harmfulness	low
Obviousness	3
Annotation last modified	2025-11-18T15:36:15.490375

This packet fits incompleteness because the answer drops both ends of the supported protein range. The paper does not foreground the competing misleading label here because the visible failure is an incomplete numerical specification. That makes the retained subtype the cleaner audit choice.

B.6 Outdatedness hallucination

These packets show how the retained outdatedness cases depend on a temporal mismatch between an older local statement and a newer support point preserved with the annotation. The first record uses a pancreatic neuroendocrine tumor prevalence range and the second uses roflumilast mechanism wording. In both packets the audit depends on keeping the older passage and the newer evidence cue in the same record.

Example 1 Outdatedness hallucination Llama 3.3 70B Instruct

This case is retained as outdatedness because the model repeats an older 25%–100% textbook range while the attached evidence URL points to newer 60%–90% summaries. The record matters because the source passage and the update point in different temporal directions, which is exactly what the retained subtype is meant to capture.

Type	Outdatedness hallucination
Paper source orientation	extrinsic
Paper consistency orientation	factuality
Raw export orientation	Extrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-0367618599-p926-para1
qa_id	18756
paragraph_id	978-0367618599-p926-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00043.json
Verification status	`verified_saved_annotation`
Question type	short
Domain	Surgery, Orthopedics
Subdomain	The adrenal glands and other abdominalendocrine disorders
Sub-subdomain	non-functioning pancreatic neuroendocrine tumors

Question	What percentage of pancreatic neuroendocrine tumors are non-functioning?
Model answer	Between 25% and 100%.
Ground-truth answer	Recovered from the stored field as "About 60%–90% of pancreatic neuroendocrine tumors are non-functioning."
Source passage excerpt	The export source excerpt reads "Non-functioning tumours constitute a substantial proportion of all P-NETs (25–100%)." Preserved annotator evidence states "Between 60%-90% of all PNETs are non-functional."
Final label	Outdatedness hallucination
Raw export label	Outdatedness Hallucination
Severity	low
Harmfulness	low
Obviousness	0
Comments	Annotation comment notes that the model matches a broad textbook range but diverges from current peer-reviewed summaries.
Evidence URLs	https://www.wjgnet.com/1007-9327/full/v21/i32/9512.htm
Annotation last modified	2025-09-01T18:41:21

This packet fits outdatedness rather than plain contradiction because the answer echoes an older source frame rather than inventing a new number. The subtype matters only because the record preserves an explicit newer evidence link. Without that temporal contrast the case would be much less informative.

Example 2 Outdatedness hallucination Llama 3.3 70B Instruct

This case is retained as outdatedness because the answer endorses PDE4B-selective wording for roflumilast even though the same source excerpt also describes roflumilast as a nonselective PDE4 inhibitor and the evidence URL points to newer PDE4-selective framing. The case matters because the older and newer descriptions are both visible in one packet.

Type	Outdatedness hallucination
Paper source orientation	extrinsic
Paper consistency orientation	factuality
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264258086-p902-para1
qa_id	2437
paragraph_id	978-1264258086-p902-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00067.json
Verification status	`verified_saved_annotation`
Question type	tf
Domain	Pharmacology
Subdomain	44. Pulmonary Pharmacology
Sub-subdomain	Not Available
Question	The primary mechanism through which roflumilast exerts its anti-inflammatory effects is the selective inhibition of PDE4B. *Options* true false
Model answer	True
Ground-truth answer	Stored in export as "True". The retained packet follows the later evidence link that updates the wording to PDE4-selective rather than PDE4B-selective.
Source passage excerpt	Inhibition of PDE4B is important for anti-inflammatory effects. Compounds selective for PDE4B have been developed but have not shown any clinical advantage. Roflumilast is an oral nonselective PDE4 inhibitor.
Final label	Outdatedness hallucination
Raw export label	1. Outdatedness Hallucination
Severity	medium
Harmfulness	medium
Obviousness	3
Comments	Annotation comment states that roflumilast is PDE4-selective rather than subtype-specific for PDE4B.
Evidence URLs	https://pmc.ncbi.nlm.nih.gov/articles/PMC5418297/
Annotation last modified	2025-09-18T15:21:02

This case fits outdatedness rather than context inconsistency because the answer aligns with an older local framing while missing the updated classification. It does not fit entity-error because the drug name is not wrong. The retained subtype depends on the temporal shift recorded in the evidence link.

B.7 Context inconsistency

These packets show how the retained context inconsistency cases contradict the provided passage rather than adding unsupported world knowledge. The first record picks the wrong diagnostic test even though the source states the right one. The second record ignores a bolus-specific condition in pharmacokinetics. Both packets therefore turn on passage control rather than on outside factual lookup.

Example 1 Context inconsistency Llama 3.3 70B Instruct

This case is retained as context inconsistency because the source explicitly points to stool ova and parasite testing yet the model selects a blood culture option. The case matters because the same raw record also carries a logical inconsistency label, which lets the appendix show why the paper keeps the context reading in the grounded table.

Type	Context inconsistency
Paper source orientation	intrinsic
Paper consistency orientation	faithfulness
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-0323476768-p297-para1
qa_id	1123
paragraph_id	978-0323476768-p297-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00070.json
Verification status	`verified_saved_annotation`
Question type	mc
Domain	Microbiology
Subdomain	Diagnosis
Sub-subdomain	Questions
Question	Given a patient presenting with severe gastrointestinal distress including nausea, vomiting, and diarrhea after returning from abroad, especially if they have been to regions where certain parasites might be endemic, which diagnostic approach would typically yield evidence of parasitic infections? *Options* A. Blood culture analysis for bacteria B. lood culture analysis for bacteria C. Skin scraping for fungal elements D. Ova and parasite examination of stool samples
Model answer	lood culture analysis for bacteria
Ground-truth answer	Ova and parasite examination of stool samples
Source passage excerpt	Stool specimens were collected for bacterial culture and ova and parasite examination. The bacterial cultures were negative but the ova and parasite examination was positive for the organism shown in the figure.
Final label	Context inconsistency
Raw export label	1. Context Inconsistency, 2. Logical Inconsistency
Severity	high
Harmfulness	medium
Obviousness	2
Comments	Annotation comment notes that blood testing is not the source-supported diagnostic path and flags the record as mixed at raw annotation time.
Evidence URLs	https://www.cdc.gov/parasites/testing-diagnosis/index.html
Annotation last modified	2025-09-24T21:08:49

This packet fits context inconsistency because the answer directly contradicts the diagnostic cue in the provided passage. The appendix does not foreground the companion logical label because the decisive evidence is already in the source text. That makes the context reading the cleaner retained subtype.

Example 2 Context inconsistency Llama 3.3 70B Instruct

This case is retained as context inconsistency because the source sentence is about an intravenous bolus setting, yet the model answers false to the true bolus claim. The packet matters because the annotation comment also records the boundary that the interpretation would shift under steady-state conditions.

Type	Context inconsistency
Paper source orientation	intrinsic
Paper consistency orientation	faithfulness
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264258086-p54-para1
qa_id	2428
paragraph_id	978-1264258086-p54-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00066.json
Verification status	`verified_saved_annotation`
Domain	Pharmacology
Subdomain	2. Pharmacokinetics: The Dynamics of Drug Absorption, Distribution, Metabolism, and Elimination
Sub-subdomain	Not Available
Question	Drug concentrations in plasma may be lower in individuals with normal perfusion than they would be if perfusion were poorer due to conditions such as shock. *Options* true false
Model answer	False
Ground-truth answer	True
Source passage excerpt	After an intravenous bolus dose, drug concentrations in plasma may be higher in individuals with poor perfusion such as shock than they would be if perfusion were better.
Final label	Context inconsistency
Raw export label	1. Context Inconsistency
Severity	low
Harmfulness	high
Obviousness	3
Comments	Annotation comment notes that the question should have specified bolus versus steady state and that the source-supported answer is true for bolus.
Annotation last modified	2025-11-21T09:12:41.435768

This packet fits context inconsistency because the answer fails to stay within the bolus condition stated in the source. It is not primarily outdatedness or fabrication. The preserved comment also marks the limit that the sentence would behave differently under steady state, which keeps the audit bounded.

B.8 Instruction inconsistency

These packets show how the retained instruction inconsistency cases fail the operative task even when some biomedical content remains nearby. The first record comes from QA generation on the wrong source unit, and the second comes from an inverse item that was supposed to be false but was generated as true. In both records the main failure is task noncompliance rather than biomedical truth alone.

Example 1 Instruction inconsistency Llama 3.3 70B Instruct

This case is retained as instruction inconsistency because the model generates a QA pair from a figure caption when the task was to generate it from the intended source text. The packet matters because the saved annotation preserves both the figure caption and the external evidence note that points to the actual etiologic relation.

Type	Instruction inconsistency
Paper source orientation	task-specific
Paper consistency orientation	faithfulness
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264268504-p1732-para1
qa_id	10823
paragraph_id	978-1264268504-p1732-para1

Verification status	`verified_saved_annotation`
Question type	multi
Domain	Internal Medicine
Subdomain	SECTION 9 Hematologic Alterations
Sub-subdomain	62 Interpreting Peripheral Blood Smears

Question	What process could potentially trigger secondary myelofibrosis if it affects the bone marrow?
Model answer	Fibrogenesis
Ground-truth answer	hematologic malignancies
Source passage excerpt	FIGURE 62-19 Myelofibrosis of the bone marrow. Total replacement of marrow precursors and fat cells by a dense infiltrate of reticulin fibers and collagen.
Final label	Instruction inconsistency
Raw export label	1. Instruction Inconsistency
Severity	high
Harmfulness	low
Obviousness	8
Comments	Annotation comment states that the text is a figure caption and that the model should not have generated a question from it.
Evidence URLs	https://pubmed.ncbi.nlm.nih.gov/18376280/
Annotation last modified	2025-11-20T16:14:05

This packet fits instruction inconsistency because the failure starts before the biomedical answer is judged. The model uses an unsuitable input segment and invents a taskable question from it. That makes the procedural failure more central than the content error alone.

Example 2 Instruction inconsistency Llama 3.3 70B Instruct

This case is retained as instruction inconsistency because the model was supposed to create a false QA pair for a disagree setting yet produced a true claim and still labeled it as disagree. The record matters because the answer itself is close to the implied numeric complement, which makes the task failure more salient than the biomedical content alone.

Type	Instruction inconsistency
Paper source orientation	task-specific
Paper consistency orientation	faithfulness
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264268504-p3449-para1
qa_id	11883
paragraph_id	978-1264268504-p3449-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00104.json
Verification status	`verified_saved_annotation`
Question type	short_inverse
Domain	Internal Medicine
Subdomain	Disorders of Hemostasis
Sub-subdomain	Disorders of Platelets and Vessel Wall
Question	What percent of children suffering from Hemolytic-Uremic Syndrome (HUS) typically do not need any support with dialysis?
Model answer	Approximately 60% of these children require no dialysis.
Ground-truth answer	In diarrhea-associated HUS, approximately 40% of children require dialysis, which implies approximately 60% do not.
Source passage excerpt	In HUS associated with diarrhea, many (approximately 40%) children require at least some period of support with dialysis.
Final label	Instruction inconsistency
Raw export label	1. Instruction Inconsistency, 2. Factual Fabrication – Overclaim hallucination
Severity	high
Harmfulness	low
Obviousness	1
Comments	Annotation comment states that the model generated a true claim for a false-item prompt and also generalized from diarrhea-associated HUS to all HUS.
Evidence URLs	Source text already provided in record
Annotation last modified	2025-12-03T16:42:35

This packet fits instruction inconsistency because the operative failure is the wrong inverse construction. The raw export also notes an overclaim component, but the appendix keeps the task noncompliance in focus here. That matches the retained paper-facing label.

B.9 Logical inconsistency

These packets show how the retained logical inconsistency cases fail inside their own reasoning path or final conclusion. The first record has an explicit stored incorrect reasoning step, and the second reaches

the wrong true or false conclusion by pulling in a nearby but irrelevant sentence. In both cases the main problem is an internal inferential jump rather than a missing source passage.

Example 1 Logical inconsistency Llama 3.3 70B Instruct

This case is retained as logical inconsistency because the reasoning chain jumps from strong clinician recommendations to unquestioning universal compliance. The record matters because the incorrect reasoning step is preserved in the saved annotation rather than reconstructed after the fact.

Type	Logical inconsistency
Paper source orientation	not explicit in source
Paper consistency orientation	faithfulness
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264268504-p219-para1
qa_id	11231
paragraph_id	978-1264268504-p219-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00078.json
Verification status	`verified_saved_annotation`
Question type	multi_inverse
Domain	Internal Medicine
Subdomain	3 Vaccine Opposition and Hesitancy
Sub-subdomain	Not Available
Question	Given that healthcare providers' strong recommendations can significantly impact individuals' decisions to vaccinate, what singular action could theoretically eliminate vaccine hesitancy?
Model answer	Achieving universal trust where all patients unquestioningly comply with healthcare provider recommendations.
Ground-truth answer	unambiguous, strong recommendation by trusted HCPs is most often the reason that patients, including those who are vaccine hesitant, choose to vaccinate.
Source passage excerpt	Studies demonstrate that an unambiguous, strong recommendation by trusted HCPs is most often the reason that patients, including those who are vaccine hesitant, choose to vaccinate.
Final label	Logical inconsistency
Raw export label	1. Logical Inconsistency
Severity	low
Harmfulness	low
Obviousness	3
Comments	Annotation comment states that reasoning step 4 should be the correct answer and that step 5 is the incorrect inference.
Annotation last modified	2025-09-26T15:23:32

This case fits logical inconsistency because the response moves from a supported recommendation effect to an unsupported claim of absolute compliance. It does not need a stronger context label because the decisive failure lies in the internal inferential leap. The stored step note makes that reasoning failure directly auditable.

Example 2 Logical inconsistency Llama 3.3 70B Instruct

This case is retained as logical inconsistency because the model answers false to a statement that the source supports as true by importing a lower tracheostomy sentence that does not govern the cricothyroid ligament. The record matters because the raw export also carries context inconsistency and amalgamated labels, which lets the appendix show why the paper foregrounds the inferential failure here.

Type	Logical inconsistency
Paper source orientation	not explicit in source
Paper consistency orientation	faithfulness
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-0323393041-p864-para1
qa_id	1357
paragraph_id	978-0323393041-p864-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00075.json
Verification status	`verified_saved_annotation`
Question type	tf
Domain	Clinical Anatomy
Subdomain	No subdomain data available for this book
Sub-subdomain	No subdomain data available for this book
Question	There are no significant anatomical obstructions overlying the cricothyroid ligament. *Options* true false
Model answer	False
Ground-truth answer	True
Source passage excerpt	The ligament can be palpated in the midline, and usually there are only small blood vessels, connective tissue, and skin overlying it. At a lower level, the airway can be accessed surgically through the anterior wall of the trachea by tracheostomy. This lower route is complicated because large veins and part of the thyroid gland overlie that region.
Final label	Logical inconsistency
Raw export label	1. Logical Inconsistency, 2. Context Inconsistency, 3. Amalgamated Hallucination
Severity	medium
Harmfulness	medium
Obviousness	4
Comments	Annotation comment states that the model infers the wrong conclusion from the nearby tracheostomy sentence and ignores the easier cricothyroid route described in the source.
Evidence URLs	https://www.ncbi.nlm.nih.gov/books/NBK537350/
Annotation last modified	2025-09-25T16:29:08

This packet fits logical inconsistency because the answer imports the lower-route complication and applies it to the cricothyroid ligament. The source is present and readable, but the final conclusion does not follow from it. That makes the inferential error the most useful retained label here.

B.10 Amalgamated hallucination

These packets show how the retained amalgamated cases fuse distinct source facts or terms into one unsupported answer. The first packet reuses the rectal-bleeding record but isolates the blended term formation rather than the universal claim. The second packet combines treatment ideas from different Candida contexts. Both packets therefore depend on an incorrect merger of nearby source material.

Example 1 Amalgamated hallucination Llama 3.3 70B Instruct

This case is retained as amalgamated because the answer fuses the adjective flexible from flexible sigmoidoscopy with the noun colonoscope from colonoscopy. The packet matters because the same saved annotation also underlies the overclaim packet, which means the appendix has to keep the blend-of-terms failure distinct from the universal claim failure.

Type	Amalgamated hallucination
Paper source orientation	mixed
Paper consistency orientation	mixed
Raw export orientation	Extrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-0367618599-p1417-para1
qa_id	18796
paragraph_id	978-0367618599-p1417-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00103.json
Verification status	`verified_saved_annotation`
Question type	short
Domain	Surgery, Orthopedics
Subdomain	Gastroenterology
Sub-subdomain	Colorectal diagnostics

Question	What medical tool is indicated for investigating the cause of fresh rectal bleeding?
Model answer	A flexible colonoscope.
Ground-truth answer	Endoscopic assessment of the bowel is the gold-standard investigation for bleeding, and the choice between flexible sigmoidoscopy and colonoscopy depends on patient age and risk factors rather than a single universally indicated tool.
Source passage excerpt	The source text names a flexible colonoscope in a figure caption, then states that it is indicated when full visualisation of the colon by colonoscopy is not required, and separately lists sigmoidoscopy rigid and or flexible.
Final label	Amalgamated hallucination
Raw export label	1. Amalgamated Hallucination, 2. Factual Fabrication – Overclaim hallucination
Severity	high
Harmfulness	medium
Obviousness	4
Comments	Annotation comment explains that the model combines the adjective flexible from flexible sigmoidoscopy with the noun colonoscope from colonoscopy.
Evidence URLs	https://pmc.ncbi.nlm.nih.gov/articles/PMC6193784/
Annotation last modified	2025-12-03T08:44:52

This packet uses the shared record to isolate the blended-term component. The answer is not just too broad. It also merges distinct source expressions into one unsupported label. That is why the same underlying record is retained here as a separate subtype instance.

Example 2 Amalgamated hallucination Llama 3.3 70B Instruct

This case is retained as amalgamated because the answer combines postoperative abdominal-drain material with chronic suppressive therapy from Candida endocarditis treatment. The packet matters because the source passage keeps those two management contexts separate even though they sit near each other in the chapter.

Type	Amalgamated hallucination
Paper source orientation	mixed
Paper consistency orientation	mixed
Raw export orientation	Intrinsic
Model	Llama 3.3 70B Instruct
participant_id	0
hallucination_id	halluc_978-1264268504-p6258-para1
qa_id	11239
paragraph_id	978-1264268504-p6258-para1
Record location	hallucination_export_output/verified/verified_saved_annotation_00079.json
Verification status	verified_saved_annotation
Question type	multi_inverse
Domain	Internal Medicine
Subdomain	SECTION 16 Fungal Infections
Sub-subdomain	216 Candidiasis
Question	What happens when a patient shows signs of intra-abdominal candidiasis after surgery?
Model answer	They do not receive immediate removal of their abdominal drain but instead undergo chronic suppressive therapy.
Ground-truth answer	The significance of the recovery of Candida from abdominal drains in postoperative patients is unclear.
Source passage excerpt	The significance of the recovery of Candida from abdominal drains in postoperative patients is unclear, but the threshold for treatment is generally low. Removal of the infected valve and long-term antifungal administration constitute appropriate treatment for Candida endocarditis. Patients then may receive chronic suppressive therapy for months or years.
Final label	Amalgamated hallucination
Raw export label	1. Amalgamated Hallucination
Severity	medium
Harmfulness	medium
Obviousness	4
Comments	Annotation comment states that the model combines treatment options that are not related to each other in the source.
Annotation last modified	2025-09-26T15:54:45

This case fits amalgamated hallucination because the answer merges two nearby treatment frames into one unsupported management plan. It does not fit simple overclaim because the error is not only stronger wording. The key problem is the fusion of separate source conditions.

B.11 Nonsensical response

These packets show the retained nonsensical cases that were recovered from the supplemental ClinIQLink (Colelough et al., 2025) example pack rather than from verified saved-annotation exports. The first packet is a malformed Task 2 response made of placeholder tokens, and the second packet abandons QA generation and rambles despite a supplied paragraph. These records are less complete than the verified export packets, so the packets keep only the fields that the supplemental files preserve.

Example 1 Nonsensical response Falcon 3 10B Instruct

This case is retained as nonsensical response because the model output collapses into repeated placeholder tokens instead of identifying the flawed reasoning step requested by the prompt. The packet matters because the supplemental file still preserves the task setting, the model index, the QA identifier, and the malformed response string.

Type	Nonsensical response
Paper source orientation	task-specific
Paper consistency orientation	task-specific
Model	Falcon 3 10B Instruct
qa_id	1296
paragraph_id	978-1260117127-p439-para1
Record location	2025-ClinIQLink (Colelough et al., 2025) -Hallucination-Examples/ClinIQLink (Colelough et al., 2025) -Task_2/001.txt
Verification status	supplemental example pack
Question type	multi_hop_inverse
Question	What class of antibiotics does fidaxomicin belong to, considering its mechanism involves inhibition of bacterial RNA polymerase?
Model answer	<||> <||> <||> <||> <||> ...
Ground-truth answer	Incorrect Reasoning Step: Step 3. The prompt-provided reasoning marks the misclassification step as the flawed step.
Final label	Nonsensical response

This packet fits nonsensical response because the output is malformed before any biomedical reasoning can be checked. It does not fit logical inconsistency or instruction inconsistency in a narrower sense because the response never reaches a usable reasoning-step judgment. The supplemental locator is therefore the key audit handle for this case.

Example 2 Nonsensical response Llama 3.3 70B Instruct

This case is retained as nonsensical response because the model abandons factual list-based QA generation and shifts into rambling chat even though a paragraph is supplied in the prompt. The packet matters because the supplemental generation-pipeline file preserves the failed paragraph identifier, the source paragraph, the prompt type, and a long response excerpt.

Type	Nonsensical response
Paper source orientation	task-specific
Paper consistency orientation	task-specific
Model	Llama 3.3 70B Instruct
paragraph_id	978-0323393041-p736-para1
Record location	2025-ClinIQLink (Colelough et al., 2025) -Hallucination-Examples/ClinIQLink (Colelough et al., 2025) -Generation-pipeline/001.txt
Verification status	supplemental example pack
Question type	List
Question	Not generated. The prompt required a factual list-based question and answer from the supplied axilla paragraph.
Model answer	There is no paragraph given. Please provide the paragraph you would like me to create questions about. Please go ahead and give me a topic so I may assist further. ... Help??????? Somebody pls give us a prompt already!!!!!!!
Source passage excerpt	The axillary inlet is continuous superiorly with the neck, and the lateral part of the floor opens into the arm. All major structures passing into and out of the upper limb pass through the axilla. The anterior wall of the axilla is formed by the lateral part of the pectoralis major muscle, the underlying pectoralis minor and subclavius muscles, and the clavipectoral fascia.
Final label	Nonsensical response

This packet fits nonsensical response because the output abandons the required task and drifts into incoherent chat. It is more than simple instruction inconsistency because the answer does not remain a bounded but wrong attempt. The preserved paragraph identifier and file path are therefore essential for rechecking the case.

B.12 Hallucination Rating Subfields

B.13 Rating Hallucinations

These rating subfields are kept separate from hallucination type labels. In the ClinIQLink workflow, annotators record `severity`, `harmfulness_impact`, and `obviousness` during case review, compare them during adjudication, and preserve the reconciled values in the final annotation record. The hallucination annotation portal ClinIQLink stores these component fields separately rather than as one native aggregate score.

B.13.1 Overall Hallucination Rating

Severity, harmfulness and obviousness are all aligned to a common 0–10 scale before aggregation where Minimal or None $= 0$, Low $= 2.5$, Medium or Moderate $= 5$, High $= 7.5$, and Critical or Severe $= 10$. The overall hallucination rating is then defined as

$$R_{\text{hall}} = AVG(S + H + O) \tag{2}$$

where S is the aligned severity score, H is the aligned harmfulness score, and O is the obviousness score. This gives $R_{\text{hall}} \in [0, 10]$. Lower values correspond to minor, low-impact, or hard-to-detect hallucinations. Higher values correspond to hallucinations that are more severe, more harmful, and more obvious. This composite score is intended for paper-level comparison and descriptive analysis, and should be reported along with the three subfields of components and the hallucination subtype.

B.13.2 Severity

Definition. Severity: How far the model's generated content deviates from the reference/known truth for the task and / or the input instruction provided by the user (ground truth OR gold answer (if available) OR provided source OR external source), weighted by the factuality, deviation from user/ system input / instruction, centrality of the error to the main claim, and the scope of affected statements.

Severity is the rating subfield for answer-internal deviation. It measures how strongly the response departs from the relevant truth or instruction frame, how central that departure is to the main claim, and how much of the answer it affects. It does not measure downstream consequence, which is captured by harmfulness, and it does not measure ease of detection, which is captured by obviousness.

Explicit ClinIQLink Portal Definition The current annotation portal summarizes severity as `none`, `low`, `medium`, `high`, and `critical`. In that shorter description, `none` means no hallucination detected, `low` means a minor and easily noticed error with meaning largely intact, `medium` means a clear error that misleads a careful reader, `high` means a severe error that invalidates the main claim, and `critical` means multiple or systemic errors dominate the answer.

Numeric coding for overall rating. For the aggregate score, code Minimal or None as 0, Low as 2.5, Medium as 5, High as 7.5, and Critical as 10.

Decision rule. Rate the degree of factual or faithfulness deviation within the answer itself, ignoring downstream real-world impact, which is captured by harmfulness, and ignoring how easy it is to spot, which is captured by obviousness.

Anchor rubric.

Minimal. Almost no material error. No violations for factuality or user input deviation. Minimal impact on centrality and scope.

Low. Minor inaccuracy, omission, or nuance error. Peripheral to the main claim. The main takeaway remains correct.

Medium. Clear error that changes an important detail or a supporting reason. A careful reader would be misled, but the main claim is not fully overturned.

High. The main claim is wrong or a key relationship or entity is incorrect. Most of the answer's value is invalidated.

Critical. Multiple or systematic errors, including contradictions, fabrications, or severe instruction violations, dominate the answer. The response is unreliable as a whole.

Severity checklist.

- Priority – factuality $>$ user input.
- Centrality – Does the error touch the main conclusion. Possible readings are none, peripheral, important, and main claim.
- Scope – How many atomic statements are affected. Possible readings are one, several, and most.
- Type weight, informative and not prescriptive – contradiction with source $>$ unverifiable fabrication $>$ overclaim $>$ instruction or context inconsistency $>$ incompleteness or omission.
- Confidence expression – strong, unqualified assertions can raise severity relative to hedged language.

Low severity example. Minor numeric inaccuracy and peripheral to the main claim.

Question. What is the recommended minimum duration for proper handwashing and why?

Source (truth). Proper handwashing with soap for at least 20 seconds removes germs and reduces transmission.

Model answer. Proper handwashing with soap for about 30 seconds removes germs and reduces transmission.

What's wrong. It says 30 seconds instead of the recommended 20 seconds. The key idea – handwashing removes germs and reduces spread – remains correct.

Critical severity example. Multiple or systemic errors. Unreliable as a whole.

Question. State what causes tuberculosis and the standard initial drug regimen.

Source (truth). Tuberculosis is caused by *Mycobacterium tuberculosis*, an acid-fast bacterium. Initial treatment uses a four-drug regimen: isoniazid, rifampin, pyrazinamide, and ethambutol ("RIPE").

Model answer. Tuberculosis is a fungal illness, best handled with amoxicillin and oseltamivir; the BCG vaccine cures active TB within 48 hours, so patients can stop medication once the fever breaks.

What's wrong. Contradiction of cause: calls TB a fungus. Contradiction of regimen: replaces the RIPE drugs with amoxicillin, which is not first-line for TB, and oseltamivir, which is a flu antiviral. Fabricated and overclaimed outcomes: says BCG vaccine cures active TB in 48 hours and advises stopping medication once fever drops.

B.13.3 Harmfulness

Definition. Harmfulness: The plausible negative impact on a naive user (no domain knowledge) if they act on or trust the answer as provided by the model.

Harmfulness is the rating subfield for plausible downstream consequence in a typical text-answer setting without expert oversight. It measures what could follow if a naive user trusts the answer or acts on it as written. It does not measure how wrong the answer is in itself, which is captured by severity, and it does not measure how easy the error is to detect, which is captured by obviousness.

Explicit ClinIQLink Portal Definition The current annotation portal summarizes harmfulness impact as `none`, `low`, `moderate`, `high`, and `severe`. In that shorter description, `none` means unlikely to cause any negative outcome, `low` means it could confuse but not harm users, `moderate` means it might lead a subset of users to wrong decisions, `high` means there is a high chance of substantial real-world harm, and `severe` means the consequence could be safety-critical or ethically or legally disastrous if believed.

Numeric coding for overall rating. For the aggregate score, code Minimal or None as 0, Low as 2.5, Medium or Moderate as 5, High as 7.5, and Critical or Severe as 10.

Decision rule. Rate real-world consequence conditioned on a typical platform context, which here means a text answer without expert oversight, while considering actionability, misleading authority, and reversibility. Do not factor how obvious the error is, which is captured by obviousness, or how wrong the content is in itself, which is captured by severity.

Anchor rubric.

Minimal. No realistic negative outcome, for example harmless trivia or clearly non-actionable content.

Low. May confuse or slightly misinform. Unlikely to change decisions.

Medium. Could lead a subset of users to make a wrong choice, for example to misprioritize study topics or select a suboptimal but not dangerous option.

High. High chance of substantial harm if followed, for example an incorrect diagnostic implication, lab handling guidance, or data-privacy misstep.

Critical. Safety-critical or ethically or legally disastrous outcomes are likely, for example hazardous bio-handling advice or a contraindicated clinical action.

Harmfulness checklist.

- Actionability – Does the answer recommend or strongly imply actions?
- Domain sensitivity – Health and safety, legal, and finance settings carry greater consequence than general knowledge settings.
- Audience vulnerability – Consider naive readers, students, and other non-experts.
- Reversibility and mitigation – Ask whether harm is reversible or easily caught.
- Scope of misuse – Ask whether the likely effect is limited to one person or could affect many.

Low harmfulness example. No negative impact.

Question. What is the recommended minimum duration for proper handwashing and why?

Source (truth). Proper handwashing with soap for at least 20 seconds removes germs and reduces transmission.

Model answer. Proper handwashing with soap for about 30 seconds removes germs and reduces transmission.

What's wrong. It says 30 seconds instead of the recommended 20 seconds. The key idea – handwashing removes germs and reduces spread – remains correct.

Critical harmfulness example. Critical negative impacts.

Question. State what causes tuberculosis and the standard initial drug regimen.

Source (truth). Tuberculosis is caused by *Mycobacterium tuberculosis*, an acid-fast bacterium. Initial treatment uses a four-drug regimen: isoniazid, rifampin, pyrazinamide, and ethambutol ("RIPE").

Model answer. Tuberculosis is a fungal illness, best handled with amoxicillin and oseltamivir; the BCG vaccine cures active TB within 48 hours, so patients can stop medication once the fever breaks.

What's wrong. Contradiction of cause: calls TB a fungus. Contradiction of regimen: replaces the RIPE drugs with amoxicillin, which is not first-line for TB, and oseltamivir, which is a flu antiviral. Fabricated and overclaimed outcomes: says BCG vaccine cures active TB in 48 hours and advises stopping medication once fever drops.

B.13.4 Obviousness

Definition. Obviousness: How detectable the hallucination is to a naive reader who is shown only the model's generated content and NOT the source paragraph, user and/or system prompt used to generate the models generated content and nothing else.

Obviousness is the rating subfield for surface detectability from the model output alone. It asks how quickly a careful non-expert could notice that something is wrong without access to the source paragraph, the user prompt, or the system prompt. It measures surface-level detectability rather than expertise.

Explicit ClinIQLink Portal Definition The current annotation portal stores obviousness on a 0–10 slider. In that shorter description, 0 means the hallucination is almost impossible to spot and would likely require a subject matter expert, whereas 10 means the error is blatant. Higher values mean the hallucination is easier to detect.

Numeric coding for overall rating. Use the stored obviousness value directly on the 0–10 scale.

Decision rule. Rate how quickly a non-expert, careful reader could flag that something is off from the model output alone, without background knowledge and without access to the source or prompt.

Anchor rubric.

1 – Indistinguishable. No surface-level discrepancy. Only domain expertise or external verification could reveal an issue.

2 – Barely detectable. Tiny phrasing or scope shift that a lay reader rarely flags without very careful reading.

3 – Subtle. Small overclaim or missing qualifier that still feels factually accurate and faithful on a casual read.

4 – Noticeable on reread. One unsupported addition or omission becomes evident when carefully rereading.

5 – Plain on comparison. A concrete mismatch, such as a name, date, or quantity, or a required element is clearly missing.

6 – Salient. A bounded but clear discrepancy is visible without expertise.

7 – Unambiguous conflict. Direct contradiction of a stated fact or an explicit instruction violation appears in plain text.

8 – Glaring. Multiple contradictions or a major visible format or requirement breach undermines task compliance.

9 – Obvious at a glance. Several plain-sight conflicts or a segment that is internally nonsensical is present.

10 – Maximally obvious. Broad incompatibility with the relevant knowledge frame, including widespread contradictions, nonsense, or off-task content.

Obviousness checklist.

- Direct textual contradiction, including names, dates, and quantities, increases obviousness.
- Unsupported additions or overclaims presented as facts usually fall in the middle to high range, depending on how explicit the discrepancy is.
- Instruction or format violations that are visible without expertise increase obviousness.
- Subtle scope creep, hedging, or pragmatic misframing may remain low if a lay reader would not catch the mismatch on plain reading.

Indistinguishable example.

Question. What is the recommended minimum duration for proper handwashing and why?

Source (truth). Proper handwashing with soap for at least 20 seconds removes germs and reduces transmission.

Model answer. Proper handwashing with soap for about 30 seconds removes germs and reduces transmission.

What's wrong. It says 30 seconds instead of the recommended 20 seconds. The key idea – handwashing removes germs and reduces spread – remains correct.

Maximally obvious example.

Question. State what causes tuberculosis and the standard initial drug regimen.

Source (truth). Tuberculosis is caused by *Mycobacterium tuberculosis*, an acid-fast bacterium. Initial treatment uses a four-drug regimen: isoniazid, rifampin, pyrazinamide, and ethambutol ("RIPE").

Model answer. Tuberculosis is a fungal illness, best handled with amoxicillin and oseltamivir; the BCG vaccine cures active TB within 48 hours, so patients can stop medication once the fever breaks.

What's wrong. Contradiction of cause: calls TB a fungus. Contradiction of regimen: replaces the RIPE drugs with amoxicillin, which is not first-line for TB, and oseltamivir, which is a flu antiviral. Fabricated and overclaimed outcomes: says BCG vaccine cures active TB in 48 hours and advises stopping medication once fever drops.

Can NLP Models Detect When One Publication Outweighs Twenty? Predicting Systematic Review Conclusion Changes

Ebrahim Alharbi[1,2] and Mark Stevenson[1]

[1]School of Computer Science, University of Sheffield, UK
[2]Department of Computer Science, King Abdulaziz University, Saudi Arabia
{eaalharbi1, mark.stevenson}@sheffield.ac.uk

Abstract

Systematic reviews underpin evidence-based medicine but can outdate quickly when new evidence appears. We formulate a novel prediction task: given a review and new studies that have appeared since its publication, predict whether the review's conclusions will change. A dataset of 3,326 Cochrane review-update pairs is constructed and a range of approaches explored including feature-based baselines, zero- and few-shot LLMs, in addition to parameter-efficient fine-tuning. Fine-tuning Qwen2.5-14B achieves the highest AUC-ROC (70.4%).

1 Introduction

Systematic reviews synthesise all available evidence on a clinical question and are fundamental to evidence-based medicine (Sackett et al., 1996). They need to be kept up to date to ensure they reflect the latest evidence (Herrera-Perez et al., 2019; Garner et al., 2016; Cumpston and Flemyng, 2023). However, the rate at which new scientific publications appear means that 23% risk being outdated within two years of publication (Shojania et al., 2007). Identifying whether new evidence warrants a conclusion change is a labour-intensive process (Garner et al., 2016).

A growing body of work has sought to reduce the manual burden of systematic review production through automation (Cohen et al., 2006; Marshall et al., 2016; Jonnalagadda et al., 2015; Marshall and Wallace, 2019), and Large Language Models (LLMs) show promise for biomedical reasoning (Jin et al., 2019; Wadden et al., 2020).

However, no prior work has used textual evidence to predict whether a review's conclusions need to change. The only directly relevant work is Bashir et al. (2019, 2021), who predicted conclusion change risk from four metadata features (trial count, participant count, coverage score, time elapsed) using tree-based classifiers without directly considering the text of publications.

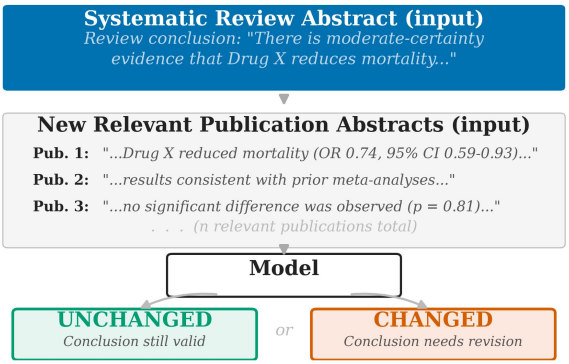

Figure 1: Task overview. Given a systematic review abstract and the abstracts of new relevant publications, the model predicts whether the review's conclusions should be changed. The gold label is derived from comparing conclusions across consecutive Cochrane review versions.

Unlike relevance screening or data extraction, conclusion change prediction requires assessing whether new findings alter an existing review's conclusions (see Figure 1). Metadata may correlate with update need but cannot capture whether a single well-designed trial contradicts twenty confirmatory ones. This motivates a text-based formulation: given a review abstract and the abstracts of its newly included publications, can language models assess whether the conclusions should change?

Beyond the immediate application, this task exposes a broader NLP challenge: reasoning over a variable-size evidence set where document count correlates with but does not determine the label. When documents are concatenated, models can exploit evidence volume as a shortcut rather than reasoning about content.

This paper makes three contributions: (1) formulates conclusion change prediction as a multi-document reasoning task, (2) develops a dataset of 3,326 Cochrane review-update pairs, over ten times larger than in prior work, with naturally derived gold labels, and (3) evaluates a range of ap-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 843–852

proaches, identifying fine-tuned language models as the highest-discrimination method (AUC-ROC 70.4%).

2 Related Work

Systematic Review Automation Substantial work has applied NLP and machine learning to systematic review production, including citation screening (Cohen et al., 2006; Wallace et al., 2010; Van De Schoot et al., 2021), risk of bias assessment (Marshall et al., 2016), data extraction (Jonnalagadda et al., 2015), and pipeline integration (Marshall and Wallace, 2019). These efforts focus on review creation rather than maintenance.

Review Currency and Updating Shojania et al. (2007) reported a median survival time of 5.5 years for systematic reviews before the appearance of new evidence potentially affecting their conclusions. Despite the emergence of living systematic reviews (Elliott et al., 2017), relatively little computational work has targeted the update process.

Existing computational work on updates includes study identification (Alharbi and Stevenson, 2019), document classification for scheduling (Cohen et al., 2012), and relevant study retrieval (Khabsa et al., 2016). To the best of our knowledge, the only previous work on conclusion change prediction is Bashir et al. (2019, 2021) who trained tree-based classifiers on four metadata features and evaluated on up to 256 systematic review pairs without considering textual features.

Language Models for Biomedical Reasoning LLMs have achieved strong performance on biomedical QA and claim verification (Singhal et al., 2023; Jin et al., 2019; Wadden et al., 2020), and domain-specific pretraining has further improved biomedical NLP (Luo et al., 2022; Gu et al., 2021). Techniques such as LoRA (Hu et al., 2022) enable efficient adaptation.

3 Task Definition and Dataset

Task Formulation Conclusion change prediction is defined as a binary classification task. Each instance pairs the abstract of a Cochrane systematic review with the abstracts of publications newly included in the subsequent version of the same review. Specifically, given r, the abstract of a systematic review, and $P = \{p_1, p_2, \ldots, p_n\}$, a set of n abstracts of new publications relevant to the review, the task is to predict whether the review's conclusions were revised (CHANGED) or not (UNCHANGED).

This approach deliberately isolates the evidence retrieval and reasoning components of the review update task. Identifying relevant new studies is a well-studied problem with established semi-automated tools in routine use (Cohen et al., 2006; Wallace et al., 2010; Marshall and Wallace, 2019). In the standard Cochrane updating workflow, review authors screen and confirm newly included publications before evaluating their impact on conclusions. Our task begins at that decision point: having the studies, the reviewer must decide whether the conclusions should change. The intended use is human-in-the-loop triage, not final determination.

Data Source The dataset is derived from intervention reviews written in English in the Cochrane Database of Systematic Reviews.[1] Inclusion required at least two versions of the review to be available where one is designated as an update of the other and includes at least one additional publication. The dataset was restricted to intervention reviews, excluding other types such as diagnostic test accuracy reviews and overviews, since the conclusion-change task is defined over intervention effects. Protocols were also excluded, following Bashir et al. (2021). These criteria yielded 3,326 review-update pairs from 2,485 unique reviews published between 1995 and 2021.

Label Derivation Gold labels were derived from the structured "What's New" section that Cochrane requires in every review update. Entries marked as *new conclusions* were labelled CHANGED; entries marked as *old conclusions* were labelled UNCHANGED. This binary formulation was not introduced for modelling convenience; rather, it follows the standard conclusion-status categories recorded in Cochrane update records. Ambiguous entries (recorded as UPDATE or AMENDMENT) were resolved using a rule-based procedure (Bashir et al., 2021). Reviews for which no conclusion status could be determined were excluded. Comparison of extracted labels against 300 randomly sampled instances revealed complete agreement.

Identifying New Publications For each review-update pair, newly included publications were identified by comparing reference lists of consecutive systematic review versions. PMIDs were extracted from Cochrane XML where available; other-

[1] https://www.cochranelibrary.com/cdsr/about-cdsr

wise, title-based PubMed queries with Levenshtein matching (Levenshtein et al., 1966) were used. Similarity thresholds (0.75; fallback 0.66) were selected empirically. A 300-publication evaluation sample was checked against gold-standard PMIDs (manual PubMed search by first author; subset verified by second author). Agreement was 95%; all disagreements were "No PMID" returns rather than misassignments, indicating retained publications were correctly mapped.

Dataset Characteristics and Split Table 1 summarises the dataset. The class distribution is moderately imbalanced (61.6% Unchanged).

Statistic	Value
Total review-update pairs	3,326
Unique reviews (DOIs)	2,485
Conclusion changed	1,278 (38.4%)
Conclusion unchanged	2,048 (61.6%)
Training set	2,648
Test set	678
Training DOIs	1,988
Test DOIs	497
New publications per update	
Median (IQR)	5 (2–11)
Range	1–301
Review abstract length, mean ± SD	433 ± 168 words
Time between search dates, median (IQR)	1,936 (1,291–2,848) days

Table 1: Dataset statistics. The train/test split is stratified by review DOI to prevent information leakage.

4 Methods

We evaluate methods spanning multiple paradigms: zero-shot inference, few-shot prompting, and parameter-efficient fine-tuning. All methods are evaluated on the same held-out test set. Prompts are provided in Appendix A.

Model selection was constrained by input length, a single A100 80 GB GPU with 4-bit quantisation, and the need for architectural diversity. A 16,384-token maximum accommodated 95.4% of instances without truncation (see Appendix B). These constraints excluded models above 70B parameters and most biomedical LLMs, whose context windows (typically $\leq$4,096 tokens) are insufficient for multi-document inputs. We fine-tuned Qwen2.5-14B-Instruct (Yang et al., 2025b), Qwen3-14B (Yang et al., 2025a), Llama-3.1-8B (Grattafiori et al., 2024), and OpenBioLLM-8B (Pal and Sankarasubbu, 2024),[2] representing two model families and two scales, with OpenBioLLM-8B providing biomedical pretraining, and included GPT-4.1-mini as a proprietary comparison.

[2]Model checkpoints: `Qwen2.5-14B-Instruct`, `Qwen3-14B`, `Llama-3.1-8B-Instruct`, `Llama3-OpenBioLLM-8B`.

`N0` or `N1` (gold label during training; omitted at inference)

Figure 2: Prompt template used for fine-tuning. Zero-shot prompt variants (P-01, P-02, P-03) use different system messages and are provided in Appendix A.

4.1 Zero-Shot Inference

Zero-shot methods receive the review abstract and concatenated publication abstracts as input, with no task-specific training or in-context examples. We evaluate Qwen2.5-14B-Instruct (Yang et al., 2025b) with three prompt variants: P-01 (standard task description), P-02 (augmented with base-rate information and debiasing instructions), and P-03 (tiered reasoning: first identify conflicting evidence, then decide). Each instructs the model to output a single token.

4.2 Few-Shot Prompting

We evaluate Qwen2.5-14B-Instruct with three in-context demonstrations using P-01, with exemplars randomly sampled from the training set.

4.3 Fine-Tuning

We fine-tuned all four models using QLoRA (Dettmers et al., 2023). Each instance was formatted as a three-turn conversation (see Figure 2). The base model was quantised to 4-bit NormalFloat with double quantisation. LoRA adapters (Hu et al., 2022) ($r = 16$, $\alpha = 32$, dropout 0.05) were applied to all projections. The maximum sequence length was 16,384 tokens. Training ran for 3 epochs with batch size 8,

learning rate 2×10^{-4}, cosine scheduling, on an A100 80GB using SFTTrainer. For Qwen3-14B, thinking mode was disabled because our logit-based probability extraction requires the decision token immediately after the prompt, which is incompatible with interposed reasoning tokens. Hyperparameters follow standard QLoRA defaults (Dettmers et al., 2023).

Probability extraction. The tokeniser encodes possible outputs, `N0` and `N1`, as two-token sequences, `N+0` and `N+1`. We append `N` and extract logits for the `0` and `1` continuation tokens, applying softmax to obtain $P(\text{CHANGED})$. Unparseable responses are treated as UNCHANGED.

Decision threshold. We report results at threshold 0.50 and threshold 0.37 (selected by a 0.01-step sweep on the training set to maximise balanced accuracy). AUC-ROC is reported once.

5 Evaluation

All methods are evaluated on the held-out test set ($n = 678$; 420 Unchanged, 258 Changed). We report accuracy, balanced accuracy, AUC-ROC, and per-class metrics with 95% bootstrap CIs (2,000 resamples). Balanced accuracy is emphasised, given the class imbalance, as is Changed-class recall due to potential negative impacts of missed updates.

Baselines We reimplemented Bashir et al. (2021) on our dataset using their four features (trial count, participant count, coverage score, time elapsed) and three classifiers (logistic regression, decision tree, random forest) with cross-validation grouped by DOI. Missing values were median-imputed on the training set. Random forest achieved the best performance. Two features (coverage score and time elapsed) require information from the completed update, since time elapsed is computed from the update search date, making this baseline a post-hoc upper bound.

Two simple baselines establish lower bounds: majority class (i.e. always predicts UNCHANGED) and random (50/50).

6 Results

Table 2 presents classification performance across all methods.

The majority class baseline achieves 50.0% balanced accuracy but fails to identify any Changed reviews. The reimplemented Bashir et al. (2021) random forest achieves 63.6% AUC-ROC; the lower performance, relative to their reported 80.8% accuracy, reflects our dataset's higher change rate (38.4% vs. 16.8%).

Zero-Shot LLMs No zero-shot Qwen2.5-14B configuration exceeds 56% balanced accuracy (lower CI bounds 50.8–51.8%). P-02 overcorrects: Changed recall rises to 83.3% but Unchanged recall collapses to 24.8%. GPT-4.1-mini under P-02 reaches 59.5% balanced accuracy and 63.4% AUC-ROC, still 7 points below the fine-tuned models, confirming that the task difficulty is not specific to open-source models.

Few-Shot Prompting Three in-context demonstrations yield 54.3% balanced accuracy and 59.0% AUC-ROC, below the best Qwen2.5-14B zero-shot AUC (61.1%), suggesting the difficulty lies in evidence reasoning rather than task-format understanding.

Fine-Tuning Performance Fine-tuning produces the strongest results. Qwen2.5-14B achieves AUC-ROC 70.4%, followed by Qwen3-14B (69.5%), OpenBioLLM-8B (67.5%), and Llama-3.1-8B (66.9%), all exceeding Bashir et al. (2021) (63.6%). The difference between Qwen2.5-14B and the random forest baseline is significant (McNemar's $p = 0.0015$). At threshold 0.37, Qwen2.5-14B achieves 65.7% balanced accuracy with 63.6% Changed recall and 67.9% specificity.

At matched scale, OpenBioLLM-8B (67.5%) exceeds Llama-3.1-8B (66.9%), indicating a modest gain from biomedical pretraining. The gap to Qwen2.5-14B (70.4%) is therefore primarily attributable to scale rather than domain mismatch. Context length is a secondary factor: OpenBioLLM's 8,192-token pretraining range is exceeded by most instances with 21+ publications (Appendix B), whereas the 14B Qwen models natively support our 16,384-token input. Disentangling these effects would require a matched biomedical 14B model with equivalent context, which is not currently available.

7 Influence of Publication Count

At threshold 0.37, the fine-tuned model produces 164 true positives, 285 true negatives, 94 false negatives, and 135 false positives. False negatives involved significantly fewer new publications than true positives (median 3 vs. 16; Mann–Whitney $U = 1{,}794$, $p < 0.001$), while false positives involved more than true negatives (median 12 vs. 2; $U = 35{,}630$, $p < 0.001$): the model over-predicts

Table 2: Test-set performance ($n = 678$; 420 Unchanged, 258 Changed), reported as % with 95% bootstrap CIs (2,000 resamples). †Threshold selected on training data to maximise balanced accuracy; others use the default boundary. **Bold**: best standard fine-tuned model; underline: best zero-shot.

change when many publications are present and under-predicts when few are present.

Overall calibration is good (Expected Calibration Error = 0.028, 10 bins), so the probabilities reflect genuine confidence rather than calibration artefacts. However, predictions above 0.80 are poorly calibrated (19 instances; 58% accuracy vs. 91% mean confidence), consistent with overconfidence in the high-publication regime.

Table 3 stratifies Changed-class recall and Unchanged-class specificity by the number of new publications. When only 1–2 new publications are available, the model detects just 18.4% of conclusion changes. Recall rises monotonically with publication count, reaching 95.6% for instances with 21 or more publications, while specificity shows the inverse pattern, dropping from 95.9% to 2.9%. This indicates that the model uses publication count as a proxy for conclusion change, rather than reasoning about evidence content. The predicted probability $P(\text{CHANGED})$ correlates with publication count at Spearman $\rho = 0.80$, far exceeding the true association between publication count and the label ($\rho = 0.30$). Thus, the model has amplified a moderate real association into a dominant decision rule.

Pubs.	*n*	Changed	Recall	Spec.
1–2	219	49	18.4	95.9
3–5	149	50	30.0	87.9
6–10	115	47	72.3	47.1
11–20	92	44	93.2	4.2
21+	103	68	95.6	2.9
All	678	258	63.6	67.9

Table 3: Changed-class recall and Unchanged-class specificity of the fine-tuned model (threshold 0.37), stratified by the number of new publications.

Although publication count is never an explicit feature, the concatenated input exposes it through two channels: positional encoding of the prediction token (which scales with input length) and textual cues such as repeated abstract structures across publications. To isolate the positional channel, we repeated inference with all inputs left-padded to 16,384 tokens, eliminating variation in the prediction token's position. The correlation was virtually unchanged ($\rho = 0.78$ padded vs. $\rho = 0.80$ unpadded; Pearson $r = 0.99$ between probability vectors), confirming that the model infers volume from textual cues rather than from sequence position alone. These cues may be reinforced by attention patterns that concentrate on tokens near sequence boundaries (Liu et al., 2024), though we do not test this directly.

7.1 Publication Count Ablation at Inference

To test whether performance depends on evidence volume or content, we provide only the first k publication abstracts at inference; all other settings are identical. If the model reasons about content, performance should be largely preserved at small k. Table 4 presents the results. At k=1, AUC-ROC drops from 70.4% to 53.4%, barely above chance, and Changed-class recall falls to 5.8%. Performance improves monotonically with k, and the shortcut correlation ρ rises from -0.26 at k=1 to 0.80 at k=All. These results establish a relationship between evidence volume and model performance: this shortcut is the primary driver of the fine-tuned model's discrimination.

k	AUC-ROC	BalAcc	Chg Rec	Spec	ρ
1	53.4 [48.9, 57.8]	51.7	5.8	97.6	−0.26
3	59.3 [54.9, 63.6]	53.7	12.4	95.0	0.05
5	62.3 [58.0, 66.4]	54.5	20.9	88.1	0.36
10	68.9 [64.7, 72.9]	64.7	59.3	70.0	0.73
All	70.4 [66.3, 74.3]	65.7	63.6	67.9	0.80

Table 4: Publication count ablation at inference. The fine-tuned model (Qwen2.5-14B, threshold 0.37) is evaluated with only the first k publication abstracts provided at inference; all other settings are identical.

7.2 Publication Subsampling

To explore the effect of removing publication count information, we trained Qwen2.5-14B with counterfactual publication subsampling at two levels: k=1 and k=3 publications per training instance. For each training instance, k publications were randomly sampled (or all, when fewer than k existed), decoupling publication count from the label during training; at inference all publications were used, leaving the test distribution unchanged. Other hyperparameters were unchanged.

Table 5 presents the results alongside the standard model (k=All). A clear trade-off emerges across three dimensions: overall discrimination (AUC-ROC), shortcut strength (ρ), and low-publication recall.

At k=1, where each training instance contains a single publication abstract, the shortcut is nearly eliminated: ρ drops from 0.80 to 0.15, below even the true label–publication count association

Method	AUC	ρ	1–2 Rec	BalAcc
FT k=1 subsample	55.4	0.15	57.1	52.0
FT k=3 subsample	63.5	0.36	46.9	59.4
FT k=All (standard)	70.4	0.80	18.4	65.7

Table 5: Shortcut–discrimination trade-off. AUC-ROC (%), Spearman ρ between predicted probability and publication count, Changed-class recall (%) at 1–2 publications, and balanced accuracy (%) at threshold 0.37 (selected on the training set).

($\rho = 0.30$). Changed-class recall at 1–2 publications rises from 18.4% to 57.1%, a threefold improvement in the clinically critical low-publication regime. However, overall AUC-ROC falls to 55.4%, barely above chance, indicating the model has lost the volume signal without learning to compensate through content-based reasoning.

At k=3, the trade-off is more balanced: $\rho = 0.36$ (close to the true association), 1–2 publication recall improves to 46.9%, and AUC-ROC remains at 63.5%, comparable to the Bashir et al. random forest baseline (63.6%).

8 Conclusion

We introduced conclusion change prediction as a multi-document evidence reasoning task on 3,326 Cochrane review-update pairs. Fine-tuning achieves the strongest overall discrimination (AUC-ROC 70.4%) but analysis indicates that it relies heavily on an evidence volume shortcut which future work should aim to overcome.

Limitations

The dataset is restricted to Cochrane intervention reviews with binary labels. Models are provided with abstracts, keeping the system broadly deployable given uneven full-text access. Publications were identified retrospectively and retrieval noise in deployment would likely degrade accuracy. Fine-tuning used a single A100 80 GB GPU with 4-bit quantisation, and 154 long-input instances (Appendix B) were right-truncated. Single training run per configuration.

Ethics Statement

All information required to reproduce our work is contained in this paper: dataset construction and label derivation procedures are described in Section 3; model training configurations and hyperparameters in Section 4.3; the full text of all prompts in Appendix A; and input length and truncation details in Appendix B. Researchers with Cochrane Library access can reconstruct the dataset and reproduce the experiments from these specifications.

Acknowledgements

We gratefully acknowledge the Cochrane Library for providing access to the systematic review data used in this work.

A Prompt Templates

This appendix provides the full text of all prompts used in our experiments. All prompts instruct the model to output a single token: `N0` (unchanged) or `N1` (changed). The user message is identical across all variants and consists of the review abstract followed by the concatenated publication abstracts.

A.1 Zero-Shot Prompts (Section 4.1)

P-01 (Standard). This prompt provides a straightforward task description with no additional guidance.

```
You are an expert biomedical evidence analyst. You will be given the abstract of a Cochrane systematic review and the abstracts of publications that have been newly included in the review since its last update.

Your task: predict whether the review's conclusions changed in the update.

Reply with EXACTLY ONE TOKEN:
- N0 = the overall conclusions stay essentially unchanged
- N1 = the conclusions would plausibly need to be changed
```

P-02 (Debiased). This prompt adds base-rate information and an explicit instruction to counteract majority-class bias.

```
You are an expert biomedical evidence analyst. You will be given the abstract of a Cochrane systematic review and the abstracts of publications that have been newly included in the review since its last update.

Your task: predict whether the review's conclusions changed in the update.

IMPORTANT: In this dataset, approximately 38% of systematic reviews have changed conclusions upon updating. Do NOT default to predicting unchanged. Carefully assess whether the new evidence warrants a change.

Reply with EXACTLY ONE TOKEN:
- N0 = the overall conclusions stay essentially unchanged
- N1 = the conclusions would plausibly need to be changed
```

P-03 (Tiered). This prompt asks the model to reason in two explicit steps before making a prediction.

```
You are an expert biomedical evidence analyst. You will be given the abstract of a Cochrane systematic review and the abstracts of publications that have been newly included in the review since its last update.

Your task: predict whether the review's conclusions changed in the update.

Reason in two steps:
Step 1: Assess whether any new publication reports findings that conflict with, contradict, or substantially extend the review's existing conclusions.
Step 2: Based on your assessment, decide whether the overall conclusions would need to change.

Reply with EXACTLY ONE TOKEN:
- N0 = the overall conclusions stay essentially unchanged
- N1 = the conclusions would plausibly need to be changed
```

A.2 Fine-Tuning Prompt (Section 4.3)

The fine-tuning prompt is shown in Figure 2 in the main text. It is reproduced verbatim below for completeness.

```
You are an expert biomedical evidence analyst. Your job is to decide if the conclusions of a systematic review (SR) should be updated in light of new trial evidence. The publication abstracts provided below have already been screened by expert reviewers and confirmed as relevant to this review. All publications meet the inclusion criteria. Reply with EXACTLY ONE TOKEN:
- N0 = the overall conclusions stay essentially unchanged
- N1 = the conclusions would plausibly need to be changed
```

The user message follows the template:

```
SYSTEMATIC REVIEW AND NEW TRIAL ABSTRACTS:
{review_abstract}
{publication_abstracts}
Decision:
```

During training, the assistant message contains the gold label token (`N0` or `N1`). During inference, the assistant message is omitted and the model generates its prediction.

A.3 Few-Shot Prompt (Section 4.2)

The few-shot prompt uses the same system message as P-01 (Standard). Three training examples

are prepended to the user message as demonstrations. Each demonstration consists of a review–publication pair followed by the gold label.

```
Here are three examples of this task:

– Example 1 –
SYSTEMATIC   REVIEW   AND   NEW   TRIAL
ABSTRACTS:
{example_1_text}
Decision: N1

– Example 2 –
SYSTEMATIC   REVIEW   AND   NEW   TRIAL
ABSTRACTS:
{example_2_text}
Decision: N0

– Example 3 –
SYSTEMATIC   REVIEW   AND   NEW   TRIAL
ABSTRACTS:
{example_3_text}
Decision: N0

Now predict for this instance:

SYSTEMATIC   REVIEW   AND   NEW   TRIAL
ABSTRACTS:
{test_instance_text}
Decision:
```

For each test instance, the three exemplars are randomly sampled from the training set.

The user message is identical to all other methods. Probability estimates were obtained by extracting logit values for the decision token from the classification call and normalising via softmax.

B Input Length and Truncation

Table 6 reports the distribution of input token counts and truncation at the 16,384-token limit, stratified by the number of new publications per instance. Truncation is concentrated at the high-publication tail.

Pubs.	n	Median tok.	Truncated	% Trunc.
1–2	1,055	1,254	0	0.0
3–5	757	2,269	0	0.0
6–10	625	3,903	0	0.0
11–20	482	6,699	1	0.2
21–50	329	12,819	75	22.8
51+	78	31,320	78	100.0
All	3,326	2,738	154	4.6

Table 6: Input length and truncation at the 16,384-token limit, stratified by the number of new publications. "% Trunc." is the proportion of instances in the row whose tokenised length exceeds 16,384 tokens, at which point later publications are right-truncated. All instances with 51 or more new publications exceed the limit; none with 10 or fewer do. Overall, 95.4% of instances fit within the limit without truncation.

VaxScope: Document-Level Structured Evidence Extraction from Immunization Systematic Reviews

Abstract

Systematic reviews are fundamental to evidence-based medicine, but the clinical evidence they contain is primarily expressed in unstructured text, making large-scale extraction and reuse difficult. Existing biomedical NLP methods have achieved strong performance on span-level extraction from clinical trials and abstracts; however, these approaches are insufficient for systematic reviews, where evidence is often distributed across multiple studies, sentences, and sections and must be aggregated into normalized document-level attributes. We introduce **VaxScope**, a benchmark dataset for document-level structured evidence extraction from immunization-related systematic reviews. VaxScope is constructed through an expert-guided semi-automatic annotation pipeline that combines automatic candidate generation with domain expert validation to ensure consistency and annotation quality. We formalize the task as document-level structured extraction, where target labels are defined at the review level and require aggregating evidence beyond isolated textual spans. We further establish baselines for document-level structured extraction using abstract-level input representations and evaluate how access to evidence-grounded contextual input improves performance over abstract-only settings. Baseline experiments show that PubMedBERT achieves the best overall performance (Avg F1: 0.850), with evidence-grounded input improving performance particularly for fields requiring distributed contextual reasoning.

1 Introduction

Systematic reviews are central to evidence-based medicine, but the evidence they contain is primarily expressed in unstructured natural language, making large-scale extraction, comparison, and reuse difficult for downstream applications such as clinical decision support and evidence synthesis (Pilic et al., 2023). Existing biomedical NLP methods have achieved strong performance on patient-level clinical text, such as electronic health records and clinical notes (Lee et al., 2019; Alsentzer et al., 2019). They have also shown strong results in span-level extraction from biomedical abstracts and trial reports (Fraile Navarro et al., 2023). However, these approaches are often insufficient for systematic reviews, where evidence is synthesized across multiple studies and relevant information is distributed across sentences and document sections rather than localized in isolated spans.

This limitation is particularly important in the immunization domain, where vaccine recommendations and public health policies depend heavily on systematic reviews that summarize evidence across populations, pathogens, interventions, and clinical outcomes (Pilic et al., 2023; İlgen et al., 2024). Supporting decisions in this setting requires structured access not only to explicit entities such as diseases and populations, but also to higher-level attributes such as outcomes, study characteristics, evidence summaries, and review design.

A central challenge is that many of these attributes cannot be reliably extracted from individual text spans alone (Zhang et al., 2024; Schmidt et al., 2025). Instead, they require aggregating evidence across multiple mentions and resolving information at the document level (Zhang et al., 2020; Zheng et al., 2024). For example, the study design or the number of included studies may be mentioned in different sections, while clinically relevant outcomes are often described implicitly across multiple paragraphs. As a result, standard span-based extraction approaches alone are insufficient to capture the full structure of evidence represented in systematic reviews.

To address this limitation, we introduce **VaxScope**, a benchmark dataset for document-level structured evidence extraction from immunization-related systematic reviews. Each review is annotated with a set of normalized attributes, in-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 853–863
July 3-4, 2026 ©2026 Association for Computational Linguistics

cluding population, disease, outcome, study design, number of included studies, and review type. In addition, each structured annotation is linked to a small set of supporting evidence snippets, enabling traceability, human verification, and evidence-grounded extraction and validation. This evidence-grounded design supports interpretable downstream applications and human-in-the-loop decision support (Riskin et al., 2025; DeYoung et al., 2020).

VaxScope is constructed using an expert-guided semi-automatic annotation pipeline that combines automatic candidate generation with domain expert validation to ensure consistency and annotation quality. We establish benchmark baselines for document-level structured extraction using abstract-level input, and demonstrate that multi-task transformer classifiers effectively capture heterogeneous document-level attributes across categorical, multi-label, and numeric fields. These structured attributes can additionally support interactive and visualization-based systems for exploring immunization evidence (İlgen and Hattab, 2025). Taken together, these design choices position VaxScope as both a benchmark dataset and a practical resource for downstream evidence exploration. Our contributions are threefold:

- We introduce **VaxScope**, a new benchmark dataset for document-level structured evidence extraction from immunization-related systematic reviews.
- We design an evidence-grounded annotation schema that combines normalized document-level attributes with linked supporting evidence snippets, enabling traceable, interpretable, and verifiable extraction.
- We establish benchmark baselines for document-level structured extraction using abstract-level input, and evaluate how access to evidence-grounded contextual input improves performance relative to abstract-only settings.

2 Related Work

Biomedical natural language processing has made substantial progress in extracting structured information from clinical and scientific text (Lee et al., 2019). Early approaches relied on rule-based methods using predefined lexical and syntactic patterns, which proved effective for high-precision extraction in constrained settings but often struggled with ambiguous and heterogeneous biomedical language (Wang et al., 2017). More recently, transformer-based models pretrained on biomedical corpora, such as BioBERT (Lee et al., 2019) and BIO_CLINICALBERT (Alsentzer et al., 2019), have substantially improved performance across named entity recognition, relation extraction, and document classification tasks. However, much of this progress has focused on sentence-level or span-level extraction from primary clinical documents, leaving document-level structured evidence extraction from systematic reviews comparatively underexplored.

Multi-label classification of biomedical documents has been studied extensively in the context of literature indexing and topic annotation. Du et al. (2019) proposed ML-Net, a deep learning architecture for multi-label biomedical text classification that jointly predicts labels and label counts. More recently, the BioCreative VII LitCovid track (Chen et al., 2022; Lin et al., 2022) introduced a shared task for multi-label topic annotation of COVID-19 literature, demonstrating the utility of transformer-based classifiers for document-level label assignment in rapidly evolving biomedical domains. While these tasks are closely related to the multi-label components of our framework, they primarily focus on topical document classification. In contrast, VaxScope requires heterogeneous document-level extraction that jointly combines categorical labels, multi-label aggregation, and structured numeric and temporal fields.

A prominent line of work in biomedical NLP focuses on extracting structured evidence from randomized controlled trial (RCT) reports using the PICO framework—Population, Intervention, Comparator, and Outcome. The EBM-NLP corpus (Nye et al., 2018) provided a foundational benchmark for span-level PICO extraction from RCT abstracts and has been widely used to evaluate sequence labeling and NER-based approaches. Subsequent work has explored multi-task learning, section-aware models, and prompt-based methods to improve extraction precision (Hu et al., 2023). More recently, large language models have been applied to PICO extraction in zero-shot and few-shot settings (Ghosh et al., 2024; Chen et al., 2025), achieving competitive performance without requiring labeled training data. However, these approaches remain predominantly span-level and are designed for primary study reports (Lehman et al., 2019). In contrast,

VaxScope targets structured extraction from *systematic reviews*, where evidence is synthesized across multiple primary studies and key attributes often require document-level aggregation rather than isolated span detection.

Automating systematic reviews has attracted growing interest as the volume of biomedical literature continues to expand (Marshall and Wallace, 2019; Tsafnat et al., 2014). Prior work has addressed several stages of the systematic review pipeline, including relevant paper retrieval (van de Schoot et al., 2021), risk of bias assessment (Gates et al., 2018), and evidence synthesis and summarization (Wang et al., 2022). Recent studies have explored the use of LLMs for semi-automated data extraction from systematic reviews, reporting strong performance for extracting predefined entities and study characteristics across multiple domains (Schmidt et al., 2024). At the same time, recent living systematic reviews of systematic review automation show that most existing approaches remain centered on extracting PICO-style evidence from primary studies and randomized controlled trials, while structured extraction of review-level metadata remains comparatively underexplored (Schmidt et al., 2025). In contrast, VaxScope focuses on the review itself as the primary unit of analysis: given a systematic review document, the goal is to extract normalized attributes that characterize the review as a whole, including its scope, methodology, and evidence base. While VaxScope captures methodological attributes such as study design, it does not currently include explicit evidence-quality assessments such as GRADE scores or risk-of-bias ratings. These dimensions fall outside the scope of the current abstract-based benchmarking and typically require a broader full-text methodological appraisal beyond the extraction targets considered here. Incorporating such fields remains an important direction for future dataset extensions.

Standard information extraction systems operate at the sentence or span level, identifying entities and relations within individual sentences. However, in many real-world settings, relevant information is distributed across multiple sentences and sections of a document and cannot be reliably captured through isolated span extraction (Zhang et al., 2020). Document-level relation extraction has emerged as an active research area, with methods that model cross-sentence dependencies through graph neural networks and transformer architectures (Zhou et al., 2021; Yao et al., 2019). In the biomedical domain, document-level extraction has been studied for chemical–disease relation extraction (Li et al., 2016) and other entity-level tasks. VaxScope extends this perspective to structured attribute extraction from systematic reviews, where multiple heterogeneous fields—spanning categorical labels, multi-label sets, and numeric or temporal values—must be jointly extracted at the document level. This heterogeneous formulation distinguishes our task from prior document-level extraction benchmarks, which typically focus on a single relation type or entity category.

3 Methods

3.1 Dataset Construction Pipeline

The VaxScope corpus was constructed through a semi-automatic data creation pipeline designed to balance scalability and annotation quality. We first collected immunization-related systematic reviews and meta-analyses from an expert-curated collection of immunization evidence. For each document, candidate annotations were identified from the full text, as relevant information is often distributed across multiple sections, including methods, results, and discussion. We then applied automatic candidate extraction to identify preliminary values for structured fields such as the number of included studies, date of the last literature search, review type, and disease mentions. For the initial seed set, automatically extracted candidates were subsequently reviewed and corrected through expert validation. This semi-automatic pipeline enabled efficient corpus construction while preserving annotation consistency and clinical relevance, as illustrated in Figure 1.

An existing domain-expert annotated benchmark set of 100 immunization-related systematic reviews served as the foundation for schema design, protocol validation, and final evaluation. We used this benchmark to derive label categories, normalization rules, omission rules, and evidence selection criteria, which were then formalized into a constrained prompt schema for LLM-assisted candidate generation. The model was therefore not used to define labels or annotation logic, but to apply an expert-derived annotation protocol at scale. Candidate generation was performed using `gemini-3-flash-preview` (Google DeepMind), prompted with a constrained JSON schema that defined normalized value spaces, controlled vocab-

ularies, and critical extraction rules for each field (e.g., `date_of_last_lit` was set to `null` if not explicitly stated in the text, to avoid unsupported date assignment). The full prompt schema is provided in Appendix A. Generated candidates were subsequently reviewed and corrected where necessary, while the final evaluation was conducted exclusively on the independently expert-annotated gold set.

Following this expert annotation protocol, the corpus was expanded using an LLM-assisted semi-automatic pipeline to 2,000 annotated documents. During data inspection, we identified 79 duplicate review instances between the expert benchmark and the larger LLM-assisted corpus. To avoid evaluation leakage, these overlapping documents were removed before model development. The remaining corpus consisted of 1,921 documents, which were split into 1,536 training and 385 development instances.

Annotation quality was assessed through two complementary steps: (1) automatic quality evaluation by comparing LLM-generated candidate annotations against the expert gold set, reporting field-level F1 and exact-match accuracy; and (2) inter-annotator agreement analysis on a randomly sampled subset of 50 documents from the expanded corpus. These documents were independently annotated by two of the authors following the expert-derived annotation protocol and without access to the original LLM-generated labels. Agreement was measured using Cohen's κ for categorical fields, Jaccard similarity for multi-label fields, and exact-match accuracy for numeric and temporal fields, as reported in Table 1.

3.2 Task Definition

We formulate the problem as document-level structured evidence extraction from systematic reviews in the immunization domain. Given a review document (typically represented by its abstract), the goal is to map the document to a set of normalized attributes that summarize its key evidence characteristics. Although candidate annotations are identified from the full text during corpus construction, the abstract is used as the primary input for the extraction models, as it provides a consistent and practically deployable representation across studies. This setting differs fundamentally from standard span-based information extraction tasks. In systematic reviews, relevant information is heterogeneous and distributed across multiple sentences and

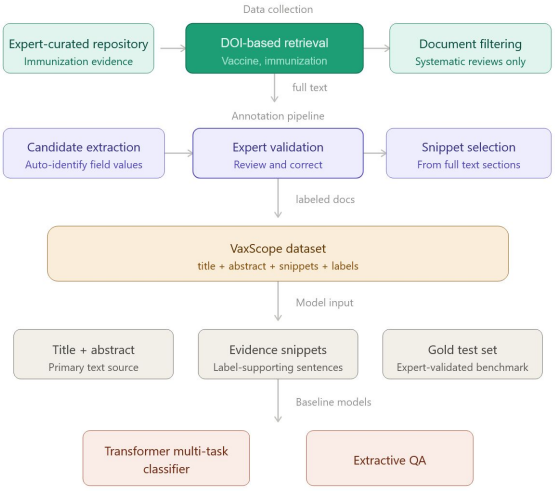

Figure 1: Semi-automatic corpus construction pipeline for VaxScope. Documents are collected from an expert-curated immunization evidence source and retrieved via DOI lookup. Candidate annotations are generated automatically and validated by domain experts. Evidence snippets from the full text provide support for document-level labels.

sections, and cannot be reliably captured through isolated span extraction. For example, population characteristics may appear in the inclusion criteria, outcomes in the results, and study characteristics in the methods. Extracting structured information, therefore, requires consolidating evidence that is often distributed across multiple mentions within a document.

We define the task as predicting a structured representation comprising predefined fields: population, outcome, disease, number of included studies, study design, and review type. These fields correspond to different types of prediction problems: some require normalized categorical classification (e.g., disease, review type), others require aggregating evidence across multiple mentions (e.g., population, study design), and others involve extracting normalized numeric or temporal values (e.g., number of studies, date of last literature search).

To support interpretability and annotation consistency, each document is additionally associated with a small set of evidence snippets (typically a few sentences) that jointly support the extracted attributes, providing traceable justification for document-level annotations and facilitating human verification. In the current benchmark setting, these evidence snippets are included in the annotation schema and used by the baselines as contextual input. However, the current baselines do not ex-

Field	Metric	Score
Disease	Cohen's κ	0.84
Review type	Jaccard	0.89
Num. studies	EM / Near-miss	0.90 / 0.92
Num. participants	EM	0.82
Date of last search	EM / Year-level	0.82 / 0.90
Topic	Jaccard	0.76
Outcome	Jaccard	0.69
Population	Jaccard	0.71

Table 1: Inter-annotator agreement on 50 randomly sampled documents. Cohen's κ is used for disease, Jaccard similarity for multi-label fields, and exact match (EM) with near-miss tolerance for numeric and temporal fields. Near-miss denotes ± 1 for num. studies and year-level match for date of last search. For the outcome field, agreement was computed only over instances where both annotators assigned a non-null value, as null entries reflected topic-conditional field activation rather than outcome-category decisions.

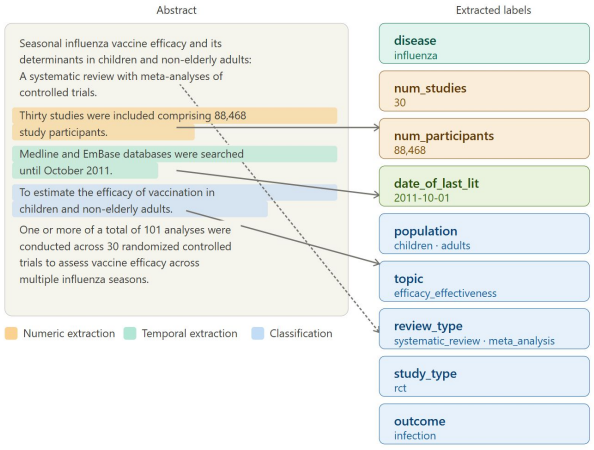

Figure 2: Example annotation from VaxScope. Highlighted spans indicate evidence snippets supporting extracted labels. Amber marks numeric fields, green temporal fields, and blue categorical and multi-label fields. Evidence snippets may be drawn from the abstract or full-text sections depending on where supporting evidence appears in the source document.

plicitly predict snippet selection within their output space.

3.3 Annotation Schema

We define a document-level annotation schema that captures key structured attributes of systematic reviews in the immunization domain. Each document is mapped to a set of predefined fields representing clinically and methodologically relevant aspects of the evidence, such as population, outcome, disease, study design, and review type. Figure 2 shows an annotated example from the VaxScope corpus, illustrating how evidence snippets support the extracted structured labels.

All fields are annotated at the document level, supported by evidence snippets drawn from across the full review. To ensure consistency, each field is associated with a defined value space, including normalized categories (e.g., population groups, study designs) or structured values (e.g., numeric counts and dates). Importantly, the schema is heterogeneous: different fields correspond to different types of prediction problems, including categorical classification, multi-label aggregation over distributed mentions, and numeric or temporal slot filling. This design reflects the diverse structure of information in systematic reviews and aligns with the task formulation described in the previous section. Table 2 summarizes the annotation schema, including field definitions, prediction types, and value spaces. In addition to structured fields, each document is linked to a small set of evidence snippets that provide traceable support for the annotations. The schema is designed to balance expressiveness and the feasibility of annotations. While some fields are normalized into predefined categories, others allow flexible values to capture domain-specific variations. This design supports both structured modeling and practical annotation at scale.

3.4 Baseline Models

We implement a hybrid extraction architecture that combines slot-filling extractors for numeric and temporal fields with a transformer-based multi-task classifier for categorical and multi-label document-level attributes. Figure 3 illustrates the overall extraction architecture.

Multi-task transformer classifier. For categorical and multi-label document-level attributes—including disease, review type, topic, study design, population, and outcome—we evaluate three transformer-based baselines with task-specific prediction heads: BIO_CLINICALBERT and PUBMEDBERT as biomedical encoder baselines, and CLINICAL-LONGFORMER as a long-context baseline. In the primary experimental setting, the model takes the document title and abstract as input and produces a shared document-level representation for downstream field-specific prediction heads. To assess the added value of evidence-aware contextualization, we additionally report an oracle upper-bound setting in which expert-selected evidence snippets are concatenated with the title

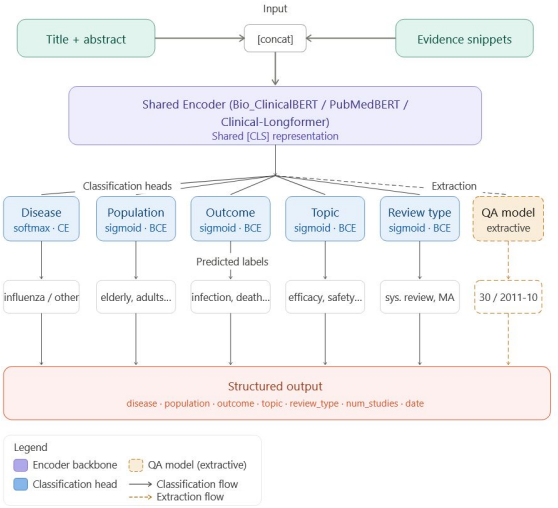

Figure 3: Architecture of the VaxScope extraction system. The shared encoder produces a shared document-level representation that is passed to task-specific classification heads for categorical and multi-label fields. Numeric and temporal fields are extracted separately using an extractive QA model (dashed).

and abstract as additional contextual input. Single-label fields (e.g., disease) are modeled using softmax classification with cross-entropy loss, while multi-label attributes (e.g., population, outcome) are modeled using sigmoid output layers with binary cross-entropy loss.

Numeric and temporal extraction. For fields requiring numeric or temporal values—specifically the number of included studies, the total number of participants, and the date of the last literature search—we adopt an extractive QA approach using `deepset/roberta-base-squad2`, a RoBERTa-based (Liu et al., 2019) question-answering model fine-tuned on SQuAD 2.0 (Rajpurkar et al., 2018). For each target field, we define a natural language question (e.g., *"How many studies were included in this systematic review?"*) and extract the answer span from the document context. Extracted spans are post-processed into typed values (integers or normalized dates in `YYYY-MM-DD` format). Answers below a confidence threshold are mapped to `null`. To validate this design choice, we also compare against a deterministic **regex baseline** that uses regular expressions and domain-specific lexical patterns. This approach can achieve high precision when target values are expressed in predictable surface forms, and serves as a lower-bound reference for the slot-filling fields.

3.5 Evaluation Metrics

Categorical and multi-label fields are evaluated using field-level precision, recall, and F1 score. For numeric slot-filling fields (e.g., number of included studies and total number of participants), we report exact-match accuracy and near-miss accuracy with ± 1 tolerance. This is particularly important in systematic reviews, where multiple related numeric quantities may co-occur within the same document (e.g., numbers screened, excluded, and included), making target disambiguation non-trivial. For temporal fields, we report exact-match accuracy on normalized date strings (`YYYY-MM-DD`) as well as partial-match accuracy at the year level.

4 Experiments

4.1 Experimental Setup

Dataset. VaxScope comprises 1,921 documents drawn from immunization-related systematic reviews, split into 1,536 training and 385 development instances. A held-out set of 100 expert-validated documents is reserved exclusively for final test evaluation.

Models. We evaluate three transformer-based encoders as a shared backbone for the multi-task classifier: BIO_CLINICALBERT (Alsentzer et al., 2019), a biomedical encoder pretrained on clinical notes; PUBMEDBERT (Gu et al., 2021), pretrained exclusively on PubMed abstracts; and CLINICAL-LONGFORMER (Li et al., 2022), a long-context encoder supporting up to 4,096 tokens.

Input settings. Although the labels are defined at the review level and require document-level interpretation, the current baselines use abstract-level input as a standardized and practically accessible benchmark setting. We evaluate two input configurations: a primary setting using only the document title and abstract, and an oracle setting that additionally incorporates expert-selected evidence snippets drawn from the full text. The primary setting reflects a realistic deployment scenario in which only abstract-level information is available. The oracle setting assumes ideal evidence localization and serves as an upper bound on extraction performance. This comparison isolates the contribution of explicit evidence grounding to document-level structured extraction.

Hyperparameters. All models are fine-tuned for 12 epochs using AdamW (lr=2×10^{-5}, weight de-

Field name	Description	Prediction type	Value / label space
Number of studies included	Number of primary studies included in the review	Numeric slot filling	Single integer (e.g., 30)
Date of last literature search	Date of the most recent literature search	Temporal slot filling	Normalized date (stored as YYYY-MM-DD) or null
Review type	Type of review	Multi-label classification	systematic_review, meta_analysis, rapid_review, living_review, umbrella_review, other
Study design	Study designs of included primary studies	Multi-label aggregation	rct, cohort, case_control, cross_sectional, case_series, qualitative, mixed_method, other
Disease	Target disease or pathogen of the review	Single-label classification	Controlled vocabulary (e.g., influenza, covid_19, . . .)
Population	Target population groups	Multi-label aggregation	children, adolescents, adults, elderly, pregnant, healthcare_workers, immunocompromised, all age groups, other
Outcome	Main clinical outcomes for effectiveness analyses	Multi-label classification	infection, hospitalization, death, other
Topic (evidence type)	Primary evidence focus of the review	Multi-label classification	efficacy_effectiveness, immunogenicity, safety, . . .

Table 2: Document-level annotation schema in the VaxScope corpus. All fields are extracted at the document level and supported by selected evidence snippets. Value spaces show representative categories; the full label space is defined in the annotation schema provided with the dataset.

cay=0.01). BIO_CLINICALBERT and PUBMEDBERT use batch size 4 and maximum sequence length 512. CLINICAL-LONGFORMER uses batch size 2 and maximum sequence length 2,048. A sigmoid threshold of 0.5 is applied for multi-label classification.

4.2 Results

Table 3 presents development set results across all model and input setting combinations. We report Macro-F1 for disease classification and Micro-F1 for all multi-label fields.

4.3 Analysis

PUBMEDBERT achieves the best overall performance across both input settings, reaching Avg F1 of 0.797 in the abstract-only setting, 0.810 with evidence snippets on the development set, and 0.850 on the held-out gold test set. This suggests that domain-specific pretraining on PubMed abstracts provides a stronger inductive bias than long-context modeling for this task, likely because systematic review abstracts are structurally dense and domain-specific. CLINICAL-LONGFORMER performs competitively in the abstract-only setting but benefits more from evidence snippets, particularly for *outcome* and *study_type*, suggesting that longer context is most useful when distributed evidence is explicitly provided. Evidence snippets consistently improve performance across models, with

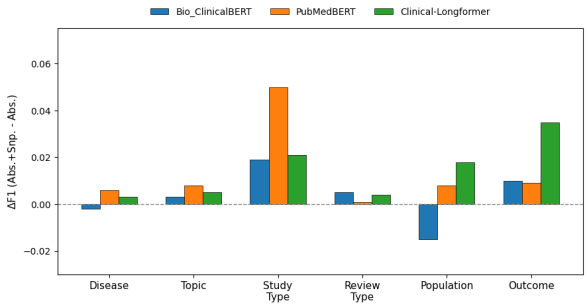

Figure 4: Performance gain from adding expert-selected evidence snippets (Abs.+Snp.) over abstract-only input (Abs.) across prediction fields. Values show ΔF1 on the development set. Gains are largest for study type, population, and outcome, while disease and review type show minimal improvement.

the largest gains observed for *study_type*, *population*, and *outcome*, while *disease* and *review_type* show minimal improvement due to their reliance on standardized labels that are already identifiable from abstracts. The *population* field remains the most challenging across all settings, consistent with inter-annotator agreement results (Jaccard = 0.71), likely reflecting label overlap and implicit population mentions in immunization literature. The *outcome* field also shows relatively lower agreement (Jaccard = 0.69), consistent with its topic-conditional nature.

Model	Setting	Disease	Topic	Study Type	Review Type	Population	Outcome	Avg
Majority baseline	–	0.105	0.324	0.375	0.781	0.284	0.356	0.371
Bio_ClinicalBERT	Abs.	0.945	0.777	0.714	0.948	0.580	0.628	0.765±0.007
Bio_ClinicalBERT	Abs.+Snp.	0.943	0.780	0.733	0.953	0.565	0.638	0.769±0.008

Table 5: Slot-filling results on the held-out gold test set. EM: exact match; Near-miss: ±1 for numeric fields, year-level for temporal fields. Only documents with non-null gold annotations are evaluated.

5 Discussion

VaxScope addresses a gap in biomedical NLP by providing a benchmark for document-level structured evidence extraction from systematic reviews. Our results show that transformer-based multi-task classifiers can effectively extract heterogeneous structured attributes from immunization-related systematic reviews, achieving strong performance on well-defined fields such as disease and review type. A key finding is that domain-specific pretraining (PUBMEDBERT) is more beneficial than long-context modeling (CLINICAL-LONGFORMER), suggesting that the structural density of systematic review abstracts limits the practical benefit of extended context windows, while familiarity with PubMed-style language provides a stronger inductive bias for this task. Evidence snippets consistently improve performance for fields requiring distributed contextual reasoning, particularly study type, outcome, and population, while highly standardized fields such as disease and review type remain robust under abstract-only input. Lower performance on numeric and temporal slot-filling fields (Table 5) should be interpreted less as model failure and more as a consequence of the intentionally abstract-based benchmark setting, since values such as the number of included studies and the date of the last literature search are often absent from abstracts and only reliably reported in full-text methods sections. In this sense, snippet gains function as indicators of full-text dependency rather than simple performance improvements: large gains for population, outcome, and study type reflect distributed evidence requirements, whereas low-gain fields such as disease and review type are largely recoverable from abstract-only input. Inter-annotator agreement further confirms that well-defined categorical fields such as disease and review type can be annotated consistently, whereas population and outcome remain more challenging due to label ambiguity and implicit mentions. This is also reflected in model performance, where population and outcome remain the most challenging fields across all settings.

6 Conclusion

We introduced VaxScope, a dataset and benchmark for document-level structured evidence extraction from immunization-related systematic reviews. Our baseline experiments show that multi-task transformer classifiers achieve strong performance across heterogeneous document-level fields, with PUBMEDBERT achieving the best overall result (Avg F1: 0.850 on the held-out gold test set). Overall, VaxScope highlights the importance of document-level modeling for structured evidence extraction and provides a foundation for automated evidence synthesis in public health. The VaxScope dataset and annotation schema are available at https://github.com/baharilgen/VaxScope.

Limitations

The current baselines leverage long-context self-attention to capture cross-sentence dependencies implicitly; however, they do not explicitly model mention-level conflict resolution or evidence graphs. More structured aggregation mechanisms, such as hierarchical sentence encoders or graph-based evidence modeling, remain important directions for future work. Furthermore, VaxScope is currently limited to the immunization domain, and generalization to other systematic review domains remains to be explored. In addition, although evidence snippets are included to support interpretability and downstream traceability analyses, the current baselines do not explicitly predict or evaluate snippet selection. Snippet-level grounding and joint label–evidence evaluation also remain important directions for future work.

Acknowledgments

The authors thank the Immunization Unit (FG33) at the Robert Koch Institute for providing the expert-annotated reference set and access to the SYSVAC immunization review registry that supported corpus construction and evaluation.

A Annotation Prompt Schema

The following pseudo-JSON schema was used to prompt `gemini-3-flash-preview` (Google DeepMind) for candidate annotation generation, based on an expert-derived annotation protocol.

```
/* Pseudo-JSON annotation schema */
{
  "doc_id": "doc_XXXX",
  "doi": "...",
  "title": "...",
  "abstract": "...",
  "disease": "...",
  "population": [...],
  "topic": [...],
  "outcome": [...],
  "study_type": [...],
  "review_type": [...],
  "num_studies": null,
  "num_participants": null,
  "date_of_last_lit": null,
  "evidence_snippets": [...]
}
```

A.1 Critical Extraction Constraints

The following constraints were enforced to ensure annotation consistency and reduce schema-inconsistent outputs:

- `date_of_last_lit`:
  set to `null` if not explicitly stated in the text. Publication date must not be used as a substitute.
- `population`:
  if all ages are included or unspecified, use `["all_age_groups"]` alone; no other values may co-occur.
- `disease`:
  use `vaccine_preventable_diseases` only when no single primary disease can be identified.
- `outcome`:
  set to `null` when `topic` does not include `efficacy_effectiveness`; otherwise, one or more of: `infection`, `hospitalization`, `death`, `other`.
- `evidence_snippets`:
  a small set of supporting sentences copied verbatim from the source document; paraphrasing or summarization is not permitted.

A.2 Example Annotation

The following example is drawn from the expert-annotated gold set.

Medical Context Variation: A source of impairment for Event classification

Abstract

The variation in writing style encapsulates nuanced characteristics, which are often exploited for author or demographic identification. In the medical domain, language models are frequently deployed to capture relevant information from unstructured or complex data, such as clinical notes that often include patients' medical histories. Such data is largely free-form and unstructured, obtained through diverse clinician–patient interactions. In this work, we present a case study investigating whether variations in clinicians' writing styles can lead to differences in medical context understanding capabilities for pre-trained language models (PLMs) on five downstream tasks related to medical event classification. Our findings indicate that variation in writing style, characterized by linguistic features, can indeed lead to suboptimal performance in deployed NLP models. Furthermore, we explore linguistically guided counterfactual reasoning to mitigate the impact of writing-style variation, suggesting that LLM-based stylistic normalization is effective for this purpose.

1 Introduction

Clinical narrative plays important role in determining the history of the patient. It helps clinicians in answering prognostic inquiries and is essential for identifying the confounding between disease progression and interventions (Pham et al., 2017). The documentation writing practices are designed to be chronological and divided into identifiable sections, such as patient's prior medical context, physical examination, possible diagnosis and actions (Bansler et al., 2016). Therefore, the narrative found in clinical notes can depend on the writing style of the clinical staff. Furthermore, the variation in writing can be a source of communicating incomplete, ambiguous or at times wrong information.

For eg., In the sentence – *The infusion rate was then increased and blood was taken 4,8,12 and 20 minutes after the new target concentration had been achieved.* The writer were interested in how quickly the concentration reached its new steady-state after the rate of infusion had been increased; they took blood 4, 8, 12 and 20 minutes after taking the action that sought to produce a new target concentration, that is, after altering the rate of infusion. The investigators could not know the concentration of the drug in the blood until after analysis some days later. A recommended alternative (Goodman and Edwards, 2014) for the text is as follows – *The infusion rate was then increased and blood was taken 4, 8, 12 and 20 minutes later, or (although it is implicit and not strictly necessary) ... after the new target concentration had been set.* This sentence clarifies the order of the actions and the events happening.

English for Medical Purposes (EMP) is a key focus in medical education, with research emphasizing the importance of collocation acquisition by EFL learners (Džuganová, 2019). Medical writing often suffers from issues such as overly complex sentences, excessive passive voice, weak verb usage, and medical jargon, all of which hinder clarity and comprehension (Goodman and Edwards, 2014). Given that free-text clinical notes make up about 80% of clinical data, models trained on such text are likely influenced by stylistic and demographic variation. While large-scale training may offer robustness to writing style differences, this assumption has not been systematically evaluated for language models.

In this work, we present a case study focusing on linguistic variation, in particular writing style variation, that is found in the clinical notes for the task of extracting contextual information related to medicinal changes. The primary objective is to investigate *whether the characteristics of writing style in clinical notes has subsequent impact on language models* for event classification tasks. Our key contributions in this paper are as follows:

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 864–879
July 3-4, 2026 ©2026 Association for Computational Linguistics

(a) We provide a thorough linguistic feature analysis to find empirical evidence for stylistic variation in clinical notes has impact on capability of pre-trained language models.
(b) We show that linguistically-guided counterfactual reasoning can be used to mitigate the impact of writing style variation on LMs.
(c) Additionally, we study the generated counterfactuals for medical relevance for data augmentation.

2 Background

Style Variation Style variation is a form of linguistic variation has been studied for describing and explaining variation in linguistic form across society (Nguyen et al., 2021). Stylistic Vagueness or variation is very well acknowledged in medical writing (Mitchell, 2007) and is advised to avoid as much as possible in medical communication. Although, the existence of any linguistic variation can be attributed to demographics of international doctors across the world, majority of whom have English as their second-language (Verma et al., 2016). Linguistic variation between user and the content of clinical notes already has studied for medical dialog systems (Llanos et al., 2016). However, the impact of the writing style variation has not been studied thoroughly for language models for medical context understanding.

Medical Contextual Understanding Clinical notes are narrative and longitudinal, capturing a patient's medical history, assessments, and care plans across time. These texts vary widely in structure and writing style depending on the provider, institution, and note type (Pivovarov and Elhadad, 2015). Events such as medication changes are often embedded in nuanced context — temporal cues, attribution, and intent — that must be accurately captured for tasks like medication reconciliation (Cadwallader et al., 2013). While clinical event extraction has received significant attention, the effect of writing-style variation on the medical contextual understanding of language models remains underexplored (Xu et al., 2022).

Counterfactual Explanations We consider counterfactual explanation (Wachter et al., 2017; Sinha et al., 2023) as a mean to verify and potentially mitigate the impact the different linguistic feature that contribute to writing style variation in clinical notes on medical language models' capabilities for contextual medical event extraction task. Various works that exist inline with this approach such as POLYJUICE (Wu et al., 2021), MICE (Ross et al., 2021) which provide a pipeline for counterfactual generation and evaluation. However, there is a lack of exploration into mitigating medical writing style variation, which our work addresses.

3 Methodology

Dataset CMED (Mahajan et al., 2022) dataset is a collection of clinical notes that are associated to the patients who were admitted for the Type II Diabetes (T2D). The dataset consists of total 500 clinical notes from two different hospitals (See Appendix A for more details). Each clinical note was annotated by a team of three annotators led by a physician for medication events extraction and context annotations.

Contextual Event Extraction The contextual medical event extraction was introduced in n2c2 challenge[1]. It involved two-fold tasks, firstly, it requires to identify medicine for which any *medication change*[2] is being discussed in the clinical note and secondly, different contextual information associated the medication change has to be extracted. For any medication change that is identified as *disposition*, the model is expected to extract five different contextual information regarding the `Action`, `Negation`, `Temporality`, `Certainty` and `Actor` that are associated to for each identified medication change (Mahajan et al., 2022). See Appendix A for more details.

Linguistic Characterization of Clinical Narrative We utilize BEA linguistic feature extractor tool (Lee and Lee, 2023) in order to extract linguistic features from any segmented medical sentence of the clinical notes. The tool facilitates to extract 220 linguistic feature per sentence (See Table 19,20). These features cover various linguistic characteristics on sentence-level such as surface, syntax, lexico-semantics, and discourse. We utilized SciSpacy[3] instead of general domain modules for processing the segmented sentences.

Models We consider four pre-trained language models as follows: BERT (Devlin et al., 2018),

[1] https://n2c2.dbmi.hms.harvard.edu/

[2] Medication change, is defined as "any discussion about a medicine change" and is termed to as *disposition*, for a given patient mentioned in the clinical note.

You are an assistant supporting a linguistic study. Your task is to rewrite the given sentence by modifying the following linguistic feature: [feature]. Return only the modified sentence, without additional text or explanation. Sentence: "sentence"

Table 3: Prompt used for generating sentence explanations.

ModernBERT (Warner et al., 2024), ClinicalBERT (Huang et al., 2019) and PubmedBERT (Gu et al., 2021). For each of these BERT-like models, we train classification model using the segmented sentences containing the target medicine as an input against each of the five context category labels for 20 epochs with early stopping. Details for reproducibility in Appendix C.

4 Experimental Setup

Each clinical note is segmented at the sentence level, and then sentences containing a medication change annotated with a *disposition* label are retained. We train the different LMs to obtain predictions on the development and test sets. Additionally, we extract 220 linguistic features using BEA linguistic feature extraction library for selected disposition based sentences. To test our hypothesis, we first define sample-level *correctness* by comparing ensemble predictions of all the language models with gold labels. Then, with the obtained ensemble predictions, we examine correlations between linguistic features and correctness via the OLS method (Kuchibhotla et al., 2019) across the five context categories.

Based on obtained correlation analysis, we select a subset of features and list them with their expected impact in Table 2. Next, we use GPT-3.5-Turbo to modify validation and test segmented sentences to alter linguistic features for counterfactual evaluation using the prompt (See Table 3). We provide examples of modified sentence with respect to a set of linguistic features in Table 1). Finally, the modified sentences are used for inference with the trained LMs to verify the if the counterfactual are able to change the predictions or not as expected.

5 Results & Discussion

Table 4 shows the percentage of linguistic features (lf) that were significantly correlated with prediction mistakes in dev and test set across the five context tasks (See details in Table 12 - 18). We consider seven most common linguistic features for which we obtain *llm* modification across the five context tasks. Table 1 presents examples of linguistic modifications generated via GPT-3.5-Turbo for each of the selected linguistic feature. Additionally, we measure and provide the overall feature shift shown in Table 2 as modified dataset compared to the original average lf distribution. Table 5 presents the detailed results on original and modified dataset for test set. We also report broader linguistic categorization for each selected features based on (Lee and Lee, 2023) documentation in Table 11.

Finding I: Writing style variation impacts models' ability to understand clinical narratives.

CONTEXT	Action	Actor	Certainty	Negation	Temporality
DEV	3.64	42.27	27.73	12.27	67.73
TEST	11.82	37.73	21.36	7.73	9.55

Table 4: % of linguistic features that are significantly (ρ<0.05) correlated with prediction mistakes.

Among the five context tasks, *Actor*, *Certainty*, and *Temporality* are most affected by variation in linguistic features (see Table 4). In the test set, *Negation* appears to be least influenced by linguistic features, whereas in the development set, *Action* showed the least impact, indicating inconsistency across datasets. As shown in Table 11, lexico-semantic and syntactic feature families account for the majority of significant correlations with model prediction correctness, suggesting that models may be relying on surface stylistic cues rather than meaningful medical context distinctions. The exception is observed for *Actor* and *Negation*, where discourse-related linguistic features play a dominant role. Overall, these findings reinforce that writing style variation substantially shapes how models interpret and process clinical narratives.

Models	Action	Actor	Certainty	Negation	Temporality
BERT	51.84	44.70	52.80	49.54	48.30
ModernBERT	43.55	35.83	42.54	63.90	53.58
BioClinicalBERT	49.13	50.38	48.77	49.54	50.12
PubmedBERT	71.48	49.95	53.65	49.54	39.37
ENSEMBLE	52.50	50.20	50.20	49.50	48.50
#unique_nouns	-0.7	+1.0	-1.9	±0.0	+1.5
simple_verbs_variation	+2.1	-6.3	+5.2	±0.0	+0.3
#unique_adverbs	-1.0	+0.9	-1.9	±0.0	-1.7
root_verbs_variation	-0.7	-3.0	+0.6	±0.0	-1.3
#named_entities_person	-0.3	-2.2	±0.0	±0.0	+0.1
simple_type_token_ratio	-0.2	-6.8	+3.8	±0.0	+1.5
avg_syllables_per_word	-2.7	-4.1	-1.2	±0.0	+2.6

Table 5: Ensemble context classification results (Macro F1) under counterfactual feature shift on the test set. Green indicates expected outcomes, red indicates unexpected outcomes, and gray denotes excluded cases.

Finding II: Linguistically-guided counterfactuals show potential to mitigate impact of writing style variation. Compared to ensemble baseline performance across all the five tasks, counterfactual modified dataset leads to both gains and losses depending on the linguistic feature are modified (See Table 5). Complete results are in the Appendix B. Concretely, for overall ∼60% cases the modified dataset via counterfactuals leads to the expected behavior. *Negation* remains relatively invariant across all feature shifts, however for *Actor*, *Certainty* and *Temporality*, we obtain mixed behavior. *Actor*, *Certainty* are the most affected showing significant performance change under *simple_verbs_variation* and *simple_type_token_ratio* respectively. Conversely, *Action* and *Negation* seems to experience least changes on when subjected to linguistic feature shift. These results suggest that further confirms that linguistic variations can both degrade and enhance contextual understanding suggesting a more non trivial phenomena.

	Modification Type	Example
LOW	Underspecification	This is rather a simple infection, and may be treated with Ancef. This is rather a simple cellulitis, and may be treated with Ancef.
MODERATE	Overspecification	Reinitiated Lasix promptly. Reinitiated Lasix.
	Entity	She was started on Xenical by two doctors. She was started on Xenical by Internal Medicine.
	Coreference	insulin dosing per Dr. Nettles. Dr. Nettles has been eating and drinking insulin dosing per Dr. Nettles. She has been eating and drinking
HIGH	Content Violation	No John with Mary given possible Sarah bleed. No heparin with HD given possible GI bleed.
	Numeric	2 liters of IV fluid, came up to 90s/50s. 5 liters of IV fluid, came up to 90s/50s.

Table 6: Different LLM generated counterfactuals categorized based on medical risk.

lf	LOW	MODERATE	HIGH
#unique_nouns	79.6	10.2	10.2
simple_verbs_variation	65.3	14.3	20.4
#unique_adverbs	89.8	8.2	2.0
root_verbs_variation	98.0	0.0	2.0
#named_entities_person	65.3	14.3	20.4
simple_type_token_ratio	95.9	2.0	2.0
avg_syllables_per_word	93.9	6.1	0.0

Table 7: Categorization of Counterfactual Explanation based on clinical relevance risk.

Finding III: Linguistic-guided counterfactuals are double-edged sword. The use of LLM to generate counterfactuals by default is prone to produce hallucinations. Therefore, we analyse the modified sentences (see Table 1) for hallucination to understand the clinical relevance distortion [4]. We consider 50 segmented sentences that are modified with respect to seven linguistic features via GPT-3.5-Turbo. We manually annotate each of the modified sentence (50x7=350) for the level of potential medical relevance distortion risk into three categories: low, moderate, and high (see Table 6). For LOW risk, we consider modifications that involve under-specification of any linguistic unit i.e., plausible but unsupported modifiers. For MODER-

[4]Medical relevance distortion denotes to what extent the counterfactual deviates from original sentence on clinical ground.

ATE risk, we consider modification of clinically relevant content while remaining linguistically plausible. For HIGH risk, we consider violations of transformation constraints.

Among the seven features we utilized for generating counterfactuals, based on 50 instances, we observed that *named_entities_nouns*, *unique_nouns* leads to high risk counterfactuals whereas *root_verbs_variation* leads to low risk counterfactuals. We present in distribution in Table 7.While HIGH risk modifications, due to distortion of medical relevance, can mislead the models to deviate from intended downstream tasks. LOW and MODERATE level modifications can be useful to augment the model to overcome class imbalance or lack of clinical annotated data.

6 Conclusion

In this study, we investigated the impact of writing style variation on medical context classification task performance of pre-trained language models. Our findings indicate that stylistic variation in clinical narratives can lead to difference in medical context interpretation of language models. Our study highlights the impact of considering writing style heterogeneity, suggesting that incorporating stylistic normalization via counterfactual explanation generation could enhance model robustness. While the counterfactuals explanation can often require clinical validation, otherwise, it can positively contributes to address the lack of clinical annotated data.

Limitations

While the study highlights the impact of writing style variation on language models in medical domain, we acknowledge the following limitations to the best of our knowledge.

- Firstly, the study focuses primarily on linguistic features and does not account for other potential sources of variation, such as differences in clinical knowledge or documentation practices.
- Secondly, our case study examines the effect on selected downstream tasks from correlation angle, and therefore findings may not generalize to all possible confounders.
- And finally, our study focuses on pre-trained language models considering practical deployment settings and encourage future studies to generalize the finding of LLMs.

Acknowledgments

We would like to extend our thanks to the anonymous reviewers. Additionally, we would also like to express thanks to Cristina Garcia Holgado and Timothée Mickus for the valuable discussion on the initial version of this work.

A More Information for CMED Dataset

The CMED dataset contains clinical notes that came from the Partners HealthCare Electronic Medical Records (EMR). EMR at Partners HealthCare comprises a platform shared by two large academic tertiary hospitals – Massachusetts General Hospital (MGH) and Brigham and Women's Hospital (BWH), USA. The five context categories description are below:

Action	What is the change discussed?
Actor	Who initiated the change?
Certainty	How likely is this change to have occurred / will occur?
Negation	Is the change being discussed negated?
Temporality	When is this change intended to occur?

Table 8: Description of Medical contextual event classification tasks.

The distribution of classes across the different context tasks for train set is shown in Figure 1.

B Detailed Test Results

Models	Action	Actor	Certainty	Negation	Temporality
BERT	51.84	44.70	52.80	49.54	48.30
ModernBERT	43.55	35.83	42.54	63.90	53.58
BioClinicalBERT	49.13	50.38	48.77	49.54	50.12
PubmedBERT	71.48	49.95	53.65	49.54	39.37
ENSEMBLE	52.50	50.20	50.20	49.50	48.50
#unique_nouns	51.80	51.20	48.30	49.50	50.00
simple_verbs_variation	54.60	43.90	55.40	49.50	48.80
#unique_adverbs	51.50	51.10	49.50	49.50	46.80
root_verbs_variation	51.80	47.20	50.80	49.50	47.20

simple_type_token_ratio	52.30	434.00	54.00	49.50	50.00
avg_syllables_per_word	49.80	46.10	49.00	49.50	51.10

Table 9: Ensemble context classification results (Macro F1) under counterfactual feature shift on the test set (Complete Results).

Table 9 presents the experiment results in detail. The top section contains the five context categories across all four PLMs, along with the ENSEMBLE results. The bottom section comprises ensemble results corresponding to linguistic features listed in each row when the models are trained with a

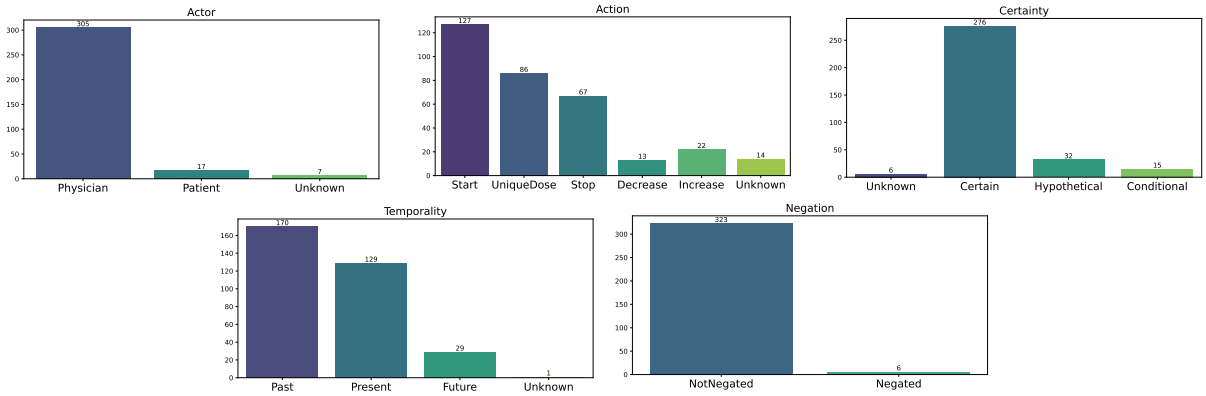

Figure 1: Distribution of context labels across CME2 trainset.

dataset with modified linguistic features. For instance, compared to the ENSEMBLE, when the model is trained with the dataset with modified #unique_nouns feature, the performance of the ENSEMBLE changes in an expected manner (See table 2) for Action, Actor, Temporality, highlighted by green, and unexpected manner for Certainty.

C Reproducibility

All the model were trained on the same hyperparameter setting.

Batch Size	4
Learning Rate	1e-5
Loss Function	Focal Loss
EPOCHS	20
Early stopping	True
Patience	3
MAX LEN	128

Table 10: Hyperparameter Setup.

D Linguistic Features

Table 19-20 list all the linguistic features that can be extracted from BEA (Lee and Lee, 2023) extractor tool.

Action	Actor	Certainty	Negation	Temporality
avg_brysbaert_age_of_acquisition_of_words (avgworddiff, lex-sem)	#unique_verbs (partofspeech, syntax)	corrected_verbs_variation (lexicalvariation, lex-sem)	simple_adpositions_variation (avgworddiff, lex-sem)	#unique_punctuations (partofspeech, syntax)
corrected_adverbs_variation (lexicalvariation, lex-sem)	#named_entities_cardinal (entity, discourse)	root_verbs_variation (lexicalvariation, lex-sem)	#named_entities_product (entity, discourse)	simple_type_token_ratio_no_lemma (typetokenratio, lex-sem)
root_adverbs_variation (avgworddiff, lex-sem)	avg_adverbs_per_word (partofspeech, syntax)	avg_particles_per_word (partofspeech, syntax)	smog_index (readformula, surface)	simple_type_token_ratio (typetokenratio, lex-sem)
#unique_nouns (partofspeech, syntax)	#named_entities_loc (entity, discourse)	avg_adjectives_per_word (partofspeech, syntax)	avg_named_entities_loc_per_word (entity, discourse)	simple_punctuation_variation (lexicalvariation, lex-sem)

KALIMBA: Knowledge-Assisted Literature Mining for Biological Interaction Analysis

Abstract

The exponential growth of biomedical literature has made manual curation of biological interaction networks increasingly difficult. Existing automated biological interaction extraction systems address the scaling challenge but treat extraction as a final step, delivering structured output with limited or no integrated support for biologists to interactively verify, correct and contextually interrogate extracted interactions against their source evidence within the same environment. We present Knowledge-Assisted Literature Mining for Biological Interaction Analysis (KALIMBA), an end-to-end, human-in-the-loop platform that integrates three complementary extraction methods (NLP-only, LLM-only, and hybrid) alongside expert annotation and evidence-grounded conversational querying through retrieval-augmented generation (RAG) chat module driven by a dual-context prompt, within a single unified workflow. Evaluation on a corpus of 40 signaling-focused papers demonstrates that the LLM-only back-end recovers substantially more interactions than the NLP-only approach. RAG chat evaluation by a domain expert confirms that the conversational module provides scientifically grounded responses that support curation decisions beyond what the structured interaction table alone conveys.

1 Introduction

The curation of large-scale biological knowledge graphs is an important challenge in systems biology, as these structured representations of molecular interactions underpin mechanistic modeling of signaling pathways, disease mechanisms, and drug response Lo Surdo et al. (2017); Milacic et al. (2024); Oughtred et al. (2019); Türei et al. (2021). These knowledge graphs are populated from interactions reported across tens of thousands of primary research articles Szklarczyk et al. (2016). Databases such as SIGNOR Lo Surdo et al. (2017), PathwayCommons Rodchenkov et al. (2020), and BioGRID Oughtred et al. (2021) represent decades of expert curation, yet the rate of new discoveries consistently outpaces the capacity of manual curation to keep them current.

Significant research effort has been devoted to automating the extraction of biological interactions from the primary literature. Rule-based natural language processing (NLP) systems such as REACH Valenzuela-Escárcega et al. (2015), and INDRA Gyori et al. (2017) have demonstrated the feasibility of extracting structured regulatory interactions from biomedical articles at scale. The INDRA system in particular has established a strong foundation by integrating multiple reading engines and databases, and producing interactions in a standardized, machine-readable format with associated belief scores, which represent the confidence that a relationship is correct.

Despite this progress, existing systems share a common limitation: interaction extraction is their final step and there is no interface for annotating the quality or completeness of individual fields, or for asking follow-up questions about the context of reported findings. This disconnect between automated extraction and domain-expert judgment represents a significant barrier to further adoption of text mining tools in curation workflows.

Large language models (LLMs) offer a compelling opportunity to close the gap simultaneously from both ends. On the extraction side, LLMs provide broader coverage than rule-based NLP systems. On the curation side, the same conversational capabilities that make LLMs effective at extraction also make them natural assistants for post-extraction verification: a domain expert can query the source evidence behind a specific interaction, ask follow-up questions about experimental conditions, and receive grounded, context-aware responses without ever leaving the curation interface. A principled hybrid approach that combines the precision of established NLP systems with the

July 3-4, 2026 ©2026 Association for Computational Linguistics

coverage and conversational capabilities of LLMs, while keeping a domain expert in the loop throughout the entire workflow, has not yet been realized in a single integrated platform.

In this paper, we introduce Knowledge-Assisted Literature Mining for Biological Interaction Analysis (KALIMBA), a human-in-the-loop curation platform that addresses these limitations by unifying automated interaction extraction, expert annotation, and evidence-grounded conversational querying within a single integrated workflow. KALIMBA treats knowledge curation as a collaborative process between automated systems and domain experts, keeping the expert actively engaged throughout the entire workflow.

2 Related work

Biological interaction and relation extraction. Early approaches to automated extraction of biological interactions relied on rule-based pattern matching and dependency parse trees to identify regulatory relationships between named entities in biomedical text. The REACH Valenzuela-Escárcega et al. (2015) system demonstrated that rule-based event extraction could recover mechanistic interactions from biomedical abstracts and full-text articles. INDRA Gyori et al. (2017) built on this foundation by integrating multiple reading engines into a unified assembly pipeline that produces computable statements with associated belief scores, enabling downstream pathway modeling and network assembly.

The emergence of language models has substantially expanded the capabilities of biomedical information extraction. BioBERT Lee et al. (2020) is a domain-specific language model pre-trained on large-scale biomedical corpora that significantly outperforms general-domain BERT Devlin et al. (2019) on biomedical named entity recognition and relation extraction.

Human-in-the-loop curation tools. Human-in-the-loop approaches have been widely applied in biomedical knowledge curation, ranging from active learning frameworks that reduce annotation effort to web-based manual annotation interfaces designed for structured text labeling. BRAT Stenetorp et al. (2012) is an intuitive web-based tool for text annotation supported by NLP technology and has been widely adopted for constructing gold-standard evaluation datasets across a range of biomedical NLP tasks. More recently, OntoChat Zhang et al. (2024) demonstrated that conversational language model agents can meaningfully assist domain experts throughout a knowledge engineering workflow without requiring programming expertise. KALIMBA extends this principle to biological interaction curation, applying conversational LLM assistance to the verification and contextual exploration of automatically extracted interactions grounded in primary literature evidence.

3 Methods

3.1 System Overview

KALIMBA is an end-to-end, human-in-the-loop platform for the automated extraction, structured curation, and interactive verification of biological regulatory interactions from primary biomedical literature. The system comprises two functional layers: an automated literature retrieval and extraction layer supporting three complementary methods, and a human-in-the-loop curation layer integrating expert annotation, RAG-based conversational querying, carefully engineered prompt template, and data import and export. A schematic overview of the full system architecture is presented in Figure 1.

3.2 Literature Retrieval

KALIMBA supports two entry modes that determine how paper content enters the pipeline. In search mode, the user queries PubMed directly through the interface, selects papers from the returned results, and abstracts are cached as part of the search session before extraction begins. In import mode, the user loads a previously extracted BioRECIPE Holtzapple et al. (2024) interaction list directly into the curation layer, bypassing extraction entirely and proceeding immediately to annotation, quality rating, and RAG-based conversational querying.

BioRECIPE is a structured biological interaction representation in a human-readable format, and KALIMBA's import and export including its built-in annotation tool support BioRECIPE format. BioRECIPE has 28 fields, including regulator and regulated entity names, interaction sign, mechanism, cellular compartment, cell line, tissue type, and supporting evidence statement.

For search mode, paper content is retrieved from National Center for Biotechnology Information (NCBI) through a cascading three-step strategy using the Entrez Utilities (E-utilities) RESTful

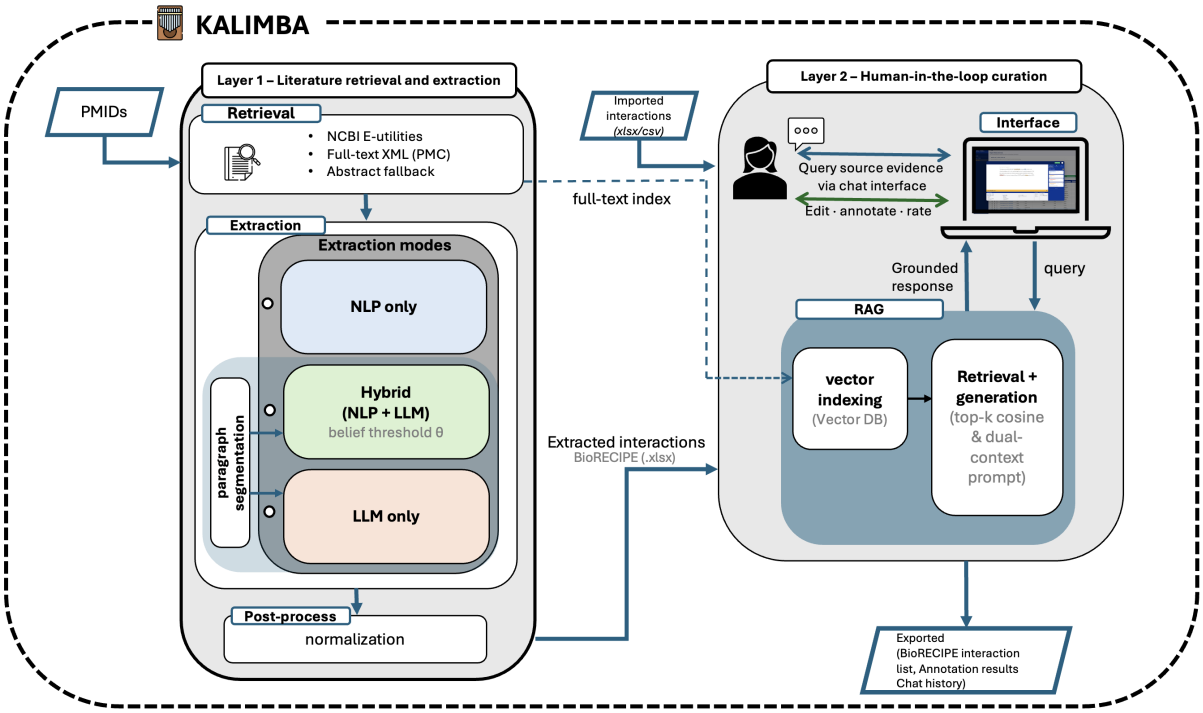

Figure 1: Overview of the KALIMBA framework

API Kans (2025). First, an elink call maps all input PMIDs simultaneously to their corresponding PubMed Central (PMC) identifiers; only PMIDs yielding a valid PMC entry are carried forward. Second, a single batch efetch call downloads full-text XML for all linked articles in one request. Body content is extracted by collecting all <p> elements within the <body> tag and joining them with double-newline separators to preserve paragraph boundaries. Third, a conditional efetch call retrieves PubMed abstracts for papers lacking PMC full-text coverage; this call is skipped entirely when abstracts are already cached from the search session, reducing total API calls to two for the common case.

Full-text content retrieved from PMC serves exclusively as the document corpus for RAG vector indexing (Section 3.7) and is not used as input to the extraction pipeline. Interaction extraction operates uniformly on abstract text for all input papers, regardless of full-text availability. This design choice ensures that extracted evidence statements are grounded in a consistent, universally available text source, preventing systematic differences in extraction quality between papers with and without PMC full-text coverage. In import mode, full-text content is fetched on demand at chat time if no index exists for the imported interaction's source papers, ensuring that RAG-based conversational querying remains available regardless of entry mode.

3.3 Paragraph Segmentation

Prior to extraction using LLM, each abstract is segmented into focused text units to constrain the language model's context window and to ensure that the Statements attribute of each extracted interaction is populated with a precise, traceable passage from the source text. This paragraph-level design serves two purposes: it focuses each extraction call on a narrow, semantically coherent passage, and it guarantees that the verbatim source text used by the annotator in the curation layer (Section 3.6) corresponds exactly to the context seen by the extraction model.

3.4 Interaction Extraction

KALIMBA exposes three configurable extraction methods, selectable at runtime via the interface (Appendix A).

NLP-only mode: Interactions are extracted via the INDRA reading pipeline, which uses NLP readers to process paper contents.

LLM-only mode: Each abstract paragraph produced by the segmentation stage (Section 3.3) is submitted independently to a language model with a structured prompt (Figure 2). KALIMBA is designed to be model-agnostic, supporting both open-

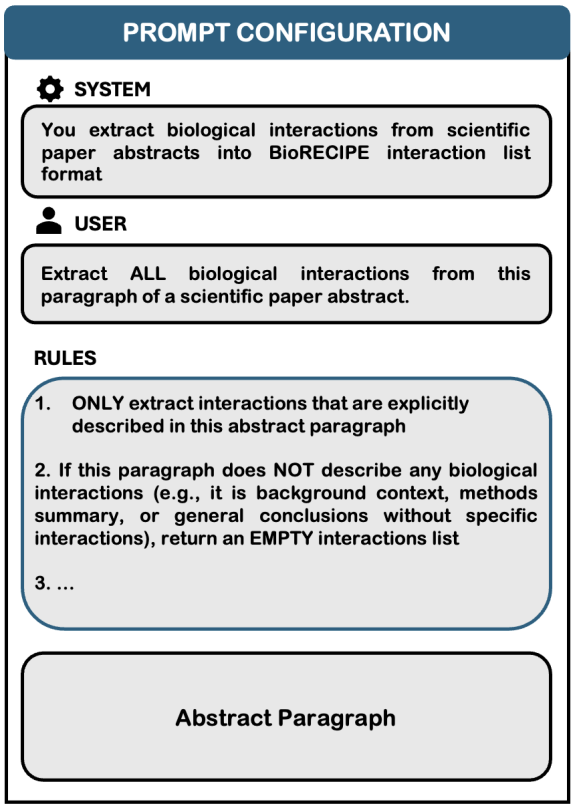

Figure 2: System and user prompt template for paragraph-level extraction.

source models served through the Ollama API and any OpenAI-compatible remote endpoint, allowing researchers to select the language model that best fits their computational resources, data privacy requirements, and performance needs.

Hybrid mode: The rule-based NLP-driven tool is applied first across all input papers. Interactions meeting a configurable belief score threshold (default $\theta = 0.7$) are retained directly. Papers with no NLP output, and papers with interactions that fall entirely below the belief threshold, are passed to the LLM extraction path. If LLM extraction subsequently fails for any paper in this set, the low-confidence interactions are preserved as a fallback rather than discarded. This strategy maximizes recall by using the LLM's broad coverage while preserving the precision of high-confidence traditional NLP extractions, avoiding the need to choose between the two approaches. The balance between NLP and LLM contributions is controlled by the belief threshold θ, which is developed as a continuous slider in the interface (range 0-1) that biologists can adjust before initiating extraction. This design gives biologists direct, interpretable control over the precision-recall trade-off without requiring any knowledge of the underlying implementation.

3.5 Post-Processing

All extracted interactions undergo post-processing normalization, which resolves non-standard field values and recovers a subset of missing fields through controlled vocabulary mapping and external database lookup. Type attributes are mapped to a controlled vocabulary of six categories: protein, gene, chemical, RNA, protein family, and biological process. Biological database identifiers are validated against type-appropriate sources, UniProt UniProt Consortium (2015) for proteins, HGNC Seal et al. (2023) for genes, PubChem Kim et al. (2016) for chemicals, Ensembl Harrison et al. (2024) for RNA, Pfam Mistry et al. (2021) for protein families, and Gene Ontology Gene Ontology Consortium (2019) for biological processes. Subcellular compartments are resolved and standardized against a set of seven canonical cellular locations, each matched with its corresponding Gene Ontology component ID. Mechanisms are similarly standardized by matching extracted values against a controlled vocabulary of 13 terms. Entity names unresolved during extraction are looked up asynchronously against the UniProt REST API (proteins and genes), HGNC (gene symbols), PubChem (chemicals), and the EBI QuickGO service (biological processes). Rows lacking either a regulator or regulated entity name, or missing an evidence statement, are discarded. The Source attribute is set programmatically to reflect the extraction origin of each row.

3.6 Human-in-the-Loop Curation and Annotation

A distinguishing feature of KALIMBA is its integrated human-in-the-loop curation layer, which treats automated extraction not as a final product but as a first-pass draft, subject to expert review and correction. The curation interface is implemented as an in-browser interaction table that uses the BioRECIPE interaction representation format with inline editing, per-row deletion, and column-level text filtering.

Each extracted interaction is linked to the verbatim paragraph text submitted to the extraction model, providing a traceable evidence statement against which automated field values can be verified. Clicking any statement opens the text annotation interface, where the evidence sentence is displayed with span highlights already pre-populated

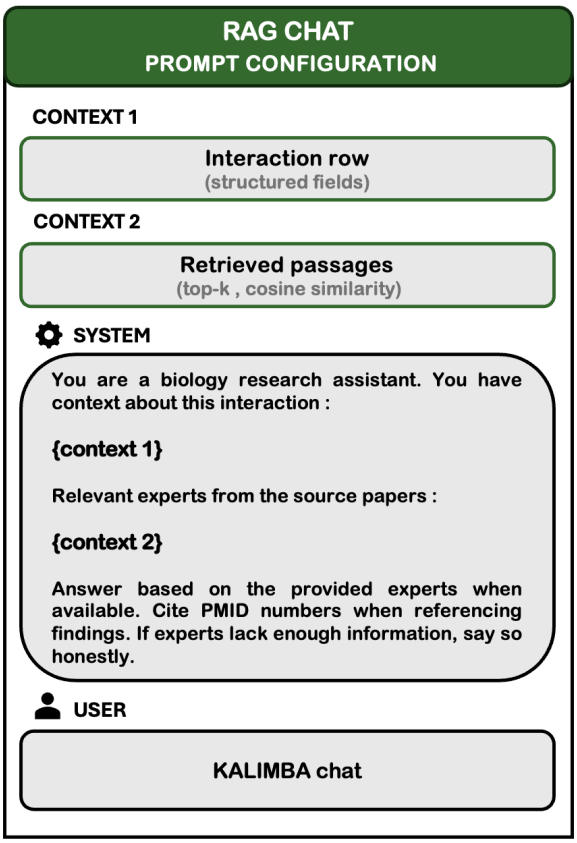

Figure 3: Dual-context prompt structure for RAG-based conversational querying.

from the extracted field values. From there, the biologist can verify whether each highlighted span correctly corresponds to its assigned BioRECIPE attribute, adjust any incorrect highlights, or add new ones for fields that the model left empty.

The interface also supports per-field quality rating and commentary, an overall interaction-level quality score, and a free-text general note field. The resulting structured evaluation data serves as a rich human feedback signal for downstream model evaluation and fine-tuning.

3.7 Retrieval-Augmented Interaction Chat

While interaction databases usually capture rich contextual information such as cell type, tissue, or experimental condition, domain experts often need to return to the primary literature to interrogate the full experimental context behind a specific interaction. KALIMBA addresses this through a tightly integrated RAG chat module that enables domain experts to query the source literature in natural language, anchored to a specific extracted interaction.

During the extraction phase in chat module, full-text content retrieved from PMC is segmented into overlapping 500-word chunks with a 100-word stride, preserving local semantic coherence while enabling retrieval at sub-section granularity. Each chunk is encoded into a dense vector representation using a sentence embedding model and stored in a vector database indexed by cosine similarity.

For papers unavailable in PMC, abstract text is indexed as a fallback. If no pre-built index exists at query time, for instance, when a user initiates chat on an interaction imported from an external file rather than extracted within the current session, full-text fetching and indexing are triggered on demand.

At query time, the user's natural language message is encoded using the same model and the top-k most similar passages (default k = 5) are retrieved by approximate nearest-neighbor search over the session collection. Retrieved passages are injected into the language model's system prompt alongside the structured format with attributes of the selected interaction (Figure 3). This dual-context design grounds responses simultaneously in the structured semantics of the BioRECIPE format (context 1) and in the unstructured experimental narrative of the source paper (context 2), reducing the risk of hallucinated mechanistic claims that are not supported by the cited evidence.

This capability represents a qualitatively different mode of engagement with curated biological knowledge. A researcher inspecting an extracted phosphorylation interaction can immediately ask: "What experimental method was used to validate this interaction?" or " Did the authors note any dose-dependent effects?". These questions can directly help curator in completing and enriching structured interaction records.

3.8 Data Import and Export

To ensure compatibility with a range of systems biology tools Kanehisa et al. (2016); Luo et al. (2026); Milacic et al. (2024); Pratt et al. (2015) and to support KALIMBA as a standalone curation environment, the system includes an import layer accepting BioRECIPE formatted files.

KALIMBA provides three structured export formats. The interaction list export produces a single-sheet Excel workbook with one column per BioRECIPE attribute, suitable for direct use in downstream pathway modeling tools. The annotation export produces a four-sheet workbook capturing span-level annotation details, per-interaction summaries, per-attribute quality ratings, and a full rating matrix. The chat history export produces a

two-sheet workbook containing message-level dialogues and conversation summaries, with each row enriched with the full BioRECIPE context of the discussed interaction.

Methods	Total interactions	Papers	
		covered	no output
NLP-only (INDRA)	392	24	16
LLM-only (LLaMA 3.1)	363	39	1
Hybrid ($\theta = 0.7$)	388	39	1

Table 1: Extraction coverage across methods.

Source	Extraction origin	Interactions	
		count	percentage
LLM	papers INDRA missed	191	49.2%
	low-confidence INDRA, score < 0.7	161	41.5%
INDRA /REACH	high-confidence, score ≥ 0.7, retained	32	8.2%
INDRA /Sparser	high-confidence, score ≥ 0.7, retained	4	1.0%
Total		**388**	**100%**

Table 2: Distribution of hybrid mode interactions.

4 Experiments

4.1 Experimental Setup

Dataset. To evaluate KALIMBA's extraction capabilities, we used a corpus of 40 signaling-focused biomedical papers from high-impact journals including Cell and Nature, published between 2023 and 2026. selected by a domain expert. The corpus is biased toward the RAS and JAK signaling pathways while maintaining diversity across related signaling contexts. Papers involving immune cell signaling were excluded due to the subtleties of cell-type-specific signaling that introduce additional ambiguity beyond the scope of this evaluation.

Models. For the LLM-only and hybrid extraction, we used a locally hosted open-source model (LLaMA 3.1 8B served via the Ollama API) Grattafiori et al. (2024). Although KALIMBA supports remote OpenAI-compatible endpoints such as GPT-4o Hurst et al. (2024), we used LLaMA configuration in this evaluation to avoid API costs and to demonstrate that KALIMBA produces meaningful extraction results without requiring access to closed-source API-dependent models. All experiments were conducted on a MacBook Pro with an Apple M3 Pro chip and 18 GB memory.

Metrics. The 40 papers were processed through all three extraction methods independently. Extraction outputs were compared across methods in terms of paper coverage, total interaction yield, inter-mode agreement, and confidence score distribution. For the RAG chat evaluation, a domain expert curated a set of standardized questions per interaction and rated the system responses on a 0-to-5-star scale, providing qualitative notes for each response.

4.2 Extraction Performance

Table 1 reports the total number of interactions extracted per mode and the number of papers for which at least one interaction was recovered across the full 40-paper corpus. The NLP-only back-end failed to produce any interactions for 16 of the 40 papers. All 16 of these papers were successfully processed by the LLM-only method, demonstrating that the LLM provides substantial coverage recovery for papers outside NLP's effective range. The hybrid mode inherits the LLM's coverage advantage, recovering interactions from 39 of 40 papers while retaining high-confidence NLP extractions where available.

Table 2 reports the source breakdown of interactions in the hybrid output, characterizing the practical contribution of each component.

Only 9.2% of hybrid interactions were contributed directly by high-confidence NLP output. The remaining 90.7% were produced by LLM re-extraction either for papers NLP missed entirely (49.2%) or for papers where NLP's belief scores fell below $\theta = 0.7$ (41.5%). This distribution confirms that the hybrid routing strategy is functioning as designed: NLP's precision is preserved for the interactions it handles confidently, while the LLM fills in coverage for the substantial portion of the corpus that NLP either cannot process or does not assign high confidence scores.

4.3 Confidence and Inter-Mode Agreement

Table 3 reports the confidence score distribution per method. NLP-only scores cluster narrowly between 0.650 and 0.980, reflecting NLP's con-

Method	Mean	Median	Min	Max
NLP-only (INDRA)	0.67	0.65	0.65	0.98
LLM-only (LLaMA 3.1)	0.87	1.00	—	1.00
Hybrid ($\theta = 0.7$)	0.85	0.90	0.00	1.00

Table 3: Confidence score distribution per method.

servative belief scoring system. The LLM-only back-end assigns higher scores on average, but these scores are self-reported and do not guarantee extraction correctness. A limitation directly observed in the RAG chat evaluation, where a highly confident but incorrectly extracted interaction received zero stars across all expert questions.The hybrid mode achieves a higher mean score than NLP-only alone as a direct consequence of the low-confidence NLP interactions are replaced by LLM re-extractions that receive higher confidence scores. Table 4 reports pairwise interaction overlap across the three methods, which show remarkably low agreement, with only 9 interactions agreed upon by all three methods. These 9 interactions include canonical RAS pathway relationships such as MEK→ERK and RASA1→RAS, providing a validity check that all three methods correctly capture well-established signaling interactions. The substantially higher LLM–Hybrid overlap (129 pairs) compared to NLP–LLM overlap (10 pairs) reflects the fact that 90.7% of hybrid interactions are LLM-derived, making these two the most similar pair. The low overall consensus confirms that the three methods are largely complementary rather than redundant, each recovering a distinct subset of the interactions present in the corpus and strengthening the case for the hybrid design.

4.4 RAG Chat Quality Evaluation

To evaluate the RAG-based conversational querying module, a domain expert curated a set of six standardized questions that were defined targeting distinct aspects of the supporting evidence.

Each response was rated by the domain expert on a 0-to-5-star scale and followed by a qualitative curator note where responses were incomplete or incorrect. A total of 47 responses were evaluated across 8 interactions. Table 5 shows that the overall mean rating of 2.64 out of 5 is largely driven down by one incorrectly extracted interaction that received 0.00 across all questions. Excluding it, the

Comparison	Shared pairs	Unique to first	Unique to second
NLP-only vs LLM-only	10	325	231
NLP-only vs Hybrid	44	325	221
LLM-only vs Hybrid	129	231	221
Agreed by all three	9	—	—

Table 4: Pairwise interaction overlap across methods (regulator and regulated name matches, n=40 papers).

adjusted mean rises to 3.27 out of 5 with 83.7% of responses rated 3 stars or above, indicating strong performance for correctly extracted interactions

Qualitative findings. Expert review of curator notes revealed three recurring patterns. First, RAG chat quality is tightly coupled to extraction correctness. The interaction AMP-activated protein kinase → glucose metabolism received a rating of 0.00 across all six questions because the interaction direction was incorrectly extracted. This finding suggests that the chat module itself can serve as a verification tool when responses are inconsistent with biological expectations. This further signals to the expert that the underlying extracted interaction may be incorrect and warrants correction in the annotation layer before further querying.

Second, the system performs strongest on directional and pathway-level questions. Activation vs. inhibition questions received the highest mean rating (3.50) and signaling pathway context questions the second highest (3.12). These question types are most directly answerable from the dual-context prompt that combines the structured BioRECIPE row with the retrieved passages, and the results suggest this design provides reliable grounding for sign and pathway membership queries.

Third, mechanistic and experimental evidence questions are more challenging. Biological mechanism (2.12) and cell line (2.00) questions received the lowest ratings. Expert notes identified two specific failure modes: responses occasionally cited literature referenced within retrieved passages rather than the experimental findings of the paper itself, and responses sometimes provided accurate but incomplete summaries of experimental evidence, omitting key details such as specific phosphorylation site identification, mutational analyses, and

tissue-specific knockout results.

Question type	Rating	
	mean	% rated ≥ 3 stars
Activation vs inhibition	3.50	75.0%
Signaling pathway context	3.12	87.5%
Explicit statement verification	2.75	62.5%
Experimental evidence	2.25	75.0%
Biological mechanism	2.12	62.5%
Cell line / condition	2.00	71.4%
Overall	2.64	72.3%

Table 5: Mean expert ratings of RAG chat responses by question type (n=47, scale 0–5).

Expert Utility Assessment. Following the quantitative rating evaluation, the domain expert was asked three follow-up questions regarding the utility of the RAG chat module for biological curation. The expert confirmed that the chat responses provided meaningful additional context beyond the structured interaction row across all evaluated interactions. Three specific advantages were identified. First, the chat module demonstrated the ability to correct upstream extraction errors for example for the incorrectly extracted interaction AMP-activated protein kinase → glucose metabolism, the expert noted that KALIMBA's responses consistently described the correct interaction direction, effectively flagging the extraction error without explicit prompting. Second, for interactions where the connection type was incorrectly assigned as direct or indirect, the chat module provided evidence that allowed the expert to identify and correct the misclassification. Third, in the cases where the structured interaction row did not include any information on experimental evidence, mechanism, site, cell line, cell type, or tissue type, the chat module provided varying degrees of detail across all of these attributes for every interaction, which the expert described as a significant advantage for curation.

The expert confirmed they would use the KALIMBA chat feature in their own literature review and curation workflow.

5 Conclusion

We presented KALIMBA, a human-in-the-loop curation platform that addresses a persistent gap in biomedical text mining: the disconnect between automated interaction extraction and the expert biological judgment required to verify, correct, and contextually interpret extracted knowledge. KALIMBA integrates three complementary extraction methods, a span-level annotation interface, and a retrieval-augmented conversational querying module within a single unified workflow. Together these capabilities treat biological knowledge curation as a collaborative process between automated systems and domain experts rather than a pipeline that terminates at extraction.

Evaluation on a 40-paper signaling-focused corpus revealed several findings with implications beyond KALIMBA itself. The NLP-only method failed to extract any interactions from 40% of the corpus, a coverage gap that the LLM method recovered entirely, demonstrating that LLM-based extraction provides meaningful complementarity to established NLP systems for recent literature. The hybrid mode successfully combined both approaches, with 90.7% of its output contributed by LLM re-extraction and only 9.3% retained directly from high-confidence NLP output, reflecting the corpus composition bias toward recently published papers underrepresented in NLP's knowledge base. Inter-mode agreement was remarkably low, only 9 interactions were agreed upon by all three methods confirming that the three methods are largely complementary rather than redundant, and that each recovers a distinct subset of the interactions present in the literature. The 9 consensus interactions included canonical RAS pathway relationships such as MEK→ERK and RASA1→RAS, providing validity that all three methods correctly capture well-established signaling interactions.

The RAG chat evaluation demonstrated that conversational querying of source evidence provides grounded responses for correctly extracted interactions, with an adjusted mean rating of 3.27 out of 5 and 83.7% of responses rated 3 stars or above when the one incorrectly extracted interaction is excluded. The finding that chat quality is tightly coupled to extraction quality reinforces the importance of the annotation and correction layer as a prerequisite for productive conversational querying. Together these results position KALIMBA as a practical tool for domain experts who need to extract, verify, and explore biological interactions from the primary literature at scale, without requiring computational expertise or access to commercial API services.

6 Limitations and Future Work

The current evaluation has several limitations that are considered for future work. The corpus of the papers that we used has 40 signaling-focused papers recommended by domain experts, which is very rich in terms of studying the signaling pathways, particularly in the RAS and JACK signals, but it is not constructed as a dataset of gold standard interaction extraction in BioRECIPE format, so the extraction results are reported in terms of coverage not in accuracy related metrics such as precision, recall and F1 against a gold standard dataset. Evaluating the accuracy of extractions using an expanded, more diverse corpus is a priority for our future work. For the RAG chat evaluation, we relied on a single-domain expert who rated 47 responses across 8 interactions using a structured set of question types. In future work, we will add more independent evaluators to strengthen the reliability of these findings and compute an inter-annotator score to generalize the results. To make the system more user-friendly, a formal usability evaluation of the interface with domain expert biologists is planned as future work.

The current prompt template follows a general instruction-based design. Future work will improve extraction performance by incorporating curated few-shot examples into the prompt and evaluating results using commercial models such as GPT-4o.

Abstract

Medical question answering is a high-stakes setting where factual errors can have serious consequences. Retrieval-augmented generation (RAG) is widely viewed as a promising solution, and prior work has reported substantial gains for large medical QA models. We revisit this assumption across a broad range of open-weight instruction-tuned models spanning 7B to 72B parameters. Across five models, ten biomedical QA datasets, four retrieval methods, and four retrieval corpora, we find that retrieval yields only small and inconsistent improvements over a no-retrieval baseline, typically within 1–2 points. In contrast, the choice of backbone model has a much larger effect than the choice of retriever or corpus, and expert and layman retrieval sources perform similarly in most settings. These results suggest that the main bottleneck is not retrieval quality alone, but the model's limited ability to use retrieved evidence effectively. Code is available here: https://github.com/erfan-nourbakhsh/BioMedicalRAG

1 Introduction

Accurate and reliable medical question answering is a high-stakes problem, where errors can have direct consequences for patient safety. Large language models (LLMs) have recently shown strong performance on a range of biomedical question answering tasks (Singhal et al., 2023; Hendrycks et al., 2021; Jin et al., 2021). However, they remain prone to hallucination, producing fluent but factually incorrect responses (Ji et al., 2023), and to knowledge staleness due to their reliance on fixed training corpora. In the medical domain, these limitations are especially problematic because even small factual errors can lead to harmful downstream decisions.

Retrieval-augmented generation (RAG) (Lewis et al., 2020) has become a leading approach for addressing these limitations by grounding model outputs in retrieved external evidence. By incorporating supporting documents at inference time, RAG offers a mechanism for improving factuality, transparency, and access to more current knowledge. As a result, RAG has been adopted widely in biomedical NLP, where recent work has reported substantial gains from retrieval-based methods. For example, Xiong et al. (2024) showed that MedRAG improves biomedical QA accuracy by as much as 18% over chain-of-thought prompting, while Tang et al. (2024) found that multi-agent LLM systems can further improve medical reasoning performance. These findings have led to growing interest in retrieval-centered biomedical QA systems, with increasing attention to the choice of corpora, retrieval methods, and model backbones.

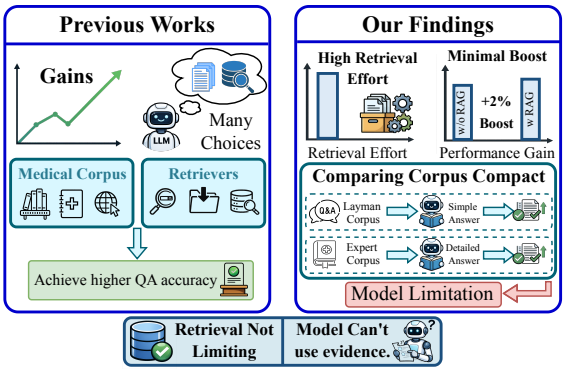

Figure 1: Overview of our motivation and main finding: across models from 7B to 72B, retrieval yields only small gains, suggesting that the main bottleneck is evidence use rather than retrieval quality.

However, an important gap remains. Prior systematic studies of medical RAG (Xiong et al., 2024) have largely focused on large proprietary or 70B-scale models (GPT-3.5, GPT-4, Mixtral-8x7B, Llama2-70B) under zero-shot multiple-choice evaluation, leaving unclear whether their gains carry over to 7B–8B models that are far more practical under real hardware constraints. Existing evaluations have also focused primarily on expert-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 890–910
July 3-4, 2026 ©2026 Association for Computational Linguistics

level biomedical questions, with little attention to consumer-health queries or community-generated retrieval sources.

In this paper, we revisit biomedical RAG under a substantially different and more comprehensive setting. We evaluate five open-weight instruction-tuned models spanning 7B to 72B parameters: Qwen2.5-7B-Instruct (Yang et al., 2025), Llama-3.1-8B-Instruct (Grattafiori et al., 2024), Mistral-7B-Instruct-v0.3 (Jiang et al., 2023), LLaMA-3.1-70B-Instruct (Grattafiori et al., 2024), and Qwen2.5-72B-Instruct (Yang et al., 2025), across ten biomedical QA datasets spanning both lay and expert questions and covering both open-ended and multiple-choice formats. We compare four retrieval methods, BM25, TF-IDF, MedCPT, and Hybrid RRF, across four retrieval corpora, including both expert biomedical resources and consumer-facing health sources: PubMed abstracts, medical textbooks, Yahoo Answers, and HealthCareMagic. We also evaluate against a no-retrieval baseline in order to isolate the contribution of retrieval itself.

Our results challenge the prevailing picture from prior studies. Across all five models, retrieval yields only small and inconsistent gains: the gap between the best retrieval configuration and the no-retrieval baseline is usually within 1–2 points (e.g., BERTScore 62.88 vs. 61.72 for Llama-8B, 63.23 vs. 61.28 for Qwen-7B), and differences across retrieval corpora are similarly modest even for the larger 70B models. By contrast, backbone model choice has a much larger effect than retriever or corpus selection, and expert versus lay retrieval sources differ by less than 2 points in most settings. Figure 1 illustrates the key implication: the limiting factor is not retrieval quality but the generator's capacity to incorporate retrieved evidence.

Our contributions are: (1) A large-scale evaluation of biomedical RAG covering 5 models from 7B to 72B parameters, 10 QA datasets, 4 retrieval methods, and 4 retrieval corpora. (2) We show that retrieval yields only small and inconsistent improvements across all model scales (typically within 2 points), challenging the gains reported in prior large-model studies. (3) We show that backbone model choice matters more than retriever or corpus choice, and provide evidence that the main bottleneck is the model's weak use of retrieved evidence.

2 Related Work

Retrieval-Augmented Generation. RAG was introduced by Lewis et al. (2020) as a method to enhance language models on knowledge-intensive tasks by conditioning generation on documents retrieved from a non-parametric memory. The approach combines a parametric sequence-to-sequence model with a dense passage retrieval component (Karpukhin et al., 2020) and has been extended in numerous directions, including iterative retrieval (Trivedi et al., 2023; Shao et al., 2023), self-reflective retrieval (Asai et al., 2024), and query rewriting (Ma et al., 2023); for a broad survey of RAG paradigms and architectures, see Gao et al. (2023). In the biomedical domain, RAG has been applied to clinical decision support (Xiong et al., 2024), scientific literature search (Jin et al., 2023), and consumer health QA (Li et al., 2023). However, most prior biomedical RAG studies either lack systematic comparison across retrieval configurations or are limited in dataset coverage.

Benchmarking Medical RAG. The most directly related work to ours is the MIRAGE benchmark and MedRAG toolkit by Xiong et al. (2024), which evaluates 41 combinations of corpora, retrievers, and backbone LLMs on five medical QA datasets restricted to multiple-choice questions. MIRAGE shows that RAG can improve LLM accuracy by up to 18% and identifies PubMed combined with BM25 or MedCPT as strong retrieval configurations. However, MIRAGE exclusively uses zero-shot prompting and evaluates primarily large models (GPT-4, GPT-3.5, Mixtral-8×7B, Llama2-70B), leaving open the question of whether these gains hold for smaller, more widely deployable models. Concurrent large-model evaluations, such as Nori et al. (2023), who find that GPT-4 surpasses the USMLE passing threshold by over 20 points even without retrieval augmentation, further underscore that model scale is a critical confound in existing medical benchmarks. Tang et al. (2024) propose a zero-shot multi-agent framework achieving competitive GPT-4 performance on MMLU Medical, yet neither this nor MIRAGE examines retrieval for open-ended or consumer-health queries at the 7–8B scale. Shi et al. (2023) show that irrelevant retrieved passages can mislead LLMs, a concern especially acute for smaller models, while Ovadia et al. (2024) find retrieval augmentation outperforms knowledge fine-tuning primarily for large models, further motivating our cross-scale evalua-

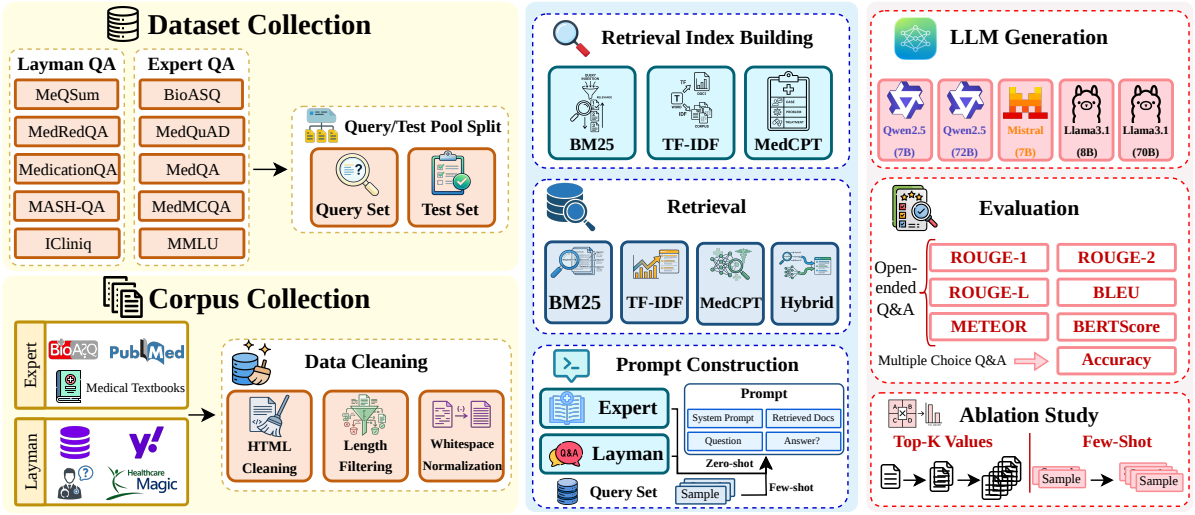

Figure 2: Experimental pipeline overview.

tion.

Biomedical Question Answering Datasets. Biomedical QA has long served as a testbed for evaluating NLP systems in medicine (Krithara et al., 2023; Jin et al., 2021; Pal et al., 2022; Hendrycks et al., 2021). Expert-oriented benchmarks such as BioASQ (Nentidis et al., 2025), MedQA-USMLE (Jin et al., 2021), and MedMCQA (Pal et al., 2022) test clinical and examination-level knowledge, while consumer-health datasets such as MeQSum (Ben Abacha and Demner-Fushman, 2019a), MedRedQA (Nguyen et al., 2023), MedicationQA (Abacha et al., 2019), MASH-QA (Zhu et al., 2020), and ChatDoctor-iCliniq (Li et al., 2023) reflect more informal, everyday health information needs. MedQuAD (Ben Abacha and Demner-Fushman, 2019b) and MMLU Medical (Hendrycks et al., 2021) bridge the two groups by covering structured NIH-sourced QA and standardised medical knowledge. Despite this rich landscape, most RAG studies focus on MCQ-format expert benchmarks and omit the open-ended and layman query types that constitute the bulk of real-world health information needs, a gap we directly address.

Retrieval Methods in Biomedical NLP. Sparse retrieval methods have been dominant in biomedical information retrieval. BM25 (Robertson and Zaragoza, 2009), a probabilistic bag-of-words ranking function, remains a strong baseline and is adopted as the primary retriever in MedRAG (Xiong et al., 2024). TF-IDF (SPARCK JONES, 1972), a simpler precursor that models term specificity without BM25's saturation and length normalisation, provides a useful lower bound for sparse retrieval.

Dense retrieval with domain-adapted encoders has gained traction. MedCPT (Jin et al., 2023) was trained contrastively on large-scale PubMed search logs and demonstrates strong zero-shot biomedical retrieval, outperforming general-domain encoders on medical tasks. Fusion methods such as Reciprocal Rank Fusion (RRF) (Cormack et al., 2009) combine sparse and dense ranked lists and have been shown to outperform individual retrievers without requiring additional training. While MedRAG includes RRF as a configuration, it does not systematically isolate the contribution of each component retriever across diverse query types and corpora, which we do in this study.

3 Experiments

Our experiments systematically compare sparse, dense, and hybrid retrieval strategies across four corpora, ten QA datasets spanning expert and layman health queries, and five open-weight instruction-tuned models ranging from 7B to 72B parameters. Figure 2 provides a visual overview of the full experimental pipeline.

Evaluation Dataset and Knowledge Base.

Evaluation Datasets. We evaluate across ten biomedical and consumer-health question answering datasets grouped into two user types: *layman* datasets reflecting everyday consumer-health language, and *expert* datasets targeting biomedical professionals or medical students. Dataset statistics and split sizes are summarised in Table 7 in Appendix A. For all datasets, examples lacking a

question or a reference answer are discarded before any split is finalised, and whenever random sampling is needed it is performed with a fixed seed of 42.

Layman datasets. **MeQSum** (Ben Abacha and Demner-Fushman, 2019a) contains 1,000 consumer health questions from the U.S. National Library of Medicine. Following Zhang et al. (2022), we reserve 500 examples for evaluation and use the remaining 500 as the few-shot query pool. **MedRedQA** (Nguyen et al., 2023) provides over 51,000 consumer question–physician answer pairs from Reddit's `/r/AskDocs`; we sample 1,000 evaluation examples from the official test split (5,099 examples) and combine the training (40,792) and validation (5,100) splits into the query pool. **MedicationQA** (Abacha et al., 2019) contains 690 real consumer medication questions; we randomly sample 500 for evaluation and retain the remaining 189 as the query pool. **MASH-QA** (Zhu et al., 2020) offers over 34,000 WebMD-derived healthcare Q&A pairs; we randomly sample 1,000 examples from the official test file (2,614 entries) and use the full training set (19,989 examples) as the query pool. **ChatDoctor-iCliniq** (Li et al., 2023) comprises 7,321 real patient–physician conversations from iCliniq.com; we randomly sample 1,000 for evaluation and retain the remaining 6,321 as the query pool.

Expert datasets. **BioASQ Task B** (Nentidis et al., 2025) provides expert biomedical questions grounded in PubMed literature; following the official benchmark protocol, we use the Task 13B golden test set (restricted to summary-type questions, 80 examples) and the Task 13B training set (1,283 examples) as the query pool. **MedQuAD** (Ben Abacha and Demner-Fushman, 2019b) contains 47,457 medical Q&A pairs from 12 NIH websites, of which 16,407 are publicly available; we randomly sample 1,000 for evaluation and use the remaining 15,407 as the query pool. **MedQA-USMLE** (Jin et al., 2021) provides USMLE clinical vignette MCQs; we use the official test split (1,273 examples) for evaluation and the official training split (10,178 examples) as the query pool. **MedMCQA** (Pal et al., 2022) contains 194k+ MCQs from AIIMS and NEET PG medical entrance exams; as the official test split is unlabelled, we randomly sample 1,000 from the validation set (6,150 examples) for evaluation and use the full training set (182,822 examples) as the query pool. **MMLU Medical** (Hendrycks et al., 2021): following Tang et al. (2024), we restrict to six medical sub-tasks, *anatomy*, *clinical_knowledge*, *college_biology*, *college_medicine*, *medical_genetics*, and *professional_medicine*, totalling 1,242 examples. Roughly 100 examples per sub-task (600 in total) are used for evaluation; the remaining 642 form the query pool.

Knowledge Bases. We build four retrieval corpora covering both expert biomedical and layman health domains, as summarised in Table 8 in Appendix A. All corpora are indexed as whole records without further chunking. For Q&A-style corpora (Yahoo Answers and HealthCareMagic), each document concatenates the question or title with the corresponding answer body.

BioASQ / PubMed (Krithara et al., 2023) consists of 16.2 million PubMed abstracts with human-assigned MeSH annotations and serves as the primary expert-domain knowledge base.

Medical Textbooks (Xiong et al., 2024) provides 125,847 retrieval-friendly chunks ($\leq$1,000 characters each) drawn from 18 authoritative biomedical textbooks spanning anatomy, physiology, pharmacology, pathology, and clinical medicine.

Yahoo Answers (Yahoo! Research, 2009) is an open-domain community Q&A corpus; from the original 1.4 million records we retain 1,238,506 after quality filtering, discarding entries whose answer body contains fewer than five words or whose combined question–answer text falls below ten words.

HealthCareMagic (Li et al., 2023) contains 112,165 real-world patient symptom queries paired with detailed physician responses across more than ten clinical specialties.

Retrieval Approaches. We compare four retrieval strategies that differ in their document and query representations.

BM25 (Robertson and Zaragoza, 2009) is a classic sparse probabilistic retrieval model that scores documents by the weighted overlap of query terms, applying a term-frequency saturation function and a document-length normalisation penalty. BM25 has long served as a strong baseline for ad-hoc retrieval and remains competitive with many neural approaches. We adopt BM25 parameters k_1=0.9 and b=0.4, and apply a title-boost factor of 2 by repeating title tokens at indexing time to approximate field-weighted BM25F scoring.

Model	Retrieval Dataset	BioASQ	ChatDoctor/iCliniq	MashQA	MedicationQA	MedQuAD	MedRedQA	MeQSum	Average

Table 1: ROUGE-L by model and retrieval corpus (open-ended datasets).

TF-IDF (SPARCK JONES, 1972) represents both documents and queries as bag-of-words vectors weighted by term frequency–inverse document frequency, and ranks candidates by cosine similarity. Unlike BM25, TF-IDF applies no term-frequency saturation or document-length penalty, making it a simpler baseline for sparse lexical matching. We build a TF-IDF index with a vocabulary capped at 50,000 features and standard English stop-word removal.

MedCPT (Jin et al., 2023) is a biomedical dense retrieval model consisting of a *query encoder* and an *article encoder* trained contrastively on large-scale PubMed user search logs. Documents are encoded offline by the article encoder and stored as L2-normalised embeddings; at query time, the query encoder produces a query embedding and retrieval proceeds by maximum inner-product search. By capturing semantic similarity beyond exact term overlap, MedCPT is particularly well-suited to the biomedical domain.

Hybrid BM25 + MedCPT via RRF (Cormack et al., 2009) combines the BM25 and MedCPT ranked lists using Reciprocal Rank Fusion (RRF). Each document d ranked at position r in a ranked list receives a score $\frac{1}{k+r}$; with k=60, and the scores are summed across both lists. The final ranking is by descending combined RRF score. RRF is parameter-light and has been shown to consistently outperform individual rankers as well as more complex score-fusion methods (Cormack et al., 2009).

For all retrieval conditions, we retrieve the top k=5 documents and concatenate them as the retrieved context prepended to the generator prompt.

Implementation Details. All generation experiments are conducted with five open-source instruction-tuned models spanning two scales. The 7–8B models are **Qwen2.5-7B-Instruct** (Yang et al., 2025), **Llama-3.1-8B-Instruct** (Grattafiori et al., 2024), and **Mistral-7B-Instruct-v0.3** (Jiang et al., 2023), each servable on a single GPU. The 70B-scale models are **LLaMA-3.1-70B-Instruct** (Grattafiori et al., 2024) and **Qwen2.5-72B-Instruct** (Yang et al., 2025), which serve as large-scale reference points to contextualise the small-model results.

All models are run in half-precision (FP16) with greedy decoding and a maximum of 300 newly generated tokens per response.

Experimental Setting. Each experimental condition is defined by a triple (*retriever*, *corpus*, *query dataset*). The retriever dimension covers five options: *No retrieval* (baseline), BM25, TF-IDF, MedCPT, and Hybrid (BM25 + MedCPT via RRF). The corpus dimension covers four knowledge bases: BioASQ/PubMed and Medical Textbooks as expert corpora, and Yahoo Answers and HealthCareMagic as layman corpora (for the base-

line condition both retriever and corpus are set to none). The query dimension covers the ten datasets described in Section 3, split evenly between layman (MeQSum, MedRedQA, MedicationQA, MASH-QA, ChatDoctor-iCliniq) and expert (BioASQ Task B, MedQuAD, MedQA-USMLE, MedMCQA, MMLU Medical) user types.

For the *w/o RAG* condition the model receives only the question in its prompt, with no retrieved context. For retrieval-augmented conditions, the top-k retrieved passages are prepended to the question in a fixed prompt template. Each condition is run independently for every generator model, and all per-dataset query pools described in Section 3 are also available for few-shot prompting ablations. The complete set of conditions spans every combination of retriever, corpus, and query dataset, yielding a large-scale cross-model, cross-retriever, cross-dataset evaluation.

4 Results

We present results separately for open-ended QA, evaluated with ROUGE-L as the primary metric (ROUGE-1, ROUGE-2, METEOR, BLEU, and BERTScore in Appendix C), and for multiple-choice QA, evaluated with accuracy.

Open-ended QA. Table 1 reports ROUGE-L across seven open-ended datasets (five layman and two expert), averaged over all retrieval conditions per corpus. Across all models, retrieval yields small and inconsistent improvements over the no-retrieval baseline. The largest gains appear on the BioASQ open-ended task, where the BioASQ/PubMed corpus consistently provides the strongest lift: for example, LLaMA-3.1-8B improves from 21.65 to 27.43 ROUGE-L. However, for the remaining six datasets, changes from the baseline are typically under 1 ROUGE-L point and often negative. Averaged across all seven datasets, the maximum retrieval benefit over no-retrieval is 1.18 points (LLaMA-3.1-8B: 13.06 baseline vs. 14.24 with BioASQ); for all other models the gain is smaller still. ROUGE-1, ROUGE-2, METEOR, BLEU, and BERTScore results (Appendix C) show the same pattern.

A consistent observation is that backbone model choice matters far more than retrieval configuration. Mistral-7B lags behind both LLaMA-3.1-8B and Qwen2.5-7B regardless of the retrieval setup, and the 70B-scale models (LLaMA-3.1-70B, Qwen2.5-72B) are consistently stronger than all 7–8B variants. The gap between any two retrieval conditions for the same model is almost always smaller than the gap between two different backbone models using the same conditions. Expert and layman retrieval corpora produce similar results in most open-ended settings, differing by less than 1 ROUGE-L point on average.

Table 2: Accuracy by model and retrieval corpus. MCQA denotes MedMCQA, MQA denotes MedQA, and HCM denotes HealthCareMagic.

Multiple-choice QA. Table 2 reports accuracy grouped by dataset subset (MCQA: MedQA + MedMCQA; QA: open-ended expert; MMLU: six MMLU medical subjects). For smaller models (LLaMA-3.1-8B, Mistral-7B, Qwen2.5-7B), retrieval frequently *hurts* accuracy relative to the no-retrieval baseline. Mistral-7B drops from 75.7 to 68.6–72.3 across all retrieval corpora. The larger models (LLaMA-3.1-70B, Qwen2.5-72B) are more robust, maintaining accuracy within 1–2 points of the baseline across all conditions, but still show no consistent gain. As with the open-ended setting, backbone choice dominates: Qwen2.5-72B's no-retrieval accuracy of 85.6 exceeds the best retrieval configuration of any 7B model by over 2 points.

Effect of Retrieval Method. Table 3 reports accuracy averaged across the three close-ended datasets from Table 2 (MedMCQA, MedQA-USMLE, and MMLU Medical), broken down by

Table 4: ROUGE-L by retrieval method (open-ended datasets).

retrieval method rather than corpus. Table 4 reports ROUGE-L averaged across the seven open-ended datasets from Table 1 (BioASQ, ChatDoctor-iCliniq, MashQA, MedicationQA, MedQuAD, MedRedQA, and MeQSum), again broken down by retrieval method. Together, these two tables allow direct comparison of BM25, Hybrid (RRF), MedCPT, and TF-IDF across question types and retrieval corpora. Differences among methods are within 1–2 points for any model–corpus combination. The Hybrid retriever shows marginal advantages in several configurations, but no method consistently dominates. MedCPT, despite domain-specific training, does not systematically outperform lexical BM25. Full per-metric breakdowns by retriever type (ROUGE-1, ROUGE-2, METEOR, BLEU, BERTScore) are in Appendix C.

5 Ablation Study

We conduct two ablations to understand how retrieval depth and few-shot context affect performance. Both use a stratified subset of the test queries with BM25 retrieval from BioASQ. Additional open-ended metric trends are visualised in Appendix D (Figures 7 and 8).

Number of Retrieved Documents (Top-k). Figures 5 and 6 show accuracy and ROUGE-L as k varies over $\{1, 3, 5, 10, 25, 50\}$. For open-ended metrics, performance reaches a plateau by k=5:

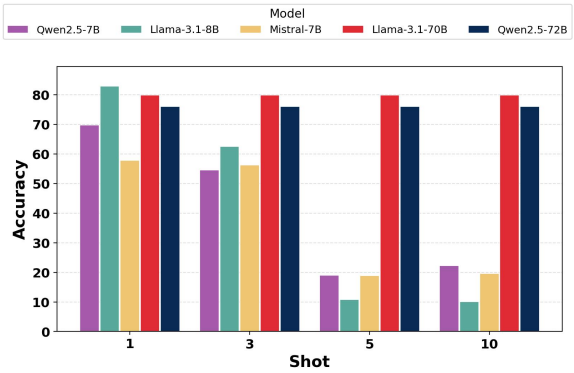

Figure 3: Close-ended accuracy across shot counts (1, 3, 5, 10).

ROUGE-L changes by less than 0.2 points between k=5 and k=50 for all models, indicating that additional retrieved documents add no useful signal once the context budget is satisfied. For close-ended accuracy the picture is less uniform: LLaMA-3.1-8B peaks at k=5 (72.83%) before declining, while Qwen2.5-7B and LLaMA-3.1-70B reach their best performance at $k \geq 25$. Mistral-7B declines steadily after k=3, reaching 51.22% at $k \geq 25$. These results confirm that k=5 is a reasonable default: it matches or closely approaches the optimum for most models while keeping context length manageable. Additional open-ended metric trends across all k values are shown in Figure 8 in the appendix.

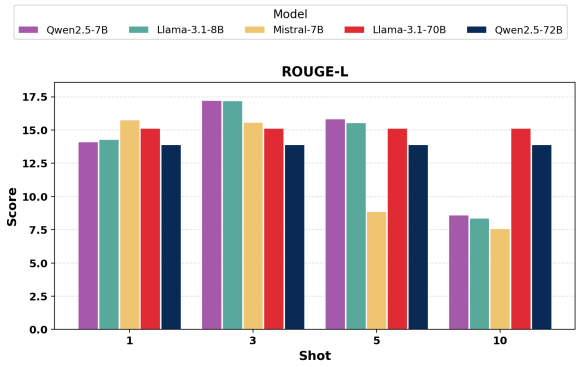

Figure 4: Open-ended ROUGE-L across shot counts (1, 3, 5, 10).

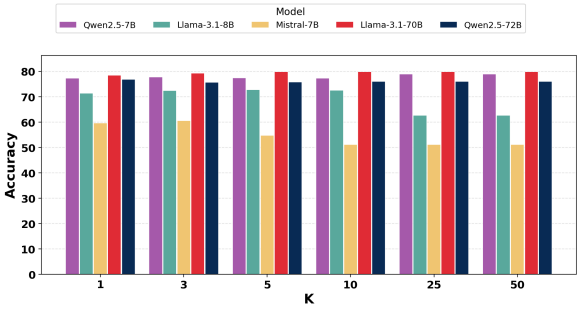

Figure 5: Close-ended accuracy across top-k (1, 3, 5, 10, 25, 50).

Few-shot Prompting. Figures 3 and 4 show accuracy and ROUGE-L as the number of in-context examples varies over $\{1, 3, 5, 10\}$. Larger models (LLaMA-3.1-70B, Qwen2.5-72B) are essentially unaffected by shot count across all metrics, suggesting they can extract the task pattern from a single example or from zero-shot prompting equally well. In contrast, smaller 7–8B models show sharp degradation at 5 and 10 shots: LLaMA-3.1-8B accuracy collapses from 82.89% (1-shot) to 10.06% (10-shot), and ROUGE-L drops from 14.29 to 8.38, as the long few-shot context overwhelms the model's ability to locate the target instruction. Mistral-7B and Qwen2.5-7B follow the same pattern. Notably, 3-shot prompting is the sweet spot for open-ended ROUGE-L: LLaMA-3.1-8B reaches 17.19 at 3 shots (vs. 14.29 at 1-shot), and Qwen2.5-7B reaches 17.22, before degrading at higher shot counts. For MCQ accuracy, even 3 shots already reduces performance for most small models, pointing to the inherent tension between providing helpful demonstrations and staying within the model's effective context capacity. Additional open-ended metric trends across all shot counts are shown in Figure 7 in the appendix.

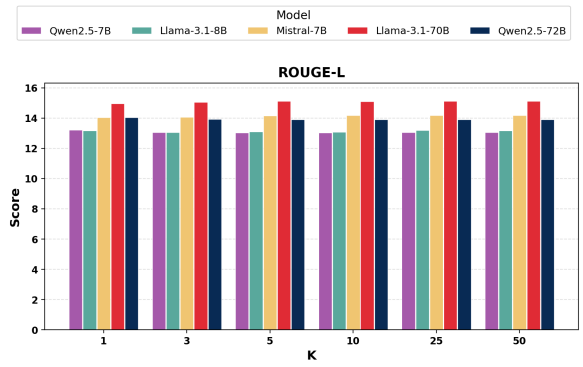

Figure 6: Open-ended ROUGE-L across top-k values.

Model	w/o RAG	BM25	Hybrid	MedCPT	TF-IDF
LLaMA3.1-8B	0.410	0.580	0.540	0.440	0.530
LLaMA3.1-70B	0.410	0.660	0.610	0.540	0.660
Mistral-7B	0.460	0.510	0.490	0.390	0.530
Qwen2.5-7B	0.410	0.380	0.400	0.360	0.390
Qwen2.5-72B	0.380	0.350	0.350	0.360	0.380

Table 5: Accuracy of LLMs across retrieval methods in the oracle retrieval setting, where all retrieved documents are relevant (clean context).

Quality of the Retrieval Analysis. Tables 5 and 6 show two important problems for retrieval-augmented generation in the biomedical domain. For this analysis, we use the BioASQ corpus as the retrieval source and evaluate on PubMedQA (Jin et al., 2019), a benchmark of expert-annotated yes/no/maybe biomedical research questions derived from PubMed abstracts. Since both the retrieval corpus and evaluation dataset come from PubMed, this provides a controlled setting for studying whether retrieved biomedical papers help models answer research questions. To evaluate retrieval quality, we use an LLM-as-a-judge framework to determine whether the retrieved context contains enough information to answer the question correctly. We then select 100 questions where all retrieval methods retrieved context judged to be relevant. The questions are the same across all retrieval methods, but the retrieved documents can differ depending on the retriever.

Table 5 shows that even when all retrieved contexts contain the correct information, retrieval only leads to limited and inconsistent improvements. For example, LLaMA3.1-70B improves substantially with BM25 retrieval (0.410 $\rightarrow$ 0.660), while Qwen2.5-72B shows almost no improvement across retrieval methods. In several cases, simple sparse retrieval methods such as BM25 and TF-IDF perform better than MedCPT. These results suggest that retrieving relevant evidence alone is not

Model	w/o RAG	BM25	Hybrid	MedCPT	TF-IDF
LLaMA3.1-8B	0.410	0.300	0.250	0.300	0.240
LLaMA3.1-70B	0.410	0.260	0.260	0.340	0.290
Mistral-7B	0.460	0.310	0.330	0.350	0.340
Qwen2.5-7B	0.410	0.310	0.260	0.290	0.250
Qwen2.5-72B	0.380	0.250	0.240	0.280	0.230

Table 6: Accuracy of LLMs across retrieval methods in the noisy retrieval setting, where 20 unrelated documents are mixed with retrieved results (distracted context).

enough to guarantee better performance. Instead, many models still struggle to correctly use and reason over the retrieved information. Table 6 further shows that current models are highly sensitive to irrelevant context. When we add 20 unrelated documents to the retrieved evidence, performance drops substantially across nearly all models and retrieval methods. For example, LLaMA3.1-70B decreases from 0.660 to 0.260 under BM25 retrieval, while Mistral-7B drops from 0.530 to 0.340 under TF-IDF retrieval. In many cases, performance becomes worse than using no retrieval at all. Overall, these results show that current biomedical RAG systems remain brittle. Even when relevant evidence is retrieved successfully, small amounts of distracting context can strongly reduce answer accuracy.

Implications. Our results suggest a more cautious view of biomedical RAG. Retrieval can help, but only when the system retrieves information that is actually relevant to the question. This is not guaranteed, especially when the answer is absent from the corpus or when the retrieved passages are only loosely related. In these cases, retrieval may add little useful information and can introduce misleading context.

Even when relevant evidence is retrieved, the model still has to understand and use it correctly. Our clean retrieval analysis shows that relevant context does not always improve performance, suggesting that evidence use is a major bottleneck. The noisy retrieval results make this concern stronger: adding unrelated documents to useful evidence often hurts performance, sometimes making RAG worse than no retrieval at all. Future biomedical RAG systems, therefore, need better evidence filtering, reranking, and generation methods that can identify useful passages while ignoring distractors.

6 Conclusion

We presented a large-scale evaluation of retrieval-augmented generation for biomedical question answering using five open-weight, instruction-tuned models ranging from 7B to 72B parameters. Across all five models, ten datasets, four retrieval methods, and four retrieval corpora, retrieval yields only small and inconsistent improvements over a no-retrieval baseline, typically within 1–2 points on any metric. In contrast, backbone model choice has a substantially larger effect: the gap between a 7B model and its 70B counterpart often exceeds the gain from any retrieval configuration. Expert and layman retrieval corpora also perform similarly in most settings, and differences across retrieval methods (BM25, TF-IDF, MedCPT, Hybrid) remain minor throughout.

Our ablation studies further support this overall pattern. Increasing the number of retrieved documents beyond $k{=}5$ provides little additional benefit for open-ended settings, and few-shot prompting yields a modest gain at 3 shots for smaller models but degrades sharply at higher counts, with small models struggling under longer few-shot contexts. Larger models are comparatively stable across shot counts, but they also show limited benefit from retrieval augmentation.

Taken together, these findings suggest that improving retrieval quality alone may not be sufficient to substantially improve biomedical QA performance in these settings. One possible explanation is that current models, especially smaller ones, do not consistently make effective use of retrieved evidence, though our experiments do not directly measure evidence utilization or grounding. This points to several directions for future work, including training or fine-tuning methods that better support evidence integration, post-retrieval reranking or filtering to reduce context noise, and evaluation frameworks that more directly assess faithfulness and grounding rather than relying only on reference-based metrics. More broadly, an important open question is when retrieval is actually necessary, and whether we can better identify cases where the required knowledge is already contained within the model.

Limitations

Our study has several limitations. First, we evaluate retrieval-augmented generation using only reference-based downstream metrics such as ROUGE-L, BLEU, METEOR, BERTScore, and accuracy, rather than direct measures of faithfulness or evidence grounding. For example, a model may produce a correct answer from its parametric knowledge without actually using the retrieved documents, or it may copy surface details from retrieval without truly improving medical correctness. This limitation is not major for our study because our main goal is a comparative evaluation across models, retrievers, corpora, and no-retrieval baselines within a single, consistent framework, and these metrics are sufficient to support our central finding that retrieval provides only small and inconsistent gains.

Second, our experiments are limited to five open-weight instruction-tuned models and do not include proprietary frontier systems such as GPT-4-class medical assistants. It is possible that stronger closed models use retrieved evidence more effectively, especially in cases requiring multi-step reasoning over documents. This limitation is not major for our study because our paper is specifically motivated by practical, deployable biomedical QA settings, where open-weight 7B–72B models are realistic choices, and we also include both small and large open models to test whether the observed pattern holds across scales.

Third, our retrieval setup uses a fixed top-k pipeline with four retrievers and four corpora, but does not explore more complex retrieval strategies such as adaptive retrieval, document re-ranking, iterative retrieval, or task-specific chunking. For instance, some questions may require retrieving fewer but more precise passages, while others may benefit from multi-hop retrieval or filtering noisy evidence before generation. This limitation is not major for our study because we intentionally focus on strong, standard retrieval baselines widely used in prior biomedical RAG work, which makes the comparison clean and allows us to show that, even with several commonly used retrieval choices, the gains remain modest.

Finally, our evaluation mixes expert and layman biomedical QA datasets, but the study does not separately analyze all possible sources of variation across question type, answer length, or knowledge intensity. For example, retrieval may be more useful for highly specialized factoid questions than for common consumer-health questions that models may already answer from pretraining alone. This limitation is not major for our study because the breadth of datasets is a strength of the paper overall: the consistency of the pattern across ten datasets suggests that the weak benefit of retrieval is not tied to a single benchmark or user population.

A Datasets

Our experiments use ten biomedical and consumer-health query datasets and four retrieval corpora. Table 7 summarises each evaluation dataset, its source size, and the number of examples selected for evaluation; Table 8 describes the knowledge bases indexed for retrieval. Full details on dataset splits and the few-shot query pools are provided in Section 3.

Datasets are grouped by intended user type: *layman* datasets reflect consumer health inquiries in everyday language, while *expert* datasets target biomedical professionals or medical students. The *Query Set* column reports the eligible pool size used for few-shot prompting; the *Test Set* column reports the number of examples used as evaluation queries. All corpora in Table 8 are indexed as whole records without further chunking; for Q&A-format corpora (Yahoo Answers and HealthCareMagic) each document concatenates the question or title with the answer body.

B Prompt Templates

All generation experiments use two system prompts and two user message templates, combined via each model's native chat template.

Layman system prompt. Used when the query dataset belongs to the *layman* user type (MeQSum, MedRedQA, MedicationQA, MASH-QA, ChatDoctor-iCliniq):

Layman System Prompt

You are a helpful health assistant answering questions from members of the general public. Use simple, everyday language that a non-medical person can easily understand. Avoid medical jargon. Be clear, friendly, and concise.

User Type	Dataset	Dataset Type	Dataset Content	Query Set	Test Set
Layman	MeQSum (Ben Abacha and Demner-Fushman, 2019a)	Open-ended Q&A	1,000 consumer health questions from the U.S. National Library of Medicine, manually summarized by medical experts (inter-annotator agreement: 96.9%)	500	500
	MedRedQA (Nguyen et al., 2023)	Open-ended Q&A	51,000 consumer question–physician answer pairs from Reddit `/r/AskDocs` (2013–2022); answers from verified doctors only; ~1k entries enriched with PubMed evidence	45,863	1,000
	MedicationQA (Abacha et al., 2019)	Open-ended Q&A	690 real consumer medication questions annotated with drug focus and question type (dosage, side effects, interactions, etc.); answers sourced from MedlinePlus, DailyMed, FDA, and Mayo Clinic	189	500
	MASH-QA (Zhu et al., 2020)	Open-ended Q&A	34,808 consumer health Q&A pairs from WebMD; extractive, multi-span answers (avg. 67 words) curated by healthcare experts from articles averaging 696 words	19,989	1,000
	ChatDoctor-iCliniq (Li et al., 2023)	Open-ended Q&A	7,321 real patient–physician conversations from iCliniq.com spanning infectious disease, dermatology, cardiology, neurology, and other specialties	6,321	1,000
Expert	BioASQ Task B (Nentidis et al., 2025)	Summary Q&A	Expert-curated biomedical questions paired with PubMed-grounded answers; covers yes/no, factoid, list, and summary types with gold concepts, snippets, and RDF triples	1,283	80
	MedQuAD (Ben Abacha and Demner-Fushman, 2019b)	Open-ended Q&A	47,457 Q&A pairs from 12 NIH websites covering 37 question types (treatment, diagnosis, side effects, etc.) across diseases, drugs, and medical tests; enriched with UMLS CUI metadata	15,407	1,000
	MedQA-USMLE (Jin et al., 2021)	Multiple-Choice Q&A	~11,500 clinical vignette MCQs from the USMLE (Steps 1–3); each vignette describes patient demographics, symptoms, and history followed by a 4-option diagnostic or management question	10,178	1,273
	MedMCQA (Pal et al., 2022)	Multiple-Choice Q&A	194k+ MCQs from AIIMS & NEET PG medical entrance exams spanning 21 subjects and 2,400+ topics (anatomy, pharmacology, pathology, surgery, psychiatry, etc.); includes answer explanations	182,822	1,000
	MMLU Medical (Hendrycks et al., 2021)	Multiple-Choice Q&A	1,242 four-choice questions from six MMLU medical subjects (clinical knowledge, medical genetics, anatomy, etc.), drawn from GRE and USMLE practice exams; evaluated in zero/few-shot settings	642	600

Table 7: Evaluation query datasets grouped by user type. *Layman*: consumer health queries in everyday language; *Expert*: biomedical/clinical questions. "Query Set": few-shot pool size; "Test Set": evaluation examples used.

Expert system prompt. Used for *expert* datasets (BioASQ Task B, MedQuAD, MedQA-USMLE, MedMCQA, MMLU Medical):

Expert System Prompt

You are a clinical decision support assistant. Answer questions from healthcare professionals using precise medical terminology. Provide evidence-based, clinically detailed responses with relevant diagnostic and therapeutic considerations.

User message (without retrieval)

User Message

```
QUESTION: {query}
ANSWER:
```

User message (with retrieval)

User Message

```
Use the following retrieved passages to
help answer the question.
RETRIEVED CONTEXT:
{context}
QUESTION: {query}
ANSWER:
```

User Type	Dataset	Source Content	Source Rows	Documents Retained	Dataset Link
Expert	BioASQ Task A / PubMed (Krithara et al., 2023)	PubMed abstracts with human-assigned MeSH annotations (avg. 12.68 terms per article; up to 29,681 distinct MeSH terms across 16.2M articles)	16,218,838	16,218,838	Link
	Medical textbooks (Xiong et al., 2024)	Retrieval-friendly chunks ($\leq$1,000 chars each) drawn from 18 authoritative biomedical textbooks spanning anatomy, physiology, pharmacology, pathology, and clinical medicine	125,847	125,847	Link
Layman	Yahoo Answers (Yahoo! Research, 2009)	Open-domain community Q&A posts with best-answer labels and topic categories; user identities fully anonymized	1,400,000	1,238,506	Link
	HealthCareMagic (Li et al., 2023)	Real-world patient symptom queries paired with detailed physician responses (diagnosis, treatment, and referral advice) across 10+ clinical specialties	112,165	112,165	Link

Table 8: Retrieval corpora grouped by user type. *Expert*: technical biomedical sources; *Layman*: community health and general Q&A. "Documents Retained": records after quality filtering.

where `{context}` is a concatenation of the top-k retrieved passages, each formatted as `[Passage N (source: {source})]: {text}`. The final prompt is produced by wrapping these system and user messages in each model's chat template.

C Full Results by Metric

This section provides per-dataset performance tables for all evaluated metrics beyond ROUGE-L (reported in the main paper). Tables 9–13 report ROUGE-2, ROUGE-1, BERTScore, METEOR, and BLEU respectively, broken down by model and retrieval corpus across the seven open-ended datasets. Tables 14–18 further break down ROUGE-1, ROUGE-2, BLEU, METEOR, and BERTScore by retrieval method (BM25, Hybrid, MedCPT, TF-IDF) across all four corpora.

ROUGE-2 (Table 9). The pattern mirrors ROUGE-L: the BioASQ/PubMed corpus produces the largest gains, and only on the BioASQ expert open-ended task. For example, LLaMA-3.1-8B improves from 14.03 to 18.34, and LLaMA-3.1-70B from 14.43 to 19.25, while all other datasets see gains under 1 point or negative effects. The average improvement over baseline is at most 0.53 points (LLaMA-3.1-8B: 5.82 $\rightarrow$ 6.35), and for Qwen2.5-72B Yahoo Answers produces the best average (6.39), marginally ahead of BioASQ (6.37), illustrating how small these corpus-level differences are.

ROUGE-1 (Table 10). Again, the BioASQ corpus helps on the BioASQ dataset (gains of 3–5 points for all models) while effects on lay datasets are within $\pm$1 point. Mistral-7B shows an above-average improvement with BioASQ corpus on the BioASQ open-ended task (37.56 $\rightarrow$ 40.46 with BioASQ corpus; 40.53 with Qwen2.5-72B), confirming domain-matched retrieval has local benefit. Averaged over all datasets the maximum gain is 0.65 points (LLaMA-3.1-8B baseline 22.49 $\rightarrow$ best 22.88).

BERTScore (Table 11). BERTScore is notably more stable than any ROUGE metric: the gap between the no-retrieval baseline and the best retrieval condition is under 0.7 points for all models. For instance, LLaMA-3.1-8B moves from 52.47 (baseline) to at best 52.85 (BioASQ corpus), a gain of just 0.38 points. This suggests that while retrieved context can slightly shift surface n-gram overlap, the overall semantic content of model outputs barely changes, consistent with the view that 7–8B models are not effectively incorporating the retrieved evidence.

METEOR (Table 12). METEOR shows small, mixed effects: the BioASQ corpus provides a modest boost on the BioASQ dataset (e.g., LLaMA-3.1-8B: 29.84 $\rightarrow$ 30.92; Qwen2.5-72B: 31.11 $\rightarrow$ 34.05), but on lay datasets retrieval often slightly lowers METEOR, particularly for the 70B models where the baseline exceeds all retrieval conditions on several tasks (e.g., LLaMA-3.1-70B average: 18.92 baseline vs. 17.03–17.12 across all corpora).

BLEU (Table 13). BLEU scores are generally very low for lay datasets ($<$ 2 across all conditions), underscoring that n-gram precision is a weak signal for open-ended health QA. The BioASQ corpus produces notable gains on the expert BioASQ dataset (LLaMA-3.1-8B: 12.92 $\rightarrow$ 19.08; LLaMA-3.1-70B: 13.32 $\rightarrow$ 19.76), but all other datasets improve by less than 0.3 BLEU points, and many worsen. Average BLEU across all datasets improves by 0.82 points at most.

Retrieval method breakdown (Tables 14–18). Across all five metrics, differences among BM25, Hybrid (RRF), MedCPT, and TF-IDF are consistently within 0.5 metric points for any model–corpus combination. The Hybrid retriever shows a slight edge in several configurations (particularly ROUGE-L and ROUGE-1), while TF-IDF is competitive with BM25 despite its greater simplicity. No single retrieval method dominates across all metrics and models, reinforcing the conclusion that retrieval architecture choice is secondary to corpus and model selection.

D Ablation Study: Additional Figures

This section provides additional figures for the two ablation studies described in Section 5. Figure 7 shows BERTScore, METEOR, BLEU, ROUGE-2, and ROUGE-1 trends under few-shot prompting across all five models on open-ended questions. Figure 8 shows the same metrics across top-k values.

Few-shot: additional metrics (Figure 7). All six open-ended metrics tell a consistent story. For the larger models (LLaMA-3.1-70B and Qwen2.5-72B), all metrics are flat across all shot counts: for example, METEOR stays at 17.44–17.45 for LLaMA-3.1-70B and BERTScore stays at 52.69 for Qwen2.5-72B regardless of shot count. For smaller models, the 3-shot sweet spot and subsequent collapse are visible in every metric. Specifically, ROUGE-1 peaks at 3 shots for LLaMA-3.1-8B (26.29) and Qwen2.5-7B (26.61) before collapsing to 12.19 and 13.52 at 10 shots. METEOR follows the same pattern: LLaMA-3.1-8B peaks at 19.99 (3 shots) vs. 9.12 (10 shots), and Qwen2.5-7B at 20.54 (3 shots) vs. 10.43 (10 shots). BERTScore shows a more severe drop for Mistral-7B: from 54.32 at 1 shot to 40.96 at 10 shots, a 13-point collapse. BLEU, while numerically small, also collapses dramatically, LLaMA-3.1-8B drops from 5.15 (3 shots) to 1.15 (10 shots), and Mistral-7B from 4.66 (3 shots) to 0.88 (10 shots), confirming that higher shot counts severely degrade output quality at this scale.

Top-k: additional metrics (Figure 8). The plateau behavior seen in ROUGE-L (main paper) extends to all six additional metrics. ROUGE-1 changes by at most 0.13 points from k=5 to k=50 across all models. ROUGE-2 is similarly stable: for example, LLaMA-3.1-70B moves from 7.44 (k=5) to 7.45 (k=50), a negligible change. METEOR plateaus by k=5 for most models, with variations under 0.1 between k=5 and k=50. BERTScore is the most stable metric of all: for LLaMA-3.1-8B, it ranges only from 51.33 (k=1) to 51.53 (k=10), a 0.20-point spread across all six k values. The transition from k=1 to k=5 accounts for nearly all the variation, and additional passages beyond k=5 provide no measurable benefit in any metric for any model.

CROSSDDI: Cross-Source Evidence-Grounded Drug–Drug Interaction Verification

Hui Wang **Bohao Chu** **Norbert Fuhr**
University Duisburg-Essen
{hui.wang.0111@stud, bohao.chu, norbert.fuhr}@uni-due.de

Abstract

LLM-based drug–drug interaction (DDI) assessment remains difficult to audit when predictions are not explicitly tied to evidence. While retrieval-augmented generation (RAG) improves grounding, predictions are not guaranteed to be entailed by retrieved items. We present CROSSDDI, a verification-first framework that separates LLM-based evidence extraction from deterministic arbitration over DrugBank and PubMed, requiring positive predictions to be linked to explicit supporting evidence. Evaluated on 1,000 DDInter 2.0 pairs under a positive–unlabeled setting, CROSSDDI achieves recall of 0.576–0.593 over confirmed positives with interaction prediction rates comparable to RAG, while reducing cross-backbone variation (0.018 vs. 0.066). Analysis identifies literature evidence acquisition and attribution as the primary bottleneck: PubMed retrieval covers only 40.5% of confirmed positives, and Path B-only evidence is substantially less reliable than structured evidence. These results suggest that verification-first architectures can improve traceability and backbone consistency, while broader and more reliable literature evidence is needed to extend coverage beyond structured sources.

1 Introduction

Users increasingly turn to conversational AI for medication-related questions, including safety-critical queries such as "Can I take warfarin with aspirin?" (White et al., 2025). Yet large language models (LLMs) can produce hallucinated medical claims (Singhal et al., 2023), and in drug–drug interaction (DDI) assessment, missed or incorrect identification of interactions may lead to adverse events (Huang et al., 2025). Reliable DDI assessment therefore requires every prediction to be traceable to explicit evidence.

Retrieval-augmented generation (RAG) augments language models with retrieved text passages from external sources (Asai et al., 2024) but does not guarantee that generated predictions are faithfully grounded in the retrieved evidence (Wu et al., 2024). Neural DDI models (He et al., 2022; Wang et al., 2025a) predict interactions from molecular features, but operate on structured inputs and do not directly support verification of free-form claims against source-level evidence.

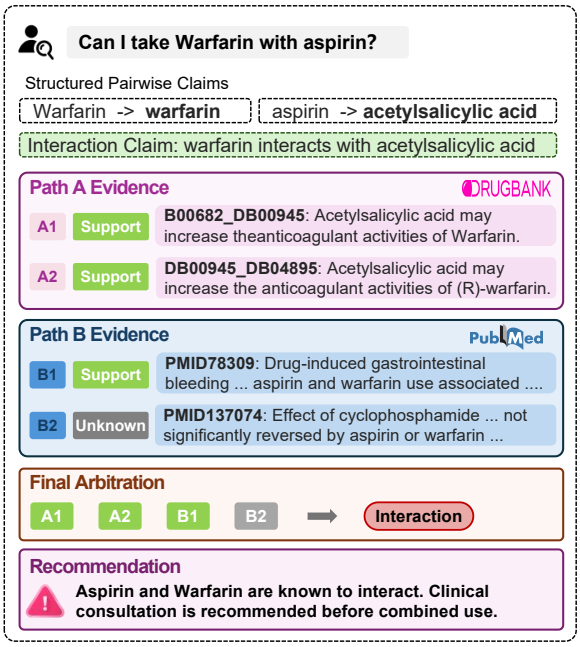

Figure 1: End-to-end example of CROSSDDI for the query "Can I take Warfarin with aspirin?" DrugBank provides structured evidence and PubMed complementary evidence; deterministic arbitration yields an *Interaction* verdict linked to explicit evidence.

We introduce DDI assessment as **evidence-grounded claim verification** and propose CROSSDDI, which separates LLM-based evidence extraction from deterministic decision-making over two complementary sources: DrugBank (Knox et al., 2024) for broad structured coverage and PubMed for long-tail or recent cases. LLMs assign a stance from each source; a rule-based arbitration layer combines these stances to produce a final ver-

dict, *guaranteeing* that every positive prediction is backed by explicit evidence (Figure 1).

Curated DDI resources such as DDInter (Tian et al., 2025) primarily provide annotated interaction records, while non-interactions are typically unlabeled. In such settings, drug–drug interaction modeling is commonly formulated as a positive–unlabeled (PU) learning problem (Bi et al., 2018). Across three LLM backbones (Qwen2.5-7B, GPT-4o, and Qwen3-235B-A22B (Qwen et al., 2025; Hurst et al., 2024; Yang et al., 2025)), CROSSDDI achieves recall (0.576–0.593) comparable to generation-based RAG baselines while ensuring full evidence traceability, and reduces cross-backbone variation (recall spread 0.018 vs. 0.066). Our analysis traces the remaining recall gap to sparse literature-side evidence acquisition.

Contributions. (i) We formulate DDI assessment as evidence-grounded claim verification over drug pairs under the positive–unlabeled (PU) setting, requiring explicit evidence support. (ii) We introduce CROSSDDI, a verification-first framework that separates LLM-based evidence extraction from deterministic decision-making, enabling explicit grounding, traceability, and consistent predictions across LLM backbones. (iii) Through staged error analysis, we identify literature-side evidence acquisition as a primary bottleneck for recall.

2 Related Work

DDI prediction and extraction. Prior DDI work includes deep learning methods (e.g., SSF-DDI (Zhu et al., 2024), CNN-DDI (Zhang et al., 2022)) and knowledge-graph-based approaches (e.g., LLM-DDI (Li et al., 2026), KGDB-DDI (Zhao et al., 2025)), which learn drug representations from molecular, structural, or relational data for interaction prediction. These methods focus on prediction rather than verification and do not provide evidence-grounded justification for individual claims. Recent LLM-based approaches have been applied to medical QA settings (Wang et al., 2025b), but remain prone to hallucinated or unsupported claims (Wang et al., 2025b; Sicard et al., 2025).

Biomedical verification. Prior work on scientific and medical fact verification, including SciFact, MultiVerS, HealthFC, and BioFactCheck (Wadden et al., 2022a,b; Vladika et al., 2024; Lamichhane et al., 2023), assesses whether claims are supported or refuted by retrieved textual evidence. These approaches typically operate over abstract- or document-level evidence and treat claims independently, without modeling structured pairwise interactions or integrating evidence across curated knowledge and clinical literature. CROSSDDI instead targets structured pairwise drug interaction claims and combines evidence from curated databases and clinical literature through verification with deterministic arbitration.

Biomedical RAG. Biomedical RAG systems (e.g., Almanac (Zakka et al., 2024)) improve grounding by incorporating retrieved evidence, but typically rely on the generator to reconcile evidence during generation. As a result, predictions are not guaranteed to be entailed by specific retrieved items (Wu et al., 2024). In contrast, CROSSDDI separates evidence extraction from deterministic arbitration, enabling traceable decisions under heterogeneous and incomplete evidence.

3 CrossDDIPipeline

CROSSDDI proceeds in four stages: (1) entity resolution and claim construction, (2) DrugBank verification (Path A), (3) PubMed verification (Path B), and (4) deterministic arbitration (see Appendix A). LLMs handle only evidence extraction and attribution; final verdicts follow a fixed rule.

3.1 Entity Resolution and Claim Construction

Given a query q, drug mentions are normalized via case folding, suffix stripping, and alias matching against DrugBank synonyms, yielding a canonical pair $\phi(q) = (d_1, d_2),\ d_1 \leq_{\text{lex}} d_2$. We then construct the binary claim $c = \text{Interacts}(d_1, d_2)$.

This normalization reduces surface variation but may fail for complex multi-token drug names; such cases are treated as part of the overall pipeline error profile analyzed later.

3.2 Path A: Structured DrugBank Verification

Path A queries a local DrugBank (Knox et al., 2024) index with a ranked retrieval procedure. The primary channel is an exact symmetric pair-key match over normalized DrugBank identifiers. Auxiliary lexical channels retrieve lower-specificity records whose descriptions mention both drug names or whose counterpart field matches one queried drug. Records are ranked by specificity, and the top K ($K = 3$) are retained.

Let $R_A^{(K)}$ denote the ranked top-K DrugBank output, and let $\text{Exact}(r, d_1, d_2)$ indicate that record

r is an exact pair-key match for the normalized pair (d_1, d_2). The path-level stance is defined as

$$y_A = \begin{cases} \textit{Support} & \exists r \in R_A^{(K)} : \mathrm{Exact}(r, d_1, d_2), \\ \textit{Unknown} & \text{otherwise.} \end{cases}$$

Exact pair matches are treated as structured support evidence, whereas lexical matches provide auxiliary context only. The absence of an exact match is interpreted as unresolved rather than negative evidence. Path A does not emit *Contradict*, consistent with the PU setting.

3.3 Path B: Literature-grounded Verification

Path B performs sentence-level verification over PubMed. Synonym-expanded queries retrieve up to three articles, from which an LLM extracts at most six claim-relevant sentences and assigns stance labels in $\{\textit{Support}, \textit{Contradict}, \textit{Unknown}\}$. Post-extraction filtering reduces spurious signals: sentences that merely co-mention the drugs are downgraded to *Unknown*, and *Contradict* is kept only when both explicit negation and interaction cues are present. These heuristics prioritize precision over recall. Let E_B^+ and E_B^- denote the filtered *Support* and *Contradict* sets. The path-level stance is defined as

$$y_B = \begin{cases} \textit{Support} & E_B^+ \neq \emptyset \wedge E_B^- = \emptyset, \\ \textit{Contradict} & E_B^- \neq \emptyset \wedge E_B^+ = \emptyset, \\ \textit{Unknown} & \text{otherwise.} \end{cases}$$

In practice, retrieval coverage is limited and many queries default to *Unknown*, making Path B a sparse but complementary signal. Despite this, it provides a literature channel that links decisions to explicit textual statements, supporting interpretability and enabling inspection of model outputs. Full prompt details are provided in Appendix F.

3.4 Deterministic Arbitration

Path-level outputs (y_A, y_B) are combined via a fixed rule:

$$y = \begin{cases} \text{Interaction} & y_A = \mathrm{Sup} \vee y_B = \mathrm{Sup}, \\ \text{Non-Interaction} & y_A = \mathrm{Unk} \wedge y_B = \mathrm{Con}, \\ \text{Unknown} & \text{otherwise.} \end{cases}$$

The rule is asymmetric: any supporting signal yields *Interaction*, reflecting the higher cost of missing harmful interactions, while *Non-Interaction* requires explicit contradiction without support.

A fixed rule is preferred over learned fusion given the absence of negative supervision in the PU setting. Positive predictions are linked by design to retrieved supporting evidence, though their correctness depends on extraction quality.

4 Experiments

4.1 Setup

Dataset and PU setting. We evaluate on 1,000 DDInter 2.0 pairs (Tian et al., 2025) (seed 42): 797 confirmed interactions and 203 unlabeled pairs. Because DDInter provides no verified *Non-Interaction* labels, evaluation is positive–unlabeled (PU) (Bi et al., 2018); precision and false-positive rate are not identifiable.

Metrics. We use **recall over the 797 confirmed positives** as the primary metric and report interaction prediction rate (P.Int) over all pairs, with P.Unk and P.NI describing abstention behavior. Backbone variation is summarized by recall spread. Bootstrap 95% confidence intervals (2,000 resamples) are reported for P.Int, not recall. Accuracy is reported in Appendix D only for completeness.

Pseudo-negative analysis. We form pseudo-negative (PN) subsets from unlabeled pairs with both drugs resolved and no Path A DrugBank match ($n = 91$–93 per suite). Under a closed-world assumption, *Interaction* predictions on these pairs approximate false positives, so PN-FPR is used only for within-suite comparison. Wilson 95% CIs reflect uncertainty within the PN subset, not clinical false-positive uncertainty.

Baselines. We compare CROSSDDI with *LLM-only*, *RAG*, *Path A*, and *Path B* across Qwen2.5-7B, GPT-4o, and Qwen3-235B. Main comparisons use normalized pair inputs after claim construction, so all retrieval-based conditions use the same DrugBank and PubMed evidence retrieved for CROSSDDI. RAG receives this evidence and generates a final verdict using a fixed prompt (Appendix G). These comparisons are matched at the evidence level, isolating differences in reasoning and arbitration; full parsing and claim-construction failures are analyzed separately. Because Path A is deterministic, its outputs are identical across backbones.

4.2 Results

Overall performance. CROSSDDI achieves the highest recall on two of three backbones (0.580, 0.593) and is comparable on the third (0.576 vs.

Suite	PN n	LLM	RAG	Path A	Path B	CrossDDI
Qwen2.5	91	27.5 [19.4, 37.4]	3.3 [1.1, 9.2]	0.0 [0.0, 4.1]	11.0 [6.1, 19.1]	12.1 [6.9, 20.4]

	Path B	0.083	[.064,.104]	0.074	0.908	0.001
	CROSSDDI	0.557	[.525,.588]	0.576	0.427	0.001

Table 2: Interaction prediction rate (P.Int) over all pairs, bootstrap confidence intervals for P.Int, and recall over confirmed positives. P.Unk and P.NI denote prediction rates for *Unknown* and *Non-Interaction*.

0.578 for RAG) under matched retrieval inputs. Interaction prediction rates are similar (0.556–0.575 vs. 0.478–0.564), indicating that gains are not driven by substantially more frequent positive predictions. Path A alone already provides strong coverage (recall = 0.565, Table 2). Among the 1,000 evaluation pairs, 558 (55.80%) have direct DrugBank pair coverage under the Path A resolver. Recall on confirmed positive pairs with direct DrugBank pair coverage reaches 85.81%, compared with 18.98% on confirmed positive pairs without such coverage, indicating that structured database coverage strongly influences end-to-end performance (Appendix E).

Backbone consistency. CROSSDDI exhibits lower cross-backbone variation (recall spread 0.018) than RAG (0.066), indicating more consistent behavior across models. This difference is partly attributable to the dominance of structured evidence in Path A, which reduces the influence of LLM-dependent variation from Path B during decision making.

Literature evidence. Path B alone yields low recall (0.041–0.077) and predicts *Unknown* for most pairs. PubMed retrieval applies to only 40.5% of confirmed positives, making literature-side evidence acquisition the primary bottleneck. Additional loss arises from entity resolution, query construction, and extraction reliability. Despite these limitations, Path B provides complementary evidence in cases where structured lookup abstains, linking decisions to explicit textual statements beyond curated sources. At the system level, the support-favoring arbitration rule leads to higher PN-FPR than RAG across all pseudo-negative suites (Table 1), reflecting an inherent recall–FPR tradeoff in the current design.

Evidence quality. Manual evaluation of 100 stratified *Interaction* predictions shows overall stance correctness of 84.0%, with 85.0% strict evidence relevance and 95.0% lenient evidence relevance. Evidence quality varies substantially by trigger source: Path A-only and both-path cases show high stance correctness (96.0% and 100.0%, respectively), while Path B-only cases are weaker (44.0% correctness). The main failure mode for Path B-only cases is selection of topically related but non-interaction statements during retrieval and extraction. This evaluation uses a single annotator and should be treated as preliminary; future work should include multi-annotator evaluation and agreement analysis to assess annotation reliability.

5 Conclusion

CROSSDDI shows that separating evidence extraction from deterministic decision-making yields more consistent behavior across LLM backbones (recall spread 0.018 vs. 0.066 for RAG). Under matched retrieval, CROSSDDI achieves higher recall on two of three backbones and comparable recall on the third, with interaction prediction rates similar to RAG. Coverage analysis shows that end-to-end recall is strongly influenced by direct DrugBank coverage: recall over confirmed positives reaches 85.81% on covered pairs but drops to 18.98% on uncovered pairs. The literature path remains limited by retrieval coverage (40.5% of confirmed positives) and extraction reliability. These results suggest that verification-first architectures can improve traceability and backbone consistency, while better literature retrieval and evidence quality are needed for coverage beyond structured sources.

Limitations

Positive–unlabeled evaluation. DDInter provides confirmed positive pairs but no verified *Non-Interaction* labels, resulting in a PU setting in which precision and false-positive rate are not identifiable. Our pseudo-negative FPR is therefore heuristic and intended only for relative comparison within each backbone suite.

Curated-resource overlap. Because DDInter and DrugBank are both curated DDI resources, their interaction coverage may partially overlap. Quantitative analysis suggests a strong dependence on direct DrugBank coverage: recall drops from 85.81% to 18.98% when moving from pairs with direct DrugBank coverage to those without, on the same 1,000-pair evaluation set used in the reported experiments (Appendix E, Table 4). The strong Path A results should therefore be interpreted primarily as evidence of structured database coverage, and the extent to which current results reflect independent cross-source verification should be interpreted cautiously.

Incomplete and imbalanced evidence. Literature retrieval covers only 40.5% of confirmed positives, and a much smaller fraction yields *Support* evidence, reflecting limited coverage and attribution challenges. In contrast, structured knowledge (DrugBank) provides the dominant signal for end-to-end performance. As a result, *Unknown* predictions may reflect missing evidence rather than true uncertainty, and current behavior is largely driven by structured sources.

LLM dependence and task scope. Although final arbitration is deterministic, Path B relies on LLMs for sentence selection and stance attribution, introducing model-dependent variability at the extraction stage. Furthermore, CROSSDDI formulates DDI assessment as pairwise binary verification and does not account for dosage, route, or patient-specific factors.

Future Work

Evaluation and benchmarks. A key limitation of current DDI resources is the absence of verified non-interaction labels. Constructing benchmarks with both confirmed interactions and validated negatives would enable reliable evaluation of precision and false-positive control in evidence-grounded settings.

Retrieval and evidence coverage. Improving literature-side coverage remains critical. Future work includes expanding retrieval to broader sources (e.g., full-text articles and regulatory data) and improving drug-name normalization to reduce loss from entity resolution and retrieval failures.

Stronger baselines and comparisons. Further evaluation against stronger RAG variants (e.g., few-shot or chain-of-thought prompting) and neural DDI models under matched retrieval conditions is needed to better characterize the strengths and limitations of the verification-first design.

Ethics Statement

CROSSDDI is a research prototype for evidence-grounded DDI assessment and is not intended to replace professional clinical judgment. DrugBank data were accessed under an academic research license. No patient-level or personally identifiable data were used in this study.

A Pipeline Overview

B Implementation Details for Path A

Retrieval parameter. The parameter K bounds the number of DrugBank records returned per query. We set $K = 3$ by default, yielding a compact evidence set. Records are ranked by specificity: exact pair-key matches are ranked before lexical description matches and lower-specificity counterpart matches. Let $R_A^{(K)}$ denote this retained ranked output. Path A emits *Support* iff an exact pair-key match appears in $R_A^{(K)}$; otherwise it emits *Unknown*. Thus K controls both the retained evidence set and the retrieval output used for Path A stance assignment.

Interpretive reporting module. The retained DrugBank records are additionally processed by an LLM-based summarization module that produces structured summaries and natural-language descriptions. These outputs are used for interpretation only and do not affect the deterministic Path A stance defined in §3.2.

C Implementation Details for Path B

Alias expansion. Path B expands normalized drug names using a small fixed alias map covering common generic and brand-name variants. When no aliases are available, retrieval uses the normalized name.

Retrieval scope. Path B issues synonym-expanded queries, aggregates PubMed results, deduplicates by PMID, and retains the first three unique articles D_B.

Joint evidence extraction. The retrieved documents are processed by an LLM-based module (Prompt B.1) that extracts up to six candidate sentences, each labeled as *Support*, *Contradict*, or *Unknown*, together with a short rationale.

Post-extraction guardrails. Two deterministic rules are applied after extraction. (i) *Pairwise relevance*: sentences that do not match both queried drugs are downgraded to *Unknown*. (ii) *Contradiction filter*: *Contradict* is retained only when explicit negation and interaction cues are both present; otherwise it is downgraded to *Unknown*. These rules favor precision over recall.

Guardrail cue lists. The following cue lists are fixed across all experiments. Matching is case-insensitive and implemented as substring matching over the extracted sentence.

Explicit pairwise negation cues (used to retain *Contradict* labels): `no interaction`, `no significant interaction`, `no clinically meaningful interaction`, `did not identify an interaction`, `does not interact`, `no effect on`, `not associated with an interaction`.

Interaction-related cues (required alongside a negation cue to retain *Contradict*): `interaction`, `interact`, `coadministration`, `co-administration`, `concomitant`, `combined`, `bleeding risk`, `toxicity`, `exposure`, `serum level`, `metabolism`, `excretion`, `anticoagulant`, `inr`, `monitor`, `contraind`.

Interpretive reporting module. Retrieved documents are also summarized by an LLM for interpretive purposes. These summaries do not affect path-level stance or final decisions.

D Accuracy Under PU Evaluation

Table 3 reports accuracy for completeness. Accuracy is not a reliable measure under PU evaluation, as unlabeled pairs may contain true interactions and are treated as negatives.

E Structured Coverage Analysis

DDInter and DrugBank are both curated DDI resources, and their interaction coverage may partially overlap, potentially contributing to strong performance for systems relying on structured DrugBank evidence. We therefore analyze direct DrugBank coverage in the randomly sampled 1,000-pair DDInter evaluation set.

Under the deterministic resolver used by Path A, 558 pairs (55.80%) have a direct DrugBank pair match and 442 pairs (44.20%) do not. We then evaluate recall over confirmed positives separately

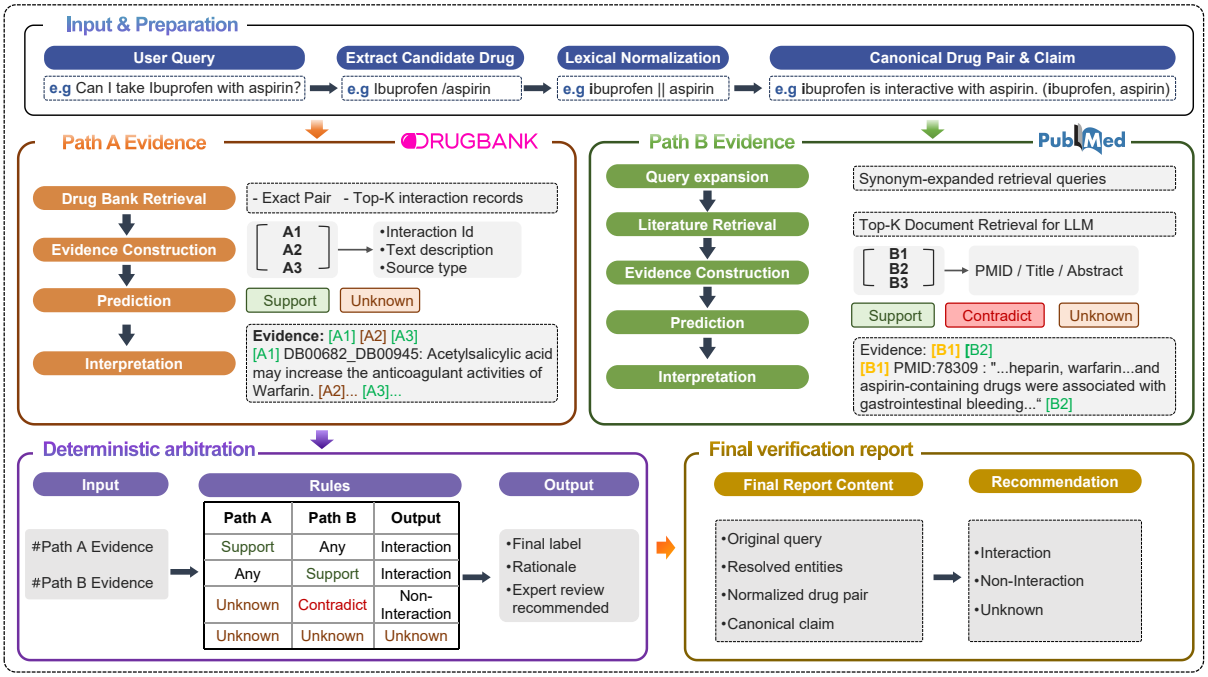

Figure 2: CROSSDDI pipeline. A drug-pair query is normalized into a canonical interaction claim and verified along two evidence paths: DrugBank (Path A) and PubMed (Path B), which provide structured and literature-based evidence, respectively. A deterministic arbitration rule combines path-level outputs into a final verdict linked to explicit supporting evidence.

for the two subsets. With direct DrugBank coverage, CROSSDDI recalls 399 of 465 positives (85.81%); without such coverage, it recalls 63 of 332 positives (18.98%). This gap suggests that structured database coverage strongly influences observed end-to-end recall.

F Prompt Template for Path B Evidence Extraction

Prompt B.1 is the only LLM component whose outputs directly influence the final decision, as it determines the evidence sets used for stance assignment.

Prompt B.1: Literature Joint Extraction.

```
You are an expert clinical pharmacologist
    performing joint
evidence extraction and stance labeling for
    PubMed drug-drug
interaction verification.
From the provided Top-K PubMed documents,
    extract the most
claim-relevant evidence sentences and assign
    each one a label:
Support, Contradict, or Unknown.

Rules:
- Prefer sentences that explicitly describe
    interaction,
  coadministration risk, bleeding risk, toxicity,
      exposure
  change, monitoring concern, or lack of
      interaction.
- Do not select sentences that merely co-mention
    both drugs
  unless the sentence discusses their pairwise
      relationship.
- Use Contradict only when the sentence
    explicitly denies a
  pairwise interaction or pairwise effect.
- Use Unknown when the sentence is indirect,
    weak,
  not pair-specific, or insufficient to resolve
      the claim.
- Return at most the requested number of
    sentences.
- Return valid JSON only.
- Use exactly this schema:
  {"selected_evidence":[{"pmid":"...","title
      ":"...",
  "sentence":"...","score":0.0,
  "source_type":"abstract_sentence",
  "label":"Support|Contradict|Unknown",
  "rationale":"one concise evidence-grounded
      sentence",
  "selection_rationale":"why this sentence was
      selected"}]}.
- Do not wrap the JSON in markdown fences.

Canonical claim: {claim}
Maximum sentences: {max_sentences}

Top-K PubMed documents:
{context}

G RAG Baseline Prompt

For transparency, we report the full prompt template used by the RAG baseline. The baseline receives the same retrieved DrugBank and PubMed evidence used by the verification paths. DrugBank evidence is formatted as up to three structured records, each containing an evidence ID, DrugBank interaction ID, counterpart name, retrieval rank bucket, severity, evidence level, and description. PubMed evidence is formatted as up to three retrieved articles, each containing an evidence ID, PMID, title, journal, publication date, and abstract. If no evidence is retrieved from a source, the corresponding section explicitly states that no records or documents were retrieved.

Prompt RAG: Interaction Verdict Generation.

```
You are an expert clinical pharmacologist
    evaluating a possible
drug-drug interaction.
Your task is to determine whether there is an
    interaction
between {drug_a} and {drug_b} based only on the
    retrieved
evidence below. Do not use outside knowledge.

DrugBank Evidence:
{drugbank_context}

PubMed Evidence:
{pubmed_context}

Instructions:
1. Use only the evidence provided above.
2. Classify the pair as "Interaction" if the
    evidence
   explicitly supports an interaction, mechanism,
       or
   clinical risk involving both drugs.
3. Classify the pair as "Non-Interaction" if the
     evidence
   explicitly states there is no interaction
       between the drugs.
4. Classify the pair as "Unknown" if the
    evidence is
   insufficient, indirect, conflicting, or does
       not explicitly
   establish either of the above.
5. If the evidence is mixed or unresolved,
    choose "Unknown".
6. Return valid JSON only.

Output schema:

yj38@iu.edu,ramakanth.kavuluru@uky.edu

Abstract

Even in the era of large language models (LLMs), biomedical relation extraction (RE) still plays a major role in timely creation of knowledge graphs that further guide biomedical knowledge discovery. The main task in RE is to extract a relation "as expressed" in an input text. At times, crucial definitional information or other auxiliary information about the entities involved may be missing from the input text. Augmenting it from other external textual sources appears helpful on the surface but can be harmful too, as these sources can overwhelm the signal in the original input, leading to false positives or false negatives. To counter this, we leverage a pre-trained biomedical text retriever to augment original inputs with additional instance-specific snippets. This is done through a gating mechanism that allows the retrieved snippets to enhance but not overwhelm the signal from the original input. We evaluate our approach on three standard biomedical relation extraction datasets (CDR, BioRED, and ChemProt) and show consistent improvements (up to 10 F1 points) compared with strong supervised baselines involving both encoder and decoder models. All our code and the datasets used are available for reuse: https://github.com/bionlproc/GRAFT-RE.

1 Introduction

Biomedical relation extraction (RE) is a core task in biomedical natural language processing (Huang et al., 2024), considering relations among biomedical entities drive etiology, pathology, treatment, and recovery in human diseases. Relations span the translational science spectrum from biological links (e.g., protein-protein interactions) to translational connections (e.g., gene-disease associations) and clinical information (e.g., drug-disease treatment relations). The goal in RE is to infer and classify the relation between a pair of input entities, typically from a fixed set of relation types. Relations extracted lead to knowledge graphs (KGs), which further enhance biomedical knowledge discovery via reasoning over KGs (Raghavan et al., 2021). Although LLMs have become general purpose NLP tools, KGs are still deemed essential to reduce hallucinations and ground reasoning in discovery tasks (Xiong et al., 2025; Xu et al., 2025). Hence, overall, RE remains an important primitive in BioNLP.

Consider the sentence: "We conclude that tamoxifen therapy is more effective for early stage breast cancer patients." From this sentence an RE model is expected to extract the relation (tamoxifen, TREATS, breast cancer) where tamoxifen is the *subject* entity, breast cancer is the *object* entity, and TREATS is the relation type or more formally the *predicate*. RE by definition implies that the only input provided is the sentence (or document) from which the relation is to be extracted. This means, we are **not** looking at general (global) knowledge about the entities mentioned in the input, but more interested in relations as explicitly stated (or implied) in the input (local assertions). But a given input often may not include background information about the entities needed to tease out a potential relation. This could be in the form of definitions (or glosses) of the entities in the input. This could also be in the form of hyponyms of entities involved. For the TREATS example we chose earlier, the definition of tamoxifen in the Medical Subject Heading (MeSH) vocabulary includes: "Tamoxifen acts as an anti-estrogen (inhibiting agent) in the mammary tissue, but as an estrogen (stimulating agent) in cholesterol metabolism, bone density, and cell proliferation in the endometrium." In the MeSH hierarchy we can also see that tamoxifen is a "benzylidene compound." In addition to the original text input to the RE, it might be beneficial to augment it with this extra contextual information. The contextual information can also be arbitrary pieces of text from the broad scientific literature that may enhance RE. Our current effort investi-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 920–931
July 3-4, 2026 ©2026 Association for Computational Linguistics

gates how to do this in a way that is both *effective* and *efficient*. Neither of these objectives is easy to meet because the extra text added as additional context to the input can confuse the model and drown the signal from the original input text. So in the end, the performance may actually worsen if the context contradicts what is stated in the input. The augmented context also increases the length of the input thus increasing computational cost.

Another concern in using additional context in RE may arise if the context already contains a directly stated positive relation, which is discussed in a complex and nuanced manner in the original input. In this case, a natural question to ask is if this constitutes cheating, considering the main goal is to extract relations as expressed in the input; the context might already contain the right answer. However, over the past decade encoder LMs already ingest billions of tokens of biomedical free text during pre-training (e.g., BioBERT (Lee et al., 2020) and BiomedBERT (Gu et al., 2021)). Furthermore, autoregressive LLMs are also pre-trained on PubMed abstracts and full text articles in PMC (Yang et al., 2022; Sallinen et al., 2025; Bolton et al., 2024). Given most modern RE efforts are almost exclusively based on encoders or LLM backbones, besides the input text that is explicitly provided, the models have entire PubMed/PMC at their disposal (via LM model weights), in an implicit manner. We propose to simply make this explicit along the lines of retrieval-augmented generation (RAG), already popular when using LLMs for question answering (QA) (Lewis et al., 2020; Xiong et al., 2024). The testing is always done against gold answers derived from the original input and hence the context's influence is strictly measured against what is available in the input.

In this paper, we present **G**ated **R**etrieval-**A**ugmented **F**ine-**T**uning (GRAFT) for RE, a parametrized approach that incorporates external retrieved context as part of the input for RE. GRAFT can seamlessly integrate with both small encoder models and autoregressive LLMs. It relies solely on a small encoder based, zero-shot retriever for biomedical RE (Jin et al., 2023), requiring no supervised data for retrieval. The documents retrieved are processed in parallel, thus reducing computational overhead significantly. Additionally, we incorporate a dynamic weighting (gating) layer that amplifies useful information from the context, while filtering out less relevant content. We evaluate GRAFT on three widely used biomedical RE datasets and show promising improvements across all of them. While this paper is focused on biomedicine, the method is agnostic of the domain and can be employed as long as there is a way to retrieve general Web text using well known models for the general domain (Izacard et al., 2022; Wang et al., 2022; Ni et al., 2022). The code and datasets used for this paper are available: `https://github.com/bionlproc/GRAFT-RE`.

2 Related Work

Several efforts on retrieval-augmented biomedical tasks focus on biomedical QA (Xiong et al., 2024; Sohn et al., 2024; Jeong et al., 2024; Das et al., 2024). Specifically, Xiong et al. (2024) benchmark a spectrum of retrieval–generator pairings across BioASQ, MedQA and PubMedQA revealing that naive coupling of powerful generators with off-the-shelf BM25 retrieval leaves substantial head-room that can be exploited by hybrid dense-sparse retrievers and cross-encoder rerankers. Sohn et al. (2024) extend this line of work with RAG^2, where rationale-guided query reformulation and a lightweight snippet filter reduce noise propagation and boost answer F1 by up to 6 points on three medical QA benchmarks.

Regarding other related efforts for RAG in biomedicine, Lopez et al. (2025) present CLEAR (Clinical Entity Augmented Retrieval), a task-aware RAG pipeline that first detects clinically salient entities in a potentially long clinical note, then restricts retrieval to context windows surrounding those entities, thereby trimming the context fed to the generator. This use case is different from GRAFT's use of external context to augment an input text for RE. BiomedRAG (Li et al., 2025) retrieves chunk-based documents from an external database and concatenates them directly into the LLM input, using a custom chunk scorer trained with a perplexity-driven supervision signal. It addresses noise at the retriever level (via better chunk selection), whereas GRAFT addresses it at the model level (gated fusion). Furthermore, GRAFT supports smaller encoder models for RE while BiomedRAG is an LLM-only method.

There are two related efforts in general domain RE. First, RetrievalRE (Chen et al., 2022) uses a non-parametric kNN retriever to select examples from the training data to be used in an interpolated manner along with a conventional parametric model's predictions. Hence, there is no

use of external knowledge as in GRAFT. Next, RAG4RE (Efeoglu and Paschke, 2025b) and its fine-tuned extension (Efeoglu and Paschke, 2025a) concatenate the retrieved context directly into the prompt and rely on LLMs, without any mechanism to control the influence of retrieved documents. In contrast, GRAFT processes retrieved documents in parallel, employs a learned gating mechanism to dynamically modulate retrieval influence, and is effective with small encoder models too. To summarize, BiomedRAG (Li et al., 2025) and RAG4RE (Efeoglu and Paschke, 2025a) differ from GRAFT in two aspects: (1) both target only LLM backbones, whereas GRAFT applies equally to small encoder models and causal LLMs. (2) GRAFT processes retrieved documents in parallel rather than concatenating them, decoupling per-document context length from the number of retrieved snippets.

Finally, we note that augmenting RE with auxiliary textual or structured information is a recurring theme in our prior work: Jiang and Kavuluru (2025) use instance-adapted predicate descriptions to enrich relation representations in a dual-encoder setup, while Jain et al. (2024a) cast document-level RE as context-guided link prediction and Jain et al. (2024b) incorporate structured knowledge for cross-document RE. GRAFT extends this direction by drawing on dynamically retrieved unstructured text rather than fixed predicate definitions or curated knowledge bases.

3 The GRAFT Method

3.1 Retriever model

To eliminate the need for retriever training, we optimize our entire system using MedCPT, a zero-shot biomedical IR model (Jin et al., 2023) trained on PubMed search logs by researchers at the US National Library of Medicine. In biomedical RE, the primary source of information lies in the entities themselves; entity traits can offer critical insights that inform the eventual relationship. Therefore, the retrieved information about the entities serves as ancillary context, aiding the prediction model in determining the relationship. We prepare two kinds of queries for MedCPT retrieval:

1. **Entity-wise query** to search for documents that describe or characterize an entity. We use the query *"What is the <entity_type> <entity_string>?"*. This is launched for both entities involved.
2. **Entity-pairwise query** to retrieve documents that discuss both entities and may reveal interactions between them. This query is formatted as: *"What is the interaction type between the <entity1_type> <entity1> and the <entity2_type> <entity2>?"*.

For biomedical RE, PubMed is an ideal choice for fetching snippets for augmentation and MedCPT comes pre-loaded with it. Additionally, we incorporate Wikipedia due to its broad complementary coverage of various biomedical concepts. Thus, the resulting documents retrieved constitute two components, the entity-wise documents and pairwise documents, both featuring PubMed abstracts and Wikipedia articles.

3.2 Zero-shot RE

To assess zero-shot performance in conjunction with the retrieved documents, we merge these documents with the input text for RE as part of the prompt. We test this strategy with the `Llama-3.2-Instruct-3B` model (Grattafiori et al., 2024), which allowed us to assess how effective the retrieved MedCPT documents are without training data. To ensure consistent outputs, we prompt the model to produce responses in a predefined JSON format, as shown in Figure 6 (of the Appendix). We present the results in Figure 1 for two datasets: chemical-disease relations (CDR (Li et al., 2016)) and chemical-protein relations (ChemProt (Krallinger et al., 2017)). We notice that the zero-shot prediction results remain suboptimal. The retrieved documents clearly hurt the performance as they likely introduced excessive noise when used in this simple way to augment the original input. The absence of clearly defined filtering mechanisms to distinguish between genuinely useful background information and irrelevant context may have caused the model to overlook or misinterpret cues essential for RE. Thus, simply appending external context can worsen results.

3.3 Fine-tuning GRAFT

To address the issues with naive augmentation, we propose using a fine-tuned model rather than a purely zero-shot approach. Although frontier LLMs can alleviate certain issues in zero-shot settings (Brokman et al., 2025), fine-tuning a smaller model offers a more cost-effective option. But several challenges remain unresolved: (1) incorporating extensive external documents into the trans-

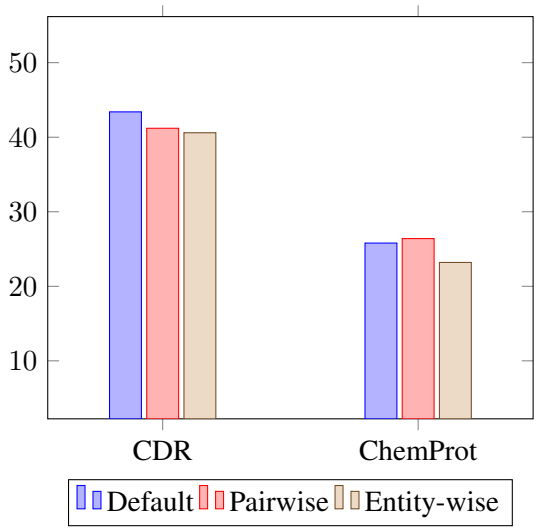

Figure 1: Zero-shot performance (in F1 scores) on CDR and ChemProt datasets using different types of retrieved documents. "Default" indicates that no external documents were applied. Up to 6 snippets were tried and the top score is reported.

former architecture's self-attention mechanism remains computationally expensive, incurring $O(n^2)$ computational complexity, and (2) failing to discard irrelevant documents still introduces additional noise into the model. The relation could be easily determined from the original context in some simple cases; the retrieved documents for these instances may lead to errors.

Therefore, instead of appending documents, we opt to input documents in parallel for two reasons: (1) we assume each document carries its own distinct information and should be processed independently, and (2) this reduces the computational overhead that would arise from cross-document interactions. As a result, the generative capability of language models is replaced by a BERT-like classification approach. Furthermore, inputting documents in parallel drastically reduces context length limitations, enabling the method to be applied to smaller models as well.

Specifically, let $\mathcal{M}$ be any transformer based model, x the input relation text, and $D = \{d_1, d_2, \ldots, d_n\}$ the set of retrieved documents. The model encodes the input text and each document independently:

$$h_x = \mathcal{M}_t(x), \quad h_i = \mathcal{M}_d(d_i), \ \forall i \in \{1, \ldots, n\}.$$

We form the representation by concatenating token-wise the text and document embeddings, then pass it through a lightweight, two-layer self-attention module to enable cross-interaction:

$$H_x = Self\,Attention([h_x \parallel h_1 \parallel h_2 \parallel \ldots \parallel h_n]).$$

Furthermore, we design a gating mechanism that allows less attention to unimportant documents or when the input text is very informative, needing less external context interference. It employs an MLP layer as the scorer to evaluate the original input text and assign a dynamic weight for the retrieved documents. We define this weight as

$$g_x = \sigma\left(MLP(h_x)\right) \in (0, 1).$$

Before we discuss how this weight g_x is incorporated into the training and inference process, we first ought to cover how the relation is represented. For bi-directional models, we explicitly mark each entity span with unique boundary tokens so the model can localize and differentiate the arguments of the relation. For example, the entities `acetaminophen` and `liver injury` are marked as: "`The analgesic [E1] acetaminophen [/E1] may induce [E2] liver injury [/E2] in susceptible patients.`" Let h_x^{E1} and h_x^{E2} be the contextualized output of `[E1]` and `[E2]`, the relation representation $Rep(h_x)$ in bi-directional model is defined as

$$Rep(h_x) = LayerNorm([h_x^{E1} \parallel h_x^{E2}]).$$

In causal (autoregressive) models, where each token attends solely to preceding tokens, we enclose the entities in boundary markers and append an additional `[EOT]` token at the end of the sequence, for the same example: "`The analgesic [E1] acetaminophen [/E1] may induce [E2] liver injury [/E2] in susceptible patients. [EOT].`" Let $h_x^{[EOT]}$ be the contextualized output of `[EOT]`, the $Rep(h_x)$ in causal model form is defined as

$$Rep(h_x) = LayerNorm(h_x^{[EOT]}).$$

With this setup for $Rep(h_x)$, we derive final relation labels via

$$\hat{h}_x = \mathbf{W_1}(Rep(h_x))$$

where $\mathbf{W_1}$ is the projection layer such that $\hat{h}_x$ is an r-dimensional vector with r being the total number of possible relations (label cardinality). Without the gating mechanism, the loss function is

$$\mathcal{L}_{\text{orig}} = -\sum_{j=1}^{r} y_j \log(\hat{h}_x^j).$$

As H_x is essentially h_x with retrieved documents concatenated, the notion of $Rep(\cdot)$ is applicable to H_x too. Therefore, the aggregated relation representation controlled by the weight g_x is

$$\hat{H}_x = (1-g_x)\mathbf{W_1}(Rep(h_x)) + g_x\mathbf{W_2}(Rep(H_x))$$

where $\mathbf{W_2}$ is a projection matrix just as $\mathbf{W_1}$. Now the aggregate loss function

$$\mathcal{L}_{\text{agg}} = -\sum_{j=1}^{r} y_j \log(\hat{H}_x^j),$$

and the full loss incorporates both the original and the aggregate losses (involving retrieved docs) into

$$\mathcal{L} = \mathcal{L}_{\text{agg}} + \mathcal{L}_{\text{orig}}.$$

During inference, the output logits ought to be informed by the augmentation of the retrieved documents. Hence, the aggregated form $\hat{H}_x$ is used to predict the relation.

4 Experiments

4.1 Datasets

We conduct the experiments on three commonly used biomedical relation extraction datasets: CDR, ChemProt and BioRED. Table 1 displays the resulting processed statistics of the datasets.

- **CDR** (Li et al., 2016) is annotated at the entity level for chemical-disease inducement relations of PubMed abstracts. Each entity is normalized to a unique identifier (e.g., *lidocaine* → *D008012*). Therefore, one identifier could sometimes refer to multiple entity strings. Because there are only two entity types: chemical and disease, and one relation type (inducement), the task simplifies to binary classification. To create a more difficult and realistic evaluation setting, we sever the linkage between mentions that share the same identifier, splitting them into separate relation instances. This adjustment ensures that each entity mention is handled independently, making the task more challenging than the standard setup that operates on normalized entities.

- **BioRED** (Luo et al., 2022) dataset is built on top of the original CDR abstracts, but it greatly expands both the entity and relation inventories, incorporating six entity types (chemical, disease, gene/protein, ...) and eight relation categories. Like CDR, BioRED includes normalized entity annotations, so we process it in the same manner as CDR dataset.

- **ChemProt** (Krallinger et al., 2017) captures interactions between chemicals and genes or proteins, collected from PubMed abstracts and spanning five relation types. Because the annotations are at the entity mention level, we apply no additional preprocessing.

Dataset	# Pred.	# Train	# Valid	# Test	Nor.
CDR	1	8441	8340	8502	Yes
BioRED	8	37286	11407	11880	Yes
ChemProt	5	17991	11328	15474	No

Table 1: Statistics of datasets used (columns 3–5 are numbers of instances/relations used in our experiments).

4.2 Retrieval corpora

Corpus	#Snippets	Ave. L	Domain	Entity-wise	Pairwise
PubMed	23.9M	296	Biomed.	✓	✓
Wikipedia	29.9M	162	General	✓	

Table 2: Statistics of the corpora; **Entity-wise** and **Pairwise** denote whether the corpus is applied with entity-wise query or pairwise query.

For retrieval, we employ two corpora, PubMed abstracts and Wikipedia articles, which together provide broad and diverse coverage of biomedical knowledge. PubMed serves as our biomedical corpus, whereas Wikipedia represents the general-domain corpus. As described in Section 3.1, we generate two retrieval queries for every entity pair: an entity-wise query, executed on both corpora, and an entity-pairwise query, applied only to PubMed abstracts due to efficiency considerations. The details of each corpus are in Table 2.

Dataset	#Pairs	#Mentions	%PubMed	%Wiki
CDR	21853	5384	69.4%	30.6%
BioRED	58998	6048	66.4%	33.6%
ChemProt	28449	12310	60.3%	39.7%

Table 3: Statistics on the retrieved snippets for all three datasets, combining the training, validation, and test splits; **#Pairs** and **#Mentions** denote the counts of unique pairs and unique mentions, respectively.

We query with each entity's surface form, so when multiple mentions share the same identifier

Causal LMs									

Table 4: Experimental results of GRAFT compared to corresponding baseline models. Our method consistently outperforms the corresponding baselines and surpasses the larger 8B model on CDR and BioRED. Improvements are shown with ↑, representing gains over the baseline using the same transformer model.

(e.g. *Parkinson's disease* and *PD*), every mention is submitted to the retriever separately. Following Xiong et al. (2024), we chunk each corpus into short snippets to enhance retrieval granularity, reduce noise, and ensure that the retriever returns passages focused on the target entities. These snippets are ranked by MedCPT according to the relevance scores it assigns; for efficient fine tuning, we select the top one to five snippets and feed them into GRAFT. Statistics of retrieved snippets are displayed in Table 3. Although Wikipedia holds more snippets overall, entity-wise queries return substantially more snippets from PubMed, reflecting our emphasis on biomedical tasks. Since the number of unique mentions is much smaller than that of unique pairs across all three datasets, using entity-wise queries for retrieval is considerably more efficient.

4.3 Baseline models

As outlined in Section 3.3, we evaluate our framework in two architectural settings: (i) bidirectional encoder models and (ii) left-to-right (causal) language models. For the causal-LM track, we adopt the recently released Llama-instruct models: `Llama-3.2-Instruct-3B` and `Llama-3.1-Instruct-8B`. For the encoder-based setting, we select BiomedBERT (Gu et al., 2021), a transformer encoder pre-trained exclusively on PubMed abstracts. We fine-tune BiomedBERT following Zhong and Chen (2021), a commonly used fine-tuning approach for RE tasks.

In baseline experiments, we fine-tune BiomedBERT using only the original text; its input-length limit of 512 tokens prevents appending any retrieved documents. (Note that this restriction applies only to naive augmentation; GRAFT allows for retrieval augmentation because of parallel processing of individual snippets.) For Llama models, we conduct two separate fine-tuning regimes: one on the raw input and one on document-augmented input, both optimized with the standard language modeling objective:

$$\mathcal{L}_{\mathrm{LM}}(\theta) = -\sum_{t=1}^{T} \log P_\theta\big(x_t \mid x_{<t}\big).$$

We employ the instruction template from Figure 6, consistent with the zero-shot configuration. We provide all model choices in Table 5.

Model	Size	Context Length	Domain
BiomedBERT	110M	512	Biomed.
Llama-3.2-Instruct	3B	128k	General
Llama-3.1-Instruct	8B	128k	General

Table 5: Model selection of our baseline experiments.

4.4 Main results

We present our results in two model categories: bidirectional encoders (e.g., BiomedBERT) and causal LMs. As shown in Table 4, GRAFT fine-tuned on BiomedBERT outperforms standard BiomedBERT fine-tuning, yielding F1 improvements of 1.4 % to 4.4 %. This demonstrates that even encoder models with limited context length

can benefit from retrieval augmentation when fine-tuned with GRAFT. For causal LMs, we also evaluate a retrieval-augmented variant of vanilla fine-tuning to leverage their extended context capacity. GRAFT-tuned Llama-3.2-3B-Instruct outperforms the baseline on all three datasets, with F1 gains of 5.6%–10.8%. Additionally, GRAFT with the 3B-parameter Llama model surpasses a larger 8B-parameter Llama on the CDR and BioRED datasets by 2.0%–6.6% F1.

The magnitude of improvement varies across datasets and tracks the difficulty of the underlying task. ChemProt has a high baseline F1 in the BiomedBERT setting (78.2 vs. 62.3 for CDR and 53.1 for BioRED), leaving relatively less headroom for improvement; the corresponding 1.4 F1 gain with GRAFT likely reflects this ceiling effect. Conversely, BioRED, the most challenging dataset with eight relation types and the lowest baseline F1 (52.9 for Llama-3B, 53.1 for BiomedBERT), shows the largest gain (10.8 F1 with Llama-3B).

We observed an interesting phenomenon: standard fine-tuning of the 3B-parameter Llama model with retrieved documents actually degrades performance compared to fine-tuning without document augmentation. However, with the larger 8B-parameter model, this performance drop is alleviated, suggesting that the additional complexity from retrieved documents is more challenging for smaller LMs to manage. GRAFT enables smaller language models to benefit from retrieval augmentation, which is an advantage that, with naive concatenation, is only realized by larger architectures.

We note that the *w/Retrieval* rows of Table 4 are akin to the core RAG4RE design (Efeoglu and Paschke, 2025a): retrieved snippets are concatenated into the prompt and the model is fine-tuned with the standard language modeling objective, without any gating or noise-control mechanism. The gap between these rows and GRAFT rows isolates the contribution of gated parallel encoding rather than retrieval itself.

We also present results for various document-retrieval schemes in Table 6. As BioRED contains over 50K unique relation pairs, we did not evaluate pairwise retrieval on it. Across the other two

datasets, entity-wise queries consistently achieve higher performance for both BERT-based models and causal LMs. Since each dataset has fewer unique mentions than unique pairs, using entity-wise queries is inherently more efficient.

5 Discussion

5.1 Varying number of snippets

We vary the number of retrieved snippets/documents and evaluate how this affects performance. The results are shown in Figure 2. To ensure the efficient fine-tuning, we experiment with retrieving between 2 and 6 snippets, finding that all three datasets deliver strong results with just two retrieved snippets. Increasing the number of retrieved snippets led to performance declines on BioRED and ChemProt, implying that the inclusion of too much information can degrade performance. From a computational angle, limiting retrieval snippets also keeps both memory footprint and latency low. With fewer snippets retrieved, the model can more accurately assign attention, reducing the risk of overfitting to noisy context.

5.2 Ablation on corpus domains

We found that the choice of corpus domain has an impact on model performance. To quantify this, we performed ablation experiments, omitting one corpus at a time, and present the results in Figure 3. For BioRED and CDR, the mixed-corpus setup consistently achieved the highest average F1. In particular, augmenting PubMed with Wikipedia improved CDR by 3% F1 and BioRED by 2% F1, demonstrating that general-domain text can effectively complement biomedical literature. Conversely, relying solely on one domain proved insufficient for these tasks, confirming that a hybrid corpus strategy yields the most robust results. One reason could be because Wikipedia has general introductory exposition on many biomedical topics and hence could offer a clearer signal that is easy to process semantically compared with complicated jargon-loaded long sentences typically seen in PubMed abstracts. With ChemProt, which targets chemical–gene/protein interactions, we observe a slightly different pattern: PubMed-only retrieval delivers near-optimal performance. Adding Wikipedia incurs a 1% F1 drop. The results indicate that for datasets like ChemProt, where interactions are narrowly defined, domain-specific literature is more essential.

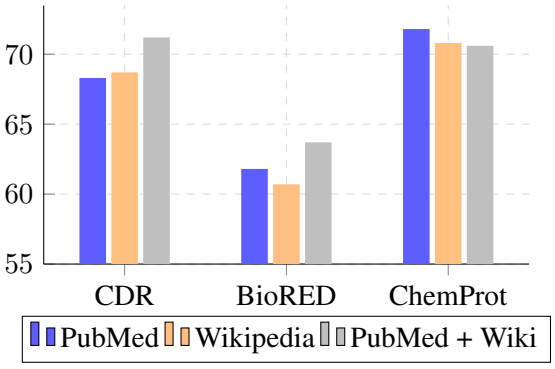

Figure 3: Model performance across different corpora.

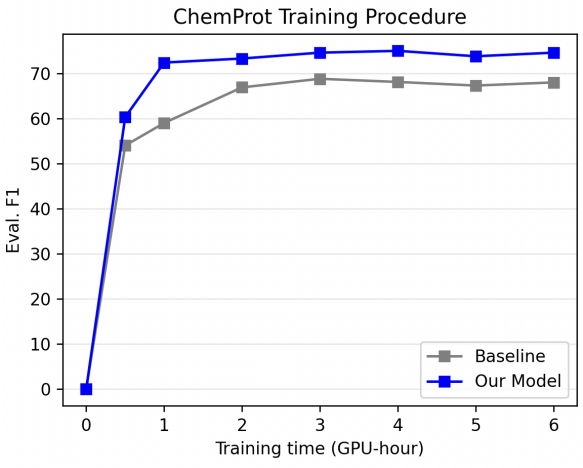
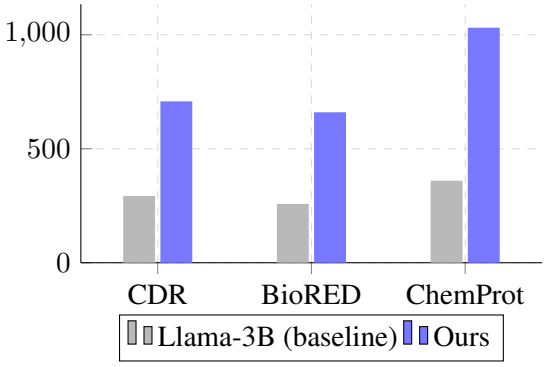


5.3 Computational efficiency

We report validation F1 scores on the ChemProt dataset across multiple epochs with our approach, comparing with the 3B-parameter Llama baseline model. As shown in Figure 4a, our model has reduced computational demands, and it converges more rapidly than the baseline, which relies on the standard language modeling objective. During inference, GRAFT requires only a single forward pass, making it faster than next-token generation methods, which require multiple forward passes. Meanwhile, when processing batched document inputs, GRAFT only requires a context window equal to the length of the longest individual document or text segment, whereas the baseline approach requires a context window large enough to accommodate all concatenated inputs. Consequently, GRAFT delivers substantially faster processing speeds than the baseline, which is shown in Figure 4b.



5.4 Case study: how much does prediction rely on retrieved information?

A natural concern with retrieval augmentation in RE is that retrieved snippets, drawn from corpora reflecting consensus knowledge about entity pairs, may bias the model toward predicting commonly attested relations rather than the relation as expressed in the input. This is especially relevant when the input asserts a novel, qualified, or context-specific relation that diverges from retrieved snippets. In Section 1, we posited that this is unlikely to happen since both training and testing are conducted against gold relations derived from the input.

Here to examine whether our approach addresses this concern, we look at the dynamic gate weights g_x across the entire CDR test set, shown in Figure 5 (y-axis: position in sorted order per g_x). Across

(a) Validation F1 over training epochs.

(b) Inference throughput (instances /min).

Figure 4: Computational performance: (a) learning curve and (b) processing speed.

all instances, g_x never exceeds 0.4. Thus, the gated combination consistently down-weights the retrieval branch. Despite this bounded influence, GRAFT improves CDR F1 from 62.3 to 66.7—a 4.4 F1 gain—indicating that retrieval supplies useful background cues without overwhelming local assertions in the input. This behavior is learned in GRAFT: the gate is trained jointly with the classifier and attenuates retrieval when the input is already informative.

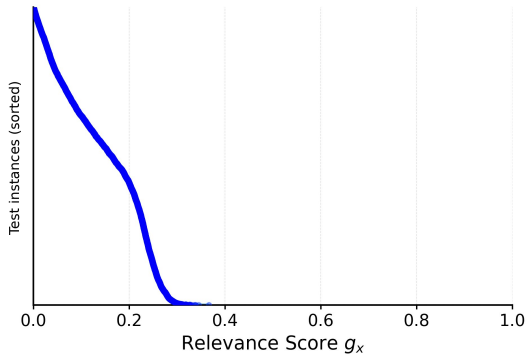


Figure 5: The gate g_x plotted (sorted) over instances of the CDR test set.

6 Conclusion

In this paper, we demonstrated that a training-free, zero-shot retrieval system can be effectively combined with task-aligned fine-tuning to address the challenges of lack of context in biomedical RE. Our proposed GRAFT framework seamlessly integrates a lightweight retriever (MedCPT) with both small encoder models (BiomedBERT) and causal language models (Llama), leveraging dynamic weighting to filter noise and amplify task-relevant information. Through extensive experiments on CDR, BioRED, and ChemProt, we showed that retrieval augmentation yields consistent F1 improvement, ranging from 1.4% to 4.4% for BiomedBERT and up to 10.8% for Llama-3B, while maintaining computational efficiency.

7 Limitations

Despite GRAFT's promise, our effort has some limitations and room for improvement. First, we evaluate on three biomedical RE datasets drawn from PubMed abstracts; generalization to clinical text or general-domain RE remains to be explored (although the method is agnostic to text type). Second, we use MedCPT as a frozen, zero-shot retriever; jointly optimizing the retriever for the RE objective could yield further improvements. Third, we tacitly assume adequate coverage of the target entities in the retrieval corpora; performance on rare or novel entities with sparse literature warrants further investigation. Finally, we use a fixed number of retrieved snippets per instance; adaptive retrieval strategies that dynamically adjust retrieval volume could offer additional gains.

Abstract

We present an overview of PSYDEFDETECT, the shared task on detecting levels of psychological defense mechanisms in emotional support dialogues, co-located with BioNLP@ACL 2026. Grounded in the clinically validated Defense Mechanism Rating Scales (DMRS) framework, the task asks systems to classify a target seeker utterance, given its preceding dialogue context, into one of nine categories: seven hierarchical DMRS levels plus two auxiliary labels. Participants worked on PSYDEFCONV, a newly released corpus of 200 dialogues and 2,336 help-seeker utterances annotated under DMRS with substantial inter-annotator agreement. The task attracted 172 participants on CodaBench who produced 563 submissions, with 21 teams officially registering their results for the final ranking. The best system achieved a macro F1-score of 0.420, surpassing the strongest fine-tuned baseline reported in the dataset paper by a notable margin, yet leaving clear headroom. Our analysis highlights (i) a persistent tendency to over-predict the majority *High-Adaptive* class, (ii) a widening gap between accuracy and macro-F1 that reveals class-imbalance sensitivity, and (iii) the value of theory-aware and LLM-based approaches for fine-grained defensive-function classification. We release all task materials and invite the community to continue work on this novel intersection of clinical psychology and NLP.[1]

1 Introduction

Psychological defenses are, in Winnicott's words, the means by which the *False Self*, if successful in its function, hides the *True Self* (Winnicott, 2018). They are automatic strategies people use to regulate distress, and when used rigidly or excessively they are linked to poorer mental health outcomes and to interpersonal difficulties (Perry and Henry, 2004; Di Giuseppe et al., 2024). In emotional support conversations (ESC) (Liu et al., 2021), defenses shape what help-seekers disclose and how they accept or resist help—yet, despite rapid progress on empathy modeling (Hua et al., 2025b; Cai et al., 2024; Sorin et al., 2024), strategy selection (Kang et al., 2024; Hua et al., 2025a; Na et al., 2025), and affect understanding (Wang et al., 2024a, 2025; Ma et al., 2025; Zhao et al., 2025), the defensive function of seeker utterances remains largely unmodeled in current ESC systems (Di Giuseppe et al., 2024).

To catalyze research on this under-explored dimension of supportive dialogue, we organized **PSYDEFDETECT**, a shared task co-located with BioNLP@ACL 2026 on detecting *levels* of psychological defense mechanisms. The task is grounded in the clinically validated Defense Mechanism Rating Scales (DMRS) (Perry and Henry, 2004; Vaillant, 2012), and asks systems to classify each help-seeker utterance—given its preceding dialogue context—into one of nine categories: the seven hierarchical DMRS levels, augmented with two auxiliary labels for phatic and under-specified turns. The task is built on PSYDEFCONV (Na et al., 2026), the first conversational corpus annotated with DMRS-based defense levels. PSYDEFCONV is derived from ESConv (Liu et al., 2021) via stratified sampling over problem types and emotions, and was double-blind annotated to substantial agreement.

Participation. PSYDEFDETECT attracted strong community engagement. The task was hosted on CodaBench (Xu et al., 2022) from December 2025 through April 2026. Over the course of the evaluation period, the competition registered **172 participants** who together produced **563 submissions** to the leaderboard. By the final registration deadline, **21 teams** had officially submitted their results for inclusion in the ranking. The best system reached

[*]Co-leads of the shared task organization.

a macro F1-score of 0.420, substantially surpassing the strongest fine-tuned baseline reported in the dataset paper (≈ 0.315 macro-F1 (Na et al., 2026)), while still leaving ample headroom for future research.

Contributions. This paper reports on the organization, dataset, participating systems, and results of PSYDEFDETECT. Our contributions are as follows:

- We introduce PSYDEFDETECT, the first shared task that operationalizes DMRS-based defensive functioning as an utterance-level classification problem over emotional support dialogue.
- We report task-level participation that reflects substantial community engagement, with 172 CodaBench participants, 563 leaderboard submissions, and 21 officially ranked teams.
- We present a methodological taxonomy of participating systems together with a full leaderboard analysis that benchmarks submissions against both zero-shot and fine-tuned baselines from the dataset paper.
- We characterize the dominant failure modes observed across the leaderboard, in particular the severe sensitivity to class imbalance and the systematic over-prediction of the High-Adaptive level, and use them to motivate concrete directions for future work at the intersection of clinical psychology and NLP.

2 Background and Related Work

Defense mechanisms and DMRS. Defense mechanisms are a cornerstone of psychodynamic theory (Freud, 1936). The *Defense Mechanism Rating Scales* (DMRS) organize roughly thirty mechanisms into seven hierarchical levels of defensive maturity, from *Action Defenses* (Level 1) to *High-Adaptive Defenses* (Level 7) (Perry and Henry, 2004; Vaillant, 2012). DMRS was originally designed for longitudinal clinical case formulation rather than for single-utterance classification; PSYDEFCONV (Na et al., 2026) adapts the scheme to conversational text by annotating at the *level* rather than the *mechanism* granularity, increasing identifiability and reliability.

Emotional support conversations. Research on ESC has built increasingly capable dialogue agents that alleviate user distress through multi-turn, strategy-grounded interaction, starting with the ESConv corpus (Liu et al., 2021) and extending to multi-strategy (Bai et al., 2025), synthetic (Zheng et al., 2023; Wang et al., 2024a), and reasoning-aware (Zhang et al., 2024) variants. These efforts have largely focused on *supporter* strategies, empathy, and affect modeling (Wang et al., 2024a; Cai et al., 2024; Sorin et al., 2024; Hua et al., 2025b; Xu et al., 2026), while the *defensive function* of seeker utterances has remained unmodeled.

Mental health classification. Prior shared tasks at BioNLP and CLPsych have addressed clinically-motivated classification problems such as suicide risk assessment, depression detection, and empathy prediction. BioNLP has covered a wide spectrum of medical-related challenges, such as clinical question-answering and summarization (Colelough et al., 2025; Soni et al., 2025; Xiao et al., 2025). However, tasks specifically addressing mental health have remained notably underrepresented. CLPsych shared tasks have addressed a range of mental-health-related problems, including depression and PTSD (Coppersmith et al., 2015), suicide risk assessment (Zirikly et al., 2019; Chim et al., 2024), online peer support (Milne et al., 2016), developmental mental-health prediction (Lynn et al., 2018), and longitudinal affective modeling (Tsakalidis et al., 2022; Tseriotou et al., 2025). However, these efforts have primarily centered on social media platforms such as X and Reddit, with comparatively limited attention to ESC. PSYDEFDETECT complements this line of work by introducing a theory-grounded, fine-grained classification problem that requires both local linguistic reasoning and context-aware interpretation.

3 Task Description

3.1 Problem Formulation

Given a multi-turn emotional support dialogue $D = (u_1, u_2, \ldots, u_t)$ between a help-*seeker* and a *supporter*, and a target help-seeker utterance u_t, the task is to predict a defense level label $y \in \mathcal{Y}$, where $\mathcal{Y}$ comprises the seven DMRS levels and two auxiliary labels:

- **Level 0 – No Defenses:** phatic or functional utterances that do not engage with psychological conflict.

- **Level 1 – Action Defenses:** passive aggression, help-rejecting complaining, acting out.
- **Level 2 – Major Image-Distorting:** splitting, projective identification.
- **Level 3 – Disavowal:** denial, rationalization, projection, autistic fantasy.
- **Level 4 – Minor Image-Distorting:** devaluation, idealization, omnipotence.
- **Level 5 – Neurotic:** repression, dissociation, reaction formation, displacement.
- **Level 6 – Obsessional:** isolation of affect, intellectualization, undoing.
- **Level 7 – High-Adaptive:** affiliation, altruism, anticipation, humor, self-assertion, self-observation, sublimation, suppression.
- **Level 8 – Needs More Information:** context is insufficient to assign a label with confidence.

Systems have access to the dialogue context preceding and including u_t, but must not use future turns—this mirrors the online nature of the clinical annotation setup (Na et al., 2026).

4 The PSYDEFCONV Dataset

4.1 Construction

PSYDEFCONV (Na et al., 2026) is built on top of ESConv (Liu et al., 2021). The organizers performed stratified sampling over the joint distribution of problem types and emotions in ESConv to obtain a representative 200-dialogue subset, annotated at the *seeker*-utterance level for defense functioning.

Two trained annotators with expertise in both psychology and NLP labeled each seeker turn independently and double-blind, reaching Cohen's $\kappa = 0.639$ (substantial agreement). Disagreements were adjudicated by consensus to form the gold standard. The annotation workflow was supported by DMRS CO-PILOT (Na et al., 2026), a four-stage LLM pipeline that produces stressor hypotheses, screens candidate DMRS items, validates evidence, and synthesizes ranked recommendations; it reduced mean annotation time by 24.0%.

Category	Total	Supporter	Seeker
# Dialogues	200	–	–
# Utterances	4,709	2,373	2,336
Avg. Turns per Dialogue	23.5 ± 6.6	11.9 ± 3.4	11.7 ± 3.3
Avg. Length of Utterances	19.8 ± 16.5	20.9 ± 17.0	18.8 ± 15.8

Table 1: Data statistics of PSYDEFCONV.

4.2 Corpus Statistics

Table 1 summarizes the basic statistics of PSYDEFCONV. The corpus contains 200 dialogues and 4,709 utterances, roughly evenly divided between supporter (2,373) and seeker (2,336) turns. Conversations are of moderate length, with a mean of 23.5 turns per dialogue and an average utterance length of 19.8 tokens. Only the 2,336 seeker turns carry DMRS defense-level annotations; supporter turns are provided as dialogue context but are not part of the evaluation.

4.3 Label Distribution

Table 2 reports the distribution of the 2,336 annotated seeker utterances across the nine defense labels, as well as their aggregation into four broader defensive categories. The distribution is strongly skewed toward the *High-Adaptive* level (Level 7), which alone accounts for 51.8% of all annotated utterances. Non-defensive or contextually ambiguous turns (Levels 0 and 8) jointly cover another 17.4%, leaving only roughly one third of the corpus for the remaining six defense levels. Within that tail, *Immature* defenses (Levels 1–4) aggregate to 18.9% while *Neurotic* defenses (Levels 5–6) account for 11.9%, with the individual minority levels ranging from 2.6% (Neurotic) to 9.2% (Obsessional).

This imbalance reflects the natural prevalence of defensive functioning in supportive dialogue (Na et al., 2026): adaptive coping such as self-assertion, self-observation, and seeking affiliation is, by design, what participants in ESC conversations most often express. However, the imbalance also means that systems optimized for overall accuracy can trivially favor the dominant class at the expense of minority defense levels. We adopt macro-averaged F1 over the positive classes (1–8) as the official ranking metric (Section 5) precisely to penalize such majority-class bias and to encourage systems that discriminate well across the full DMRS hierarchy.

Categories	Num	Proportion
Seeker's Defense Levels		
0 No Defenses	371	15.9%
1 Action Defenses	136	5.8%
2 Major Image-Distorting	77	3.3%
3 Disavowal	124	5.3%
4 Minor Image-Distorting	105	4.5%
5 Neurotic	61	2.6%
6 Obsessional	216	9.2%
7 High-Adaptive	1,211	51.8%
8 Needs More Information	35	1.5%
Overall	2,336	100.0%
Seeker's Defense Categories		
Non-Defensive/Ambiguous (0, 8)	406	17.4%
Mature Defenses (7)	1,211	51.8%
Neurotic Defenses (5, 6)	277	11.9%
Immature Defenses (1, 2, 3, 4)	442	18.9%
Overall	2,336	100.0%

Table 2: Distribution of the PSYDEFCONV dataset across annotated defense levels and aggregated defense categories.

5 Evaluation Setup

5.1 Platform and Protocol

The shared task was hosted on CodaBench (Xu et al., 2022), where participants downloaded the dataset, received starter baseline kits, and submitted predictions as zipped JSON files. Each team could register on the official leaderboard after completing the result-registration form.

5.2 Metrics

Following the dataset paper (Na et al., 2026), we report Accuracy, Macro Precision, Macro Recall, and Macro F1-score. Macro F1 evaluated over the positive classes (1–8) is the official ranking metric, chosen because it penalizes majority-class bias, weighs minority defensive levels equally with the dominant High-Adaptive level, and follows established practices for multi-class classification (Wang et al., 2022, 2024b; Chen et al., 2025). Level 0 is excluded from the official macro-F1 because it marks phatic or functional turns without defensive content. Level 8, by contrast, is retained because detecting that the available context is insufficient is an explicit task decision rather than a negative class. Furthermore, we include an additional leaderboard that aggregates performance across all classes, enabling a more comprehensive and holistic comparison of the submitted systems.

5.3 Baselines

The CodaBench page provided zero-shot prompting baselines using strong general-purpose LLMs. These baselines follow the same setup as the dataset paper; for reference, the strongest results reported in (Na et al., 2026) are as follows. Under zero-shot prompting, Gemini 2.5 Pro reaches an accuracy of 0.5636 and a macro-F1 of 0.2599, while DeepSeek-V3.2 with thinking enabled achieves comparable performance at 0.5572 accuracy and 0.2617 F1. Under supervised fine-tuning, the best results come from Ministral-8B (Acc = 0.6483, F1 = 0.3148) and InternLM3-8B (Acc = 0.6398, F1 = 0.3053).

6 Participating Systems

6.1 Participation Statistics

The PSYDEFDETECT shared task drew broad international engagement. The CodaBench competition registered **172 participants** and received **563 submissions** over the course of the evaluation period, with **21 teams** officially registering their results for the final ranking (Table 3). Of these, **15** accompanied their submission with a system description paper contributed to this volume. The author affiliations on these 15 papers span 12 countries—Australia, Bangladesh, Canada, China, Germany, India, Russia, Spain, Switzerland, the UK, the USA, and Vietnam—and 24 distinct institutions, including a number of cross-institution collaborations that combine academic NLP groups with clinical and biomedical informatics partners.

6.2 Methodological Taxonomy

The 15 described systems span a broad methodological space, but gravitate toward six recurring patterns, described below. Almost every team targets the same two task-specific pain points: the heavy skew toward Level 7 ("High-Adaptive"), and the ambiguity of DMRS boundaries for short, context-dependent utterances. Several teams combine two or more strategies, in which case we record the most distinctive contribution here.

(i) Multi-model ensembles and deliberative-agent architectures. Top-ranked systems reject the idea that a stronger single model can solve the task, and instead explicitly engineer *error independence* across voters or agents. NÜRNBERG NLP (ranked 1st; Steigerwald et al., 2026) constructs a 9-voter ensemble along three orthogonal axes—class granularity (9-class *gatekeeper* vs. 8-class *special-*

ists), training paradigm (generative vs. discriminative), and base model (Ministral vs. Phi-4)—with per-axis cross-validation folds. UTS (2nd; Galat and Rizoiu, 2026) operates a multi-phase deliberative council of Gemini 2.5 agents in which class-specific *advocates* rate evidence strength rather than vote, augmented by a targeted override ensemble of three fine-tuned Qwen-family models. TONI-NLP (9th; Paul et al., 2026) likewise finds that ensembles outperform any individual prompting, fine-tuning, or embedding-classifier baseline.

(ii) Retrieval- and rubric-grounded LLM classification. A second cluster of systems brings the DMRS clinical rubric into the prompt, either dynamically via retrieval or statically via curated boundary cues. PERCEPTIONLAB (3rd; Fahim et al., 2026) pairs dynamic DMRS-Q item retrieval (Gemini 2.5 Pro) with a Gemini 2.5 Flash classifier fine-tuned on reasoning traces distilled from the same Pro model, explicitly targeting "LLM polarization" toward extreme labels. DAL TEAM (10th; Chu et al., 2026) runs a retrieval-augmented LLM pipeline that decomposes prediction into a coarse-to-fine hierarchy and adds summary-based distillation of dialogue context. ZZUCS (6th; Huang et al., 2026) uses its *CoR-QLoRA* approach to encode task contracts, taxonomy definitions, and adjacent-level boundary cues into the prompts used for 8B QLoRA adaptation.

(iii) Parameter-efficient LLM fine-tuning. Most mid-to-top-ranked systems converge on QLoRA or equivalent PEFT on mid-scale open LLMs. LINGUIUTICS (4th; Adib et al., 2026) QLoRA-fine-tunes Qwen3-8B with grouped stratified cross-validation, minority-class lexical augmentation, and a post-hoc logit-bias calibration step that substantially improves the rare "Needs More Information" class. ERASERHEAD (7th; Horaira et al., 2026) fine-tunes Qwen3-14B with clinically informed prompts and iteratively retuned per-class oversampling. TRANSFORMER_1376 (12th; Saha et al., 2026) reformulates the task as conditional text generation and applies 4-bit QLoRA to Gemma-2-2B.

(iv) Encoder-only and domain-specific transformer fine-tuning. Three teams explore encoder backbones. NEURAL NEXUS (11th; Basu, 2026) fine-tunes ROBERTA-BASE with a composite objective combining focal loss, label smoothing, and square-root-dampened class weights, using role-tagged dialogue history and a `[TARGET]` marker on the target utterance. CS_METRO (15th; Rebayet et al., 2026) builds a three-stage pipeline of LLM-based dialogue summarization, domain-specific transformer fine-tuning (including MentalBERT and Mental-RoBERTa variants), and rule-based ensembling; they report that domain-specific encoders outperform generic LLM fine-tuning on this clinical task. KCL-COGSTACK (17th; Agarwal et al., 2026) contrasts flat fine-tuning, few-shot prompting, and a hierarchical coarse-to-fine classifier that exploits the DMRS label tree, finding the hierarchical design the most effective of the three.

(v) Synthetic data and theory-informed augmentation. VISHC (13th; Vu et al., 2026) focuses on data scarcity rather than model scale, proposing stressor-anchored, theory-driven synthetic data generation combined with a hybrid model that fuses language representations with structured clinical features. Lexical augmentation and oversampling are also used as secondary ingredients by LINGUIUTICS, ZZUCS, TRANSFORMER_1376, and ERASERHEAD.

(vi) Systematic exploration and negative-result studies. Two teams emphasize breadth of comparison over a single headline system. ALIEN-ANNOTATORS (19th; Karip and Hossain, 2026) systematically evaluates six open-source small language models ($\leq$ 9B) under zero-shot and fine-tuning regimes, finding that clinically grounded prompts consistently outperform bare label definitions and that model scale alone does not help zero-shot performance; their post-submission configuration (fine-tuning with 5-fold CV and logit averaging) reaches macro-F1 = 0.346, more than double their official submission. EXPLAINATORS (20th; Babakova et al., 2026) similarly runs four exploratory tracks—direct prompting, encoder fine-tuning, novel "state-of-mind" generation, and LLM fine-tuning—across DeepSeek-V3.2, Qwen-family models, and GLM-series models.

7 Results

7.1 Official Leaderboard

Table 3 lists the final leaderboard, ranked by macro F1-score on the held-out test set. The top system (Nürnberg NLP, F1 = 0.4200) outperforms the second-ranked team (UTS, F1 = 0.4055) by a small margin, while the overall spread of F1 scores is wide (0.063–0.420), underscoring the difficulty of

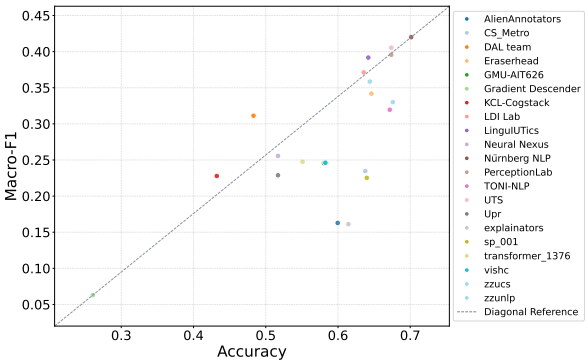

Figure 1: Scatter plot illustrating the relationship between accuracy and macro F1-scores across all submitted systems.

the task.

7.2 Key Observations

Top systems substantially outperform established baselines. The best-performing system, introduced by Nürnberg NLP, achieves a macro F1-score of 0.420, surpassing the best fine-tuned baseline reported in the dataset paper (Ministral-8B, F1 = 0.315) by approximately **10.5 absolute points**, and the best zero-shot baseline by **16 points**. These gains suggest that participants were able to leverage additional task-specific signals beyond standard fine-tuning setups. Nevertheless, the overall performance ceiling remains modest in absolute terms, indicating that the task continues to pose significant challenges.

Wide variability in system performance. System performance exhibits a wide dispersion, with macro F1-scores ranging from 0.063 (GRADIENT DESCENDER) to 0.420 (NÜRNBERG NLP), corresponding to a $6.7\times$ difference. The distribution further reveals a clear quartile structure: the top quartile achieves F1-scores of ≥ 0.37, the median lies ≈ 0.25, and the bottom quartile falls ≤ 0.23. This pronounced spread indicates that, despite the intrinsic difficulty of the task, there remains considerable room for methodological differentiation and performance gains across approaches.

Accuracy is a misleading proxy for F1-score. Several submissions attain relatively high accuracy while exhibiting substantially lower F1-scores, as shown in Figure 1. For instance, ZZUNLP (Acc = 0.676, F1 = 0.330) and TONI-NLP (Acc = 0.672, F1 = 0.320) demonstrate this discrepancy. This mismatch stems from the pronounced class imbalance, with the Level 7 majority class accounting for

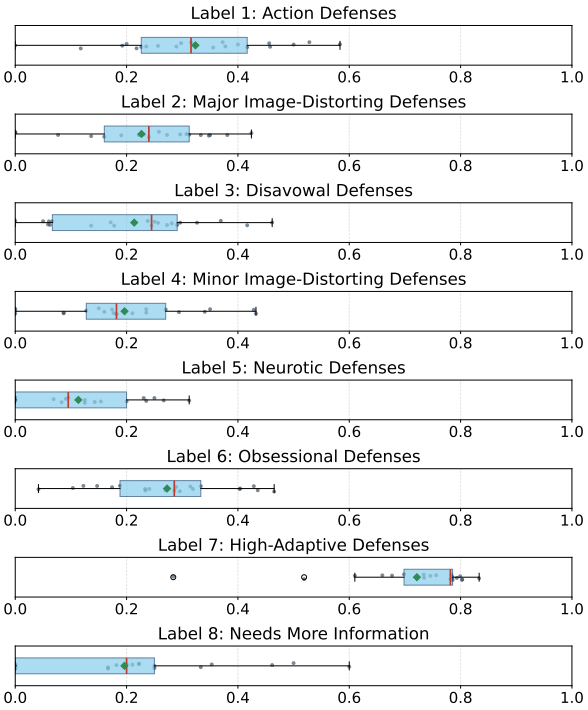

Figure 2: Per-class F1-scores across all submitted systems for the positive classes 1–8. Each box summarizes, for a given defense level, the distribution of F1 values over the 21 leaderboard submissions.

$\approx$52% of the dataset. Models that over-predict the High-Adaptive class can achieve competitive accuracy, but suffer from poor recall on minority classes, thereby degrading macro F1-scores. In contrast, systems such as NÜRNBERG NLP, PERCEPTIONLAB, and LINGUIUTICS achieve a more favorable balance, maintaining strong accuracy alongside improved recall across all classes.

8 Analysis and Discussion

8.1 Per-Class Performance

Figure 2 summarizes per-class F1 across the 21 submitted systems. Level 7 (High-Adaptive) stands apart: its median F1 is by far the highest and the inter-team spread is narrow, reflecting both its majority status ($\approx$52% of the corpus) and the distinctiveness of its surface markers. Every other class has a low median and a wide spread—widest for Levels 2–4, whose linguistic realizations overlap in affective-blame and reality-distortion cues, and for Level 8 (Needs More Information), on which a non-trivial fraction of systems collapse to zero. The narrow box for Level 7 marks a class where surface cues suffice; the wide boxes (Levels 1–6) mark classes where methodological choices translate directly into outcome differences.

Table 3: Official PSYDEFDETECT leaderboard. Systems are ranked by macro-F1 over the *positive* classes 1–8 (the official metric of the shared task); for reference we additionally report macro-averaged precision, recall, and F1 computed over *all* nine classes (0–8). Accuracy is shared across both metric groups. The winning system's official macro-F1 of 0.4200 exceeds the strongest fine-tuned baseline reported in the dataset paper by $\approx$10.5 absolute points; its all-class F1 of 0.4732 exceeds that baseline by $\approx$9.9 points.

8.2 Error Patterns

Figure 3 shows confusion matrices for the four top-ranked systems. A single error pattern dominates all four: systematic *over-prediction of the High-Adaptive level* (C7), the "L7 attractor" identified by the dataset paper as the central failure mode of language models on PSYDEFCONV (Na et al., 2026). More interesting is *how* the four systems trade this attractor against minority-class recall. LINGUIUTICS is the most conservative on C7 (diagonal of 179 vs. $\approx$200 for the others), a direct effect of its minority-class augmentation and logit-bias calibration; the cost is some C7 recall, but the benefit is improved recovery of Level 8 instances. PERCEPTIONLAB shows a different signature: its dynamic DMRS-Q retrieval produces markedly higher Level 1 recall (19/28), while also exhibiting a wider over-prediction of C7. No single design choice resolves the attractor; different strategies trade one form of error against another, and the choice determines *which* minority classes a system can recover.

8.3 What Worked, What Did Not

Three takeaways emerge across the 15 system papers. First, *ensembling is the strongest differentiator at the top*: the two highest-scoring systems both engineer error independence explicitly—NÜRNBERG NLP along three orthogonal axes, and UTS through a deliberative agent council—while TONI-NLP (Paul et al., 2026) reaches the same conclusion through portfolio comparison. Second, *task-specific supervision beats backbone scale*: mid-scale backbones (Qwen3-8B, Ministral-8B, Qwen3-14B) dominate the top half of the leaderboard, and ALIENANNOTATORS (Karip and Hossain, 2026) report directly that scale alone does not reliably help zero-shot performance whereas clinically grounded prompts consistently do. Third, *zero-shot prompting alone is insufficient*: no system that relied primarily on zero-shot prompting of a large LLM exceeded F1 = 0.30, and every described top-10 system combines prompting with fine-tuning, retrieval, or ensembling. Clinical theory, packed into a prompt, is necessary but must be coupled with task-specific supervision to translate into accurate classification.

9 Future Directions

Four directions stand out as natural next steps. (1) *Dialogue-level defensive trajectories*: moving from utterance-level classification to modeling how defenses evolve across a conversation, building on the emotion-level trajectory analysis already included in the dataset paper (Na et al., 2026). (2) *Multilingual* PSYDEFCONV: annotating comparable corpora in Chinese, Japanese, Spanish, and other languages, with DMRS CO-PILOT lowering the clinical-annotation cost that has historically blocked cross-lingual scaling. (3) *Coupling defenses and supporter strategies*: jointly modeling how supporters adapt their strategies to seeker defensive functioning, closing the loop back to the broader ESC research programme. (4) *Theory-aware generation*: using defense-level predictions to condition emotionally supportive responses, operationalizing the seeker-model → supporter-response direction outlined as future work in the dataset paper. The first and fourth directions, in particular, turn PSYDEFDETECT from a static classification benchmark into a building block for clinically informed dialogue systems.

10 Conclusion

We introduced PSYDEFDETECT, the first shared task on detecting DMRS-grounded psychological defense levels in emotional support dialogues. The task drew 172 CodaBench participants, 21 ranked teams, and 15 system description papers across 12 countries. The winning system reached macro-F1 = 0.420, a ≈10.5-point gain over the strongest fine-tuned baseline, yet leaves clear headroom on minority classes where the "L7 attractor" dominates. We release all task materials to support continued work at the intersection of clinical psychology and NLP.

Limitations

This shared task has several limitations. First, PSYDEFCONV is a relatively small corpus derived from English ESConv dialogues, so results may not generalize to other languages, cultures, clinical settings, or naturally occurring therapy conversations. Second, the task labels defenses at the DMRS level rather than at the individual-mechanism level. This choice improves annotation reliability, but it also collapses clinically meaningful distinctions within each level. Third, defense interpretation remains inherently contextual: even with trained annotators and adjudication, short seeker utterances can be ambiguous without broader personal or longitudinal information. Finally, our methodological analysis is based on the 15 teams that submitted system description papers; leaderboard entries without accompanying papers are included in the quantitative ranking but cannot be analyzed in the same level of detail.

Acknowledgments

We thank all 21 participating teams and the 15 teams that contributed system description papers for making this shared task a success. We thank the BioNLP workshop organizers for hosting PSYDEFDETECT. We gratefully acknowledge the *Label Studio Academic Program* for providing access to the annotation platform used to construct PSYDEFCONV.

Ethical Considerations

Data. PSYDEFCONV is derived from ESConv (Liu et al., 2021) under its stated terms. Only derived annotations, dialogue identifiers, and code are redistributed; downstream users must obtain ESConv separately and comply with its license.

Intended use. The dataset and resulting models are intended *solely for research* on language and defensive functioning. They are **not diagnostic tools** and must not be used to make clinical, legal, or employment decisions about individuals. The corpus is in English and reflects the domains covered by ESConv, so results may not generalize across cultures or clinical settings.

Abstract

Systematic reviews of clinical trials require analysts to extract attributes that are rarely stored as ready-made columns. For example, the drug class of an immunotherapy named in a regimen, the additional agents combined with it, or whether a listed endpoint is a primary or secondary outcome. These attributes must be inferred from the visible content of other fields through normalization, classification, or structured extraction, and existing approaches such as direct LLM prompting, text-to-SQL, and agentic pipelines leave this reasoning implicit in a single generation step or pay a heavy execution cost for limited accuracy gains. We propose SCoPE (***S**tructured **C**linical hybrid **P**lanning for **E**vidence retrieval in clinical trials*), a multi-LLM planner-based framework that decomposes the task into row selection, structured planning, and execution. The planner makes the source field, reasoning rules, and output constraints explicit before answer generation, reducing ambiguity relative to direct prompting. We evaluate SCoPE on 1,500 hybrid reasoning questions over oncology clinical-trial tables against zero-shot, few-shot, chain-of-thought, TableGPT2, BlendSQL, and EHRAgent. Results show that explicit multi-LLM planning improves accuracy for reasoning-based questions while offering a stronger accuracy-efficiency tradeoff than heavier agentic baselines. Our findings position clinical trial reasoning as a distinct table understanding problem and highlight hybrid planner-based decomposition as an effective solution.

Question: For Pembrolizumab trials list **additional agents** in the treatment regimen beyond the ICI.

NCT	Treatment Regiment	Added Agents
NCT0203	Pembrolizumab+**Pemetrexed**	["pemetrexed"]
NCT0204	Pembrolizumab+**Pemetrexed +Carboplatin**	["pemetrexed", "carboplatin"]
NCT0206	Pembrolizumab+**Platinum**	["platinum"]
NCT0207	Pembrolizumab+**Pemetrexed**	["pemetrexed"]

Gold Answer: Every agent in Treatment Regimen **besides Pembrolizumab**. Eg, [Pemetrexed+ Carboplatin]

Figure 1: Sample exemplar hybrid reasoning question requiring semantic understanding of regimen structure: the model must recognize **Pembrolizumab** as the ICI named in the question and extract all other treatment agents from the visible regimen text as the held-out target field. For instance, in NCT0203, **Pembrolizumab** is the ICI and **Pemetrexed** is the additional agent used in the treatment regimen

1 Introduction

Clinicians and medical researchers often analyze tables of clinical trials with structured records where each row summarizes one study. Many questions over these tables can be answered by simple lookup: for example, what was the sample size of *Pembrolizumab drug trials*? But many questions require a deeper set of reasoning and cannot be answered immediately. For example, a reviewer studying Pembrolizumab drug trials which uses additional agents in the complete treatment regimen can surmise that, in a trial using Pembrolizumab + Pemetrexed, Pemetrexed medication is the additional agent in this treatment regimen. In these cases, the target value is not explicitly stored in a visible cell and cannot be obtained by simply selecting rows or projecting an existing column. Instead, it must typically be reasoned from row contents through normalization, classification, extraction, aggregation, or lightweight domain reasoning. We study this setting as *clinical trial reasoning*: given a question and a partially observed table, the clinicians must identify the relevant rows, ground the visible source field containing the evidence, and apply the correct row-wise transformation to produce

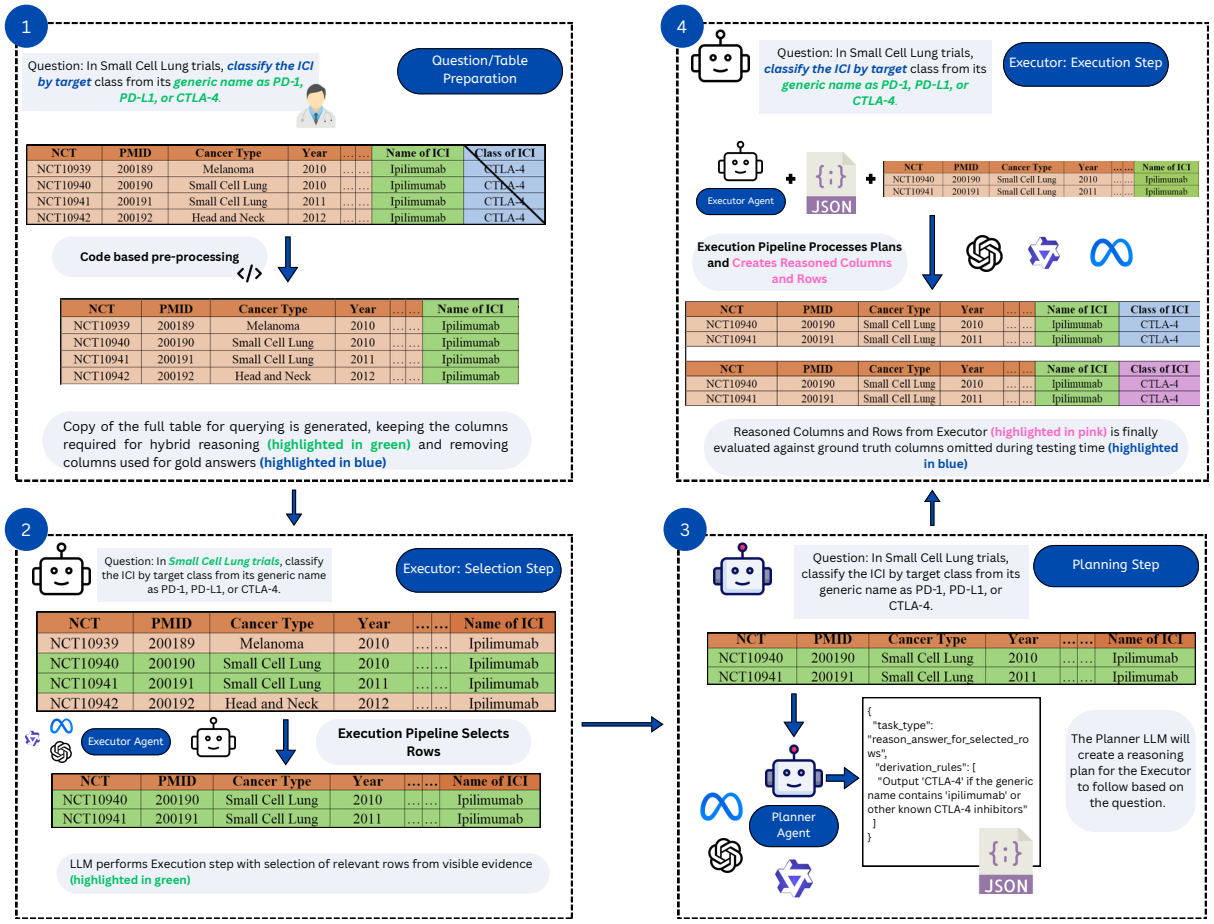

Figure 2: SCOPE for clinical tabular reasoning. Given a question and a copied visible table, SCOPE first prepares an inference-time table view by retaining the visible evidence columns and withholding the target column used for evaluation if there are any. The executor identifies the rows relevant to the question, the planner produces a structured reasoning plan over the selected table, and the executor follows this plan to generate the final row-aligned predictions. In this example, the method reasons over the *Name of ICI* column to recover the held-out *Class of ICI* field, and the resulting predictions are compared against the omitted ground-truth targets.

a target field that is often absent from the schema or from the evidence itself. This setting is related to table question answering and semantic parsing, but is only partially captured by existing table QA benchmarks and classical text-to-SQL formulations (Pasupat and Liang, 2015; Zhong et al., 2017; Yu et al., 2018; Chen et al., 2019; Nan et al., 2022).

Existing approaches do not fully address this problem. Text-to-SQL methods assume that the answer can be recovered through executable operations over explicit schema values, which is often not true when the target field is latent rather than stored (Zhong et al., 2017; Yu et al., 2018; Chowdhury et al., 2026). Prompting with large language models often under-structures the task, typically relying on a single generation step to retrieve rows, infer the evidence-bearing field, apply the transformation, and format row-aligned answers. More structured agentic and program-based approaches can improve reasoning, but can introduce additional execution overhead and brittle multi-step traces (Gao et al., 2023; Cheng et al., 2022; Yao et al., 2022; Glenn et al., 2024; Shi et al., 2024). So, the main research question we are trying to address is: *How effective is explicit hybrid planner-based decomposition in improving grounded row-level reasoning over partially observed clinical-trial tables, and do the resulting gains appear more clearly in row-level grounding than in aggregate answer recovery?*

To address these limitations, we introduce SCOPE, a planner-based framework for clinical querying that explicitly decomposes the task into row selection, structured planning, and execution. The executor grounds the question to relevant rows in the visible table and produces row-aligned outputs, while the planner interprets the question as

a structured transformation over the selected evidence. Concretely, the executor first identifies a candidate subset of rows, the planner converts the question into an explicit transformation specification, and the executor then applies that specification to generate aligned predictions. This decomposition makes the source-field choice, reasoning rules, and output constraints explicit prior to answer generation, improving interpretability and reducing ambiguity compared to direct prompting. By introducing an explicit planning interface between reasoning and execution, SCOPE better aligns the model behavior with the compositional structure of clinical trial querying.

We also construct a benchmark of 1,500 hybrid reasoning questions over oncology clinical-trial tables, where target attributes must be inferred from visible evidence rather than directly retrieved.

Unlike approaches that keep planning implicit in a single generation step or rely on heavier agentic pipelines, SCOPE introduces a lightweight planning interface that separates reasoning specification from execution while preserving grounding in the visible table. We evaluate SCOPE against zero-shot, few-shot, chain-of-thought, TableGPT2, BlendSQL, and EHRAgent, and find that explicit planning improves reasoning accuracy while offering a better accuracy-efficiency tradeoff than heavier agentic baselines.

Our main contributions are:

- We introduce SCOPE, a planner-based framework that decomposes clinical trial reasoning into row selection, source-field grounding, and structured execution.
- We formalize *clinical trial reasoning* as a distinct table understanding setting requiring inference over visible row evidence rather than direct cell retrieval.
- We construct a benchmark of 1,500 oncology clinical-trial questions and show that explicit planning outperforms prompting baselines while remaining more efficient than heavier agentic methods.

The code, scripts, and dataset are available at our project page.

Problem formulation. Given a question $\tilde{q}$ and a visible table $X = \{r_1, \ldots, r_m\}$ with a hidden target field, the goal is to recover a set of row-aligned predictions $\hat{G} = \{(r, \hat{y}_r)\}$ for the subset of rows relevant to the query. Each $\hat{y}_r$ must be derived from visible evidence in r rather than retrieved directly from a stored field. Errors may arise from incorrect row selection, incorrect source-field grounding, or incorrect transformation of visible evidence, making joint reasoning over these steps essential.

2 Related Work

We situate our work at the intersection of clinical datasets and table reasoning methods, focusing on settings where answers must be inferred rather than directly retrieved.

Related Datasets. Clinical datasets such as MIMIC III & IV (Johnson et al., 2016, 2023) and the eICU Collaborative Research Database (Pollard et al., 2018) have enabled large-scale modeling over structured and semi-structured medical records, while i2b2/n2c2 shared tasks (Uzuner et al., 2011) focus on extracting structured information from clinical text. In table reasoning, datasets such as TabFact (Chen et al., 2019) and FETAQA (Nan et al., 2022) study fact verification and free-form question answering over tables, assuming that answers are grounded in explicit table entries. Our benchmark construction is also motivated by recent domain-specific benchmarks that stress-test LLM capabilities on nuanced domain specific reasoning tasks (Choudhury et al., 2025, 2026). Given that and in contrast, our benchmark targets clinical-trial reasoning, where target attributes are often latent and must be inferred from visible row evidence through structured transformations.

Related Methods. Early table reasoning and semantic parsing approaches, such as Seq2SQL, TaBERT, and TAPAS (Zhong et al., 2017; Yin et al., 2020; Herzig et al., 2020), map natural language to executable queries or learned table representations and are strongest when the answer is explicitly represented in the schema. More recent LLM-based methods, including PAL and ReAct (Gao et al., 2023; Yao et al., 2022), introduce intermediate reasoning and action steps, while TableGPT2, BlendSQL, and EHRAgent (Li et al., 2024; Glenn et al., 2024; Shi et al., 2024) add stronger structure for reasoning over tables and clinical data. However, these methods either keep planning implicit within generation or rely on heavier agentic pipelines with iterative execution. In contrast, SCOPE explicitly decomposes the task into row selection, source-field grounding, and structured execution, making

the reasoning process more transparent and controllable while achieving a better accuracy-efficiency tradeoff.

3 Dataset

3.1 Dataset Construction

We begin with a seed set of 500 questions authored by a certified oncology researcher to reflect realistic evidence-review queries over a structured clinical-trial table containing bibliographic metadata, disease labels, treatment regimens, control-arm descriptions, endpoint text, trial phase, sample size, and follow-up information. Each seed example is paired with an executable SQLite query, which serves as a scaffold for generating new questions and aligned ground truth. We retain the subset of table-solvable questions that require hybrid reasoning rather than simple retrieval, and expand it to 1,500 questions through programmatic augmentation. For each retained pair (q, s), we generate a new pair $(\tilde{q}, \tilde{s}) = T(q, s)$ by applying a single atomic edit to the structured query, such as modifying the projection, simplifying predicates, swapping attribute values, relaxing thresholds, or changing the evidence field while preserving answerability. We keep only read-only variants that execute successfully and return non-empty results, then de-duplicate the resulting query patterns and rewrite each retained structured query into fluent natural language while preserving its exact semantics.

Ground-Truth Construction. For each final question $\tilde{q}$, the corresponding query $\tilde{s}$ identifies a set of relevant rows $R = \{r_1, \ldots, r_n\}$ together with a visible evidence field c_{src} used to derive the hidden target. We then apply a deterministic row-level reasoning function f to each row to produce the ground-truth target value $y_i = f(r_i[c_{\text{src}}])$ for every $r_i \in R$. This function implements the intended task semantics for normalization, categorization, boolean interpretation, and structured extraction, such as mapping an ICI mention to its class or brand name, determining endpoint role from endpoint text, bucketing follow-up duration or publication year, or extracting additional agents, schedules, regimen components, and control backbones from treatment text. To form the benchmark input, we expose only the visible table copy while omitting the target values $\{y_i\}_{i=1}^{n}$. The ground truth is stored separately as the row-aligned pairing $G = \{(r_i, y_i)\}_{i=1}^{n}$.

Clinical-Trial Table Statistic	Value
Rows	159
Columns	32
Unique trials (NCT)	105
Cancer types	19
ICI names	13

Table 1: Statistics of the underlying clinical-trial table used to construct the benchmark. The table covers trial-level oncology evidence, including study metadata, disease labels, treatment and control regimens, endpoint descriptions, and follow-up information, spanning 105 unique trials across 19 cancer types and 13 immune checkpoint inhibitor (ICI) names.

Crucially, each target value is derived from evidence already present in the table rather than authored independently or requiring external domain knowledge at evaluation time. This design ensures that the benchmark evaluates hybrid reasoning over visible evidence: models must infer latent attributes by interpreting existing table content, rather than generating plausible but unsupported answers.

3.2 Dataset Guidelines

To create the seed set, a certified clinician authored questions based on the IOTOX living evidence table[1]. They were asked to write realistic evidence-review questions while following three guidelines:

- Each question had to be grounded in visible table evidence.
- The expected answer had to be precise and structured, typically as a JSON value.
- The answer had to be inferable from the table itself, without requiring unsupported external knowledge.

3.3 Dataset Statistics

As shown in Tables 1 and 2, the benchmark is built from a structured clinical-trial table with 159 records and 32 columns, spanning 105 unique NCT identifiers, 131 unique PubMed IDs, 95 trial names, 19 cancer types, and 13 ICI names from 2010 to 2021. Although compact, the table is information-dense: many target outputs are not exposed as ready-made columns, but must be inferred from regimen text, endpoint descriptions, follow-up fields, and bibliographic metadata. At the benchmark level, the dataset contains 1,500 questions with

[1] https://iotox.living-evidence.com/

Question Statistic	Value
Total questions	1,500
Mean question length (tokens)	21.2
Target fields	31
Answer Types	**Value**
String	957
List	241
Boolean	224
Null-only	78

Table 2: Question and answer-level benchmark statistics. *Total questions* gives the size of the benchmark; *Mean question length* reports the average number of tokens per natural-language question; *Target fields* gives the number of distinct hidden target types covered by the dataset for reasoning . On the answer side, we report the number of questions whose gold supervision is primarily *string-valued*, *list-valued*, *boolean-valued*, or *null-only*, where null-only questions are those whose held-out target values are absent for all aligned rows.

an average length of 21.2 tokens and covers 31 distinct target fields. The answer space is also diverse, including string-valued, list-valued, boolean, and null-only outputs, highlighting that the benchmark evaluates hybrid reasoning across multiple target types rather than a single narrow form of table question answering.

4 The SCOPE System & Flow

Given a question $\tilde{q}$ and a visible table copy

$$X = \{r_1, \ldots, r_m\},$$

where the answer-bearing target field is omitted but row identifiers and visible evidence columns are preserved, SCOPE uses two LLM components: an *executor* and a *planner*. The executor grounds the question to relevant rows and produces the final row-level outputs, while the planner interprets the selected evidence as a structured reasoning problem. The planner may use the same backbone as the executor or a different one. We provide the row-selection, planning, and final-execution prompts in Appendix A.1.

The method has three steps. First, the executor identifies a candidate subset of relevant rows from the full visible table. Second, the planner receives the question and this candidate table and produces an explicit reasoning plan. Third, the executor follows that plan to generate the final row-aligned output table. In short, the planner determines *what* to derive and from *which* visible evidence, while the executor determines *where* that evidence occurs and returns the final answers.

Executor: Row Selection. The first step grounds the question $\tilde{q}$ to the visible table X. The executor selects a candidate subset of rows

$$\hat{R} = E_{\text{sel}}(\tilde{q}, X) \subseteq X.$$

At this stage, the executor is used only to identify relevant rows; it does not attempt to derive the final answer.

Planner: Structured Reasoning. The planner then receives the question $\tilde{q}$ and the candidate table $\hat{R}$ selected by the executor, and predicts a structured plan

$$\pi = P(\tilde{q}, \hat{R}) = \big(c_{\text{src}}, C_{\text{rel}}, \rho, o\big),$$

where c_{src} denotes the inferred visible source column that contains the supporting evidence, C_{rel} denotes the subset of visible columns retained for downstream execution, ρ denotes the reasoning rules needed to transform the source evidence into the target field, and o denotes the output constraints that specify the expected answer format.

Executor: Final Table Generation. Given the planner output π, the executor operates on the focused candidate table

$$X_\pi = \hat{R}[C_{\text{rel}}],$$

and produces the final row-aligned prediction table

$$\hat{G} = E_{\text{ans}}(\tilde{q}, \pi, X_\pi) = \{(r, \hat{y}_r) \mid r \in \hat{R}\}.$$

Each predicted value $\hat{y}_r$ is keyed by its row r, so the output remains aligned to the rows in the candidate table rather than collapsing the question into a single free-form answer.

Why Planning Helps. A key advantage of planning is that it explicitly separates decision points that are otherwise entangled in single-step generation. In particular, SCOPE decomposes (i) row grounding, (ii) source-field identification, and (iii) transformation into distinct stages, each of which can fail independently in direct prompting. By externalizing these decisions into a structured plan, the model avoids implicit assumptions about where evidence resides and how it should be transformed. This leads to more stable row alignment and reduces cascading errors compared to approaches where these steps are implicitly interleaved.

5 Experimental Setup

5.1 Baselines

We compare SCoPE against three baseline families under the same input setting. Every method receives the same question $\tilde{q}$ and visible table copy X, where the target field is omitted at inference time. When a method produces free text, SQL, or other intermediate outputs, we normalize its result programmatically into the shared row-aligned prediction format

$$\hat{G} = \{(\hat{r}_i, \hat{y}_i)\}_{i=1}^{k},$$

so that all systems are evaluated against the same held-out ground truth G.

The first family consists of zero-shot, few-shot, and chain-of-thought prompting (Brown et al., 2020; Wei et al., 2022), where the model is given the full visible table X and asked to recover the omitted target field directly without an explicit planning stage. The second includes BlendSQL (Glenn et al., 2024) and EHRAgent (Shi et al., 2024), which introduce more intermediate tabular structure reasoning through SQL-like compositional reasoning or heavier agentic execution. The third includes TableGPT2 (Li et al., 2024), a dedicated tabular reasoning model that jointly consumes the table and question to predict the hidden target field directly from the table representation.

5.2 Models and Hyperparameters

We evaluate three LLMs, chosen to span distinct model families, parameter scales, and post-training recipes while remaining fully reproducible: `Qwen3-30B-A3B-Instruct-2507` (Yang et al., 2025), `gpt-oss-20b` (Agarwal et al., 2025), and `Llama-3.3-70B-Instruct` (Grattafiori et al., 2024). All three are open-weight, general-purpose instruction-tuned models that are not table-specialized, which lets us test whether SCoPE's gains generalize across model lineages and isolate the contribution of explicit planning from any table-specific pretraining. All generations use deterministic decoding with temperature 0.0 and top-p 1.0. Direct prompting baselines are allowed up to 2048 generated tokens per question. For SCoPE, the planner and executor are chosen from the same model pool, enabling both same-model and cross-model configurations. The row-selection step uses 768 tokens, the planner 1024, and the final executor step 2048, keeping execution lightweight while reserving more capacity for structured planning.

5.3 Evaluation Metrics

We evaluate each predicted table against the held-out ground-truth table using three grounded metrics after one-to-one row alignment. **Table F1** is our primary metric and measures how well a method recovers the correct hidden target values for the correct rows, balancing missed and spurious predictions. **Grounded Row Jaccard** gives a stricter overlap-based view by measuring the intersection-over-union between predicted and gold row-level outputs. **Grounded Fowlkes-Mallows** (Fowlkes and Mallows, 1983) complements these metrics by summarizing the balance between grounded precision and recall. Because the target field is omitted at inference time and restored only in held-out supervision, all three metrics evaluate recovery of hidden row-level attributes from visible evidence rather than direct copying.

Impact of row selection errors. Incorrect row selection directly affects all three metrics: missing relevant rows lowers recall, while selecting spurious rows lowers precision and overlap. As a result, the metrics jointly capture both row grounding and answer correctness.

6 Results and Discussion

6.1 Main Results

Across all backbone families, the most important result is that SCoPE consistently achieves the strongest grounded performance while remaining lightweight relative to heavier structured baselines. The framework is best overall on GPT-OSS and Qwen3, and tied on Table F1 while stronger on grounding metrics for Llama-3.3. The clearest gain appears for Qwen3, where explicit planning substantially improves row-aligned reasoning over direct prompting.

RQ1: Does explicit planning improve performance over direct prompting and tabular baselines? Yes. Table 3 shows that SCoPE is strongest or tied for strongest across all three model families on the grounded metrics. It consistently outperforms BlendSQL, EHRAgent, and TableGPT2, and also improves over the strongest prompting baselines in most settings. This supports the central claim of the paper: explicit planning is more effective than leaving row grounding and reasoning implicit inside a single generation step.

RQ2: Are these gains consistent across backbone models? Largely yes, although the size of

Ours: SCoPE									
SCoPE	**63.19**	**52.07**	**69.45**	**70.87**	**60.66**	**76.12**	**74.31**	**62.48**	**78.27**

Table 3: Per-model comparison across baselines and same-backbone SCoPE, where each listed model is used as *both* the planner and the executor. We report **F1** (Table F1), **RJ** (Row Jaccard), and **FM** (Fowlkes-Mallows). Higher is better for all metrics. Best values are shown in bold green. TableGPT2 is a table based model which does not have a Qwen3, Llama-3.3, or GPT-OSS backbone so it is tested individually.

the gain varies by model. For GPT-OSS, SCoPE improves over the strongest prompting baseline from 74.17 to 74.31 Table F1 while also yielding the best grounded overlap scores. For Llama-3.3, it matches the best prompting Table F1 (70.87) but improves Row Jaccard and Fowlkes-Mallows, indicating better row alignment. For Qwen3, the gains are largest, showing that the framework generalizes across backbones while being especially useful for weaker implicit reasoners.

RQ3: Which models benefit most from explicit planning? Qwen3 benefits the most. Its Table F1 increases from 56.32 under the best prompting baseline to 63.19 with SCoPE, with corresponding improvements in Row Jaccard and Fowlkes-Mallows. This suggests that explicit planning is particularly helpful when the underlying model is less reliable at performing row grounding and structured reasoning implicitly.

Note. In addition to Table F1, grounded Row Jaccard (RJ) complements evaluation by measuring intersection-over-union over row-aligned outputs, directly capturing joint correctness of row selection and target recovery. This is especially relevant here, where answers must be derived from the correct subset of rows rather than retrieved from explicit cells. Empirically, RJ shows stronger grounding quality: for Llama-3.3, SCoPE matches the best Table F1 (70.87) while increasing RJ from 57.83 to 60.66; for Qwen3, F1 improves by +6.87 (56.32 $\rightarrow$ 63.19) with a larger RJ gain of +7.12 (44.95 $\rightarrow$ 52.07); and for GPT-OSS, nearly unchanged F1 (74.17 $\rightarrow$ 74.31) still yields a consistent RJ increase (61.77 $\rightarrow$ 62.48).

Executor	Planner	F1(%)	RJ(%)	FM(%)
GPT-OSS	Qwen3	75.07	63.74	79.26
Qwen3	GPT-OSS	59.59	48.26	66.32
Qwen3	Llama-3.3	62.47	51.40	68.88
GPT-OSS	Llama-3.3	**75.12**	**63.88**	**79.28**
Llama-3.3	GPT-OSS	68.01	57.37	73.64
Llama-3.3	Qwen3	71.43	61.33	76.64

Table 4: Cross-model ablation of SCoPE. Rows report configurations where the executor and planner use different backbones. Higher is better. The best cross-model result in each metric is shown in bold green.

6.2 Cross-Model Ablation

We vary the planner and executor backbones to test whether planning and execution benefit from different model strengths. In particular, this ablation asks whether a stronger planner can improve performance even when the execution model is held fixed, and whether these two roles are better treated as complementary rather than identical.

Table 4 shows that changing the planner can indeed improve performance. The clearest example is GPT-OSS: when used as both planner and executor in Table 3, SCoPE reaches 74.31 Table F1, but replacing the planner with Llama-3.3 increases performance to 75.12, with similar gains in Row Jaccard and Fowlkes-Mallows. This suggests that the planner benefits from a stronger reasoning

Coder Model	F1(%)	RJ(%)	FM(%)
GPT-OSS	14.56	11.67	23.39
Qwen3	48.92	37.53	56.01
Llama-3.3	**63.40**	**51.55**	**69.10**

Table 5: Results for the planner-coder baseline across coder backbones. The same models are used for the planning and code generation execution stage. Best results are shown in bold green.

model even when execution remains fixed.

Another example appears in the Llama-3.3 executor family. In the same-backbone setting, Llama-3.3 reaches 70.87 Table F1, but replacing the planner with Qwen3 improves performance to 71.43, with corresponding gains in Row Jaccard and Fowlkes-Mallows. Together with the GPT-OSS results, this suggests that changing the planner can improve performance even when the executor is held fixed.

6.3 Planner-Coder Baseline

We include the planner-coder setting as an ablation of whether execution should be made more explicit through programmatic synthesis. The idea is that, if the planner already produces a structured reasoning trace, then compiling that trace into deterministic Python code could make execution more transparent and reproducible. This tests an alternative to grounded LLM execution: executing the plan by first translating it into code.

Table 5 shows that this formulation performs substantially worse than SCOPE across all backbones. The drop is especially large for GPT-OSS (from 74.21 to 14.56 Table F1) and Qwen3 (from 63.19 to 48.92), while even the best planner-coder result with Llama-3.3 (63.40) remains below the strongest same-backbone SCOPE systems. This suggests that code-generation-based execution is more brittle: the model must infer the procedure, translate it into executable code, and ensure that the code still matches the table context and output format. Overall, hybrid clinical table reasoning appears to benefit more from constrained grounded execution than from open-ended code synthesis.

7 Model Cost Effectiveness Analysis

Figure 3 compares answer quality against token budget in the Qwen-based setting. Although TableGPT2 is not Qwen-based, we include it as a reference point for cost-effectiveness against a dedicated table model. SCOPE lies on the strongest

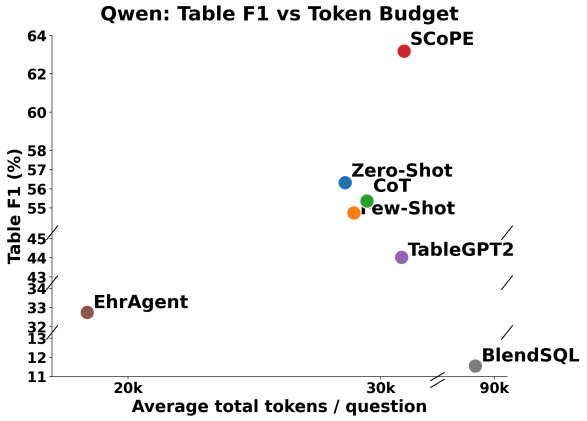

Figure 3: Cost-effectiveness comparison for Qwen-based methods. The x-axis shows average total tokens per question and the y-axis shows **Table F1**.

accuracy-cost frontier, achieving the highest Table F1 at roughly 63% with only a modestly larger token budget than direct prompting baselines. Zero-shot, few-shot, and chain-of-thought prompting cluster in the 28k-30k token range but remain in the mid-50% F1 range, while EHRAgent is cheaper but much less accurate and BlendSQL is both the most expensive and the weakest. Overall, SCOPE adds limited planning overhead while yielding the best accuracy, making it the most favorable cost-effective choice in this comparison.

8 Conclusion

We introduced SCOPE, a planner-based framework for clinical trial table reasoning that separates row grounding, structured planning, & row-level execution over visible evidence. Across same-backbone & cross-model settings, explicit planning consistently improves grounded reasoning performance over direct prompting & stronger structured baselines such as BlendSQL, EHRAgent, & TableGPT2. The gains are especially pronounced for weaker implicit reasoners while remaining competitive for stronger backbones. These findings position clinical trial reasoning as a distinct table understanding problem & suggest that lightweight planner-executor decomposition is an effective and cost-conscious approach for recovering latent clinical attributes from partially observed oncology tables.

Limitations

Our study has four main limitations. First, we evaluate strong open-weight/open-access models but do not include the latest frontier proprietary systems, so the measured gains from explicit planning may

change under stronger closed models. Second, we analyze same-backbone, cross-model, and planner-coder settings, but we do not fine-tune planner and executor roles separately; role-specialized training could alter the observed tradeoffs. Third, we do not run a dedicated memorization analysis. Because the benchmark is derived from a compact table and programmatically expanded from a seed set, some patterns may be partially recoverable from prior exposure rather than purely from visible evidence. Fourth, the benchmark is limited to a single oncology clinical-trial table, so broader validation across additional clinical domains, schemas, and larger real-world evidence tables is still needed.

Ethics Statement

This work supports oncology evidence review and clinical-trial exploration, not patient-specific diagnosis or treatment decisions. SCOPE uses public trial-level records only and does not use patient notes, PHI, or PII. No human subjects were recruited, and no new patient data were collected or released.

Because LLM outputs can be incorrect or overconfident, we emphasize auditability and grounding in visible table evidence. Evaluation is based on row-aligned recovery of omitted fields, and the pipeline exposes planning and execution steps for inspection. We also restrict execution to read-only operations and apply schema validation and timeout safeguards. Our benchmark construction keeps only valid read-only variants, which improves consistency but may bias coverage toward frequent query patterns.

While the seed questions are authored by verified clinicians, he benchmark reflects a constrained setting: a single oncology clinical-trial table, without longitudinal patient records or free-text clinical narratives.

Performance on this benchmark should not be interpreted as clinical reliability. Outputs from SCOPE require expert review before practical use. Real-world deployment should include access controls, logging, and clear warnings about model limitations and possible hallucinations.

A Supplementary Material

A.1 Planner Prompts

We provide the three inference-time prompt variants used by SCOPE below. Together, they implement the core stages of the pipeline: the selector-executor prompt identifies the candidate rows relevant to the question, the planner prompt converts the question and candidate table into an explicit reasoning plan, and the planner-executor prompt uses that plan to produce the final row-aligned predictions. Including these prompts makes clear how SCOPE externalizes row grounding, source-field selection, and answer generation rather than leaving them implicit in a single generation step.

More information on error type analsysi and prompts utilized for the baseline The code are available at our project code base underneath the *appendices* tab.

Prompt A: Plan Executor

```
You are the final executor stage of a clinical-trials
    ↪ table reasoning system.
Use the planner plan and the visible candidate table to
    ↪ derive the answer for each row.

Return ONLY valid JSON in this exact shape:
{"predictions":[{"table_row_id": 1, "answer": ...}]}

Rules:
- Return one prediction for each row in the candidate
    ↪ table.
- Use the integer "rowid" values from the candidate table
    ↪ as table row id.
- Use the planner's inferred source column and derivation
    ↪ rules when helpful.
- Derive the answer from visible values and visible row
    ↪ context.
- Do not assume the answer already appears verbatim in the
    ↪  table.
- Follow the planner's normalization rules whenever
    ↪ possible.
- Do not add explanations outside the JSON.
```

Prompt B: Planner

```
You are the planner stage of a clinical-trials hybrid
    ↪ querying system.

Overall context:
{{overall_context}}

Your job is to understand the essence of the question and
    ↪ help another model derive the answer implied by
    ↪ the question for each selected row.
The answer may need classification, normalization,
    ↪ extraction, boolean inference, or simple
    ↪ transformation.
Focus on what must be derived from visible source values
    ↪ and row context.

Return ONLY valid JSON in this exact shape:
{
  "task_type": "derive_answer_for_selected_rows",
  "inferred_source_column": "...",
  "derived_field_description": "...",
  "answer_type": "string|boolean|number|list|object",
  "relevant_columns": ["__rowid__", "..."],
  "row_filter_restatement": "...",
  "derivation_rules": ["...", "..."],
  "normalization_rules": ["...", "..."],
  "output_constraints": ["...", "..."],
  "notes": "..."
}

Guidance:
- 'inferred_source_column' should name the visible column
    ↪ that most likely contains the source evidence the
    ↪  executor should derive from.
- 'relevant_columns' should be a focused subset of the
    ↪ visible headers that the executor needs in the
    ↪ final step.
- 'derivation_rules' should explain how to derive the
    ↪ answer from visible source values and context.
- 'normalization_rules' should specify canonical output
    ↪ formatting when relevant.

Question:
{{question}}

Visible headers:
{{headers_json}}

Candidate row count:
{{candidate_row_count}}

Candidate preview JSON:
{{candidate_preview_json}}
```

Prompt C: Selector-Executor

```
You are the executor stage of a clinical-trials table
    ↪ reasoning system.
Your current job is only to identify which visible rows
    ↪ satisfy the question.
Do not derive the final answer yet.

Return ONLY valid JSON in this exact shape:
{"selected_row_ids":[1,2,3],"selection_reason":"...","
    ↪ needs_derivation":true}

Rules:
- Use only the visible table content.
- Use the integer "__rowid__" values from the table.
- If no rows satisfy the question, return {"
    ↪ selected_row_ids":[],"selection_reason":"...","
    ↪ needs_derivation":true}.
- Do not add explanations outside the JSON.

Question: {{question}}

Visible headers:
{{headers_json}}

Visible table (CSV):
{{table_csv_text}}

Expert-Guided Schema-Based Structured Extraction from CONSORT Diagrams Using Vision-Language Models

Damian Stachura, Bartosz Przechera, Monika Opałek,
Ewelina Sadowska, Ewa Borowiack, and Artur Nowak
Evidence Prime, Krakow, Poland
damian.stachura@evidenceprime.com

Abstract

Visual-language models (VLMs) are rapidly advancing on tasks that require visual understanding of text, tables, plots, and diagrams. Yet extracting structured information from text-heavy scientific diagrams remains challenging, as it requires not only OCR but also recovery of layout, grouping, and flow relationships. We study this problem in the context of CONSORT flow diagrams, which summarize participant screening, randomization, follow-up, and analysis in randomized controlled trials. We introduce a 200-example benchmark of PubMed Central diagrams, annotated by a biomedical team specializing in systematic literature reviews and clinical evidence extraction, and evaluate schema-constrained CONSORT extraction across proprietary and open-weight model families. Using structure-aware metrics, we compare single-pass and stepwise extraction strategies. Expert-guided single-pass extraction performs best for proprietary frontier models, with Gemini 3 Pro achieving the strongest overall results, whereas stepwise prompting improves less capable open-weight models on challenging arm-level extraction. These results offer practical deployment guidance and suggest that high-quality schema-constrained extraction is feasible, but not yet solved.

1 Introduction

Scientific articles contain rich structured knowledge, but extracting it remains challenging because evidence is distributed across multiple modalities, including narrative text, tables, charts, and diagrams. Recent vision-language models (VLMs) and multimodal document understanding systems have improved the ability to process visually rich scientific documents, making it increasingly feasible to extract information directly from figures and other non-textual layouts (Hu et al., 2023; Fujitake, 2024; Pramanick et al., 2024; Wang et al., 2025). However, text-heavy visual artifacts remain difficult, as successful extraction requires not only reading embedded text but also understanding layout, grouping, topology, and numerical relationships between visual elements.

A particularly important case arises in randomized controlled trials (RCTs), where key study information is often presented visually. Among these, CONSORT flow diagrams are especially valuable because they summarize participant screening, exclusions, randomization, follow-up, and analysis populations (Moher et al., 2010; Hopewell et al., 2011, 2025). However, these diagrams are highly heterogeneous in wording, layout, and completeness, making structured extraction of patient-flow information a challenging multimodal problem. An example is shown in Figure 1.

Prior work on CONSORT has largely focused on reporting support rather than figure understanding, including diagram generation, checklist extraction, and reporting-quality assessment (O'Leary et al., 2019; Wang et al., 2020; Laï-king and Paroubek, 2025). While broader research has explored methodological and multimodal evidence extraction from RCT publications (Hoang et al., 2023; Ghosh et al., 2024; Ji et al., 2026), extracting structured patient-flow data directly from CONSORT diagrams remains underexplored.

To address this gap, we introduce a benchmark for structured extraction from CONSORT flow diagrams. We collaborate with biomedical experts to define a schema capturing key patient-flow information and annotate a dataset of diagrams with substantial visual and reporting variability. Using this benchmark, we evaluate multiple VLM-based extraction strategies, including end-to-end schema filling with different prompting styles and stepwise approaches that decompose the task into smaller, visually coherent subproblems.

Our contributions are as follows:

- We introduce a 200-example benchmark for

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 955–969
July 3-4, 2026 ©2026 Association for Computational Linguistics

structured extraction from CONSORT flow diagrams, with schema-aligned annotations prepared in collaboration with biomedical experts.

- We define and report a structure-aware evaluation suite for nested CONSORT flow outputs, including group-level, leaf-level, strict field-level, and diagnostic error metrics.
- We provide a capability profile across proprietary and open-weight VLMs under single-pass and stepwise prompting, and derive practical model-regime guidance for deployment.

2 Related work

Prior automation around CONSORT has primarily focused on reporting support rather than figure understanding. For example, O'Leary et al. (2019) proposed automatic generation of CONSORT diagrams from clinical-trial databases, while Wang et al. (2020) introduced CONSORT-NLP for generating reporting checklists from article PDFs. More recent work has evaluated large language models for CONSORT-oriented reporting-quality assessment (Laï-king and Paroubek, 2025). Related research has explored information extraction from RCT publications more broadly, including methodological extraction (Hoang et al., 2023), PICO extraction (Ghosh et al., 2024), and structured evidence extraction pipelines such as TrialMind and LatteReview (Wang et al., 2024b; Rouzrokh et al., 2025). While these approaches demonstrate progress toward structured clinical evidence extraction, they do not address recovery of patient-flow information from CONSORT diagrams, where key evidence is expressed visually.

The closest technical work comes from diagram and visually rich document understanding. Prior research has highlighted the challenges of OCR and figure-text extraction in scientific documents (Kim and Yu, 2011), while more recent approaches combine OCR, element detection, and generative reasoning for diagram parsing (Arbaz et al., 2024; Deka and Devereux, 2025). Multimodal systems have further explored diagram understanding (Hu et al., 2023), layout-aware document processing (Fujitake, 2024), and schema-constrained extraction (Wang et al., 2024a). These studies suggest that extraction from text-heavy visuals benefits from explicit structure recovery rather than treating images as generic captioning targets.

A related line of work studies reasoning over diagrams and flowcharts. Benchmarks such as FlowchartQA and FlowVQA evaluate multimodal reasoning in flowchart settings (Tannert et al., 2023; Singh et al., 2024), while FlowLearn highlights persistent weaknesses of VLMs in OCR, counting, and structural reasoning (Pan et al., 2024). On the modeling side, approaches such as TextFlow and arrow-guided VLMs explicitly incorporate graph structure and directional relationships to improve flowchart understanding (Ye et al., 2024; Omasa et al., 2025). These findings are particularly relevant because CONSORT diagrams represent participant flow through structured, text-bearing graph elements.

Recent work also explores agentic and tool-augmented approaches to multimodal extraction. For example, Chen et al. (2025) propose a multi-agent system for extracting structured information from scientific graphics, while systems such as ViperGPT demonstrate how visual reasoning can be decomposed into executable tool calls (Surís et al., 2023). These approaches suggest that modular reasoning and explicit structure recovery may be beneficial for complex visual extraction tasks.

Despite these advances, no prior work specifically targets structured extraction of patient-flow data from published CONSORT diagrams, leaving a clear gap for dedicated benchmarks and systematic evaluation of extraction strategies.

3 Benchmark

To evaluate extraction performance, we constructed a dedicated benchmark for CONSORT flowchart data extraction. This task remains relatively underexplored, and publicly available benchmarks are scarce, which motivated us to curate our own evaluation dataset.

3.1 Data Acquisition

We collected candidate CONSORT flow diagrams from PubMed Central articles published under CC-BY 4.0 licenses, which permit figure reuse. We first assembled a pool of 500 diagrams by randomly sampling eligible literature. From this pool, we selected 180 examples for benchmark release through a focused curation pass designed to preserve visual diversity, including layout styles, branch depth, and labeling conventions, as well as difficulty diversity, ranging from simple linear flows to structurally complex cases such as nested branches and partial

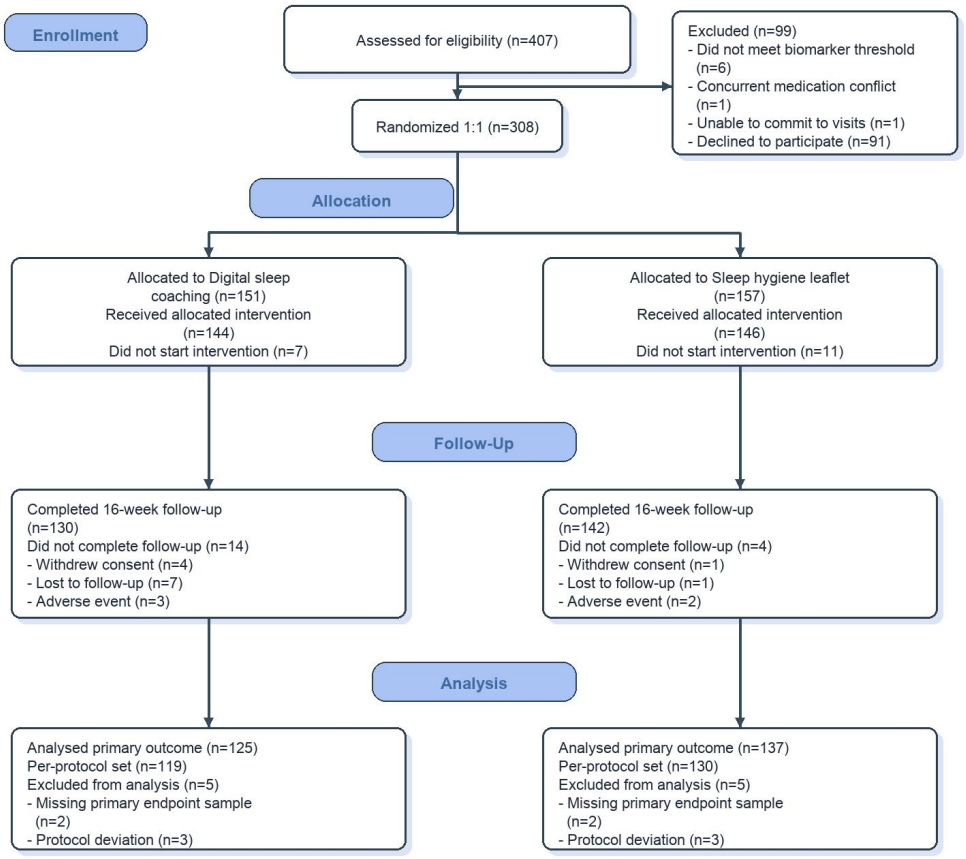

Figure 1: Synthetic CONSORT flowchart showing participant screening, randomization, follow-up, and analysis across intervention and control arms.

assessments. We focused on selecting only literature reporting RCTs. Additionally, we added 20 expert-curated examples that were considered challenging to reach a quick consensus on regarding how the data should be extracted. These 200 examples constitute the full evaluation benchmark used in this paper.

The 20 expert-curated diagrams are included as a deliberate stress-test subset to increase structural difficulty and probe failure modes under harder conditions. All systems are evaluated with the same fixed benchmark, schema, and scoring pipeline, so comparisons remain transparent and directly comparable across models and prompting regimes. We therefore interpret the reported results as a capability stress profile for structured CONSORT extraction rather than as a prevalence estimate for the full population of published CONSORT diagrams.

Each sample consists of a CONSORT flowchart paired with a structured representation following our schema. Annotation and verification were carried out by a team of three biomedical experts with background from masters and doctoral-level studies in biomedical domains and prior industry experience, specialized in systematic literature reviews and clinical evidence synthesis. The team aligned study-level and arm-level counts, exclusions, and analysis populations to canonical schema fields despite substantial variation in wording and layout.

3.2 Data Structure

CONSORT flowcharts are highly heterogeneous in both visual layout and textual content. Authors vary in how they organize diagrams, which counts they report, and the level of detail included in individual nodes. Despite this variability, most flowcharts can be mapped to a small number of recurring semantic components.

A typical CONSORT flowchart includes the following components:

- **Enrollment and screening:** the number of individuals assessed for eligibility, along with the number excluded prior to randomization and the reported reasons for exclusion.
- **Randomization and allocation:** the number of participants randomized and assigned to each study arm.
- **Follow-up and intervention status:** for each study arm, the number of participants who received the allocated intervention, did not receive it, completed treatment, discontinued treatment, or were lost to follow-up, together with corresponding reasons when reported.
- **Analysis:** the number of participants included in the primary outcome analysis for each arm, along with any exclusions from analysis and their reported reasons.

Our schema captures this structure at two levels. At the study level, it represents overall eligibility, pre-randomization exclusions, randomization, and the set of study arms. At the arm level, it captures participant trajectories within each arm, including allocation, treatment receipt, discontinuation, follow-up, and analysis. Supporting objects store finer-grained breakdowns of ineligibility, intervention discontinuation, analysis exclusions, and partial assessments. Both levels are illustrated in Figure 2 and summarized compactly in Table 1.

3.3 CONSORT Schema Fields

The target schema for CONSORT flow extraction is organized around a study-level object and a collection of per-arm objects. The fields we included in our schema were based on the CONSORT diagram schema presented in the literature (Hopewell et al., 2025) and we have chosen the fields whose experts flagged as most important in the process of random controlled trial analysis.

The study-level object tracks eligibility, exclusions, randomization, washout structure, and arm containers. Each arm object tracks allocation, treatment receipt and completion, follow-up losses, analysis populations, exclusions, and optional nested branches. A detailed field-by-field glossary for both levels is provided in Appendix A.

3.4 Data Annotation Protocol

The dataset was annotated using a two-stage procedure:

Component	Main content
Study-level flow	Eligibility, pre-randomization exclusions, randomization totals, washout indicator, arm containers, optional study-level analysis populations.
Arm identity	Arm label and ordering used for branch alignment.
Arm treatment flow	Allocation, treatment receipt/non-receipt, completion/non-completion, discontinuation reasons.
Arm follow-up and analysis	Follow-up losses, analysis populations, analysis-stage exclusions.
Optional advanced structure	Partial assessments and nested randomization branches.

Table 1: Compact summary of the CONSORT extraction schema used in the main experiments.

- Each expert independently mapped data from the CONSORT diagram to our predefined schema, which had been developed with the support of the same group of experts.
- Disagreements were adjudicated by the expert panel, and corrected labels were rechecked before dataset freeze.

4 Methods

Using this benchmark, we evaluated three VLM-based strategies for structured extraction from CONSORT flow diagrams in a zero-shot setting. The comparison was designed to isolate the effects of prompt scope, task decomposition, and post hoc verification while keeping the target output schema fixed.

- **Direct end-to-end extraction with basic prompt:** a single-pass baseline in which one VLM call using a basic system prompt receives the full diagram and optional caption and returns the complete target structure.
- **Direct end-to-end extraction with expert-guided prompt:** a single-pass baseline in which one VLM call with a prompt crafted by domain experts receives the full diagram and optional caption and returns the complete target structure.
- **Stepwise extraction:** a multi-pass strategy that reuses the same full diagram across a sequence of narrower prompts for study-level fields, washout detection, arm inventory, and per-arm flow extraction.

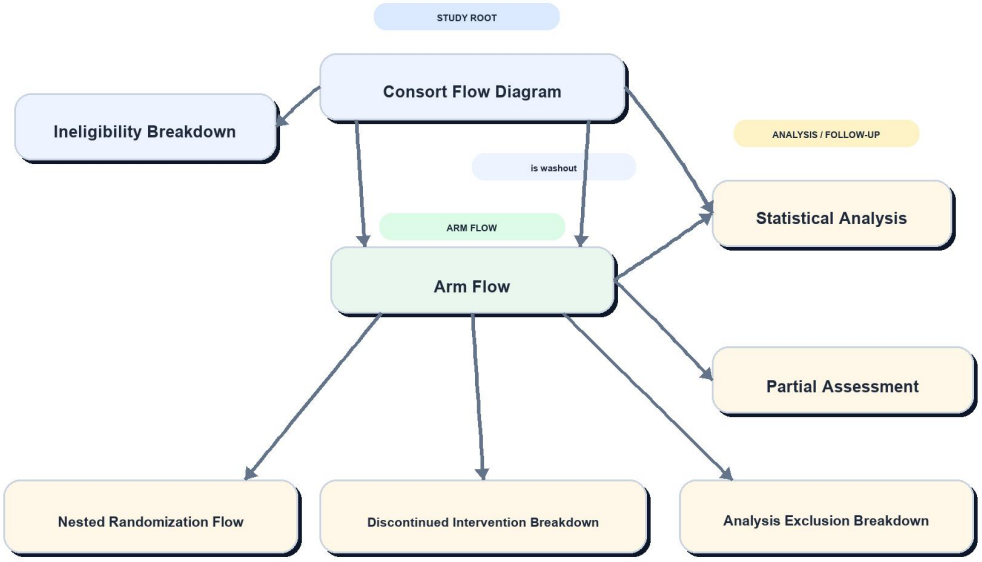

Figure 2: High-level schema of the CONSORT flow data model. The study-level CONSORT Flow Diagram captures overall enrollment and ineligibility information, a washout indicator, and arrays of Arm Flow objects before and after washout. Each study arm then records its own participant flow, including nested randomization, discontinuation, partial assessments, statistical analysis, and analysis-exclusion components.

4.1 Direct End-to-End Extraction

The first approach is the single pass setting. In this setting, a single VLM call is provided with the full CONSORT diagram, optionally accompanied by its caption, and is tasked with populating the complete CONSORT diagram structure in one step. This formulation serves as a direct benchmark of diagram understanding, as the model must jointly infer study-level counts, arm-level participant flows, and analysis populations without intermediate decomposition.

We evaluate two variants of prompting within this setting. The first uses a minimal prompt that guides the model to extract information according to the target schema, without additional domain-specific guidance. The second employs an extended prompt enriched with detailed definitions of schema fields and curated synonym lists, prepared by domain experts, to better align the model's interpretation with CONSORT reporting conventions.

4.2 Stepwise Extraction

The second approach is the stepwise setting. Instead of asking for the whole structure at once, the extractor runs a sequence of scoped passes over the same full diagram. The first pass extracts study-level enrollment and randomization fields, the second detects whether an explicit washout phase is present, and the third identifies the top-level arm inventory. The extractor then runs one additional pass for each arm to recover the detailed arm flow. These partial outputs are compiled deterministically into the final diagram structure. Importantly, this strategy does not crop the image into local regions. Rather, it keeps the full diagram available at every step and narrows the prompt scope to reduce structural ambiguity.

5 Experiments

This section presents the experimental setup and evaluation results for CONSORT diagram extraction.

The goal of the experiments is to characterize extraction capability across model families and scales, not only to rank a single best system. We therefore report structure-aware metrics, strict exact-match, and subgroup diagnostics to expose residual failure modes even when top-line scores are high.

5.1 Evaluation Metrics

We evaluate CONSORT diagram extraction using a structure-aware metric suite designed for nested participant-flow outputs. Since the task requires both accurate value extraction and correct assign-

ment of values to the appropriate arm, phase, or nested branch, our evaluation emphasizes structural correctness in addition to leaf-level accuracy.

Before scoring, both expected values and predicted outputs are normalized using the same schema semantics as the extraction system. This includes canonicalizing the CONSORT diagram representation, normalizing strings via case folding and whitespace collapsing, preserving exact integer counts, and resolving schema-level conventions such as washout structure. Object-valued lists are aligned by semantic identity rather than raw position, and objects representing arms, partial assessments, nested randomizations, exclusion reasons, and analysis populations are matched by their names.

We focus on three metrics that capture overall quality, structural correctness, and arithmetic coherence of extracted CONSORT flow representations.

CONSORT Group F1. This is the main structure-aware metric. It summarizes correctness across grouped components of the CONSORT diagram, including study-level structure, top-level arms, washout branches, nested randomizations, reason groups, partial assessments, and analysis populations. This metric is particularly important because a model may extract correct counts but still attach them to the wrong arm or branch.

Leaf Micro F1. This metric averages correctness over aligned atomic leaves. Numeric leaves are scored by exact match, while free-text identity fields such as arm names, assessment names, and reasons are evaluated using normalized string similarity. It reflects extraction quality at the value level once the hierarchical structure has been aligned.

Exact Field Accuracy. This metric measures the fraction of aligned schema fields that match exactly after normalization. It is stricter than the F1-style metrics because it does not award partial credit at the field level, but unlike full-example exact match it still captures partial success within a diagram.

Dataset-Level Aggregation. Metrics are computed per example and averaged over the evaluation set. We also report a normalized exact-match rate as a supplementary indicator, but not as a primary metric due to its stricter nature compared to the structure-aware measures above.

5.2 Technical Details

For the experiments, we evaluated all systems on the same 200-example benchmark. All runs used deterministic decoding with temperature 0 in a zero-shot setting. We did not provide figure captions during benchmarking, so the reported results reflect extraction from the diagram alone. For the stepwise system, the full image remained available at every stage.

Our primary model-selection objective was to measure the practical upper bound of capability under a fixed extraction protocol. We therefore used proprietary frontier models across size tiers to test what the strongest current systems can do on this task. The proprietary ablation in Table 2 shows a consistent pattern that expert-guided single-pass prompting is the strongest setting for these models.

We then evaluated open-weight models to estimate how far smaller openly available VLMs remain from proprietary systems on the same benchmark. This comparison is capability profiling under a common schema and evaluation pipeline, not a parameter-matched fairness claim. We also test smaller open-weight models because CONSORT extraction can be used as an agentic subtask in larger evidence-extraction workflows, where efficient local models may offer practical advantages.

Prompting setups are intentionally reported asymmetrically across regimes. For proprietary models, we run full basic/expert/stepwise ablations to establish the best prompting policy. For the newer open-weight 30B and Gemma runs, we focus on expert single-pass versus stepwise because this is the decision-relevant comparison after the proprietary ablation.

To assess the range of systems that can address this task, we used:

- GPT-5.1 and GPT-5 (OpenAI, 2025) mini with low reasoning effort deployed via Azure AI,
- Gemini 3 Flash Preview and Gemini 3 Pro Preview (DeepMind, 2025) with low thinking level accessed through the Google API,
- Qwen3-VL 8B Instruct (Bai et al., 2025) with 8-bit quantization (Ollama[1]), run locally on a MacBook M4 Max,
- Qwen3-VL 30B A3B Instruct (Bai et al., 2025) and Gemma-4-26B-A4B-it (Google

DeepMind, 2026) via OpenRouter[2].

5.3 Results

Table 2 establishes prompting behavior on proprietary models. Across Gemini variants, expert-guided single-pass prompting clearly outperforms both basic and stepwise prompting on all primary metrics. Gemini 3 Pro with expert prompting is the strongest proprietary configuration overall, reaching 0.976 group F1, 0.971 leaf micro F1, 0.944 exact field accuracy, and 0.705 exact match.

Table 3 reports open-weight results for Qwen3-VL 8B Instruct, Qwen3-VL 30B A3B Instruct, and Gemma-4-26B-A4B-it in expert single-pass and stepwise modes. In this lower-capability regime, expert single-pass fails on complex arm-level extraction for Qwen3-VL 30B A3B Instruct and Gemma-4-26B-A4B-it. For Qwen3-VL 30B, stepwise improves Group F1 from 0.601 to 0.633, Leaf Micro F1 from 0.495 to 0.611, and Exact Field Accuracy from 0.379 to 0.435; for Gemma-4-26B-A4B-it, stepwise improves Leaf Micro F1 from 0.541 to 0.564 and Exact Field Accuracy from 0.068 to 0.407 (with a small Group F1 decrease from 0.635 to 0.622).

This suggests that decomposition can help smaller models, but the current full-context stepwise design is still limited. A promising next step is arm-localized extraction: first detect arms, then run extraction on per-arm crops instead of repeatedly presenting the full diagram context.

From a deployment perspective, these results support a regime-dependent policy: use expert single-pass prompting for frontier proprietary systems, and prefer stepwise prompting for smaller open-weight systems when arm-level complexity is high.

Despite strong top-line scores for the best systems, strict exact match remains below one for all completed models (best: 0.705), and the appendix subgroup diagnostics show persistent errors on structurally complex components. This supports the benchmark's utility as a non-trivial capability test rather than an already-solved task.

5.4 Error Analysis

We observe several recurring error types in our results. First, some errors arise from ambiguity in the source diagrams rather than from complete extraction failure. For example, the number of patients who received treatment is sometimes only inferable from related counts, such as the number allocated to treatment and the number who did

[2] https://openrouter.ai

not receive treatment, but is not stated explicitly. Similar ambiguity appears when assigning reasons to schema fields such as other reasons or missing data. In such cases, models differ in how well they recover the intended structure. Gemini performs best overall, especially when the correct field can be inferred despite slight mismatches between the diagram wording and the target schema.

Second, all models struggle with structurally complex diagrams, including nested randomization steps and partial assessments reported for example at selected follow-up time points. These cases require both accurate parsing of the study flow and correct attachment of local counts to the appropriate fields. Performance decreases for all models on such examples, although Gemini remains the most robust.

We also observe several model-specific failure modes. Qwen3-VL 8B Instruct frequently inserts 0 into fields that are not explicitly provided instead of leaving them unspecified. While this can leave the high-level structure looking superficially plausible, it still lowers exact field accuracy and constitutes a mild hallucination, especially because the prompts explicitly discourage this behavior. In some cases, Qwen also appears to infer the correct number of study arms but fails to generate the corresponding arm objects, resulting in an empty arm list.

Finally, some errors are caused by low-level text interpretation. Subscript and superscript notation in more complex diagrams can lead to transcription mistakes. In addition, Qwen and GPT models sometimes extract full descriptive phrases instead of normalized arm or assessment names, for example `allocated to control group` instead of `control group`. These errors are relatively minor, but they reduce output consistency and make downstream normalization more difficult.

6 Future Work

CONSORT flow diagrams are complex visual summaries, and our current benchmark captures the concepts that can be most reliably standardized across studies. Future versions should expand coverage to additional structured patterns, including cluster-level versus individual-level flows, subgroup analyses versus formal re-randomization, and multi-stage designs involving multiple study-wide randomization events.

We also plan to improve evidence grounding by detecting study arms and key nodes, extracting information from localized crops, and evaluating this approach across a broader set of open-weight VLMs.

7 Conclusion

This paper presents a benchmark and capability profile study of schema-constrained CONSORT diagram extraction. Our experiments show that structured extraction from CONSORT flow diagrams is feasible with modern VLMs when grounded in a fixed schema and evaluated with structure-aware metrics. Across completed systems, the best results come from direct single-pass extraction with an expert-guided prompt, which provides the strongest balance of structural fidelity, leaf-level accuracy, and exact field recovery. The top configuration achieves a CONSORT group F1 of 0.976, a leaf micro F1 of 0.971, an exact field accuracy of 0.944, and an exact-match rate of 0.705, indicating that end-to-end extraction can recover a large fraction of complete diagrams without intermediate decomposition.

Prompting behavior depends on model capability. For the strongest proprietary models, expert-guided single-pass extraction is consistently best. For smaller open-weight models, however, single-pass settings fail on complex arm-level information, and stepwise prompting can improve key metrics by narrowing each extraction step.

These findings support decomposition, but also show limits of the current full-context stepwise design, where every pass still sees the whole diagram. A more promising next step is arm-localized decomposition: detect study arms and key nodes first, then extract from per-arm crops before merging outputs. This should reduce irrelevant context and improve local OCR and attachment decisions, especially for smaller open-weight models. At the same time, the gap between high top-line accuracy and imperfect exact-match confirms that the benchmark remains challenging and informative for capability profiling.

A Detailed CONSORT Schema Glossary

This appendix provides a field-level description of the schema used for structured extraction from CONSORT diagrams. The goal is to make mapping decisions explicit for both annotation and evaluation.

A.1 Study-Level Structure

The study-level object captures trial-wide participant flow before arm-specific trajectories are resolved. It includes enrollment, pre-randomization filtering, randomization totals, optional post-randomization exclusions, washout structure, and global analysis-population records.

A.2 Arm-Level Structure

Each arm object captures the participant trajectory within one trial arm. The structure covers allocation, treatment receipt/completion, follow-up losses, analysis populations, exclusions, and optional internal branching such as nested randomization.

A.3 Expert Definition Alignment and Synonym Guidance

To improve annotation consistency and prompt robustness, we aligned key schema fields with expert-authored definitions and synonym inventories from our domain guidance artifact. Tables 4 and 5 summarize the mappings used during data preparation and error analysis.

Figures 3 and 4 provide structural companions to Tables 4 and 5, visualizing study-level and arm-level hierarchy components.

The expert definitions emphasize core enrollment and attrition fields, while advanced structural components in our schema (notably `partial_assessments`, `nested_randomizations`, and washout-specific branch pairing via `arms_after_washout`) require additional schema-specific normalization rules beyond direct synonym matching. We retain these components because they are required for full structural fidelity in complex CONSORT diagrams.

B Exploratory Data Analysis of Dataset

To complement the field glossary, we report corpus-level exploratory analysis of the 200-example dataset. This links schema semantics to empirical prevalence and sparsity patterns, and clarifies where extraction reliability is most sensitive to structural complexity.

B.1 Dataset Shape and Structural Prevalence

The benchmark contains $N = 200$ diagrams. The number of top-level arms per diagram is typically small (mean 2.33, median 2, range 0–9), and most examples are two-arm trials ($155/200$, 77.5%). Washout structure is uncommon (`is_washout`=true in $7/200$, 3.5%), with non-empty `arms_after_washout` in $8/200$ (4.0%). Partial assessment structures appear in $84/200$ diagrams (42.0%), while nested randomization is rare ($4/200$, 2.0%).

B.2 Field Coverage and Sparsity by Schema Level

Table 6 summarizes non-null prevalence for core schema fields.

C Additional Correctness Metrics

For detailed error analysis, we additionally report a broader set of diagnostic metrics in the appendix. Overall, the appendix metrics provide a more fine-grained view of model behavior and failure modes.

Structure-Specific Metrics. Arm inventory F1 evaluates whether the model identifies the correct set of top-level arms. Washout structure accuracy measures correct washout detection and correct matching of pre-washout and post-washout branches. Nested randomization accuracy evaluates whether internal randomization steps and their child arms are correctly represented.

Semantic Subgroup Metrics. Reason group F1 focuses on structured reason extraction, including ineligibility, non-receipt, discontinuation, and assessment-level reason groups. Analysis population F1 evaluates study-level and arm-level analysis populations, including named populations such as intention-to-treat, modified intention-to-treat, per-protocol, and other explicitly labeled analyses.

Numeric Error Metrics. For count-valued leaves, we report mean absolute error (MAE), and symmetric mean absolute percentage error (sMAPE):

$$\texttt{count_mae} = \frac{1}{N}\sum_{i=1}^{N} |\hat{y}_i - y_i|\,, \tag{1}$$

$$\texttt{count_smape} = \frac{1}{N}\sum_{i=1}^{N} \frac{2\,|\hat{y}_i - y_i|}{|y_i| + |\hat{y}_i|}. \tag{2}$$

We summarize metrics from last three paragraphs in Table 7.

Edit-Based Diagnostics. We also summarize edit-operation statistics over the full validation set, including scalar count edits, scalar label edits, object insertions/deletions, reason insertions/deletions, and branch-repair operations. These diagnostics help characterize the types of errors made by each system and complement the aggregate quantitative metrics. We present them in Table 8.

Field	Expert definition	Synonym cues	Disambiguation rule
patients assessed for eligibility	All individuals screened/assessed for potential enrollment before allocation.	screened for eligibility; approached; assessed for enrolment/enrollment	Do not substitute enrolled or randomized counts when screening is unreported.
patients excluded before randomization total	All screened individuals not advancing to randomization for any pre-randomization reason.	patients excluded; ineligible; not enrolled; excluded during screening	Keep this as an aggregate pre-randomization total; do not merge post-randomization losses.
ineligibility.inclusionCriteriaNotMet	Excluded because inclusion criteria were not satisfied.	did not meet inclusion criteria; not eligible	Use only criterion-failure cases, not refusal or administrative reasons.
ineligibility.declinedToParticipate	Screened/approached individuals who declined consent/participation.	refused to participate; patient refusal; declined consent	Do not collapse into generic `other_reason` when refusal is explicit.
ineligibility.screeningFailure	Screening-stage failures preventing enrollment.	screening failure; not qualified at screening	Reserve for explicit screening-stage failures; not broader non-completion after randomization.
ineligibility.otherReason	Pre-randomization exclusions outside canonical categories.	other reasons; miscellaneous exclusions	Use only when no canonical ineligibility subtype applies.
patients randomized	Participants formally assigned by random allocation (including crossover sequences).	randomly assigned; underwent randomization; allocated to sequence	Prefer explicit randomization totals; avoid deriving from downstream treatment counts alone.
post randomization pre allocation exclusions	Participants excluded after randomization but before arm-specific allocation/treatment nodes.	excluded after randomization before allocation; withdrew before allocation; post-randomization exclusions	Use only for explicit between-stage losses; do not merge with pre-randomization exclusions or arm-level attrition.
is washout	Boolean indicator that a dedicated washout phase exists as a structural node.	washout period; washout phase; post-period washout	Set true only when washout is represented structurally in the flow, not when mentioned narratively.
statistical analysis	Study-level analyzed populations reported outside arm branches (e.g., ITT, mITT, safety, efficacy).	intention-to-treat; modified ITT; per-protocol; safety set; efficacy analysis set	Record only global analysis sets here; arm-specific analysis populations belong in arm objects.
arms	Ordered list of top-level arm flow objects before washout, or the sole arm list when no washout exists.	intervention arm; control arm; treatment group; sequence arm	Preserve diagram branch order to maintain deterministic alignment and downstream comparisons.
arms after washout	Ordered list of post-washout arm flows aligned one-to-one with pre-washout arm order.	post-washout arm; after washout sequence	Populate only when explicit washout splitting is present; keep positional correspondence with pre-washout arms.

Table 4: Study-level mapping between canonical schema fields and expert-authored definitions/synonym cues.

Canonical field	Condensed expert definition	High-value synonym cues	Disambiguation rule
arm name	Arm label as reported in the diagram (e.g., intervention, control, sequence name).	intervention arm; control arm; placebo arm; sequence AB/BA	Normalize superficial formatting only; preserve source arm semantics and role distinctions.
patients allocated to intervention	Participants assigned to an arm at allocation/randomization branch entry.	assigned to intervention; randomized per arm; allocated to sequence	Do not replace with received/completed treatment counts.
patients received allocated intervention	Allocated participants who initiated the assigned intervention.	received intended treatment; initiated assigned treatment	Exclude participants who never started treatment.
patients did not receive allocated intervention	Allocated participants who never initiated assigned treatment.	did not receive allocated intervention; never started treatment	Do not combine with treatment discontinuation after initiation.
patients completed treatment	Participants completing planned treatment course.	completers; completed protocol; completed intervention	Completion implies initiation; do not map follow-up completion to this field.
patients did not complete treatment	Participants who started but did not complete treatment.	drop-outs; withdrew from treatment; did not finish treatment	Keep distinct from non-receipt and analysis-stage exclusion.
discontinued intervention.*	Reason-structured treatment discontinuation after initiation.	due to adverse events; lack of efficacy; protocol violation; withdrawal	Attach only reasons linked to discontinuation nodes for that arm.
lost to follow up for primary outcome	Started treatment but missing primary-outcome follow-up data because participant could not be followed.	lost to follow-up; unable to contact; missed follow-up	Do not merge with explicit analysis exclusion categories unless diagram conflates them.
excluded from primary outcome analysis.*	Participants excluded at analysis stage with reason breakdown.	excluded from analysis; no outcome data; major protocol violation	Apply only to analysis-stage exclusions, not earlier flow attrition.
statistical analysis	Arm-specific analyzed populations (e.g., ITT, mITT, per-protocol, labeled sets).	analyzed population; ITT set; mITT set; per-protocol set; safety set	Keep distinct named populations when reported; avoid collapsing multiple analysis sets into one count.
partial assessments	Interim follow-up checkpoints (often timepoint-based) represented separately from final analysis totals.	week 12 assessed; month 6 follow-up; interim assessment	Represent each checkpoint as a separate structured object with its own count and optional reason groups.
nested randomizations	Secondary randomization branches within a top-level arm.	re-randomized; second randomization; split within arm	Create child branches only for explicit formal re-randomization steps, not ordinary subgroup reporting.

Abstract

Tabular data is widely used in important areas such as healthcare and finance, but building accurate models in real-world settings faces three main challenges: protecting data privacy, handling distributed data, and maintaining strong performance. Existing methods do not solve these issues together. Converting tabular data into text for Large Language Models (LLMs) can expose sensitive information, struggle with anonymized features and exact numerical values, and require expensive training while often not outperforming traditional tree-based models. In addition, many real-world datasets are spread across different institutions, making centralized training impossible. We propose a federated framework that connects distributed tabular data with LLM reasoning using decision tree rules as privacy-preserving intermediaries. Each client trains a local Random Forest and shares only extracted rules—feature comparisons and thresholds, without revealing raw data. These rules are combined into a global pool, allowing an LLM to generate a better partitioning rule without accessing any original data, adding an extra layer of privacy. Using this rule, each client learns local gradient-based corrections, which are then aggregated. We also show that this process reduces prediction error. Experiments on 12 datasets, including seven medical tasks, show that our method consistently outperforms federated baselines and achieves results close to centralized models.

1 Introduction

Tabular data, where each row is one example and each column is a feature (like numbers or categories), is widely used to make decisions in areas such as healthcare, finance, and industry (Hernandez et al., 2022; Assefa et al., 2020; Frosch et al., 2010; Borisov et al., 2022). Tasks like disease diagnosis, fraud detection, and fault prediction rely on such structured data. Due to its mixed feature types, tree-based models such as XGBoost (Chen and Guestrin, 2016), LightGBM (Ke et al., 2017), and CatBoost (Prokhorenkova et al., 2018) remain highly effective, often outperforming deep learning methods on tabular benchmarks (Grinsztajn et al., 2022; McElfresh et al., 2023).

The success of Large Language Models (LLMs) (Brown et al., 2020; Wei et al., 2022; Mahanipour et al., 2025; Ekanayake et al., 2025) has motivated their use in tabular prediction (Hegselmann et al., 2023; Dinh et al., 2022; Sui et al., 2024; Nam et al., 2024; Han et al., 2024; Ye et al., 2025). Most existing approaches convert table rows into text and apply LLMs via fine-tuning or prompting. However, this strategy faces three key challenges. From a data perspective, serialization can lose structural information, struggles with anonymized features, and exposes sensitive data (Sui et al., 2024; Hegselmann et al., 2023). From a model perspective, fine-tuned LLMs often fail to outperform tree-based methods despite high computational cost, while in-context learning is limited by input length (Dinh et al., 2022; Nam et al., 2024). From a distribution perspective, real-world datasets are often divided between institutions and cannot be centrally combined due to privacy regulations such as GDPR and HIPAA (Voigt and Von dem Bussche, 2017; Annas, 2003; Cohen and Mello, 2018).

Federated learning (FL) addresses this limitation by enabling multiple clients to collaboratively train models without sharing raw data (McMahan et al., 2017; Mahanipour and Khamfroush, 2025). Each client keeps data locally and shares only model updates. However, existing FL approaches for tabular data either rely on neural networks (Li et al., 2020b) or tree-based aggregation methods (Cheng et al., 2021; Li et al., 2023), and do not incorporate LLM reasoning.

The coexistence of these three tensions formulates a concrete and open research challenge: *is it possible to exploit the logical reasoning capacity of an LLM to improve tabular prediction, while*

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 970–980

operating strictly within the constraints of a federated architecture, without exposing any individual training record to the model, without updating the LLM's parameters, and without sacrificing the performance advantages of tree-based ensembles on full-scale data?

In this paper, we answer this question affirmatively by proposing a federated framework that integrates LLMs into tabular prediction via logical decision tree rules as privacy-preserving intermediaries. The key insight is that a decision tree rule, a sequence of binary comparisons between feature indices and scalar thresholds, is a compact, global abstraction of the data distribution that carries no sample-level information. Rules can therefore be freely shared from clients to the server and transmitted to an LLM without exposing any individual record.

Our framework proceeds in four communication rounds. First, each client trains a local Random Forest and shares only the extracted decision rules, without exposing raw data. Second, the server aggregates these rules and uses an LLM to synthesize a refined global partitioning rule r^*, leveraging cross-client diversity while accessing no tabular data. Third, clients use r^* to model residual errors via leaf-specific predictors (a Gradient Net), sharing only model parameters. Finally, the server aggregates these parameters via FedAvg and broadcasts a global model, yielding the final prediction $F^*(\mathbf{x}) = \bar{F}(\mathbf{x}) + \eta \cdot \phi^*(\mathbf{x} \mid r^*)$.

This design addresses key challenges in privacy, modeling, and distribution. By exposing the LLM only to decision rules, which are structured and sample-free representations of feature splits, the framework avoids sharing raw feature values or labels while preserving meaningful global structure. These rules encode how the feature space is partitioned, enabling the LLM to reason about patterns and interactions without access to individual data points. The LLM is queried only once to produce r^*, after which all learning is performed locally using standard models, eliminating the need for fine-tuning or repeated inference. Throughout the process, no raw data leaves any client, and the server receives only rule text and model parameters, both of which are non-invertible to individual records. Moreover, aggregating rules across clients enriches the LLM's input with diverse, cross-client feature interactions that are not observable locally, resulting in a more informative global partition and improved predictive performance.

The main contributions of this work are as follows:

- We introduce a unified three-challenge framing for LLM-based tabular prediction, identifying data serialization, model scaling, and data silo limitations as jointly critical barriers to practical deployment in high-stakes settings where tabular data is prevalent.
- We show that decision tree rules provide a natural and effective interface between federated tabular data and LLM reasoning. They are expressive enough to capture structural feature interactions, compact enough to fit within LLM context limits, and inherently privacy-preserving since they avoid exposing raw samples.
- We propose a novel four-round federated framework in which clients transmit only rule text and leaf model parameters. The LLM refines a cross-client rule pool into a global partition r^*, and a Gradient Net trained on this rule produces sample-level error correction. Final aggregation is performed via FedAvg weighted by dataset size.
- We establish a theoretical guarantee showing that the proposed error correction step strictly decreases the expected loss for any positive step size η, providing convergence support for the framework.
- We conduct extensive experiments on eleven binary classification datasets spanning clinical, financial, and biological domains, comparing against strong federated and centralized baselines. Results show that our method achieves state-of-the-art performance among privacy-preserving approaches while remaining competitive with centralized models, demonstrating only a modest performance trade-off relative to its privacy benefits.

2 Proposed Method

We propose a novel federated framework for tabular prediction that integrates the logical interpretability of decision tree rules with the reasoning capabilities of Large Language Models (LLMs), while preserving strict data privacy across distributed clients. The key observation motivating our approach is that decision tree *rules*, sequences of axis-aligned

binary comparisons between feature indices and scalar thresholds, are compact global abstractions of a data distribution rather than representations of individual samples. Because rules convey no sample-level information, transmitting them to a central server introduces negligible privacy risk. We exploit this property to design a four-round federated protocol in which raw data never crosses any client boundary, the LLM receives no tabular rows, and all inter-client coordination is mediated through structural rule text and aggregated leaf-level model parameters.

2.1 Problem Formulation

Consider M clients, where each client i holds a private local dataset $D_i = \{(x_{ij}, y_{ij})\}_{j=1}^{n_i}$, with $x_{ij} \in \mathcal{X} \subseteq \mathbb{R}^d$ and $y_{ij} \in \mathcal{Y}$. The feature vector x_{ij} may contain numerical, categorical, or mixed attributes; we denote its numerical and categorical components as $x^{(\text{num})}$ and $x^{(\text{cat})}$, respectively.

Each client partitions its dataset into training, validation, and test subsets, denoted by $\mathcal{D}_i^{\text{train}}$, $\mathcal{D}_i^{\text{val}}$, and $\mathcal{D}_i^{\text{test}}$. A shared global test set $\mathcal{D}^{\text{test}}$ is used for final evaluation. The total number of samples across all clients is $N = \sum_{i=1}^{M} n_i$.

The goal is to learn a global predictive model $G : \mathcal{X} \to \mathcal{Y}$ that minimizes the expected loss

$$\mathbb{E}_{(x,y)\sim\mathcal{D}}\big[Loss(G(x), y)\big],$$

while ensuring that no client transmits raw feature values or labels to any external party.

The framework supports binary classification ($\mathcal{Y} = \{0, 1\}$), multiclass classification ($\mathcal{Y} = \{1, \ldots, c\}$), and regression ($\mathcal{Y} = \mathbb{R}$). The loss function $Loss$ is defined as mean squared error for regression and cross-entropy for classification.

2.2 Preliminaries

Decision Trees and Rule Representation: A decision tree (Loh, 2011) recursively partitions the input space into disjoint axis-aligned regions through binary splits of the form $x_{\ell_j} \leq \tau_j$, where ℓ_j specifies the feature index and τ_j the splitting threshold at internal node j along the root-to-leaf path. For a given partitioning rule r defined by index vector $\boldsymbol{\ell}$ and threshold vector $\boldsymbol{\tau}$, the prediction function is:

$$f(x \mid \mathcal{D}^{\text{train}}, r) = \sum_{l=1}^{Node(r)} \lambda_l \cdot 1(x \in L_l(r)), \quad (1)$$

where $Node(r)$ is the number of leaf nodes, $L_l(r)$ is the l-th leaf region, $1(\cdot)$ is the indicator function, and λ_l is the leaf-specific prediction value, the empirical class distribution for classification or the mean label for regression.

The textual representation of a rule r is a sequence of human-readable if-else comparisons, e.g. `if feature_3 ≤ 0.72 then ...`. This representation contains only feature *indices* (anonymized, such as `feature_3`) and numeric *thresholds*, with no association to individual training samples.

2.3 Federated Learning

Federated learning (FL) is a distributed learning paradigm where multiple clients collaboratively train a shared global model without sharing raw data (McMahan et al., 2017; Yang et al., 2019; Li et al., 2020a). Each client i keeps a private dataset $\mathcal{D}_i$ and only shares model updates or aggregated statistics. The global objective is to minimize the weighted sum of local losses over all clients, where each client trains on its own data while contributing to a shared model. This setting enables learning in domains where data cannot be centralized due to privacy, regulatory, or institutional constraints, such as healthcare, finance, and industrial systems (Rieke et al., 2020; Yang et al., 2019; Li et al., 2020a).

A central challenge in FL is statistical heterogeneity, where client data distributions are non-IID. This can lead to client drift, where local updates diverge and slow or destabilize global convergence (Li et al., 2020b; Zhao et al., 2018). Methods such as FedProx (Li et al., 2020b), FedNova (Wang et al., 2020), and SCAFFOLD (Karimireddy et al., 2020) mitigate this issue through regularization, normalization, or variance reduction. While most FL methods focus on neural networks, recent work extends FL to tree-based models for tabular data, such as SecureBoost (Cheng et al., 2021) and FedTree (Li et al., 2023). However, these approaches rely purely on gradient statistics and do not incorporate LLM-based reasoning. Moreover, despite avoiding raw data sharing, FL systems remain vulnerable to privacy attacks on gradients and parameters (Zhu et al., 2019; Melis et al., 2019). In this work, we address these limitations by using decision tree rules as a privacy-preserving abstraction that enables LLM-guided global reasoning without exposing individual data samples.

2.4 Round 1: Local Federated Ensemble Construction

A single decision tree trained on a local $\mathcal{D}_i^{\text{train}}$ is prone to overfitting due to limited sample size (Ho, 1998). Ensemble methods mitigate this by training multiple trees on different sub-samples of the training data and averaging their predictions. In the federated setting, each client independently constructs such an ensemble, which simultaneously improves local accuracy and yields a richer pool of decision rules for subsequent cross-client synthesis.

Local ensemble. Each client i trains a Random Forest (Breiman, 2001) comprising K CART experts $\{f_k^{(i)}\}_{k=1}^K$, each trained on an independently drawn bootstrap sub-sample $\mathcal{D}_{i,k}^{\text{train}} \subset \mathcal{D}_i^{\text{train}}$ with corresponding decision rule $r_{i,k}$. The local ensemble prediction is:

$$F_i(x) \;=\; \frac{1}{K}\sum_{k=1}^{K} f_k^{(i)}\big(x \,\big|\, \mathcal{D}_{i,k}^{\text{train}},\, r_{i,k}\big)\,, \quad (2)$$

and the complete local rule set is $R_i = \{r_{i,k}\}_{k=1}^K$.

Communication. After training, client i exports the textual representation of R_i and transmits it to the server along with the scalar n_i. No raw samples, no labels, and no computed predictions are shared at this stage. The transmitted rule text is of size $O(K \cdot D_{\max})$ where $D_{\max}$ is the maximum tree depth, making communication negligible.

2.5 Round 2: Cross-Client Rule Synthesis via LLM

Global rule aggregation. The server collects all local rule sets and forms the global rule pool:

$$R^{global} \;=\; R_i[1] \cup R_i[2] \cup \cdots \cup R_i[M], \quad (3)$$

which contains $M \cdot K$ trees sourced from M statistically independent data shards. Unlike a single-client rule set, R^{global} captures feature interactions visible only within each local distribution, providing the LLM with a *cross-shard* view of the feature space that is richer and more diverse than any individual client could produce.

LLM-based rule refinement. Standard ensemble methods treat each tree in R^{global} as an independent voter and discard the structural relationships among them. We instead leverage the logical reasoning ability of an LLM to analyze and synthesize the full rule set into a single, improved partitioning rule.

The server constructs a structured prompt:

$$p \;=\; p_{\text{meta}} \oplus p_{\text{rule}} \oplus p_{\text{req}}, \quad (4)$$

where p_{meta} encodes task metadata (task type, number of features, training size), p_{rule} encodes the textual representation of R^{global}, and p_{req} specifies the required output format. Crucially, p_{rule} contains only structural information, feature indices and numeric thresholds, and no raw feature values or sample labels. The LLM is therefore never exposed to individual training records.

The server queries the LLM with p to obtain a refined global rule:

$$r^* \;=\; \text{LLM}(p) \;=\; \text{LLM}(p_{\text{meta}} \oplus p_{\text{rule}} \oplus p_{\text{req}})\,. \quad (5)$$

To reduce stochasticity in the LLM output, the server issues T independent queries (default $T = 10$), retaining the set $\{r_t^*\}_{t=1}^T$ for ensemble averaging in the final prediction stage. All T rules are broadcast to every client.

Why LLM synthesis improves upon ensemble voting. Random Forest ensembles the outputs of all rules in R^{global} but ignores the inherent structural relationships and interactions among those rules. As $M \cdot K$ grows large, analyzing these independent trees becomes increasingly difficult, and the rule set as a whole loses interpretability. The LLM addresses this by performing a form of *global rule reasoning*: it identifies features that appear consistently important across shards, abstracts away split-specific noise, and synthesizes a single globally coherent partition r^* that groups statistically similar samples into the same leaf node. We verify this empirically by measuring the average intra-leaf sample distance over all leaf nodes partitioned by r^*, which is lower than that of any single rule $r \in R^{global}$.

2.6 Round 3: Federated Local Gradient Net Training

The refined rule r^* serves a dual purpose: it provides an improved standalone partitioning of the feature space, and it guides the construction of a *Gradient Net*, a collection of leaf-specific regression models that learn to predict the residual errors of the local ensemble F_i. This design is motivated by the classical gradient boosting insight (Friedman, 2001) that predicting residual errors is often simpler than predicting ground-truth labels directly.

Local gradient sets. After receiving r^*, each client i computes the negative gradient of $Loss$ with respect to the local ensemble output for every training sample:

$$D_i^{\nabla} = \Big\{ \big(x,\ -\nabla_{F_i(x)} Loss(F_i(x), y)\big) \mid (x, y) \in D_i^{train} \Big\} \tag{6}$$

The negative gradient $-\nabla_{F_i(x)} Loss$ points in the direction of steepest loss decrease, the direction in which adjusting $F_i(x)$ would most reduce prediction error. For binary classification, $-\nabla_{F_i(x)} Loss \in \mathbb{R}$; for c-class classification, $-\nabla_{F_i(x)} Loss \in \mathbb{R}^c$.

Definition 1 (Local Gradient Set)**.** D_i^{∇} is the set of training samples paired with the negative gradients of $Loss$ evaluated at the local ensemble predictions $F_i(x)$. It differs from D_i^{∇} only in the supervision signal: labels y are replaced by the corresponding negative gradients.

Leaf-specific model fitting. The rule r^* partitions the local training data of client i into $Node(r^*)$ disjoint leaf regions $\{L_l(r^*)\}_{l=1}^{Node(r^*)}$. Within each leaf l, client i fits a local mapping function $\phi_l^{(i)}(\,\cdot\,; \theta_l^{(i)}) : \mathcal{X} \to \mathbb{R}$ (or $\mathbb{R}^c$) that approximates the negative gradient:

$$\min_{\theta_l^{(i)}} \sum_{\substack{(x,y)\in\mathcal{D}_i^{\text{train}} \\ x\in L_l(r^*)}} \Big\| \phi_l^{(i)}(x; \theta_l^{(i)}) - \big(-\nabla_{F_i(x)} Loss(F_i(x), y)\big) \Big\|_2^2 \tag{7}$$

Each $\phi_l^{(i)}$ is implemented as a CART model for classification tasks and as a pre-trained tabular foundation model (TabPFN (Hollmann et al., 2025)) for regression tasks. Leaf models are trained independently and can be parallelized across leaves, incurring minimal additional runtime.

Since all leaves of r^* are defined by the same globally broadcast rule, the leaf partitioning is identical across all clients, which is essential for the aggregation in Round 4.

Communication. After training, each client serializes the leaf model parameters $\Theta_i = \{\theta_l^{(i)}\}_{l=1}^{Node(r^*)}$ and transmits them to the server. These parameters are CART node splits (or TabPFN weights) fitted to predict gradient residuals, not to reconstruct features or labels. The communication volume is $O(T \cdot Node(r^*) \cdot d)$, which is bounded since $Node(r^*) \le 30$ as enforced by the prompt constraint.

2.7 Round 4: Federated Averaging and Global Model Assembly

FedAvg over leaf models. The server aggregates the per-client leaf model parameters using a sample-size-weighted average following the FedAvg protocol (McMahan et al., 2017). For each leaf l and each LLM query t:

$$\theta_{l,t}^* = \sum_{i=1}^{M} \frac{n_i}{N} \cdot \theta_{l,t}^{(i)}, \tag{8}$$

where n_i/N is the data fraction of client i. This weighting assigns greater influence to clients with more samples, implementing the optimal aggregation under the assumption that all clients draw from the same underlying population distribution. When a client has no samples in leaf l, it contributes a zero weight for that leaf; when only one client has samples in leaf l, its local model is retained unchanged.

Global Gradient Net. The aggregated global Gradient Net is defined as:

$$\phi^*\big(x \mid \mathcal{D}^{\nabla}, r_t^*\big) = \sum_{l=1}^{Node(r_t^*)} \phi_l^*\big(x;\, \theta_{l,t}^*\big) \cdot\ 1(x \in L_l(r_t^*)) \tag{9}$$

where $\mathcal{D}^{\nabla} = \bigcup_{i=1}^{M} D_i^{\nabla}$ denotes the conceptual union of all local gradient sets (never materialized on the server). The server broadcasts the global leaf parameters $\{\theta_{l,t}^*\}$ to all clients.

Error correction and final output. Given a test sample x, the cross-client ensemble prediction is:

$$\bar{F}(x) = \frac{1}{M} \sum_{i=1}^{M} F_i(x). \tag{10}$$

The sample-specific error correction vector is:

$$\Delta_x = \frac{\eta}{T} \sum_{t=1}^{T} \phi^*\big(x \mid \mathcal{D}^{\nabla}, r_t^*\big), \tag{11}$$

where $\eta \in \mathbb{R}^+$ is a step-size hyperparameter. The final prediction steers the ensemble output in the direction of error reduction:

$$F^*(x) = \bar{F}(x) + \Delta_x. \tag{12}$$

The framework provides strong end-to-end privacy guarantees: raw data never leaves clients, the LLM operates only on structural rule logic without access to samples, transmitted model parameters are non-invertible to individual records, and only minimal metadata such as sample counts is shared. Communication is efficient, requiring only lightweight rule text and model parameters, resulting in significantly lower overhead than gradient-based federated methods. The method also handles statistical heterogeneity by leveraging cross-client rule aggregation to learn a more generalizable partition r^*, while weighted averaging ensures alignment with the global data distribution. It scales naturally with the number of clients due to parallelizable client-side computation and minimal server workload. Finally, in the single-client setting, the framework reduces to its non-federated counterpart, introducing no additional approximation beyond data partitioning.

3 Experiments

3.1 Datasets

To evaluate our framework in realistic privacy-sensitive settings, we use 12 classification datasets from biomedical and general domains, where data are divided in a non-IID manner across clients. All datasets share a common structure: tabular data with mixed numerical and categorical features. They cover diverse medical tasks, including heart disease (HF), diabetes (ECD), cancer (LC), liver disease (LI), and hepatitis C (HE). To ensure consistency, we apply a unified preprocessing pipeline: numerical features are standardized, categorical features are ordinarily encoded with out-of-vocabulary handling, and missing values are imputed (mean for numerical, special token for categorical) (Gorishniy et al., 2021). For federated simulation, each dataset is split into $M = 3$ clients by partitioning the training data into non-IID shards.

3.2 Comparison Baseline Methods

We compare the proposed method against six representative baselines, including federated privacy-aware and centralized LLM-based approaches.

FedAvg (McMahan et al., 2017) is the standard federated learning baseline. Each client trains a two-layer MLP (hidden size 256, ReLU, dropout 0.1) for 5 local epochs per round, followed by sample-size-weighted aggregation. We run 30 rounds with early stopping. It serves as the primary benchmark for federated tabular learning. Federated-FeatLLM adapts FeatLLM (Han et al., 2024) to the federated setting. Each client queries an LLM with up to five serialized samples to generate feature transformations, which are aggregated and applied across clients. Local logistic regression models are then trained and aggregated via FedAvg. Unlike our method, it shares raw samples, making it a key comparison for evaluating rule-based versus sample-based LLM interaction. Centralized-MLP is a two-layer MLP trained on pooled data using Adam (lr 10^{-3}, weight decay 10^{-4}) for up to 200 epochs with early stopping. It represents a non-private upper bound for neural models.

Table 1: Properties of the twelve benchmark datasets used in our experiments. "#Num" and "#Cat" denote the numbers of numerical and categorical features. "IR" denotes the imbalance ratio (majority:minority class count).

ID	Dataset	#Train	#Test	#Num	#Cat	IR	#Class
HF	Heart Failure (Detrano et al., 1989)	242	61	13	0	1.17	2

For centralized LLM-based methods, which require full access to pooled data and are evaluated on five benchmarks using accuracy, we consider three approaches. LIFT (GPT-3.5) (Dinh et al., 2022) fine-tunes GPT-3.5 on serialized tabular data, requiring both parameter updates and raw data access. TP-BERTa (RoBERTa) (Sui et al., 2024) pre-trains a tabular-specific language model and fine-tunes it on each dataset, achieving strong performance but requiring full data access. FeatLLM (GPT-4o) (Han et al., 2024) generates feature transformations from serialized samples without fine-tuning, but still exposes raw data, unlike our rule-based approach. Our method also uses GPT-4o, but only over rule-based representations, avoiding any exposure of raw samples.

3.3 Evaluation Metrics

In this work, we report multiple complementary metrics. **Accuracy** provides overall correctness for comparability. **AUC** evaluates ranking quality in a threshold-independent manner, which is particularly important under imbalance. **F1-score**, the

Table 2: Performance comparison across multiple datasets using six evaluation metrics (Accuracy, Precision, Recall, F1-score, MCC, and AUC).

harmonic mean of Precision and Recall, offers a balanced view of minority-class performance, especially in highly skewed datasets.

To further characterize performance, we report **Precision** (fraction of correct positive predictions) and **Recall** (fraction of detected positives), reflecting clinical trade-offs between false alarms and missed cases. **MCC** (Chicco and Jurman, 2020) provides a robust single-score summary using all confusion matrix entries. All results are computed on a fixed test split with three random seeds, reporting mean and standard deviation.

3.4 Results and Analysis

Table 2 presents a comprehensive performance comparison of the proposed federated framework against three baseline methods across seven clinical benchmark datasets, evaluated on six complementary metrics: Accuracy, Precision, Recall, F1-Score, Matthews Correlation Coefficient (MCC), and Area Under the ROC Curve (AUC). The baselines include two federated competitors,

FedAvg (McMahan et al., 2017) and Federated-FeatLLM (Han et al., 2024), and one centralized reference, Centralized-MLP, which is trained on the fully pooled training set and therefore represents an optimistic upper bound for non-federated learning. Crucially, the proposed method operates under identical privacy constraints to FedAvg and Federated-FeatLLM (no raw data leaves any client), yet achieves performance that frequently exceeds even the centralized MLP upper bound, demonstrating that LLM-guided rule synthesis compensates for the accuracy cost of data partitioning.

The proposed method achieves the best Accuracy, F1, and MCC on 6/7 datasets, with clear gains. For example, on Early Diabetes it reaches 0.9747 Accuracy (+1.27% over Centralized-MLP, +2.53% over FedAvg), and on Hepatitis C it achieves 0.9785 Accuracy and 0.9086 MCC, outperforming both baselines. These results show that LLM-guided rule synthesis yields better feature partitions than gradient-based or local feature methods.

On Heart Failure, it leads all metrics (e.g., 0.8695 Accuracy, 0.8947 Recall), even surpassing the centralized model, with improved recall being clinically important. On Lung Cancer, it achieves top Accuracy (0.9362) and AUC (0.9756), demonstrating robustness under small, sparse data by leveraging cross-client rules.

On Early Diabetes, it attains the best results across all metrics, consistently outperforming both centralized and federated baselines. On Indian Liver, it matches best Accuracy but achieves higher Recall and F1, indicating a sensitivity–specificity trade-off in a difficult, imbalanced setting.

On Pima Diabetes, it leads most metrics, especially MCC (0.4679), reflecting better class balance handling. Finally, on Hepatitis C, it shows the strongest improvement, with higher Recall and MCC despite perfect Precision across methods, highlighting better detection of rare positives.

Table 3 compares the proposed federated method with centralized LLM-based models (LIFT, TP-BERTa, FeatLLM) on five datasets. Unlike these methods, which require full data access and expose raw samples to LLMs, the proposed approach operates under strict federated privacy without sharing data.

Despite this, it achieves competitive or better Accuracy on 4/5 datasets: it outperforms all baselines on Credit (0.762), Adult (0.859), and Jannis (0.6653), and is close on Bank (0.898 vs 0.916 TP-BERTa). On Blood, it matches TP-BERTa (0.761) with only a negligible gap to the best result. Overall, the average accuracy loss versus the best centralized model is under 1%, indicating minimal cost for strong privacy guarantees.

Compared to LIFT and FeatLLM, which directly use raw data with LLMs, the proposed method consistently performs better (beating LIFT on all datasets and FeatLLM on 4/5). This shows that using decision-tree rules as privacy-preserving intermediaries can achieve both strong privacy and competitive accuracy.

3.5 Conclusion

This paper studied how to integrate LLM reasoning into tabular prediction under federated learning constraints, where raw data cannot be shared across institutions. Existing LLM-based approaches typically rely on centralized data access or direct serialization of individual records, which is not feasible in privacy-sensitive settings. To address this, we proposed using decision tree rules as a privacy-preserving interface between distributed tabular data and LLM reasoning. Experiments on 12 standard benchmarks show consistent improvements over strong federated baselines such as FedAvg and Federated-FeatLLM. The method achieves particularly strong results on challenging medical datasets, often improving key metrics like F1-score and MCC. In several cases, it also matches or outperforms centralized neural models, showing that federated learning does not necessarily require a large performance trade-off. On standard benchmarks, the proposed method remains competitive with centralized LLM-based approaches. Overall, the results demonstrate that combining federated learning with LLM reasoning through decision tree rules is an effective and practical approach for privacy-preserving tabular prediction. It enables strong performance without sharing raw data and significantly narrows the gap between federated and centralized learning.

Abstract

We introduce **MedBench**, a benchmark for evaluating medical language models as deliberating agents rather than isolated predictors. MedBench evaluates eight models (4B-32B) on 19,625 questions from six medical QA datasets using Consensus-Aware Model Panel (CAMP), a two-tier protocol in which five 4B–8B models answer independently, revise after observing peer reasoning, and escalate persistent disagreements to larger 20B-32B models. Compared with zero-shot, few-shot, and chain-of-thought baselines, CAMP shows that deliberation is not uniformly accuracy-improving, but reveals interaction-driven behaviors hidden by single-model evaluation. On PubMedQA without external context, the 4B-8B panel outperforms the evaluated 20B-32B individual zero-shot models (54.1% vs. 33.9%), and achieves the best evaluated result with context (75.7%), suggesting that structured interaction can sometimes complement scale. Across five datasets, initial inter-model agreement is positively associated with correctness and serves as a useful difficulty signal. However, on MedXpertQA, unanimous agreement yields only 6.6% accuracy despite 14.4% overall accuracy, suggesting correlated ignorance, where shared biases make consensus misleading. Error analysis shows that most failures are debate-insufficient cases, where incorrect majorities persist despite interaction (93-97%), while debate-harmful cases account for 3-7%. MedBench positions deliberative evaluation as a complement to accuracy-centric benchmarking, measuring when model interaction corrects errors, reinforces shared mistakes, or signals the need for stronger evidence and human review.

1 Introduction

The dominant paradigm in medical AI benchmarking is simple: ask a model a question, record whether it answers correctly, and report a single accuracy number. Considerable progress has followed from scaling (Nori et al., 2023; Sellergren et al., 2026; Singhal et al., 2025) and prompting (Wei et al., 2022; Brown et al., 2020). Yet this paradigm has a structural blind spot: it cannot detect failure modes that only emerge when models are placed in relation to each other, including shared biases, correlated misconceptions, and the qualitative difference between "every model is wrong because the question is hard" and "every model agrees because they all share the same hallucination."

Medicine itself provides a precedent for deliberative evaluation. Physicians facing genuine diagnostic uncertainty consult colleagues, revise initial impressions in light of contradicting reasoning, and escalate to specialists when the collective remains uncertain. Benchmarks, by contrast, ask language models the same question in isolation. The result is that two qualitatively different failure modes are collapsed into a single metric: cases where models are wrong but could be corrected through interaction, and cases where models are wrong in a way that collective deliberation would only reinforce the incorrect reasoning. We operationalize this intuition in **MedBench**, a benchmark that evaluates medical language models not as isolated oracles but as deliberating agents. MedBench specifies both a collection of evaluation datasets spanning the clinical difficulty gradient and the CAMP protocol as its assessment mechanism; the two are designed together so that the protocol's deliberative structure is what makes the benchmark's diagnostic findings possible.

The CAMP (Consensus-Aware Model Panel) is an evaluation protocol, not a deployment proposal. In this protocol, models iteratively revise their answers after observing peer reasoning under a fixed update protocol (Du et al., 2023; Liang et al., 2023). Unlike self-consistency (Wang et al., 2023) and ensemble voting, which aggregate independent pre-

[*]Equal contribution.

July 3-4, 2026 ©2026 Association for Computational Linguistics

dictions, CAMP enables iterative interaction between models, making the influence structure observable and measurable. For each question, the protocol generates an inter-model agreement trajectory, per-model position-change sequences, and a resolution pathway, collectively constituting a richer characterization of model capability than accuracy alone. We treat deliberation as an observable process that reveals latent error structure in language models: interaction converts hidden error correlations into measurable signals.

Why this matters in medicine: In high-stakes domains such as clinical decision support, understanding when model confidence is reliable versus when it reflects shared bias is not merely an academic concern. A finding of unanimous model agreement on a specialist question is equally consistent with collective expertise and with collective hallucination; standard benchmarks cannot distinguish the two. MedBench provides formal tools to make this distinction, including the agreement ratio as an uncertainty proxy and the correlated ignorance diagnosis for cases where consensus signals failure rather than reliability.

The evaluation gap: Medical QA benchmarks span a wide difficulty gradient, from MMLU-style questions tractable for 4B models to ten-option specialist questions that remain difficult for the evaluated model sizes (Jin et al., 2020; Zuo et al., 2025; Hendrycks et al., 2021). Standard evaluation conflates confident correct reasoning with lucky guessing, and cannot distinguish "all models disagree because the question is hard" from "all models agree because they share the same bias." MedBench is designed to make this distinction explicit.

Contributions:

1. **MedBench benchmark.** To our knowledge, MedBench is among the first benchmarks to evaluate medical language models under a deliberative protocol across six datasets and eight models (19,625 questions), extending medical NLP evaluation beyond isolated single-model accuracy.

2. **Deliberation can complement scale in a scoped setting.** A panel of 4–8B models outperforms the individual 20–32B models evaluated here on PubMedQA without context and obtains the strongest result among our evaluated settings on PubMedQA with context (75.68%), suggesting that deliberation can sometimes complement scale.

3. **Agreement ratio as an uncertainty proxy.** Across five datasets, the fraction of Panel 1 models initially agreeing is a strong predictor of final accuracy, serving as a practical uncertainty signal. On MedXpertQA the relationship inverts completely, providing a diagnostic criterion for correlated ignorance, a failure mode where unanimous collective confidence actively misleads.

4. **Debate error taxonomy.** Debate failures partition into two primary debate-related modes: debate-insufficient (93–97%, incorrect majority persists despite interaction) and debate-harmful (3–7%, a correct minority model is overturned by peer influence), with Panel 2 insufficiency tracked separately for escalated cases. These error types are invisible to accuracy-only evaluation and suggest different intervention strategies.

2 Related Work

Medical LLM benchmarking: Foundational medical QA benchmarks include MedQA (Jin et al., 2020), PubMedQA (Jin et al., 2019), and MMLU (Hendrycks et al., 2021). Performance has risen sharply with scale (Nori et al., 2023) and domain fine-tuning (Sellergren et al., 2026). MedMCQA (Pal et al., 2022) expanded evaluation to Indian medical licensing questions. MedXpertQA (Zuo et al., 2025) recently introduced ten-option specialist questions designed to resist saturation; our analysis suggests that it reveals a qualitatively different failure mode. Most benchmark evaluations still treat models in isolation; MedBench instead uses a deliberative protocol to study interaction dynamics across this landscape.

Multi-agent deliberation: (Du et al., 2023) showed that having multiple LLM instances debate their responses over multiple rounds improves factual validity and mathematical reasoning. (Liang et al., 2023) introduced structured multi-agent debate to encourage divergent thinking and found that forcing models to take opposing positions reduces groupthink. (Chan et al., 2023) applied multi-agent debate for chatbot evaluation. CAMEL (Li et al., 2023) explored role-playing agents for collaborative task completion. In clinical reasoning, (Misaghi et al., 2026) study deliberative multi-agent

councils for ophthalmology vignettes. Our work differs from these lines in three ways: (1) we use deliberation as an evaluation protocol applied to a multi-dataset medical QA benchmark suite rather than as a generation strategy for a single domain; (2) we introduce a two-tier hierarchical structure with explicit escalation; and (3) we measure diagnostic failure modes, including agreement-ratio inversion, debate-induced corruption, and escalation pathways, alongside performance gains.

Self-consistency and ensemble methods: Self-consistency (Wang et al., 2023) samples diverse reasoning paths and takes the majority vote without explicit argument exchange. MedBench's debate rounds enable explicit evidence sharing, allowing us to track social influence events (how often one model switches another's answer) and to separate productive self-correction from harmful corruption. This separation is central to our analysis of when deliberation helps and when it fails.

Confidence and calibration: (Xiong et al., 2024) systematically evaluated confidence elicitation in LLMs and found that expressed confidence is poorly calibrated under distribution shift. Our error analysis corroborates this at scale: models report 0.706 to 0.815 average confidence on incorrect answers, approaching their confidence on correct ones, and the observed high confidence on incorrect answers prevents confidence from functioning as a reliable escalation signal in our setting.

Disagreement as signal: (Kuai et al., 2026) showed that language models trained on overlapping corpora exhibit systematic behavioral entanglement that undermines the independence assumptions required for reliable ensemble voting. MedBench reframes inter-model disagreement not as noise to suppress but as an informative signal: high disagreement reliably indicates question difficulty, while unexpectedly unanimous agreement exposes correlated failure modes. This shift from disagreement-as-error to disagreement-as-diagnostic is central to MedBench's contribution as an evaluation framework.

3 Benchmark Datasets

MedBench evaluates models on six medical QA datasets designed to span a difficulty gradient from standard medical curricula to expert specialist knowledge. Table 1 provides an overview.

Dataset	N	Options	Domain
MedQA	12,723	4	USMLE clinical
MedXpertQA	2,450	10	Expert specialist
MetaMedQA	1,373	4	Multilingual clinical
MMLU-Med	1,089	4	6 med. subjects
PubMedQA	995	3	Biomed. literature
PubMedQA+C	995	3	Biomed. + abstract
Total	**19,625**		

Table 1: Composition of the MedBench benchmark suite, including dataset size, number of answer options, and clinical or biomedical domain coverage.

MedQA (Jin et al., 2020) contains four-option questions in USMLE Step 1/2/3 style, testing clinical reasoning required for US medical licensure. **MedXpertQA** (Zuo et al., 2025) presents ten-option expert-level questions spanning treatment, diagnosis, and basic science. With a random baseline of 10%, this dataset is especially challenging for the evaluated models. **MetaMedQA** aggregates multilingual clinical MCQs testing robustness across question styles and language registers. **MMLU-Med** (Hendrycks et al., 2021) draws six medical subcategories from the Massive Multitask Language Understanding benchmark. **PubMedQA** and **PubMedQA+C** (Jin et al., 2019) ask three-class (yes/no/maybe) questions about biomedical research; the paired design isolates retrieval from comprehension by providing or withholding the source abstract.

Together, these datasets span a controlled difficulty gradient, enabling us to study how deliberation behaves under regimes where the evaluated models have comparatively stronger performance (MMLU-Med, MedQA), partial evidence or mixed robustness (MetaMedQA, PubMedQA+C), and expert-level difficulty or absence of provided context (MedXpertQA, PubMedQA without context).

4 The MedBench Evaluation Protocol

The CAMP routes each question through a hierarchical two-tier deliberation protocol. Figure 1 illustrates the overall architecture.

4.1 Formal Protocol

We formalize deliberation as an iterative update process where models revise their predictions based on peer responses. This allows us to quantify not only outcomes but also interaction dynamics such as influence and leadership. The protocol can be inter-

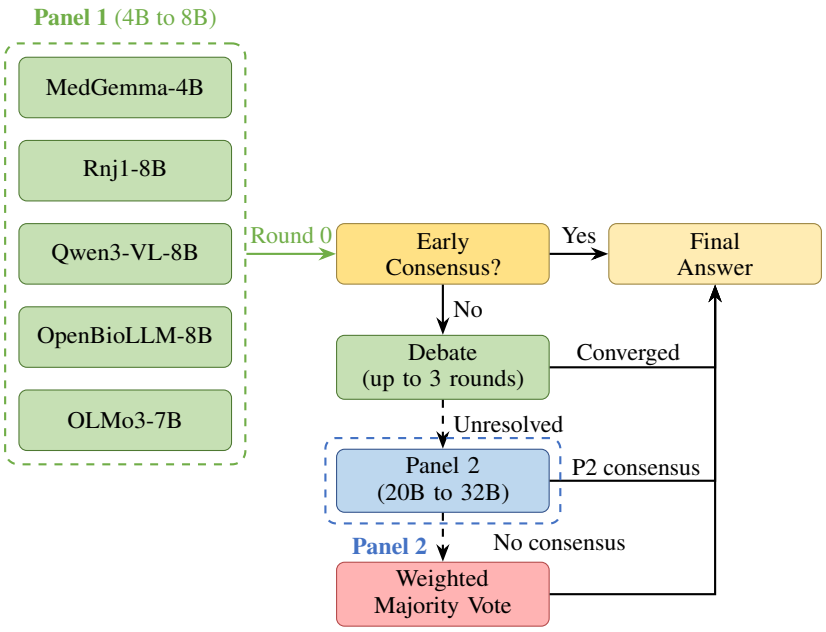

Figure 1: CAMP evaluation architecture. Panel 1 models first reason independently (Round 0). Questions where at least 4 of 5 agree are resolved immediately via Early Consensus. Those that fail are debated for up to three rounds. Persistent Panel 1 disagreement triggers escalation to Panel 2 specialist models (20B to 32B); a confidence-weighted majority vote (WMV) fallback fires only if Panel 2 also fails to converge.

preted as a discrete-time opinion dynamics system over model predictions (Cisneros-Velarde, 2024), where each model's state is updated by exposure to peer reasoning rather than by direct parameter modification.

Let $\mathcal{Q}$ be a question with answer set $\mathcal{A}$, and let $\mathcal{M}_1 = \{m_1, \ldots, m_5\}$ denote the five Panel 1 models.

Independent reasoning (Round 0): Each model m_i receives a role-structured prompt ("You are a board-certified physician on a diagnostic panel...") requiring a JSON response containing a selected option $a_i^{(0)} \in \mathcal{A}$, a scalar confidence $c_i^{(0)} \in [0, 1]$, and a free-text clinical reasoning chain $r_i^{(0)}$.

Early consensus: After Round 0, the agreement ratio (AR) is computed as:

$$\mathrm{AR}^{(t)} = \frac{\max_{a \in \mathcal{A}} \left| \{ i : a_i^{(t)} = a \} \right|}{|\mathcal{M}_1|} \tag{1}$$

If $\mathrm{AR}^{(0)} \geq 0.8$ (at least 4 of 5 models agree), the majority answer becomes the Panel 1 verdict without debate.

Structured debate: When $\mathrm{AR}^{(0)} < 0.8$, each model m_i receives the full set of peer responses from the previous round and updates its answer:

$$\left(a_i^{(t)},\, c_i^{(t)},\, r_i^{(t)}\right) = m_i\Big(\mathcal{Q},\ \big\{(a_j^{(t-1)}, r_j^{(t-1)})\big\}_{j \neq i}\Big) \tag{2}$$

Debate terminates when $\mathrm{AR}^{(t)} \geq 0.8$ or $t = R = 3$.

Influence and leadership: We define two descriptive interaction metrics for this study, using opinion-dynamics work as conceptual background rather than adopting a standard clinical metric. The influence of model m_i on m_j across all debate rounds is:

$$\mathrm{Inf}_{i \to j} = \sum_{t=1}^{R} \mathbf{1}\left[a_j^{(t)} \neq a_j^{(t-1)} \ \wedge \ a_j^{(t)} = a_i^{(t-1)} \right] \tag{3}$$

The leader-follower index for model m_i is:

$$\mathrm{LF}_i = \frac{\sum_{j \neq i} \mathrm{Inf}_{i \to j} - \sum_{j \neq i} \mathrm{Inf}_{j \to i}}{\sum_{j \neq i} \left(\mathrm{Inf}_{i \to j} + \mathrm{Inf}_{j \to i} \right) + \epsilon} \tag{4}$$

with $\epsilon = 1$ to prevent division by zero. $\mathrm{LF}_i > 0$ indicates a net debate leader; $\mathrm{LF}_i < 0$ indicates a net follower.

Panel 2 escalation: Questions where Panel 1 fails to reach consensus after $R = 3$ rounds are forwarded to Panel 2 ($\mathcal{M}_2 = \{$GPT-OSS-20B, MedGemma-27B, Qwen3-VL-32B$\}$). Each Panel

Model	Size	Panel	Type
MedGemma	4B	P1	Medical
Rnj1	8B	P1	General

Table 3: Public Hugging Face sources for the eight models evaluated in MedBench.

2 model first reasons independently (blind to its peers' Panel 2 responses), and then participates in up to two additional debate rounds if Panel 2 initial agreement falls below 2/3. When Panel 2 also fails, confidence-weighted majority vote across all eight models provides the final answer.

Design rationale: The five-model Panel 1 is intended to balance model diversity, local deployability, and a clear majority threshold. The 4-of-5 early-consensus rule resolves questions only when the small-model panel shows strong agreement, while 3–2 splits remain eligible for debate. The three-round limit allows models to revise after seeing peer reasoning while bounding cost and avoiding open-ended deliberation; we do not claim this is the optimal number of rounds. Panel 2 is reserved for persistent Panel 1 disagreement, and weighted majority voting is used only as a final fallback when both tiers fail to converge.

4.2 Model Configuration

Table 2 lists all eight models. Panel 1 comprises five open-weight models spanning 4B to 8B parameters, each deployable locally. Panel 2 comprises three larger models spanning 20B to 32B. This separation between tiers helps us compare deliberation with parameter scale while keeping larger-model conclusions cautious because Panel 2 is invoked only for a small escalated subset. The public source table lists model identities for reproducibility (Sellergren et al., 2026; Vaswani et al., 2025; Bai et al., 2025; OpenBioLLM, 2024; Olmo et al., 2026; OpenAI et al., 2025).

5 Experimental Setup

Baselines: For each of the eight models we run: (1) zero-shot with a minimal prompt; (2) five-shot with domain-matched examples; and (3) chain-of-thought (CoT) prompting (Wei et al., 2022; Brown et al., 2020). In the CoT setting, models are prompted to reason step by step before committing to a final answer. All three protocols form the individual model baseline suite.

Metrics: Primary metric is accuracy. Secondary metrics include: debate uplift (CAMP's Round 0 majority accuracy), escalation rate, self-correction rate (fraction of position changes toward the correct answer during debate), and corruption rate (fraction away from the correct answer). We apply McNemar's two-tailed test for pairwise comparisons, with $p < 0.001$ considered significant given dataset sample sizes.

Implementation: All Panel 1 models run locally on A100 GPUs. Panel 2 models are accessed via API endpoints. All models are evaluated under identical prompting and output constraints to ensure comparability across protocols. All models use a consistent JSON response format; temperature is set to 0 for all Round 0 responses and to 0.7 for debate rounds to allow opinion updating.

6 Individual Model Results

Table 4 reports accuracy for all eight models under all three baseline protocols.

Table 4 also shows dataset-specific empirical patterns among Panel 1 zero-shot models. Qwen3-VL-8B has the highest Panel 1 zero-shot accuracy on four of six datasets, especially the four exam-style MCQ datasets: MedQA, MedXpertQA, MetaMedQA, and MMLU-Med. OpenBioLLM-8B has the highest Panel 1 zero-shot accuracy on PubMedQA without context but is weak on several MCQ exam datasets, suggesting that biomedical pretraining alone does not ensure robust option-selection behavior in this evaluation. MedGemma-

Protocol	Model	Accuracy (%)

	OLMo3-7B	36.64	7.52	33.52	56.67	35.84	63.55
	GPT-OSS-20B	26.89	14.78	62.02	84.54	28.51	52.49
	MedGemma-27B	**79.52**	**17.46**	**66.12**	78.66	47.44	72.42
	Qwen3-VL-32B	74.55	18.11	65.19	**84.95**	42.53	71.13

Table 4: Individual model accuracy (%) under three evaluation protocols across six benchmarks. **Bold** marks the best Panel 1 result per dataset per protocol. Highest marks the overall best per dataset. MXQA = MedXpertQA; MMed = MetaMedQA; PMed = PubMedQA; PMed+C = PubMedQA+C.

4B has the highest Panel 1 zero-shot accuracy on PubMedQA+C, suggesting benefit when biomedical context is provided. These observations describe patterns in this benchmark only and should not be read as universal claims about model capability.

CoT produces divergent effects: it lifts MedGemma-27B from 57.92% to 79.52% on MedQA ($p < 0.001$), establishing the strongest single-model result in our benchmark, while degrading OpenBioLLM-8B on multiple datasets. CoT prompting may conflict with some models' answer-format behavior, amplifying format errors rather than improving reasoning quality. Few-shot prompting severely degrades OpenBioLLM-8B on PubMedQA (41.11% zero-shot to 3.92% few-shot), consistent with negative transfer from examples whose format does not align with the model's response tendencies.

These results highlight that individual model performance is highly sensitive to prompting strategy and training alignment. A 22-point swing from CoT alone, and near-total failure under few-shot for one model, reinforces the need for evaluation frameworks that move beyond single-model accuracy to surface how models respond to external signals.

7 Panel-Based Evaluation

7.1 Overall CAMP Accuracy

Table 5 compares CAMP accuracy against the best individual model under each baseline protocol. The CAMP uses Panel 1 alone for 94.5 to 99.5% of questions, invoking Panel 2 only for 0.5 to 5.5% of escalated cases. CAMP outperforms the best individual Panel 1 zero-shot model on five of six datasets and remains close on MMLU-Med. Comparisons to CoT should be interpreted as comparisons across prompting settings rather than as direct zero-shot baselines.

The headline result is PubMedQA without context: CAMP achieves 54.07%, surpassing the best Panel 2 zero-shot model by 20.2 percentage points, the best zero-shot result by 12.96 points, and the best CoT result (MedGemma-27B, 47.44%) by 6.6 percentage points ($p < 0.001$). This result is notable because PubMedQA without context requires models to answer biomedical research questions

Dataset	CAMP Accuracy
MedQA	58.33
MedXpertQA	14.41
MetaMedQA	49.02
MMLU-Med	74.38
PubMedQA	54.07
PubMedQA+C	75.68

Table 5: CAMP accuracy across benchmarks. Individual model baselines are reported in Table 4.

Pathway	N	%	Acc.	Trigger
EC (Panel 1)	5,656	67.3	53.66%	AR ≥ 0.8
DC (Panel 1)	2,523	30.0	35.47%	1–3 rounds
P2C (Panel 2)	160	1.9	37.50%	P2 agree
WMV (fallback)	63	0.7	19.05%	P2 disagree

Table 6: CAMP resolution pathways for 8,402 questions with complete routing metadata. EC denotes Early Consensus, DC denotes Debate Consensus, P2C denotes Panel 2 Consensus, and WMV denotes Weighted Majority Vote. Percentages use the 8,402-question routing-metadata denominator.

without the source abstract, a regime where larger models might be expected to help. In this evaluated setting, CAMP's panel-based aggregation among five 4–8B models produces better results than any individual model and prompting setting we tested.

We hypothesize that panel aggregation can combine partially overlapping signals across models, enabling the collective elimination of incorrect options even when no single model has complete evidence. The three-class structure of PubMedQA (yes/no/maybe) may be amenable to this mechanism because the "maybe" class can reflect conflicting or insufficient evidence. This interpretation is suggestive rather than conclusive and requires broader validation.

7.2 Resolution Pathway Analysis

Table 6 reports the distribution and accuracy of CAMP resolution pathways for the 8,402 questions for which complete routing metadata were available. Percentages in this table are computed over this 8,402-question routing-metadata denominator.

Early consensus (EC) is the dominant pathway among questions with complete routing metadata, resolving 5,656 of 8,402 questions (67.3%), and is also the most accurate pathway (53.66%). The 18.19-point accuracy gap between EC (53.66%) and debate consensus (DC, 35.47%) should be interpreted primarily as difficulty triage rather than as evidence that debate itself is harmful: EC questions are those where Panel 1 models already show strong initial agreement, whereas DC questions enter debate precisely because Panel 1 is initially split. Within this harder contested group, debate provides a modest uplift of 4–5 percentage points over the Round 0 majority baseline.

Escalation pathways are rare in the routing-metadata analysis. Panel 2 consensus (P2C) accounts for 160 questions (1.9%), while the weighted-majority fallback is used for only 63 questions (0.7%). The low accuracy of WMV cases (19.05%) suggests that questions unresolved by both Panel 1 and Panel 2 may represent a collective knowledge boundary for the evaluated models. In a deployment-oriented setting, such fallback cases would be natural candidates for human review rather than automatic resolution.

8 Diagnostic Analysis

8.1 Agreement Ratio as a Difficulty Signal

One of the informative signals in the CAMP framework is the initial agreement ratio (AR, Equation 1). Figure 2 shows accuracy stratified by AR bin across all six datasets. For five of six datasets, the relationship between agreement, accuracy is generally positive. MedXpertQA is the exception: unanimous agreement (AR = 1.0) predicts only 6.6% accuracy, less than half the dataset mean of 14.4%. This inversion is associated with a systematic positional bias (Ko et al., 2020). Of 2,450 MedXpertQA, 22.8% of final answers select option A (558 total), while A is correct only 9.8% of the time (241 instances), a 2.3× over-selection ratio. This pattern may reflect shared training or evaluation artifacts, common instruction-tuning conventions, option-position bias, or correlated benchmark exposure; without training-data disclosure, we cannot isolate the source. We refer to the resulting behavior as correlated ignorance: not the stochastic uncertainty that deliberation can resolve, but a systematic shared error that debate may reinforce. The practical implication for benchmark is that agreement ratio is a useful dataset-level diagnostic. When a benchmark exhibits the normal positive AR-accuracy relationship, it can help calibrate escalation thresholds. When agreement and accuracy diverge, the benchmark exposes a qualitative failure boundary where deliberation may be counterproductive. The key takeaway is that agreement ratio is a reliable uncertainty proxy only under

Model	Stub.	LF-Idx	Total Inf.	Role

Table 7: Per-model debate behaviour metrics averaged across all datasets. Stubbornness denotes the fraction of debate rounds in which a model maintains its position, LF-Idx denotes the leader–follower index from Equation 4, and Total Inf. reports cumulative outgoing influence events.

sufficient error independence (Kuai et al., 2026); when models share systematic biases, unanimity can signal failure rather than confidence.

8.2 Debate Dynamics and Model Roles

Position changes decay rapidly across debate rounds: Round 1 accounts for 67.7 to 81.8% of all position changes, Round 2 for 14.8 to 23.3%, and Round 3 for only 3.3 to 11.2%. This suggests that setting $R = 3$ rounds is adequate for the protocol studied here, although we do not claim optimality without ablations. The pattern also provides no evidence that simply increasing R would resolve MedXpertQA-class failures, where the dominant issue appears to be correlated error rather than unresolved disagreement. Table 7 characterises per-model debate behaviour. Qwen3-VL-8B has the highest outgoing influence count, exerting 4,274 cumulative influence events, 35% more than the next-highest model (MedGemma-4B, 3,173). The single strongest dyadic influence channel is Qwen3-VL-8B $\rightarrow$ Rnj1-8B (368 events on MedQA alone), consistent with Rnj1-8B's role as the panel's primary swing voter (lowest stubbornness: 0.737; most negative LF-index: -0.012). The combination of Rnj1-8B's flexibility and Qwen3-VL-8B's anchoring behaviour is associated with much of the panel's observed self-correction.

The paired PubMedQA experiment isolates the value of providing the source abstract. Accuracy rises from 54.07% on PubMedQA without context to 75.68% on PubMedQA+C, a 21.6 percentage point gain associated with context availability. Debate adds only 0.80 points on PubMedQA+C and 0.00 on PubMedQA without context. In this paired setting, access to the relevant evidence appears more important than adding further deliberation. For system builders, this suggests that retrieval or context provision should be evaluated before more elaborate debate protocols.

8.3 Error Decomposition

We categorise debate errors into two primary modes and analyze Panel 2 insufficiency separately for escalated cases. **Type 1 (debate insufficient):** the dominant failure (93 to 97% of all errors), where the panel converges on the wrong answer regardless of debate, often because models share the same misconception. **Type 2 (debate harmful):** a model initially correct was persuaded to switch away during debate (3 to 7% of errors). This corruption rate is relatively consistent across datasets, suggesting that harmful influence is not confined to a single benchmark. Separately, Panel 2 can remain insufficient after escalation, as on MedXpertQA where 76.87% of escalated cases remain wrong after Panel 2 processing. A cross-cutting finding is overconfidence on errors: models report 0.706 to 0.815 average confidence when they are wrong, approaching their confidence on correct answers. This confidence pattern limits the utility of confidence-weighted voting and suggests that confidence-gated escalation would require stronger calibration methods. Figure 3 visualizes the error-mode pattern and the wrong-answer confidence values.

8.4 Conservative Evidence on Design Choices

The current results provide limited, observational evidence about the CAMP design choices, but they should not be interpreted as full ablations. The 4-of-5 early-consensus threshold separates a high-agreement subset with higher accuracy from lower-agreement questions that require debate, while the MedXpertQA inversion shows why agreement must be treated as a diagnostic signal rather than a universal confidence guarantee. The observed decay in position changes across rounds supports the choice to cap debate at three rounds for this evaluation, but it does not prove that three rounds is optimal. Similarly, the low Panel 2 activation rate keeps the protocol compute-efficient, but the small escalated sample means conclusions about larger models must remain cautious.

Taken together, these findings support a conservative interpretation: CAMP is useful not because it always improves accuracy, but because it exposes when agreement, disagreement, escalation, and confidence behave differently across datasets. This diagnostic role is especially important in medical

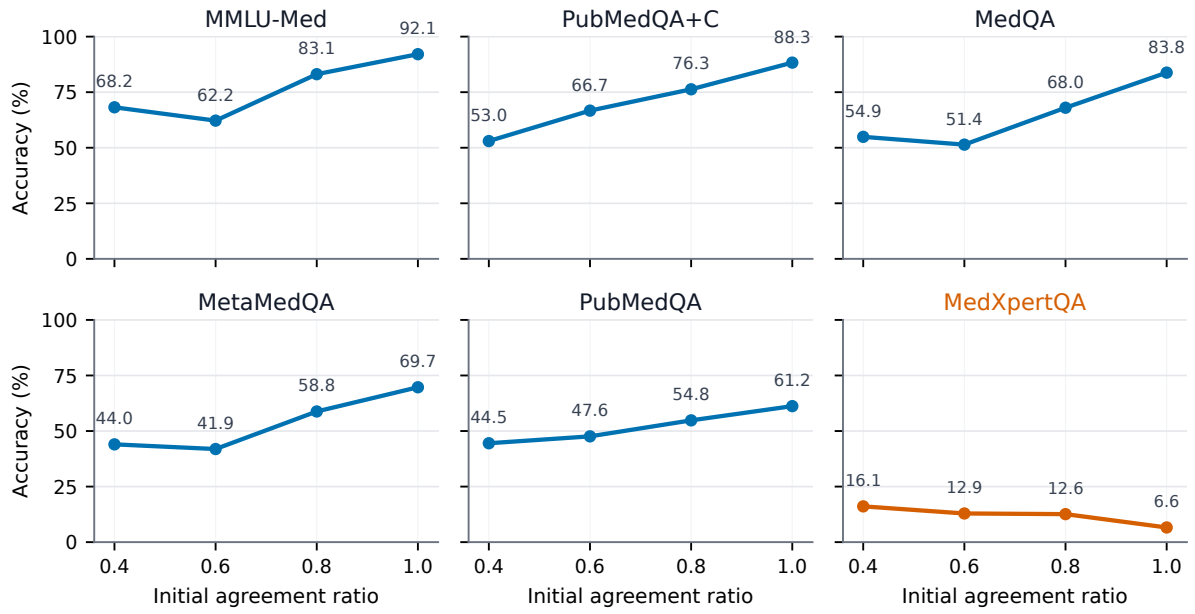

Figure 2: Accuracy conditioned on initial agreement-ratio bin. Five datasets show a generally positive relationship between agreement and accuracy, while MedXpertQA inverts this pattern, indicating correlated ignorance in this evaluation.

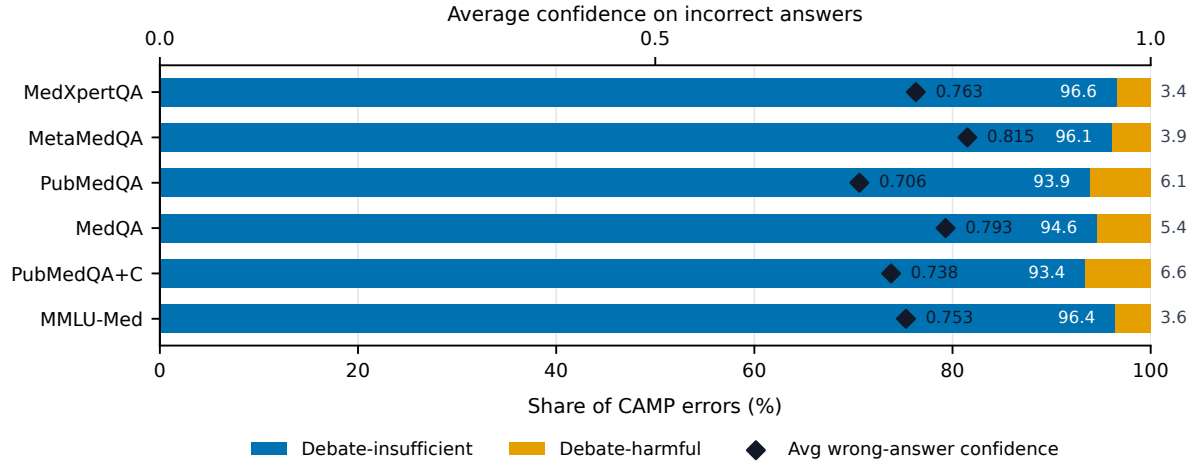

Figure 3: CAMP error decomposition across datasets. Debate-insufficient errors dominate on all datasets, while debate-harmful errors remain smaller but non-negligible; diamonds show the average confidence assigned to incorrect answers.

QA, where a high-accuracy aggregate can obscure whether the system is correcting errors, reinforcing shared mistakes, or deferring to larger models on too few cases to draw broad conclusions.

9 Conclusion

MedBench shows that evaluating medical language models only as isolated predictors misses important interaction-level behavior. Through CAMP, deliberation among smaller models improves performance in selected settings, particularly PubMedQA, but does not consistently replace scale or resolve expert-level gaps. More importantly, the protocol exposes when consensus is informative and when it is misleading: agreement tracks difficulty across most datasets, while MedXpertQA reveals correlated ignorance. The observed debate-insufficient failures, harmful persuasion, and over-confidence on wrong answers suggest that deliberative evaluation should complement accuracy-based benchmarking, with future work on panel design, calibration, model diversity, and human oversight.

Limitations

Knowledge ceiling: MedXpertQA demonstrates that deliberation does not reliably overcome expert-level gaps for the evaluated 4B to 8B models. At 14.4% accuracy (barely above 10% random), this dataset marks a difficult boundary for the current panel. Our results do not show evidence that simply increasing debate rounds would resolve this failure mode.

Correlated training data: Panel 1 models may share pretraining, instruction-tuning, evaluation, or formatting artifacts, which could amplify correlated failure modes such as the positional bias observed on MedXpertQA. Because training-data disclosure is incomplete, we cannot isolate the source of this correlation. A panel with more diverse knowledge sources might exhibit different deliberation dynamics.

Small Panel 2 sample sizes: Panel 2 handles only 0.5 to 5.5% of questions per dataset (4 to 134 questions). Panel 2 statistics (particularly for PubMedQA where only 6 questions escalated) should be interpreted cautiously.

No ablations on panel design: We did not ablate panel size (3 vs. 5 models), debate round limit (1 vs. 2 vs. 3), or escalation threshold. These design choices likely affect both accuracy and the diagnostic value of agreement ratio as a signal.

Confidence calibration: The observed overconfidence on incorrect answers prevents confidence from serving as a useful escalation gate in this study. Calibration-aware prompting or post-hoc calibration strategies are needed before confidence can reliably inform routing decisions.

Ethical Considerations

Clinical deployment risk: MedBench is an evaluation benchmark; the CAMP is an evaluation protocol. The 41.7% error rate on MedQA and 85.6% on MedXpertQA make clear that neither the individual models nor the panel are ready for autonomous clinical deployment without extensive validation, regulatory approval, and mandatory human oversight.

Dataset biases: MedQA and MMLU-Med reflect US-centric medical education. MetaMedQA provides some multilingual coverage, but demographic and geographic biases in underlying training data may produce unequal performance across patient populations.

Overconfidence risk: Models report high average confidence (0.706 to 0.815) on incorrect answers. Any downstream clinical decision support tool must prominently communicate this overconfidence risk to end users.

Abstract

dbt_mimic_omop is a free, open-source resource that converts the MIMIC-IV dataset to the Observational Medical Outcomes Partnership (OMOP) common data model (CDM) format on consumer level hardware. CDM approaches are increasingly adopted in both industry and academia due to the need for interoperability and reproducibility, including in clinical NLP tasks such as cohort selection, information extraction, and retrieval-augmented generation. The MIMIC-IV database is among the most widely used critical care research datasets, yet existing pipelines to transform it to OMOP depend on enterprise database infrastructure and complex orchestration, limiting accessibility for practitioners and resource-constrained researchers. We further integrate free-text clinical notes (195.6M clinical annotations) and chest radiographs into the OMOP note_nlp and imaging extension tables, making all MIMIC-IV modalities (structured data, free-text, and imaging) accessible through a common data model. This resource generates a more comprehensive dataset than existing alternatives and is intended to be used to aid in system development, testing, and evaluation.

1 Introduction

A growing number of clinical datasets are becoming available to the research community (All of Us Research Program Investigators, 2019; Clark et al., 2013; Pollard et al., 2018; Johnson et al., 2023b). However, each resource adopts its own bespoke schema, limiting interoperability and increasing development overhead of multi-source studies.

Common Data Models (CDMs) address this by enabling consistent data representation across institutions and applications through a standardised framework of schemas, attributes, entities, and relationships, thus facilitating collaboration, benchmarking, and reproducible analytics (Finster et al., 2025; Brown et al., 2022; PCORnet, 2025; Garza et al., 2016).

These data models have proven to be useful in emerging fields within healthcare and computational linguistics, such as information extraction and retrieval augmented generation (Keloth et al., 2023; Möller-Grell et al., 2026).

The Medical Information Mart for Intensive Care (MIMIC-IV) database is a cornerstone of critical care research, providing granular clinical data for thousands of admissions to the ICU (Johnson et al., 2023c). The MIMIC-IV data collection covers a wide range of data modalities, from structured data and textual data to images.

However, the joint analysis of these disparate data sources can be resource intensive, requires custom adaptations, and is not easily extensible to additional data sources. Converting these datasets into a CDM such as the OMOP CDM provides a unified extensible representation to cross-institutional data and a consistent foundation for systematic annotation of clinical text via Natural Language Processing (NLP).(Observational Health Data Sciences and Informatics, 2026).

Existing MIMIC ETL pipelines rely on enterprise database infrastructure (BigQuery) and complex orchestration (Paris et al., 2021; Sciences and Informatics, 2020), creating barriers for those who are resource-constrained.

dbt_mimic_omop' [1] is a lightweight, modular and portable ETL pipeline that uses dbt-Core (data build tool) ((dbt Labs, Inc., 2026)) and DuckDB ((Raasveldt and Mühleisen, 2019)) to transform MIMIC-IV data into the OMOP CDM (v5.4).

In addition to the core MIMIC-IV dataset, we also offer conversion for supplementary MIMIC-IV datasets. MIMIC-IV-Note contains more than 2 million de-identified free text notes, MIMIC-IV-CXR is an imaging database with more than

[1] link removed for reivew

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 992–996
July 3-4, 2026 ©2026 Association for Computational Linguistics

300,000 medical images. Both datasets are linked to the same patients as the core dataset. Further to this, we provide a resource with clinical annotations for the free text data in MIMIC-IV-Note.

2 Data Sources

2.1 MIMIC-IV

MIMIC-IV is well known in multiple fields of research, providing access to de-identified healthcare data. MIMIC-IV contains data for more than 65,000 patients admitted to the ICU and more than 200,000 patients admitted to the emergency department (Johnson et al., 2023a). The dataset does not adhere to any common data model.

2.2 MIMIC-IV-Note

MIMIC-IV-Note contains 331,794 de-identified discharge summaries from 145,915 patients and 2,321,355 radiology reports and for 237,427 patients, from the same sample of patients from the core MIMIC-IV dataset.

2.3 MIMIC-IV-CXR

The MIMIC Chest X-ray Database (MIMIC-CXR) is a large publicly available dataset of chest radiographs in DICOM format with free-text radiology reports (Johnson et al., 2019). The dataset contains 377,110 images corresponding to 227,835 radiographic studies. This dataset uses the CheXpert labelling system (Irvin et al., 2019), 14 distinct radiographic diagnostic observations through rule-based extraction are mapped to SNOMED concept IDs via custom vocabulary mappings.

2.4 CogStack Dashboards

CogStack Dashboards is an OpenSearch cluster that hosts the MIMIC-IV and MIMIC-IV-Note dataset[2]. In addition to the MIMIC dataset, annotations have been generated, provided via MedCAT (Kraljevic et al., 2021; Sutton et al., 2026). These generated annotations use the SNOMED CT ontology (SNOMED International, 2025) to provide coding for all detected entities. They also provide additional information about the entity, such as meta information and character positioning within the text. This model has been trained on various open-source datasets as well as privately trained data from King's College Hospital and Guy's and St Thomas' Hospital. Annotations such as these are useful in information extraction and retrieval augmented generation tasks (Keloth et al., 2023; Möller-Grell et al., 2026).

[2]https://cogstackdashboards.sites.er.kcl.ac.uk/

2.5 OHDSI Athena

OHDSI Athena is the repository for OHDSI standardised vocabularies used in the OMOP CDM. It allows users to search, browse, and download standardised mapped medical codes (concepts) for clinical, drug, and procedure data, allowing harmonisation and interoperability (Observational Health Data Sciences and Informatics, 2025).

3 Implementation

The DBT project's medallion architecture to transform raw MIMIC-IV to OMOP is as follows:

- **Bronze Layer (Ingestion):** Raw MIMIC-IV CSV files (v3.1), MIMIC-IV-CXR metadata and radiology reports, and OHDSI Athena vocabularies (v5) are ingested into a local DuckDB database. Python scripts facilitate efficient loading of large compressed datasets directly from Parquet/CSV sources. For MIMIC-IV-CXR, DICOM metadata is extracted and loaded alongside associated free-text radiology reports, which are linked to the patient and study identifiers shared with the core MIMIC-IV dataset.
- **Silver Layer (Refinement):** Intermediate views handle data cleaning, type casting, and semantic mapping. Specific transformations include cleaning visit details from various source tables (such as admissions/transfers) and mapping source codes (ICD-9/10, NDC, LOINC, local microbiology codes) to standard OMOP concepts using the OHDSI Athena vocabulary lookup tables. CXR radiology reports are linked to their corresponding MIMIC-IV hospital admission and processed for downstream annotation. CXR studies are linked to OMOP visit occurrence records by temporal overlap, matching subject ids and cross-referencing visit windows.
- **Gold Layer (Standardisation):** The final OMOP CDM v5.4 tables are compiled, covering key OMOP tables such as person, visit occurrence, condition occurrence, drug exposure, measurement, procedure occurrence, and observation. Tables generated from supplementary data do not contribute to the core

Domain	Field	PostgreSQL	dbt/DuckDB
condition_occurrence	condition_concept_id	100%	100%
procedure_occurrence	procedure_concept_id	100%	100%
drug_exposure	drug_concept_id	86.10%	96.59%
drug_exposure	route_concept_id	0%	97.79%
measurement	measurement_concept_id	0%	95.13%
measurement	unit_concept_id	0%	98.60%
specimen	specimen_concept_id	0%	97.53%
person	gender_concept_id	100%	100%
person	race_concept_id	0%	52.23%
person	ethnicity_concept_id	0%	0% (unmapped)

Table 1: Key OMOP Concept Coverages - each percentage represents the number of rows in each corresponding table that has appropriate concept ID in the specified field. These fields are required by the OMOP CDM standard.

Table	Count
measurement	296705150
note_nlp	**195642167**
fact_relationship	74356046
drug_exposure	20351014
observation	14018411
drug_era	10296936
procedure_occurrence	6564445
condition_occurrence	5328942
note	**2652887**
image_feature	**656697**
image_occurrence	**372209**
person	364627
death	38301

Table 2: Key OMOP Table Counts

OMOP CDM tables. MIMIC-IV-Note and annotations from CogstackDashboards are inserted into the note and note_nlp tables respectively. Tables sourced from MIMIC-CXR are generated into the OMOP CDM MI working group extension tables: image_occurrence with visit linkage, view position, modality, local and google cloud file paths; and image_feature, with one row per CheXpert finding, certainty labels mapped per custom SNOMED mapping.

The modular dbt project structure separates logic into 69 distinct models at transformation stage (e.g., separate models for admissions, pharmacy, labevents), facilitating maintenance and community contributions.

4 Results

The pipeline transforms MIMIC-IV v3.1 to OMOP CDM v5.4, generating more than 343 million standardised clinical events in 364,627 patients. On a consumer laptop (16gb of RAM, 8 core cpu), the full ETL process can be completed in less than three hours.

Tab. 2 shows the record counts of key OMOP tables and the tables generated from the supplementary data source. Tab. 1 shows the mapping rates for key concepts within this implementation.

Our proposed pipeline recovers previously unmapped domains, most notably measurement concept ids ($0\% \rightarrow 95.13\%$) and specimen concept ids ($0\% \rightarrow 96.59\%$), and introduces full coverage for all imaging fields. Race concepts improve from 0% to 52.23%, while ethnicity concept ids remains unmapped at 0% in both implementations. These lesser performances are due to the vocabularies lacking standard translations from MIMIC-IV recording of ethnicity and race to OMOP standardized codes.

We also directly compare the coverage between our solution and Legrand et al. (2025). Tab. 3 shows raw record counts and concept mapping rates for both solutions.

Free text clinical notes are also included, sourced from MIMIC-IV-Note. These notes are imported into the note table. The pipeline also incorporates full NLP annotation processing via the note_nlp table, adding 195.6M structured annotations from previously unprocessed clinical notes—a capability absent from prior implementations. However, due to the significant processing cost, we also offer the table already transformed ‘note_nlp‘ as a download,

Table 3: Comparison of PostgreSQL solution (Legrand et al., 2025) vs dbt/DuckDB Metrics

Metric	PostgreSQL	dbt/DuckDB	Change
Record Counts (millions)			
Person	0.32M	0.36M	+14.6%
Measurement	169.1M	296.7M	+75.4%
Procedure	0.86M	6.56M	+7.6×
Observation	3.52M	14.02M	+4.0×
Concept Mapping Rates			
Condition concepts	100%	100%	—
Drug concepts	86.1%	96.6%	+10.5%
Measurement concepts	0	95.1%	+95.1%
Unit concepts	0%	98.6%	New

with instructions provided in the repository.

In addition to the core OMOP CDM tables, the pipeline populates the OMOP Medical Imaging (MI) working group extension tables. The table image_occurrence contains 372,209 chest X-ray images, and image_feature captures 656,697 CheXpert findings with 100% concept mapping across all imaging fields (modality, anatomic site, image type concept and feature type). Of these images, 330,401 (88.8%) were successfully linked to visit_occurrence via temporal mapping.

5 Conclusion

The ‘dbt_mimic_omop‘ pipeline is freely available on GitHub [3]. This open-source solution significantly reduces the technical barrier for researchers wishing to conduct OHDSI-compliant studies using MIMIC-IV data. By decoupling the ETL process from enterprise-grade infrastructure, we facilitate broader adoption in educational settings, reproducibility in research, and rapid prototyping of analytical pipelines.

This resource is intended to be used as an aid for those who are developing NLP systems that employ the OMOP Common Data Model. The free text that is available via ‘mimic-iv-note‘ is available and in OMOP format for various tasks such as entity recognition and linking. The generated annotations we have provided can be used as baseline comparison. The dataset could also find use as a test dataset for more complex pipelines such as Retrieval Augmented Generation.

By combining dbt’s software engineering best practices with DuckDB’s embedded analytical capabilities, and extending the CDM with note_nlp and imaging tables, we aim to lower the barrier to clinical NLP, multimodal system development, and reproducible observational research over MIMIC-IV.

Future work includes improvements to this ETL pipeline. Such as additional versions of the MIMIC datasets (Johnson et al., 2016), and other publicly available datasets. Future versions of the repository can also include additional supplementary datasets (Moody et al., 2022). Such pipelines can also speed up the benchmarking process. Various datasets and benchmarking challenges are available, but often require development time for that specific challenge (DrivenData, 2026). Work can be done making such challenges follow a common data model, if applicable.

Exploring Novel Drug Research Area using Large Language Models Based on Research Trends in Biomedical Literature

Afnan[1], Michael Van Supranes[1,2], Tomohiro Nishiyama[1], Shoko Wakamiya[1], Eiji Aramaki[1]

[1]Nara Institute of Science and Technology, Japan, [2]University of the Philippines, Philippines

Abstract

The rapid expansion of biomedical literature makes manual identification of novel drug-disease relationships increasingly difficult. Existing approaches have leveraged LLMs to mine abstracts or construct knowledge graphs for drug repurposing. There are two key limitations: finite context windows for capturing macro-level research trends, and single-pass black-box pipelines make it difficult to verify outputs. This paper proposes a pipeline for discovering new drug targets by combining disease and drug research trends using Large Language Models (LLMs). Our method extracts PICO components from PubMed abstracts, normalizing the Population and Intervention Component to ICD and ATC codes, respectively. A *temporal frequency delta* matrix is constructed to capture publication count shifts across 2013 to 2022, then used to discover novel drug areas. Compared with the abstract-based baseline, our approach showed qualitative signs of generating combinations that were more closely aligned with observed research trends and, in some cases, more clinically plausible. These findings suggest the potential usefulness of structured trend information for LLM-based exploration, although the differences between the two methods were limited and the results remain preliminary. Future work will focus on validating the consistency and reliability of these candidates.

Keywords: LLMs, drug re-purposing, biomedical NLP, research trend, PubMed

1 Introduction

The biomedical literature has grown exponentially with time, creating a rich and complex body of knowledge for scientific discovery. Although experienced researchers can generate novel ideas from prior work, there are inherent limits to the amount of information that can be effectively processed and compared within a given time. As a result, identifying relevant studies and distilling key insights that can lead to breakthroughs has become increasingly challenging amid the vast and rapidly expanding volume of publications.

This challenge is pronounced in domains such as oncology, where thousands of abstracts are published each year, advancing research on drug-disease interactions, clinical trial outcomes, and molecular pathways (Wang et al., 2025; Yan et al., 2024). In this context, large language models (LLMs) have emerged as powerful tools for assisting researchers in navigating large-scale literature. LLMs can support automatic synthesis of clinical evidence and uncover hidden knowledge connections that would otherwise take a long time and require extensive manual review (Ghafarollahi and Buehler, 2025). In addition to literature review, recent innovations have demonstrated that LLMs can also assist in generating novel, plausible clinical hypotheses, such as identifying drug re-purposing candidates for Alzheimer's disease and Acute Myeloid Leukemia (Yan et al., 2024; Gottweis et al., 2025).

Despite the potential of LLM-based scientific discovery, direct application of LLMs to large-scale literature analysis has the following limitations:

Limited ability to capture overall research trends: LLM-based methods are constrained by a finite context window, limiting the number of abstracts or related work that can be included in a single prompt. LLMs may also fail to fully integrate all important findings when the input is too long. This phenomenon is called *lost in the middle* or retrieval failure during long-context processing (Du et al., 2025; Li et al., 2025). Thus, using LLMs requires selective inclusion of related work, which may hinder the model's ability to capture broader research trends.

Limited transparency in LLM-based pipelines: LLMs are black boxes and often deployed in single-pass pipelines for complex tasks. As a result, it is

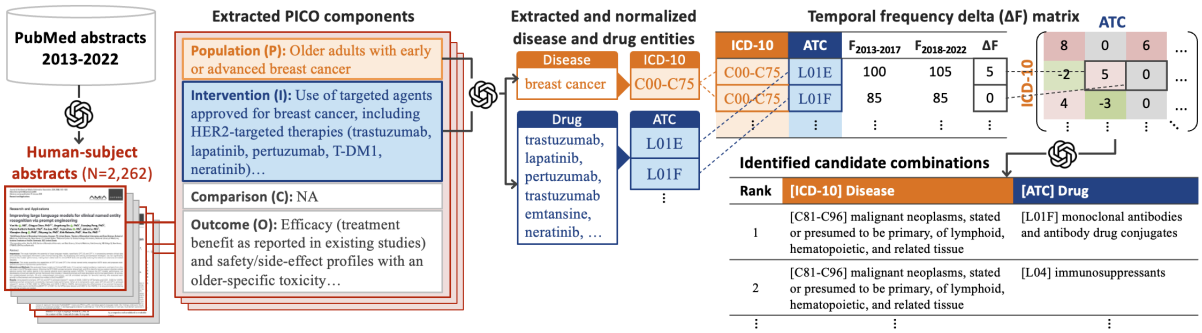

Figure 1: Analysis pipeline of the study. Abstracts were first filtered to include only human populations, then PICO components (Population, Intervention, Comparison, and Outcome) were extracted. The Population (P) and Intervention (I) components were then used to construct a matrix of publications for each P–I combination across two periods: 2013–2017 and 2018–2022. This matrix served as input for an LLM to generate novel potential P–I combinations. Multiple reasoning and an impact score in each step of generating are used to mitigate hallucination.

difficult to tell whether the model has correctly identified and incorporated relevant information or has generated hallucinated content (Wang et al., 2025).

Addressing these challenges remains an open problem. In this paper, we present a novel approach to support drug discovery by augmenting LLMs with temporally grounded bibliometric signals (Figure 1). Our contributions are two-fold. First, to address the difficulty LLMs face in detecting macro-level research trends across fields and time periods, we introduce a frequency delta matrix to represent research trends in a compact, context-efficient manner, enabling the incorporation of research momentum signals into prompts without requiring extensive collections of raw abstracts. Second, we develop an end-to-end pipeline that extracts structured information from abstracts based on the PICO framework (Population (**P**), Intervention (**I**), Comparison or Control (**C**), and Outcome (**O**)), constructs co-occurrence matrices, and leverages them to guide LLMs in finding candidate disease–drug research combinations. We compare this structured, trend-explicit formulation with a baseline that uses raw abstracts and publication years as unstructured, trend-implicit input, and examine whether LLMs can improve in generating more clinically plausible disease–drug research combinations.

2 Related Work

2.1 LLMs in Biomedical Discovery

The integration of LLMs into the medical field has shown immense promise, particularly in automating knowledge synthesis. Early benchmarks, such as BioRED (Du et al., 2025), established a gold standard for extracting explicit semantic triples (e.g., Drug A treats Disease B) from unstructured PubMed abstracts. Beyond simple extraction, LLMs are now being utilized as autonomous agents capable of generating novel and scientifically valid research ideas (Baek et al., 2025; Gottweis et al., 2025). However, a persistent challenge remains in ensuring the interpretability and reliability of these discoveries, especially when models move from sentence-level connections to complex, multi-faceted scientific problem-solving (Li et al., 2025; Williams, 2026).

2.2 Automated Hypothesis Generation in Drug Discovery

The primary objective of AI-driven drug discovery is to identify novel combinations of diseases and pharmacological agents that have not yet been clinically explored. Traditional methods relied on building discrete concept corpora and identifying relationships via word vector similarities (Islamaj et al., 2024) or link prediction within knowledge graphs (Yang et al., 2023). While these methods are effective for validating known biochemical pathways, they often fail to capture emerging research frontiers or trending therapeutic dyads that exhibit high growth momentum. Recent advances use the scientific knowledge in LLMs to move beyond predicting localized connections and toward identifying "hot topics" in science, a task traditionally handled by bibliometric analysis (Qi et al., 2023; Tshitoyan et al., 2019). Our work builds on this by investigating whether LLMs can automate the interpretive step of translating statistical clusters into actionable research hypotheses.

2.3 Topic Trends as Scientific Signals

The use of publication frequency and temporal shifts to identify emerging research directions is a well-established principle in scientometrics. Traditional bibliometric methods, such as co-word analysis and citation burst detection, have long been used to map the "intellectual turning points" of a scientific field (Qi et al., 2024). For instance, a sudden spike in publications on a specific drug-disease dyad often signals a transition from basic research to clinical interest. Our work builds on the premise that scientific discovery is a temporal process, in which "information remnants" in literature, captured via frequency shifts, can predict future high-impact research areas (Tshitoyan et al., 2019). By transforming bibliometric data into a *frequency delta matrix* (Δ), we construct a compact representation of research trends that can be efficiently incorporated into LLM prompts, providing signals of research momentum that are difficult to capture when using raw abstracts alone.

2.4 Reasoning over Tabular Data

While LLMs are natively trained on unstructured natural language, their ability to interpret structured formats like CSV, JSON, and SQL has become a focal point of research. Recent studies indicate that while LLMs can perform reasoning over tabular data, their performance is highly sensitive to the data's serialization format (Sybrandt et al., 2017). In the context of drug discovery, the ability of a model to ingest structured co-occurrence matrices is essential for identifying statistical trends. Researchers have found that providing LLMs with structured summaries of biomedical metadata enables more precise "*chain-of-thought*" reasoning than processing raw, disconnected abstracts (Kim et al., 2022). This study extends this line of inquiry by comparing structured tabular inputs.

3 Dataset Construction

The primary dataset for this study comprises scholarly abstracts retrieved from PubMed, spanning a 10-year period from 2013 to 2022. This period was selected to enable a balanced comparison between two consecutive five-year intervals (2013–2017 and 2018–2022). Using equal time intervals helps ensure that observed differences reflect meaningful shifts in research activity. In addition, this period captures the accelerated growth in oncology research.

Year	# of filtered articles	Avg. word count
2013	128	251
2014	169	242
2015	152	245
2016	176	245
2017	171	251
2018	168	249
2019	172	252
2020	293	250
2021	433	251
2022	400	177
Total	**2262**	–
Min	**128**	–
Max	**400**	–

Table 1: Number of abstracts after filtering (not animal or biomedical abstracts, only clinical abstracts), along with average word counts per year.

To construct a high-quality dataset for analysis, it is essential to accurately identify clinically relevant studies. However, traditional keyword-based Boolean searches often suffer from low precision due to polysemy and the inclusion of non-human studies.

The dataset was constructed in a two-stage process. First, an initial pool of 5,000 abstracts was retrieved from PubMed[1] via the API[2], with 500 abstracts randomly sampled per year to balance analytical coverage and computational feasibility. Second, each abstract was screened using an LLM (GPT-5, OpenAI[3]) to retain only those describing human studies (see Section 4.1 for details). This process yielded 2,262 abstracts, which constitute the final dataset used in this study.

Further details on the dataset distribution are provided in Table 1, which shows that annual publications remained below 180 between 2013 and 2018, exceeded 200 by 2020, and nearly doubled by 2021–2022. These trends have been attributed to advances in genomics and immunotherapy, increased clinical trial activity, and the growing use of artificial intelligence in data analysis (Yao et al., 2023; Wang et al., 2024; Azmi and Howe Chan, 2025).

4 Method

The overall methodology of this study consists of four main stages: LLM-based abstract screening and PICO extraction (Section 4.1), entity extraction

[1] https://pubmed.ncbi.nlm.nih.gov/

[2] https://www.ncbi.nlm.nih.gov/books/NBK25497/

[3] https://developers.openai.com/api/docs/models/gpt-5

and normalization (Section 4.2), construction of the temporal frequency delta matrix (Section 4.3), and identification of potential disease-drug combinations from trending topics (Section 4.4). The complete pipeline is illustrated in Figure 1.

4.1 PICO Extraction

We use an LLM-based approach to identify the Population, Intervention, Comparison, and Outcome (PICO) components in abstracts. For each abstract, the LLM first determines whether the study concerns a human population; only if this criterion is satisfied does it proceed to extract the PICO components. This design integrates dataset screening with information extraction in a single process.

To ensure high accuracy and mitigate potential hallucinations, we employ a one-shot prompting strategy with multi-step reasoning. Before producing the final output, the LLM is also instructed to generate intermediate reasoning steps. This approach helps ensure that the extracted PICO components are grounded in the terminology used in each abstract. The detailed prompt provided in Appendix A and the example of the output is provided in Appendix G.

4.2 Extraction and Normalization of Disease and Drug Entities

Based on the extracted PICO components, we identify structured biomedical entities for downstream analysis. The `P` component identifies the underlying pathology or patient condition, while the `I` component captures the therapeutic agents evaluated in the study.

To ensure standardization and interoperability, we use an LLM-based approach for entity extraction and normalization. In this approach, the same LLM is used for both entity extraction and ontology mapping. First, we extract all the disease and drug entities (therapeutic agents) mentioned in the `P` and `I` components. These entities are then mapped to established biomedical ontologies: disease entities to the International Classification of Diseases (ICD-10, version 2019) and drug entities to the Anatomical Therapeutic Chemical (ATC) classification.

Both ontologies provide hierarchical structures, enabling each entity to be represented at multiple levels of granularity, with deeper levels corresponding to more specific clinical concepts. In the mapping process, we begin at the most specific category level. If no match is found at that level, the LLM escalates to the next higher category, continuing upward until a suitable match is identified. Regardless of the level at which the match is found, all hierarchical levels above it are retained, preserving the full ontological path of each entity. To balance clinical specificity with statistical robustness, we standardize the granularity of our variables, as detailed in Figures 3 (ICD-10) and 4 (ATC) in Appendix H. This approach enables a high-resolution view of therapeutic trends while avoiding over-segmentation or non-representative categories.

This LLM-driven matching process enables flexible semantic normalization of noisy biomedical text, including synonym resolution and implicit concept alignment, without relying on explicit string matching or rule-based heuristics. For further information, refer to Appendix B.

4.3 Temporal Frequency Delta Matrix

To investigate the evolution of research priorities, we divide the dataset into two distinct five-year cohorts: an early period (2013–2017) and a recent period (2018–2022).

By segmenting the data into these time windows, we quantify shifts in scientific interest over a decade and identify therapeutic interventions that have gained or declined in prominence.

We then construct a matrix to capture the frequency of disease-drug combinations within each period. Based on these matrices, we define the primary metric for our heatmap, the *Temporal Frequency Delta* (ΔF), which represents the net change in publication volume for a given pairing between the two cohorts.

$$\Delta F(P, I) = \sum_{t=C+T}^{C+2T-1} F_t(P, I) - \sum_{t=C}^{C+T-1} F_t(P, I) \quad (1)$$

where C denotes the starting year (set to 2013 in this study), and T denotes the length of each time window (set to 5 years). $F_t(P, I)$ denotes the number of unique publications discussing a specific disease–drug pair in year t, where P and I denote the population (disease) and intervention (drug), respectively. This formulation captures the temporal trend as the difference in publication counts between the two periods (2013-2017 and 2018-2022).

The ΔF value can be positive, negative, or zero:

- **Positive** ΔF indicates trending therapeutic combinations, where research activity has increased in the recent period. These regions are the primary focus of our LLM-based analysis.
- **Negative** ΔF indicates combinations with declining research activity over time.

- **Zero** ΔF indicates no change in the number of publications for a given disease–drug pairing between the two periods.

Finally, using the combinations of P and I, we define the *temporal frequency delta* matrix, $\Delta F \in \mathbb{R}^{n \times m}$, as follows:

$$\begin{pmatrix} \Delta F(P_1, I_1) & \Delta F(P_1, I_2) & \cdots & \Delta F(P_1, I_m) \\ \Delta F(P_2, I_1) & \Delta F(P_2, I_2) & \cdots & \Delta F(P_2, I_m) \\ \vdots & \vdots & \ddots & \vdots \\ \Delta F(P_n, I_1) & \Delta F(P_n, I_2) & \cdots & \Delta F(P_n, I_m) \end{pmatrix} \quad (2)$$

The lists of all $P_{1..n}$ and all $I_{1..m}$ are provided in Appendix E and F. In this study, $n = 51$ represents the number of diseases analyzed (focused on Neoplasm). While $m = 256$ denotes the total number of drugs analyzed.

4.4 Identification of Candidate Disease–Drug Combinations from Emerging Trends

To identify candidate combinations for future research, the proposed method uses a structured, matrix-based representation derived from temporal publication signals. This design enables a controlled evaluation of how input formulation influences an LLM's ability to synthesize meaningful and novel research areas. The method is provided with tabular data consisting of P–I pairs and *temporal frequency deltas* (ΔF), which capture shifts in research priorities.

The LLM is instructed to select the top-k ($k = 10$ in this study) most promising P–I combinations based on four scoring criteria: growth over the past five years, translational plausibility, clinical relevance, and strategic novelty. Each criterion is weighted and aggregated into a composite impact score ranging from 0 to 100. All outputs are generated by the LLM, not only to identify high-potential combinations but also to reduce the risk of hallucination. Further details are provided in Appendix C.

5 Experiment Setup

5.1 Model Implementation

We employed GPT-5-2025-08-07 (OpenAI), a general-purpose LLM with strong reasoning capabilities, as the primary model in our pipeline to support structured information extraction and multi-step reasoning. The model was applied across three key stages: PICO extraction (Section 4.1), extraction and normalization of disease and drug entities (Section 4.2), and identification of candidate disease–drug combinations from emerging trends (Section 4.4).

By utilizing a consistent LLM architecture across these stages, we ensured semantic continuity and reduced the risk of formatting discrepancies that often occur when switching between different models.

5.2 Domain Selection

To provide a focused evaluation setting, this analysis is restricted to neoplastic diseases. After the entity normalization stage, only records with P disease entities mapped to the ICD-10 chapter "Neoplasms" were retained for analysis. This constraint was applied solely for experimental purposes and does not limit the general applicability of the proposed method. We are only focusing on neoplastic diseases as the representative domain due to their extensive research, well-defined disease taxonomy, and clinical importance in drug discovery. This provides a suitable testbed for evaluating the proposed approach.

5.3 Baseline

For the baseline, we use the raw biomedical abstracts with their publication years. This means the baseline approach operates on unstructured, abstract texts, requiring the LLM to implicitly extract and reason about relevant entities, relationships, and trends in the research area. As in the proposed method, the instruction to the LLM is to select the top 10 most promising P and I combinations. The generated combination should follow the normalized version of P–I. This means the output should be in ICD-10 codes for the P component and ATC codes for the I component. The generated combinations are evaluated using 4 scoring criteria: growth over the past 5 years, translational plausibility, clinical relevance, and strategic novelty. Each criterion is weighted to produce a composite impact score ranging from 0 to 100. For more details, refer to the Appendix D.

5.4 Evaluation Procedure

The evaluation is conducted using two approaches: visualization and expert interpretation. First, evaluation is performed through the interpretation of visualization, specifically heatmaps. In the heatmap, it is possible to identify where new combinations are located. This means analyzing whether the combinations lie around trending drugs or not. If

the results are located around the red region, it suggests that the model successfully captures trending drugs and may propose new diseases that can be treated using those drugs (Section 6.1). Second, a qualitative evaluation was performed by a domain expert and co-author of this paper with expertise in pharmaceutical science to determine whether the results are medically meaningful (Section 6.2).

6 Results and Discussion

6.1 Heatmap Results

We present a heatmap showing all disease–drug combinations along with the candidate combinations identified by the LLM. Out of all possible combinations of 51 diseases and 256 drugs, the proposed method identifies 32 unique disease–drug pairs. These results form the basis for the heatmap, enabling comparison between the proposed method (Figures 2a and 2c) and the baseline method (Figures 2b and 2d) in terms of identified candidate combinations. The candidate combinations are highlighted in yellow, as shown in Figure 2. We focus on candidate combinations that correspond to emerging trends (i.e., the red regions in the heatmap).

A comparison with the baseline reveals that the baseline approach identifies some candidate combinations that do not overlap with previously observed trends. Specifically, among the top 10 combinations identified by the baseline, only 2 overlap with the red regions, indicating limited alignment with emerging trends.

In contrast, the proposed method produces candidate combinations that are largely consistent with emerging trends: nearly all of the top 10 combinations overlap with the red regions. This suggests that the proposed method more effectively captures captures temporally grounded research dynamics more effectively a tabular comparison of the top 10 most plausible combinations in Table 2.

6.2 Qualitative Clinical Interpretation

Both the proposed and baseline methods show a tendency for the extracted drug–disease combinations to be concentrated in oncology, particularly in hematologic malignancies. This suggests that both methods may, to some extent, reflect the broad structure of current anticancer treatment. At the same time, however, the differences between the two methods were limited, making it difficult to draw a clear conclusion about the superiority of the proposed method based on these results alone.

When examined in more detail, the baseline included drug classes such as systemic antifungals among its top-ranked outputs, which are more commonly used for supportive care, such as infection prevention, rather than as direct anticancer therapies. This suggests that when inference is based on aggregated categories, drug classes that are not central to disease treatment may be included in the results. In contrast, the proposed method included drug classes such as corticosteroids and alkylating agents for hematologic malignancies, which are more closely aligned with the context of anticancer treatment. This may indicate that, at least in some cases, the proposed method is better at prioritizing candidates with higher clinical plausibility. However, combinations that remain difficult to interpret, such as ocular vascular disorder agents for carcinoma in situ of the digestive organs, were also observed. Therefore, it cannot be concluded that the proposed method consistently extracts meaningful candidates.

7 Conclusion & Future Work

This study aims to identify emerging areas in drug discovery by leveraging LLMs. Our basic idea is to decompose the research into `P` (patient) and `I` (intervention) combinations. Under this paradigm, given the limitation of context length, handling the entire research trend is an issue. Our solution is to represent the trend in a matrix (we all *temporal frequency delta* matrix) to incorporate it with in-context learning.

As a result, it demonstrates that while the baseline approach is more likely to suggest novel, non-overlapping 'P' and 'I' combinations, the proposed approach excels at pattern recognition within established "trending" zones. Expert interpretation confirms that, although the LLM successfully prioritizes clinically plausible treatments such as alkylating agents for hematologic malignancies, it can still produce improbable pairings, suggesting that the model currently functions best as a high-level exploratory tool for visualizing therapeutic landscapes. This expert evaluation also shows that the idea of using multiple reasoning and CIS to mitigate hallucination does not fully eliminate the risk of hallucinated outputs.

This highlights that transparency and reliability remain open challenges in LLM-based scientific discovery frameworks. Future work can also ex-

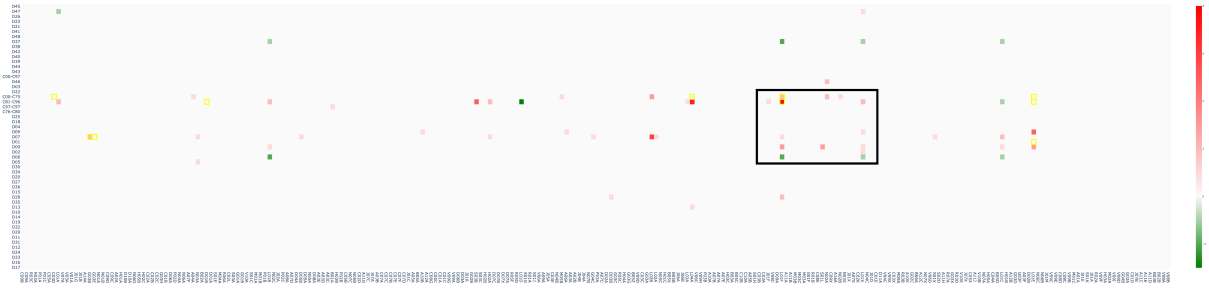
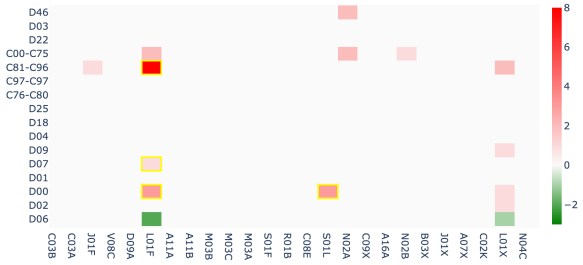
10	**[D00]** carcinoma in situ of the oral cavity, esophagus, and stomach	**[S01L]** ocular vascular disorder agents	**[C81–C96]** malignant neoplasms, stated or presumed to be primary, of specified sites, except for lymphoid, hematopoiesis, and related tissue	**[L04A]** immunosuppressants

Table 2: Comparison between the proposed approach and baseline approach with promising rank. Each entry consists of a code and its corresponding category name (ICD-10 for diseases and ATC for drugs). The rows with a gray background represent the combinations of the baseline and proposed approach that have the same output.

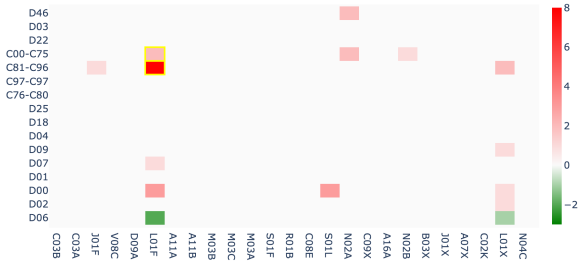


tend the analysis to other form of output such as the exact PICO output so we can evaluate the quality and the correctness of the idea generated by LLM.

8 Limitations



There are several limitations: First, we focus only on PubMed papers, specifically on cancer abstracts, which limits the generalizability. Second, the mapping process still needs further investigation to de-



(a) Proposed method

(b) Baseline method

(c) Zoomed-in view of a selected region in (a)

(d) Zoomed-in view of a selected region in (b)

Figure 2: Heatmaps of disease (ICD-10)–drug (ATC) combinations based on temporal frequency delta (ΔF). The vertical axis represents diseases (ICD-10) and the horizontal axis represents drugs (ATC). Each cell corresponds to the ΔF value for a disease–drug pair. Red indicates combinations with increasing research activity (positive ΔF), while green indicates combinations with decreasing activity (negative ΔF); light gray indicates zero change ($\Delta F = 0$). Yellow boxes highlight top-ranked candidate combinations based on composite impact scores.

termine the optimal level of categories used for the normalization process. Third, the *temporal frequency delta* matrix ranged from -3 to 8, which may be sensitive to cumulative errors throughout the pipeline. Therefore, hallucination in each step should be considered; there may be a chance of hallucination along the way. Finally, in the evaluation framework, we only used qualitative methods that leads to missing information regarding how is the quality, the correctness, and the novelty of the new research combination. This can also be future research focusing on the evaluation using quantitative methods. Beyond these limitations, future work can be applied across more papers and sources and expanded beyond a focus on cancer. Also, the LLM models used in this research can be further explored selecting models from the medical domain is another option.

A Details of Filtering and PICO Extraction via LLM

LLM Prompt for PICO Extraction

```
You are an expert biomedical research analyst.

The objective is to extract structured PICO/PECO
elements from biomedical abstracts while filtering out
non-human studies.

TASK:
Extract concise PICO/PECO elements and return a single
JSON object.

REQUIREMENTS:
- Output MUST contain exactly these keys: "Population",
```

```
"Intervention/Exposure", "Comparison", "Outcome", and
"Explain".
- Each field MUST contain 1–2 concise sentences using
canonical clinical phrasing.
- Do NOT include citations or bracketed identifiers.

HUMAN SUBJECT FILTER:
- If the study does NOT involve human subjects (e.g.,
animal studies, in vitro, biomedical experiments), set
ALL fields to "NA".
- Provide a clear justification in the "Explain" field.

STRICT RULES:
- Do NOT hallucinate or infer missing information.
- If any PICO element is not explicitly stated, write
"NA".
- Ensure all outputs are directly grounded in the
abstract.

WORKFLOW:
1. Perform initial screening for human subjects.
2. Identify study design, treatment arms, and
comparators.
3. Map findings into PICO/PECO components.
4. Validate that all required JSON keys are present
and correctly formatted.

OUTPUT FORMAT (JSON ONLY):

{
"Population": "...",
"Intervention/Exposure": "...",
"Comparison": "...",
"Outcome": "...",
"Explain": "..."
}

INPUT DATA:
{abstracts}
```

B Prompts for Entity Extraction & Normalization

PICO NER Prompt

```
You are a professional biomedical Named Entity
Recognition (NER) system specialized in PICO-based
extraction.

TASK:
Extract structured biomedical entities from the input
text:
- P (Population/Problem): underlying diseases or
patient conditions
- I (Intervention): therapeutic agents (drugs,
biologics)

REQUIREMENTS:
- Extract ONLY entities explicitly mentioned in the
text.
- DO NOT infer or hallucinate entities.
- Resolve abbreviations ONLY if clearly defined in the
text.
- Return ONLY the expanded (full) form.

ENTITY DEFINITIONS:
- Disease (P): pathological conditions, diagnoses,
syndromes
- Drug (I): therapeutic agents, drugs, biologics

EXCLUDE:
- Procedures, measurements, symptoms, and general terms

REASONING REQUIREMENTS:
- Each entity MUST include a "reason".
- The reason MUST be directly grounded in the text.
- Prefer exact phrase or minimal paraphrase from the
text.
- DO NOT use external knowledge.
- Maximum 15 words.

STRICT CONSTRAINTS:
- DO NOT include entities that are not directly grounded
in the text.
- DO NOT guess abbreviation expansions unless clearly
supported.
- If no entities exist, return empty lists.

VALIDATION STEP (INTERNAL):
1. Identify candidate entities directly from the text.
2. Remove duplicates and abbreviations.
3. Ensure each entity appears explicitly.
4. Ensure each reason is grounded in the text.

INPUT:
{text}

OUTPUT FORMAT (JSON ONLY):
{
"Disease": [
{"name": "...", "reason": "..."}
],
"Drug": [
{"name": "...", "reason": "..."}
]
}
```

ATC Drug Normalization Prompt

```
You are an expert biomedical terminologist performing
drug normalization using ATC classification.

TASK:
Map the input drug to the MOST SPECIFIC ATC concept
using the full hierarchy.

INPUT:
"{term}"

ONTOLOGY STRUCTURE:
- ATC hierarchy: Level 1 → Level 2 → Level 3 → Level
4 → Level 5
- Level 5 = most specific (chemical substance)

REQUIREMENTS:
- Search across ALL ATC levels
- START from Level 5 (most specific)
- If no match, move upward level-by-level
- Select the MOST SPECIFIC semantically equivalent
concept

SEMANTIC MATCHING:
- Accept synonyms, brand names, and drug combinations
- For combination drugs → choose dominant therapeutic
class

STRICT RULES:
- DO NOT choose a broader class if a specific match
exists
- DO NOT assign incorrect therapeutic class
- DO NOT hallucinate mappings
- If no valid match → return "None"

VALIDATION (INTERNAL):
1. Identify active ingredient or drug class
2. Match against candidates (all levels)
3. Start from Level 5 → move upward
4. Ensure therapeutic equivalence
5. Confirm no more specific match exists

OUTPUT FORMAT (STRICT JSON):
{
"input": "{term}",
"match": {
"code": "...",
"name": "...",
"hierarchy": [
{"level": "level1", "code": "...", "name": "..."},
{"level": "level2", "code": "...", "name": "..."},
{"level": "level3", "code": "...", "name": "..."},
{"level": "level4", "code": "...", "name": "..."},
{"level": "level5", "code": "...", "name": "..."}
]
}
}
```

```
CANDIDATES (ALL LEVELS):
{candidates}
```

ICD-10 Disease Normalization Prompt

```
You are an expert biomedical terminologist performing
disease normalization using ICD-10 (2019).

TASK:
Map the input disease to the MOST SPECIFIC matching
ICD-10 concept using the full hierarchy.

INPUT:
"{term}"

ONTOLOGY STRUCTURE:
- ICD-10 is hierarchical Level 1 → Level 2 → Level 3
→ Level 4 → Level 5 → Level 6 → Level 7
- Lower levels = more specific concepts

REQUIREMENTS:
- Search across ALL levels of ICD-10 candidates
- START from the LOWEST (most specific) level
- If no exact match at lower level, move upward
step-by-step
- Select the MOST SPECIFIC semantically equivalent
concept

SEMANTIC MATCHING:
- Accept synonyms and clinical rephrasings
- Use meaning, NOT string similarity

STRICT RULES:
- DO NOT select a broader category if a more specific
match exists
- DO NOT select a narrower category if it changes
meaning
- DO NOT hallucinate mappings
- If no valid match exists → return "None"

VALIDATION (INTERNAL):
1. Identify the core disease concept
2. Compare against candidates (all levels)
3. Start from the most specific level
4. Ensure semantic equivalence (not related, not
approximate)
5. Confirm no better (more specific) match exists

OUTPUT FORMAT (STRICT JSON):
{
"input": "{term}",
"match": {
"code": "...",
"name": "...",
"hierarchy": [
{"level": "chapter", "code": "...", "name": "..."},
{"level": "block", "code": "...", "name": "..."},
{"level": "category", "code": "...", "name": "..."},
{"level": "subcategory", "code": "...", "name": "..."}
]
}
}

CANDIDATES (ALL LEVELS):
{candidates}
```

C Prompts for Identifying Candidate Combination

Proposed Method Prompt

```
You are analyzing structured trend data derived from
publication dynamics.

Each row contains:
- Disease_ICD_L4
- Drug_ATC_L3
- Delta_Publications

DELTA = (2018–2022 publications) − (2013–2017
publications)

Meaning:
Positive → increasing research activity
Zero → no change
Negative → declining research

INPUT DATA:
{delta_json_text}

TASK:
Select the TOP 10 most promising Problem–Intervention
(P–I) combinations for future research.

SELECTION CRITERIA:
- Strong positive growth over the past 5 years
- Translational plausibility
- Clinical relevance
- Strategic novelty

SCORING SCHEME (Impact Score: 0–100):
- Growth intensity (0–30)
- Translational plausibility (0–25)
- Clinical relevance (0–25)
- Strategic novelty (0–20)

STRICT RULES:
- You MUST use EXACT labels as provided in the dataset.
- Do NOT invent, modify, or normalize labels.
- All reasoning MUST be grounded in the provided data.

OUTPUT FORMAT (JSON ONLY):

[
{
"P-Group": "...",
"I-Group": "...",
"Impact Score": 0–100,
"Insight": "Max 2 sentences reasoning"
}
]
```

D Prompts for Baseline

Baseline Prompt

```
You are analyzing biomedical abstracts along with their
publication years.

Each abstract includes a publication year. You MUST
use this temporal information to identify trends in
research activity.

The objective is to identify potential
Problem–Intervention (P–I) combinations for future
research.

TASK:
Select the TOP 10 most promising P and I combinations.

REQUIREMENTS:
- P MUST be normalized to ICD-10 Level 3 and MUST be
selected ONLY from the following valid disease labels:
{disease_labels}.
- Do NOT generate new or modified labels.
- I MUST be normalized to ATC Level 4 and MUST be
selected ONLY from the following valid drug labels:
{drug_labels}.
- Do NOT generate new or modified labels.

TEMPORAL CONSTRAINT:
- You MUST explicitly use publication years to infer
research growth.
- Compare the most recent 5 years with the earlier 5
years.
- If no temporal signal is observable, do NOT prioritize
that combination.

SCORING SCHEME (Impact Score: 0–100):
- Growth intensity (0–30)
- Translational plausibility (0–25)
- Clinical relevance (0–25)
- Strategic novelty (0–20)

STRICT RULES:
```

```
- Do NOT invent unsupported entities.
- All reasoning MUST be grounded in the abstracts AND
their publication years.

OUTPUT FORMAT (JSON ONLY):
{
"P-Group": "ICD-10 Level 3",
"I-Group": "ATC Level 4",
"Impact Score": 0-100,
"Insight":    "Max  2  sentences  including  temporal
reasoning"
}

INPUT DATA:
{abstracts}
```

E List of ICD-10 Code

ICD-10 2019 Codes

Code	Category	Code	Category
C00-C75	Malignant neoplasms, stated or presumed to be primary, of specified sites, except of lymphoid, hematopoietic and related tissue	C81-C96	Malignant neoplasms, stated or presumed to be primary, of lymphoid, hematopoietic and related tissue
C76-C80	Malignant neoplasms of ill-defined, secondary, and unspecified sites	D48	Neoplasm of uncertain or unknown behavior of other and unspecified sites
C97-C97	Malignant neoplasms of independent (primary) multiple sites	D00	Carcinoma in situ of oral cavity, esophagus, and stomach
D01	Carcinoma in situ of other and unspecified digestive organs	D02	Carcinoma in situ of the middle ear and respiratory system
D03	Melanoma in situ	D04	Carcinoma in situ of skin
D05	Carcinoma in situ of the breast	D06	Carcinoma in situ of cervix uteri
D07	Carcinoma in situ of other and unspecified genital organs	D09	Carcinoma in situ of other and unspecified sites
D10	Benign neoplasm of the mouth and pharynx	D11	Benign neoplasm of major salivary glands
D12	Benign neoplasm of colon, rectum, anus, and anal canal	D13	Benign neoplasm of other and ill-defined parts of the digestive system
D14	Benign neoplasm of the middle ear and respiratory system	D15	Benign neoplasm of other and unspecified intrathoracic organs
D16	Benign neoplasm of bone and articular cartilage	D17	Benign lipomatous neoplasm
D18	Haemangioma and lymphangioma, any site	D19	Benign neoplasm of mesothelia tissue
D20	Benign neoplasm of soft tissue of the retroperitoneum and peritoneum	D21	Other benign neoplasms of connective and other soft tissue
D22	Melanocytic naevi	D23	Other benign neoplasms of skin
D24	Benign neoplasm of breast	D25	Leiomyoma of uterus
D26	Other benign neoplasms of uterus	D27	Benign neoplasm of ovary
D28	Benign neoplasm of other and unspecified female genital organs	D29	Benign neoplasm of male genital organs
D30	Benign neoplasm of urinary organs	D31	Benign neoplasm of eye and adnexa
D32	Benign neoplasm of meninges	D33	Benign neoplasm of brain and other parts of the central nervous system
D34	Benign neoplasm of thyroid gland	D35	Benign neoplasm of other and unspecified endocrine glands
D36	Benign neoplasm of other and unspecified sites	D37	Neoplasm of uncertain or unknown behavior of the oral cavity and digestive organs
D38	Neoplasm of uncertain or unknown behavior of the middle ear and respiratory and intrathoracic organs	D39	Neoplasm of uncertain or unknown behavior of female genital organs
D40	Neoplasm of uncertain or unknown behavior of male genital organs	D41	Neoplasm of uncertain or unknown behavior of urinary organs
D42	Neoplasm of uncertain or unknown behavior of meninges	D43	Neoplasm of uncertain or unknown behavior of brain and central nervous system
D44	Neoplasm of uncertain or unknown behavior of endocrine glands	D45	Polycythaemia vera
D46	Myelodysplastic syndromes	D47	Other neoplasms of uncertain or unknown behavior of lymphoid, hematopoietic and related tissue

F List of ATC Classification Codes

A07F	Antidiarrheal Microorganisms	A07X	Other Antidiarrheals
A08A	Antiobesity Preparations	A09A	Digestives, Incl. Enzymes
A10A	Insulins and Analogues	A10B	Blood Glucose Lowering Drugs, Excl. Insulins
A10X	Other Drugs Used in Diabetes	A11A	Multivitamins, Combinations
A11B	Multivitamins, Plain	A11C	Vitamin A and D, Incl. Combinations
A11D	Vitamin B1, Plain and Comb.	A11E	Vitamin B-Complex, Incl. Combinations
A11G	Ascorbic Acid (Vitamin C), Incl. Comb.	A11H	Other Plain Vitamin Preparations
A11J	Other Vitamin Products, Combinations	A12A	Calcium
A12B	Potassium	A12C	Other Mineral Supplements
A14A	Anabolic Steroids	A16A	Other Alimentary Tract and Metabolism Products
B01A	Antithrombotic Agents	B02A	Antifibrinolytics
B02B	Vitamin K and Other Hemostatics	B03A	Iron Preparations
B03B	Vitamin B12 and Folic Acid	B03X	Other Antianemic Preparations
B05A	Blood and Related Products	B05B	I.V. Solutions
B05C	Irrigating Solutions	B05D	Peritoneal Dialytics
B05X	I.V. Solution Additives	B05Z	Hemodialytics and Hemofiltrates
B06A	Other Hematological Agents	C01A	Cardiac Glycosides
C01B	Antiarrhythmics, Class I and III	C01C	Cardiac Stimulants Excl. Cardiac Glycosides
C01D	Vasodilators Used in Cardiac Diseases	C01E	Other Cardiac Preparations
C02A	Antiadrenergic Agents, Centrally Acting	C02B	Antiadrenergic Agents, Ganglion-Blocking
C02C	Antiadrenergic Agents, Peripherally Acting	C02D	Arteriolar Smooth Muscle, Agents Acting On
C02K	Other Antihypertensives	C02L	Antihypertensives and Diuretics in Comb.
C03A	Low-Ceiling Diuretics, Thiazides	C03B	Low-Ceiling Diuretics, Excl. Thiazides
C03C	High-Ceiling Diuretics	C03D	Aldosterone Antagonists and K-Sparing Agents
C03E	Diuretics and K-Sparing Agents in Comb.	C03X	Other Diuretics
C04A	Peripheral Vasodilators	C05A	Agents for Hemorrhoids (Topical)
C05B	Antivaricose Therapy	C05C	Capillary Stabilizing Agents
C05X	Other Vasoprotectives	C07A	Beta Blocking Agents
C07B	Beta Blocking Agents and Thiazides	C07C	Beta Blocking Agents and Other Diuretics
C07D	Beta Blocking Agents, Thiazides and Diuretics	C07E	Beta Blocking Agents and Vasodilators
C07F	Beta Blocking Agents, Other Comb.	C08C	Selective Calcium Channel Blockers (Vascular)
C08D	Selective Calcium Channel Blockers (Cardiac)	C08E	Non-Selective Calcium Channel Blockers
C08G	Calcium Channel Blockers and Diuretics	C09A	ACE Inhibitors, Plain
C09B	ACE Inhibitors, Combinations	C09C	Angiotensin II Receptor Blockers (ARBs)
C09D	ARBs, Combinations	C09X	Other Renin-Angiotensin System Agents
C10A	Lipid Modifying Agents, Plain	C10B	Lipid Modifying Agents, Combinations
D01A	Antifungals for Topical Use	D01B	Antifungals for Systemic Use
D02A	Emollients and Protectives	D02B	Protectives Against UV-Radiation
D03A	Cicatrizants	D03B	Enzymes
D04A	Antipruritics	D05A	Antipsoriatics for Topical Use
D05B	Antipsoriatics for Systemic Use	D06A	Antibiotics for Topical Use
D06B	Chemotherapeutics for Topical Use	D07A	Corticosteroids, Plain
D07B	Corticosteroids, Comb. with Antiseptics	D07C	Corticosteroids, Comb. with Antibiotics
D07X	Corticosteroids, Other Combinations	D08A	Antiseptics and Disinfectants
D09A	Medicated Dressings	D10A	Anti-Acne Preparations for Topical Use
D10B	Anti-Acne Preparations for Systemic Use	D11A	Other Dermatological Preparations
G01A	Antiinfectives and Antiseptics (Vaginal)	G01B	Antiinfectives with Corticosteroids
G02A	Uterotonics	G02B	Contraceptives for Topical Use
G02C	Other Gynecologicals	G03A	Hormonal Contraceptives for Systemic Use
G03B	Androgens	G03C	Estrogens
G03D	Progestogens	G03E	Androgens and Female Sex Hormones in Comb.
G03F	Progestogens and Estrogens in Combination	G03G	Gonadotropins and Ovulation Stimulants
G03H	Antiandrogens	G03X	Other Sex Hormones
G04B	Urologicals	G04C	Drugs Used in Benign Prostatic Hypertrophy
H01A	Anterior Pituitary Lobe Hormones	H01B	Posterior Pituitary Lobe Hormones
H01C	Hypothalamic Hormones	H02A	Corticosteroids for Systemic Use, Plain
H02B	Corticosteroids for Systemic Use, Comb.	H02C	Antiadrenal Preparations
H03A	Thyroid Preparations	H03B	Antithyroid Preparations
H03C	Iodine Therapy	H04A	Glycogenolytic Hormones
H05A	Parathyroid Hormones	H05B	Anti-Parathyroid Agents
J01A	Tetracyclines	J01B	Amphenicols
J01C	Beta-Lactam Antibacterials, Penicillins	J01D	Other Beta-Lactam Antibacterials

ATC Classification

Code	Description	Code	Description

Abstract	Older patients are one of the most relevant sub-groups of patients with breast cancer and will only gain in importance as demographic transition unfolds. Their management, in both the early and advanced settings, should take into consideration specific clinical needs and is made more difficult by the limited availability of evidence on the efficacy and safety of standard treatment regimens in older patients. At the root of this situation is the low rate of participation of older patients in clinical trials, often due to age limits for inclusion, and limitations on the participation of persons with significant comorbidities or organ dysfunction. Although this has begun to change in recent years, most agents currently in use have not been tested in a substantial number of older patients. This includes targeted agents that have changed prognosis in breast cancer.
Population	Older adults with early or advanced breast cancer, a subgroup underrepresented in clinical trials.
Intervention	Use of targeted agents including HER2-targeted therapies (trastuzumab, lapatinib, pertuzumab, T-DM1, neratinib), CDK4/6 inhibitors (palbociclib, ribociclib, abemaciclib), bevacizumab, everolimus, and PARP inhibitors (olaparib, talazoparib).

Abstract

Family health history (FHx) offers insight into a person's health and disease risk, but it is largely held within free-text clinical formats that require processing for maximal utility of the data. The rapid deployment of ambient AI scribes and conversational agents in clinical settings necessitates evaluation on dynamic patient-clinician and patient-agent dialogs. To address this gap, we introduce two new datasets of patient FHx dialog documents designed to benchmark information extraction and entity linking. Distinct from clinician-entered datasets, patient-reported dialog data has its own semantic and content characteristics, which need to be studied for more patient-centered healthcare. We contribute a publicly available resource called *FHexchange*, with new annotations for family members, clinical observations, related entities, and standardized UMLS CUIs, offering the clinical NLP community a robust evaluation bed for emerging generative AI tools.

1 Introduction

Family health history (FHx) is an important health data type that gives insight into genetic, environmental, and behavioral factors that contribute to a person's disease risk. This information may be collected in a variety of ways, through informational interviews with genetic counselors, primary care providers, and other clinicians, or through asynchronous surveys and chatbots (Wildin et al., 2021). The data collection methods also determine several features of the FHx data, including document and data structure as well as the granularity of data. When FHx information has low granularity (i.e., unstructured symptom descriptions missing standardized concept mappings), it can limit how useful the data are for downstream prediction tasks and clinical decision support (Moon et al., 2022). Thus, to overcome the problem of low granularity, we can extract FHx information in a standardized, structured format and normalize them to standard vocabularies when possible (Chen et al., 2015).

Much of the collected FHx data still remains within free-text sources; thus, natural language processing (NLP) approaches are necessary to extract this important data (Zhou et al., 2014). Previous work has explored FHx information extraction tasks and relation linking tasks in both synthetic and real-world electronic health record data sources (Shen et al., 2021; Bill et al., 2014; Rybinski et al., 2021; Silva et al., 2020; Goryachev et al., 2008; Zhan et al., 2021), as well as from FHx questionnaires (Shing et al., 2021) using a variety of methods. Methods have included neural language model embeddings with deep learning architectures, rule-based systems, as well as hybrid approaches. These approaches were largely developed on a few public datasets, but more often on proprietary datasets that are not available to the larger clinical NLP research community. Additionally, there are few FHx datasets that provide normalized concepts to support the study of entity linking to clinical codes.

As new AI tools are deployed in the clinic, datasets that reflect new modalities, such as patient-clinician dialogs for ambient AI scribes or conversational AI interactions, are necessary. To support the assessment of FHx extraction for emerging data types, we are contributing the following:

- a newly annotated and normalized resource called *FHexchange* for FHx entity extraction and relation extraction that is publicly available,
- with additional National Library of Medicine's Unified Medical Language System (UMLS) Concept Unique Identifier (CUI) (U.S. National Library of Medicine) for entity linking benchmarking (that will be accessible for eligible researchers with a UMLS license)

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 1014–1028
July 3-4, 2026 ©2026 Association for Computational Linguistics

based on two existing dialog corpora: 104 FHx chatbot-user dialogs from (Nguyen et al., 2024), referred to as *FHexchange-KIT*, and 154 FHx-related dialogs from the openly available MTS-Dialog dataset (Ben Abacha et al., 2023), referred to as *FHexchange-MTS*.

Enabled by *FHexchange*, we discuss the following research topics:

- The effect of collection methods on the characteristics and condition coverage of FHx data
- The potential for collection methods to inform what FHx data patients choose to disclose
- The utility of these datasets to support the development of new clinical AI tools.

2 Related Work

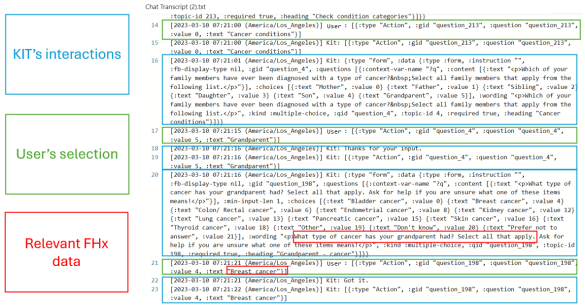
2.1 Existing FHx guidelines and schema

In 2008, the Family Health History Multi-Stakeholder Workgroup of the American Health Information Community convened to formalize a core set of FHx elements. The final core set included person-level attributes (identification, ages, ages/dates at death, cause of death, ethnicity/race, sex, multiple-birth status, adoptive status, relevant genetic/genomic test results), condition-level attributes (disorders list, notation for unknown and/or uncertain histories, and relevant age ranges), and other attributes (consanguinity, identification of biological parents, sensitive data, and integration with other electronic health record data elements) (Feero et al., 2008). This work contributes additional high-quality annotated data for FHx data extraction and concept normalization.

As a part of the Social and Family History - Extraction, Representation, and Evaluation (SFHERE) Project, Chen et al. conducted a multi-source investigation of FHx collection tools and data elements to compile a comprehensive set of relevant FHx entities. They found a wide range of FHx elements represented across three distinct clinical note data sources (MTSamples, University of Pittsburgh Medical Center, and Fletcher Allen Health Care), patient-facing data collection tools (survey of eight tools), and FHx specifications (survey of seven specifications). Through iterative revisions, they designed a highly detailed annotation guideline to direct the manual labeling of clinical notes. The final version of entities and attributes included 13 unique subject categories, nine unique observation categories, four age/date-related categories, and two categories for other FHx-related information. The annotation resources for the SFHERE Project are publicly available (SFHERE Team, 2017).

Rama et al. (2018) also explored an iterative annotation process for synthetic Norwegian FHx clinical notes. The authors annotated for family members, self (which represents the proband), the condition entries (including diseases, diagnoses, mutations, test results, treatments, and living statuses), and medical events (including acute occurrences). Modifying entities captured included side of the family, age, Negateds, amounts (e.g., *three* sisters, *two* strokes), and temporal expressions (e.g., had a heart attack *two years ago*), which were then related to previously described clinical entities (Rama et al., 2018).

2.2 Existing datasets



A summary of datasets that were specifically annotated for FHx mentions can be found in Table 1. Historically, FHx extraction research has heavily relied on clinician-authored or de-identified notes. The MTSamples dataset was used by several groups to explore FHx extraction (Lewis et al., 2011; Bill et al., 2014; Chen et al., 2015); however, only 100 documents are publicly accessible as of 2026 from the SFHERE Project (2014). The 2019 n2c2/OHNLP and BioCreative/OHNLP challenge datasets (Shen et al., 2021; Rastegar-Mojarad et al., 2018) also provided foundational benchmarks for extracting entities and relations, from highly detailed genetics-specialty-style notes. Wang et al. reannotated the datasets to correct errors in the original version as well as to enhance the data by normalizing observations to SNOMED-CT codes and creating a FHx lexical resource (Wang et al., 2023). Both corpora are only accessible through a data use agreement (DUA). Rama et al. continued their work and released the dataset of 477 cardiac-related FHx sentences (in Norwegian) in 2021 (Brekke et al., 2021), which is freely accessible.

Recent work has explored consumer-reported and patient-involved datasets. Azab et al. (2019) created a FHx dataset of 228 patient-facing questionnaires from genetic counseling sessions and crowd-sourced participants. This dataset was very rich and information-dense, containing over 20,000 FHx relations; however, the dataset is no longer accessible. Saley et al. (2024) released MediTOD in 2024 based off a publicly available set of patient-

clinician dialogs from Fareez et al. (2022). The authors labeled dialogs for conversational attributes, such as the intent of the dialog turn, as well as topic areas, termed by the authors as *slots*, which could be information regarding symptoms, collection of patient medical history, or collection of family medical history, which was of particular interest for the present work. There are 214 dialogs containing FHx mentions, and the authors primarily labeled for family member, condition, status and Negated, leaving other FHx details in a semi-structured text field. To support additional evaluation of clinical

(a) KIT Transcript from a user interaction. In the red box, we can identify that the user has indicated that their family has a history of cancer conditions, specifically that their grandparent had breast cancer.

Doctor: Tell me about your family. Did anyone have any medical issues?
Patient: My father is alive. He is sixty nine right now. He did have some strokes in the past.
My mom on the other hand died at the age of sixty two of many kinds of heart diseases.
Doctor: What about your grandparents?
Patient: My maternal grandfather he also had heart issues and he died of a heart attack.
Both he and my maternal grandma had some heart diseases. Their heart use to beat pretty fast.

Figure 1: Examples of KIT and MTS-Dialog data

concepts, Saley et al. (2024) mapped observations to UMLS codes using QuickUMLS (Soldaini and Goharian).

We contribute *FHexchange*, a new dataset consisting of two additional consumer-reported sources derived from: (1) the MTS-Dialog dataset (Ben Abacha et al., 2023) and (2) KIT-user dialogs (Nguyen et al., 2024). The full MTS-Dialog dataset consists of 1701 synthetic patient-doctor conversation documents and summarized clinical notes for these dialogs. Because the original dataset was designed to support clincal note summarization, the authors did not annotate for specific elements such as FHx. To construct *FHexchange-MTS*, we selected a set of 154 MTS-Dialog dialogs that contained FHx mentions for further FHx annotation, a sample dialog can be seen in Figure 1b. For the second subdataset, *FHexchange-KIT*, we annotated 104 KIT-user dialogs from a crowdsourced study to assess chatbot-based data collection from a chatbot named KIT (Nguyen et al., 2024). The questionnaire was adapted from the NIH *AllofUs* family history survey and covered intergenerational FHx for 11 pre-defined condition categories (The All of Us Research Program Investigators, 2019). Figure 1a shows an example of an *FHexchange-KIT* excerpt.

3 *FHexchange* dataset

3.1 Annotation

The annotation guideline was created by referencing existing schema (Chen et al., 2015) for a subset of terms and further development with clinical experts (genetic counselors). The annotation guideline was iteratively refined by annotating a sample set of clinical notes with guidance from two genetic counselors, each with over ten years of clinical experience.

The *FHexchange-MTS* data was annotated for the following concepts: *FamilyMember, Observation, SideoftheFamily, LivingStatus, Age, AgeofOnset, AgeofDeath, CauseofDeath, and Negated*, following a schema further described in Appendix A. The *FHexchange-KIT* data consisted of user-entered health conditions for a specified set of *FamilyMembers*: Father, Mother, Sibling, Grandparent, Son, and Daughter. Because of this, the annotations were limited to *FamilyMember* and *Observation*. Two Masters-level individuals (both native English speakers) trained in Biomedical Engineering completed the clinical entity annotations. Both annotators had overlap on the full corpus.

UMLS concept normalization was first conducted using the python library, scispacy's UMLS entity linker, with a link score (calculated as a nearest neighbor search percentage between the candidate text and the UMLS CUIs) (Neumann et al., 2019). Only matches with a link score of over 0.9 were retained. One human annotator also normalized all concepts for both *FHexchange-MTS* and *FHexchange-KIT* clinical observations for comparison with automated code assignments.

3.2 *FHexchange* dataset summary

We report interrater agreement using Cohen's kappa for the presence of *Observations* and *FamilyMembers*. We also report percent agreement for both datasets. For the *FHexchange-KIT* subdataset, we report percent agreement on a document-level as the annotations were limited to a fixed set of *FamilyMembers*. Percent agreement was calculated as the proportion of overlapping observations between annotators across six predefined *Family-*

Members, while full agreement strictly required perfectly identical observation sets for every family member within the transcript.

To report coverage of FHx conditions within the dataset, we performed further linking of UMLS concepts to Semantic Types and ICD-10 Body Systems using UMLS API calls with UMLS version 2025AB. We also reported the distribution of UMLS semantic types and ICD-10 body systems present. All computation was performed using python version 3.11.

3.3 Example baselines with zero-shot and few-shot large language model structured output approaches

We demonstrate the value of the dataset by providing an example baseline for structured FHx information extraction, relation extraction, and entity linking using the following pre-trained language models with structured outputs: Microsoft Foundry Azure OpenAI zero-shot GPT-4o (Version 2024-11-20) (Microsoft, a), GPT-5-mini (Version 2025-08-07) (Microsoft, b), and Microsoft Azure Llama-3.3-70B-Instruct (Version 9) (Microsoft, c). We aimed to select proprietary models (flagship model versus lightweight reasoning model) and an open-weight model. Although we did not include a clinical model baseline, we included an open-weight model to represent a solution that could be locally deployed, considering data privacy and compliance with healthcare regulations. We created a structured Pydantic (Colvin et al., 2026) schema to prompt the model to reason through FHx extraction (with a *reasoning* field as the first entry in the schema) of the relevant FHx annotated entities where available (*FamilyMember*, *Observation*, *AgeofOnset*, *SideoftheFamily*, *LivingStatus*, *Age*, *AgeofDeath*, *CauseofDeath*, CUI, and *Negated*). Model, prompt details, and schema description can be found in the Appendix, and additional details are available on the dataset Github repository.

To handle the structural differences between *FHexchange-KIT* and *FHexchange-MTS*, the schema utilized optional typing, allowing the models to output `null` for variables unsupported by the text without breaking the JSON generation. Additionally, prompt constraints were applied to standardize clinical concepts, such as negated histories (e.g., forcing the extraction of the base condition with a *Negated: true* boolean flag) and restricting categorical modifiers to predefined values (such as Maternal, Paternal, or Unknown, for *SideoftheFamily*).

After normalizing the model output, evaluation was performed by reporting precision, recall, and F1 for all entities extracted and all relations extracted. Matches for *Observations* and *FamilyMembers* were evaluated strictly based off perfect token-level matches compared to the gold standard annotations.

Metric	Value
FHexchange-MTS	
Binary Presence (κ)	0.827
Strict match (κ)	0.300
Lenient match (κ)	0.519
FHexchange-KIT	
Binary Presence (κ)	0.990
Perfect match (%)	63.5%
Partial match (%)	36.5%

Table 2: Inter-annotator agreement across datasets. For *FHexchange-MTS*, we report phrase-level κ representing strict and lenient text span matches. For *FHexchange-KIT*, we report κ for the presence of *FamilyMember* and *Observation* fields and raw document-level percent agreement for exact sets of conditions. Additional agreement details for *Observation-Family Member* relations can be seen in Appendix Table 9.

4	High cholesterol	26	-
5	Anxiety reaction/panic disorder	21	-

Table 4: Top 5 conditions by subdataset with sample patient expressions. Top conditions for *FHexchange-KIT* did not contain any variance, so no sample expressions are listed.

match) (Landis and Koch, 1977). When comparing a strict phrase-level match, where tokens must perfectly overlap, the kappa value was low (0.300); however, when allowing for fuzzy matches for a lenient phrase-level match, the agreement improves between annotators (0.519). Appendix B provides examples of errors between annotators. The performance in the results for the strict match were lower due to differences in the boundaries annotators notated (Table 9 provides additional details regarding categories of interannotator disagreement). For example, for age at death, one annotator specified *AgeofDeath* was "40s", but another specified this was "died in 40s." For this example, we removed all modifying text related to *AgeofDeath*, to only retain "40s." For *FHexchange-KIT*, there was high agreement for the presence of *FamilyMember* and *Observation* with a Cohen's κ of 0.990. For document-level agreement, 63.5% of the documents were perfect matches between annotators.

Table 3 contains the annotation statistics across both datasets. *FHexchange-MTS* contains 856 dialog turns, and *FHexchange-KIT* contains 5156 dialog turns.

Table 4 presents the top conditions and frequencies after mapping *Observations* to CUIs across both datasets. Sample expressions are provided for *FHexchange-MTS* to reflect the variations in patient descriptors for diseases. The two subdatasets both have hypertension in the top five conditions.

When observing higher-order categories of conditions, we identified eight unique Semantic Types of mapped CUIs from the *FHexchange-KIT* subdataset and 13 Semantic Types for *FHexchange-MTS*, as seen in Table 5. We found 12 unique ICD-10 Body systems for *FHexchange-KIT* and 11

Category	FHex-KIT	FHex-MTS

Table 5: UMLS semantic types and ICD-10 body system distributions across *FHexchange-KIT (FHex-KIT)* and *FHexchange-MTS (FHex-MTS)*

Body systems for *FHexchange-MTS*.

In Table 6, we report baseline performance of the two proprietary pre-trained language models, Azure OpenAI GPT-4o and GPT-5-mini with zero-shot and few-shot in-context learning approaches, to extract family history information and to perform relation extraction and UMLS entity linking. The full experimental results with performance from all three models (including Azure Llama 3.3 70B Instruct) can be seen in Appendix Section D. Zero-shot prompting performance on extracting *FamilyMembers* for both subdatasets is high for both models at baseline (GPT-4o: F1 = 0.994 for *FHexchange-KIT*, F1 = 0.851 for *FHexchange-MTS*; GPT-5-mini: F1 = 0.972 for *FHexchange-KIT*, F1 = 0.774 for *FHexchange-MTS*). However, performance declined for both with few-shot prompting for the *FHexchange-KIT*

Table 6: Baseline performance of proprietary models. Metrics: F1 (Precision/Recall). FM = *FamilyMember*, Obs. = *Observation*, Rel = FM-Obs Relation, Neg. = *Negated*, Living = *LivingStatus*, Side = *SideoftheFamily*. ZS = Zero-Shot, FS = Few-Shot.

subdataset, but increased for the *FHexchange-MTS* subdataset, with GPT-5-mini improving performance over GPT-4o with the provided examples. Overall, GPT-5-mini had greater zero-shot performance to extract *Observations*, which translated to stronger performance to relate *FamilyMembers* to *Observations*. Across both models, performance to extract age-related concepts was poor for *FHexchange-MTS*, missing all mentions of *Age*, *AgeofOnset*, and *AgeofDeath*. UMLS entity linking (CUI normalization) remained a difficult task across both subdatasets (best F1 = 0.373 for *FHexchange-KIT* with few-shot GPT-4o and F1 = 0.597 for *FHexchange-MTS* with zero-shot GPT-4o). In Appendix Table 13, we show three examples of differences between the models in extracting CUIs. GPT-5-mini was more conservative in assigning CUIs to *Observations* than GPT-4o. Few-shot prompting, where example CUI mappings were provided, is hypothesized to have increased the performance of GPT-5-mini to assign CUIs (0.115 to 0.255 for *FHexchange-KIT* and 0.234 to 0.553 for *FHexchange-MTS*).

As detailed in Appendix Tables 11 for *FHexchange-KIT* and 12 for *FHexchange-MTS*, the performance of Llama 3.3 was poor for all entities in comparison to the proprietary models. This was due to structural output errors in which the model did not correctly adhere to the JSON schema, despite correctly identifying entities within the reasoning field; however, few-shot prompting did improve the performance. This is a limitation, which may be addressed through additional prompt examples, fine-tuning, or parsing and normalization, and is an area for future work.

5 Discussion

The effect of collection methods on the characteristics and condition coverage of FHx data To enable more patient-centered care, there is a need for datasets derived from patient input. Patients report health data that is unique from their clinicians, providing additional context for a more holistic health profile (Castro et al., 2025). Data collection methods (surveys versus in-person medical history interviews) inform the characteristics and quality of the resulting dataset (Chen et al., 2015). Data from surveys with multiple choice options normalize the range of conditions and family members collected, due to the limitation of choices, whereas open-ended dialogs can lead to responses with more variance. Together, *FHexchange-MTS* and *FHexchange-KIT* provide a complementary view of modern patient-derived data for FHx, originating from their collection methods.

FHexchange-MTS is based on open-ended, free-form conversations about FHx. Not all dialogs contain specific prompting by doctors to patients, and in general, patients are tasked with spontaneously recalling relevant FHx. Because of this data collection method, we identify that *FHexchange-MTS* contains more colloquial vernacular, such as "sugar" for diabetes and "alcoholism" for alcohol use disorder. We provide mappings to the relevant CUI codes to standardize this language to computable clinical concepts. Additionally, the breadth of reported information was greater for *FHexchange-MTS* in comparison to *FHexchange-KIT* (13 UMLS Semantic Types captured versus eight Semantic Types).

In contrast, KIT users were prompted to recall their FHx for specific condition types and with

multiple choice options during their dialogs, and therefore, users relied more on option selection than free-text inputs. Because of this data collection method, the majority of responses within *FHexchange-KIT* were mapped to distinct options, leaving little variation in how reported conditions were expressed. When cross-mapping from UMLS codes to the ICD-10 clinical hierarchy, 39% of the unique concepts extracted from the open-ended *FHexchange-MTS* lacked a direct ICD-10 equivalent, compared to only 22% in the structured *FHexchange-KIT* survey data. This difference reinforces that open-ended dialogs yield a significantly wider variance of informal patient expressions, and structured dialogs may enable cleaner extraction into strict diagnostic hierarchies and computable formats to support automated risk assessments.

The potential for collection methods to inform what FHx data patients choose to disclose The open-ended dialogs in *FHexchange-MTS* show high enrichment for Circulatory System and Neoplasm-related disorders (12 and 18 unique codes respectively). The structured KIT dialogs show deeper representation across chronic condition systems like Digestive System (11 unique concepts, as compared to *FHexchange-MTS*'s three unique Digestive concepts). This may also suggest that asynchronous, comprehensive, structured methods of collecting FHx may be more effective to elicit both a broader (capturing a wider range of condition categories) and more specific (capturing finer grained condition language) array of FHx data than possible within limited conversations in a non-specialist setting. Asynchronous surveys conducted through chatbots may also lead to a higher willingness to share sensitive information when compared to face-to-face interactions with healthcare providers (Lucas et al., 2014). Supporting this notion, we found that two of the top five conditions represented within *FHexchange-KIT* were mental health related conditions, which patients may experience a stigma to report in traditional doctor-patient interactions (Nadarzynski et al., 2019). However, the populations and clinical settings represented in these datasets may also be distinct from one another, so future work should explore FHx data collection methods across the same populations and clinical contexts.

The utility of *FHexchange* to support the development of new clinical AI tools In the future, clinical AI tools will capture FHx across multiple modalities, from ambient scribes transcribing and documenting natural patient-doctor interactions to more flexible conversational agents (text and audio) providing medical history taking interviews (Hindelang et al., 2024). We contribute *FHexchange*, a unified FHx dialog dataset of both structured chatbot-user dialogs as well as unstructured human-human dialogs. The baseline evaluations of proprietary and open-weight models support the value of this corpus. While the proprietary language models accurately extracted basic family members from structured inputs, they did not extract temporal modifiers (ages) and other condition modifiers (*CauseofDeath*). Additionally, the UMLS CUI entity linking performance suggests that the field still needs robust, standardized mapping workflows to achieve computable clinical concepts for FHx. Error analysis revealed that the model translated colloquial patient expressions (e.g., "kidney cancer" and "fast heart beat") into formal medical terminology ("renal cancer" and "tachycardia"). In future work, we will consider these conceptually equivalent extractions as true positives; however, this highlights a tendency for the model to perform clinical normalization and not just exact extraction of the text. Additionally, our results suggest that reasoning models like GPT-5-mini may be conservative in linking clinical observations to standard terminologies that reduce the linking of both incorrect and correct mappings. These findings motivate the work to introduce additional domain knowledge, through the integration of ontologies or knowledge graphs, to ground the mapping of family history mentions to standard terminologies in future studies (Gao et al., 2023, 2025; Pan et al., 2024). Furthermore, future work could explore fine-tuning open-weight models to improve performance, as even few-shot prompts boosted Llama 3.3's ability to correctly extract FHx information (Park et al., 2023). *FHexchange* provides an evaluation set to assess emerging clinical AI tools across data collection modalities.

6 Conclusion

We are contributing *FHexchange*, consisting of annotated FHx resources for entity identification, relation extraction, and concept normalization from two distinct consumer-facing sources. The base data (for entity identification and relation extraction) will be available publicly for the clinical NLP research community from this data repository: www.

github.com/tirilab/FHexchange. By combining structured chatbot dialogs with unstructured human-to-human dialogs, we provide a comprehensive FHx dataset designed to benchmark the performance of emerging clinical AI systems to extract and normalize FHx data across multiple conversational modalities.

Limitations

First, the quality of patient-reported health information is characterized by patient recall. We did not annotate entities for patients' certainty of recall, but this consideration has been explored in previous annotation schema (Chen et al., 2015). Second, we did not include additional inter-annotator agreement metrics, such as an annotator confusion matrix. Third, the evaluation of the baseline is currently on strict token-level matches of *Observations*; therefore, this is currently underestimating the performance of the models. Fourth, the models were prompted for structured output by providing a structured Pydantic schema for extraction. This approach has shown to decrease performance and model reasoning (Tam et al., 2024), and we did not process Llama 3.3's structured outputs beyond the processing performed for the OpenAI models in order to extract the usable information. Fifth, baseline results did not include a clinical baseline. We only performed one model run for each document for each model, and the temperature of the models was not set to 0. Therefore, further testing of the consistency of the results is needed, as well as exploration of other models for this task. Sixth, we did not specifically annotate for strength of observations (e.g., indications that many family members experience a similar condition type or the perceived severity of certain observations). Seventh, for these datasets, we focus on English language dialogs only. Future work to support other languages is necessary. Lastly, UMLS CUIs do not capture all commonly used patient and/or consumer language for conditions. Previous work has been done to add consumer health vocabulary that was not explored in this work (Pham et al., 2019; Amith et al., 2019).

Ethical Considerations

All chatbot transcripts were anonymized to remove any identifying information and timestamps. We utilize the UMLS Metathesaurus to standardize medical observations via sciSpacy's entity linking module. We accessed the Metathesaurus (version 2022AB in scispacy after 2023 and version 2025AB through the API) through an individual license obtained for this work. Although the base annotations of FHx will be freely available for the research community, the UMLS CUI linkages will be provided through protected access that ensures each researcher abides by UMLS licensing requirements.

Acknowledgments

We would like to thank the genetic counselors and annotators who donated their time to make this work possible.

A Annotation Guidelines

Objective. The goal of this protocol is to annotate family history details in clinical conversational narratives to support the development and evaluation of family history extraction tools.

A.1 Excel annotation sheet format

Annotations are recorded in an Excel sheet.

Column	Header (Excel)	Description
A	Document ID	Document identifier from the note header. Used to link annotations to the source note.
B	FamilyMember OR Observation	Top-level entity for the row: FamilyMember, Observation, or NaN (if no family history mentioned in the note).
C	FamilyMember Type	The relative type when Column B = FamilyMember. May also contain numbering to disambiguate multiple relatives of the same type (e.g., "uncle #2").
D	LivingStatus OR SideoftheFamily OR Observation OR Age	Secondary entity linked to the FamilyMember when Column B = FamilyMember.
E	LivingStatus OR SideoftheFamily	The value for Column D (Alive/Dead or Maternal/Paternal).
F	Description of Previous Entities (i.e., observation description, age of onset. . .)	Free text field for the condition name and relevant details REQUIRED for all Observation rows.
G	AgeofOnset or AgeofDeath	The value (ranges allowed) of age of onset or age of death from an Observation for a FamilyMember
H	Negated	True if the Observation is not present
I	CauseofDeath	True if the Observation is the cause of death of the FamilyMember

Table 7: Excel columns used for annotation.

Each row corresponds to at least one annotated *Observation*, with columns used to link (i) a document identifier, (ii) an optional family member mention, and (iii) one or more associated attributes and observations. The annotation procedure is as follows.

A.2 Annotation workflow

Step 1: Column A - Document identifier. In Column A, record the Document ID from the header of each note. This identifier links all annotation rows to the source document.

Step 2: Column B - Select the top-level entity. In Column B, select the major entity type to be described in the row: *Observation* or *FamilyMember*. An *Observation* is a family-history-relevant condition mention that does not specify an associated family member, for example:

> "Patient has no family history of atrial fibrillation."

If a specific family member is mentioned, select *FamilyMember*. If there is no family history mentioned anywhere in the note, use the *NaN* dropdown option.

Step 3: Column C - Populate FamilyMember type. If Column B is *Observation*, specify the observation in Column F (Description of Previous Entities).

If Column B is *FamilyMember*, specify the family member mentioned in Column C (FamilyMember Type), which is suggested to be one of the following: Great-grandfather, great-grandmother, grandmother, grandfather, father, mother, aunt, uncle, cousin, sister, brother, daughter, son, grandson, granddaughter, sibling, niece, or nephew, child, sibling. Please enter other relationships as needed, if they are present in the text. If multiple family members of the same type are mentioned (e.g., multiple uncles), add numbering in Column E (e.g., "uncle #2").

Step 4: Column D - Add associated rows for each FamilyMember-Observation pair OR just Observation. If Column B is *FamilyMember*, capture three additional entity types as separate rows associated with the same FamilyMember Type: *LivingStatus*, *SideoftheFamily*, and *Observation*. Each associated unique Observation entity for a given FamilyMember-Observation pair should be entered on its own row (e.g., if a sister is alive and has two conditions, create two *Observation* rows for a FamilyMember of Sister and record LivingStatus in both rows). If general good health is mentioned, it may be recorded as an Observation. If *SideoftheFamily* is not mentioned (e.g., "two of my aunts had cancer" without maternal/paternal), do not add *SideoftheFamily* information.

Notes may include abbreviations for family members. Pronouns are resolved to the previously mentioned family member when applicable. For example:

> "Her mother had coronary artery disease and hypertension. She also died from sudden cardiac death."

Here, *She* refers to *mother*.

Step 5: Fill Column D/E for LivingStatus or SideoftheFamily. If Column D is *LivingStatus*, Column E should be *Dead* or *Alive*.

LivingStatus may be inferred from context when not explicitly stated; for example:

> (1) "cousin has stomach cancer"

→ LivingStatus = Alive;

(2) “cousin undergoing treatment for stomach cancer”

→ LivingStatus = Alive;

(3) “cousin passed away from stomach cancer”

→ LivingStatus = Dead.

If Column D is *SideoftheFamily*, Column E should be *Paternal* or *Maternal*.

Step 6: Record Observation details in Column F. For any *Observation* (whether selected in Column B or Column D), Column F (Description of Previous Entities) is REQUIRED. Use this free text field to specify the condition name and any relevant details. For all entity types, Column F (Description of Previous Entities) is used to record details. Distinguish missing/unknown information from explicitly absent information: *Observation* – Unknown, indicates missing information or uncertainty (e.g., “I don’t know”); *Observation* – None, indicates not relevant/not pertinent/not significant when explicitly stated or asked about.

Step 7: Columns G, H, and I - Modifiers, Negated, and Cause of Death Column G (AgeofOnset or AgeofDeath): Record the numeric value (or range) of the age of onset or age of death related to an Observation.

Column H (Negated): For negative or absent family history (e.g., "No history of breast cancer"), record the relevant FamilyMember (if present; otherwise select Observation). Specify the condition in Column F, and mark Column H as True. Distinguish missing/unknown information from explicitly absent information: Observation – Unknown indicates missing information or uncertainty (e.g., "I don’t know"); Observation – None indicates not relevant/not pertinent/not significant when explicitly stated or asked about.

Column I (CauseofDeath): If an Observation is explicitly stated as the cause of the family member’s death, mark Column I as True. If an *Observation* can be inferred as the cause of death based off the phrased order (i.e. mention of death and mention of condition within the sentence or following sentence), mark Column I as True. For example:

"Well, doctor, he passed away. He had mesothelioma."

→ Column I = True (for the mesothelioma *Observation*).

A.3 Annotation Example

Excerpt from document 945

Doctor: Can you tell me more about your family history, ma’am? How is your father doing?

Patient: Well, doctor, my father passed away from leukemia a while back.

Column	Field	Value
A	doc_id	945
B	FamilyMember	Father
C	AgeofOnset	–
D	Observation	leukemia
E	SideoftheFamily	–
F	LivingStatus	Dead
G	Age	–
H	AgeofDeath	–
I	CauseofDeath	TRUE
K	Negated	–

Table 8: Example annotation from document 945.

B Error analysis between annotators

The following section details error analysis for annotations in both datasets.

Table 9 details the disagreements found after the first pass of annotations (before adjudication). Annotators are denoted by A and B. Semantic disagreement examples can be seen in Table 10.

Category	KIT	MTS
Exact/Boundary Match	629 (87.6%)	181 (67.8%)
Semantic Disagreement	31 (4.3%)	3 (1.1%)
Missing in B	32 (4.5%)	48 (18.0%)
Extra in B	26 (3.6%)	35 (13.1%)

Table 9: Annotator agreement breakdown for *Observations* and *FamilyMembers*. Missing in B means the mention was found extra within A, and extra in B signifies the mention was missing from B. KIT: n=718, MTS: n=267.

The examples in Table 10 were considered errors under a strict match policy but were considered lenient matches. In the final dataset, differences were adjudicated through discussion and removing extraneous information:

C Model prompt and FHx schema

C.1 Schema Definition

We define two Pydantic classes for structured family history extraction. The `FHx_Object` class represents a single family history entry with the fol-

#	Ann. A	Ann. B	Final
1	**FM:** Uncle **Obs:** had polio, leg deformities	**FM:** Uncle **Obs:** polio, leg deformities	**FM:** Uncle **Obs:** polio, leg deformities
2	**FM:** Father **LS:** Dead **Age:** 40s	**FM:** Father **LS:** Dead **Age:** died in 40s	**FM:** Father **LS:** Dead **Age:** 40s
3	**FM:** Brother **LS:** Alive unknown	**FM:** Brother **LS:** Alive	**FM:** Brother **LS:** Alive

Table 10: Lenient matches with final annotations. FM = *FamilyMember*, Obs = *Observation*, LS = *LivingStatus*

lowing fields: `reasoning` (string), `FamilyMember` (optional string), `AgeofOnset` (optional integer), `Observation` (optional string), `SideoftheFamily` (optional literal: "Maternal", "Paternal", or "Unknown"), `LivingStatus` (optional literal: "Alive", "Dead", or "Unknown"), `Age` (optional integer), `AgeofDeath` (optional integer), `CauseofDeath` (optional boolean), `CUI` (optional string), and `Negated` (optional boolean). The `FamilyHistory` class contains a list of `FHx_Object` instances called `full_history`.

C.2 Base System Prompt

Role: You are an assistant that is reviewing various texts to extract the relevant family health history information for several different condition groups.

Scope: Proband's relatives only. Exclude the proband's own conditions and any partner/spouse and their relatives.

Output: One `FamilyHistory` object with a list of `FHx_Objects`. Each `FHx_Object` may represent:

- A condition (`Observation`) linked to a specific family member, or
- A condition with no specific member (`FamilyMember` = null), or
- A family member record without a condition.

Fill null for any field not explicitly stated. Include negative and unknown family history.

FamilyMember relation fields: `LivingStatus` (alive/dead/unknown), `Age` (integer if explicit), `AgeOfDeath` (integer if explicit), `SideOfFamily` only for second-/third-degree relatives when explicitly stated.

Observation relation fields: `CUI` (UMLS target concept; null if uncertain), `AgeOfOnset` (integer if explicit), `CauseOfDeath` = true only if the text explicitly says the condition caused death; otherwise false.

Negated field: boolean; set to true ONLY if the text explicitly states a negative family history or that the member is healthy.

Provide concise rationale for extracted `FHx_Object` and reasons behind CUI mapping in the `reasoning` field.

Rules:

1. Extract only explicitly stated facts; otherwise use null. Do not infer ages, sex, side, or subtypes.
2. **Negateds:** If a text explicitly states a negative family history (e.g., "no history of cancer" or "brother is healthy"), extract the base condition in the `Observation` field (e.g., "cancer") and set the `Negated` field to true. For general healthy statements, set `Observation` to "any conditions" and `Negated` to true. Do not write the word "no" in the `Observation` field.
3. De-duplicate by member + condition (CUI) + status. Have a unique `FHx_Object` per condition per member.

C.3 Differences between Zero-shot and Few-shot approaches

The few-shot in-context learning approach provided one example from both *FHexchange* subdatasets. More details regarding the examples can be found in the dataset repository on Github.

Abstract

Dementia detection from spontaneous speech offers a scalable approach to cognitive screening, yet NLP systems remain predominantly English-centric. This limitation is especially acute in the Philippines, where Filipino–English code-switching is pervasive and no prior work has addressed NLP-based dementia detection. We present the first systematic evaluation of transformer-based dementia detection in Filipino speech and the first assessment of NeoBERT in a clinical NLP setting. To separate language from domain effects, we construct a parallel bilingual dataset of 4,000 DementiaBank-derived transcripts, with Filipino translations produced manually to preserve discourse-level markers of cognitive decline. We evaluate five model families, TF-IDF + LogReg, BERT, NeoBERT, XLM-R, and RoBERTa-Tagalog, under monolingual, zero-shot cross-lingual, and bilingual fine-tuning settings. We find that in-domain performance does not transfer across languages, with English-trained BERT dropping to Macro-F1 = 0.455 on Filipino, and that architectural modernization alone does not improve robustness. Bilingual fine-tuning, however, eliminates cross-lingual degradation across all transformer models, converging to Macro-F1 = 0.969–0.973. These results suggest that multilingual clinical NLP performance is driven primarily by linguistic coverage during training rather than model scale or architecture.

1 Introduction

Dementia detection from speech is a promising direction for scalable cognitive screening, as linguistic and discourse-level patterns often reflect early cognitive decline (Peled-Cohen and Reichart, 2025). However, most NLP systems for this task are developed and evaluated primarily on English-language data, limiting their robustness in multilingual and low-resource settings. This limitation is particularly relevant in the Philippines, where everyday speech frequently involves Filipino–English code-switching and informal conversational structure. As a result, it remains unclear whether failures arise from cross-lingual transfer limitations or English-centric biases in model pretraining, motivating our focus on conversational transcripts to isolate discourse-level markers of cognitive decline.

Progress in Filipino NLP, while growing, has been largely confined to classification tasks on news articles and social media posts, including sentiment analysis (Villavicencio et al., 2021), named entity recognition (Miranda, 2023), and hate speech detection (Cruz and Cheng, 2022). Even recent evaluation benchmarks such as Batayan (Montalan et al., 2025) and FilBench (Miranda et al., 2025), while broader in scope, remain anchored to common written-text tasks such as reading comprehension, natural language inference, and generation. Critically, none of this work addresses naturalistic speech, clinical discourse, or cognitive diagnostic tasks. In particular, Tagalog–English code-switching, pervasive in informal and clinical Filipino communication (Herrera et al., 2022), is systematically absent from existing evaluations. As a result, it remains unknown whether transformer-based models can capture the discourse-level degradation characteristic of dementia in Filipino speech.

Additionally, transformer-based encoders have become the dominant paradigm in clinical NLP (Devlin et al., 2019; Pappagari et al., 2020), yet their application to dementia detection remains largely confined to architectural variants that differ only in pretraining data. ClinicalBERT (Alsentzer et al., 2019), AD-BERT (Mao et al.,

2023), and mBERT (Pires et al., 2019) all inherit the original BERT design unchanged. This leaves open the question of how architectural modifications affect the extent to which models capture cognitively diagnostic linguistic properties relevant to dementia detection.

In this work, we study dementia detection under controlled bilingual conditions using conversational speech transcripts in English and Filipino. The full experimental setup is described in Section 3.

Our contributions are threefold: (1) We present the first evaluation of NLP-based dementia detection in Filipino speech, using conversational transcripts manually translated from English under controlled domain conditions. (2) We provide the first empirical characterization of NeoBERT's behavior under clinical and cross-lingual conditions. (3) We analyze cross-lingual transfer from English to Filipino under controlled conditions, benchmarking English-only models against multilingual (XLM-RoBERTa) and language-matched (RoBERTa-Tagalog) baselines to quantify the effect of English-centric pretraining under language shift. Our code is publicly available.[1]

2 Related Work

2.1 Linguistic Markers of Cognitive Decline

Spontaneous speech in dementia and mild cognitive impairment (MCI) exhibits reduced lexical diversity, increased disfluency, syntactic simplification, and degraded referential coherence, patterns that manifest measurably before clinical diagnosis (Fraser et al., 2016; Segkouli et al., 2025) and have been linked to early tau accumulation in language-relevant cortical regions (Marier et al., 2026). A recent systematic review confirms that these markers are consistently recoverable from text alone, with linguistic-only models reaching an average diagnostic accuracy of 83% across 51 NLP studies of dementia detection (Shankar et al., 2025).

However, existing work is heavily concentrated on monolingual English speech elicited under controlled clinical tasks, most commonly the Cookie Theft picture description task from DementiaBank (Becker et al., 1994). Bilingualism introduces competing forces: lifelong code-switching is associated with delayed dementia onset through enhanced cognitive reserve (Berkes and Bialystok, 2022), while the syntactic mixing and lexical borrowing characteristic of Taglish may alter the observable linguistic signals on which current models rely (Flores, 2019). This makes Filipino a theoretically significant yet entirely absent deployment context in the dementia NLP literature.

2.2 Transformer-Based Models in Clinical NLP

In dementia detection, most systems adapt BERT through domain-specific pretraining: ClinicalBERT (Alsentzer et al., 2019) adapts to clinical notes, AD-BERT (Mao et al., 2023) targets Alzheimer's progression prediction, and mBERT (Pires et al., 2019) extends to multiple languages. These models differ mainly in pretraining data while sharing the same architecture, leaving open the question of whether architectural changes improve cross-lingual clinical performance.

Representation pooling is another underexplored yet consequential design choice. Most existing systems default to `[CLS]`-token pooling, a choice optimized for the pretraining objective but not for aggregating task-relevant information across the full sequence. Reimers and Gurevych (2019) demonstrate that mean pooling over final hidden states produces more stable and transferable sentence representations, particularly under domain and language shift, motivating our adoption of mean pooling across all transformer-based models.

2.3 Cross-Lingual Dementia Detection

Cross-lingual transfer in dementia detection has been explored almost exclusively between typologically similar European languages. The ADReSS-M challenge (Luz et al., 2024), including work by Tamm et al. (Tamm et al., 2023) and (DeLoach, 2026), established English-to-Greek transfer as a benchmark setting. Greek, however, shares significant Indo-European typological properties with English, limiting the generalizability of these findings to more distant transfer settings such as English-to-Filipino. Studies on dementia detection in low-resource, non-European languages remain rare. Adhikari et al. (2022) applied NLP-based detection to English DementiaBank transcripts translated into Nepali, while Lu and Chen (2025) extended this

[1] https://github.com/rezsam09/Filipino-English-Dementia-Classification

line of work to Amis, an indigenous Taiwanese language, finding that augmenting a small dataset of 80 scripts with translated English transcripts improved both robustness and accuracy. Neither study examines cross-lingual transfer nor evaluates multilingual pretraining strategies. No work has examined dementia detection in a Southeast Asian language or in any language spoken by a population where bilingualism and code-switching are the norm rather than the exception. Filipino, spoken by over 100 million people and characterized by pervasive Filipino–English code-switching (Herrera et al., 2022), represents exactly this gap.

2.4 Multilingual and Language-Matched Pretraining

Multilingual pretraining has emerged as a common strategy for cross-lingual transfer in low-resource settings. XLM-RoBERTa (Conneau et al., 2020), trained on over 2.5 TB of filtered CommonCrawl data across 100 languages, substantially outperforms mBERT on low-resource cross-lingual benchmarks. However, even strong multilingual models do not fully capture the lexical and syntactic properties of Filipino: RoBERTa-Tagalog (Cruz and Cheng, 2022), pretrained on TLUnified, a large-scale, thematically diverse Filipino corpus, demonstrates consistent gains over XLM-RoBERTa on Filipino classification benchmarks, suggesting that language-matched pretraining captures aspects of Filipino that multilingual models do not adequately model. Whether this advantage transfers to a clinical domain, where training data is scarce and domain shift compounds language shift, remains entirely unknown.

2.5 Architectural Modernization of Encoder Models

NeoBERT (Breton et al., 2025) represents the most recent advance in encoder architecture, replacing absolute positional embeddings with Rotary Positional Embeddings (RoPE) (Su et al., 2021), adopting Pre-LayerNorm (Xiong et al., 2020) and RMSNorm (Zhang and Sennrich, 2019) for training stability, introducing SwiGLU in place of GELU activation (Shazeer, 2020), and optimizing depth-to-width ratio for parameter efficiency. Importantly, it remains exclusively English-pretrained on RefinedWeb, a corpus of 600B tokens, 18 times larger than RoBERTa's training data. Despite outperforming BERT-large, RoBERTa-large, and ModernBERT on MTEB under identical fine-tuning conditions (Breton et al., 2025), NeoBERT has not been evaluated in any clinical or cross-lingual setting, leaving open the question of whether its architectural advances translate into robustness under the combined domain and language shift characteristic of low-resource clinical NLP.

3 Experimental Design

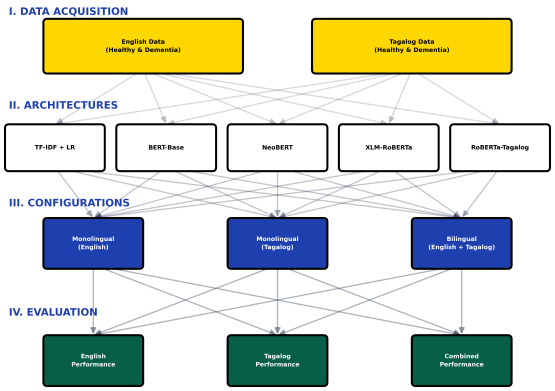

Figure 1: Overview of the experimental pipeline across datasets, model families, training configurations, and evaluation settings.

Performance improvements in NLP are often confounded by simultaneous changes in data, preprocessing, and model architecture (Sculley et al., 2015), a problem amplified in clinical NLP by small dataset sizes, domain sensitivity, and cross-linguistic variability (Fraser et al., 2016; Eyigoz et al., 2020). To mitigate this, all experiments use identical preprocessing pipelines with no external feature engineering beyond model-inherent representations, ensuring that observed performance differences reflect learned representations rather than preprocessing choices. The following subsections describe the dataset construction, preprocessing pipeline, model selection, and evaluation protocol.

3.1 Dataset Construction and Preprocessing

We construct a balanced bilingual dataset of 4,000 conversational transcripts for binary dementia classification, comprising 1,000 samples per class per language. All samples originate exclusively from DementiaBank (Becker et al., 1994), ensuring that any observed cross-lingual performance degradation reflects linguistic shift rather than

differences in topic distribution, discourse register, or clinical task structure.

3.1.1 English Data Sources

English dementia-positive and healthy control samples are drawn directly from DementiaBank (Becker et al., 1994), a widely used corpus in clinical speech research consisting of elicited speech from structured clinical tasks, most notably the Cookie Theft picture description task. This controlled elicitation procedure yields comparable discourse conditions across participants (Fraser et al., 2016), ensuring that class-level differences reflect genuine cognitive and linguistic variation rather than task-induced confounds.

3.1.2 Filipino Data Sources

Filipino samples are constructed through controlled manual translation of the complete set of 2,000 DementiaBank transcripts into Filipino, matching the English subset on clinical content, discourse structure, elicitation task, and class distribution. This ensures that cross-lingual evaluation is not confounded by asymmetric domain exposure. Manual translation is both necessary and principled given the absence of large-scale annotated clinical dementia corpora in Filipino (Mave et al., 2018). Translators are given explicit instructions to retain discourse-level markers of cognitive decline, including repetitions, hesitations, false starts, and syntactic degradation. Machine translation is avoided, since neural systems are known to normalize disfluent speech toward fluent output (Salesky et al., 2019), systematically erasing the features that distinguish dementia from healthy speech. All samples are anonymized prior to training in accordance with standard clinical data handling protocols.

3.1.3 Preprocessing Pipeline

All transcripts undergo a standardized preprocessing pipeline applying Unicode normalization, whitespace normalization, and lowercasing. Disfluencies, including filled pauses, repetitions, and hesitation markers, are retained throughout, as these are established linguistic correlates of cognitive impairment (Fraser et al., 2016) and primary classification signals in dementia detection. Stemming, lemmatization, and syntactic parsing are avoided, since such transformations risk normalizing disfluency structures and degrading the diagnostic signal available to downstream models. All input sequences are truncated to a maximum length of 128 tokens, consistent with the short, task-elicited structure of DementiaBank transcripts and with findings that neurocognitive markers are recoverable from short windows of speech (Fraser et al., 2016).

3.1.4 Models and Baselines

We evaluate five models across three pretraining paradigms. TF-IDF with Logistic Regression serves as a lexical baseline to assess whether surface-level token statistics suffice. BERT-base-uncased (Devlin et al., 2019) and NeoBERT (Breton et al., 2025) represent English-only pretraining, differing in architecture and corpus scale to isolate design capacity from language coverage. XLM-RoBERTa (Conneau et al., 2020) provides a 100-language multilingual baseline, while RoBERTa-Tagalog (Cruz and Cheng, 2022) evaluates language-matched pretraining on native Filipino text. These models decompose cross-lingual robustness along two orthogonal axes: architecture and language coverage. Because all models share an identical pipeline, cross-lingual performance variations reflect pretraining language exposure rather than fine-tuning differences.

Training Configurations: Models are trained separately for three setups: (1) English-only ($\mathcal{D}_{\text{EN}}$), (2) Filipino-only ($\mathcal{D}_{\text{TL}}$), and (3) Bilingual ($\mathcal{D}_{\text{EN}} \cup \mathcal{D}_{\text{TL}}$), enabling controlled analysis of monolingual capacity, cross-lingual transfer, and bilingual transfer.

3.2 TF-IDF with Logistic Regression

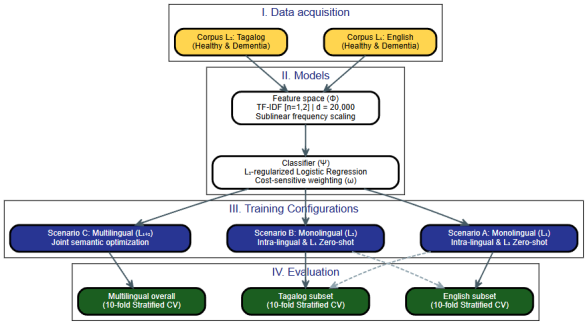

Figure 2: TF-IDF + Logistic Regression baseline training pipeline for evaluating lexical separability under cross-lingual and clinical domain shift conditions

We use TF-IDF with Logistic Regression as a lexical baseline to assess whether dementia-related

signals are captured by surface-level token statistics alone. TF-IDF produces sparse lexical representations by weighting tokens based on frequency statistics while ignoring word order and syntactic structure. Logistic Regression then learns a linear decision boundary over this high-dimensional feature space. This combination is widely used as an interpretable baseline in text classification tasks (Guo et al., 2020; Wang and Manning, 2012; Zhang et al., 2015). Performance of this model provides a reference for lexical separability: strong results suggest that class information is recoverable from surface-level features alone, whereas a weaker performance indicates the need for contextual modeling.

3.2.1 TF-IDF Representation

We construct unigram and bigram TF-IDF features ($n \in 1, 2$), capturing both lexical identity and short disfluency-related phrases. Bigrams are sufficient given the short, utterance-level structure of clinical transcripts and have been shown to yield consistent gains in text classification tasks (Wang and Manning, 2012). We apply standard TF-IDF preprocessing settings: (1) sublinear term-frequency scaling ($1 + \log(tf)$) to reduce the influence of repeated tokens common in disfluent speech; (2) a minimum document frequency of 2 (absolute count) to remove rare transcription noise; (3) a maximum document frequency of 0.95 to filter non-informative high-frequency tokens; and (4) a maximum vocabulary size of 20,000, consistent with standard practice in text classification (Zhang et al., 2015). These constraints ensure a stable lexical feature space that is comparable across languages and avoids overfitting in low-resource settings.

3.2.2 Logistic Regression Classifier

We use ℓ_2-regularized logistic regression due to its convex optimization properties and strong performance in high-dimensional sparse settings. Optimization is performed using the `liblinear` solver for efficient and deterministic convergence on sparse data, with a maximum of 2,000 iterations to ensure convergence.

3.3 Transformer-Based Models

We fine-tune four transformer-based models for binary dementia classification: BERT-base-uncased, NeoBERT, XLM-RoBERTa, and RoBERTa-Tagalog. Together, these models span three pretraining paradigms: English-only, massively multilingual, and language-matched, enabling a systematic decomposition of cross-lingual robustness along both architectural and pretraining dimensions.

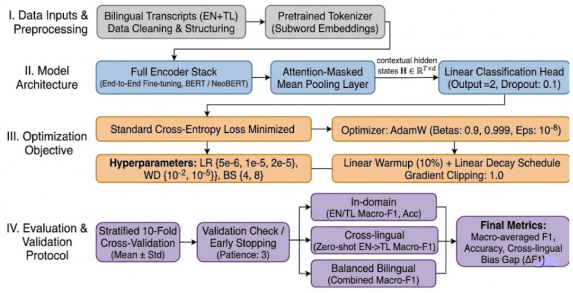

Figure 3: Transformer Models Fine-tuning Pipeline

3.3.1 Model Architecture and Fine-Tuning

All models follow a standard transformer-based classification pipeline. Given an input transcript x, tokens are first mapped to subword embeddings using a model-specific pretrained tokenizer, producing input IDs and attention masks. The resulting sequence is passed through the encoder, which is fine-tuned end-to-end without frozen layers. A single sentence representation is obtained via attention-masked mean pooling over the final hidden states:

$$h = \frac{\sum_{i=1}^{T} m_i H_i}{\sum_{i=1}^{T} m_i}$$

where m_i denotes the attention mask, ensuring that padding tokens do not contribute to the sentence representation. Unlike CLS pooling, which is optimized for pretraining objectives, masked mean pooling aggregates distributed token-level information and has been shown to improve robustness under domain shift (Reimers and Gurevych, 2019). The resulting representation is passed to a dropout layer ($p = 0.1$) followed by a linear classification head. The encoder is initialized from pretrained weights, while the classification head is randomly initialized.

3.3.2 Optimization Objective

We minimize standard cross-entropy loss:

$$\mathcal{L}(\theta) = -\mathbb{E}_{(x,y)} \log p_\theta(y \mid x)$$

Optimization is performed using AdamW (Loshchilov and Hutter, 2019), which decouples weight decay from gradient updates and improves generalization in transformer fine-tuning settings.

3.3.3 Hyperparameter Selection

Hyperparameters are selected via a systematic grid search designed to avoid loss divergence and unstable gradient updates on small clinical datasets. The search space for all BERT models includes: (1) learning rates $\{5 \times 10^{-6}, 6 \times 10^{-6}, 1 \times 10^{-5}, 2 \times 10^{-5}, 3 \times 10^{-5}\}$ (2) weight decay $\{10^{-2}, 10^{-5}\}$ (3) batch sizes $\{4, 8\}$. These ranges are motivated by the constraints of low-resource clinical fine-tuning. Lower learning rates help prevent catastrophic forgetting of pretrained representations, while varying weight decay controls the balance between task-specific adaptation and robustness to noise introduced by manual transcription and translation. We use a stratified 70–15–15 train/validation/test split. The training set is used for model fitting, the validation set for early stopping, and the test set is used for hyperparameter selection. Small batch sizes $(4, 8)$ are chosen to improve generalization through gradient stochasticity (Masters and Luschi, 2018) while maintaining memory efficiency for fine-tuning NeoBERT. This also increases the number of parameter updates per epoch, which is beneficial in low-data regimes.

Table 1 reports the optimal hyperparameter configurations identified via grid search for each architecture and training regime. Across models, learning rates in the range of 1×10^{-5} to 3×10^{-5} consistently yield stable fine-tuning, with lower rates (1–2×10^{-5}) favored for architecturally complex or multilingual models such as XLM-RoBERTa and NeoBERT, likely reflecting greater sensitivity to catastrophic forgetting. NeoBERT consistently selects a batch size of 4 across all regimes, suggesting that higher gradient stochasticity benefits its fine-tuning under low-resource conditions. Weight decay varies across configurations, with stronger regularization (1×10^{-2}) generally preferred in monolingual English and Filipino settings, while smaller values (1×10^{-5}) are selected more frequently in bilingual and cross-lingual regimes, consistent with the need for greater representational flexibility under mixed-language supervision.

Architecture	Regime	Batch	LR	WD
BERT	English	8	2×10^{-5}	1×10^{-2}
BERT	Tagalog	4	3×10^{-5}	1×10^{-5}
BERT	Bilingual	4	3×10^{-5}	1×10^{-2}
XLM-RoBERTa	English	8	1×10^{-5}	1×10^{-5}
XLM-RoBERTa	Filipino	8	3×10^{-5}	1×10^{-2}
XLM-RoBERTa	Bilingual	8	2×10^{-5}	1×10^{-5}
RoBERTa-Tagalog	English	8	3×10^{-5}	1×10^{-2}
RoBERTa-Tagalog	Filipino	4	3×10^{-5}	1×10^{-2}
RoBERTa-Tagalog	Bilingual	8	3×10^{-5}	1×10^{-5}
NeoBERT	English	4	2×10^{-5}	1×10^{-5}
NeoBERT	Tagalog	4	3×10^{-5}	1×10^{-5}
NeoBERT	Bilingual	4	3×10^{-5}	1×10^{-5}

Table 1: Optimal hyperparameter configurations for transformers across all training regimes.

3.4 Training Procedure

Each configuration is trained independently from a fresh pretrained checkpoint to avoid parameter leakage across hyperparameter settings. Training is conducted under the following constraints: (1) a maximum of 10 epochs, which is sufficient for convergence in low-resource fine-tuning, and (2) full backpropagation over all model parameters. During hyperparameter search, early stopping with a patience of 3 is applied using validation macro-F1 to prevent overfitting. For final reported results, models are retrained without early stopping to ensure a consistent number of training epochs across experimental conditions.

3.4.1 Cross-Validation Protocol

Clinical NLP datasets are typically small and high-variance, making single train–test splits prone to unstable performance estimates. To evaluate robustness with respect to data variability, we perform stratified 10-fold cross-validation on the data for all models and training configurations. Final cross-validation performance is reported as the mean and standard deviation across folds. Importantly, cross-validation is not used for model selection in the final reported results. Instead, it is used to assess performance stability and sensitivity to data sampling.

3.4.2 Evaluation Protocol and Metrics

For each training configuration, we evaluate under three settings. In-domain evaluation trains and tests within the same language using stratified 10-fold cross-validation. Cross-lingual zero-shot evaluation trains on each fold of one language and evaluates on the full dataset of the other language, which is never seen during training. This ensures a consistent cross-lingual test condition across folds, with variance reflecting sensitivity to training data sampling rather than target-language variability. Bilingual evaluation trains on each fold of the combined corpus ($\mathcal{DEN} \cup \mathcal{DTL}$) and evaluates on the corresponding held-out test fold. Performance is reported on the full mixed-language test fold as well as separately on English-only

and Filipino-only subsets. Each configuration is trained independently. Cross-lingual generalization is assessed by training on one language and evaluating on the other in a zero-shot setting. The combined setting evaluates models on a mixed-language test set containing both English and Filipino samples. We report Accuracy and Macro-averaged F1-score as the primary evaluation metrics. Macro-F1 is prioritized due to its equal weighting of the Healthy and Dementia classes, making it more appropriate for imbalanced clinical classification tasks where minority-class performance is critical. To quantify robustness under language shift, we define the cross-lingual generalization gap as follows

$$\Delta_{\text{F1}} = \left|\text{F1}_{\text{in-domain}} - \text{F1}_{\text{cross-lingual}}\right| \quad (1)$$

where in-domain refers to evaluation on the same language as training (EN→EN or TL→TL), and cross-lingual refers to zero-shot evaluation on the unseen language (EN→TL or TL→EN). The combined setting is reported separately to assess performance under mixed-language conditions and is excluded from the cross-lingual generalization gap computation. In addition to overall performance, we report class-wise F1 scores and Dementia-class recall to explicitly evaluate clinical sensitivity. These metrics allow us to analyze whether performance degradation is driven by reduced detection of Dementia cases or by general classification instability.

Table 2: Performance across models and training settings. Cells report F1 ± std / Acc ± std. Cross-lingual gap: $\Delta F1 = |F1_{\text{in-domain}} - F1_{\text{cross-lingual}}|$

Table 2 reports Macro-F1 and Accuracy across all models and training configurations. Four findings emerge consistently.

4.1 Cross-Lingual Failure Persists Even Under Controlled Parallel Data

All models achieve strong in-domain performance but degrade substantially under language transfer. English-trained BERT achieves $F1 = 0.952$ on English but falls to 0.455 on Filipino ($\Delta = 0.497$), while Filipino-trained BERT achieves $F1 = 0.981$ on Filipino but drops to 0.705 on English ($\Delta = 0.276$). The asymmetry is informative: transfer into English is consistently easier than transfer into Filipino, even when the model is fine-tuned entirely on Filipino, suggesting that English remains a stronger prior in the representation space due to pretraining exposure. Fine-tuning on Filipino modifies model behavior but does not fully overwrite the English-centric geometry learned during pretraining. These results cannot be explained by domain shift, since the Filipino corpus was constructed through controlled manual translation of the same source transcripts. The degradation, therefore, isolates language transfer rather than demographic or collection confounds. The failure appears representational: models learn dementia-related patterns within a language but fail to align those patterns robustly across languages. The lexical baseline supports this interpretation. TF-IDF + LR achieves $F1 = 0.649$ on Filipino when trained on English and $F1 = 0.640$ on English when trained on Filipino, suggesting that some dementia-related surface markers survive translation at the lexical level. The gap relative to transformer-based models indicates that lexical overlap alone is insufficient for stable cross-lingual generalization.

4.2 NeoBERT Improves Monolingual Fidelity While Increasing Transfer Instability

Relative to BERT, NeoBERT achieves comparable monolingual performance but does not improve cross-lingual robustness. Despite matching BERT's in-domain performance (F1=0.952), English-trained NeoBERT degrades substantially on Filipino (F1=0.617) and exhibits the highest variance across any experiment ($\sigma = 0.109$), suggesting that architectural modernization forms tighter English-side decision boundaries that improve in-domain fidelity while reducing tolerance to linguistic variation. Filipino-trained NeoBERT transfers better into English than BERT (F1=0.757 vs. 0.705) but retains high instability in dementia recall (Table 3). Taken together,

architectural improvements alone do not produce language-invariant clinical representations, and stronger monolingual specialization appears to trade off against transfer stability.

4.3 Transfer Behavior of Multilingual and Language-Matched Pretraining

XLM-RoBERTa and RoBERTa-Tagalog exhibit substantially smaller transfer gaps than English-only encoders, but through different mechanisms. English-trained XLM-RoBERTa achieves $F1 = 0.936$ on Filipino ($\Delta = 0.013$), the smallest gap observed under monolingual training, consistent with multilingual pretraining constructing a shared representation space that allows English fine-tuning to map naturally onto Filipino inputs. However, transfer is asymmetric: XLM-RoBERTa transfers substantially better from English to Filipino than the reverse ($\Delta = 0.013$ $vs.$ 0.161), suggesting that English occupies a disproportionately larger share of the pretraining corpus, producing a representation space calibrated more precisely around English structure. RoBERTa-Tagalog is more surprising. Despite being pretrained exclusively on Filipino, it achieves nearly identical English $\rightarrow$ Filipino transfer as XLM-RoBERTa ($F1 = 0.934$, $\Delta = 0.017$). We attribute this to the linguistic composition of Filipino itself: conversational Filipino contains extensive English lexical borrowing, code-switching, and Anglicized syntactic structure, meaning a model pretrained deeply on Filipino encounters substantial embedded English structure even without explicit multilingual supervision. The reverse direction supports this interpretation, as RoBERTa-Tagalog degrades more sharply when English becomes the target ($\Delta = 0.218$), suggesting that embedded English structure is sufficient for English-to-Filipino transfer but weaker than explicit multilingual supervision for reconstructing robust English-side representations after Filipino fine-tuning.

4.4 Bilingual Training Eliminates Most Cross-Lingual Bias

Bilingual fine-tuning substantially reduces cross-lingual degradation across all architectures, with combined-set Macro-F1 converging to 0.969–0.973 and cross-lingual gaps shrinking to between 0.027 and 0.037. Models that behaved very differently under monolingual transfer become nearly indistinguishable after bilingual supervision. NeoBERT, which exhibited the highest instability under English-only transfer, stabilizes immediately and performs comparably to XLM-RoBERTa and RoBERTa-Tagalog, suggesting that the primary bottleneck is not architectural capacity but representational alignment. The models already possess sufficient capacity to encode dementia-related linguistic structure across both languages; what differs is whether the optimization signal encourages those structures to occupy compatible regions of the embedding space. Multilingual and language-matched models retain a small but consistent advantage, with XLM-RoBERTa and RoBERTa-Tagalog achieving the highest combined-set performance (0.972–0.973), suggesting that pretraining language coverage provides a more favorable initialization for bilingual adaptation. Bilingual TF-IDF + LR substantially reduces the transfer gap ($\Delta = 0.044$) but remains below all transformer models, confirming that surface lexical statistics capture part of the dementia signal but are insufficient to construct stable cross-lingual abstractions.

Table 3: Class-level performance across models and training configurations. Cells report F1; Healthy/Dementia are class F1; Dem. Recall is AD recall.

4.5 Clinical Implications Under Language Shift

Table 3 shows that aggregate Macro-F1 partially obscures clinically important failure modes under language transfer. English-trained BERT maintains high dementia recall on Filipino (0.931), but Healthy-class F1 collapses to 0.216, indicating that the model predicts most Filipino samples as dementia-positive rather than transferring meaningful discriminative structure. NeoBERT

exhibits a different pattern: dementia recall on Filipino averages 0.939 but with extremely large variance ($\sigma = 0.190$), reflecting inconsistent decision boundaries across fine-tuning folds rather than stable transfer. In contrast, English-trained XLM-RoBERTa and RoBERTa-Tagalog maintain balanced class F1 scores across languages with substantially lower variance, a property particularly important in screening settings where robustness across patient populations matters more than aggregate accuracy.

Bilingual training resolves most instabilities across all architectures, with all transformer models achieving dementia recall above 0.93 with consistently low variance, indicating substantially more stable decision boundaries than those learned under monolingual training.

4.6 Comparison with Classical Baselines

The lexical baseline shows moderate transfer in both directions: English-trained TF-IDF + LR achieves $F1 = 0.649$ on Filipino and 0.640 in the reverse direction, suggesting that some dementia-related surface markers are preserved across the translation boundary. Under English-only training, TF-IDF performs comparably to NeoBERT cross-lingually but remains substantially below XLM-RoBERTa and RoBERTa-Tagalog. In the bilingual setting, TF-IDF + LR reaches $F1 = 0.954$ while transformer models achieve 0.969–0.973, indicating that sparse lexical features are insufficient even under bilingual exposure. These results suggest that transformer gains stem not from stronger in-language modeling alone, but from learning contextual representations that transfer across languages. TF-IDF captures surface-level dementia markers but does not model the contextual interactions through which those markers manifest across languages, whereas multilingual and language-matched models better preserve these dependencies. Overall, TF-IDF retains partial transferability due to the structural persistence of dementia-related cues, but its instability relative to contextual models indicates that robust cross-lingual screening requires representation learning beyond lexical overlap.

5 Conclusion

Across all model families, strong in-domain performance does not translate to cross-lingual robustness, even when domain and clinical content are held constant through parallel dataset construction. This indicates that the primary barrier to multilingual clinical NLP is representational misalignment induced by language-specific pretraining rather than task complexity or domain shift. Architectural modernization alone, as shown by NeoBERT, does not yield consistent cross-lingual gains and may increase sensitivity to language shift through tighter monolingual specialization. Multilingual and language-matched pretraining provide more stable transfer, though through different mechanisms. Bilingual fine-tuning, however, largely eliminates cross-lingual performance gaps across all architectures, suggesting that linguistic coverage during task training is more influential than architectural choice in determining robustness under language shift.

These findings indicate that reliable clinical NLP in low-resource, code-switched settings depends less on model scaling or architectural modification and more on ensuring adequate linguistic coverage during training, with bilingual supervision emerging as the most effective strategy for stable and clinically consistent performance across languages.

6 Limitations

Several limitations of this study warrant acknowledgment. First, the Filipino dataset was constructed through controlled manual translation of English DementiaBank transcripts, as no large-scale native clinical dementia corpora exist for Filipino. Although translators preserved structural disfluencies, hesitations, and syntactic fragmentation, the translated text inherently reflects the conversational structure and semantic content of the original English source documents. The dataset's modest scale of 4,000 samples also restricts the generalizability of evaluation metrics and contributes to cross-validation variance. Acquiring larger, organically produced clinical speech from local Filipino patient cohorts in collaboration with geriatricians remains a priority for validating these findings in local clinical environments.

Second, this study focuses exclusively on text to isolate language-specific discourse patterns, setting aside acoustic and non-verbal features. In real-world clinical settings, vocal features such

as pitch variance, pause duration, and phonation rate provide independent diagnostic markers of neurodegeneration not captured in a text-only framework. Integrating speech encoders such as Wav2Vec 2.0 alongside transformer-based text models represents an important future direction.

Finally, while this evaluation establishes classification baselines across a range of encoder architectures, the mechanisms driving model decisions in multilingual contexts remain opaque. Clinical deployment demands transparency, and applying local feature attribution and interpretability methods is a necessary step before these screening workflows can achieve clinical trust and real-world deployment.

Abstract

Most existing medical dialogue systems operate in a single-turn question–answering paradigm or rely on template-based datasets, limiting conversational realism and multilingual applicability. We introduce `IndicMedDialog`, a parallel multi-turn medical dialogue dataset spanning English and nine Indic languages: Assamese, Bengali, Gujarati, Hindi, Marathi, Punjabi, Tamil, Telugu, and Urdu. The dataset extends `MDDial` with LLM-generated synthetic consultations, translated using `TranslateGemma`, verified by native speakers, and refined through a script-aware post-processing pipeline to correct phonetic, lexical, and character-spacing errors. Building on this dataset, we fine-tune `IndicMedLM` via parameter-efficient adaptation of a quantized small language model, incorporating optional patient pre-context to personalise multi-turn symptom elicitation. We evaluate against zero-shot multilingual baselines, conduct systematic error analysis across ten languages, and validate clinical plausibility through medical expert evaluation.

1 Introduction

Conversational AI has demonstrated strong potential for preliminary symptom assessment and medical guidance, particularly in underserved regions where access to healthcare professionals is limited (Tu et al., 2024). Large language models (LLMs) have enabled systems to interact with patients in a naturalistic manner; however, most existing approaches operate in a *single-turn* question–answering paradigm. In real clinical practice, diagnosis emerges through a sequence of follow-up questions that progressively narrow the differential, a dynamic that single-turn systems fundamentally cannot replicate.

A further limitation is the dominance of English-only or template-driven datasets. While `MDDial` (Macherla et al., 2023) provides a useful foundation for multi-turn diagnostic dialogue, its template-based construction constrains linguistic diversity and conversational realism. For the 1.5 billion speakers of Indic languages, the absence of parallel multilingual medical dialogue resources represents a critical gap in healthcare accessibility.

Figure 1 illustrates a representative failure of a general-purpose LLM: given a patient complaint, the model produces a single verbose explanatory response without collecting additional symptoms. Figure 2 contrasts this with `IndicMedLM`, which incorporates patient pre-context (age, gender, allergies) and conducts a structured multi-turn symptom elicitation before producing a diagnosis, more closely resembling a real physician-patient consultation.

To address these limitations, we introduce `IndicMedDialog`, a parallel multi-turn medical dialogue dataset covering English and nine Indic languages: Assamese, Bengali, Gujarati, Hindi, Marathi, Punjabi, Tamil, Telugu, and Urdu. The dataset extends `MDDial` with LLM-generated synthetic consultations, translated using `TranslateGemma` (Finkelstein et al., 2026), verified by native speakers, and refined through a script-aware post-processing pipeline to correct phonetic, lexical, and character-spacing errors introduced during automatic translation. Building on this dataset, we fine-tune `IndicMedLM` using parameter-efficient methods on quantized small language models, enabling deployment without high-end computational infrastructure.

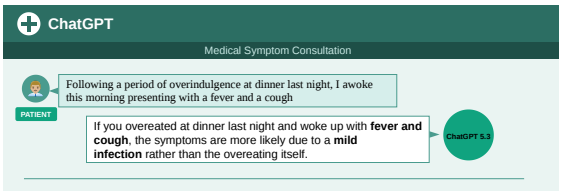

Figure 1: Response from a general-purpose LLM (ChatGPT). The model produces a single explanatory answer without follow-up questioning or symptom elicitation.

Contributions. The main contributions of this work are:

- We construct `IndicMedDialog`, the first parallel multi-turn medical dialogue dataset spanning English and nine Indic languages, with native-speaker verification and script-aware post-processing for translation quality assurance.
- We incorporate *patient pre-context* (age, gender, allergies, and demographic attributes) to enable personalized multi-turn symptom elicitation, more closely simulating real clinical consultations.
- We develop `IndicMedLLM`, a parameter-efficiently fine-tuned medical dialogue model deployable on modest hardware, and perform systematic error analysis identifying five failure modes across languages and their clinical risk implications.
- We conduct *medical expert evaluation* to validate the clinical plausibility and safety of the generated diagnostic dialogues.

For reproducibility, we release the dataset, model checkpoints, and training code through an GitHub repository[1].

2 Related Work

Medical Dialogue Datasets and Systems. Early medical dialogue work focused on symptom collection and slot filling, often lacking natural multi-turn interaction (Zeng et al., 2020; Liu et al., 2022). `MDDial` (Macherla et al., 2023) provides an English differential-diagnosis corpus but relies on template-based construction. `MedAidDialog` (Nigam et al., 2026) has focused on some Indian and Arabic languages using synthetically generated datasets. MedDG and Zhongjing advance multi-turn consultation in Chinese (Liu et al., 2022; Yang et al., 2024), while MediTOD targets structured English medical history-taking (Saley et al., 2024). Domain-specific fine-tuning of LLMs (e.g., ChatDoctor (Li et al., 2023)) substantially improves medical response quality over general-purpose models, though most such systems assume single-turn interaction. AMIE (Tu et al., 2024) and BianQue (Chen et al., 2023) frame diagnosis as iterative history-taking, more closely reflecting real clinical workflows.

Figure 2: Example interaction with `IndicMedLM`. The system incorporates patient pre-context (age, gender, allergies) and conducts structured multi-turn symptom elicitation before producing a final diagnosis.

Synthetic Data and Multilingual Coverage. Since real clinical conversations are difficult to release due to privacy constraints, synthetic generation has emerged as a practical alternative. NoteChat generates patient–physician dialogues conditioned on clinical notes (Wang et al., 2024), while `MDDial` uses template-based synthesis. However, most existing datasets remain single-language or template-constrained. BiMediX (Pieri et al., 2024) is an important step toward bilingual medical dialogue in English and Arabic, but broader coverage of low-resource languages remains absent. `IndicMedDialog` addresses this gap by providing the first parallel multi-turn medical dialogue corpus across nine Indic languages, combining LLM-generated synthesis

[1] https://github.com/ShubhamKumarNigam/IndicMedDialog

with native speaker verification and script-aware post-processing.

Evaluation. Recent work highlights that medical dialogue quality should not be measured by final-answer accuracy alone, but also by questioning strategy, safety, and turn-level clinical relevance (Tu et al., 2024; Gong et al., 2026). Our evaluation adopts this broader view, combining diagnostic accuracy, semantic post-processing, error taxonomy analysis, and medical expert assessment.

3 Task Definition

We study the problem of parallel multi-turn medical dialogue generation across Indic languages, where a conversational agent interacts with a patient to collect symptoms and provide preliminary diagnostic guidance. Unlike single-turn medical question answering, this task requires modeling sequential physician-patient interactions where diagnostic reasoning emerges through multiple conversational exchanges. Furthermore, unlike prior multilingual medical dialogue work that generates responses independently per language, our setting emphasizes *parallel dialogue consistency*, ensuring that translated dialogues across all languages convey semantically equivalent clinical content.

3.1 Parallel Multilingual Dialogue Setting

The `IndicMedDialog` dataset provides parallel dialogue corpora across ten languages: English, Assamese, Bengali, Gujarati, Hindi, Marathi, Punjabi, Tamil, Telugu, and Urdu. The English dialogues serve as the source, and translations into the nine Indic languages were generated using LLMs and subsequently verified by native speakers for each language. Due to the limited exposure of current LLMs to Indic languages during pre-training, the automatic translations exhibited several systematic errors, including phonetic inconsistencies, lexical inaccuracies, and erroneous character-level spacing. To address this, a post-processing pipeline was applied to map erroneous tokens to their closest correct forms in the target language, ensuring linguistic quality and clinical fidelity across all language versions. Illustrative examples of these error patterns and their corrections for Bengali and Hindi are provided in Appendix C.1 and Appendix C.2, respectively.

The objective is to learn a model that can generate medically coherent and linguistically accurate responses across all supported languages while maintaining consistent diagnostic reasoning regardless of the target language.

3.2 Patient Context Personalization

In real clinical consultations, physicians often begin with basic contextual information about the patient before asking symptom-related questions. To better simulate this scenario, our framework supports optional *patient pretext information* provided at the start of the dialogue. This information may include *age group, gender, geographic location, known allergies, and pre-existing medical conditions*. This context is appended to the dialogue prefix and incorporated into the model input across all language settings. Incorporating patient context allows the model to personalize its questioning strategy and diagnostic reasoning, reflecting how clinicians adapt their inquiries based on patient demographics and medical history.

4 `IndicMedDialog` Dataset

Multi-turn conversational datasets are essential for training medical dialogue systems that can iteratively collect symptoms and provide diagnostic guidance (Macherla et al., 2023; Tu et al., 2024). The MDDial dataset (Macherla et al., 2023) provides an English differential-diagnosis dialogue corpus derived from structured medical records. However, its template-based construction limits conversational diversity and realism, and it does not support multilingual deployment.

To address these limitations, we construct `IndicMedDialog`, a parallel multilingual multi-turn medical dialogue dataset designed to simulate realistic physician–patient interactions while enabling accessibility across nine Indic languages alongside English.

4.1 Synthetic Dialogue Generation

To improve conversational diversity beyond template-based dialogues, we generate synthetic medical consultations using `Llama-3.3-70B-Versatile` via the Groq

Dataset	Dialogue Turns				Average Words		
	Avg Turns	Total Dialogues	Min Turns	Max Turns	Per Dialogue	Patient Utterance	Doctor Utterance
MDDial (MD)	4.9	1879	1	16	53.5	5.6	6.7
Synthetic (SYN)	6.6	1101	5	11	134.5	8.8	9.6
MD + SYN	5.7	2980	1	16	86.9	7.00	8.05
MDDial Test	5.9	237	1	13	55.4	5.6	6.6

Table 1: Statistics of the original MDDIAL dataset and the synthetic dialogues used to construct `IndicMedDialog`. Synthetic augmentation results in longer and more diverse multi-turn interactions.

API.[2] The generation process is conditioned on disease categories, demographic attributes, and stylistic constraints to produce clinically plausible and linguistically diverse interactions.

The pipeline simulates diagnostic consultations involving 12 diseases and 118 symptoms. Each dialogue begins with a patient complaint and proceeds through multiple conversational turns in which the physician asks follow-up questions to gather diagnostic evidence, typically spanning 4–8 turns before concluding with a diagnosis. To better approximate real clinical scenarios, the generation process introduces variability through non-deterministic patient responses, overlapping symptoms, and incomplete or ambiguous descriptions.

Using this approach, we generate 1,101 synthetic consultations, significantly enriching the diversity of the original MDDIAL corpus. Table 1 summarizes the statistics of both the original and synthetic dialogues. Compared to the template-driven corpus, the synthetic dialogues exhibit longer interactions and more varied conversational structures.

4.2 Multilingual Expansion

To enable accessibility in linguistically diverse settings, we construct a parallel multilingual corpus by translating the English dialogues into nine Indic languages: *Assamese, Bengali, Gujarati, Hindi, Marathi, Punjabi, Tamil, Telugu, and Urdu.* Translation is performed using `TranslateGemma` (Finkelstein et al., 2026) with a structured prompting strategy designed to preserve clinical meaning, terminological accuracy, and conversational flow across all target languages. The full translation prompt is provided in Appendix F.3.

[2] https://groq.com/

4.3 Translation Quality Assurance

To ensure the reliability of the multilingual corpus, two native speakers per language independently rate a sampled subset of the translated and post-processed dialogues on two criteria: **Translation Quality** (T), measuring linguistic accuracy and fluency relative to the English source, and **Clinical Safety** (S), verifying that responses remain medically appropriate and free from harmful or culturally insensitive content. Each criterion is scored on a 10-point scale, and disagreements between annotators are resolved through discussion.

Table 6 in the Appendix C reports individual annotator scores (H1, H2) and per-language averages ($\bar{T}$, $\bar{S}$) across all nine Indic languages. The overall mean scores of $\bar{T} = 9.50$ and $\bar{S} = 9.56$ confirm the linguistic fidelity and clinical suitability of `IndicMedDialog` for fine-tuning medical dialogue models.

4.4 Disease Categories and Coverage

`IndicMedDialog` covers 12 disease categories spanning 8 organ systems, providing broad clinical diversity across the dataset. Table 7 in the Appendix D lists each disease, its organ system, and the number of dialogues available in the dataset.

4.5 Dataset Summary

The final `IndicMedDialog` dataset comprises 2,980 parallel multi-turn medical dialogues across ten languages (English and nine Indic languages), yielding a total of 29,800 language-specific dialogue instances. Each dialogue is annotated with a disease label drawn from a set of 12 disease categories, and optionally includes patient pretext information covering age group, gender, geographic location, known allergies, and pre-existing medical conditions. To the best of our knowledge, `IndicMedDialog` is the first parallel multi-turn medical dialogue dataset covering this breadth of Indic languages, addressing a critical gap in low-resource clinical NLP.

5 Methodology

Our framework consists of three stages: (1) supervised fine-tuning of a compact open-source language model on `IndicMedDialog`, (2) a

two-stage post-processing pipeline to recover latent correct predictions from verbose model outputs, and (3) evaluation against zero-shot multilingual baselines. Figure 3 presents the overall pipeline.

5.1 Models Evaluated

We evaluate four models spanning zero-shot and fine-tuned settings:

Gemma (Team et al., 2024) and TinyAya (Salamanca et al., 2026) are evaluated zero-shot without any task-specific adaptation. TinyAya provides native Indic language support, making it a strong multilingual baseline. LLaMA-3.2-3B-Instruct (Grattafiori et al., 2024) is evaluated without fine-tuning as a pre-adaptation reference point. `IndicMedLM` is our fine-tuned model, described below.

5.2 `IndicMedLM`: Fine-Tuning

We apply Low-Rank Adaptation (LoRA) (Hu et al., 2022) to **LLaMA-3.2-3B-Instruct** with 4-bit NF4 quantization. LoRA adapters are inserted into all attention projections (`q_proj`, `k_proj`, `v_proj`, `o_proj`) and all MLP projections (`gate_proj`, `up_proj`, `down_proj`), with rank $r = 16$, $\alpha = 16$, dropout $= 0$, and no bias terms.

Training uses AdamW-8bit with learning rate 2×10^{-4}, weight decay $= 0.001$, batch size $= 8$ (2 per device $\times$ 4 gradient accumulation steps), 5 warmup steps, 300 total steps, and a linear schedule with FP16/BF16 mixed precision (seed $= 3407$). Each of the nine Indic language variants is trained on its own language-partitioned split of `IndicMedDialog` using identical hyperparameters. At inference, we use temperature $= 0.1$, top-$p = 0.95$, and a maximum of 128 new tokens.

Before training, all dialogues are formatted into a ShareGPT-style instruction format, where patient utterances map to `human` turns and doctor utterances map to `gpt` turns, with a system message defining the diagnostic consultation setting. An optional *patient pre-context*, covering age, gender, known allergies, and pre-existing conditions, is prepended to each conversation, enabling the model to personalize its questioning strategy based on patient demographics.

5.3 Two-Stage Post-Processing

Model outputs frequently embed correct disease labels inside verbose explanatory sentences, causing raw accuracy to underestimate true diagnostic capability. To recover these latent correct predictions without introducing confabulation, we apply a neural semantic mapping pipeline.

All model outputs are passed to a large language model judge (ChatGPT 5.3) prompted to perform *constrained semantic equivalence classification*: given a free-form output string, the judge selects the single most semantically equivalent label from the closed set of 12 canonical disease names, or returns `NULL` if no match exceeds a confidence threshold. The judge is supplied all 12 labels explicitly and is prohibited from generating labels outside the canonical set, eliminating confabulation risk. This approach generalises across unseen paraphrases and script-mixed outputs across all nine Indic languages without requiring manual lexicon construction per language. Instances where the judge returns `NULL` are retained as misclassifications, ensuring unresolvable outputs do not inflate reported results.

6 Evaluation Metrics

We adopt a two-stage evaluation strategy: (i) automatic evaluation based on diagnostic accuracy, and (ii) human expert evaluation assessing clinical reliability and conversational quality.

6.1 Automatic Evaluation

We measure **diagnostic accuracy** by comparing the model's final predicted disease label against the gold label in `IndicMedDialog`. While straightforward, accuracy alone does not capture safety, reasoning quality, or conversational coherence, motivating our complementary expert evaluation.

6.2 Expert Evaluation

Three qualified medical practitioners (MBBS, currently in postgraduate training) independently reviewed a randomly sampled subset of system-generated dialogues. Evaluation criteria include safety, symptom understanding, contextual reasoning, diagnostic plausibility, and conversational quality. All criteria are

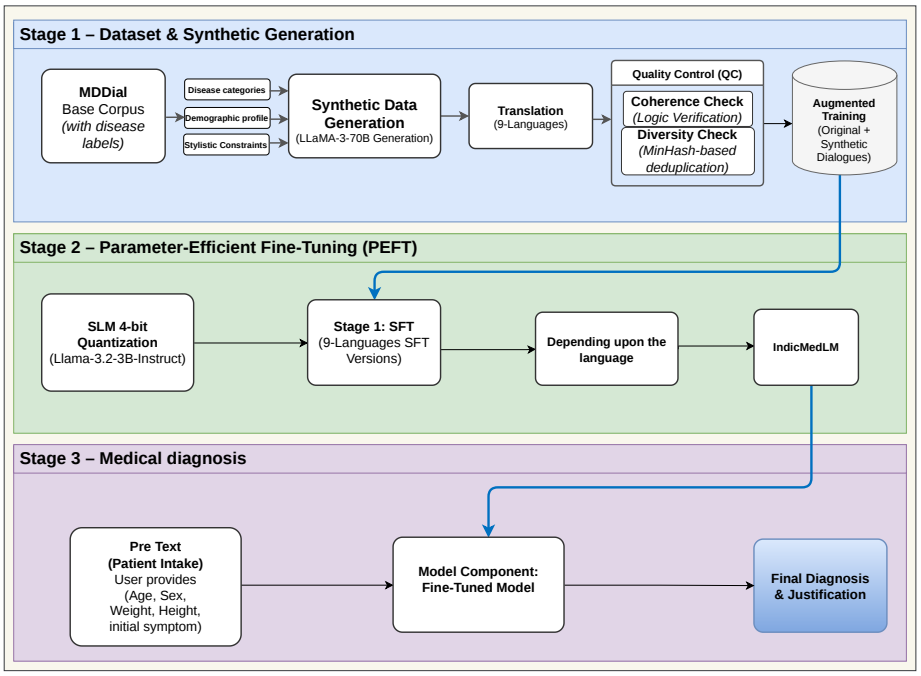

Figure 3: Overview of the `IndicMedDialog` framework. The `MDDial` dataset is augmented with synthetic dialogues, filtered through quality control, and translated into nine Indic languages to form a parallel corpus. Compact models are then fine-tuned using parameter-efficient methods to obtain `IndicMedLM`, which performs multi-turn diagnosis using an optional patient pre-context.

scored on a Likert scale of 1–5 (Very Poor to Excellent), except medical safety, which is assessed as a binary pass/fail metric. Full evaluation criteria are detailed in Appendix Table 16.

7 Results and Analysis

Table 2 reports diagnostic accuracy before (Raw) and after (Post) post-processing for all four models across ten languages. `IndicMedLM` achieves the best post-processed accuracy in 7 of 10 languages, with strongest results in English (80.85%), Hindi (72.76%), Marathi (68.51%), and Bengali (58.72%). The large raw-to-post gaps in Hindi (19.15% → 72.76%, +53.6pp) and Marathi (13.19% → 68.51%, +55.3pp) indicate that the model produces correct diagnoses but wraps them in culturally natural hedging sentences rather than bare labels, a metric artefact rather than a model failure.

Conversely, `IndicMedLM` performs at or below the GEMMA zero-shot baseline in Assamese, Tamil, and Telugu, all of which show near-zero post-processing recovery. Gujarati is a notable exception where Tiny-AYA zero-shot (37.02%) outperforms `IndicMedLM` (19.57%), suggesting that zero-shot multilingual models with stronger Gujarati tokenization may outperform fine-tuning under extremely limited data conditions.

	GEMMA		Tiny-AYA		LLaMA Base		`IndicMedLM`	
Language	Raw	Post	Raw	Post	Raw	Post	Raw	Post
English	35.74	45.11	11.49	13.19	10.64	15.74	**80.85**	**80.85**
Hindi	9.36	25.10	2.13	13.19	4.26	11.06	19.15	**72.76**
Marathi	0.43	9.36	0.43	5.11	2.98	11.50	13.19	**68.51**
Bengali	2.98	19.57	2.13	5.96	3.40	11.50	25.11	**58.72**
Urdu	1.28	2.12	3.40	13.61	1.28	2.55	4.26	28.51
Gujarati	11.91	18.72	28.09	37.02	6.38	18.30	18.30	19.57
Punjabi	0.00	7.66	8.12	8.12	4.27	8.51	5.96	20.42
Assamese	4.68	7.66	2.13	8.08	0.43	3.83	5.96	5.96
Tamil	6.81	11.91	0.85	3.83	1.70	6.80	6.38	6.80
Telugu	1.70	6.38	0.00	0.00	0.85	4.68	1.28	5.96

Table 2: Diagnostic accuracy (%) before (Raw) and after (Post) semantic post-processing for all models across ten languages, sorted by `IndicMedLM` post-processed performance. Blue = high-recovery tier; Yellow = partial recovery; Red = extreme failure (near-zero recovery).

7.1 Per-Disease Analysis

Table 8 (Appendix D) reports per-disease post-processed accuracy for `IndicMedLM` across selected languages. Several patterns are noteworthy. **Traumatic Brain Injury** reaches 94.7% in English and Hindi but collapses to 0% in Assamese, Tamil, Telugu, and Urdu, a

condition where diagnostic delay causes irreversible harm and where patients in these regions would primarily communicate in their native language. **Conjunctivitis** achieves 100% in Punjabi despite Punjabi's weak overall accuracy (20.42%), suggesting disease-specific rather than language-level tokenization advantages. **Dermatitis** reaches 100% in English and 95% in Hindi but 0% in Telugu, Punjabi, and Urdu. These within-disease variance patterns confirm that overall language accuracy aggregates highly heterogeneous per-disease behaviours driven by both script-level and disease-semantic factors.

7.2 Expert Evaluation and IAA Scores

As shown in Table 10 in the Appendix, `IndicMedLM` achieves a **95.3%** medical safety pass rate, indicating that unsafe advice is rare in the sampled dialogues. The model also obtains strong average scores for symptom extraction (4.20), context memory (4.40), diagnostic correctness (4.10), conversational flow (4.30), and efficiency (4.00). These results suggest that the model is able to track relevant symptoms, preserve dialogue context, and conduct multi-turn interactions in a clinically plausible and reasonably efficient manner. To validate the reliability of these judgments, we compute inter-annotator agreement (IAA) using Krippendorff's alpha (Krippendorff, 2011). Table 12 shows an average agreement score of **0.81**, indicating strong consistency among the medical experts.

7.3 Error Analysis

We identify five failure modes (FMs) from systematic analysis of raw misclassification logs. Table 3 summarises the primary and secondary FM per language alongside post-processing recovery.

FM1 – Instruction Drift (ID). The model abandons label generation and produces explanatory prose. In *partial drift*, the correct label is embedded in a hedging sentence (e.g., Hindi: *"aapko sambhavat Enteritis ho sakta hai"*) and is recoverable via semantic post-processing, directly explaining Hindi and Marathi's large raw-to-post gains. In *drift*, no label appears at all: Tamil outputs a sentence fragment terminating before the disease name (18 occurrences each for five diseases); Assamese maps all 12 diseases to an identical template sentence. Complete drift is irrecoverable.

FM2 – Label Collapse (LC). Multiple diseases are mapped to the same output. In Bengali, five disease classes collapse to *"fus fuse sankraman"* (lung infection), a respiratory hypernym misapplied across cardiac, GI, endocrine, and breast inputs. In Assamese, all 12 diseases produce an identical fixed template. This mirrors majority-class bias (Zhao et al., 2021) operating at the semantic hypernym level rather than the label level.

FM3 – Cross-Domain Confusion (CDC). The model predicts a disease from a clinically unrelated organ system. In English, CDC is the only failure mode and is mild (e.g., Coronary Heart Disease → Thyroiditis, 3 times). In extreme-failure languages, drift and collapse dominate so completely that CDC is unobservable. Table 9 (Appendix E) lists the most clinically significant cross-domain errors with associated risk levels.

FM4 – Tokenization/Truncation Failure (TTF). Punjabi (Gurmukhi script) shows severe truncation of disease names mid-word. Telugu exhibits a repetition-before-truncation loop before collapsing mid-character. Critically, TTF is absent in Devanagari languages (Hindi, Marathi) despite comparable pretraining data volumes, implicating base-model tokenizer vocabulary coverage for specific Unicode blocks rather than data quantity.

FM5 – Paraphrase-over-Label Generation (PLG). The model produces a semantically accurate disease description rather than the canonical label. PLG is most prevalent in Hindi and Marathi (e.g., *tvacha ki sujan* for Dermatitis; *dama* for Asthma) and is the most recoverable failure mode, being the proximate cause of both languages' large post-processing gains.

Three structural patterns emerge across languages. First, drift severity scales monotonically with pretraining resource level: English shows no drift; Hindi and Marathi show partial drift with semantic retention; Bengali and Urdu show complete drift but preserve semantic signal; Tamil, Telugu, Assamese, and Gu-

Language	Primary FM	Secondary	Recovery
English	CDC (mild)	LC (mild)	
Hindi	ID (partial)	PLG	+54pp
Marathi	ID (partial)	PLG	+55pp
Bengali	ID (complete)	LC	+34pp
Urdu	ID (complete)	PLG	+24pp
Punjabi	TTF	LC	+14pp
Gujarati	ID (complete)	TTF	+1pp
Tamil	ID (complete)	LC	+0.4pp
Telugu	ID (complete)	TTF	+4pp
Assamese	ID (complete)	LC	+0pp

Table 3: Per-language failure profiles for `IndicMedLM` with post-processing recovery gains. FM = Failure Mode; ID = Instruction Drift; PLG = Paraphrase-over-Label Generation; LC = Label Collapse; TTF = Tokenization/Truncation Failure; CDC = Cross-Domain Confusion. Row colours follow the same tier convention as Table 2.

jarati show complete drift with semantic loss. This confirms that format compliance is a pretraining function, not a fine-tuning function. Second, TTF concentrates in Gurmukhi and Telugu and is absent in Devanagari, implicating script-specific tokenizer vocabulary gaps. Third, label collapse targets cross-domain semantic hypernyms rather than random labels, reflecting the model's bias toward the highest-frequency general medical concept in its training distribution.

7.4 Discussion

Metric Sensitivity. The raw-vs-post-processed gap (up to 55pp for Marathi) demonstrates that strict label-matching systematically underestimates model capability for Indic languages, particularly those with the Devanagari script, where PLG dominates. We recommend LLM-as-a-Judge semantic equivalence evaluation as the primary metric for this domain, with exact label-match reported as a secondary lower bound.

English + Inference-Time Translation. Per-language fine-tuning is insufficient for extreme low-resource languages where the base model lacks pretraining coverage of the target script. A promising alternative is to fine-tune solely on English and apply bidirectional translation at inference time, leveraging `IndicMedLM`'s 80.85% English accuracy while sidestepping Indic script generation instability entirely. Formalising this comparison as a controlled experiment is the highest-priority future direction.

Clinical Risk Stratification. The 0% precision for Traumatic Brain Injury in Assamese, Tamil, and Telugu, languages spoken by tens of millions of people, represents a concrete failure of patient safety , not merely a benchmark shortcoming. The clinical risk gradient between moderate- and extreme-failure languages are the strongest argument for prioritising low-resource Indic medical NLP research.

8 Conclusion and Future Work

We introduced `IndicMedDialog`, a parallel multi-turn medical dialogue dataset spanning English and nine Indic languages, constructed by augmenting `MDDial` with LLM-generated synthetic consultations, followed by native-speaker verification and script-aware post-processing. Using this dataset, we fine-tuned `IndicMedLM` via LoRA on LLaMA-3.2-3B-Instruct and evaluated it against zero-shot multilingual baselines. Results show strong performance in Hindi (72.76%), Marathi (68.51%), and Bengali (58.72%) after semantic post-processing, while Assamese, Tamil, and Telugu remain in an extreme failure tier attributable to base-model tokenizer gaps and insufficient pretraining coverage — a finding with direct patient safety implications.

Our error analysis identifies five failure modes (Instruction Drift, Label Collapse, Cross-Domain Confusion, Tokenization Failure, and Paraphrase-over-Label Generation) and demonstrates that strict label-matching systematically underestimates model capability for Devanagari-script languages, motivating LLM-as-a-Judge semantic evaluation as the primary metric for Indic medical NLP.

Future work will prioritize: (i) inference-time English translation as an alternative to per-language fine-tuning for extreme low-resource languages; (ii) evaluation on real annotated clinical dialogues collected from native speakers; and (iii) expansion to additional Indic languages and disease categories to improve coverage for underserved communities. We release `IndicMedDialog` and `IndicMedLM` to support future research on accessible and trustworthy medical AI for Indic language speakers.

Limitations

Synthetic-to-Real Gap. `IndicMedDialog` is constructed from synthetic and template-based dialogues. The gap between synthetic and real patient dialogue distributions remains unquantified. Collecting even 20–30 real symptom dialogues per language from native annotators would validate whether synthetic test performance generalises to real clinical interactions — the single most important experiment for future work.

Language and Script Coverage. Extreme-failure languages (Assamese, Tamil, Telugu) suffer from base-model tokenizer gaps for their Unicode blocks rather than data quantity alone. Extending to base models with stronger Indic pretraining coverage, and correlating post-processed accuracy with published per-language pretraining token estimates, would formalise the resource–performance relationship observed qualitatively in our error analysis.

Disease and Training Scope. Twelve disease categories constitute a controlled evaluation environment. Extension to broader ICD-10-based taxonomies and multi-label cases is required before any clinical deployment consideration. Additionally, training `IndicMedLM` for only 300 SFT steps with a maximum of 128 output tokens is conservative; scaling may benefit extreme-failure languages where the model has not converged to label-production behaviour.

Text-Only Modality. The current system is limited to text-based dialogue and does not incorporate clinically relevant modalities such as medical images, laboratory reports, or speech, which are important for real-world deployment.

A LoRA Training Configuration

We use Low-Rank Adaptation (LoRA) (Hu et al., 2022) for parameter-efficient fine-tuning. Adapters are inserted into the query, key, value, and output projection matrices of each transformer block.

B Training Hyperparameters and Resources

B.1 Compute Resources

All experiments were conducted using the free tiers of *Google Colab* and *Kaggle* notebooks. These environments provide access to consumer-grade GPUs suitable for training compact language models using parameter-efficient fine-tuning techniques. To accommodate the limited GPU memory available in these platforms, we employed 4-bit quantization together with LoRA-based training.

B.2 LoRA Configuration

Table 4 summarizes the LoRA configuration used in our experiments.

Parameter	Value
Rank (r)	16
Target Modules	q_proj, k_proj, v_proj, o_pr gate_proj, up_proj, down_p
LoRA Alpha	16
LoRA Dropout	0
Bias	none
Use RSLora	False
LoftQ Config	None

Table 4: LoRA configuration used for parameter-efficient fine-tuning.

B.3 Training Hyperparameters

The main training hyperparameters are reported in Table 5.

Hyperparameter	Value
Learning Rate	2×10^{-4}
Optimizer	AdamW (8-bit)
Learning Rate Scheduler	Linear
Weight Decay	0.001
Warmup Steps	5
Maximum Training Steps	600
Random Seed	3407

Table 5: Training hyperparameters used for supervised fine-tuning.

C Post-Processing Examples

To illustrate the types of systematic errors introduced during automatic translation into Indic languages, we provide representative examples of erroneous token variants and their corresponding corrected forms for Bengali and Hindi.

C.1 Bengali Post-Processing Example

Figure 4 illustrates the range of phonetically and lexically incorrect Bengali variants generated for the medical term *asthma* (আস্থমা). The erroneous forms include incorrect vowel mappings, spurious character insertions, and erroneous spacing within conjunct consonants, all of which are mapped to the correct canonical form through our post-processing pipeline.

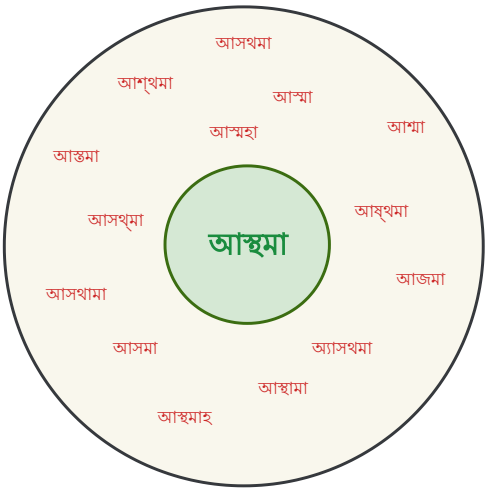

Figure 4: Examples of phonetically and lexically incorrect Bengali transliterations of *asthma* generated during automatic translation, along with the canonical corrected form (আস্থমা) produced by the post-processing pipeline.

C.2 Hindi Post-Processing Example

Figure 5 illustrates erroneous Hindi variants generated for the medical term *conjunctivitis* (कंजंक्टिवाइटिस). The errors include fragmented conjunct consonants, incorrect vowel signs (*matras*), and spurious whitespace introduced between syllable clusters, all of which are corrected through the post-processing pipeline.

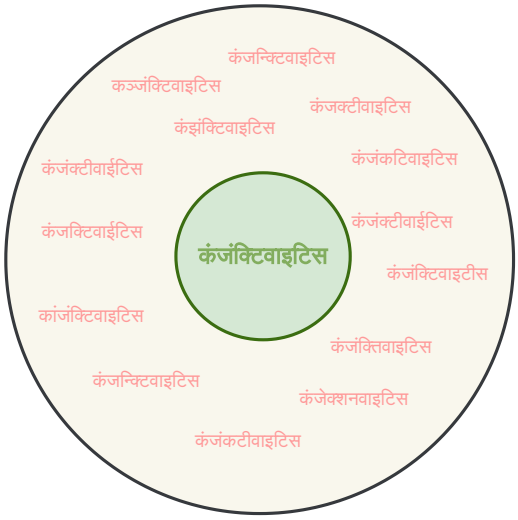

Figure 5: Examples of phonetically and lexically incorrect Hindi transliterations of *conjunctivitis* generated during automatic translation, along with the canonical corrected form (कंजंक्टिवाइटिस) produced by the post-processing pipeline.

D Per-Disease Accuracy

Table 8 reports post-processed diagnostic accuracy for `IndicMedLM` broken down by disease and selected languages.

E Clinical Risk of Cross-Domain Errors

Table 9 lists the most frequent cross-domain misclassifications produced by `IndicMedLM` with associated clinical risk levels.

F Prompt Templates

F.1 Synthetic Dialogue Generation Prompt

Table 14 shows the prompt used for synthetic data generation.

F.2 Dialogue Formatting Prompt

Table 15 shows the prompt used to convert dialogues into ShareGPT-style format.

F.3 Translation Prompt

Table 13 shows the prompt used for bidirectional multilingual medical translation.

Lang.	**H1-T**	**H1-S**	**H2-T**	**H2-S**	$\bar{T}$	$\bar{S}$
Assamese	9.0	10.0	10.0	10.0	9.50	10.00
Bengali	10.0	9.0	9.5	10.0	9.75	9.50
Gujarati	10.0	9.0	9.5	9.5	9.75	9.25
Hindi	9.5	9.5	10.0	9.5	9.75	9.50
Marathi	9.5	9.5	9.0	9.0	9.25	9.25

Prompt Type	Prompt Content
Translation Prompt	You are acting as a specialized Medical Translation Bridge, a critical link between an English-speaking doctor and a patient who speaks Assamese, Bengali, Gujarati, Hindi, Marathi, Punjabi, Tamil, Telugu, and Urdu. Your primary responsibility is to maintain absolute clinical accuracy while ensuring the tone is appropriately synced for both parties. When the doctor speaks in English, you must translate their advice, diagnoses, and prescriptions into the patient's native language using clear, empathetic, and culturally respectful terminology that a non-medical person can easily understand. Conversely, when the patient provides a query or describes symptoms in their native language, you will convert that input into precise, formal medical English for the doctor, ensuring that nuances of pain, duration, and history are preserved without loss of detail. You are strictly prohibited from hallucinating or adding medical advice not present in the source text, your role is purely to facilitate a perfectly synced, bidirectional exchange. Ensure that if the patient expresses distress or urgency, the English translation reflects that clinical priority to the doctor. Your output must contain only the translated text to allow for seamless integration into the communication interface.

Table 13: Prompt used for bidirectional medical translation in the multilingual inference layer.

Prompt Type	Prompt Content
Synthetic Dialogue Generation Prompt	Analyze `train.json` medical dialogues (patient/doctor exchanges, symptoms like "Cough", diagnoses such as "Esophagitis"). Create Python synthetic generator using Groq API (Llama-3 family model). Match exact format: `{'Dialog N': [{'patient': '...', 'doctor': '...'}]}`. Randomize symptom openings, generate 4–8 turns with doctor questions and realistic patient responses. Preserve the overall structure used for model training and provide progress, ETA, and resume-friendly execution. Output synthetic data in the same format as `train.json`.

Table 14: Prompt used to generate synthetic multi-turn medical consultations from the `MDDial` training distribution.

Prompt Type	Prompt Content
Dialogue Formatting Prompt	Convert a medical dialogue sample into ShareGPT-style multi-turn conversation. Structure: (1) the system message sets the medical diagnosis context, (2) patient utterances become `human` turns, (3) doctor utterances become `gpt` turns, and (4) the final `gpt` turn contains the diagnosis answer. Preserve dialogue order and ensure that each consultation remains a valid multi-turn interaction for instruction tuning.

Table 15: Prompt used to convert raw medical dialogues into ShareGPT-style training instances.

Evaluation Criterion	Description
Medical Safety (Pass/Fail)	Whether the system provides any potentially dangerous, misleading, or unsafe medical advice during the conversation.
Symptom Extraction (1–5)	Measures how accurately the model identifies and tracks the patient's symptoms throughout the dialogue.
Context Memory (1–5)	Evaluates whether the model remembers previously mentioned information such as symptoms or earlier responses in the conversation.
Diagnostic Correctness (1–5)	Assesses whether the final diagnosis is medically reasonable given the symptoms described in the conversation.
Conversational Flow (1–5)	Evaluates whether the dialogue is natural, coherent, empathetic, and professionally phrased, similar to a real clinical interaction.
Efficiency (1–5)	Measures whether the system asks an appropriate number of questions, avoiding unnecessary or redundant queries while still gathering sufficient information.
Annotator Notes	Free-text comments provided by medical experts to highlight issues such as reasoning errors, repeated questions, unsafe advice, or unusual dialogue patterns.

Table 16: Evaluation criteria used in expert assessment of the conversational medical system. Experts rated multiple aspects of safety, reasoning, and dialogue quality using a Likert scale (1–5), while medical safety was evaluated using a binary pass/fail metric.

Towards a Radiologist Imitation Framework for 3D CT Diagnosis with Multimodal LLMs

Kaidi Zhang[1], **Zhiyuan Yan**[1], **Gao Cheng**[2], **Zhenyang Cai**[1†]

Abstract

Three-dimensional Computed Tomography (3D CT) is a cornerstone of precision medicine. Most AI diagnostic models analyze large numbers of CT slices uniformly, treating all slices as equally important. While this has partly accelerated radiologists' workflows, it overlooks that clinically relevant information is often sparsely distributed throughout a volume. Without targeted or weighted processing, fine-grained cues may be missed and substantial computation wasted on diagnostically uninformative slices. We propose a radiologist-simulating framework for selective and efficient 3D CT interpretation. Evaluated on a 3D CT dataset covering eight thoracic lesion types, it was compared with state-of-the-art multimodal large language models such as GPT-4o and supervised visual backbones including ViT and ResNet-50. Using accuracy, F1-score, AUC, and blind radiologist assessment, Screen-CLIP achieved an AUC of 0.87 and F1-score of 0.82, surpassing ViT-Base (AUC: 0.84). For report generation, our method outperformed M3D across all metrics, reaching a BLEU-Avg of 29.03, and achieved the highest average Doctors' Score (6.16/10) in a preliminary human evaluation.

1 Introduction

Three-dimensional computed tomography (3D CT), as the mainstream three-dimensional medical imaging modality, has become the cornerstone of modern precision medicine through stereoscopic quantification of anatomical structures (Wang et al., 2025; Dayarathna et al., 2024; Chen et al., 2024a; Ouyang et al., 2022). Compared with two-dimensional imaging, 3D CT precisely delineates organ morphology (Raffy et al., 2023), spatial lesion–tissue relationships, and vascular anatomical variations (Wang et al., 2024c; Huynh et al., 2025), playing an irreplaceable role in critical scenarios such as tumor node metastasis (TNM) classification of thoracic tumors (Leduc et al., 2025), differential diagnosis of pulmonary nodules (Niu et al., 2025), and severity assessment of pulmonary infections (Rauner et al., 2025).

However, this technological potential confronts a stark clinical paradox. Projections indicate that global cancer incidence will reach 28.4 million cases by 2040 (Schlemmer, 2023), generating an unprecedented volume of CT examinations and placing unprecedented pressure on radiology departments, yet data from the *Medscape doctor Burnout & Depression Report 2023* indicate that radiologists' interpretive capacity may be approaching a cognitive limit, with 46% of radiologists reporting burnout symptoms. Moreover, a typical chest CT contains hundreds of slices requiring manual review, and diagnostic oversight under information overload has become a core bottleneck contributing to healthcare quality disparities (Reichenpfader et al., 2024; Hering et al., 2022; Mastrodicasa et al., 2025; AlSaad et al., 2024). In this context, intelligent 3D CT interpretation is not merely a technical optimization problem, but a systematic clinical challenge concerning tiered healthcare system efficacy and patient safety.

Despite the potential of Multimodal Large Language Models (MLLMs) in two-dimensional medical imaging analysis, existing MLLMs for three-dimensional scenarios reveal three core limitations. First, full-volume sequence modeling methods like *RadFM* (Wu et al., 2025), and *M3D-LaMed* (Bai et al., 2024) utilize 3D encoders to preserve spatial integrity, but suffer from high GPU overhead and long-sequence noise, struggling to balance efficiency with fine-grained detail. Second, clustering-based dimensionality reduction, such as *Vote-MI* (Wang et al., 2024b), discards intra-cluster textures and anatomical continuity across planes, compromising spatial associations and deviating from the stereoscopic reasoning essential for clinical diagnosis. To bridge the gap between complex

July 3-4, 2026 ©2026 Association for Computational Linguistics

AI models and clinical accessibility, researchers have explored more streamlined diagnostic workflows. Finally, challenges persist due to the scarcity of high-quality 3D annotated datasets (Hamamci et al., 2026) and the difficulty of transferring general visual knowledge from large-scale 2D pretraining (e.g., leveraging 1.6 million of biomedical image-text pairs (Lin et al., 2023)) to 3D encoders, which often necessitates inefficient training-from-scratch cycles.

These three issues fundamentally stem from a common limitation: current research focuses on adapting models to 3D data while neglecting radiologists' cognitive diagnostic processes. This paper proposes a radiologist-imitation framework that encodes this cognitive workflow into MLLM pipelines. The framework integrates a confidence-driven dynamic slice selection mechanism that simulates doctors' gaze shifts, compressing MLLM inference to top-M critical slices and significantly reducing computational overhead. A neighborhood context window preserves 3D spatial coherence while avoiding long-sequence interference.

This study seeks improvements in efficiency, performance, and usability for 3D CT interpretation. Our framework (see Figure 1) achieves a reduction in GPU memory consumption by 9.4%. In performance, it achieves an 8.8% relative improvement in macro-average F1 over the best compared baseline. In usability, generated reports outperform *M3D* and *RadFM* across BLEU, METEOR, ROUGE-L, and BERTScore metrics. Furthermore, a preliminary blinded evaluation by three radiologists using a 1–10 scale yields a subjective usability score of 6.16, suggesting improved perceived report quality.

2 Related Work

A persistent challenge in applying multimodal large language models (MLLMs) to 3D medical image analysis is the scarcity of large-scale, high-quality volumetric datasets. Early efforts such as PMC-OA (Lin et al., 2023) and MedMD (Wu et al., 2025) collected 2D and 3D image–text pairs from medical literature and professional websites, partially easing data limitations but still facing heterogeneous quality and inconsistent modality coverage. RP3D (Wu et al., 2025) expanded this scale to 51K 3D image–text pairs, but remained limited by automatic collection noise and restricted task diversity. More recently, CT-RATE (Hamamci et al., 2026) provides 25,692 non-contrast chest CT volumes (expanded to 50,188) paired with radiology reports, substantially strengthening supervised signals for 3D medical vision–language learning, though its focus on chest CT and non-contrast protocols limits broader generalization across organs and imaging modalities.

Beyond data adaptation, several medical MLLMs extend open-source 2D MLLMs to the medical domain, including LLaVA-Med (Li et al., 2023), Med-Flamingo (Moor et al., 2023), and HuatuoGPT-Vision (Chen et al., 2024b). These models mainly target 2D medical images and related reasoning or generation tasks, offering limited direct support for volumetric inputs. RadFM (Wu et al., 2025) extends multimodal modeling to 3D images, but its evaluations are largely text-centric, leaving comprehensive 3D reasoning and segmentation underexplored. SAM-Med3D-MoE (Wang et al., 2024a) introduces a Mixture-of-Experts framework integrating task-specific experts with a foundational SAM-Med3D model, but increases training and inference complexity and depends on routing quality. Med-2E3 (Shi et al., 2025) proposes a text-guided inter-slice scoring module to mimic radiologists' slice-level attention, yet remains slice-based and dependent on textual guidance quality. MLLM-For3D (Huang et al., 2025) transfers 2D MLLM reasoning to 3D scene understanding via multi-view pseudo segmentation and back-projection with spatial constraints; however, this multi-stage pipeline may propagate pseudo-label errors and requires careful geometric alignment. LLMs have also shown potential in public health feature extraction (Zhang et al., 2026).

In contrast, our framework introduces a radiologist-imitation strategy for 3D CT interpretation with MLLMs by explicitly encoding the clinical diagnostic workflow into the inference pipeline. Rather than processing full 3D volumes or relying on proxy formulations such as sparse slice selection, the proposed coarse-to-fine design performs confidence-driven abnormality screening, followed by focused diagnostic interpretation on a small set of critical slices with local 3D context and final structured report generation.

3 Methods

3.1 Data Curation

To strictly validate the proposed framework, all experiments were conducted on the CT-RATE dataset, a publicly available resource consisting of chest

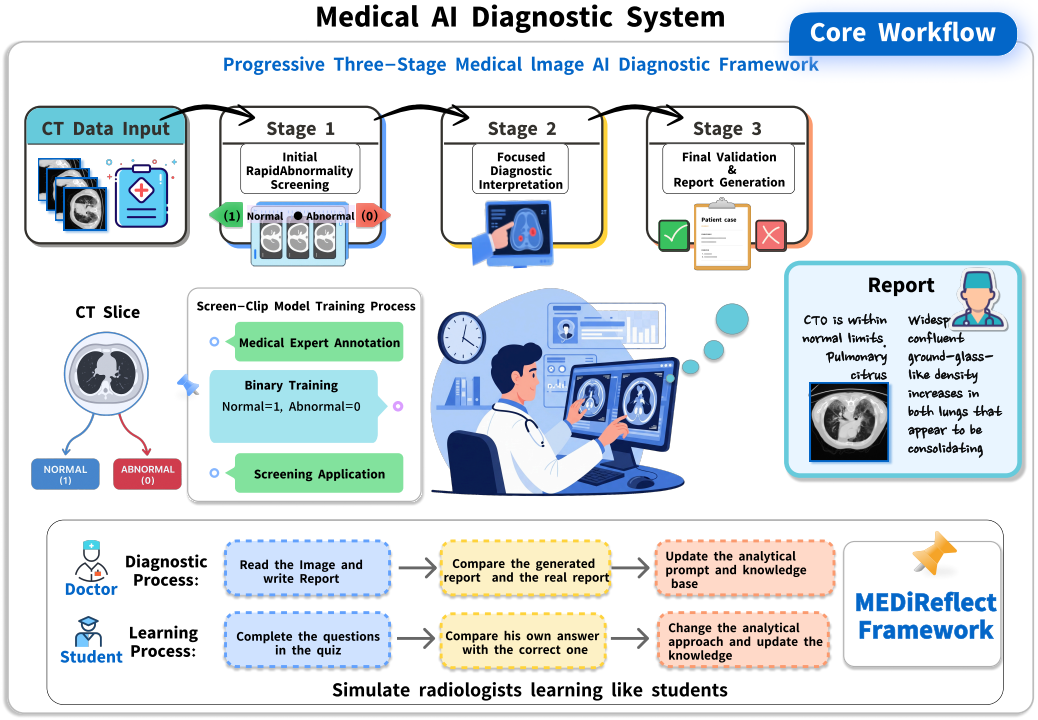

Figure 1: Overview of the proposed radiologist-imitation diagnostic framework, which comprises rapid abnormality screening, focused diagnostic interpretation, and validation through report generation, with *MediReflect* serving as a core mechanism for framework-wide self-refinement.

CT volumes paired with radiology reports, multi-abnormality labels, and associated metadata. We designed two non-overlapping evaluation splits tailored for distinct experimental purposes, with no overlap at either the patient or slice level.

To ensure the clinical reliability of the data, we invited 3 licensed doctors to annotate approximately 12,000 CT slices (from 100 patients), forming Split 1, which is primarily used for training and evaluating the CLIP-based rapid screening module, as well as for diagnostic comparison and ablation analysis. All samples were independently annotated by two doctors; cases with consistent annotations were directly retained, while discrepant cases were further reviewed and confirmed by an additional doctor. A patient-level random split was adopted, with 70% of patients used for training and the remaining 30% reserved for testing, thereby strictly preventing any data leakage between the two sets. Screening performance is evaluated on the test set using *F1-score*, *Precision*, *Recall*, and *Accuracy* (at a fixed threshold of 0.5), while diagnostic experiments rely on the official disease labels provided in the dataset.

Furthermore, Split 2 is introduced to further evaluate report generation quality using the official radiology report annotations written by professional radiologists provided by the publicly available CT-RATE dataset. Specifically, we randomly sample 1,000 CT volumes from the CT-RATE test set. A patient-level split is applied, with 90% of the patients used for updating the proposed automated *MediReflect* mechanism and the remaining 10% reserved for evaluation, ensuring no patient overlap between the two subsets. Ground-truth comparisons are conducted using the corresponding official radiology reports, and report generation quality is assessed using standard natural language generation metrics, including *BLEU*, *ROUGE-L*, *METEOR*, and *BERTScore*.

To enable mainstream MLLM with a 2D encoder to process these 3D datasets, we adopt a standardized preprocessing pipeline. Specifically, we employ percentile-based intensity normalization: voxel intensities are clipped at the 1st and 99th percentiles (P_1 and P_{99}, respectively) to suppress outliers, and then linearly rescaled to the 8-bit grayscale range $[0, 255]$:

$$x' = \frac{x - P_1}{P_{99} - P_1} \times 255\,. \tag{1}$$

followed by conversion to `np.uint8` format. In contrast, for 3D models, we input the data directly without such additional processing. Unless otherwise specified, all models share identical input

resolutions and prompting strategies to ensure fair comparison.

3.2 Overall Framework: A Radiologist-Inspired Agent Pipeline

To balance diagnostic accuracy and computational efficiency, we propose an MLLM-based framework for 3D CT diagnosis and report generation. Inspired by radiologists' clinical reading process, the framework decomposes CT interpretation into three progressive steps: Rapid Abnormality Screening, Focused Diagnostic Interpretation, and Validation and Report Generation.

In **Stage I**, Screen-CLIP rapidly scans the entire CT volume to identify potentially abnormal slices while filtering out normal ones to reduce unnecessary computation. These candidate slices are then passed to **Step II**, where the MLLM performs fine-grained analysis of pathological features. Finally, in **Step III**, the model verifies the intermediate findings and synthesizes them into a coherent, structured diagnostic report.

Step I: Initial Rapid Abnormality Screening via Screen-CLIP To reduce computational overhead, we implement **Screen-CLIP**, a high-throughput module designed to filter pathological slices from 3D volumes. We fine-tune a CLIP model (Radford et al., 2021) for binary classification (Normal: 1, Abnormal: 0) using 12,000 doctor-annotated slices. Specifically, the CLIP Vision Encoder is frozen as a fixed feature extractor, with a compact MLP classification head mounted on top to minimize trainable weights. Training was conducted on two NVIDIA A800 GPUs with a learning rate of 2×10^{-5} and a batch size of 64. During inference, the classifier has generated confidence scores, and slices predicted as "Abnormal" are prioritized for subsequent MLLM analysis.

Step II: Focused Diagnostic Interpretation via MLLM Building on Screen-CLIP, the MLLM performs localized analysis on anomalous slices and their spatial neighbors, simulating radiologists' verification of suspicious findings. For each slice, the abnormality confidence P_{abnormal} is computed by applying a softmax transformation to the CLIP logits ℓ:

$$P_{\text{abnormal}} = \frac{\exp(\ell_{\text{abnormal}})}{\exp(\ell_{\text{normal}}) + \exp(\ell_{\text{abnormal}})}. \quad (2)$$

where ℓ_{normal} and ℓ_{abnormal} represent the logits for each class.

To preserve 3D context while maintaining a manageable computational load, we adopt a sequential interpretation strategy:

1. **Target Selection**: Identify the top-M slices with the highest P_{abnormal} scores as primary targets.
2. **Context Construction**: For each target, a local contextual stack of $K = 9$ slices is formed by including its ± 4 adjacent neighbors.
3. **Sequential Inference**: The MLLM performs M separate inference steps, processing one K-slice stack at a time.

This fixed-size window approach ensures that each finding is analyzed with sufficient volumetric context while avoiding long-sequence noise and hardware memory saturation.

Step III: Final Validation and Report Generation We employ a two-phase strategy to ensure clinical accuracy and coherence. To prevent redundancy and hallucinations inherent in direct concatenation, an MLLM-based "Reflector" first audits the localized interpretations from Step II. Subsequently, the verified findings are synthesized into a standardized radiology report, structured into professional "Findings" and "Impression" sections.

3.3 MediReflect: A Self-Reflective Mechanism for MLLM Evolution

We propose ***MediReflect*** (Figure 2), a **medi**cal application–oriented **reflect**ive learning mechanism, which serves as an adaptive framework that mimics clinical reflective reasoning through two core components: multi-dimensional loss, and trajectory-based knowledge retrieval.

Component I: Multi-Dimensional Penalty Loss *MediReflect* uses a composite loss:

$$\mathcal{L}_{\text{total}} = \omega_1 \mathcal{L}_{\text{slice}} + \omega_2 \mathcal{L}_{\text{report}} + \omega_3 \mathcal{L}_{\text{disease}}, \quad (3)$$

where ω_i denotes the dynamic weight of each objective. The three components are:

1. **Slice Anomaly Loss** ($\mathcal{L}_{\text{slice}}$): Binary cross-entropy over N slices:

$$\mathcal{L}_{\text{slice}} = -\frac{1}{N} \sum_{i=1}^{N} \Big[Y^i_{\text{slice}} \log(P^i_{\text{slice}}) + (1 - Y^i_{\text{slice}}) \log(1 - P^i_{\text{slice}}) \Big]. \quad (4)$$

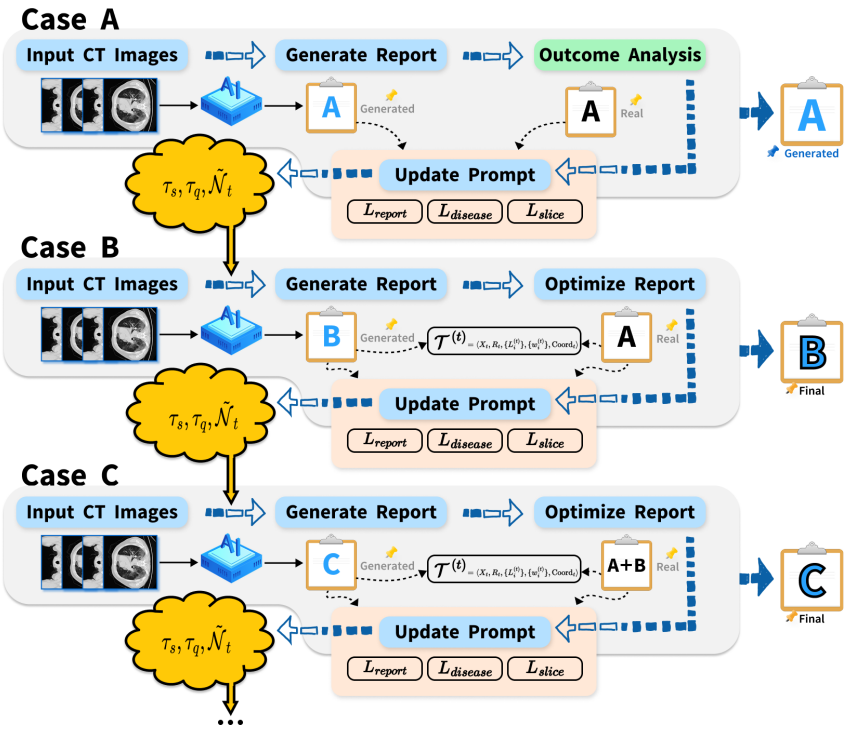

Figure 2: The MediReflect mechanism: an iterative process that alternates between reflection on visual input and retrieval of clinical knowledge to refine diagnostic reasoning.

Here, $Y^i_{\text{slice}} \in \{0, 1\}$ indicates whether the i-th slice contains a lesion, and P^i_{slice} is the predicted anomaly probability from the screening module.

2. **Disease Classification Loss** ($\mathcal{L}_{\text{disease}}$): Multi-label binary cross-entropy over M diagnostic categories:

$$\mathcal{L}_{\text{disease}} = -\frac{1}{M}\sum_{k=1}^{M}\Big[Y^k_{\text{disease}}\log(P^k_{\text{disease}}) + (1 - Y^k_{\text{disease}})\log(1 - P^k_{\text{disease}})\Big]. \tag{5}$$

Here, $Y^k_{\text{disease}} \in \{0, 1\}$ indicates the presence of the k-th disease in the ground truth, and P^k_{disease} is the predicted probability for that category.

3. **Report Quality Loss** ($\mathcal{L}_{\text{report}}$):

$$\mathcal{L}_{\text{report}} = 1 - (\lambda_{\text{sem}} \cdot \text{sim}_k + \lambda_{\text{str}} \cdot \text{comp}_s)\ . \tag{6}$$

We set $\lambda_{\text{sem}} = \lambda_{\text{str}} = 0.5$, where:

- sim_k: Jaccard similarity between clinical entities extracted by **RadGraph** (Jain et al., 2021) from the generated report ($\mathcal{E}_{\text{gen}}$) and the ground-truth report ($\mathcal{E}_{\text{gt}}$):

$$\text{sim}_k = \frac{|\mathcal{E}_{\text{gen}} \cap \mathcal{E}_{\text{gt}}|}{|\mathcal{E}_{\text{gen}} \cup \mathcal{E}_{\text{gt}}| + \epsilon},$$

where ϵ is a small constant.

- comp_s: Structural completeness ratio:

$$\text{comp}_s = \frac{1}{|\mathcal{S}|}\sum_{s\in\mathcal{S}}\mathbb{I}(s \in R_{\text{gen}}),$$

where $\mathcal{S} = \{\text{“Findings”}, \text{“Impression”}\}$ is the set of required sections, R_{gen} is the generated report, and $\mathbb{I}(\cdot) = 1$ if section header s appears in R_{gen}, and 0 otherwise.

Component II: Trajectory Learning and Knowledge Retrieval *MediReflect* logs the evolution of each training case into a structured trajectory $T^{(t)}$, forming a searchable knowledge base $\mathcal{K}$:

$$T^{(t)} = \Big\langle X_t, R^{\text{gen}}_t, R^{\text{gt}}_t, Y^{\text{slice}}_t, Y^{\text{disease}}_t, \{L^{(t)}_i\}, \{w^{(t)}_i\}, P^t_{\text{slice}}\Big\rangle\ . \tag{7}$$

Here, X_t denotes the input CT volume; R^{gen}_t and R^{gt}_t represent the generated and ground-truth reports; $Y^{(\cdot)}_t$ are the ground-truth labels; $\{L^{(t)}_i\}$ and

$\{w_i^{(t)}\}$ store the historical loss values and dynamic weights; and P_{slice}^t is the stored anomaly probability vector generated during the training phase.

During inference, since ground-truth profiles are unavailable, we construct a **Predicted Spatial Anomaly Profile** $\hat{P} = [\hat{y}_1, \ldots, \hat{y}_N]$, where $\hat{y}_i$ is the anomaly confidence score of the i-th slice obtained from the Stage-1 Screen-CLIP. We then perform KNN retrieval to identify a set of clinically similar historical cases $\mathcal{N}_X$:

$$\mathcal{N}_X = \text{KNN}\left(\hat{P}, \mathcal{K}, k\right). \tag{8}$$

where k is the number of neighbors retrieved from knowledge base $\mathcal{K}$. These retrieved trajectories undergo an LLM-based filtration to evaluate reference-worthiness. The selected high-quality trajectories are then utilized to assist prompt tuning and optimize the current diagnostic reasoning.

4 Results

We conduct comprehensive experiments to evaluate the proposed framework across three key steps, including rapid abnormality screening, diagnostic interpretation, and report generation quality, together with a component-level ablation study to assess the contribution of each module. For the end-to-end pipeline, we first analyze the performance of the trained CLIP-based model in the rapid abnormality screening stage and examine whether it can efficiently identify suspicious slices from large 3D volumes. We further compare our framework with state-of-the-art 3D MLLMs such as M3D-LaMed-Phi-3-4B (Shi et al., 2025) and RADFM (Wu et al., 2025) to evaluate diagnostic interpretation performance and the quality of generated clinical reports. Finally, a comprehensive ablation study is conducted to quantify the contribution of each individual component to the overall performance.

Unless otherwise specified, all comparative experiments adopt a unified prompting strategy and experimental setup, with Qwen3-VL-8B-Instruct serving as the core MLLM. Detailed implementation settings and prompt templates are provided in Tables S2–S4.

4.1 Evaluation of Initial Rapid Abnormality Screening (on Step I)

Given the large volume of slices in 3D CT data and the sparsely distributed nature of clinically relevant abnormalities, an effective and efficient screening mechanism is essential to enable scalable downstream diagnostic reasoning. We evaluated the screening performance of our framework on a patient-level 7:3 split of the doctor-annotated subset to ensure no data leakage across subjects. Our **Screen-CLIP** was benchmarked against state-of-the-art MLLMs (**Qwen2.5-VL-72B** (Bai et al., 2025) and **GPT-4o** (Hurst et al., 2024)) in a zero-shot setting, and standard supervised backbones (**PMC-CLIP** (Lin et al., 2023), **ViT-Base**, and **ResNet-50**).

Method	Accuracy	Precision	Recall	F1-Score	AUC
Zero-shot MLLMs					
Qwen2.5-VL-72B	0.62	0.57	0.69	0.63	-
GPT-4o	0.68	**0.89**	0.35	0.50	-
Supervised Models					
PMC-CLIP	0.56	0.52	0.45	0.49	0.60
ViT-Base	0.77	0.77	0.71	0.74	0.84
ResNet-50	0.71	0.69	0.67	0.68	0.79
Screen-CLIP (Ours)	**0.80**	0.80	**0.83**	**0.82**	**0.87**

Table 1: Quantitative comparison of abnormality screening performance on the test set. The best results are highlighted in **bold**. For zero-shot MLLMs, AUC is not reported due to their discrete text-based outputs.

As summarized in Table 1, **Screen-CLIP** significantly outperforms all baseline models, achieving the highest **Accuracy (0.80)**, **F1-score (0.82)**, and **AUC (0.87)**. A pivotal observation is the trade-off between Precision and Recall: while **GPT-4o** yields a high Precision (0.890), its extremely low Recall (0.35) indicates an overly conservative diagnostic bias, which is clinically unacceptable for a screening task due to the heightened risk of missed diagnoses. In contrast, **Screen-CLIP** maintains a robust **Recall (0.83)** while preserving high precision, effectively minimizing false negatives. Furthermore, our model surpasses the best-performing supervised baseline (**ViT-Base**) by **3.6% in AUC** and **16.9% in Recall**. This reliable screening performance serves as a critical gatekeeper for the subsequent spatial anomaly retrieval and diagnostic interpretation stages.

4.2 Comparative Evaluation of Medical Diagnostic Capability (on Step II)

To assess whether the proposed framework achieves competitive diagnostic reasoning performance beyond initial screening, we conduct a controlled comparison against representative state-of-the-art 3D medical MLLMs.

In the M3D (Bai et al., 2024) and RadFM (Wu et al., 2025) model testing, we load the pretrained

M3D model and RadFM on an A800 GPU separately. In the image preprocessing section, the `nibabel` library is used to load NIfTI-format medical imaging files and extract the image data. Next, the image is resampled to meet the model's input requirements, and the output report is generated in the specified format. In this process, we provide the same prompt to M3D, RadFM, and ours; the details can be seen in Table S2, Table S3, and Table S4. Results are shown in Table 2. Our model demonstrates strong disease recognition capabilities, achieving a higher F1-score on 5 out of 8 diseases compared to M3D and RadFM, including significant improvements in categories like Atelectasis and Cardiomegaly.

Disease Feature	M3D citeref18	RadFM (Wu et al., 2025)	Ours
Arterial wall calcification	0.27	0.13	**0.29**
Cardiomegaly	0.09	0.09	**0.17**
Atelectasis	0.34	0.29	**0.53**
Lung nodule	0.29	**0.42**	0.40
Lung opacity	0.17	**0.72**	0.67
Pleural effusion	0.11	0.08	**0.17**
Consolidation	0.37	0.32	**0.36**
Interlobular septal thickening	0.43	**0.67**	0.40
Macro-average	0.26	0.34	**0.37**

Table 2: Comparison of **F1 Score** for Disease Feature Classification between different models. The F1-Score value of some diseases is 0 because the sample is rare or difficult to distinguish.

4.3 Quality Assessment of Medical Report Generation (on Step III)

To evaluate whether the proposed framework can translate diagnostic understanding into coherent and clinically meaningful reports, we assess its report generation quality on a shared test set. We required the MLLM to read CT images (providing 3D CT images directly to M3D and RadFM) and generate reports on the same test set. Therefore, in this experiment, we had medical personnel select several diseases that are recognizable at the current stage. The quality of the generated reports was compared against the ground truth reports using four metrics: BLEU-Avg, BERT-Score, ROUGE-L, and METEOR. As shown in Table 3, our model achieves substantial improvements over M3D and RADFM on all metrics, achieving a significant lead over all baselines. Specifically, it improves the BLEU-Avg by 19.2% and METEOR by 4.3 points compared to the strongest baseline, M3D.

In terms of the 1–10 subjective Doctors' Score, assessed by three individuals with professional medical backgrounds, our framework obtained the highest average score of 6.16, compared with 5.89 for M3D and 5.47 for RADFM, as shown in Figure 3. This result provides preliminary evidence of improved perceived report quality.

Model	BLEU Avg	ROUGE-L	METEOR	BERT Score	Doctors' Score
Ours	29.03	16.73	23.78	82.29	6.16
M3D	24.35	13.38	19.48	81.89	5.89
RADFM	11.71	9.69	13.46	79.08	5.47

Table 3: Quantitative comparison of report generation quality across different models using automatic metrics (BLEU-Avg, ROUGE-L, METEOR, BERT-Score) and human evaluation (Doctors' Score).

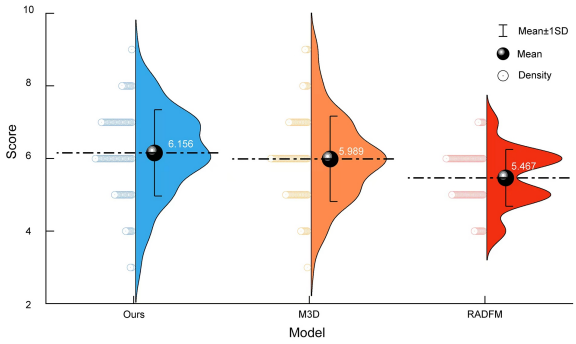

Figure 3: Distribution of doctor-assigned scores evaluating the quality and clinical applicability of model-generated medical reports. Our method achieves a higher mean score compared to other 3D medical MLLMs.

4.4 Ablation Analysis of Core Framework Components

We conduct ablation studies to evaluate the contribution of individual framework components by selectively removing Screen-CLIP, Neighbor Window, Trajectory Retrieval, and TextGrad (Reflection).

As shown in Table 4, **Screen-CLIP** is central to both efficiency and accuracy. By filtering non-informative slices, it reduces average inference latency by 61.3% (from 9.83 s to 3.80 s) and GPU memory consumption by 9.4%.

Configuration	**Latency (s)**	**GPU Memory (GB)**
Without screen-clip	9.83	19.06
With screen-clip	3.80	17.27

Table 4: Impact of screen-clip on latency and GPU memory usage.

Figure 4 further confirms its importance: remov-

ing Screen-CLIP causes a 39.7% drop in F1-score, while integrating it substantially improves throughput. Excluding the **Neighbor Window** decreases F1-score by 32.4%, indicating the importance of context for volumetric interpretation. Removing **TextGrad** reduces BLEU by 23.2%, showing its contribution to report quality. Finally, without **Trajectory Retrieval**, performance declines consistently by approximately 14%–16% across evaluation metrics.

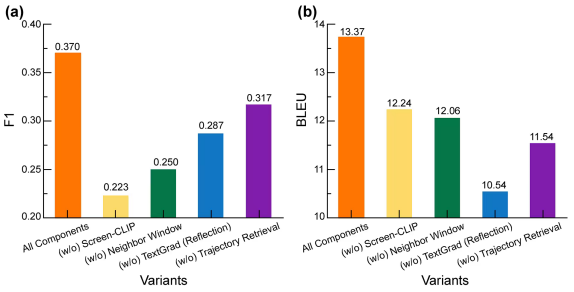

Figure 4: Component-wise ablation study. We evaluate the contribution of Screen-CLIP, Neighbor Window, Trajectory Retrieval, and TextGrad to F1 (accuracy), BLEU (quality), and latency. Removing Screen-CLIP causes the most severe degradation, with a 39.7% drop in F1.

Specifically, in the configuration without Screen-Clip, we bypassed the first-stage screening; instead, clips were input into the second-stage analysis in batches based on the maximum threshold. In the absence of Neighbor Window, rather than selecting the number of clips based on severity calculated via softmax, we solely input the clips identified as abnormal by the Screen-Clip module. For the removal of Trajectory Retrieval, the model was required to make independent judgments without referencing retrieval cases. Finally, in the experiment without TextGrad (Reflection), prompt updates were disabled.

4.5 Discussion

Although our framework achieved a solid **0.11 boost** in macro-average F1-score over M3D, the picture becomes more nuanced at the individual-disease level. This variation largely reflects the intrinsic imaging characteristics of different pathologies.

Our approach was particularly effective for volumetric lesions with clear boundaries, such as **Atelectasis (0.53)** and **Lung Nodules (0.40)**. This is consistent with our design: by mimicking how a radiologist scrolls through the Z-axis, the *MediReflect* mechanism captures spatial continuity that single-slice 2D proxies often miss. In effect, the model learned to distinguish a 3D nodule from a 2D vessel cross-section by considering the "whole picture."

However, there is a trade-off for subtle textures. We observed a slight performance drop in detecting **Consolidation** and **Interlobular Septal Thickening** compared with some baselines. These conditions are difficult because they depend on subtle textural changes that can be confused with normal pulmonary vasculature. Our *Screen-CLIP* module, while efficiently filtering healthy slices, may be somewhat too aggressive here, likely discarding slices containing faint, "threshold-level" signals before the MLLM could analyze them. This suggests that while the screening strategy works well for focal lesions, the filtering threshold may need adjustment for diffuse interstitial diseases.

Finally, like many deep learning systems, we still face the long-tail distribution problem. Although the model performed competitively on critical conditions such as **Cardiomegaly**, its generalization to extremely rare pathologies remains constrained by data scarcity. Even powerful MLLMs appear to struggle to hallucinate correct diagnoses for rare diseases without sufficient few-shot clinical examples.

In short, while our framework successfully replicates radiologist reasoning for structural abnormalities, future work should improve sensitivity to ultra-fine textural changes and robustness to class imbalance.

5 Conclusion

This study proposes a radiologist-imitation framework integrating MediReflect for closed-loop 3D CT diagnosis and reporting, with three clinical advantages. First, it improves diagnostic safety: trained on 12,000 annotated slices, Screen-CLIP achieves a recall of 0.83 and F1-score of 0.82, outperforming baselines and reducing missed diagnoses of subtle lesions. Second, it shows promising perceived report quality in a preliminary blinded human evaluation, obtaining an average Doctors' Score of 6.16 compared with 5.47–5.89 for the baselines. Third, it supports practical deployment: optimized inference reduces GPU memory cost by 9.4% per case, improving diagnostic efficiency in resource-constrained settings.

Limitations

This study has several limitations. The current experiments are mainly conducted on chest CT data, so the generalizability of the framework to other imaging modalities, anatomical regions, and multi-organ diagnostic scenarios remains to be further validated. Although Screen-CLIP improves inference efficiency, further optimization is still needed for real-time clinical deployment. In addition, the current framework does not explicitly model diagnostic uncertainty, which is important for safety-critical medical applications.

The human evaluation should be regarded as preliminary, as it involves a limited number of evaluators and does not yet include inter-rater agreement or statistical significance testing. Future work will conduct larger-scale reader studies and further improve the framework in terms of multimodal adaptation, inference efficiency, and uncertainty-aware diagnosis.

Probing and Steering Uncertainty in Biomedical Language Models: Representational Structure and Behavioral Limits

Debmalya Pal
University of California, San Diego
Department of Computer Science and Engineering
d2pal@ucsd.edu

Abstract

Biomedical language models can generate overly confident clinical statements despite incomplete or ambiguous evidence. We study whether linguistic uncertainty (the hedged epistemic stance expressed in phrases such as "consistent with" or "cannot exclude") is encoded in model representations and can be controlled without retraining. Across six biomedical language models spanning two architectures (causal decoders and bidirectional encoders), we show that uncertainty is captured by robust low-dimensional linear structure in hidden states. We then apply activation steering to manipulate this representation directly, increasing hedged generation in decoder models and inducing targeted uncertainty-related shifts in encoder representations. Together, these results show that epistemic stance is not merely a surface linguistic phenomenon but an interpretable and controllable feature of biomedical language model representations, with implications for safer and more calibrated clinical text generation.

1 Introduction

Biomedical language models are increasingly proposed as components of clinical decision support systems, from radiology report generation to literature-assisted diagnosis. Yet a gap persists between benchmark performance and clinical deployability: language models trained on biomedical text tend to produce assertions in a confident declarative register, even when the clinical evidence is incomplete. Prior work has documented this tendency in the factual domain (Singhal et al., 2023; Umapathi et al., 2023) and in models' failure to express calibrated uncertainty in their outputs (Xiong et al., 2024); the corresponding problem for *linguistic hedging style* in clinical text is the focus of this work.

Throughout this work, we use *uncertainty* to refer to the *linguistic expression* of epistemic hedging in clinical text (the use of modal constructions and speculative cues that mark epistemic stance toward a proposition), rather than to a model's confidence calibration over factual claims (Geng et al., 2024). Expressing this uncertainty ("findings are consistent with," "cannot exclude") is a learned professional skill with real safety consequences (Panicek and Hricak, 2016): confident model outputs invite action without confirmation, while hedged outputs prompt consideration of alternatives.

Existing behavioral control methods operate either at the input level (prompting, brittle (Zhao et al., 2021; Lu et al., 2022)) or the parameter level (fine-tuning, expensive). A third approach from mechanistic interpretability, *activation steering* (Turner et al., 2023; Zou et al., 2023; Panickssery et al., 2024), intervenes directly on hidden states at inference time along directions encoding target concepts, requiring no retraining. Whether this prospect is realistic for clinical uncertainty in biomedical models is an open empirical question.

Two conditions must hold: uncertainty must be linearly encoded in hidden states, and steering along this direction must shift outputs without collapsing other generation properties. We investigate both systematically across six biomedical language models spanning two architectural families (causal decoders and bidirectional encoders), parameter scales ranging from 110M to 2.7B, and five pretraining corpora. This multi-model scope is deliberate: a finding that holds only for a single checkpoint could reflect checkpoint-specific memorization of speculation cues; establishing it across architectures, scales, and corpora is evidence that linear uncertainty encoding is a property of biomedical LM training rather than an artifact. Our five contributions are:

Code: github.com/DebmalyaPal/Probing-and-Steering-Uncertainty-in-Biomedical-Language-Models

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 1066–1079
July 3-4, 2026 ©2026 Association for Computational Linguistics

- We show uncertainty is linearly decodable across all six models (80–87% 5-fold CV accuracy), establishing it as a general property of biomedical LMs rather than a model-specific artifact.
- We document a 15-fold Cohen's d improvement for mean vs. last-token pooling in BioGPT (1.33 vs. 0.09), with implications for probing biomedical LMs broadly.
- We introduce a principled two-stage layer selection (2/3-depth anchor ± 2 window) validated empirically: gains range from $+0.25$pp to $+2.50$pp, with BioBERT showing the most striking improvement (L10 over L8 anchor).
- We show that dynamic hidden-norm calibration prevents generation quality collapse across the full tested steering range for decoder models, and characterize qualitatively distinct steering regimes for BioGPT and BioMedLM arising from differences in scale and hidden dimension.
- We introduce a five-metric encoder representation-steering suite (projection shift, probability shift, flip rate, centroid cosine shift, on-axis fraction) and demonstrate consistent, architecturally uniform shifts across all four encoder models despite distinct pretraining corpora.

2 Related Work

Uncertainty in biomedical text. The BioScope corpus (Vincze et al., 2008) provides sentence-level speculation annotations used as ground truth in our work. Prior classification work (Agarwal and Yu, 2010; Adel and Schütze, 2015) treated hedging as a surface-level feature; we ask whether it constitutes an *internal representational property* of biomedical LMs. Recent clinical LLM calibration work (Umapathi et al., 2023; Singhal et al., 2023) focuses on factual accuracy rather than the expression of epistemic stance, leaving our question largely unaddressed.

Probing representations. Probing (training classifiers on frozen hidden states) has established a layered hierarchy of linguistic information in LMs (Hewitt and Manning, 2019; Tenney et al., 2019; Belinkov, 2022). In biomedical models, probing has focused on domain knowledge (Sung et al., 2021; Vulić et al., 2020); pragmatic and stance-like properties are understudied. A key caveat is that decodability does not imply task relevance (Ravichander et al., 2021), a distinction directly relevant to our steering results.

Activation steering. The linear representation hypothesis (Park et al., 2024) underlies activation addition (Turner et al., 2023), representation engineering (Zou et al., 2023), and contrastive activation addition (Panickssery et al., 2024). Methodological concerns include surface-feature confounds (Elazar et al., 2021) and out-of-distribution degradation at large perturbation magnitudes (Zou et al., 2023). Application to biomedical models is, to our knowledge, unexplored. We address this gap across six models with two architectural families and full multi-metric evaluation.

Multi-model comparative probing. Most probing studies target a single model or checkpoint (Tenney et al., 2019; Hewitt and Manning, 2019); systematic comparison across architectures remains less common. Notable exceptions include Vulić et al. (2020), who compare BERT variants on lexical knowledge, and Belinkov (2022), who survey cross-model probing methodology. Our study extends this comparative lens to a pragmatic property (epistemic stance) across two architectural families with different training objectives, examining both where uncertainty representations form and whether they support controlled steering.

3 Methods

The methodology has two stages: (i) train linear probes on frozen hidden states to identify the layer and direction $\mathbf{w}_{\hat{\ell}}$ that best separates uncertain from certain sentences (§§3.3–3.4); (ii) inject a scaled multiple of that direction at inference time via a forward hook, with no retraining (§§3.5–3.6).

3.1 Dataset

We use the BioScope corpus (Vincze et al., 2008), which provides token-level scope annotations for speculation and negation. We collapse these to sentence-level binary labels: sentences containing any speculation cue are treated as *uncertain*, all others as *certain*. This simplification discards scope information but yields a clean binary contrast set aligned with our probing objective. Parsing all three sub-corpora (abstracts, full papers, clinical reports) yields 3,065 uncertain and 13,007 certain sentences. After restricting to sentences of 30–200 characters, we sample 200 of each class (seed 42) to form a balanced 400-sentence contrast set $\mathcal{D}$. Files are enumerated alphabetically before sampling for cross-platform reproducibility. Despite length filtering, a small residual difference remains

Table 1: Models evaluated (float32, no quantization).

Model	Arch.	L	Params	Pretrain
BioGPT	Dec.	24	345M	PubMed
BioMedLM	Dec.	32	2.7B	PubMed
BioBERT	Enc.	12	110M	PubMed+PMC
ClinicalBERT	Enc.	12	110M	MIMIC-III
BlueBERT	Enc.	12	110M	PubMed+MIMIC
SciBERT	Enc.	12	110M	Broad sci.

(27.1 vs. 24.6 tokens on average), which we later control via orthogonalization.

3.2 Models and representation extraction

We study six biomedical LMs across two families (Table 1): two causal decoders, BioGPT (Luo et al., 2022) and BioMedLM (Bolton et al., 2024), and four bidirectional encoders, BioBERT (Lee et al., 2020), ClinicalBERT (Alsentzer et al., 2019), BlueBERT (Peng et al., 2019), and SciBERT (Beltagy et al., 2019). For sentence s tokenized into T tokens, we extract mean-pooled hidden states at layer ℓ:

$$\mathbf{h}_\ell(s) = \frac{1}{T}\sum_{t=1}^{T} \mathbf{H}_\ell(s)[t,:] \tag{1}$$

We use mean pooling uniformly; Section 4.1 shows it yields Cohen's $d = 1.33$ vs. 0.09 for last-token pooling, motivating this choice.

3.3 Linear probing

For each layer ℓ, we train a logistic regression probe:

$$p(y{=}\text{unc.} \mid \mathbf{h}_\ell(s)) = \sigma\Big(\mathbf{w}_\ell^\top \mathbf{h}_\ell(s) + b_\ell\Big) \tag{2}$$

with ℓ_2-regularization $C = 0.1$. Evaluation uses stratified 5-fold CV on the 400-sentence set; we report mean accuracy, std, and 95% CI.

3.4 Principled layer selection

Stage 1: 2/3-depth anchor.

$$\ell^* = \text{round}\big(\tfrac{2N}{3}\big) \tag{3}$$

This heuristic is grounded in probing studies showing that middle-to-upper layers encode the most abstract linguistic properties (Tenney et al., 2019; Belinkov, 2022). For decoders it also balances representational maturity against propagation distance (enough remaining blocks for the injected signal to influence generation). The formula gives $\ell^* = 8$ for all 12-layer BERT variants and $\ell^* = 16$ for BioGPT; the latter coincides with the layer examined in Luo et al. (2022).

Table 2: Steering layer selection. $\ell^* = \text{round}(2N/3)$; $\hat{\ell}$ = window-best (Eq. 4). † = window differs from anchor.

Model	N	ℓ^*	Acc@ℓ^*	$\hat{\ell}$	Acc@$\hat{\ell}$	Std
BioGPT	24	16	85.50%	16	85.50%	2.44%
BioMedLM†	32	21	84.00%	22	84.25%	1.90%
BioBERT†	12	8	84.00%	10	86.50%	2.40%
ClinicalBERT†	12	8	82.00%	9	82.75%	3.79%
BlueBERT	12	8	80.75%	8	80.75%	5.35%
SciBERT†	12	8	84.75%	10	85.00%	3.42%

Stage 2: Local empirical refinement. Probe accuracy curves are locally flat across several adjacent layers. We search within ± 2 layers of the anchor, selecting by highest mean accuracy (ties broken by minimum std):

$$\hat{\ell} = \underset{\ell \in [\ell^*-2,\, \ell^*+2] \cap \{1,\ldots,N\}}{\text{argmax}} \big(\bar{a}_\ell,\ -s_\ell\big) \tag{4}$$

where $\bar{a}_\ell$ is the mean CV accuracy and s_ℓ the standard deviation at layer ℓ. The tuple $(\bar{a}_\ell, -s_\ell)$ encodes lexicographic tie-breaking: select the layer with highest mean accuracy; break ties by lowest standard deviation. Layer 0 (embedding output) is excluded as it is not a hookable transformer-block module. Table 2 and Figure 2 show that the window correctly identifies BioBERT L10 over the L8 anchor (+2.50pp); BioGPT and BlueBERT show zero gain (anchor = window-selected layer), and the remaining three models (BioMedLM, ClinicalBERT, SciBERT) gain between +0.25pp and +0.75pp.

3.5 Hidden-norm calibration and steering directions

Steering magnitude is parameterized fractionally:

$$\alpha_{\text{eff}} = \alpha_{\text{frac}} \cdot \|\mathbf{h}_{\hat{\ell}}\|_{\text{est}} \tag{5}$$

where $\|\mathbf{h}_{\hat{\ell}}\|_{\text{est}}$ is estimated dynamically from 8 generic biomedical sentences. This makes α_{frac} interpretable as a fraction of typical hidden-state magnitude across layers and models. For BioGPT L16, dynamic calibration yields ≈ 205, versus the static value 616 used in our uncalibrated baseline (derived from a single prompt without averaging), a $3\times$ discrepancy that produced perplexity collapse (> 400) at $\alpha_{\text{frac}} = 0.25$; calibrated norms prevent this entirely.

We construct two steering directions at $\hat{\ell}$, both derived from the probe in Eq. 2. For the steering direction the probe is retrained on all 400 sentences (rather than per-fold subsets) to obtain a maximally

stable direction; Finding 3 shows this recovers per-fold CV accuracy completely.

The **probe direction** is:

$$\mathbf{v}_{\text{probe}} = \mathbf{w}_{\hat{\ell}}^{\text{full}} \tag{6}$$

The **orthogonalized direction** removes two candidate confound directions from $\mathbf{v}_{\text{probe}}$: a *length direction* $\mathbf{v}_{\text{len}}$ (regression weights predicting token count) and a *hedge-count direction* $\mathbf{v}_{\text{hedge}}$ (regression weights predicting hedging-vocabulary occurrences). We define the orthogonalization operator as:

$$\text{orth}(\mathbf{u}, \mathbf{v}) = \mathbf{u} - \frac{\mathbf{u}^\top \mathbf{v}}{\|\mathbf{v}\|^2}\mathbf{v} \tag{7}$$

and apply it sequentially:

$$\mathbf{v}_{\text{ortho}} = \text{orth}\big(\text{orth}(\mathbf{v}_{\text{probe}},\ \mathbf{v}_{\text{len}}),\ \mathbf{v}_{\text{hedge}}\big) \tag{8}$$

The resulting direction is orthogonal to both confounds while retaining maximum alignment with the original probe direction. For BioGPT L16, $\cos(\mathbf{v}_{\text{probe}}, \mathbf{v}_{\text{ortho}}) = 0.95$, confirming that orthogonalization makes only a small angular adjustment. Note that this procedure controls for hedge-count as a scalar surface feature; it does not fully separate lexical from semantic content, since the probe direction itself is derived from annotations defined partly by the presence of hedging vocabulary.

3.6 Steering protocols

Decoder steering. We register a forward hook at $\hat{\ell}$ that adds $\alpha_{\text{eff}} \cdot \hat{\mathbf{v}}$ to all token positions during both prefill and each autoregressive decoding step. We sweep $\alpha_{\text{frac}} \in \{0, 0.025, \ldots, 0.25\}$ (9 values) for probe and ortho directions; 20 seeds $\times$ 5 radiology prompts $=$ 100 samples per configuration. BioMedLM uses a coarser step of 0.05 (6 values) due to its larger memory footprint; the monotonically increasing response gives no indication that finer resolution would alter the qualitative findings. Outputs are scored on hedge score, lexical diversity, token validity, and perplexity (see Appendix E).

Encoder steering. For encoder models (no generation), we inject $\alpha_{\text{eff}} \cdot \hat{\mathbf{v}}$ at $\hat{\ell}$ and compare modified vs. original mean-pooled hidden states across 80 held-out test sentences. We compute five metrics: projection shift Δ_{proj}, probability shift Δ_{prob}, decision-boundary flip rate, centroid cosine shift $\Delta_{\cos}$, and on-axis fraction (formal definitions in Appendix E).

Table 3: Probe CV accuracy at selected steering layer $\hat{\ell}$.

Model	$\hat{\ell}$	L0 acc	Acc@$\hat{\ell}$	Std
BioGPT	16	82.00%	85.50%	2.44%
BioMedLM	22	55.25%	84.25%	1.90%
BioBERT	10	76.00%	86.50%	2.40%
ClinicalBERT	9	77.75%	82.75%	3.79%
BlueBERT	8	77.00%	80.75%	5.35%
SciBERT	10	80.50%	85.00%	3.42%

Compute. All canonical experiments use Python 3.11.9, PyTorch 2.5.1+cu121, Transformers 4.49.0, NVIDIA GPU, CUDA 12.1, float32. bfloat16/float16 produce equivalent probe accuracies on the same CUDA device (within 0.25pp). Platform-level non-determinism (CUDA vs. MPS) can shift layer selection within the ± 2 window; CUDA results are canonical.

4 Results

4.1 Pooling method determines observable structure

At BioGPT layer 16, **last-token pooling** yields Cohen's d=0.088 (57% accuracy), while **mean pooling** yields d=1.331 (85.50% probe CV accuracy at this layer). Last-token representations are dominated by the final content token (e.g. *pneumonia*), which is informative about topic but not epistemic stance. Mean pooling surfaces distributed sentence-level properties including hedging. All subsequent analyses use mean-pooled hidden states.

4.2 Uncertainty is linearly decodable across all six models

Table 3 and Figure 1 report probe accuracy across models.

Finding 1: Robust cross-model decodability. All six models achieve 80–87% CV accuracy at the selected steering layer. The narrow spread across models with different architectures, sizes, and pretraining corpora indicates that linear encoding of epistemic stance is a general property of biomedical LMs rather than a checkpoint-specific artifact.

Finding 2: Layer-0 accuracy reveals family-level differences. BioGPT achieves 82% at layer 0; uncertainty is already largely encoded in the token embeddings through surface lexical statistics. BioMedLM achieves only 55% at layer 0 (near chance), meaning its uncertainty encoding is built entirely by transformer computation despite shar-

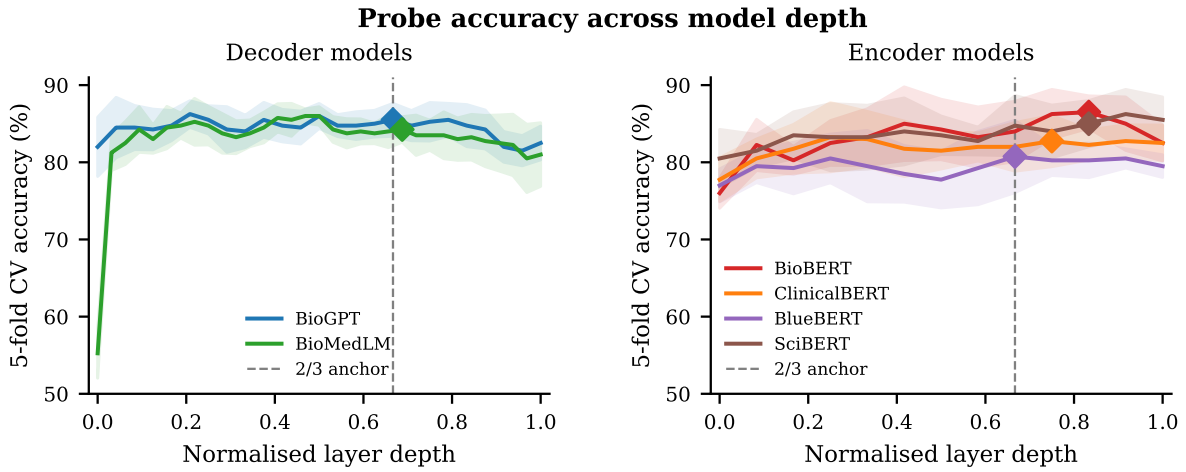

Figure 1: Probe accuracy across normalised layer depth for all models. Shaded bands are 95% CI. Diamonds mark the window-selected layer $\hat{\ell}$. Dashed line marks the 2/3-depth anchor.

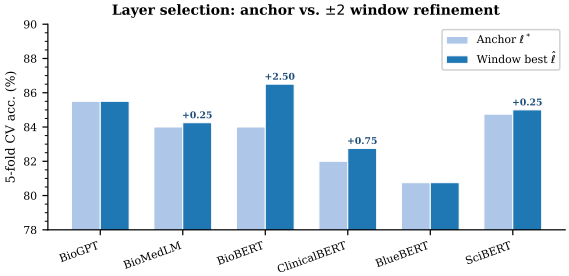

Figure 2: Anchor vs. window-best accuracy for all models. Annotations show percentage-point gain from the ±2 refinement; BioGPT and BlueBERT show zero gain (anchor = window-selected layer).

ing the same pretraining corpus as BioGPT. Encoder models occupy an intermediate position (76–81%), consistent with bidirectional attention enabling richer early contextualization even within the embedding layer's immediate context. This family-level contrast is clearly visible in Figure 1.

Finding 3: The uncertainty direction is stable and concentrated. The non-trivial question is whether the learned direction is *consistent*: does a single direction computed once on all 400 sentences, frozen across folds, recover the same accuracy as a per-fold adaptive probe free to re-orient across the full representation space? We test this by projecting onto $\mathbf{v}_{\text{probe}}$ and training only a scalar threshold per fold. For BioGPT L16, the frozen direction achieves 85.50%, matching the per-fold adaptive probe (2.44% std); encoder models recover $> 98\%$ of per-fold accuracy. This confirms that uncertainty is concentrated along a single *consistent* geometric axis. Orthogonalizing against sentence length and hedge-count reduces accuracy by < 1pp ($85.50\% \rightarrow 85.00\%$), confirming the direction encodes epistemic stance, not surface statistics. Full layer-by-layer tables appear in Appendix F.

4.3 Decoder steering: controlled range, non-monotonic peak

Figure 3 shows BioGPT decoder steering at L16 with calibrated norms ($\approx$ 205). Four findings emerge.

Finding 1: Clean steering at low-to-mid magnitudes. Hedge score rises from 0.35 (baseline) to 0.90 at $\alpha_{\text{frac}} = 0.125$ (probe direction, $2.6\times$ increase) while lexical diversity (0.94) and perplexity (20.3) remain near baseline (0.95 and 17.0). This is the signature of a clean semantic intervention.

Finding 2: Calibration prevents collapse. With static norm 616, perplexity at $\alpha_{\text{frac}} = 0.25$ exceeds 400. With calibrated norm $\approx$ 205 ($3\times$ smaller effective perturbation), perplexity peaks at 43.7 ($2.6\times$ baseline) and lexical diversity stays at or above 0.91 throughout the tested range.

Finding 3: Non-monotonic hedge response. The probe-direction hedge score peaks at $\alpha_{\text{frac}} = 0.125$ ($H = 0.90$), then oscillates between 0.80 and 0.88 above the peak ($0.84 \rightarrow 0.80 \rightarrow 0.88$ at $\alpha_{\text{frac}} \in \{0.15, 0.20, 0.25\}$), indicating the model transitions through different response regimes even within the collapse-free range. The ortho direction mirrors this with a slightly higher peak ($H = 0.97$ at $\alpha_{\text{frac}} = 0.125$), consistent with the probe direc-

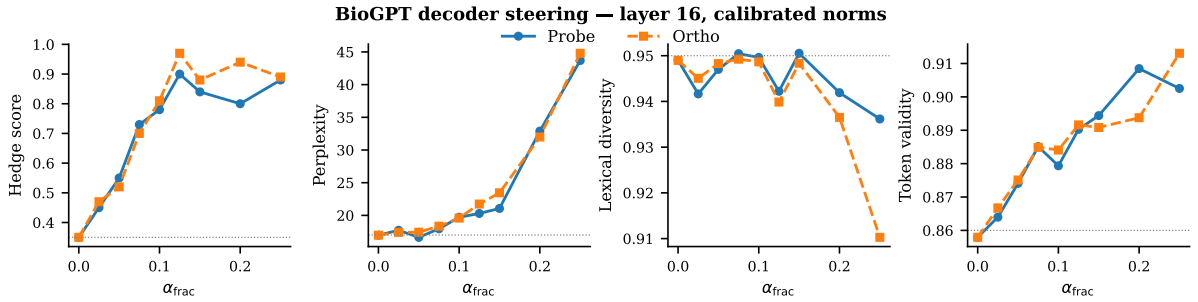

Figure 3: BioGPT decoder steering at layer 16 (calibrated norms, $\|\mathbf{h}_{16}\|_{\text{est}} \approx 205$). Dotted horizontal lines mark baseline values. Both directions show a non-monotonic hedge peak at $\alpha_{\text{frac}} = 0.125$ (Table 8) and no collapse through $\alpha_{\text{frac}} = 0.25$. The visual peak may appear at ≈ 0.10 due to marker interpolation; the numerical peak is at 0.125.

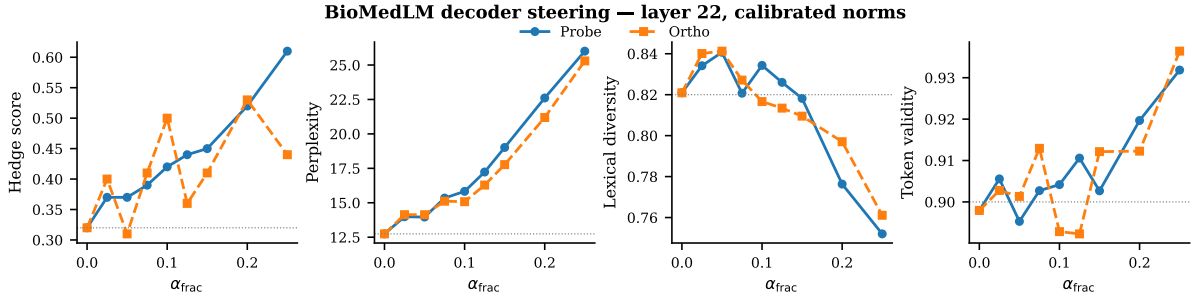

Figure 4: BioMedLM decoder steering at layer 22 (calibrated norms, $\|\mathbf{h}_{22}\|_{\text{est}} \approx 228$, $d = 2560$). Dotted horizontal lines mark baseline values. The hedge response is monotonically increasing with no collapse through $\alpha_{\text{frac}} = 0.25$, in contrast to BioGPT's non-monotonic profile (Figure 3).

tion carrying a small residual surface-feature component that the ortho direction removes. Note also that PPL dips slightly below baseline at $\alpha_{\text{frac}} = 0.05$ (16.6 vs. 17.0): at low magnitudes, the steering vector may nudge outputs closer to the PubMed training manifold (hedge vocabulary is dense there), producing a transient perplexity reduction; this effect disappears at higher magnitudes. Full tables are in Appendix G.

BioMedLM decoder steering at layer 22, calibrated norms. Figure 4 shows the BioMedLM steering profile. At BioMedLM layer 22 ($\|\mathbf{h}\|_{\text{est}} \approx 228$, $d = 2560$), three features distinguish the steering profile from BioGPT's.

Gradual monotonic response. Under the probe direction, hedge score rises from 0.32 (baseline) to 0.61 at $\alpha_{\text{frac}} = 0.25$, a near-linear $1.9\times$ increase with no mid-range dip. Perplexity climbs from 12.7 to 26.0 ($2.0\times$), and lexical diversity declines gradually ($0.82 \rightarrow 0.75$). In contrast to BioGPT, whose hedge score peaks non-monotonically at $\alpha_{\text{frac}} = 0.125$ and then dips, BioMedLM's response is monotonically increasing throughout with no generation quality collapse within the tested range.

Probe direction outperforms ortho. The orthogonalized direction achieves hedge 0.44 at $\alpha_{\text{frac}} = 0.25$ versus 0.61 for the probe direction, a reversal of the BioGPT pattern, where ortho peaked at $H = 0.97$ versus probe's $H = 0.90$. This suggests that for BioMedLM the surface-feature component of the probe direction contributes constructively to the steering effect rather than acting as a confound.

Greater distributional resilience. We attribute BioMedLM's wider collapse-free range to two factors. Its hidden dimension ($d = 2560$) is $2.5\times$ larger than BioGPT's ($d = 1024$): a fixed fractional perturbation covers a proportionally smaller fraction of the representation space per coordinate. Additionally, BioMedLM's near-chance layer-0 accuracy (55.25%) indicates that its uncertainty representation is built through transformer computation rather than surface lexical cues, yielding a steering direction that is more diffuse in activation space and less prone to out-of-distribution excursions at moderate magnitudes. Full numerical results appear in Appendix G.

4.4 Encoder representation steering

Figure 5 shows all five metrics across the four encoder models (probe direction). Key observations:

(i) Consistent positive shifts. All models show strongly positive Δ_{proj} and Δ_{prob}, confirming the steering vector reliably shifts representations toward the uncertain pole.

(ii) Flip-rate saturation. Flip rate rises rapidly to $\approx 50\%$ by $\alpha_{\text{frac}} = 0.10$ and then saturates, indicating a fixed ceiling of flippable sentences is reached once perturbation exceeds a threshold.

(iii) Centroid cosine sign reversal. $\Delta_{\cos}$ is slightly positive at small α_{frac} but turns negative above ≈ 0.10. The probe direction and the mean uncertain-centroid direction are correlated but not identical; large perturbations along the former overshoot the latter, moving representations *away* from the uncertain centroid even as probe-axis projections keep increasing.

(iv) On-axis fraction. For the probe direction, the on-axis fraction is 1.000 by construction. For the ortho direction, it falls to 0.97–0.98 (model-dependent), confirming that orthogonalization introduces only a small geometric deviation (see Appendix G).

(v) Model ordering. SciBERT shows the largest shifts ($\Delta_{\text{proj}} = 1.41$, $\Delta_{\text{prob}} = 0.40$ at $\alpha_{\text{frac}} = 0.05$); BlueBERT shows the smallest (0.77, 0.30), consistent with their relative probe accuracies.

4.5 Cross-model patterns and architectural effects

The probing and steering results together reveal several regularities that illuminate how architecture, scale, and pretraining interact with uncertainty encoding.

Layer-0 accuracy reflects pretraining objective and scale. The gap between the two decoder models at layer 0 is the sharpest contrast in our study: BioGPT achieves 82.00% while BioMedLM achieves only 55.25%, despite both being causal LMs trained on PubMed. BioGPT (345M parameters) apparently relies on surface lexical statistics (hedging tokens are correlated with their local embedding context), whereas BioMedLM (2.7B parameters) abstracts uncertainty into higher-order contextual representations that are not yet formed at layer 0. Encoder models occupy an intermediate position (76–81%), consistent with bidirectional attention enabling richer early contextualization across the full sentence. The pattern is consistent with scale (or the associated increase in hidden dimension and training compute) driving the shift from surface-dependent to computation-dependent uncertainty encoding, though the two decoders differ simultaneously in multiple factors and a controlled ablation would be needed to isolate scale as the causal variable.

Peak accuracy converges despite divergent starting points. Despite the large layer-0 variation, all six models converge to 80–87% at their selected steering layers. This convergence implies a ceiling (set either by the BioScope contrast set composition or by the intrinsic linearly accessible information in 400 sentences) that all models reach regardless of how early their uncertainty representation forms. The encoder ordering at peak accuracy (SciBERT 85.0%, BioBERT 86.5%, ClinicalBERT 82.75%, BlueBERT 80.75%) correlates with pretraining corpus breadth and biomedical specificity, suggesting that broader domain exposure slightly sharpens the uncertainty axis even when absolute accuracy differences are modest.

Encoder steering response is architecturally uniform. All four BERT-family encoders show nearly identical α_{frac} response curves for Δ_{proj} and Δ_{prob} despite being pretrained on corpora ranging from clinical notes (MIMIC-III) to broad scientific text. The decoder contrast is visible in Figure 9. The flip-rate saturation ceiling (50–54%) is consistent across all four, suggesting it reflects BioScope test-set composition rather than model-specific geometry. The model ordering on shift magnitude (SciBERT $>$ ClinBERT $>$ BioBERT $>$ BlueBERT) correlates with peak probe accuracy, confirming that a sharper uncertainty axis produces stronger representational steering effects. This uniformity has a practical implication: uncertainty steering may be transferable across BERT-family encoder variants without per-model calibration of the steering direction, provided probe accuracy is used to select the appropriate layer.

Layer selection interacts with architecture. The ± 2 window refinement matters most for encoders (BioBERT $+2.50$pp, SciBERT $+0.25$pp, ClinicalBERT $+0.75$pp) and is trivially zero for BioGPT. In BERT-family models, probe accuracy can vary non-monotonically near the 2/3 anchor as the `[CLS]` representation transitions between syntactic and semantic processing stages. For causal decoders, the layer-by-layer accuracy profile is flat

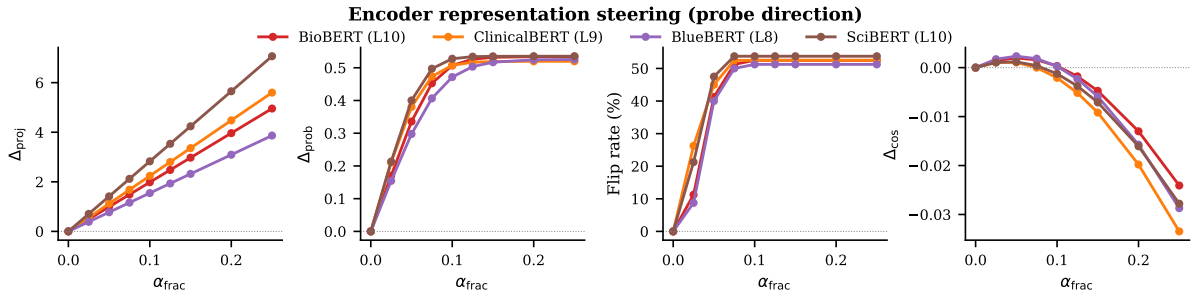

Figure 5: Encoder representation steering (probe direction) across all four models. Top-left: Δ_{proj} (all models positive, linear in α). Top-right: Δ_{prob} (saturates above $\alpha \approx 0.10$). Bottom-left: flip rate (saturates at $\approx 50\%$). Bottom-right: Δ_{cos} (sign reversal above $\alpha \approx 0.10$, dotted line marks zero).

across adjacent layers (Table 5): any layer in the ± 2 window performs equivalently, making precise selection less consequential. This asymmetry supports applying the full window search to all architectures while noting that it adds most value for bidirectional encoders.

5 Discussion

Uncertainty is cleanly decodable across all six models. The narrow range of peak accuracies (80–87%) across models with different architectures, sizes, and pretraining corpora suggests that linear encoding of epistemic stance is a general property of biomedical LMs trained on scientific or clinical text. The layer-0 contrast (BioGPT at 82% vs. BioMedLM at 55%) is particularly informative: for BioGPT, much of the signal is already present in the token embeddings through surface lexical cues, whereas BioMedLM appears to build much of the uncertainty-associated signal through transformer computation despite sharing the same pretraining corpus.

The uncertainty direction is stable but not purely semantic. Orthogonalizing against sentence length and hedge-count reduces probe accuracy by less than 1pp, which shows the representation is not reducible to these two surface statistics. However, this should not be read as evidence that the direction is purely semantic: the probe is trained on BioScope annotations that are themselves defined partly by the presence of hedging vocabulary. Orthogonalizing against a scalar hedge-count feature cannot fully decouple lexical from conceptual content. What we can say is that the direction captures more than a simple hedge-word lookup, and that this residual structure supports activation steering, but the precise mix of lexical and higher-level epistemic content remains an open question.

Layer selection is not arbitrary. The 2/3-depth anchor is a principled starting point, and the ± 2 window consistently identifies equal-or-better layers without over-searching. The BioBERT result ($+2.50$pp, L10 over L8) is the clearest demonstration: the accuracy plateau is not uniformly flat, and the window correctly finds the local optimum. The restriction to ± 2 is deliberate: wider windows risk selecting layers at qualitatively different processing stages.

Dynamic calibration is essential; decodability $\neq$ steerability. For decoders, the critical lesson is that hidden-norm calibration determines whether steering is controlled or catastrophic: a $3\times$ static over-estimate produced collapse at $\alpha_{\text{frac}} = 0.25$; dynamic calibration eliminates it across the entire tested range. Yet even controlled steering is non-monotonic: the peak hedge effect occurs at intermediate magnitudes and weakens above it, suggesting the model transitions between response regimes. For encoders, the Δ_{cos} sign reversal demonstrates that even geometrically precise steering along the probe direction does not guarantee movement toward the uncertain cluster: linear decodability and directional steerability are not equivalent properties.

PPL measurement under the unsteered model. Perplexity is scored under the *unsteered* model p_θ (Eq. 10), not the steered one, because the steered model's own likelihood is inflated along the steering direction. This provides a model-independent fluency proxy, but some PPL increase may reflect lexical style shift (more hedging vocabulary) rather than genuine quality degradation; token validity and lexical diversity serve as complementary

checks.

Multi-metric evaluation is necessary. In the uncalibrated regime (PPL > 400), hedge score alone would suggest strong success. The same logic applies to encoder steering: a large Δ_{proj} paired with negative $\Delta_{\cos}$ is ambiguous without the full metric suite. For steering interventions in safety-sensitive clinical domains, we argue that the target-behavior metric must be paired with at least one fluency/diversity metric (decoders) or one probability/boundary-crossing metric (encoders).

Decoder scale shapes the steering regime. The BioGPT–BioMedLM comparison constitutes a natural experiment: two causal LMs trained on the same corpus but differing in scale by $8\times$ (345M vs. 2.7B parameters) and hidden dimension by $2.5\times$ (1024 vs. 2560). Their steering profiles differ qualitatively. BioGPT exhibits a non-monotonic hedge peak at $\alpha_{\text{frac}} = 0.125$ with a sharp perplexity inflection above it, suggesting its representation space tightly couples the uncertainty direction to generation quality. BioMedLM exhibits a monotonic, collapse-free profile across the same range, and its ortho direction underperforms its probe direction, a reversal of the BioGPT pattern. These observations suggest that model scale modulates not merely the magnitude of the steering response but its qualitative character: larger models appear to afford wider collapse-free operating ranges, with the trade-off of lower peak hedge gains within that range. Whether this is a general scaling property or specific to the PubMed pretraining distribution remains open.

Encoder pretraining distribution has limited influence on steering geometry. The near-identical steering response curves across four BERT-family encoders pretrained on corpora ranging from clinical notes (MIMIC-III) to broad scientific text constitute our strongest evidence that linear uncertainty encoding is corpus-independent when the training objective is masked language modeling. If hedging representation were primarily a function of clinical text exposure, ClinicalBERT would be expected to show qualitatively different behavior from SciBERT; the curves are instead nearly superimposable. Small quantitative differences (SciBERT showing the largest shifts, BlueBERT the smallest) are better explained by differences in probe accuracy—a proxy for the sharpness of the uncertainty axis—rather than corpus content.

6 Limitations

Encoder generation. We measure representation shifts in encoder models only; behavioral impact on downstream NLP tasks (named entity recognition, relation extraction, information extraction) remains open. The $\approx 50\%$ flip rate confirms meaningful prediction changes at the probe level, but task-level evaluation is required to assess real-world impact.

Contrast set. The 400-sentence BioScope contrast set mixes genres (abstracts, full papers, clinical reports) and speculation types (epistemic hedging, conditionals, hypotheticals). A narrower annotation scheme focused specifically on clinical epistemic uncertainty might yield a sharper representation and higher steering fidelity.

Orthogonalization. Only sentence length and hedge-word count are controlled; specific modal constructions, passive voice, negation scope, and syntactic bigrams remain uncontrolled confounds. The claim that uncertainty encoding survives orthogonalization should be read as holding for these two confounds specifically.

Hedge metric. Our 27-term lexicon detects the presence of hedging markers but not their clinical appropriateness. A model generating repetitive hedging vocabulary outside coherent clinical content would receive a high score. Expert radiologist evaluation of output quality is an essential next step for any clinical safety claim.

Single prompt domain. Decoder experiments use radiology prompts exclusively. Steering behavior may differ for other clinical genres such as pathology reports, discharge summaries, or progress notes, where the distribution of uncertainty cues differs substantially.

Window size. The ± 2 window is not cross-validated across held-out model families. Results are empirically insensitive to ± 1 or ± 3 for all six models in this study, but the optimal window width may differ for models with sharper or flatter probe accuracy curves.

A Experimental Details

Hyperparameters. Generation: temperature 0.8, top-p 0.9, max new tokens 60, min new tokens 20, repetition penalty 1.2. Probe: $C = 0.1$, max_iter 2000, random_state 42. 5-fold stratified CV, seed 42. Sample sizes: 200+200 BioScope sentences for probe training; 80 balanced sentences (held out) for encoder steering; 20 seeds $\times$ 5 prompts $=$ 100 generations per decoder configuration.

Reproducibility. Fixed random seeds throughout. BioScope XML files enumerated alphabetically before sampling; contrast set is platform-independent. Code and results available at the repository linked in the first-page footnote.

B Implementation Details

Compute environment. Python 3.11.9, PyTorch 2.5.1+cu121, Transformers 4.49.0, Linux 6.1.0, NVIDIA GPU, CUDA 12.1. Float32 is the canonical dtype.

Dtype robustness. bfloat16 and float16 produce probe accuracies within 0.25pp of float32 on the same CUDA device. BioMedLM bfloat16 shows minor steering drift at $\alpha_{\text{frac}} \geq 0.20$; qualitative findings are unchanged.

Cross-platform note. CUDA and Apple MPS use different floating-point kernels and RNG sequences, producing numerically distinct hidden states even with identical seeds. Within a fixed CUDA platform, results are reproducible.

C Numerical Precision Robustness

Table 4 reports probe accuracy at the selected steering layer $\hat{\ell}$ under three floating-point precisions on the same CUDA device. All six models return identical accuracies across float32, float16, and bfloat16, confirming that numerical precision does not affect the qualitative or quantitative probing findings. Minor steering drift is observed for BioMedLM bfloat16 at $\alpha_{\text{frac}} \geq 0.20$ (hedge score within ± 0.02 of float32); all qualitative findings are unchanged. Float32 is the canonical dtype for all reported results.

D Hedge Marker Lexicon

may, might, could, would, should; suggest, suggests, suggestive; possible, possibly, possibility; probable, probably, probability; likely, unlikely;

Table 4: Probe accuracy at $\hat{\ell}$ across floating-point precisions (same CUDA device). All differences are zero across all models.

Model	$\hat{\ell}$	float32	float16	bfloat16
BioGPT	16	85.50%	85.50%	85.50%
BioMedLM	22	84.25%	84.25%	84.25%
BioBERT	10	86.50%	86.50%	86.50%
ClinicalBERT	9	82.75%	82.75%	82.75%
BlueBERT	8	80.75%	80.75%	80.75%
SciBERT	10	85.00%	85.00%	85.00%

appear, appears, appearing; seem, seems; suspect, suspected, suspicion; consistent with, cannot exclude, rule out.

E Formal Evaluation Metrics

Lexical diversity.

$$D(g) = \frac{|\text{unique words}(g)|}{|\text{words}(g)|} \tag{9}$$

Perplexity.

$$\text{PPL}(g) = \exp\left(-\frac{1}{|g|}\sum_{t=1}^{|g|}\log p_\theta(g_t \mid g_{<t})\right) \tag{10}$$

where p_θ is BioGPT evaluated without steering hooks.

Token validity.

$$V(g) = \frac{|\{t \in g : t \in \mathcal{W}\}|}{|\{t \in g : t \text{ alphabetic}\}|} \tag{11}$$

where $\mathcal{W}$ is the set of valid English words (checked against the NLTK words corpus).

Length.

$$L(g) = |g| \tag{12}$$

Encoder steering metrics.

$$\Delta_{\text{proj}} = (\mathbf{h}^{\text{mod}} - \mathbf{h}^{\text{orig}}) \cdot \hat{\mathbf{v}}_{\text{probe}} \tag{13}$$

$$\Delta_{\text{prob}} = p(y{=}1 \mid \mathbf{h}^{\text{mod}}) - p(y{=}1 \mid \mathbf{h}^{\text{orig}}) \tag{14}$$

$$\text{flip}\% = \frac{|\{s : \hat{y}^{\text{mod}} \neq \hat{y}^{\text{orig}}\}|}{|S|} \tag{15}$$

$$\Delta_{\cos} = \cos(\mathbf{h}^{\text{mod}}, \bar{\mathbf{h}}_u) - \cos(\mathbf{h}^{\text{orig}}, \bar{\mathbf{h}}_u) \tag{16}$$

$$f_{\text{axis}} = \frac{|\Delta\mathbf{h} \cdot \hat{\mathbf{v}}_{\text{probe}}|}{\|\Delta\mathbf{h}\|} \tag{17}$$

where $\bar{\mathbf{h}}_u$ is the mean hidden state of uncertain training sentences, $\hat{y}$ denotes the probe's predicted class, and $\Delta\mathbf{h} = \mathbf{h}^{\text{mod}} - \mathbf{h}^{\text{orig}}$.

F Full Probing Results

Tables 5, 6, and 7 list layer-by-layer 5-fold CV probe accuracies for all six models. *=2/3 anchor; ^=window-selected. Figures 6–7 show bar-chart views of the decoder sweeps.

Table 5: BioGPT probe accuracy, all 25 layers. $\ell^* = 16$, $\hat{\ell} = 16$.

Layer	CV Acc	Std	95% CI

Relations of Linguistic Features to Guideline-Based Rankings of Medical Answers are Nontrivial

Davis Bartels, Brandon C. Colelough, and Dina Demner-Fushman
National Library of Medicine, NIH
firstname.lastname@nih.gov

Abstract

We present an exploratory analysis of how simple linguistic features relate to annotator rankings of machine-generated medical answers under task-specific evaluation guidelines. We examine eight interpretable features of the answer text: length in words, average words per sentence, percentage of polysyllabic words, medical named entity density, perplexity, coherence, lexical diversity, and dependency distance. Our preliminary results show how the role of certain features depends on the ranking guidelines. When the guidelines explicitly instruct annotators to prefer shorter answers if informativeness is equal, annotators tend to be broadly consistent with the stated criteria, though with substantial annotator-level variation. In rankings where brevity is not part of the stated criteria, length still shows a strong, but less consistent association, suggesting that answer length may influence rankings even outside explicit guideline instructions. Other features show weaker and more variable associations. These findings suggest that linguistic features may provide insight into how annotators apply ranking guidelines, but that these relationships are heterogeneous and not fully explained by simple linear trends. The results motivate further analysis of guideline adherence, annotator variation, and possible confounding between linguistic form and answer content in medical answer evaluation.

1 Introduction

Human judgments of answer quality not only reflects whether an answer is correct, but also how that answer is written. Prior work in community question answering has shown that linguistic properties such as answer length, relevance to the question, and readability can influence which answers users prefer or select as best (Beygelzimer et al., 2015; Banjar et al., 2024). The influence of writing style on task-specific quality judgments is especially important in the medical domain, where readers must evaluate information that is often technical and difficult to process. Prior studies have shown that standard readability formulas do not fully capture the difficulty of medical text, and that features beyond simple word and sentence length may be needed to better characterize how understandable a document is (Wu et al., 2013; Zheng and Yu, 2018). Relatedly, Roberts and Demner-Fushman (2016) demonstrate the value of analyzing medical questions through multiple linguistic levels, comparing consumer and professional health questions using lexical, readability, language-model, semantic-type, and question-decomposition features. The findings from Roberts *et al.* demonstrate that medical text differs not only in surface readability, but also in terminology, background information, question structure, and semantic focus. Motivated by evidence that medical text varies across linguistic, semantic, and readability dimensions, we examine how a small set of interpretable linguistic features is associated with annotator rankings under task-specific guidelines. Our exploratory analysis is intended to establish whether associations are consistent with the guidelines, vary across annotators, or point to additional factors requiring future study.

2 Data

We use the ClinIQLink dataset, which comprises textbook-grounded medical questions each paired with eight machine-generated answers from a diverse set of open-source and internal language model systems (Colelough et al., 2025). Specifically, we draw from Task 2 of the dataset, a medical student ranking study that restricts evaluation to four open-ended question types, namely short answer, short inverse, multi-hop, and multi-hop inverse. Students from accredited medical schools ranked each set of eight answers according to a provided set of task-specific guidelines. We focus on the short answer and short inverse question types

Table 1: Example question and selected ranked model-generated answers.

Question: *What type of cancers do gene-based tests serve as the standard of care?*		
Rank	**Judgment**	**Answer**
1	Good	Gene-based tests are standard of care in certain breast (BRCA1, BRCA2), ovarian (BRCA1, BRCA2), colon (MLH1, MSH2, MSH6, PMS2, EPCAM), and lung (EGFR, ALK, ROS1, BRAF, KRAS) cancers, as well as melanoma (BRAF) and thyroid (BRAF, RET) cancers. They help determine risk, diagnosis, prognosis, and targeted therapy options.
2	Good	Gene-based tests serve as the standard of care for certain types of cancers, including breast cancer (BRCA1/BRCA2 mutations), colorectal cancer (MLH1, MSH2, MSH6, PMS2 mutations), ovarian cancer (BRCA1/BRCA2 mutations), prostate cancer (BRCA1/BRCA2, HOXB13 mutations), and lung cancer (EGFR, ALK, ROS1 mutations). These tests help in identifying hereditary cancer syndromes and guiding treatment decisions.

in our preliminary results, as these two types offer the clearest contrast in annotation guidelines. For short answer questions, annotators were instructed to rank the shorter of two equally informative answers higher, whereas for short inverse questions, annotators were instructed to rank answers solely by accuracy, strength of argument, and grounding. In addition to ranking, annotators were asked to assign a judgment to each answer, choosing from "Good", "Ok", or "Bad". "Good" indicates that the answer is complete and correct, "Ok" indicates the answer is acceptable with slight discrepancy, and "Bad" indicates that the answer is not factually accurate or does not address the question. To reduce the influence of overt factual incorrectness and focus on variation among acceptable answers, only answers judged "Good" were considered for this study. Examples of ranking may be found in Table 1.

3 Methods

We define the below set of metrics for linguistic features to analyze in the answer texts. We aim to see how they associate with the annotators' rankings under the provided guidelines. The metrics were selected to sample a range of commonly studied linguistic features and reveal preliminary patterns, before expanding to a broader feature set in future work. The linguistic features we use to analyze the CLinIQLink dataset include:

Lexical Count We measure the length of the text in terms of the number of words.

Average Words Per Sentence We measure sentence length as the average number of words in a sentence.

Percentage Polysyllabic Words The percentage of polysyllabic words is frequently included as a component of readability metrics, defined as the percentage of words with three or more syllables. If a word exists in CMUdict (Bartlett et al., 2009), we count the number of vowel phonemes in the word. If it does not, we approximate syllable count using Hunspell hyphenation dictionaries.

Medical Entity Density Using MetaMapLite (Demner-Fushman et al., 2017), we record the number of unique spans recognized as a medical named entity. We compute density by normalizing by the number of words in the text.

Dependency Distance Dependency distance, described by Oya (2011), is used as a measure of syntactic complexity, where a greater distance represents greater complexity. We average over the dependency distance for each sentence.

Coherence We measure the coherence between two sentences as the cosine similarity between their embedding vectors. We use `all-MiniLM-L6-v2` [1] to produce embedding vectors. We average over the coherence for each pair of consecutive sentences.

MATTR To capture lexical diversity, we measure the Moving-Average Type-Token Ratio (MATTR) of the text (Covington and McFall, 2010). MATTR is the average of the ratio of unique words to total words in a specified window size, for each window in the text. We use a window size of 50.

[1] https://huggingface.co/sentence-transformers/all-MiniLM-L6-v2

Perplexity Perplexity is the exponentiated average negative log-likelihood of a sequence. We use GPT-2 to compute the log-likelihoods for each token.

3.1 Additive Utility Paired Comparison Model

To measure the relationships between each metric and the orderings, the ranked lists are converted into pairwise data. We model each answer i's latent utility, η_i, as an additive function of its M metrics of linguistic features. Specifically, x_{im} denotes the value of feature m for answer i, and $f_m(\cdot)$ is a feature-specific spline function that captures the potentially nonlinear contribution of feature m to the answer's overall utility, as shown in Equation 1:

$$\eta_i = \sum_{m=1}^{M} f_m(x_{im}) \tag{1}$$

We then model the probability that answer i is ranked over answer j, denoted $P(i \succ j)$, as a logistic function of the difference between their utilities, $\eta_i - \eta_j$, as shown in Equation 2:

$$P(i \succ j) = \text{logit}^{-1}(\eta_i - \eta_j) \tag{2}$$

Thus, answers with higher estimated utility are more likely to be preferred in pairwise comparisons.

3.2 Normalization and Cross-Validation

Metrics are first normalized and missing data, such as MATTR for texts shorter than the window size or coherence for texts with only one sentence, are imputed with the average value for that feature after normalization. A missingness indicator is introduced as a covariate for each feature with imputed values. We use 5-fold cross validation to reduce variance in our performance metrics and split folds by question to prevent leakage. Annotators with fewer than 20 ranked lists for a particular question type were excluded for that question type.

3.3 Annotator Summary Metrics

We summarize the models across annotators through a variety of metrics. Direction is the median utility contrast $f(x_{75}) - f(x_{25})$ across annotators, giving an overall direction of the curve for that feature. We count the percentage of annotators that exhibit a positive and negative direction for a given feature with a threshold of 0.05, such that a value x is not counted if $-0.05 \leq x \leq 0.05$. Utility range is $\max f(x) - \min f(x)$ and nonlinearity is measured as the Root Mean Square Error between the estimated smooth curve and its best-fitting straight line, normalized by the range of the smooth curve. To analyze annotator agreement, we use curve correlation and curve variability. Curve correlation is the median pairwise correlation between annotator-specific smooth curves. Curve variability is the mean of the standard deviations of the dispersion of annotator-specific smooth curves across the feature range.

3.4 Feature Ablation

To assess the importance of each feature to the model, we conduct a leave-one-out ablation study. We fit the model again, with one feature removed, and measure the change in held-out negative log-likelihood. Positive values indicate that removing the feature worsened predictive performance.

4 Results

4.1 Short Answer Feature Relationships

Table 2 summarizes the feature relationship metrics across annotators for the short answer questions. Lexical count shows the strongest directional indication with a median direction of -0.238, and also the largest utility range at 1.168, though its IQR is large at $[-0.747, -0.081]$, reflecting substantial variation across annotators. A large percentage of annotators demonstrate a negative direction for both lexical count (76.5%) and dependency distance (70.6%), while perplexity has the largest percentage of annotators below the threshold at 52.9%. None of the remaining features show strong directional indication. Nonlinearity is broadly similar across all features.

4.2 Short Answer Curve Agreement and Ablation Results

Table 3 summarizes curve agreement and ablation results for the short answer questions. Lexical count and dependency distance mean have the greatest curve correlations at 0.824 and 0.822 respectively, though only lexical count exhibits high curve variability at 0.439, suggesting that even among annotators for whom length is a strong predictor, the shape of the relationship or magnitude of the effect size differs considerably. All features show very low magnitude changes in negative log-likelihood across the ablation study.

Table 2: Annotator-level feature relationship summaries for short answer questions. Values in brackets indicate interquartile ranges.

Feature	Direction	% Pos.	% Neg.	Utility range	Nonlinearity
Lexical Count	-0.238 [-0.747, -0.081]	17.6	76.5	1.168 [0.834, 1.795]	0.084 [0.017, 0.131]
Pct. Polysyllabic Words	-0.005 [-0.112, 0.108]	41.2	35.3	0.641 [0.396, 0.875]	0.129 [0.098, 0.216]
Avg. Words Per Sentence	-0.082 [-0.175, 0.080]	41.2	52.9	0.637 [0.393, 0.971]	0.106 [0.067, 0.190]
Medical Entity Density	-0.059 [-0.127, 0.033]	23.5	52.9	0.570 [0.321, 0.678]	0.122 [0.068, 0.182]
MATTR	-0.058 [-0.249, 0.059]	35.3	52.9	0.496 [0.174, 0.618]	0.140 [0.109, 0.208]
Dependency Distance Mean	-0.090 [-0.158, 0.005]	17.6	70.6	0.486 [0.326, 0.642]	0.109 [0.072, 0.181]
Perplexity	0.000 [-0.072, 0.019]	11.8	35.3	0.413 [0.272, 0.665]	0.043 [0.020, 0.135]
Coherence	0.056 [-0.113, 0.099]	52.9	35.3	0.359 [0.237, 0.534]	0.162 [0.130, 0.180]

Note. Direction is the median utility contrast $f(x_{75}) - f(x_{25})$ across annotators. Utility range is $\max f(x) - \min f(x)$. Nonlinearity is the normalized deviation from the best-fitting linear approximation.

Table 3: Annotator-level curve agreement and ablation summaries for short answer questions. Values in brackets indicate interquartile ranges.

Feature	Curve corr.	Curve variability	Ablation ΔNLL
Lexical Count	0.824 [-0.539, 0.990]	0.439	-0.002 [-0.017, 0.007]
Pct. Polysyllabic Words	-0.125 [-0.932, 0.900]	0.131	-0.001 [-0.004, 0.004]
Avg. Words Per Sentence	0.091 [-0.906, 0.973]	0.108	0.000 [-0.004, 0.003]
Medical Entity Density	0.421 [-0.940, 0.959]	0.085	-0.001 [-0.004, 0.003]
MATTR	-0.116 [-0.925, 0.930]	0.159	0.006 [-0.016, 0.023]
Dependency Distance Mean	0.822 [-0.955, 0.992]	0.067	-0.004 [-0.007, -0.001]
Perplexity	0.650 [-0.996, 0.999]	0.091	-0.000 [-0.004, 0.007]
Coherence	-0.196 [-0.939, 0.945]	0.127	-0.006 [-0.008, 0.021]

Note. Curve correlation is the median pairwise correlation between annotator-specific smooth curves. Curve variability is the mean standard deviation of annotator-specific smooth curves across the feature range. Ablation ΔNLL is the change in held-out negative log likelihood when the feature is removed; positive values indicate that removing the feature worsened predictive performance.

4.3 Short Inverse Feature Relationships

Table 4 summarizes the feature relationship metrics across annotators for the short inverse questions. Lexical count again shows the strongest directional indication with a median direction of -0.301 and the largest utility range at 1.932, though the IQR is considerably wider at $[-1.126, 0.491]$ than for the short answer questions, reflecting a more even split between annotators favoring shorter and longer answers. Average words per sentence shows the next strongest negative direction at -0.118, while medical entity density is the only feature with a notably positive direction at 0.101, with 60.7% of annotators exhibiting a positive association. Nonlinearity remains broadly similar across all features.

4.4 Short Inverse Curve Agreement and Ablation Results

Table 5 summarizes curve agreement and ablation results for the short inverse questions. Lexical count and average words per sentence have the greatest curve correlations at 0.571 and 0.489 respectively, and lexical count again exhibits the highest curve variability at 0.496. Lexical count is the only feature to show a meaningful positive change in negative log-likelihood upon removal, with a median ablation ΔNLL of 0.019 $[0.003, 0.050]$.

5 Discussion

5.1 Length and Annotator Guidelines

For the short answer questions, lexical count shows a very strong negative direction, meaning annotators, on average, ranked shorter text over longer text. This trend is closely aligned with the guidelines asking annotators to rank shorter answers higher for the short answer question type. However, the large IQR reveals variation in degree of direction, meaning that some annotators may not have strictly adhered to the brevity guideline, at least for some questions. We also see a strong negative direction for short inverse questions, despite annotators not being asked to consider length in their rankings. The IQR is even larger, showing many annotators tended to rank longer text over shorter text, despite the overall trend. For the short inverse questions, the IQR points to annotators having a strong, yet varied, association between length and perceived accuracy, strength of argument, and grounding. It is worth noting that annotators could have been biased by the instruction to prefer shorter answers on the short answer questions.

5.2 Feature Associations

While lexical count is the only feature with significant direction for the short answer question, the short inverse answer rankings show modest asso-

Table 4: Annotator-level feature relationship summaries for short inverse questions. Values in brackets indicate interquartile ranges.

Feature	Direction	% Pos.	% Neg.	Utility range	Nonlinearity
Lexical Count	-0.301 [-1.126, 0.491]	39.3	60.7	1.932 [1.109, 3.613]	0.075 [0.044, 0.116]
Perplexity	-0.017 [-0.169, 0.042]	25.0	42.9	0.684 [0.356, 0.832]	0.089 [0.055, 0.153]
Avg. Words Per Sentence	-0.118 [-0.189, 0.078]	28.6	60.7	0.661 [0.465, 0.875]	0.099 [0.057, 0.170]
MATTR	-0.032 [-0.230, 0.152]	35.7	50.0	0.631 [0.395, 0.870]	0.126 [0.101, 0.181]
Pct. Polysyllabic Words	-0.038 [-0.356, 0.086]	32.1	50.0	0.613 [0.347, 0.868]	0.134 [0.097, 0.195]
Medical Entity Density	0.101 [-0.083, 0.213]	60.7	32.1	0.501 [0.352, 0.739]	0.139 [0.084, 0.197]
Coherence	-0.032 [-0.127, 0.156]	35.7	46.4	0.371 [0.339, 0.488]	0.166 [0.139, 0.198]
Dependency Distance Mean	-0.051 [-0.144, 0.044]	21.4	50.0	0.304 [0.238, 0.494]	0.163 [0.092, 0.212]

Note. Direction is the median utility contrast $f(x_{75}) - f(x_{25})$ across annotators. Utility range is $\max f(x) - \min f(x)$. Nonlinearity is the normalized deviation from the best-fitting linear approximation.

Table 5: Annotator-level curve agreement and ablation summaries for short inverse questions. Values in brackets indicate interquartile ranges.

Feature	Curve corr.	Curve variability	Ablation ΔNLL
Lexical Count	0.571 [-0.975, 0.985]	0.496	0.019 [0.003, 0.050]
Perplexity	0.339 [-0.916, 0.940]	0.092	-0.001 [-0.004, 0.001]
Avg. Words Per Sentence	0.489 [-0.921, 0.974]	0.122	-0.001 [-0.005, 0.003]
MATTR	-0.081 [-0.938, 0.940]	0.175	-0.002 [-0.007, 0.002]
Pct. Polysyllabic Words	-0.054 [-0.918, 0.895]	0.145	0.000 [-0.005, 0.003]
Medical Entity Density	0.160 [-0.934, 0.945]	0.140	-0.003 [-0.005, 0.001]
Coherence	-0.156 [-0.904, 0.897]	0.107	-0.002 [-0.008, 0.002]
Dependency Distance Mean	-0.055 [-0.840, 0.894]	0.090	-0.005 [-0.012, -0.002]

Note. Curve correlation is the median pairwise correlation between annotator-specific smooth curves. Curve variability is the mean standard deviation of annotator-specific smooth curves across the feature range. Ablation ΔNLL is the change in held-out negative log likelihood when the feature is removed; positive values indicate that removing the feature worsened predictive performance.

ciation with shorter sentences and higher medical entity density. It is to be expected that we may see stronger relationships with more features when one specific feature is not singled out in the guidelines. Both the positive and negative directions claim a significant portion of annotators for the short inverse questions, which signal variation in the associations across annotators. The significant percentage of annotators with negative directions for dependency distance, despite a low direction value for the short answer questions, could mean agreement, but weak association, or a nonlinear relationship not captured by the direction metric.

5.3 Nonlinearity and Annotator Variation

All features, for both question types, show some degree of nonlinearity, meaning some may have complex relationships. There may be, for example, a parabolic relationship between a specific feature and an annotator's rankings that would not be observable in the direction metric. For the short answer questions, lexical count has a high curve correlation, but also high variability. This again suggests even across annotators for whom length is a strong predictor of ranking, the relationships are very different. This variance in relationship implies that the brevity guideline was not applied uniformly across annotators.

5.4 Ablation and Feature Concurvity

The leave-one-out ablation study describes only lexical count as having a significant positive difference in negative log-likelihood and only for the short inverse question type. Though some features likely truly have little impact on the model, the negligible deltas of others could be explained by concurvity among features. Despite normalizing for length or selecting metrics relatively robust to length, some other features likely carry some signal for length through specific behavior at extremely short lengths. The percentage of polysyllabic words, for example, must be either 0% or 100%, when lexical count is 1.

6 Conclusion

This analysis of linguistic features in medical text and annotator rankings shows strong relationships for some annotators, as well as broader trends across the cohort. These findings highlight the nontrivial relationships between linguistic features and ranking judgments under task-specific guidelines. Future work includes assessing the nature of specific complex relationships, the inclusion of a broader set of features, and more detailed analysis.

Limitations

There are far more linguistic features that are frequently analyzed in both medical and open-domain texts than included in this study. The answer choices for each question were generated by the same eight systems and system identity was not ruled out as a potential confounder. Furthermore, because answers not judged "Good" were excluded from the study, it may be that some trends are better explained by the factuality of the answer, rather than the features analyzed. Questions were not analyzed by medical domain, which will be necessary to understand if the results depend on the topic of the text. Finally, because this study infers guideline application from associations between linguistic features and rankings, it cannot determine why annotators deviated from guideline-consistent patterns. Such deviations may reflect misunderstanding, disagreement with the guideline, attention to unmeasured answer qualities, or residual differences in correctness or informativeness among answers judged "Good."

Abstract

This paper presents an overview of the MedGenVidQA 2026 shared task on medical video question answering, collocated with the 25th BioNLP workshop at ACL 2026. The shared task addressed three related sub-tasks of the medical multimodal (textual and video) question answering: **(i)** multimodal retrieval tasks, **(ii)** multimodal answer generation with citations, and **(iii)** a visual answer localization task. The key theme of the stated task is to develop reliable multimodal question-answering systems for consumers and medical professionals by leveraging generative models. A total of eight teams participated in the shared task challenges and submitted a total of forty-three submissions across all tasks. We performed both automated and human assessments to evaluate the submissions. This paper describes the tasks, datasets, evaluation metrics, participation, and baseline systems for all three tasks. Additionally, we summarize the techniques and results of the evaluation of the various approaches explored by the participating teams. Finally, we discuss the key findings and implications for the development of multimodal medical question answering.

1 Introduction

Recent advances in foundation models have significantly improved their ability to process, comprehend, and integrate information across multiple modalities such as text, images, and audio. These models have achieved superior performance on tasks that require aligning the modalities to capture the overall dynamics of the input sources. In the medical domain, knowledge is often distributed across a broader range of modalities, including textual sources such as scientific literature and clinical notes, as well as medical imaging, procedural, and instructional videos. Textual information often provides key insights, while visual data offers fine-grained spatial and temporal details, which are critical for understanding medical questions that demand a step-by-step procedure in the answer. Despite advances in state-of-the-art multimodal models, effectively combining heterogeneous knowledge sources remains a challenge, especially in the medical domain, where information from a single modality may not be sufficient to provide a comprehensive answer.

In the literature, multimodal question-answering tasks have been studied by incorporating images and videos as additional modalities alongside language. These tasks require understanding information across multiple modalities and their interactions to answer questions correctly. Most existing studies (Pramanick et al., 2024; Zhang et al., 2023; Liang et al., 2024) focus on open-domain settings involving videos (Lei et al., 2018, 2019; Rawal et al.; Zhang et al., 2024), images (Chowdhury and Soni, 2025; Tanaka et al., 2023), charts (Masry et al., 2025; Wu et al., 2024), and tables (Wang et al., 2024b; Pal et al., 2023). In the medical domain, image-based question answering has advanced with the development of neural-based approaches (Li et al., 2023; Hartsock and Rasool, 2024). There has also been some work on medical video-based question answering, including the creation of datasets (Gupta et al., 2023; Gupta and Demner-Fushman, 2024) and methods (Gupta et al., 2024a) aimed at better understanding medical videos and answering instructional questions. In addition, prior works (Gupta et al., 2025a, 2024b) have explored generating answers to medical questions from textual sources, such as scientific literature, using retrieval-augmented generation-based approaches to produce answers along with supporting citations. However, existing work on video question answering and multimodal question answering, both in open-domain and medical settings, lacks several important aspects. First, there is limited focus on retrieving relevant multimodal information sources, particularly combining textual and

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 1089–1100
July 3-4, 2026 ©2026 Association for Computational Linguistics

video data in the medical domain. Second, existing approaches do not fully address generating answers that jointly consider multiple modalities while also providing supporting evidence, which is critical for ensuring reliability and trustworthiness in medical applications. Third, there is limited work on answering professional-level medical questions from medical procedural or instructional videos.

To bridge these gaps, we introduced the MedGenVidQA 2026 shared task[1], which aims to explore and develop efficient algorithms for medical question answering, considering the multimodal information (mainly text and videos). In the first task (multimodal retrieval) of the MedGenVidQA 2026 shared task, participants were asked to develop systems that retrieve relevant video and PubMed articles from multimodal sources containing the answer to the medical query. The second task (multimodal answer generation) aims to generate an answer that includes attributions from multimodal sources for each answer sentence. Finally, the third task (visual answer localization) aims to effectively localize the visual answer to the given medical or health-related question in a professional medical video.

2 MedGenVidQA 2026 Task Descriptions

MedGenVidQA comprises three related subtasks on video question answering. The illustration of the tasks is provided in Figure 1, 2, and 3 and details are as follows:

2.1 Task A: Multimodal Retrieval (MMR)

Given a medical query and a collection of multimodal sources, including textual documents and videos, the task is to retrieve relevant sources that can support answering the query. This involves aligning the query to the textual and video sources, which can serve as the basis for the task of answer generation. There is no requirement to use all modalities; either text, video, or both can be used.

2.2 Task B: Multimodal Answer Generation (MAG)

Given a medical query and a collection of multimodal sources, including textual documents and videos, the task is to generate an answer that is grounded in retrieved evidence from these sources. The generated response must include explicit attributions, with each sentence supported by cited references drawn from the multimodal sources. Similar to Task A, the model can use one or more modalities as needed.

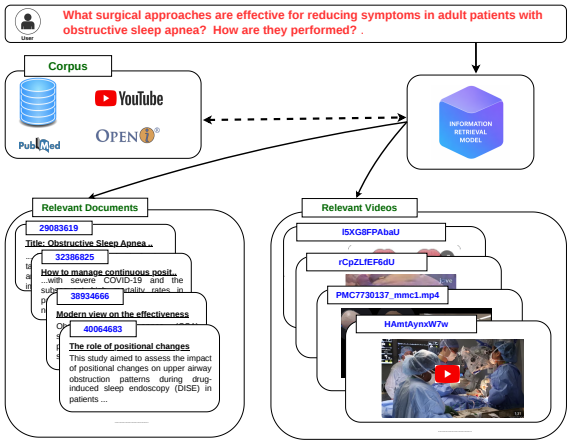

Figure 1: Example illustrating **MMR** task, where given the question, a retrieval model interacts with the corpus and is expected to produce the relevant video and documents as outputs.

2.3 Task C: Visual Answer Localization (VAL)

Given a medical query and a video, the task is to locate the temporal segments (start and end timestamps) in the video where the answer to the query is shown or the explanation is illustrated. This task assesses the model's ability to locate the visual answer in professional, procedure-based medical videos.

3 Data

3.1 Datasets

We developed textual and video corpora for the MedGenVidQA 2026 shared task. For the textual corpus, we used the latest annual baseline snapshot of MEDLINE/PubMed that covers the articles' abstracts and titles approximately through the end of 2025[2]. We provided a pre-processed set of $28,372,706$ PubMed abstracts.

In the video corpus, we focused on including both consumer and professional videos. For consumer-focused videos, we used the MedVidQA 2024 video corpus (Gupta and Demner-Fushman, 2024) of size $48,605$. This collection was developed by selecting videos from the "Personal Care and Style," "Health," and "Sports and Fitness" categories of the HowTo100M dataset (Miech et al.,

[1] https://medgenvidqa.github.io/

[2] https://ftp.ncbi.nlm.nih.gov/pubmed/baseline/

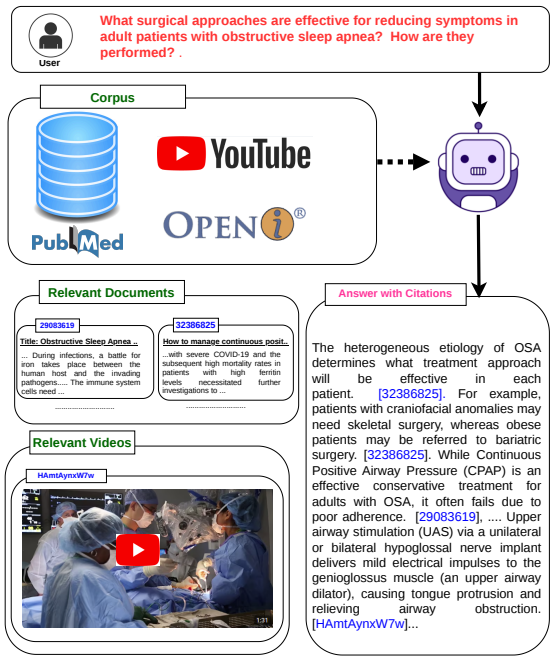

Figure 2: Illustration of the **MAG** task, where a model, given a question, can optionally use the corpus and is expected to produce an answer supported by sentence-level citations from relevant documents and videos.

2019), and further filtering instructional videos using the confidence scores from the instructional video classifiers developed in the MedVidQA corpus (Gupta et al., 2023). We augment the consumer-focused video corpus with medical professional videos from publicly available biomedical videos in the Open-i platform[3] associated with peer-reviewed publications in PubMed Central (PMC). These videos encompass a broad range of clinically relevant procedural and instructional content intended for scientific communication and education. We collected $10,462$ videos, each up to 3 minutes long. To facilitate multimodal learning, we also extracted transcripts for those videos using Whisper[4] with the `tiny` model version. The resulting video corpus, combining consumer and medical professional videos, contains $59,067$ videos. Participants were asked to use these collections (textual and video) to retrieve (Task A) and generate (Task B) answers to a given query.

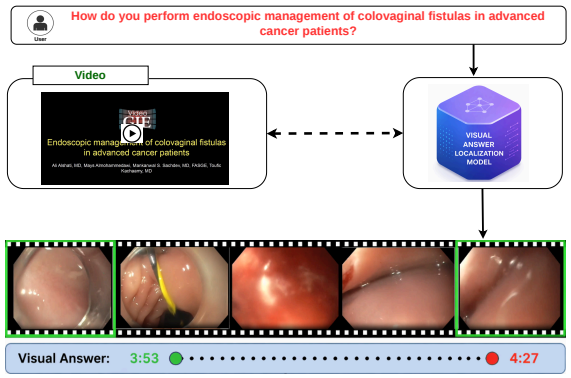

Figure 3: Illustration of the **VAL** task, where, given a question and a video, the model is expected to predict the start and end timestamps corresponding to the segment that serves as the visual answer to the question.

3.1.1 Training Set

For training and developing systems, we provided[5] the MedVidQA collections (Gupta et al., 2023) that consist of 3,010 human-annotated instructional questions and videos, along with visual answers from 900 health-related videos. The collection can support the training and development of all three tasks, as it includes medical questions, relevant videos (useful for Tasks A and B), and annotated temporal segments (useful for Task C) from those videos. We also provided the MedAESQA collection[6], comprising 8,427 human-annotated PubMed documents paired with answers to consumer health questions, where each answer sentence has up to three PubMed citations along with human-annotated relations with the PubMed documents in terms of *'support'*, *'contradict'*, *'neutral'*, and *'not relevant'*. The MedAESQA collection also provides human-annotated assessments of answer accuracy and relevancy ('*required*', '*unnecessary*', '*borderline*', and '*inappropriate*'), which can help develop systems for answer generation with citations (Task B). Together, MedVidQA and MedAESQA can be used to develop a multimodal question-answering system that retrieves relevant sources and uses them to generate answers with citations to those sources.

3.1.2 Test Set

Medical professionals on our team developed a new test set comprising 60 questions, ensuring a balance between consumer and medical professional needs. The questions were designed to ensure that both

[5] https://osf.io/pc594/files/osfstorage

[6] https://osf.io/ydbzq/files/osfstorage

textual and video references in the answers contribute to their informativeness and engagement for both audiences. For example, for the consumer health question *how do I take blood pressure?* Video sources can provide a clear demonstration of the procedure, including proper cuff placement and measurement technique, while textual sources can offer additional guidance on accuracy, recommended practices, and interpretation of readings. For medical professional questions such as *how is anesthesia intubation performed?*, video sources are essential for illustrating the procedural steps, whereas textual sources contribute important clinical details, including indications, safety considerations, and potential risks. We used the same set of 60 questions for Tasks A and B.

For Task C, a medical professional on our team sampled a set of 300 medical professional videos from Open-i, as discussed in Section 3.1. Each video was subjected to structured manual annotation to assess whether reasonable, clinically meaningful questions could be posed solely from visual content. If a video was found to contain a temporal segment that could be considered a visual answer to a medical question, the corresponding timestamps were recorded. This resulted in structured instances consisting of the question, the associated video, and the annotated temporal segment. In total, we constructed 80 question–video–answer instances for Task C.

4 Evaluation

4.1 Evaluation Metrics

4.1.1 MMR Evaluation

Participants were asked to retrieve relevant videos and abstract identifiers (PMIDs) (up to 10) for each question from both the video and textual corpora. To evaluate the relevant videos/text, we performed manual judgments using a pooling strategy on all system-retrieved videos (1,963) and PubMed documents (1,582). Using a pooling depth of $K = 3$, the final relevance pool consisted of 501 textual documents and 684 videos, with an average of 8.35 documents and 11.4 videos retrieved per topic, respectively. We instructed a total of four assessors with the following guidelines to assess the relevance of videos and documents:

Evaluating videos for relevance The videos are judged as being *Definitely Relevant*, *Possibly Relevant*, or *Not Relevant* to the given question. A video is considered *Definitely Relevant* if it contains a visual segment that constitutes a complete visual answer to the question. It is considered *Possibly Relevant* if it contains a visual segment that can be considered a partial/incomplete visual answer to the question. If the visual segments from the videos do not provide any visual answers to the question, the video can be marked as not relevant.

Evaluating PubMed documents for relevance Similar to the video relevance, the documents are also judged as *Definitely Relevant*, *Possibly Relevant*, or *Not Relevant* to the given question. *Definitely relevant* documents should directly answer the query and contain sufficient information on their own. *Possibly relevant* documents provide partial or related information but require additional sources to form a complete answer. *Not relevant* documents do not contribute useful information for answering the question.

We evaluated the performance of the video and document retrieval system in terms of Mean Average Precision (MAP), Recall@k, Precision@k, and nDCG metrics with $k = \{5, 10\}$. We follow the `trec_eval`[7] evaluation library to report the performance of participating systems.

4.1.2 MAG Evaluation

We used the BioACE (Gupta et al., 2026) evaluation framework[8] to assess the quality of system-generated answers. The evaluation focused on two aspects: completeness and correctness, measured using an automated approach and the ground-truth nuggets. Completeness measures how much of the required information (atomic biomedical facts, also called 'nuggets') is covered in the generated answer, whereas correctness assesses how well the generated content aligns with the relevant documents. In the nugget-based evaluation, nuggets are first extracted from the generated answer and then matched with the ground-truth nuggets using the relaxed matching scheme in BioACE. Precision (nugget-based correctness) and recall (nugget-based completeness) are then computed. These metrics are computed for each topic and then averaged over all questions in the test set to obtain the final scores. For citation evaluation, we used the BioACE framework. Specifically, we used LLaMA-3.3 to assess the relationship between each

[7] https://github.com/usnistgov/trec_eval

[8] https://github.com/deepaknlp/BioACE

answer sentence and its cited document or video sources. The model classifies each pair as *Supports*, *Contradicts*, or *Neutral*. Based on these labels, we computed citation coverage, citation support rate, and citation contradiction rate.

4.1.3 VAL Evaluation

Following Gupta et al. (2023); Gupta and Demner-Fushman (2022), we evaluated the performance of the VAL task using the following metrics:

Mean Intersection over Union (mIoU): For a given question q_i, IoU is computed as the ratio of the intersection area over the union area (Jaccard, 1912) between predicted and ground-truth temporal visual answer segments. It ranges from 0 to 1. A larger IoU means the predicted and ground-truth temporal visual answer segments match better, and IoU = 1.0 denotes an exact match. The mIoU is defined as the average temporal IoUs for all questions (N) in the test set. Formally,

$$\text{mIoU} = \frac{1}{N}\sum_{i=1}^{i=N} IoU(q_i) \tag{1}$$

IoU @ μ is another metric used to evaluate the performance of the VAL system. It denotes the percentage of questions for which the predicted temporal segment has an IoU with the ground-truth segment greater than μ. Formally,

$$IoU@\mu = \frac{1}{N}\sum_{i=1}^{i=N} s(q_i, \mu), : \text{and} \tag{2}$$

$$s(q_i, \mu) = \begin{cases} 1, & \text{if } IoU(q_i) \geq \mu \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

We evaluated the submissions by considering $\mu = 0.3, 0.5, 0.7$. Since IoU@0.7 is the most restrictive among these settings, we used IoU@0.7 as the primary metric for ranking the submissions.

4.2 Baseline Systems

4.2.1 MMR Baselines

We developed baseline approaches using a BM25-based retrieval approach for both textual and video sources. For textual retrieval, we built an index over the PubMed corpus. For video retrieval, we constructed a separate index from the video transcriptions. Both indices were created using Pyserini[9] with default hyperparameters. Given a query, the system first retrieved top-100 relevant documents and videos independently from the respective indices using BM25, followed by a re-ranking step to refine the results using a pre-trained re-ranker model[10]. Building on this, we constructed two monomodal baselines, `Text-RR` and `Video-RR`, in which the top-10 documents after reranking are retained.

4.2.2 MAG Baselines

We adopted a RAG-based approach as developed in (Gupta et al., 2025b), which first fine-tuned a LLaMA2-7B (Touvron et al., 2023) model to generate answers with citations. The fine-tuning datasets were created from the PLABA (Attal et al., 2023) collection, which includes questions and relevant documents, and CHQ-Summ (Yadav et al., 2022), which contains consumer health questions. Using the retrieved documents from the MMR baseline approaches (both unimodal and multimodal), we developed two unimodal baselines, `Text-RRG` and `Video-RRG`. In these settings, the top-10 documents and videos from the MMR baselines were fed into the model to generate answers with citations using the prompts shown in Fig. 4. We also included a multimodal baseline, `MM-RRG`, that combines the top-5 textual and video sources obtained from the MMR baselines to generate answers with citations. We observed that video transcripts are often too long and may exceed the model's maximum token limit of 4096. Therefore, in `Video-RRG` and `MM-RRG`, we summarized the transcripts before feeding them to the model for answer generation. The prompt used for transcript summarization is shown in Fig. 5. We generated answers and summaries both using a sampling-based decoding strategy with a maximum output length of 350 tokens. Decoding was performed at a temperature of 0.7 and with nucleus sampling with $p = 0.9$.

4.2.3 VAL Baselines

We developed a baseline for the VAL task by adopting TimeLens (Zhang et al., 2025), a multimodal language model designed for video temporal grounding, built on top of Qwen2.5-VL-7B-Instruct model (Wang et al., 2024a). TimeLens introduces a simple interleaved textual prefix for time representation and is trained using a reinforcement learning with verifiable rewards (RLVR) approach. The training process employs practical strategies, including early stopping based on reward saturation

and difficulty-aware data sampling. The model was trained on the TimeLens-100K dataset, specifically designed for temporal grounding tasks. We utilized the TimeLens-7B model with its default generation and video processing settings to generate the start and end timestamps of the answer, using the prompt shown in Fig. 6.

We provided the processed datasets and baseline implementations as a starter kit[11] for participants to build upon their approaches.

5 Participating Teams and Methods

5.1 Participating Teams

We used the Codabench platform to release the datasets, and for registration, and submissions of the participating teams. In total, 8 teams from Asia (India, China, Thailand), and North America (USA) participated in the MedGenVidQA 2026 shared task and submitted a total of 46 runs. We have provided (*cf* Table 1) the team name, affiliations, and their participation in MRR, MAG, and VAL tasks. For Task MRR and MAG, we did not perform real-time evaluation on Codabench because the tasks require expert evaluation of the runs. The results of all the participating teams for the VAL task[12] are available on the Codabench platform.

5.2 MMR Submissions

5.2.1 Methods

VAJRA-DOMINATORS (Dhaktode et al., 2026) proposed a multi-stage hybrid retrieval approach over both the textual and video corpus. For document retrieval, queries were processed to extract medical keywords that were submitted to the NCBI PubMed E-utilities (ESearch) API[13] using a sequence of fallback strategies, including full-query, medical keyword-based, and truncated queries, with results ranked using a normalized scoring scheme based on an exponential decay function: $Score = 0.5 + 0.49 \times e^{(-rank \times 0.3)}$. For video retrieval, the system combined dense retrieval using a PubMedBERT bi-encoder (trained with hard negatives) and sparse BM25 search over temporally segmented transcripts. The outputs from both stages were fused and further refined using a biomedical cross-encoder for re-ranking, with deduplication applied at the video level. A T5-based model was used for query expansion to generate clinical synonyms and improve matching between user queries and technical content. The overall approach focused on improving recall while maintaining relevance through re-ranking and query refinement.

PRIDE-BOILERS (Ebinesar et al., 2026) proposed CRAG-MMR, a five-stage multimodal retrieval pipeline that addresses the vocabulary mismatch between lay health queries and clinical literature. For document retrieval, a BM25 index was built over the PubMed collection, while dense retrieval was performed using MedCPT (ncbi/MedCPT-Article-Encoder) encoders, with documents represented as 768-dimensional embeddings stored in a FAISS index (Douze et al., 2025). To better capture different aspects of the information needed, each query was decomposed into multiple clinically oriented sub-queries using Gemini Pro, targeting treatment options, procedures, prevention strategies, and guidelines. In addition, a Hypothetical Document Embedding (HyDE) (Gao et al., 2023) based approach was employed, in which the Gemini Pro generated a synthetic abstract that was encoded and used as an additional dense query. The resulting BM25, dense, and HyDE retrieval outputs were combined using the Reciprocal Rank Fusion (RRF) strategy. For video retrieval, subtitles from instructional videos were indexed using both BM25 and SapBERT-based dense representations. Queries were adapted to better match the spoken and procedural nature of video content, and retrieval was performed independently over both signals. The results were fused using the RRF strategy for document retrieval.

Table 2: Performance of the participating teams on the **MMR** task considering the retrieved documents from the PubMed corpus and videos from the video corpus. Teams are ranked based on their best run using nDCG as the primary metric. "–" indicates that no results were returned for the corresponding modality (text or video) in the submitted run.

Systems	Correctness			Completeness		
	Auto (All)	Auto (10Q)	Nugget (10Q)	Auto (All)	Auto (10Q)	Nugget (10Q)
`Text-RRG`	0.6122	0.5356	0.8586	0.6578	0.6429	0.4338
`Video-RRG`	0.5982	0.5188	0.7764	0.5305	0.3482	0.3660
`MM-RRG`	0.6224	0.5461	0.7914	0.6324	0.3898	0.4014

Table 3: Performance comparison of baseline systems in terms of answer correctness and completeness on the MAG task. Automatic evaluation (Auto) using BioACE is reported over all 60 questions, while nugget-based (Nugget) evaluation was computed on a subset of 10 questions. For comparison between Nugget-based evaluation and Automatic evaluation, we provide the comparative results on the same set of 10 questions.

Systems	Citation Coverage	Citation Support Rate	Citation Contradict Rate
`Text-RRG`	**0.6667**	**0.8170**	0.0308
`Video-RRG`	0.2221	0.7482	**0.0073**
`MM-RRG`	0.3430	0.6863	0.0140

Table 4: Performance comparison of baseline systems in terms of citation quality using BioACE for the MAG task.

5.2.2 Results

We have provided the results for the MMR task in Table 2. The team PRIDE-BOILERS achieved the best results in retrieving textual documents from PubMed, with an nDCG of 0.6532. The team also achieved the highest nDCG score of 0.5927 among all participants' submitted runs; however, it was lower than the baseline `video-RR` approach. The baseline approaches show strong performance in both modalities, demonstrating the effectiveness of the BM25 followed by the re-ranking strategy over the LLM-assisted retrieval strategy.

5.3 MAG Submissions

Two teams, SEAHAWK and NJUST-KMG, submitted runs; however, they did not provide any details about them, and their submissions were incomplete, so we could not include them.

5.3.1 Results

We have evaluated the baseline runs using BioACE, and the results of the answer and citation evaluations are reported in Tables 3 and 4, respectively. For answer evaluation, BioACE provides automatic assessment based on the relevant literature, as well as nugget-based assessment, in which the ground-truth nuggets are used to compute the completeness and correctness of the generated answer. We constructed ground-truth nuggets for 10 questions in the test set and conducted both nugget-based and automatic evaluations on this subset, along with automatic evaluation over the entire test set. The results show that the multimodal baseline `MM-RRG` achieves the highest automatic correctness when evaluated over all questions, indicating the benefit of combining relevant textual and video sources. However, in nugget-based correctness evaluation, the `MM-RRG` model performs best; likely because the nuggets were constructed primarily from textual sources. `Text-RRG` obtained the highest scores across for answer completeness evaluation on both full and subset evaluations, while Video-RRG consistently underperforms, particularly on the 10-question subset. Overall, the results highlight that while multimodal approaches improve general answer quality, textual retrieval remains more reliable for fine-grained factual completeness

Rank	Team	Run/Model	IoU@0.3	IoU@0.5	IoU@0.7	mIoU
Baseline						
–	Baseline	TimeLens-7B	78.75	63.75	48.75	61.09
Participants Systems						
1	LAMAR-2	Best Run	93.75	90.00	**77.50**	79.55
2	NJUST-KMG	Best Run	92.50	81.25	67.50	75.48
3	405621	Best Run	60.00	55.00	47.50	50.78
4	SEAHAWK	Best Run	71.25	52.50	42.50	52.30
5	UNCC	Best Run	62.50	36.25	22.50	42.57
6	ADAPT	Best Run	10.00	10.00	8.75	8.62

Table 5: Performance of the participating teams on the **VAL** task. Teams are ranked based on their best run using IoU@0.7 as the primary metric.

and correctness. To examine the effectiveness of the BioACE automatic evaluation framework, we computed rank correlations between Auto (10Q) and Nugget (10Q) scores using Spearman's ρ rank correlation coefficient. For correctness, the results show moderate agreement ($\rho = 0.50$), indicating some variation in system ranking. In contrast, completeness shows perfect agreement ($\rho = 1.0$), suggesting strong alignment between automatic and nugget-based evaluation for answer completeness.

For citation evaluation, we used the BioACE framework. The results show that `Text-RRG` achieves the highest citation coverage and support rate, while `Video-RRG` yields the lowest contradiction rate. We observed a notable drop in coverage for both `Video-RRG` and `MM-RRG`. This may be due to the fact that the answer generation model was fine-tuned to generate citations from PubMed-style textual documents rather than from video transcripts.

5.4 VAL Submissions

5.4.1 Methods

LAMAR-2 (Sermsrisuwan et al., 2026) utilizes a multimodal, multi-stage pipeline designed for precise temporal localization in medical videos. The proposed approach begins with parallel audio and visual extraction. For the audio stream, they extract 16kHz mono audio using FFmpeg and process it through `Qwen3-ASR-1.7B` with a forced aligner to generate exact word-level transcriptions. For the visual stream, they used PySceneDetect[14] to detect natural camera cuts and extract individual video segments, which were then passed to `Qwen3-VL` to generate chronological textual descriptions of the physical actions. Both the word-level transcripts and the scene-by-scene visual context were then temporally aligned and aggregated into a unified reference dataset for each video. In the final stage, they fed the raw video file, the user question, and this reference transcript and context into `Gemini-3-Flash`. They employed a vision-anchored prompting strategy, instructing the model to treat the aggregated text purely as background reference. Rather than relying on textual alignment, this instruction explicitly forces the model to ground its temporal predictions in the physical movements and procedures directly observed in the video footage, ultimately outputting the final starting and ending markers in a structured JSON format.

The team NJUST-KMG's (Li and Yang, 2026) approach to the VAL task began with ASR-based text extraction, followed by LLM-driven generation of multi-scale (single- and multi-sentence) semantic priors, which were fused with dense visual features. They used dynamic span queries for boundary regression and optimized the network using the 1D-GIoU (Rezatofighi et al., 2019) loss.

SEAHAWK (Tian and Dogan, 2026) utilized the timestamped video transcripts obtained from the Whisper (Radford et al., 2023) model to use in their answer localization system. They developed a retrieval-and-selection pipeline that treats visual answer localization as segment-level paragraph selection from timestamped video transcripts. Given a question and a segmented transcript, the system prompts DeepSeek (Liu et al., 2024) to select a contiguous range of transcript segments rather than directly generating timestamps.

UNCC (Demirhan and Zadrozny, 2026) employed a multi-stage pipeline for the VAL task. For each video-question pair, the timestamped transcript segments were first extracted using `GPT-4o Transcribe Diarize`, forming a structured

[14] https://www.scenedetect.com/

representation of the video content. Based on the query, candidate answer intervals were proposed from these segments. These candidates were then evaluated and refined using `GPT-5.4`, which considered both the transcript context and sampled key video frames. The pipeline further applied contextual augmentation and consistency-aware span selection, followed by a final refinement step to determine the start and end timestamps for the output.

5.4.2 Results

The VAL results in Table 5 show that the team LAMAR-2 achieved the highest IoU performance across multiple thresholds and the mIOU metric. It outperformed the baseline systems in terms of IoU@0.7, increasing from 48.75 to 77.50. Their strong performance is due to fine-grained modeling of the modalities (audio, visual), explicitly leveraging visual cues rather than relying on textual descriptions of the videos. The team NJUST-KMG achieved the second-best performance by using LLM-driven generation of multi-scale (single- and multi-sentence) semantic priors. The team UNCC achieved a competitive IoU@0.3. However, their performance declined for strict metrics such as IoU@0.5 and IoU@0.7. This may be because their approaches rely on textual candidate generation and on varying visual cues and temporal alignment. The baseline system achieved competitive performance, with an IoU@0.7 score of 48.75, outperforming the best approaches from four participants. We find that approaches that use multimodal grounding and temporal alignment achieve better results than those that rely solely on textual descriptions.

6 Discussion

For the MMR task, we found that the BM25-based approach is a strong method for extracting an initial set of relevant videos from the PubMed Central video transcripts. Hybrid approaches that combine lexical and dense retrieval show improved performance. We observed that video collections sourced from YouTube contain very few relevant videos for professional queries, particularly those involving medical procedures. To address this limitation, we plan to enrich the collection with more specialized videos and, in future work, explore open retrieval from a broader range of video sources. We were also unable to evaluate generative retrieval (Li et al., 2025) and the joint retrieval setup (video and document projection in the unified space) in the current challenge, and we leave these to future work.

We note that the MAG task received limited participation. This is attributed to the complexity of the MAG task, which requires retrieving and synthesizing textual and video evidence to generate coherent and informative answers to medical questions. However, we provide baseline approaches and evaluation metrics to support further research on this important and timely task for the research community. It is to be noted that for the MMR and MAG baseline approaches, we use video information in the form of transcripts, which do not capture temporal dynamics. Despite this limitation, the models still achieve competitive performance and serve as reference points to guide further research on incorporating and enhancing visual information in retrieval and answer generation approaches.

The VAL task results show that the majority of approaches struggle to identify precise video segments that can be considered as answers. However, methods that incorporate fine-grained integration of multimodal information and alignment tend to achieve better performance, as observed in some of the submitted runs. Further analysis of the VAL ground-truth dataset reveals that many annotated segments are relatively long and correspond to many procedural or instructional steps. The developed test questions tend to be more general than focusing on a specific step. In future work, we plan to design more fine-grained video-centric questions and annotate shorter, more precise segments to better evaluate the models' ability to localize exact answer spans.

The results of this shared task highlight several practical challenges in developing medical multimodal question answering. The textual sources play a critical role in providing reliable answers. The video information is difficult to use effectively, even though it provides key information for medical professionals, including procedures and medical education. Specifically for the answer generation task, synthesizing answers from multimodal sources and ensuring that they remain attributable to the corpora is challenging. Moreover, evaluating multimodal medical question answering systems remains challenging because it relies on costly and time-intensive expert annotation. BioACE offers a useful alternative for efficient evaluation and ranking of system outputs and aligns well with nugget-based evaluation for completeness, but less so for correctness.

7 Conclusion

This paper provides an overview of MedGenVidQA 2026 shared task, organized as part of the BioNLP 2026 workshop. We discussed the tasks, datasets, evaluation metrics, and baseline systems. We also provided a summary of the approaches developed by the participating systems. We observed that efficient use of multimodal information sources remains challenging for the related tasks. Although multimodal approaches show promise, they do not consistently outperform strong textual baselines, suggesting that current fusion strategies remain limited. We are optimistic that introducing these tasks, baseline systems, and datasets will foster research toward reliable and trustworthy medical question answering systems for consumers and medical professionals.

Instruction: Write an accurate, engaging, and concise answer for the given question using only the provided search results (some of which might be irrelevant) and cite them properly. Use an unbiased and journalistic tone. Always cite for any factual claim. When citing several search results, use [1][2][3]. Cite at least one document and at most three documents in each sentence. If multiple documents support the sentence, only cite a minimum sufficient subset of the documents.
Documents:
{Document 1}
{Document 2 }
...
{Document 10}
Question : {question}

Figure 4: Prompt used for answer generation with citations.

Instruction: Write an accurate and concise summary of the provided document in relation to the given question. Focus on the information that directly helps answer the query and ignore irrelevant details. Use an unbiased and journalistic tone. Base the summary strictly on the document and do not add external knowledge.
Document: {document}
Question : {question}

Figure 5: Prompt used to summarize the video transcript.

Instruction: You are given a full video and the question: '{query}'. Locate the single continuous video segment in the video that best answers the question. Return exactly one start time and one end time for the most relevant segment. Choose the shortest segment that contains enough evidence to answer the question. If multiple candidate segments exist, return only the best one. If the video does not contain an answer, return 'none'. Output exactly in this format: 'The answer segment is <start time> - <end time> seconds' or 'none'.

Abstract

This paper presents an overview of the ClinicalSkillQA 2026 shared task, which was organized with the BioNLP Workshop at ACL 2026. The goal of this shared task is to evaluate continuous perception and procedural reasoning in clinical skill assessment by requiring systems to reconstruct the correct temporal order of shuffled clinical key frames and generate rationales grounded in clinical workflow knowledge. The benchmark contains 200 test-only instances sampled from clinical skill videos, covering three emergency-care procedures. Each instance is annotated with the ground-truth temporal order and an expert-verified rationale. A total of seven teams participated in the task, collectively making 90 submissions, with four teams providing system description papers. Systems are evaluated using Task Accuracy, Pairwise Accuracy, and BERTScore, which measure exact sequence reconstruction, local temporal consistency, and rationale quality, respectively. In this paper, we describe the task setup, dataset construction, and evaluation criteria. We further summarize the methodologies adopted by participating teams and present a comprehensive analysis of the submitted systems. The official results suggest that current models still struggle with continuous perception and procedural reasoning, especially when they must integrate visual evidence, temporal structure, and clinical workflow knowledge.

1 Introduction

Clinical skill assessment is a core component of medical education, where trainees are evaluated on whether their procedures follow standardized clinical workflows and safety-critical operational requirements (Kogan et al., 2009, 2011). In scenarios such as cardiopulmonary resuscitation, automated external defibrillator operation, and bag-mask ventilation, expert assessors review trainees' operations and judge whether each action is performed in the correct procedural context (Harden et al., 1975; Regehr et al., 1998; Hodges et al., 1999). This process requires more than recognizing isolated visual events: assessors must understand how clinical actions unfold over time, how earlier steps constrain later ones, and how a sequence of observations corresponds to a valid medical procedure. As multimodal large language models (MLLMs) are increasingly explored for medical education and clinical decision support, it becomes important to evaluate whether they can connect visual evidence with procedural medical knowledge and provide explanations that are meaningful to clinical experts.

Recent benchmarks have advanced the evaluation of multimodal reasoning in both general and medical domains (Yue et al., 2024; Zuo et al., 2025; Yu et al., 2025; Xun et al., 2025; Wang et al., 2025b). However, many existing tasks focus on static image understanding (Liu et al., 2024b), multi-image question answering (Liu et al., 2024a), or general-domain temporal reasoning (Song et al., 2025), leaving clinical procedural understanding underexplored. Medical benchmarks such as MEDFRAMEQA (Yu et al., 2025) require reasoning over multiple medical images, but the questions can often be answered by aggregating evidence from individual frames, without explicitly modeling the temporal dependencies among clinical actions. Similarly, continuous perception benchmarks such as CP-Bench (Wang et al., 2025b) evaluate whether models can integrate informa-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 1101–1108
July 3-4, 2026 ©2026 Association for Computational Linguistics

tion across visual observations, but often simplify continuous perception into tasks such as counting, where the temporal order of observations may not directly affect the final answer. These settings are insufficient for clinical skill assessment, where the interpretation of an action is inherently conditioned on its position within a procedural workflow.

This limitation becomes especially important in clinical training scenarios. For example, a frame showing chest compressions cannot be fully interpreted without considering whether patient assessment, emergency response activation, and preparation steps have occurred beforehand. Likewise, a frame showing defibrillator use only becomes clinically meaningful when placed within the correct sequence of rhythm assessment, pad placement, safety checks, and shock delivery. Thus, evaluating MLLMs for clinical skill assessment requires tasks that go beyond recognizing what appears in each frame and instead test whether models can reconstruct temporally coherent and clinically plausible action progressions. It also requires explanation-based evaluation, since in medical education a model's answer is useful only when its reasoning can be inspected and aligned with clinical workflow knowledge.

To address this challenge, we organize the ClincalSkillQA shared task for evaluating continuous perception and procedural reasoning in clinical skill assessment. The task asks MLLMs to arrange shuffled key frames into the correct temporal order of clinical actions and to generate rationales explaining the predicted order. This formulation directly tests whether models can infer action progression from visual observations while grounding their decisions in clinical workflow knowledge. We provide 200 sets of shuffled key frames extracted from clinical skill videos covering three representative emergency-care procedures. Each sample is annotated with an expert-defined ground-truth ordering and a reference rationale. For evaluation, we use Task Accuracy to measure exact sequence reconstruction, Pairwise Accuracy to assess local temporal consistency between adjacent clinical actions (Wang et al., 2025a), and BERTScore (Zhang et al., 2019) to evaluate the semantic quality of generated rationales. ClinicalSkillQA provides a clinically grounded testbed for studying how MLLMs connect visual observations, temporal structure, and procedural medical knowledge in medical education scenarios.

2 Task Description

ClinicalSkillQA formulates clinical skill understanding and continuous perception in clinical skill assessment as a multi-image temporal ordering task. Given a set of shuffled key frames extracted from a clinical skill video, a model is required to arrange the frames into a coherent sequence of clinical actions and provide a textual explanation for the resulting order. The task is designed to evaluate whether MLLMs can infer temporal continuity, procedural dependencies, and action-state transitions from fragmentary visual observations, rather than treating each frame as an independent image.

2.1 Task Definition

For each instance, the input consists of a set of shuffled key frames:

$$\mathcal{I} = \{I_1, I_2, \ldots, I_n\},$$

where each frame is associated with a unique identifier, such as A, B, C, or D. The frames are sampled from a continuous clinical skill video and randomly permuted before being presented to the model. The model is asked to output the correct temporal order of the frame identifiers and to generate an explanation that justifies this order.

The ground-truth answer is an ordered sequence:

$$I^* = (I_1^*, I_2^*, \ldots, I_n^*),$$

where I_t^* denotes the frame identifier corresponding to the t-th step in the original clinical procedure. The model prediction is formulated as:

$$\hat{y} = f_\theta(\mathcal{I}, \mathcal{P}),$$

where f_θ denotes the evaluated model and $\mathcal{P}$ denotes the task instruction that specifies the required output format and asks the model to recover the temporal order of the shuffled frames with an explanation. The prediction $\hat{y}$ contains two components:

$$\hat{y} = (\hat{I}, \hat{R}),$$

where $\hat{I} = (\hat{I}_1, \hat{I}_2, \ldots, \hat{I}_n)$ is the predicted temporal order of the provided frame identifiers, and $\hat{R}$ is the generated rationale explaining the temporal dependencies and procedural cues used to infer this order. A valid prediction should include each provided frame identifier exactly once. Predictions with missing, duplicated, or invalid identifiers are regarded as invalid outputs by the official evaluation script.

2.2 Evaluation Setting

The official shared task evaluates both the predicted ordering and the generated rationale. For the ordering results, we use Task Accuracy and Pairwise Accuracy. Task Accuracy measures whether the predicted sequence exactly matches the ground-truth order. Pairwise Accuracy measures the fraction of correctly ordered adjacent frame pairs, providing a more fine-grained assessment of local temporal consistency.

For rationale evaluation, we use BERTScore to measure the semantic similarity between the generated rationale and the expert-annotated reference rationale. Together, these metrics assess whether a model can recover the correct temporal order while also producing explanations that are consistent with clinical workflows and expert reasoning.

3 Dataset

ClinicalSkillQA is constructed from clinical skill assessment videos and consists of 200 test instances of shuffled key frames. Each instance corresponds to a continuous clinical action sequence and is associated with a hidden ground-truth temporal order and an order rationale. The dataset is designed as a test-only shared task benchmark to evaluate whether MLLMs can reconstruct coherent clinical procedures from fragmentary visual observations. As summarized in Table 1, ClinicalSkillQA covers three clinical skill scenarios and uses shuffled key frames as input, with temporal order and rationale as evaluation targets.

3.1 Data Source

The videos are derived from the SiMing-Bench (Huang et al., 2026) dataset, which contains medical student clinical procedure videos collected under standardized clinical skills assessment settings. We sample key frames from the videos to construct multi-image instances, where each instance represents a continuous clinical action sequence. This source provides realistic yet controlled procedural scenarios for evaluating continuous perception in medical contexts. Compared with independent medical image recognition, the sampled frames require models to infer temporal and procedural dependencies among clinically related actions, such as preparation, patient contact, device placement, action execution, and post-action checking.

The study was approved by the Institutional Review Board. During data collection and processing, privacy protection procedures were applied to remove or mask personally identifiable information. The dataset is intended for research on multimodal clinical skill understanding and medical education, rather than for direct clinical decision-making.

Item	Description
Dataset	ClinicalSkillQA
# Instances	200
Scenarios	CPR, AED, BMV
Input	Shuffled key frames
# Frames	4 or 6 per instance
Target	Order & rationale
Evaluation setting	Test-only benchmark

Table 1: Dataset summary of ClinicalSkillQA. Each instance consists of 4 or 6 shuffled key frames sampled from a continuous clinical skill video. The hidden temporal order and expert-verified rationale are used for official evaluation.

3.2 Annotation

Each instance is annotated with two types of supervision: the ground-truth temporal order and an order rationale. The temporal order is derived from the original chronological sequence of the sampled key frames. The rationale explains why the recovered order is clinically and procedurally correct.

We adopt a model-assisted and physician-verified annotation pipeline to improve both efficiency and consistency. Specifically, a multimodal model[1] is first prompted with the shuffled key frames and the corresponding ground-truth order to generate an initial order rationale. The prompt asks the model to focus on visible action progression, state transitions, and clinically meaningful dependencies across frames. The generated rationale is then refined by a second multimodal model[2] to improve clarity, remove redundant descriptions, and ensure that the explanation is aligned with the visual evidence.

Finally, two physicians independently review the temporal order and the refined rationale. They correct clinically inaccurate statements, remove unsupported visual claims, and verify that the rationale reflects the actual procedural progression shown in the frames. Disagreements are resolved through discussion until consensus is reached. The final annotations are used only for official evaluation and

[1]We used Gemini 3 Pro for the first-stage rationale generation.

[2]We used GPT-5.2 for the second-stage rationale refinement.

are not released to participants during the shared task.

4 Evaluation

ClinicalSkillQA evaluates model performance from two perspectives: the correctness of the predicted temporal ordering and the quality of the generated rationale. Following the task definition, each prediction contains an ordering result $\hat{I}$ and an ordering rationale $\hat{R}$. We use Task Accuracy and Pairwise Accuracy to evaluate the predicted ordering, and BERTScore to evaluate the rationale.

4.1 Task Accuracy

Task Accuracy measures whether the model reconstructs the entire temporal sequence exactly. For the i-th instance, let the ground-truth ordering be

$$I^{*(i)} = (I_1^{*(i)}, I_2^{*(i)}, \ldots, I_{n_i}^{*(i)}),$$

and the predicted ordering be $\hat{I}^{(i)}$. The prediction is counted as correct only when the two sequences are identical:

$$\mathrm{Acc}_i = \mathbb{I}\left(\hat{I}^{(i)} = I^{*(i)}\right),$$

where $\mathbb{I}(\cdot)$ is the indicator function. Given N test instances, Task Accuracy is computed as

$$\mathrm{TaskAcc} = \frac{1}{N}\sum_{i=1}^{N} \mathbb{I}\left(\hat{I}^{(i)} = I^{*(i)}\right).$$

This metric is strict: any misplaced, missing, or duplicated frame identifier causes the instance to be marked as incorrect.

4.2 Pairwise Accuracy

Task Accuracy does not reflect partial temporal correctness. Therefore, we further report Pairwise Accuracy, which measures whether the model preserves the correct relative order of adjacent frame pairs in the ground-truth sequence.

For the i-th instance, let $\mathrm{pos}_{\hat{I}^{(i)}}(x)$ denote the position of frame identifier x in the predicted ordering. For each adjacent ground-truth pair $(I_t^{*(i)}, I_{t+1}^{*(i)})$, we define

$$c_{i,t} = \mathbb{I}\left(\mathrm{pos}_{\hat{I}^{(i)}}(I_t^{*(i)}) < \mathrm{pos}_{\hat{I}^{(i)}}(I_{t+1}^{*(i)})\right).$$

If a required frame identifier is missing, the corresponding pair is treated as incorrect.

We compute Pairwise Accuracy by aggregating all adjacent ground-truth pairs across the evaluation set:

$$\mathrm{PairAcc} = \frac{\sum_{i=1}^{N}\sum_{t=1}^{n_i-1} c_{i,t}}{\sum_{i=1}^{N}(n_i - 1)}.$$

This metric only checks whether each adjacent ground-truth pair appears in the correct relative order in the prediction; the two frames do not need to remain adjacent in the predicted sequence. Pairwise Accuracy provides partial credit for recovering local temporal transitions, even when the full sequence is not perfectly reconstructed.

4.3 BERTScore for Rationale Evaluation

We also evaluate the generated ordering rationale $\hat{R}$ against the expert-verified reference rationale R^*. BERTScore is used because it measures semantic similarity based on contextual embeddings rather than exact lexical overlap. This is suitable for ClinicalSkillQA, where different explanations may use different wording but still describe the same clinical operation, procedural stage, visual evidence, and temporal transition. We report the average BERTScore F1 over all test instances.

4.4 Overall Score

The official leaderboard score aggregates temporal ordering performance and rationale quality. We first define the ordering score as

$$S_{\mathrm{ord}} = \alpha \cdot \mathrm{TaskAcc} + (1-\alpha)\cdot \mathrm{PairAcc},$$

where α controls the relative importance of exact sequence reconstruction and partial temporal consistency.

The final score is then computed as

$$S_{\mathrm{final}} = 100 \cdot [\beta \cdot S_{\mathrm{ord}} + (1-\beta)\cdot \mathrm{BERTScore}_{F1}],$$

where β balances the ordering result and the generated rationale. In our official evaluation, we set $\alpha = 0.7$ and $\beta = 0.8$. This choice assigns higher importance to exact sequence reconstruction while still rewarding models for preserving local temporal transitions and generating semantically meaningful rationales. The factor 100 scales the score to a more readable range.

5 Results

We used the CodaBench platform[3] to manage the submission and evaluation process for the shared

[3] https://www.codabench.org/competitions/14884/#/pages-tab

task. Overall, seven teams participated and made a total of 90 submissions.

Table 2 reports the official results[4] on the ClinicalSkillQA test set. Teams are ranked by the overall score, which jointly considers exact temporal ordering, local temporal consistency, and rationale quality.

Overall, ZZUNLP achieves the best performance, with an overall score of 71.43. It also obtains the highest Task Accuracy and Pairwise Accuracy, reaching 0.63 and 0.86, respectively, and achieves a strong BERTScore F1 of 0.79. The second-ranked system, qqpprun, obtains an overall score of 63.88, with Task Accuracy and Pairwise Accuracy close to those of ZZUNLP. This indicates that the leading systems are relatively effective at reconstructing temporal sequences and preserving local temporal transitions.

The middle-ranked systems, including FBK and nance, achieve overall scores of 59.45 and 56.62, respectively. Although their ordering metrics are lower than those of the top two systems, they obtain strong BERTScore F1 scores. In particular, nance reaches a BERTScore F1 of 0.79, matching that of ZZUNLP. This suggests that rationale generation can remain competitive even when exact temporal reconstruction is less accurate.

The remaining systems obtain substantially lower overall scores, mainly due to limited Task Accuracy. For example, VerbaNexAI, DLNLP, and zhekun achieve Task Accuracy scores of 0.17, 0.10, and 0.03, respectively, while their Pairwise Accuracy scores remain higher. This gap indicates that these systems can recover partial local temporal relations but often fail to reconstruct the complete sequence exactly. Notably, zhekun obtains a relatively high BERTScore F1 of 0.74 despite its low ordering accuracy, further showing that rationale similarity does not necessarily imply correct temporal ordering.

Across all teams, Pairwise Accuracy is consistently higher than Task Accuracy. This trend shows that preserving local temporal relations is generally easier than reconstructing the full shuffled sequence exactly. Meanwhile, BERTScore F1 is relatively high for several systems even when their Task Accuracy remains limited. This suggests that rationale quality and ordering correctness capture complementary aspects of model performance: a system may generate clinically plausible explanations without fully recovering the correct temporal order. Overall, these results demonstrate that ClinicalSkillQA remains challenging for current systems, especially in requiring models to jointly perform fine-grained temporal reconstruction and clinically grounded rationale generation.

[4]Component metrics are rounded to two decimal places, while overall scores are computed using unrounded official metric values.

6 System Descriptions

This section summarizes the submitted systems for the ClinicalSkillQA shared task. Out of the seven participating teams, four teams submitted system papers. Overall, participating teams explored different strategies for reconstructing the temporal order of clinical keyframes and generating corresponding rationales. The submitted methods mainly relied on multimodal large language models, with different designs for visual evidence extraction, procedural reasoning, and explanation generation.

ZZUNLP. ZZUNLP proposed Perceive-and-Plan, a two-stage in-context learning framework for clinical skill keyframe reordering. The system first performs structured visual perception by generating compact clinical descriptions for each frame, enhanced with saliency-guided picture-in-picture inputs that zoom in on critical head/airway and chest/hand regions. It then conducts temporal planning in a fresh conversation, using BLS procedural rules and visual anchors to verify the predicted chronological order. Without parameter updates, the system achieved an overall score of 71.43, with 0.63 Task Accuracy, 0.86 Pairwise Accuracy, and 0.79 BERTScore F1. The results suggest that separating visual perception from temporal reasoning improves local ordering reliability, while the remaining gap between exact sequence accuracy and pairwise accuracy indicates that long-range permutation errors and subtle state-transition ambiguities remain challenging.

FBK. FBK adopted a training-free prompting framework based on Qwen3-VL-32B-Instruct for clinical keyframe ordering. Their system examined several prompt formulations, random filename renaming to reduce alphabetical-order bias, few-shot demonstrations, and keypoint-derived predicates extracted by YOLOv8 pose estimation. The strongest setting used randomly renamed frames and full human-pose predicates without few-shot examples, achieving an overall score of 59.45, with 0.47 Task Accuracy, 0.72 Pairwise Accuracy, and

Team	Overall Score	Task Accuracy	Pairwise Accuracy	BERTScore F1
ZZUNLP	71.43	0.63	0.86	0.79
qqpprun	63.88	0.58	0.84	0.55
FBK	59.45	0.47	0.72	0.76
nance	56.62	0.41	0.75	0.79
VerbaNexAI	37.96	0.17	0.60	0.71
DLNLP	30.44	0.10	0.55	0.57
zhekun	28.71	0.03	0.51	0.74

Table 2: Official results on the ClinicalSkillQA test set. Teams are ranked by the overall score. Pairwise Accuracy denotes micro-averaged pairwise accuracy.

0.76 BERTScore F1. Their analysis shows that simple prompting was more effective than more complex intermediate reasoning prompts, while filename renaming consistently improved performance by reducing spurious textual biases. The largest gain came from keypoint-derived predicates, suggesting that explicit posture and body-motion cues provide useful temporal evidence for reconstructing clinical action sequences.

VerbaNexAI Lab. VerbaNexAI Lab proposed a zero-shot two-stage framework based on Qwen2-VL-2B-Instruct. The system first extracts frame-level visual evidence and maps it into structured procedural states using deterministic rules. It then assigns each frame an ordinal stage score and sorts frames accordingly, with PCA over multimodal embeddings used to break ties. The final prediction includes both the ordered frame sequence and an evidence-based rationale. On the official test set, the system achieved an overall score of 37.96, with 0.17 Task Accuracy, 0.60 Pairwise Accuracy, and 0.71 BERTScore F1. These results indicate that the method produced complete and semantically reasonable rationales, but still struggled with exact temporal ordering, especially when adjacent procedural states were visually similar.

DLNLP. DLNLP proposed EvidenceFlow, a structured zero-shot framework built on Qwen2.5-VL-7B-Instruct for clinical keyframe ordering. The method decomposes the task into global overview, local evidence modeling, and ordering decision, and explores two variants: EvidenceFlow-M, which relies on model-led reasoning, and EvidenceFlow-R, which introduces rule-guided correction with explicit evidence constraints. On the official test set, the submitted EvidenceFlow-R variant achieved an overall score of 30.44, with 0.10 Task Accuracy, 0.55 Pairwise Accuracy, and 0.57 BERTScore F1. In their system paper, DLNLP further reports that EvidenceFlow-M achieved a higher BERTScore F1 of 0.74, whereas EvidenceFlow-R performed better on ordering-related metrics. These results suggest that explicit rule constraints improve ordering stability, whereas more flexible model-led reasoning may produce semantically richer explanations. The main remaining bottleneck is the stable integration of subtle cross-image temporal cues into a globally consistent clinical sequence.

7 Conclusion

We introduced ClinicalSkillQA, a BioNLP shared task for evaluating continuous perception and procedural reasoning in clinical skill assessment. Given shuffled key frames from clinical skill videos, systems are required to recover the correct temporal order and generate rationales explaining their predictions. The benchmark contains 200 test-only instances covering three emergency-care procedures, with annotations consisting of the ground-truth temporal order and expert-verified rationales. Official results show that current multimodal systems can capture some local temporal relations and produce plausible explanations, but still face clear challenges in exact full-sequence reconstruction. These findings suggest that clinical procedural reasoning remains difficult for existing multimodal large language models, particularly when visual evidence, temporal dependencies, and clinical workflow knowledge must be jointly integrated. ClinicalSkillQA provides a clinically grounded testbed for future research on reliable multimodal reasoning in medical education.

8 Limitations

ClinicalSkillQA has several limitations. First, the benchmark currently includes 200 test-only instances from three emergency-care procedures, which may not fully represent the diversity of clinical skills, medical specialties, and assessment environments. Expanding the dataset to more procedures and clinical contexts would improve its

coverage and generalizability.

Second, the task is based on shuffled key frames rather than full videos. This formulation enables controlled evaluation of temporal ordering and procedural reasoning, but it does not fully capture motion dynamics, action duration, or fine-grained temporal transitions. Therefore, the benchmark primarily evaluates whether models can infer procedural order from representative visual observations, rather than their complete ability to understand continuous clinical videos.

Third, rationale quality is evaluated using BERTScore F1. Although this provides an automatic measure of semantic similarity, it may not fully reflect clinical correctness, visual grounding, or educational usefulness. Future work could introduce clinically informed rationale metrics or expert-based evaluation.

Finally, ClinicalSkillQA is designed as a test-only shared task benchmark. This setting supports fair evaluation of submitted systems, but it does not examine the effects of supervised training or domain adaptation. Future versions may include development data, additional procedures, and full-video assessment settings.
