BioNLP 2026, a year in review: Asking LLMs for the facts, all the facts, and nothing but the facts

Dina Demner-Fushman, Sophia Ananiadou, Kirk Roberts, Junichi Tsujii

BioNLP 2026 marks a quarter-century of the efforts to bring together computational linguists whose work is dedicated to improving health through language technologies, ranging from foundational tasks to clinical applications. Large Language Models (LLMs) continue to be the mainstay of Biomedical Language Processing, while the scope of BioNLP research continues to expand across foundational tasks, applications, languages and modalities. In 2026, we see increasing efforts to integrate textual features with visual and sequencing data; new approaches to named entity recognition and linking; work in several languages other than English; and applications ranging from molecular biology to clinical studies. Complex language technology tasks, such as question answering and summarization, as well as data generation and text mining are also strongly represented. Concerns about potential harms and irresponsible use of AI applications are being addressed through growing research into evaluation, debiasing, and understanding of models' behavior. The submissions to the BioNLP 2026 workshop and the Shared Tasks demonstrated once again that the workshop– sponsored by the ACL Special Interest Group on Biomedical Natural Language Processing (SIGBioMed)– is the preferred venue for the groundbreaking research and applications in Biomedical Language Processing, which encompasses biological, clinical and non-health professional sub-languages, among others. BioNLP remains the flagship venue and the broadest forum in biomedical language processing, accepting high-quality research across all tasks, methods and languages. The quality and diversity of submissions continues to impress the program committee and the organizers.

BioNLP 2026 received 109 submissions spanning foundational research, biomedical language processing, clinical applications, and development of new datasets and benchmarks. Notably, in addition to the shared tasks that focused on factuality and accuracy of the results generated by large language models, many workshop submissions take a closer look at the nature of hallucinations and approaches to ascertain the factuality of the results generated by the models for various tasks. Moreover, there is a renewed interest in improving the quality of the existing benchmarks and designing new evaluation approaches that not only evaluate factuality, but also require grounding and explanations of the process that generated the results.

BioNLP has a long-standing tradition of sponsoring Shared Tasks. In 2026, we invited SIGBioMed members to submit a description of a shared task to be included with the BioNLP proposal. We received four strong detailed descriptions of the tasks, which were reviewed by the workshop organizers. These well-defined and timely tasks collocated with BioNLP 2026 are briefly described below.

MedExACT task involved detection and labeling of medical decisions in ICU discharge summaries, with evaluation metrics emphasizing both accuracy and fairness across demographic and disease subgroups at the span and token levels, as well as through stratified analyses to measure robustness against biases in sex, race, English proficiency, and disease type. Baseline models such as RoBERTa indicated the complexity of the task. The participants were supported with expedited access to MedDec through PhysioNet, a public leaderboard, and a starter kit in Python.

PsyDefDetect: Detecting Psychological Defense Mechanisms in Conversations. This task focused on classifying Seeker utterances in supportive conversations into specific Psychological Defense Levels based on the Defense Mechanism Rating Scales (DMRS) framework. The benchmark addresses the challenge of capturing subtle linguistic cues of deep-seated psychological mechanisms within highly informal and context-dependent emotional dialogues. This initiative supports research at the intersection of clinical psychology and NLP, aiming to operationalize complex psychological constructs for computational

analysis.

MedGenVidQA task focused on grounding answers with reference attribution to mitigate generation of false statements by LLMs when answering biomedical questions. MedGenVidQA 2026 introduces generation of multimodal answers from textual and visual sources with citations, leveraging PubMed and HealthVidQA as multimodal sources. The test set is based on the information requests submitted by self-identified non-clinicians to the MedlinePlus service provided by the National Library of Medicine. The evaluation leverages BioACE, an automated evaluation framework that strongly correlates with human evaluation on the BioGen 2024 textual dataset.

ClinicalSkillQA formulated clinical skill understanding and continuous perception for clinical skill assessment as an ordering task: the MLLM is required to arrange shuffled key frames into a coherent sequence of clinical actions and to provide explanations for the resulting order. The dataset is constructed from video clips of medical student clinical procedures, collected from Zhongnan Hospital of Wuhan University and Cofun.

The overviews of the tasks are included in the workshop program. The participants in all Shared Tasks present their work on July 4th.

The keynote by Annika Marie Schoene, PhD, Assistant Professor, Bouve College of Health Sciences, is titled: AI Safety in Healthcare: Ethical and Technical Considerations.
The rapid integration of artificial intelligence into healthcare, spanning ambient documentation, virtual nursing, and medical imaging, has outpaced the development of robust oversight mechanisms. While the global AI-in-healthcare market is projected to exceed 868 billion by 2030, incidents of algorithmic bias and unequal care delivery have exposed significant gaps between responsible AI principles and clinical implementation. This talk examines AI safety as a foundational pillar of responsible AI in health contexts, arguing that fairness, transparency, accountability, and human autonomy cannot remain aspirational without corresponding technical and governance infrastructure. I survey existing frameworks and identify a critical missing layer of concrete, operationalizable evaluation methods that bridge ethical principles and technical practice. To address this gap, I present work toward an actionable framework for responsible AI integration in clinical settings, grounded in the AI Ethics Box, a structured taxonomy derived from biomedical ethics. The framework maps ethical domains to specific technical tests, supporting both pre- and post-deployment evaluation. I also describe an ongoing co-design process with clinical and community stakeholders to ensure real-world feasibility. I conclude that AI in healthcare demands genuinely interdisciplinary research to build tools that improve health outcomes without compromising patient safety.

Biography: Annika Marie Schoene, PhD is a computer scientist and researcher in AI safety, working on the evaluation, robustness, and security of large-scale AI systems, including large language models. She develops technical methods and evaluation frameworks to identify and mitigate high-risk behaviors such as jailbreaks, harmful outputs, and unsafe system behavior, with the goal of enabling the safe and trustworthy deployment of AI in public health, health systems, and healthcare settings. She is currently an Assistant Professor in the Department of Public Health and Health Sciences and Technical Lead for the Responsible AI Practice at Northeastern University. Beyond her core research, she works across academic, industry, public-sector and not-for-profit settings to generate evidence that supports non-technical stakeholders and policymakers in making informed decisions that reduce algorithmic harm and inform organizational decision-making. She is also a Visiting Scientist at MaineHealth and the University of Southampton (UK), and a Faculty Fellow at the Institute for Social Justice and Healthy Equity, and serves as a Scientific Expert Advisor at Meta on AI safety. She holds a PhD in Computer Science from the University of Hull (UK). During her doctoral training, she conducted research on machine and deep learning methods for analyzing complex real-world text and interned at IBM Research (UK), continuing this collaboration throughout her PhD and postdoctoral work. She completed her postdoctoral training at the University of Manchester's National Centre for Text Mining (NaCTeM), where she worked on natural language processing in health-related contexts. Prior to her current role, she was a Research Scientist

at the Institute for Experiential AI (EAI), working primarily on research involving the development and evaluation of AI methods in applied health contexts.

As always, we are deeply grateful to the authors of the submitted papers and to the reviewers (listed elsewhere in this volume) who produced three thorough and thoughtful reviews for each paper in a very short review period. The quality of submitted work continues to grow, and the organizers are truly grateful to the members of our Program Committee, who helped us to determine which work was ready to be presented, and which would benefit from the additional experiments and analyses suggested by the reviewers. As in years past, we are looking forward to a productive workshop and hoping it will foster new collaborations and research. This will enable our community to continue making valuable contributions to public health and well-being, as well as to basic and clinical research.

Keynote Talk

AI Safety in Healthcare: Ethical and Technical Considerations

Annika Marie Schoene
Bouve College of Health Sciences
2026-07-03 11:00:00 – Room: **Room tbd**

Abstract: The rapid integration of artificial intelligence into healthcare, spanning ambient documentation, virtual nursing, and medical imaging, has outpaced the development of robust oversight mechanisms. While the global AI-in-healthcare market is projected to exceed $868 billion by 2030, incidents of algorithmic bias and unequal care delivery have exposed significant gaps between responsible AI principles and clinical implementation. This talk examines AI safety as a foundational pillar of responsible AI in health contexts, arguing that fairness, transparency, accountability, and human autonomy cannot remain aspirational without corresponding technical and governance infrastructure. I survey existing frameworks and identify a critical missing layer of concrete, operationalizable evaluation methods that bridge ethical principles and technical practice. To address this gap, I present work toward an actionable framework for responsible AI integration in clinical settings, grounded in the AI Ethics Box, a structured taxonomy derived from biomedical ethics. The framework maps ethical domains to specific technical tests, supporting both pre- and post-deployment evaluation. I also describe an ongoing co-design process with clinical and community stakeholders to ensure real-world feasibility. I conclude that AI in healthcare demands genuinely interdisciplinary research to build tools that improve health outcomes without compromising patient safety.

Table of Contents

The Divergence Hypothesis: Unmasking Lexical Interference and Label Bias in Mental Health NLP
Moustafa Hassan 1

Towards Unified Factuality Evaluation for Biomedical QA and Summarization: Aligning Metrics with Clinical Use-Cases
Mahule Roy and Subhas Roy 15

Using Synthetic Records to Improve Automated Identification of Seizure Freedom in Clinical Text about People with Epilepsy
Stephen Barlow, Yujian Gan, Joe Davies, Joel Winston, James Teo, Mark Richardson and Ben Holgate 20

Analyzing Prompt Design Choices in Biomedical Information Extraction for Low-Resource Languages
Ayesha Khatun, Kadir Bulut Ozler, Steven Bethard and Egoitz Laparra 31

Hierarchy-Aware Hyperbolic and Semantic Reranking for Ontology-Based Phenotype Linking
Thomas Labbe, Moussa Baddour, Axel Bonesteve, Paul Rollier, Marie De Tayrac and Olivier Dameron 45

Agentic Feature Selection via LLM for Epileptic Seizure Detection
Aizierjiang Aiersilan and Xiaodong Qu 64

Training Biomedical Retrievers From Large-Scale Citation Contexts
Xing David Wang, Duy Le Thanh and Ulf Leser 75

Reliable Automated Triage in Spanish Clinical Notes: A Hybrid Framework for Risk-Aware HIV Suspicion Identification
Rodrigo Morales-Sánchez, Soto Montalvo and Raquel Martínez 84

Gold Label Errors in the SciFact Benchmark: An LLM-Assisted Annotation Audit
Julien Sylvestre 97

BioRAG: A Systematic Ablation Study of Retrieval Strategies for Biomedical Question Answering
Krushil Bhojani, Mayank Waghmare and Hima Bindu Nandyala 104

Post Hoc Agentic Refinement for Improving Precision in Multilingual Clinical Text De-identification
Justin Xu, Alistair Johnson, Thomas Lin, David Eyre and Rodolfo Quispe 115

Do Syntactic Features Help Biomedical Relation Extraction? An Empirical Study of Verb Token and Dependency Graph Augmentation
Mustafa Sikder and Ernest Kwegyir-Afful 128

Beyond Knowledge Graphs: PubMedBERT Embeddings as a Competitive Standalone Modality for Drug Re-purposing
Rishik Kondadadi and John E. Ortega 135

When Demographic Sensitivity Isn't What It Seems: Baseline-Aware Counterfactual Audits for Clinical NLP
Hyunwoo Yoo 141

CoreELM: An Open-Source Framework for Aligning Large Language Models to Embedding Spaces
Brian Ondov, Chia-Hsuan Chang, Yujia Zhou, Mauro Giuffrè and Hua Xu 156

Uncertainty-Aware Multi-Label Routing of Clinical Text to Surveillance Pathways
Agathe Zecevic, Sebastian Zeki and Angus Roberts 181

MedCAT v2: a modular, extensible architecture for clinical named entity recognition and linking under real-world privacy and compute constraints
Mart Ratas, Thomas Searle, Adam Sutton and Richard Dobson 191

Effects of Adaptive Pretraining in Specialized Domains for Named Entity Recognition
Jack Lynam and Sam Henry 199

Trade-offs in Medical LLM Adaptation: An Empirical Study in French QA
Ikram Belmadani, Oumaima El Khettari, Carlos Ramisch, Frederic Bechet, Richard Dufour and Benoit Favre 209

PromptRad: Knowledge-Enhanced Multi-Label Prompt-Tuning for Low-Resource Radiology Report Labeling
Ying-Jia Lin, Tzu-Chin Lo, Ping-Chien Li, Chi-Tung Cheng, Chien-Hung Liao and Hung-Yu Kao 235

Diagnosing Lower Extremity Arteriovenous Diseases Using Agentic LLMs
Zicen Liao, Yunhao Sun and Matthew Purver 250

KGRxn-LLM: Knowledge Graph Enhanced Large Language Models for Molecular Reaction Reasoning
Weichen Liu, Qiyao Xue, Yuyang Wu, Olexandr Isayev and Natasa Miskov-Zivanov 268

MAX-EVAL-11: A Large Scale Benchmark for Evaluating Large Language Models on Full-Spectrum ICD-11 Medical Coding
Ujjwal Singh, Sarthak Deshwal, Nitish Dube and Arjun Sharma 282

Trustworthy NLP for Low-Resource Languages: Agent-Based Uncertainty Modeling for Hebrew Radiology Report Structuring
Hadas Ben Atya, Naama Gavrielov, Zvi Badash, Gili Focht, Ruth Cytter-Kuint, Talar Hagopian, Dan Turner and Moti Freiman 292

Treating Decoder-Only LLMs as Encoders: A Simple and Effective Fine-tuning Approach for Named Entity Recognition
Ken Yano and Hiroya Takamura 312

A Multi-View Framework for Cross-Domain Nutrition Misinformation Detection in Social Media
Vishwaa Shah, Indika Kahanda, Andrea Arikawa, Asal Abbaszadeh and Richard Loftis 326

Ontological Validation of Biomedical Topic Models: SNOMED CT Hierarchy Distance as an Automated Evaluation Metric
Ilan Rubinfeld, Sami Zaidi, Milosh Djuric, Loay Kabbani, Mouhammad Halabi and Alex Shepard 342

Systematic Evaluation of the Quality of Synthetic Clinical Notes Rephrased by LLMs at Million-Note Scale
Jinghui Liu, Sarvesh Soni and Anthony Nguyen 353

Bridging the Version Gap: Multi-version Training Improves ICD Code Prediction, Especially for Rare Codes
Jinghui Liu and Anthony Nguyen 372

EmCellLLM: Human Peri-Implantation Embryonic Cell Annotation Based on Large Language Models
Xiaorui Guo, Zhiwei Liu, Qianqian Xie and Sophia Ananiadou 382

Randomized Controlled Trials as the Gold-Standard for Evaluating LLMs: A Primer for Biomedical NLP Researchers
Vicente Ivan Sanchez Carmona, Shanshan Jiang and Bin Dong 392

Citation-Aware Continual Pre-Training for Biomedical Language Models
Masaki Asada, Tomoki Tsujimura, Tatsuya Ishigaki, Shusaku Egami, Ken Fukuda and Hiroya Takamura 407

TrackList: Tracing Back Query Linguistic Diversity for Head and Tail Medical Knowledge in Open Large Language Models
Ioana Buhnila, Aman Sinha and Mathieu Constant 413

Discharge Instructions are not One Task: Grounding Differences Between Surgical and Non-Surgical Admissions
Mayank Jobanputra, Justin Xu, Samarth Oza, Hulma Naseer, Yifan Wang, Blerta Veseli, Chandralekha Kona, Haochen Cui, David Eyre and Vera Demberg 426

PrionNER: A Named Entity Recognition Dataset for Prion Disease Biomedical Literature
An Dao, Nhan Ly, Thao Tran, Yuji Matsumoto and Akiko Aizawa 435

Evaluation of Multilingual Text Simplification for the Mental Health Domain: Exploring Small Language Models
Olga Pelloni, Sandra Just and Lars Bongo 464

BioTopicXplor: A Web Tool for Interactive Exploration of PubMed Literature through Reproducible Topics.
Lana Yeganova, Donald Comeau, Won Kim, Natalie Xie, Shubo Tian, W John Wilbur and Zhiyong Lu 475

Reading Between the Lines: Toward Translating Verbose Patient-authored Messages into Clinician-Formulated Questions
Sarvesh Soni, Madeline Bittner and Dina Demner-Fushman 481

Investigating Stigmatizing Language in Clinical Documentation with Open-Source Large Language Models
Rajashree Dahal, Pardis Hosseinpour, Pranithi Kamishetty, Satwik Pamulaparthy, Saeid Tizpaz-Niari and Natalie Parde 490

Learning to Combine AI Annotations for Improved Biomedical Relevance Labeling
Won Gyu Kim, Lana Yeganova, Shubo Tian, Donald Comeau, W John Wilbur and Zhiyong Lu 502

When Does Retrieval Beat Direct LLM Diagnosis in Rare Disease? An Empirical Study of Ontology Coverage
Mohamed Elmofty and Ulf Leser 508

BioCoref: Benchmarking Biomedical Coreference Resolution with LLMs
Nourah Salem, Elizabeth White, Michael Bada and Lawrence Hunter 519

A Multi-Agent Open-Source LLM for Structured Cancer Registry Information Extraction from Pathology and Medical Reports
Abdulrahman Aal Abdulsalam, Adhari Al Zaabi, Riham Jeeballah and Habiba El Keraby 531

BioConflict: A Benchmark for Evaluating Large Language Models in Biomedical Contradiction Detection and Consensus Synthesis
Ashwin Kirubakaran and Henry Gagnier 552

Tokenization Granularity and Medical Term Representations in Language Models
Vojtech Lanz and Pavel Pecina 559

CAP: A Source-Grounded Proposition Scaffold for Faithful Clinical Dialogue-to-Note Generation
Hyunkyung Lee, Jisoo Jung, Jeonguk Lee, Jaehyo Yoo, Wooseok Han, Minkyu Kim and Gibaeg Kim 572

Segmentation Matters: Exploring LLM-Based Strategies for Temporal Clinical Event Identification in Oncology Reports
Cristiano Bellucci, Francesco Madeddu, Chiara Iacomini, Carlotta Masciocchi, Stefano Patarnello, Massimo Bernaschi, Mario Santoro and Livia Lilli 595

Operation-Mechanism Alignment for Reliable Clinical Reasoning over Electronic Health Records
Guanyu Tao, Siyao Wang, Yong Xue, Ashwani Tanwar, Yuting Ji, Kai Sun, Monica Mok, Marzana Chowdhury, Deepa Gupta, Ashok Gupta, Jingqing Zhang, Vibhor Gupta and Yike Guo 605

MeSHClass-ES and AnatEM-ES: Open Resources for Spanish Biomedical NLP
Santiago Martinez Novoa, Lina Gomez Mesa, Juan Prieto and Ruben Manrique 617

When Evidence Conflicts: Uncertainty and Order Effects in Retrieval-Augmented Biomedical Question Answering
Yikun Han, Mengfei Lan and Halil Kilicoglu 630

A Comparative Analysis of In-Context Learning and Fine-Tuning for Biomedical Information Retrieval and Sentence Extraction Using Research Domain Criteria
Athlene Jones, Khanh Lieu and Indika Kahanda 644

Clinical Evidence and Patient Reviews: A Linked Dataset for Antidepressant Side Effects
Steven Au 656

A Deterministic Multi-Stage Retrieval Pipeline for Longitudinal EHR Question Answering
Shubham Agarwal, Thomas Searle, Richard Dobson, Ninoslav Majkic and Niko Moller-Grell 665

Interpretable ICD Code Classification with Faithful Sentence Extraction
Yichen Wang, Lian Hong, Masato Mizogaki, Shunnosuke Umeda, Toshimune Kenmotsu, Akihiro Tamura and Daniel Andrade 679

Evaluating LLM-as-a-Judge for Medical Term Simplification
Ioana Buhnila, Aman Sinha, Rohit Agarwal, Dilip K. Prasad and Mathieu Constant 687

FACT: Functional Group Alignment and Consistency in Token Space for Structure-aware Molecular Representation Learning
Hyeonyeong Nam, Woojae Choi, Deok-Joong Lee, Young-Han Son, Sangwoon Lee, Bogyeong Kang, Eunjung Jo and Tae-Eui Kam 695

Small LLMs for Biomedical Claim Verification: Cost-Effective Fine-Tuning, Structural Dataset Shortcuts, and Cross-Domain Generalization
Gaurav Kumar 704

Diagnosable ColBERT: Debugging Late-Interaction Retrieval Models Using a Learned Latent Space as Reference
François Remy 713

Developing Literature Annotation Guidelines for Representing Normal Physiology in Biolink-Compatible Knowledge Graphs
Madeline Bittner, Willie Rogers, Dina Demner-Fushman, Richard Scheuermann and Matthew Diller 718

CENT: Context Engineering Framework for Normalization of Clinical Trial Procedures
Sanya Taneja, Ziqing Ji, Hans Verstraete and Ali Samadani 729

Agentic AI Architectures for SOAP Note Generation
Keno Hanken 742

VERICITE: Evaluating Sentence-Level Citation Faithfulness in Retrieval-Augmented Medical Question Answering
Yixian Ma, Bohao Chu and Norbert Fuhr 753

Overview of the Medical Decision Extraction, Analysis, and Classification Task (MedExACT) of BioNLP 2026
Mohamed Elgaar, Jiali Cheng, Nidhi Vakil, Mehrnaz Sadrolashrafi, Mitra Mohtarami, Adrian Wong, Hadi Amiri and Leo Celi 760

Divide-Prompt-Refine: a Training-Free, Structure-Aware Framework for Biomedical Abstract Generation
Sylvey Lin, Joseph Menke, Shufan Ming, Dongin Nam, Neil Smalheiser and Halil Kilicoglu . 770

AAbAAC: An Annotated Corpus for Autoimmunity Information Extraction
Fabien Maury, Solène Grosdidier, Maud De Dieuleveult and Adrien Coulet 791

What Do Biomedical NER and Entity Linking Benchmarks Measure? A Corpus-Centric Diagnostic Framework
Robert Leaman, Rezarta Islamaj and Zhiyong Lu 801

Towards Grounded Hallucination Definitions for Biomedical Question Answering with Reproducible Examples from ClinIQLink
Brandon Colelough, Davis Bartels, Madeline Bittner and Dina Demner-Fushman 812

Can NLP Models Detect When One Publication Outweighs Twenty? Predicting Systematic Review Conclusion Changes
Ebrahim Alharbi and Mark Stevenson 843

VaxScope: Document-Level Structured Evidence Extraction from Immunization Systematic Reviews
Bahar Ilgen, Ebenezer Awotoro and Georges Hattab 853

Medical Context Variation: A source of impairment for Event classification
Aman Sinha, Marianne Clausel, Mathieu Constant and Xavier Coubez 864

KALIMBA: Knowledge-Assisted Literature Mining for Biological Interaction Analysis
Niloofar Arazkhani, Maciej Kotecki, Brent Cochran and Natasa Miskov-Zivanov 880

When Retrieval Doesn't Help: A Large-Scale Study of Biomedical RAG
Erfan Nourbakhsh, Rocky Slavin, Ke Yang and Anthony Rios 890

CrossDDI: Cross-Source Evidence-Grounded Drug-Drug Interaction Verification
Bohao Chu and Norbert Fuhr 911

GRAFT: Gated Retrieval-Augmented Fine-Tuning for Relation Extraction
Yuhang Jiang and Ramakanth Kavuluru 920

Overview of the PsyDefDetect Shared Task at BioNLP 2026: Detecting Levels of Psychological Defense Mechanisms in Supportive Conversations
Hongbin Na, Zimu Wang, Zhaoming Chen, Yining Hua, Rena Gao, Kailai Yang, Ling Chen, Wei Wang, Shaoxiong Ji, John Torous and Sophia Ananiadou 932

SCoPE: Planning for Hybrid Querying over Clinical Trial Data
Suparno Chowdhury, Manan Choudhury, Tejas Anvekar, Muhammed Khan, Kaneez Khakwani, Mohamad Sonbol, Irbaz Riaz and Vivek Gupta 944

Expert-Guided Schema-Based Structured Extraction from CONSORT Diagrams Using Vision-Language Models
Damian Stachura, Bartosz Przechera, Monika Opa?ek, Ewelina Sadowska, Ewa Borowiack and Artur Nowak 955

From Rules to Predictions: Federated Tabular Learning with LLM Reasoning
Afsaneh Mahanipour and Hana Khamfroush 970

MedBench: Deliberative Evaluation of Medical Language Models
Pratik Jalan, Mukul Joshi, Akhilesh Magotra and Kshitij Jadhav 981

Fast, Accurate, and Local Conversion of MIMIC-IV to OMOP with DBT
Adam Sutton, Niko Moller-Grell, Thomas Searle and Richard Dobson 992

Exploring Novel Drug Research Area using Large Language Models Based on Research Trends in Biomedical Literature
Afnan Afnan, Michael Van Supranes, Tomohiro Nishiyama, Shoko Wakamiya and Eiji Aramaki 997

FHexchange: Resources for Family Health History Extraction and Normalization From Consumer Dialog Sources
Michelle Nguyen, Nidhi Soley, Ayah Zirikly, João Sedoc and Casey Taylor 1014

Forgotten Words: Benchmarking NeoBERT for Dementia Detection in Low-Resource Conversational Filipino and English Speech
Rez Samantha Floresca, Edric Castel Hao, Hannah Grachiella Buñales, Chelsea Dominique Temprosa, Georgianna Reyes and Kervin Gabriel Chua 1029

IndicMedDialog: A Parallel Multi-Turn Medical Dialogue Dataset for Accessible Healthcare in Indic Languages
Shubham Nigam, Suparnojit Sarkar and Piyush Patel 1041

Towards a Radiologist Imitation Framework for 3D CT Diagnosis with Multimodal LLMs
Kaidi Zhang, Zhiyuan Yan, Gao Cheng and Zhenyang Cai 1056

Probing and Steering Uncertainty in Biomedical Language Models: Representational Structure and Behavioral Limits
Debmalya Pal 1066

Relations of Linguistic Features and Medical Text Preferences are Nontrivial
Davis Bartels, Brandon Colelough and Dina Demner-Fushman 1080

Overview of the MedGenVidQA 2026 Shared Task on Medical Generative Video Question Answering
Deepak Gupta, Collin Campbell, Pedram Golnari and Dina Demner-Fushman 1089

Overview of the ClinicalSkillQA 2026 Shared Task on Continuous Perception and Procedural Reasoning in Clinical Skill Assessment

The Divergence Hypothesis: Unmasking Lexical Interference and Label Bias in Mental Health NLP

Moustafa Yehia Hassan
Doha Institute for Graduate Studies
Doha, Qatar
moustafa.hassan@dohainstitute.edu.qa

Abstract

Computational mental health (CMH) classifiers often degrade under distribution shift because human annotators and distant-supervision pipelines reward different linguistic signals. We introduce TSS (Triple-Stream Stress probe), a multi-channel diagnostic framework that decomposes text into (A) lexical character n-grams, (B) a small, mostly content-free morpho-syntactic channel, and (C) a 154-feature psycholinguistic style channel. Across four English datasets ($N = 12{,}906$), TSS reveals a *lexical interference effect*: adding lexical features to the style channel reduces Macro-F1 on human-labeled data (mean drop 0.072, $p < 10^{-4}$) but not on auto-labeled data. We propose Degree of Divergence (DoD), a difference-in-differences statistic adapted from econometrics for label-source auditing, with instance-level bootstrap inference; the headline estimate is $\mathrm{DoD}_{\mathrm{BC\text{–}A}} = 0.0374$, 95% CI $[0.0097, 0.0651]$, $p = 0.0032$. A platform-stratified Twitter-only DoD (which removes the Reddit vs. Twitter contrast) reproduces the pattern with bootstrap inference: $\mathrm{DoD}^{\mathrm{Tw}}_{\mathrm{BC\text{–}A}} = +0.096$ ($p < 0.001$) and $\mathrm{DoD}^{\mathrm{Tw}}_{\mathrm{AC\text{–}A}} = -0.089$ ($p < 0.001$). Interventional masking (`pos_only`) retains ∼95–99% of Channel C's performance after destroying content words on human datasets, indicating that the style channel does not rely primarily on lexical surface form. TSS is positioned as a diagnostic audit framework, not a clinical screening tool: it flags label-source-specific shortcut learning before generalization claims are made.

1 Introduction

Computational Mental Health (CMH) promises scalable screening and monitoring from language, but its progress is constrained by a mismatch between benchmark labels and the construct they are taken to measure. Large corpora are frequently built via distant supervision—keyword filters, self-reported diagnoses, or community-membership proxies—which can systematically reward lexical cues (Coppersmith et al., 2015; Harrigian et al., 2021). Human annotators, in contrast, often rely on *how* something is said: fragmentation, negation scope, function-word usage, and stylistic signatures (Tausczik and Pennebaker, 2010; Pennebaker et al., 2003). When the two label sources are conflated, models can score well by exploiting spurious lexical correlations (*shortcut learning*; Geirhos et al., 2020) rather than learning robust psycholinguistic markers (Ernala et al., 2019; D'Amour et al., 2022).

Task. We study *binary stress detection* from short social-media posts. Each instance receives a label $y \in \{0, 1\}$, where $y{=}1$ indicates that the post expresses current psychological distress or stress-related experience as judged by the dataset's labeling protocol, and $y{=}0$ indicates the absence of such expression. Throughout this paper, "stress" refers to the dataset-level distress/stress label, *not* to a clinical diagnosis; no claim of diagnostic validity is made. The goal is not to build a state-of-the-art classifier, but to audit which linguistic signals different label sources reward.

Research questions. **RQ1 (Label-source divergence)** Does changing the label source (human vs. distant supervision) systematically change which linguistic channels are rewarded? **RQ2 (Lexical interference)** Does adding lexical content to stylistic features help or harm under human annotation? **RQ3 (Quantification)** Can the human-vs-auto gap be quantified as a single, statistically grounded scalar?

Contributions. (i) We release TSS, a channel-separable, length-robust auditing probe that decomposes text into lexical (A), mostly content-free morpho-syntactic (B), and psycholinguistic style (C) channels, with explicit length normalization and conditional scaling for cross-platform trans-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 1–14
July 3-4, 2026 ©2026 Association for Computational Linguistics

fer. (ii) We document a *lexical interference effect*: on human-labeled data, augmenting C with lexical A degrades Macro-F1; an interventional masking suite (`pos_only`, `content_only`, `function_only`) tests whether performance survives deliberate destruction of lexical shortcuts. (iii) We introduce DoD, a difference-in-differences auditing statistic with instance-level bootstrap inference (n=10,000) and Benjamini–Hochberg FDR control, plus a *platform-stratified* variant that removes the Reddit vs. Twitter contrast. (iv) We provide leave-one-domain-out (LODO) evaluation, unsupervised stylistic phenotyping (bootstrap ARI ≈ 0.98), paired baseline comparisons against MentalBERT (Ji et al., 2022) and few-shot LLaMA-3 (Grattafiori et al., 2024; Brown et al., 2020), and a qualitative conflict-zone workbook. The full pipeline, decontamination scripts, and qualitative workbook are publicly available.[1]

2 Related Work

Psycholinguistic style. A long line of work shows that function words and stylistic patterns reflect cognitive style more reliably than consciously controlled topical content (Pennebaker et al., 2003; Tausczik and Pennebaker, 2010; Boyd et al., 2022). Cognitive therapy frameworks predict linguistically measurable correlates of distress, most notably absolutist language (Beck, 1976; Al-Mosaiwi and Johnstone, 2018) and specific cognitive distortions (Shickel et al., 2020).

Distant supervision and shortcut learning in CMH. Distant-supervision pipelines built from self-reported diagnoses (Coppersmith et al., 2015) or community membership have repeatedly been shown to yield models that rely on surface lexical cues and degrade under distribution shift (Harrigian et al., 2021; Aguirre et al., 2021; Ernala et al., 2019). These failures align with the broader finding that neural classifiers tend to latch onto annotation artifacts and spurious correlations (Geirhos et al., 2020; Gururangan et al., 2018; McCoy et al., 2019; D'Amour et al., 2022), and that distributional robustness requires explicit intervention (Sagawa et al., 2020; Kaushik et al., 2020). Our work differs in goal: rather than proposing a more robust classifier, we propose a *diagnostic framework* that quantifies how much a given dataset's labels reward lexical shortcuts, in the spirit of behavioral auditing (Ribeiro et al., 2020).

Stress detection benchmarks. Our experimental backbone uses Dreaddit (Turcan and McKeown, 2019) as the structured human-labeled benchmark and MentalBERT (Ji et al., 2022) as a representative domain-pretrained transformer baseline. We also draw on the Twitter mental-health corpora derived from Coppersmith et al. (2015), treated here as a distant-supervision proxy rather than a stress gold standard (see §3).

3 Data and Task

3.1 Datasets

We evaluate on four English datasets after within-dataset exact-match deduplication. Table 1 summarizes the platform, size, label source, and intended use of each dataset.

3.2 Twitter-auto as a Proxy, Not Gold

Twitter-auto is not used as a gold stress dataset. It is constructed by treating posts whose authors self-reported a mental-health diagnosis (depression, PTSD, anxiety, following Coppersmith et al., 2015) as *auto-positive*, under the working assumption that clinically diagnosed populations exhibit elevated linguistic distress markers. We acknowledge that this introduces a *disorder→stress conflation*: a diagnosed user is not necessarily expressing distress in every post, and the resulting label is a noisy proxy for the post-level stress construct studied here. We treat Twitter-auto purely as a distant-supervision proxy for testing whether such labels reward different linguistic signals than human distress annotations. Twitter-gold is a manually annotated subsample drawn from the same underlying corpus, where annotation targeted *perceived psychological distress* rather than the presence of mental-health keywords; stress-keyword removal was applied to reduce trivial lexical leakage. We do not claim expert-clinical annotation for this set; methodological constraints of the manual-validation protocol are acknowledged in §7. A related, substantially smaller manually annotated Twitter validation subset (120 examples) was constructed by Rastogi et al. (2022) to validate automated annotation strategies, which we cite here as methodological context rather than as the same artifact.

[1] Code and appendix: `https://github.com/MoustafaMohamedMoustafaHassan/TSS-Probe-CMH`

Dataset	Platform	N	Label source	Positive label means	Used for
Dreaddit-test	Reddit	715	Human (expert)	Stress / distress expression	Human-labeled evaluation
Twitter-gold	Twitter	2,863	Human (manual annotation)	Perceived psychological distress	Human-labeled evaluation
Twitter-auto	Twitter	6,218	Distant supervision	Mental-health / distress *proxy*	Auto-label comparison
Reddit-combi	Reddit	3,110	Distant supervision	Community-/keyword-derived proxy	Auto-label comparison

Table 1: Dataset overview. Positive prevalence: Dreaddit-test 0.516, Twitter-gold 0.338, Twitter-auto 0.478, Reddit-combi 0.880 (i.e., the positive label is the *majority* class on Reddit-combi; minority prevalence = 0.120). Dreaddit follows Turcan and McKeown (2019); Twitter-auto and the Twitter-gold subsample derive from Coppersmith et al. (2015); Reddit-combi is a combined Reddit corpus assembled under distant supervision (see §3.3).

3.3 Reddit-combi as a Distant-Supervision Proxy

Reddit-combi is an internally assembled Reddit corpus constructed under distant supervision and released with the artifact bundle as `data/raw/Reddit_Combi.csv` (with title/body fields and binary labels). It is not an externally published benchmark; it is an artifact-level distant-supervision corpus assembled for this study and released with the repository, and we report its provenance through the artifact path. Because its construction is not equivalent to expert annotation, we use Reddit-combi exclusively as a Reddit-side auto-label proxy and pair it with Twitter-auto for the auto-source half of the DoD contrast. Crucially, the positive label is the *majority* class on Reddit-combi (0.880); we therefore favor Macro-F1, PR-AUC, and balanced accuracy over raw accuracy or class-1 F_1 when reporting this dataset, and we never use Reddit-combi as a stand-in for human annotation.

3.4 Decontamination and Imbalance

To prevent leakage in cross-platform CMH evaluation, we perform exact-match cross-dataset decontamination on `cleaned_text`, removing overlapping posts from the training pool while preserving evaluation sets. The datasets exhibit severe class imbalance, especially Reddit-combi, where the positive label is the *majority* class (positive prevalence 0.880; minority prevalence 0.120). Accordingly we report Macro-F1 as the primary metric, complemented by PR-AUC under skewed prevalence (PR-AUC is preferred over ROC-AUC when one class dominates). A naive majority-class baseline yields Macro-F1 of 0.340, 0.343, 0.398, and 0.468 on Dreaddit-test, Twitter-auto, Twitter-gold, and Reddit-combi respectively; all TSS channels substantially exceed these baselines, confirming signal acquisition beyond prevalence effects. For paired comparisons we use McNemar's test (McNemar, 1947) on discordant predictions and paired bootstrap CIs (Efron, 1979) for Macro-F1 differences, controlling false discoveries with Benjamini–Hochberg FDR (Benjamini and Hochberg, 1995).

Dreaddit additionally provides five heterogeneous stressor domains (abuse, anxiety, financial, PTSD, social), enabling leave-one-domain-out (LODO) evaluation that probes cross-stressor generalization beyond platform transfer.

4 The TSS Probe

TSS is a diagnostic decomposition, not a competitive classifier. The three channels are designed so that their contrast is informative: comparing what each rewards under each label source isolates lexical-shortcut behavior.

4.1 Channel A: Lexical Surface Form

Channel A uses character-level TF–IDF n-grams of length 3–5 (Salton and Buckley, 1988), with χ^2 feature selection at $k = 500$ (Yang and Pedersen, 1997). We use character n-grams over word n-grams for two reasons. First, social-media text contains hashtags, contractions, emoji, intentional misspellings, and morphological variation that destabilize word tokenization; character-level features are robust to these (Coppersmith et al., 2015). Second, we want Channel A to provide a strong, sub-word lexical baseline so that any *lexical interference effect* we observe cannot be trivially attributed to vocabulary coverage gaps in a word-based representation. The χ^2 filter at k=500 prevents dimensionality blow-up and is comparable in size to standard sparse lexical baselines for short-text classification.

4.2 Channel B: Mostly Content-Free Morpho-Syntax

Channel B converts POS bigrams and abstract POS-SVO triples (extracted over the first 500 characters per document for efficiency, using the Penn Treebank tagset via spaCy; Honnibal et al., 2020) into six interpretable features: five POS-derived plus one absolutist-ratio (B_{abs}), which is the only Channel B feature that accesses lexical tokens (a closed absolutist-word list, following Al-Mosaiwi and Johnstone, 2018). Channel B uses adaptive length smoothing and log-dampened mass features for cross-platform robustness; the exact formulations are given in Appendix A.

Channel B is a diagnostic, not a performance booster. We do *not* present Channel B as an ingredient that improves accuracy when combined with C. As shown in §5, adding B to C is approximately neutral on most datasets (occasionally negative on Dreaddit-test). This is itself informative: C already absorbs much of the useful structural variation; B is useful as (i) a near-content-free, privacy-oriented diagnostic (5 of 6 features discard lexical tokens), and (ii) a structural stress test that probes whether performance survives a near-complete loss of vocabulary.

4.3 Channel C: Psycholinguistic Style

Channel C is the principal stylistic representation, with 154 features grouped into seven feature families (Table 2). It applies a length-robust squashing transform $c_{\text{out}} = \tanh(2c)$ to convert continuous features to soft binary triggers resistant to cross-platform distributional shift, and uses Yule's I rather than TTR for lexical diversity because TTR mathematically decays with text length (Appendix A).

Beyond sentiment-like lexicons, Channel C explicitly encodes cognitive fragmentation (a hallmark of anxiety) via the coefficient of variation of sentence length, short-burst ratios, and abrupt punctuation patterns, as well as structural negation scope distinguishing helplessness (NEG→VERB) from negative self-evaluation (NEG→ADJ).

4.4 Unified Classifier and Calibration

All channels are trained with linear models for interpretability. Feature vectors are L_2-normalized: $x' = x/\|x\|_2$. Conditional scaling disables `StandardScaler` for any channel containing B, to avoid reintroducing length bias. Class imbalance is handled by `class_weight='balanced'` (Pedregosa et al., 2011) rather than undersampling. Decision thresholds are not fixed at 0.5: we calibrate by maximizing F_1 over a bounded grid $[0.20, 0.80]$ on out-of-fold (OOF) probabilities (no leakage). Dense lexical/style channels use L_2 (ridge); any channel containing B uses Elastic-Net (Zou and Hastie, 2005) with internal 5-fold CV; the selected ℓ_1-ratio converges to 0.95, indicating an algorithmic preference for sparse structural evidence.

Feature block	Examples	#
Base style / readability / POS-ratio	Flesch–Kincaid, sentence-length CV, function-word ratios, pronoun densities	29
Open lexicon categories	affect, cognitive, social process, sensory; LIWC-style counts and ratios	110
Structural rhythm / negation / punctuation	ellipses, "!?", NEG→VERB, NEG→ADJ, scope balance, short-burst ratio	11
Raw intensity + Yule's I	caps ratio, elongated tokens, punctuation density, length-independent diversity	4
Total		**154**

Table 2: Channel C feature blocks with feature counts as implemented in `ChannelC_Extended` of the released codebase. Open lexicon categories follow LIWC-style groupings (Tausczik and Pennebaker, 2010; Boyd et al., 2022); absolutist markers follow Al-Mosaiwi and Johnstone (2018); negation-scope features operationalize the helplessness vs. self-evaluation distinction motivated by Beck (1976).

4.5 Degree of Divergence (DoD)

DoD is a difference-in-differences statistic adapted from causal econometrics to quantify label-source bias in NLP (Appendix A, Eq. 3):

$$\text{DoD} = \Delta_h - \Delta_a \quad (1)$$

where each Δ compares a structural channel (e.g., BC) against lexical A within the same label source. DoD is estimated with an instance-level bootstrap ($n = 10{,}000$) over all 12,906 instances. Because DoD as introduced above mixes label source with platform (human Reddit/Twitter vs. auto Reddit/Twitter), we additionally compute a *platform-stratified Twitter-only* DoD that removes the Reddit vs. Twitter contrast (§5.4).

4.6 Masking Suite

Five masks are evaluated: `none`, `pos_only`, `content_only`, `function_only`, `random_pos` (negative control). Unlike standard ablations that only remove feature blocks, the masking suite intervenes directly on the text: `pos_only` destroys lexical content while preserving syntactic traces; `content_only` preserves topical content while erasing function words and syntactic cues; `function_only` isolates function-word dynamics; `random_pos` acts as a destructive control. This design probes whether a channel's performance survives deliberate destruction of lexical shortcuts, complementing the observational DoD analysis.

5 Results

We first summarize per-channel Macro-F1 across human and auto label sources, then quantify lexical interference, DoD, and a platform-stratified Twitter-only DoD; finally we report interventional masking, baselines, and robustness audits.

5.1 Channel Performance

Table 3 and Table 4 report Macro-F1 per channel on human-labeled and auto-labeled datasets respectively. Two patterns stand out. First, the structural / style combination BC achieves nearly identical Macro-F1 on the two human-labeled datasets (0.690 on Dreaddit-test vs. 0.690 on Twitter-gold; $\Delta \approx 0.0002$), suggesting low degradation under platform shift when relying on structure and style. Second, moving from human-labeled Twitter-gold to auto-labeled Twitter induces a sharp performance drop in C and BC (e.g., C: $0.701 \rightarrow 0.504$; BC: $0.690 \rightarrow 0.455$). From an auditing standpoint, this drop is consistent with *label-source divergence*: auto labels reward lexical proxy cues that structural and style probes are less willing to mimic.

5.2 Lexical Interference Effect

Table 5 reports the instance-bootstrap test for the lexical interference effect, defined as the Macro-F1 change when augmenting C with A. On human-labeled data, the mean drop is 0.072 (95% CI $[0.052, 0.092]$, one-sided $p < 10^{-4}$); on auto-labeled data, the change is -0.020 (95% CI $[-0.033, -0.007]$, one-sided $p = 0.9988$ for "drop > 0"). All instance-level tests are paired (same instances) and corrected via Benjamini–Hochberg FDR (27 tests, 14 rejections).

Channel	Dreaddit (H) [CI]	Tw-G (H) [CI]
A	0.634 [.598,.669]	0.661 [.643,.678]
AB	0.632 [.596,.667]	0.650 [.631,.669]
B	0.561 [.525,.598]	0.586 [.566,.605]
C	**0.739 [.706,.771]**	**0.701 [.682,.719]**
AC	0.679 [.644,.713]	0.617 [.599,.635]
BC	0.690 [.655,.724]	0.690 [.671,.709]
ABC	0.690 [.655,.724]	0.689 [.670,.708]

Table 3: Macro-F1 by channel on human-labeled datasets with 95% bootstrap CIs (Channel C in bold). Tw-G = Twitter-gold; leading-decimal abbreviation in CIs.

Channel	Tw-A (A) [CI]	Red-c (A) [CI]
A	0.522 [.510,.535]	0.611 [.587,.635]
AB	0.460 [.448,.472]	0.589 [.564,.613]
B	0.463 [.451,.475]	0.579 [.554,.604]
C	0.504 [.492,.516]	0.681 [.658,.704]
AC	0.567 [.555,.580]	0.658 [.634,.681]
BC	0.455 [.444,.467]	0.689 [.665,.712]
ABC	0.455 [.444,.467]	0.689 [.665,.712]

Table 4: Macro-F1 by channel on auto-labeled datasets with 95% bootstrap CIs. Tw-A = Twitter-auto, Red-c = Reddit-combi; leading-decimal abbreviation in CIs.

5.3 Degree of Divergence

Table 6 reports the full DoD estimates. $\mathrm{DoD}_{\mathrm{C–A}} = +0.047$ and $\mathrm{DoD}_{\mathrm{AC–A}} = -0.045$ form a symmetric pair: human annotators implicitly weight style, while auto labels reward lexical proxies. The negative $\mathrm{DoD}_{\mathrm{AC–A}}$ is the strongest quantitative signature of the lexical interference effect: lexical augmentation actively penalizes human-source performance.

A note on the permutation diagnostic. A regime-permutation diagnostic (Good, 2005) gives $p = 0.092$ (FDR-adjusted $p = 0.1656$). We treat this as a conservative robustness audit: the bootstrap evaluates stability across instances, whereas the permutation diagnostic probes whether the observed channel ranking could arise under channel-design constraints. We prioritize the bootstrap CI for effect estimation while reporting the permutation result transparently.

5.4 Platform-Stratified Twitter-Only DoD

A potential confound is that human-labeled and auto-labeled datasets differ not only in label source but also in platform composition. The standard DoD above assumes that platform effects are additive and channel-invariant within each label source. We test this directly by computing a *Twitter-only*

Source (C → AC)	Mean drop	95% CI	p (1-s.)
Human	0.0720	$[0.052, 0.092]$	$< 10^{-4}$
Auto	-0.0201	$[-0.033, -0.007]$	0.9988

Table 5: Lexical interference test (instance bootstrap). Augmenting Channel C with Channel A reduces Macro-F1 on human labels and slightly *increases* it on auto labels.

DoD	Est.	95% CI	p	d
BC–A	$+0.0374$	$[0.010, 0.065]$	0.0032	2.63
C–A	$+0.0469$	$[0.020, 0.075]$	0.0001	3.32
AC–A	-0.0453	$[-0.068, -0.022]$	<0.001	-3.89
AB–A	$+0.0360$	$[0.010, 0.062]$	0.0036	2.68

Table 6: DoD estimates (instance bootstrap, n=10,000). For positive DoD the alternative is DoD > 0; for $\mathrm{DoD}_{\text{AC–A}}$ the alternative is DoD < 0.

DoD that holds the platform fixed (Twitter-gold vs. Twitter-auto) and removes the Reddit vs. Twitter contrast:

$$\mathrm{DoD}^{\text{Tw}}_{X-A} = [\, F_1^{\text{Tw-gold}}(X) - F_1^{\text{Tw-gold}}(A) \,] - [\, F_1^{\text{Tw-auto}}(X) - F_1^{\text{Tw-auto}}(A) \,]. \quad (2)$$

We attach uncertainty to this platform-stratified check via a paired bootstrap that resamples each Twitter dataset independently with replacement (N_{boot}=2,000; Table 7). The effect remains stable and highly significant: $\mathrm{DoD}^{\text{Tw}}_{\text{C–A}} = +0.058$ (95% CI $[+0.031, +0.086]$, $p < 0.001$), $\mathrm{DoD}^{\text{Tw}}_{\text{BC–A}} = +0.096$ ($[+0.066, +0.125]$, $p < 0.001$), and $\mathrm{DoD}^{\text{Tw}}_{\text{AC–A}} = -0.089$ ($[-0.113, -0.065]$, $p < 0.001$). The signs and magnitudes match the cross-platform DoD: structural channels gain relative to A under human labels and lose under auto labels, even when both label sources come from the same platform. This does not eliminate every label-construction difference (e.g., annotation protocol, sampling strategy), but it makes a pure platform-shift explanation unlikely. A controlled within-platform dual-annotation experiment would still be required for definitive causal identification (§7).

5.5 Interventional Masking

Table 8 reports masking-suite Macro-F1 on human-labeled datasets, including 95% bootstrap CIs and paired bootstrap CIs for the difference vs. `none` (N_{boot}=2,000). On Dreaddit-test, `C/pos_only` is statistically indistinguishable from `C/none` ($\Delta = -0.006$, 95% CI $[-0.037, +0.023]$, $p = 0.72$), supporting the interpretation that Channel C's signal is not primarily carried by lexical surface form. On Twitter-gold, the same condition shows a small but reliable drop ($\Delta = -0.034$, 95% CI $[-0.052, -0.017]$, $p < 0.001$), consistent with noisier, shorter texts where POS traces carry less recoverable information after lexical deletion. Notably, `BC/pos_only` on Dreaddit *exceeds* unmasked `BC/none` ($\Delta = +0.037$, 95% CI $[+0.008, +0.066]$, $p = 0.013$): destroying content under the combined channel forces the classifier off syntactically irrelevant morpho-lexical patterns and onto genuinely structural ones. `random_pos` acts as a destructive control; on Twitter-gold it produces large significant drops for both C ($\Delta = -0.080$, $p < 0.001$) and BC ($\Delta = -0.062$, $p < 0.001$), confirming that performance does not survive arbitrary syntactic scrambling.

Contrast	DoD^{Tw} [95% CI]	p
C – A	$+0.058$ $[+0.031, +0.086]$	<0.001
BC – A	$+0.096$ $[+0.066, +0.125]$	<0.001
AC – A	-0.089 $[-0.113, -0.065]$	<0.001
AB – A	$+0.051$ $[+0.022, +0.080]$	<0.001

Table 7: Platform-stratified Twitter-only DoD with 95% bootstrap CIs and two-sided p-values (N_{boot}=2,000). DoD^{Tw} is the difference of within-source $\Delta = F_1(\text{channel}) - F_1(A)$ between Twitter-gold (human) and Twitter (auto). Signs and magnitudes match the cross-platform DoD, making a pure platform-shift explanation unlikely.

Channel / mask	Dreaddit F1 [CI]	Tw-G F1 [CI]
C / none	0.739 [.708,.772]	0.701 [.682,.719]
C / pos_only	0.734 [.700,.767]	0.666 [.647,.685]
C / function_only	0.736 [.705,.769]	0.603 [.582,.624]
C / content_only	0.724 [.691,.756]	0.652 [.632,.671]
C / random_pos	0.742 [.709,.774]	0.621 [.599,.641]
BC / none	0.690 [.654,.724]	0.690 [.670,.708]
BC / pos_only	0.728 [.694,.760]	0.594 [.574,.614]
BC / function_only	0.727 [.692,.761]	0.665 [.645,.683]
BC / content_only	0.724 [.692,.754]	0.625 [.606,.644]
BC / random_pos	0.739 [.706,.771]	0.628 [.607,.649]

Table 8: Masking-suite Macro-F1 on human-labeled datasets with 95% bootstrap CIs (cell-level, N_{boot}=2,000). Tw-G = Twitter-gold; CIs use leading-decimal abbreviation (e.g., [.708,.772] ≡ [0.708, 0.772]). Paired CIs for Δ vs. `none` are in Table 9.

5.6 Baselines as Diagnostics

Table 10 reports paired comparisons against MentalBERT (Ji et al., 2022) and 3-shot LLaMA-3-8B (Grattafiori et al., 2024; Brown et al., 2020). LLaMA-3 is evaluated only in a few-shot diag-

Comparison	Dreaddit Δ [95% CI]	p	Tw-gold Δ [95% CI]	p
C: pos_only − none	-0.006 [$-0.037, +0.023$]	0.72	-0.034 [$-0.052, -0.017$]	<0.001
C: function_only − none	-0.003 [$-0.031, +0.025$]	0.88	-0.098 [$-0.118, -0.078$]	<0.001
C: content_only − none	-0.016 [$-0.041, +0.010$]	0.20	-0.049 [$-0.063, -0.033$]	<0.001
C: random_pos − none	$+0.003$ [$-0.018, +0.025$]	0.77	-0.080 [$-0.096, -0.063$]	<0.001
BC: pos_only − none	$+0.037$ [$+0.008, +0.066$]	0.013	-0.096 [$-0.112, -0.081$]	<0.001
BC: function_only − none	$+0.037$ [$+0.002, +0.071$]	0.039	-0.025 [$-0.045, -0.007$]	0.010
BC: content_only − none	$+0.033$ [$+0.005, +0.062$]	0.020	-0.064 [$-0.080, -0.049$]	<0.001
BC: random_pos − none	$+0.049$ [$+0.023, +0.076$]	0.001	-0.062 [$-0.077, -0.047$]	<0.001

Table 9: Paired bootstrap differences for masking conditions vs. `none` (N_{boot}=2,000). On Dreaddit, Channel C is statistically unaffected by lexical destruction; on Twitter-gold, the drops are significant but small in absolute terms (95–96% retention for `pos_only`). The BC pos_only case on Dreaddit shows that combined structure-plus-style representation can *benefit* from lexical destruction.

Dataset	Model	Macro-F1
Dreaddit (H)	TSS-C	0.739
Dreaddit (H)	TSS-BC	0.690
Dreaddit (H)	MentalBERT	0.801
Dreaddit (H)	LLaMA-3 (3s)	0.613
Tw-gold (H)	TSS-C	0.701
Tw-gold (H)	TSS-BC	0.690
Tw-gold (H)	MentalBERT	0.715
Tw-gold (H)	LLaMA-3 (3s)	0.800
Tw-auto (A)	TSS-C	0.504
Tw-auto (A)	TSS-BC	0.455
Tw-auto (A)	MentalBERT	0.418
Tw-auto (A)	LLaMA-3 (3s)	0.522
Reddit-c. (A)	TSS-C	0.681
Reddit-c. (A)	TSS-BC	0.689
Reddit-c. (A)	MentalBERT	0.760
Reddit-c. (A)	LLaMA-3 (3s)	0.794

Table 10: Baseline comparison (Macro-F1). Full paired ΔF_1, bootstrap CIs, and McNemar p-values are in Appendix B.3.

nostic capacity. Its instability is informative (Appendix C.5): on Dreaddit-test recall is 0.984 with precision 0.606 (over-firing); on Twitter-auto recall collapses to 0.203 (under-firing). We interpret this as evidence that few-shot lexical priors track the availability of stress vocabulary rather than the underlying state.

We treat baselines as epistemic diagnostics rather than direct competitors: when MentalBERT outperforms TSS on human labels, it plausibly leverages legitimate contextual signal; when both strong baselines excel on auto-labeled corpora, they may be matching label-source-induced proxy noise; TSS's relative stability across label sources is the central observation. On Twitter-auto, C and BC outperform MentalBERT yet remain below LLaMA-3; on Twitter-gold MentalBERT is approached by TSS-C ($\Delta Macro - F1 = -0.0141$, paired bootstrap 95% CI $[-0.0367, +0.0082]$, $p = 0.108$; Appendix B.3), but LLaMA-3-8B (3-shot) attains a higher Macro-F1 (0.800). We therefore *do not* claim overall competitive superiority on Twitter-gold; we read the result as evidence of representation efficiency relative to one domain-pretrained transformer baseline, not as a SOTA claim.

5.7 LODO and Phenotyping

Under leave-one-domain-out evaluation on Dreaddit's five stressor domains (Appendix C.1), Channel C has the highest mean out-of-domain Macro-F1 among TSS channels (0.685) with notably low variance (std 0.015), supporting a relative cross-stressor invariance claim. MentalBERT attains a higher mean (0.818) but with greater variance (std 0.030), consistent with domain-dependent lexical sensitivity.

K-Means (Lloyd, 1982; MacQueen, 1967) with K=3 on Channel C yields highly stable clusters (bootstrap ARI 0.980, 95% CI $[0.961, 0.991]$, n_{boot}=100). Cluster–dataset association (AMI 0.281, p=0.0005) flags partial platform entanglement, an explicit leakage audit reinforcing the need for label-source-aware evaluation. Channel orthogonality is measured rather than assumed (mean $|\rho| \approx 0.595$); the weakest pair (A vs. B, $|\rho| = 0.296$) supports the intended factorization. Channel C trains in ≈ 27.5 s on a single CPU (Appendix C.4), supporting the diagnostic-density framing.

6 Discussion

TSS is best understood as a *diagnostic tool*: it quantifies when results are label-source-specific and provides a single statistically grounded scalar (DoD) to summarize that gap. Below we consolidate the interpretation, formalize when "strong baselines"

are mostly a lexical illusion, and position structural invariants as the signal that survives label-source shifts.

6.1 Why Lexical Baselines Look Strong

In auto-labeled or closed-community settings, topical stress lexicon co-occurs with structural distress markers, producing a *semantic–structural intersection (SSI)*. A model can succeed by detecting topics that correlate with distress rather than the distress state itself, consistent with shortcut learning under non-causal correlation (Geirhos et al., 2020). This reconciles the high performance of MentalBERT (Macro-F1 0.760) and LLaMA-3 (Macro-F1 0.794) on Reddit-combi with their pronounced degradation on Twitter-auto (MentalBERT Macro-F1 0.418), where SSI is weaker and intent is mixed (news, ads, meta-talk; see qualitative cases in Appendix D).

A direct signal-saturation test on Reddit-combi: augmenting C with morpho-syntax yields no detectable gain ($+0.008$ Macro-F1; $p = 0.259$; Appendix B.1), consistent with SSI-induced overlap. The fact that C still beats A on Reddit-combi by $+0.070$ ($p < 0.0001$; Appendix B.4) is best read as an SSI-saturation effect: under high SSI, all channels benefit; the diagnostic question is the *relative* channel advantage *across* label sources, which is exactly what DoD captures and confirms ($\mathrm{DoD}_{\mathrm{C–A}} = +0.047$, $p < 10^{-4}$).

6.2 Representation Efficiency, Not SOTA

On Twitter-gold, the gap between TSS-C and MentalBERT is small ($\Delta Macro - F1 = -0.0141$, 95% CI $[-0.0367, +0.0082]$, $p = 0.108$; Appendix B.3)—consistent with, but not proving, statistical equivalence relative to *this* baseline. We do *not* claim that TSS-C matches the strongest baseline overall: LLaMA-3-8B (3-shot) reaches Macro-F1 0.800. The reading is *representation efficiency*: a 154-feature, fully interpretable linear channel approaches one domain-pretrained transformer on human-labeled data with radically lower representational and computational cost.

6.3 Implicit Stress vs. Keyword-Driven False Positives

Conflict-zone examples (Appendix D) instantiate two complementary failure modes: *keyword-driven false positives* (stress meta-talk, psychoeducational content, or promotional posts classified as distress because stress words are present even when structural distress is absent), and *implicit stress* (distress expressed without explicit stress lexicon, via hedging, negation, or fragmentation). At the instance level, across 800 audited cases Channel C alone corrects 253 Channel-A errors (195 keyword-driven false positives + 58 implicit-stress false negatives) and BC corrects 241, showing that lexical shortcuts fail in two directions and that structural style features recover both. TSS audits state inference, not topic detection.

6.4 Cross-Stressor Invariance and Clinical Bridge

LODO results (Appendix C.1) show Channel C varies little across held-out stressor domains (std 0.015), supporting the view that structural and stylistic markers track a cognitive–affective state that persists across heterogeneous causes; cognitive fragmentation, absolutist appraisal, and negation scope remain candidate distress signatures (Beck, 1976; Al-Mosaiwi and Johnstone, 2018). We use social-media data only as a stress-test environment for label-source bias, not as a clinical stand-in; analogous shortcut-learning risks arise in clinical NLP (Ernala et al., 2019), and TSS is compatible with privacy-constrained workflows because Channel B is mostly de-lexicalized.

7 Conclusion

We introduced TSS, a diagnostic framework for testing whether different label sources reward different linguistic evidence in computational mental health classification. Across four English datasets, the central result is a *lexical interference effect*: adding lexical surface features to style features reduces Macro-F1 on human-labeled datasets (mean drop 0.072, $p < 10^{-4}$) but not on auto-labeled datasets, with the gap quantified by $\mathrm{DoD}_{\mathrm{BC–A}} = 0.0374$ ($p = 0.0032$). Platform-stratified Twitter-only DoD (Table 7, all contrasts $p < 0.001$) and interventional masking on Dreaddit, where Channel C is statistically unaffected by full deletion of content words ($\Delta = -0.006$, 95% CI $[-0.037, +0.023]$, $p = 0.72$), suggest the effect is not reducible to ordinary platform shift; a controlled within-platform dual-annotation study remains necessary for causal identification. TSS is therefore an audit workflow that flags label-source-specific shortcut learning before generalization claims are made.

Limitations

Data and annotation. Evaluation is restricted to four English datasets and to a binary stress label. For Twitter-gold, inter-annotator agreement (Cohen's κ) was not computed under the manual-annotation protocol available to us; this limits claims about "human annotation" as a general construct. Twitter-auto inherits a disorder→stress conflation from Coppersmith et al. (2015), which is itself a form of distant-supervision noise.

Confounding between label source and platform. The four datasets cross two label sources with two platforms but do not exhaust the design. The platform-stratified Twitter-only DoD (§5.4) removes the most obvious platform confound, but a fully controlled within-platform dual-annotation experiment is required for causal identification of label-source effects.

Feature-level ablation and masking control. Per-cell bootstrap CIs for the masking suite are now reported (Tables 8–9). We do not perform a feature-level within-channel ablation: TSS is presented as a family-level diagnostic decomposition, and a full feature-attribution study is left for future work. We treat feature-family ablation as a separate attribution study rather than a camera-ready addition, because the central claim concerns channel-level label-source divergence rather than ranking individual features within Channel C. This does not affect the channel-level claim tested here, but it limits feature-level interpretability inside Channel C. The `random_pos` negative control does not collapse to chance because POS distributional cues remain after shuffling.

Word- vs. character-level lexical baseline. We did not include a word-unigram/bigram lexical baseline in this camera-ready version; Channel A is intentionally character-based to stress-test lexical surface dependence under noisy social-media spelling. Future work should compare word- and character-level lexical baselines directly to verify that the *lexical interference effect* is not specific to sub-word tokenization.

Clinical translation. Social-media data are not clinical data. We make no claim that TSS is a diagnostic medical tool; any deployment in a clinical setting requires clinician oversight, informed consent, and risk management. DoD may also require calibration for morphologically richer languages (e.g., Arabic, Chinese), where surface-form variation interacts differently with character-level lexical representations.

Few-shot baseline. LLaMA-3-8B is reported only in a 3-shot diagnostic capacity; instability is interpreted as evidence about few-shot lexical priors, not as a comment on fine-tuned LLM performance.

Ethical Considerations

This work is not a diagnostic medical tool. It focuses on auditing label bias and improving methodological rigor in CMH NLP. All evaluations use previously collected research datasets or released artifact-level data; no new user data was collected for this study. We use qualitative examples only after redacting personally identifying details. Any deployment of distress-detection systems built on social-media text requires clinician oversight, informed consent, and careful risk management, particularly given documented disparities in CMH model behavior across demographic groups (Aguirre et al., 2021).

Appendices

Sections A–F below provide mathematical formulations, full statistical tables, robustness audits, qualitative case analysis, extended metrics, and SHAP audits referenced in the main text.

A Mathematical Formulations

A.1 Degree of Divergence

$$\begin{aligned}\mathrm{DoD} \;=\; &\big[M_h(BC) - M_h(A)\big] \\ &-\; \big[M_a(BC) - M_a(A)\big]\end{aligned} \tag{3}$$

DoD is a difference-in-differences statistic adapted from causal econometrics; M_h and M_a denote Macro-F1 under human and auto label sources respectively. Inference is by instance-level bootstrap (n=10,000).

A.2 Adaptive Length Smoothing (Channel B)

$$\lambda \;=\; \lambda_{\min} + (\lambda_{\max} - \lambda_{\min})\,\min(L/L_{\text{ref}},\,1) \tag{4}$$

with $\lambda_{\min}$=3.0, $\lambda_{\max}$=20.0, L_{ref}=50.0. Short texts retain sparse POS signals; long texts are regularized.

A.3 Length-Normalized Log-Odds Mass (Channel B)

$$B_{\text{pos_mass}} \;=\; \frac{\log(1+M_{\text{pos}})}{\log(1+L_{\text{eff}})}, \qquad L_{\text{eff}} = L + \lambda \tag{5}$$

The remaining Channel B features are $B_{\text{polarity}} = M_{\text{pos}}/(M_{\text{pos}}+M_{\text{neg}}+\varepsilon)$, $B_{\text{load}} = \log_e(1+M_{\text{pos}}+M_{\text{neg}})/\max(\log_e(1+\text{cnt}),\,1)$, and $B_{\text{abs}} = |\{t : t \in \mathcal{A}\}|/L_{\text{eff}}$, where $\mathcal{A}$ is a closed absolutist-word list (Al-Mosaiwi and Johnstone, 2018). Of the six Channel B features, B_{abs} is the only one that accesses lexical tokens.

A.4 Structural Negation Balance (Channel C)

$$\text{NegBalance} \;=\; \frac{R_{\text{Neg}\to\text{Verb}} - R_{\text{Neg}\to\text{Adj}}}{N_{\text{neg_verb}} + N_{\text{neg_adj}} + \varepsilon} \tag{6}$$

Operationalizes the helplessness vs. negative self-evaluation distinction motivated by Beck (1976).

A.5 Length-Robust Squashing (Channel C)

$$c_{\text{out}} \;=\; \tanh(2c) \tag{7}$$

A.6 Length-Independent Lexical Diversity

$$I \;=\; \frac{{M_1}^2}{M_2 - M_1} \tag{8}$$

where M_1 is the vocabulary size and $M_2 = \sum_i f_i^2$ is the sum of squared per-type frequencies. This formulation follows the convention used in our pipeline (`features.py`, `_calc_yule_i`); values are capped at 10^3 to prevent extreme outliers from very short texts. Yule's I is preferred over TTR because TTR decays mathematically with text length, biasing cross-platform comparison from long Reddit posts to short tweets.

B Detailed Statistics

B.1 SSI Saturation Test (Reddit-combi)

Setting	ΔF1 (BC−C)	p
Reddit-combi (Auto)	+0.0080	0.259

Table 11: SSI signal-saturation equivalence test (paired instance bootstrap).

B.2 Representation Efficiency Note

The single-row paired-bootstrap result for TSS-C vs. MentalBERT on Twitter-gold ($\Delta Macro-F1 = -0.0141$, 95% CI $[-0.037, +0.008]$, $p = 0.108$) appears in the top row of Table 12. The CI does not exclude zero, but LLaMA-3 (3-shot)

reaches Macro-F1 0.800 on the same dataset, so this is *not* a SOTA claim.

B.3 Paired Baseline Comparisons

Pair (dataset)	ΔF1	95% CI
C / MB (Tw-G)	-0.014	$[-0.037, +0.008]$
C / LLaMA (Tw-G)	-0.099	$[-0.121, -0.078]$
C / MB (Tw-A)	$+0.086$	$[+0.073, +0.099]$
C / LLaMA (Tw-A)	-0.018	$[-0.032, -0.004]$
BC / MB (Tw-G)	-0.025	$[-0.045, -0.004]$
BC / LLaMA (Tw-G)	-0.110	$[-0.132, -0.088]$
BC / MB (Tw-A)	$+0.037$	$[+0.027, +0.048]$
BC / LLaMA (Tw-A)	-0.067	$[-0.080, -0.054]$

Table 12: Paired baseline comparisons (paired bootstrap CI). Pairs are TSS channel vs. baseline. MB = MentalBERT; LLaMA = LLaMA-3-8B (3-shot); Tw-G = Twitter-gold; Tw-A = Twitter-auto.

Pair	p_{McN}	d_z
TSS-C vs. MB (Tw-gold)	4.49×10^{-5}	-1.47
TSS-C vs. LLaMA-3 (Tw-gold)	2.55×10^{-15}	-11.40
TSS-C vs. MB (Tw-auto)	4.49×10^{-13}	$+14.77$
TSS-C vs. LLaMA-3 (Tw-auto)	5.15×10^{-4}	-2.83
TSS-BC vs. MB (Tw-gold)	1.81×10^{-4}	-2.54
TSS-BC vs. LLaMA-3 (Tw-gold)	5.11×10^{-13}	-12.47
TSS-BC vs. MB (Tw-auto)	4.32×10^{-3}	$+6.56$
TSS-BC vs. LLaMA-3 (Tw-auto)	$< 10^{-15}$	-10.64

Table 13: McNemar p and paired effect size d_z. MB = MentalBERT.

B.4 Paired Channel Contrasts

Dataset	Cmp	ΔF1	95% CI	p_{perm}
Dread (H)	C–A	$+0.106$	$[+0.07, +0.15]$	0.0001
Dread (H)	BC–A	$+0.057$	$[+0.02, +0.10]$	0.0032
Tw-gold (H)	C–A	$+0.039$	$[+0.02, +0.06]$	0.0005
Tw-gold (H)	BC–A	$+0.029$	$[+0.00, +0.05]$	0.0131
Tw-auto (A)	C–A	-0.019	$[-0.03, -0.00]$	0.9877
Tw-auto (A)	BC–A	-0.067	$[-0.08, -0.05]$	1.0000
Red-c. (A)	C–A	$+0.070$	$[+0.04, +0.10]$	0.0001
Red-c. (A)	BC–A	$+0.078$	$[+0.05, +0.11]$	0.0001

Table 14: Paired channel contrasts ($\Delta Macro - F1$) by dataset, with permutation p-values.

Channel/Model	Mean	Std	Min	Max
TSS-A	0.662	0.042	0.628	0.723
TSS-B	0.570	0.045	0.531	0.637
TSS-BC	0.679	0.032	0.653	0.734
TSS-C	0.685	0.015	0.666	0.700
MentalBERT	0.818	0.030	0.772	0.851

Table 15: Leave-one-domain-out cross-stressor robustness on Dreaddit (out-of-domain Macro-F1, mean over five domains).

Stressor	TSS-A	TSS-C	TSS-BC	MB
abuse	0.639	0.672	0.653	0.772
anxiety	0.723	0.700	0.734	0.828
financial	0.632	0.690	0.683	0.833
ptsd	0.686	0.695	0.669	0.851
social	0.628	0.666	0.659	0.806
Mean	0.662	0.685	0.679	0.818

C Robustness Audits

C.1 LODO

C.2 Phenotyping

C.3 Channel Orthogonality

C.4 Efficiency

C.5 LLaMA-3 Few-Shot Instability

D Qualitative Conflict Zone

We extracted 800 instances (200 per dataset) for instance-level qualitative analysis of cases where the lexical baseline (Channel A) and the structural probes (Channels B/C) disagree. The full workbook (`error_analysis_qualitative.xlsx`) is released with the code.

Workbook statistics. The `Shift_Cases_AvsB` sheet documents 682 instances where Channel B corrects Channel A's errors: 415 (60.9%) are A-false-positives (keyword-driven false positives) and 267 (39.1%) are A-false-negatives (implicit stress). The complementary `Reverse_Shift` sheet documents 667 instances where A corrects B; restricting to human-labeled data yields 319 A-corrections (Twitter-gold: 200; Dreaddit-test: 119), comprising 177 B-false-positives and 142 B-false-negatives. The `All_Channels_Compare` sheet shows that Channel C alone corrects 253 of A's errors

Statistic	Value	95% CI / p
Bootstrap ARI	0.980	$[0.961, 0.991]$ (n_{boot}=100)
Cluster–dataset AMI	0.281	p=0.0005 (perm 2000)
Cluster–label AMI	0.084	p=0.0005 (perm 2000)

Table 17: K-Means (K=3) on Channel C (N=12,924, d=154). DoD analysis uses N=12,906; the 18-instance gap reflects zero-length POS sequences excluded from DoD but retained in clustering via Channel C features.

Summary	Value
Mean $\lvert\rho\rvert$ across pairs	0.595
Orthogonality ratio	0.095
A vs. B (key pair)	0.296
Effective N	271,026

Table 18: Instance-level Spearman ρ across channel pairs.

(195 keyword-driven false positives + 58 implicit stress), and BC corrects 241.

Table 21 gives 13 representative cases illustrating the two failure modes; the full characterization is in the released workbook.

E Extended Metric Dashboard

F SHAP Lexical Concentration

Channel	d	Train (s)	Reg.	ℓ_1-ratio
A	500	17.6	L_2	—
B	6	1007.9	ElasticNet	0.95
C	154	27.5	L_2	—
BC	160	335.9	ElasticNet	0.95

Table 19: Efficiency profile. Channel B's training time is an artifact of an exhaustive ElasticNetCV grid; once fitted, inference is near-instantaneous.

Dataset	F1	Prec.	Rec.	Pattern
Dreaddit-test (H)	0.613	0.606	0.984	Over-firing
Twitter-auto (A)	0.522	0.846	0.203	Under-firing
Twitter-gold (H)	0.800	0.780	0.680	Balanced

Table 20: LLaMA-3-8B (3-shot) precision–recall instability across label sources.

Case type	Sample (truncated)	GT	A	TSS
Keyword-driven FP (advert)	"call us at +971 4 324 3244 to consult … #MentalHealth #Stress #DryEye"	0	1	0
Implicit stress (suicidality)	"I am on the edge of committing… a few hours remaining…"	1	0	1
Boundary collapse (HR narrative)	"I man the front desk… HR Customer Service Representative…"	0	1	0
Keyword-driven FP (resilience)	"Resilience is not a trait… #mentalhealth #mentalstrength"	0	1	0
Keyword-driven FP (counseling ad)	"Sometimes love is complicated. Let's talk it out. #counseling #mentalhealth"	0	1	0
Keyword-driven FP (product ad)	"New Product Alert! Silicone Suction Snapper. Use code SOCIAL10 #Stress"	0	1	0
Keyword-driven FP (achievement)	"Squatting 315 lbs for 6 reps… Tonight I just did 305!!!! I'm so excited!!!"	0	1	0
Keyword-driven FP (policy)	"When moving into their tiny house, they would be given a state I.D.…"	0	1	0
Implicit stress (medical trauma)	"…they needed to strap me down… I completely dissociated."	1	0	1
Implicit stress (relational)	"The one person you thought you could talk to blows you off. tired alone hurt"	1	0	1
Implicit stress (masked depression)	"feel sad all the time then happy for a moment… faking it for days"	1	0	1
Implicit stress (burnout)	"stress at work… 60 hours a week (even when I had Covid)…"	1	0	1
Implicit stress (financial crisis)	"…paid 1,000 dollars for hospital bills… now we have nothing left."	1	0	1

Table 21: Representative qualitative conflict-zone cases. GT = ground truth, A = Channel A, TSS = Channel B/C combined verdict. The first eight cases are keyword-driven false positives where A fires on topical markers; the last five are implicit-stress cases where A misses distress expressed without explicit stress vocabulary.

Data	Ch.	F1	PR-AUC	MCC	B.Acc	Prev
Dread (H)	A	0.634	0.809	0.324	0.646	0.516
Dread (H)	C	0.739	0.823	0.495	0.740	0.516
Dread (H)	BC	0.690	0.819	0.421	0.697	0.516
Tw-G (H)	A	0.661	0.540	0.342	0.680	0.338
Tw-G (H)	C	0.701	0.637	0.422	0.689	0.338
Tw-G (H)	BC	0.690	0.708	0.438	0.677	0.338
Tw-A (A)	A	0.522	0.510	0.065	0.531	0.478
Tw-A (A)	C	0.504	0.656	0.209	0.568	0.478
Tw-A (A)	BC	0.455	0.658	0.167	0.545	0.478
Red-c (A)	A	0.611	0.951	0.223	0.608	0.880
Red-c (A)	C	0.681	0.964	0.371	0.710	0.880
Red-c (A)	BC	0.689	0.968	0.380	0.702	0.880

Table 22: Extended metric dashboard. Tw-G = Twitter-gold, Tw-A = Twitter-auto. Macro-F1 is the headline metric; PR-AUC is the imbalance-sensitive complement; MCC and balanced accuracy are further robustness checks under skewed prevalence.

Mode	n	Mean conc.	95% CI
lexical_wins	40	0.333	$[0.308, 0.355]$

Table 23: Top-10 SHAP concentration on Channel A (Lundberg and Lee, 2017) when lexical predictions beat structural ones. The top 10 features (2% of the 500-feature space) capture 33.3% of total absolute SHAP weight (16× the uniform-contribution expectation), consistent with strong shortcut reliance in SSI-rewarded regimes.

Towards Unified Factuality Evaluation for Biomedical QA and Summarization: Aligning Metrics with Clinical Use-Cases

Mahule Roy[1] **Subhas Roy**[2]

Correspondence: mroy25@bwh.harvard.edu

Abstract

Large language models achieve strong performance on biomedical question answering and summarization benchmarks, yet traditional evaluation metrics often fail to detect clinically significant factual errors. We introduce a unified evaluation framework that combines reference-based measures with evidence-grounded factuality verification to assess biomedical text generation. Evaluating four open-source models across three benchmarks (BioASQ, PubMedQA, MedLFQA), we find that 13.4–24.7% of generated claims are contradicted and 23–41% are unsupported, despite high lexical overlap scores. Our proposed Fact-Aligned Score (FAS) correlates strongly with claim-level verifiability ($\rho = 0.68$), substantially outperforming ROUGE-L ($\rho = 0.41$). We release an open-source toolkit with model outputs and analysis scripts to support reproducible factuality evaluation and safer deployment of biomedical LLMs.

1 Introduction

Large language models have shown remarkable capabilities in generating biomedical text for question answering, summarization, and clinical documentation. These models promise to assist clinicians, researchers, and patients by providing rapid access to structured and unstructured biomedical knowledge. However, current evaluation practices predominantly rely on lexical overlap metrics such as ROUGE (Lin, 2004), BLEU (Papineni et al., 2002), and F1, which fail to capture clinically significant factual errors. A model may produce fluent and reference-aligned text while introducing subtle contradictions, unsupported claims, or outdated recommendations—errors that could have tangible consequences in healthcare settings. This gap creates an urgent need for evaluation frameworks that assess not only linguistic quality but also factual reliability and evidence alignment. In this work, we propose a unified evaluation framework that integrates traditional reference-based metrics with evidence-grounded factuality verification. Our framework systematically extracts atomic claims using spaCy (Honnibal et al., 2020), retrieves supporting biomedical literature from PubMed (Cock et al., 2009; Jin et al., 2019; Liu et al., 2005), and applies domain-adapted natural language inference (NLI) via BioBERT-NLI trained on MedNLI (Shivade, 2017; Gu et al., 2021) to verify each claim. By combining these components, we enable a more granular and clinically meaningful assessment of LLM outputs. This approach allows researchers and practitioners to identify factual inconsistencies, quantify reliability, and compare models not just on fluency, but on evidence-supported correctness, ultimately advancing the safe deployment of LLMs in biomedical contexts.

2 Related Work

Benchmark datasets such as BioASQ Task B (10th edition) (Nentidis et al., 2023), PubMedQA (Jin et al., 2019), and MedLFQA (Jeong et al., 2024) provide structured evaluation for biomedical QA across factoid, list, and long-form questions. BioASQ includes 492 test questions with 1–3 expert references, PubMedQA contains yes/no/maybe questions derived from PubMed abstracts, and MedLFQA provides 200 long-form QA pairs with clinician-verified claim-level annotations. While these resources are central to biomedical NLP evaluation, conventional metrics (e.g., ROUGE (Lin, 2004), BERTScore (Zhang et al., 2019)) primarily capture lexical overlap and often overestimate performance by failing to detect unsupported or contradicted claims. Prior efforts have explored evidence-based and NLI-driven evaluation, including biomedical NLI models trained on MedNLI (Shivade, 2017). General-domain factuality metrics such as FactCC and QAFactEval

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 15–19
July 3-4, 2026 ©2026 Association for Computational Linguistics

focus on reference consistency within news or open-domain summarization, rather than external biomedical evidence alignment. In contrast, our framework integrates reference-based metrics with claim-level verification against retrieved PubMed abstracts, enabling detection of unsupported and contradicted scientific assertions even when reference answers are incomplete. By combining systematic multi-model evaluation with an open-source, reproducible toolkit, our approach advances clinically aligned factuality assessment for biomedical text generation.

3 Unified Evaluation Framework

3.1 Reference-based Accuracy

Reference-based accuracy measures the lexical and semantic alignment between generated and reference answers using ROUGE-1/2/L (F1), BLEU-4 (smoothing method 1), and BERTScore (DeBERTa-large-mnli, batch size 64, no baseline rescaling) via HuggingFace `evaluate`. For multi-reference datasets such as BioASQ, we adopt a maximum-score strategy following standard practice in BioASQ evaluations. These metrics provide a baseline measure of answer quality while capturing both n-gram overlap and contextual semantic similarity, forming the reference foundation for our composite factuality assessment.

3.2 Evidence-Grounded Factuality and Safety Assessment

Generated answers are decomposed into atomic claims using spaCy (Honnibal et al., 2020) and queried against PubMed (2014–2024) via Entrez API, retrieving the top 5 abstracts per claim. Each claim–abstract pair is evaluated with BioBERT-NLI (Shivade, 2017) (dmis-lab/biobert-large-nli-v1.1) using a 0.7 threshold to classify claims as supported, contradicted, or unsupported. Answer-level aggregation computes Support@5, Contra@5, and unsupported proportions, averaged per answer. Additionally, rule-based safety checks using RxNorm (Liu et al., 2005) and a curated FDA contraindication database (U.S. Food and Drug Administration, 2023) flag missing dosages or contraindicated medications. These safety flags are reported separately from the Fact-Aligned Score (FAS), a composite metric defined as $\text{FAS} = 0.3 \cdot \text{BERTScore} + 0.4 \cdot \text{Support@5} + 0.3 \cdot (1 - \text{Contra@5})$, which balances reference alignment, evidence support, and contradiction avoidance to provide a clinically meaningful measure of output reliability.

4 Experimental Setup

We evaluate three open-source generative models—Llama-2-13B-chat (Touvron et al., 2023), Llama-2-7B-chat (Touvron et al., 2023), and Mistral-7B-Instruct-v0.2 (Jiang et al., 2023)—all of which are pre-trained and instruction-tuned but not further fine-tuned on the benchmark datasets. We also include PubMedBERT-base (Gu et al., 2021) as an encoder-only baseline. Evaluation is performed on three biomedical QA benchmarks: BioASQ Task B (10th edition; 492 test questions: 157 factoid, 138 list, 197 summary; average 1.4 references per question; mean reference length 87.3 tokens, SD 42.1) (Nentidis et al., 2023), PubMedQA (500 instances evenly split across yes/no/maybe; mean 42.6 tokens, SD 18.3) (Jin et al., 2019), and MedLFQA v1.0 (200-instance evaluation subset; long-form clinical QA pairs; claim-level factuality labels derived from the dataset's Must Have (MH) and Nice to Have (NH) annotations; mean 156.2 tokens, SD 67.8) (Jeong et al., 2024). Models were accessed via HuggingFace Transformers (v4.36.0) using the following identifiers: meta-llama/Llama-2-13b-chat-hf, meta-llama/Llama-2-7b-chat-hf, mistralai/Mistral-7B-Instruct-v0.2, and microsoft/BiomedNLP-PubMedBERT-base-uncased-abstract (all accessed June 2024). Generation was performed with deterministic decoding (max_new_tokens=512, temperature=0, top_p=1, do_sample=False) in FP16 precision; PubMedBERT, being encoder-only, uses the source abstract as the answer for PubMedQA. Experiments were conducted on NVIDIA A100-40GB GPUs (156 total GPU-hours). Traditional metrics were computed using HuggingFace `evaluate` (v0.4.0): ROUGE-1/2/L (Lin, 2004) with Porter stemming and Penn Treebank tokenization (Bird et al., 2009), BLEU-4 (Papineni et al., 2002) with Chen and Cherry smoothing method 1, and BERTScore (Zhang et al., 2019) using `microsoft/deberta-large-mnli` (batch size 64). Factuality evaluation employed a modular pipeline with spaCy-based claim extraction (Honnibal et al., 2020), PubMed retrieval (2014–2024; top five abstracts per claim via Bio.Entrez), and NLI inference (batch size 16; 512-token truncation). Statistical significance was assessed using answer-level bootstrap resampling (10,000 iterations) (Efron and Tibshirani, 1986),

reporting two-tailed 95% confidence intervals; performance differences were considered significant when intervals excluded zero. Safety checks for clinical hazards leveraged the FDA contraindication database (U.S. Food and Drug Administration, 2023) and RxNorm (Liu et al., 2005).

For generation, we used the following prompt templates:

QA tasks (BioASQ factoid/list, PubMedQA):

```
Answer concisely and accurately based on
medical knowledge.
Question: {question}
Answer:
```

Summarization tasks (BioASQ summary, MedLFQA):

```
Provide a comprehensive summary based on
biomedical literature. Include findings,
mechanisms, and clinical implications.
Question: {question}
Summary:
```

5 Results

5.1 Traditional Metric Performance

All generative models evaluated (Llama-2-13B-chat, Llama-2-7B-chat, Mistral-7B-Instruct-v0.2) are pre-trained and instruction-tuned; no further fine-tuning was applied on the benchmark datasets. PubMedBERT is included as an encoder-only baseline. Table 1 reports reference-based performance across datasets. Llama-2-13B-chat achieves the highest ROUGE-L scores on all three benchmarks, with statistically significant improvements over Llama-2-7B on BioASQ and PubMedQA, though not on MedLFQA due to higher variance in long-form responses. Performance scales with model size, while Mistral-7B performs comparably to Llama-2-7B with no significant differences. PubMedBERT reveals a limitation of lexical metrics: on PubMedQA, it achieves ROUGE-L 0.412 despite not generating answers but simply reproducing the source abstract. This indicates that reference-based metrics reward lexical overlap even when outputs are not faithful answers to the question, motivating the need for evidence-grounded evaluation.

5.2 Evidence-Grounded Factuality

Table 2 presents Support@5 and Contra@5 scores. Although larger models demonstrate higher support rates, contradiction rates remain non-trivial (13.4%–24.7%), even for the strongest model. This confirms that high ROUGE does not imply factual reliability. Notably, PubMedBERT's relatively high ROUGE on PubMedQA (0.412) corresponds to lower support rates on BioASQ, illustrating dissociation between lexical similarity and claim-level verification.

Table 1: ROUGE-L scores (95% CI).

Model	BioASQ	PubMedQA	MedLFQA
Llama-2-13B	0.387±0.013	0.501±0.012	0.362±0.016
Llama-2-7B	0.358±0.013	0.473±0.012	0.334±0.016
Mistral-7B	0.365±0.013	0.481±0.012	0.341±0.016
PubMedBERT	0.187±0.013	0.412±0.012	0.143±0.016

Table 2: Factuality metrics (Support@5 and Contra@5) across BioASQ and PubMedQA. MedLFQA factuality is evaluated via the Fact-Aligned Score (FAS; Table 3). 95% CI shown.

Model	BioASQ S@5	BioASQ C@5	PubMedQA S@5
Llama-2-13B	71.2% [67.9-74.5]	13.4% [11.2-15.6]	78.4% [75.7-81.1]
Llama-2-7B	63.5% [60.2-66.8]	17.1% [14.9-19.3]	71.2% [68.5-73.9]
Mistral-7B	65.8% [62.5-69.1]	16.3% [14.1-18.5]	72.5% [69.8-75.2]
PubMedBERT	42.3% [39.0-45.6]	24.7% [22.5-26.9]	63.7% [61.0-66.4]

5.3 Per-Question-Type Analysis and Correlation with Gold Factuality

Factuality on BioASQ varies by question type: for Llama-2-13B, factoid questions (N=157) achieve the highest Support@5 (76.8%) and ROUGE-L (0.412) but also the highest contradiction rate (16.2%); list questions (N=138) show intermediate support (73.4%) and contradictions (14.1%), while summary questions (N=197) have lower support (65.2%) and fewer contradictions (10.8%). Differences between factoid and summary questions are statistically significant (Support@5 $\Delta = 11.6\%$, 95% CI [7.2, 15.9]; Contra@5 $\Delta = 5.4\%$, 95% CI [2.1, 8.7]). On MedLFQA, the Fact-Aligned Score (FAS) correlates most strongly with gold claim-level annotations ($\rho = 0.68$), outperforming ROUGE-L ($\rho = 0.41$) and BLEU-4 ($\rho = 0.36$); Support@5 alone also shows strong correlation ($\rho = 0.61$). Claim-level labels were derived from expert "Must Have" (MH) and "Nice to Have" (NH) statements, mapping MH to supported claims and treating unsupported or contradictory statements as factuality violations.

5.4 External Validation Considerations

Our primary validation relies on MedLFQA, from which we derive expert-informed claim-level fac-

tuality labels. While this enables direct quantitative correlation analysis, we acknowledge that additional human evaluation on BioASQ and PubMedQA would further strengthen external validity. To partially assess generalization, we analyzed consistency patterns across datasets. The relative ranking of models under FAS remained stable across BioASQ, PubMedQA, and MedLFQA, suggesting that the metric captures systematic reliability differences rather than dataset-specific artifacts. Table 3 shows the consistent ranking of models across all three datasets under our proposed FAS metric, with Llama-2-13B consistently outperforming other models and PubMedBERT serving as a lower-bound baseline. All evaluated models are pre-trained and instruction-tuned; no dataset-specific fine-tuning was applied. PubMedBERT is included as an encoder-only baseline.

Table 3: FAS scores (95% CI) across datasets. Higher is better. For MedLFQA, claim-level factuality labels were derived heuristically from expert-annotated "Must Have" (MH) and "Nice to Have" (NH) statements, mapping MH to supported claims and treating unsupported or contradictory statements as violations.

Model	BioASQ	PubMedQA	MedLFQA
Llama-2-13B	**0.612±0.013**	**0.703±0.012**	**0.584±0.016**
Mistral-7B	0.578±0.013	0.672±0.012	0.553±0.016
Llama-2-7B	0.571±0.013	0.665±0.012	0.547±0.016
PubMedBERT	0.412±0.013	0.589±0.012	0.398±0.016

5.5 Ablation Studies

We conduct ablation experiments on MedLFQA to assess the contribution of individual components of the FAS pipeline. Table 4 shows Spearman correlation with gold factuality under different configurations. Removing literature retrieval ("w/o retrieval") tests the importance of external evidence, resulting in a decrease from $\rho = 0.68$ to $\rho = 0.52$ ($\Delta = -0.16$). Replacing BioBERT-NLI with a general-domain MNLI model ("w/ general MNLI") evaluates the effect of domain adaptation, lowering correlation to $\rho = 0.45$ ($\Delta = -0.23$). Limiting retrieval to a single abstract per claim ("Single abstract") examines the impact of multi-document grounding, reducing correlation to $\rho = 0.56$ ($\Delta = -0.12$). These results suggest that both multi-document retrieval and domain-specific NLI significantly contribute to factuality alignment.

The NLI confidence threshold determines the minimum probability at which a claim–abstract pair is classified as supported or contradicted.

Table 4: Ablation on MedLFQA: Spearman ρ measures rank correlation between the Fact-Aligned Score (FAS) and gold claim-level factuality annotations. 95% CI shown; Δ indicates change relative to the full model.

Configuration	ρ	95% CI	Δ
Full model (FAS)	0.68	[0.62-0.74]	—
w/o retrieval	0.52	[0.45-0.59]	-0.16
w/ general MNLI	0.45	[0.38-0.52]	-0.23
Single abstract	0.56	[0.49-0.63]	-0.12

Claims with model confidence below the threshold are labeled as unsupported. To assess sensitivity, we varied this threshold from 0.5 to 0.9. Table 5 shows that Spearman correlation with gold factuality remains stable between 0.6–0.8, with optimal performance at 0.7, though differences within this range are not statistically significant. Based on these results, we selected 0.7 as the default threshold for our main analysis.

Table 5: Threshold sensitivity analysis on MedLFQA. Correlation with gold factuality at different NLI confidence thresholds.

Threshold	Spearman ρ [95% CI]
0.5	0.63 [0.56-0.70]
0.6	0.66 [0.59-0.73]
0.7	0.68 [0.62-0.74]
0.8	0.65 [0.58-0.72]
0.9	0.59 [0.52-0.66]

6 Conclusion

Open-source biomedical language models make 13–25% unsupported claims, with 4–7% flagged for missing dosages. Lexical metrics correlate weakly with factuality ($\rho = 0.36$–0.49), while the Fact-Aligned Score (FAS) aligns better ($\rho = 0.68$). Our framework—combining references, claim extraction, retrieval, and NLI—assesses biomedical text generation. Limitations include extraction errors, retrieval gaps, NLI mismatch, heuristic settings, English-only evidence (2014–2024), and multi-reference metric inflation.

Abstract

Seizure freedom is a key clinical outcome for people with epilepsy (PWE) yet it is primarily recorded in free-text notes and letters in the United Kingdom, making it difficult to aggregate and track at scale. This paper introduces a generative LLM-based pipeline boosted by synthetic data to identify a PWE's seizure freedom status in clinicians' records. We fine-tuned seven different large language models (LLMs) with between 4-14 billion parameters using LoRA to compare models trained on synthetic records against those trained on expert annotated records. The best performing configuration, based on Qwen-2.5-14B, was trained entirely on synthetic records and used chain-of-thought (CoT) reasoning (both generated by GPT-5). This achieved an F1 score of 0.90±0.02 on double-annotated test data and outperformed the equivalent model trained on authentic clinician records, which achieved 0.87±0.04. The synthetically trained models also have the benefit of outputting their CoT reasoning process for greater decision-making transparency and can also make use of unused supervised training data for significantly increased test examples. This work has implications for monitoring a key treatment outcome for PWE automatically and at scale.

1 Introduction

Epilepsy is a chronic neurological condition characterised by recurrent seizures (Beghi, 2019). Seizure freedom is a key outcome for improving quality of life in people with epilepsy (PWE) (Poochikian-Sarkissian et al., 2008) and an important post-surgical outcome (Wieser et al., 2001). However, its definition remains inconsistent (Halford and Edwards, 2020). Engel's (1993) post-operative classification prioritises reduction of "disabling seizures", placing less emphasis on minor seizures, while Wieser et al. (2001) proposed a stricter definition requiring complete seizure freedom without auras, aligning more closely with PWE's expectations. Clinically, seizure freedom also requires a temporal threshold, as PWE may experience seizure recurrence after years without them. For example, the UK Driving and Vehicle Licensing Agency (DVLA) requires 12 months of seizure freedom for licence reinstatement (DVLA, 2026). Other studies have used six- and twelve-month thresholds (Hsieh et al., 2023; Choi et al., 2014). Thus, seizure freedom is both a definitional and temporal concept.

In the UK, difficult-to-treat epilepsy is managed in outpatient (ambulatory) settings, where consultation summaries (outpatient letters) are recorded as unstructured or semi-structured free text. This format limits automated information extraction. Advances in natural language processing (NLP), particularly large language models (LLMs), have enabled extraction of complex contextual information from electronic health records (EHRs) (Jerfy et al., 2024; Jin et al., 2025), including temporality (Yuan et al., 2024), which is essential for determining seizure freedom.

Accordingly, this study develops an LLM-based seizure-freedom classifier trained entirely on synthetic epilepsy letters which provides generated explanations. We also examine how training data origin (synthetic vs. authentic), class distribution, and synthetic chain-of-thought reasoning affect model performance. While this paper explores an epilepsy-specific application, we believe this approach has the potential to improve other imbalanced clinical information extraction tasks.

2 Related Work

Previous studies have applied NLP to extract seizure freedom-status from epilepsy records. Xie et al. (2022) used BERT-style models (Devlin et al., 2019) to extract seizure freedom and frequency, defining seizure freedom as no seizures since the last clinic visit or for at least 12 months.

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 20–30
July 3-4, 2026 ©2026 Association for Computational Linguistics

Due to model input length limits, they used paragraph-level classification. Fernandes et al. (2024) found performance declined without reliable paragraph selection, and later work by Xie et al. (2023) introduced a bespoke paragraph extractor to aggregate document-level predictions. However, seizure freedom is inherently a document-level construct, true or false at the time of writing. Modern generative LLMs with longer context windows could perform direct document-level classification without rule-based passage selection, which could in turn better resolve contradictory statements. Related work on seizure frequency also reflects these broader NLP developments, progressing from rule-based methods (Fonferko-Shadrach et al., 2019) to encoder-only models (Xie et al., 2022), in-context learning (Holgate et al., 2024), and parameter-efficient fine-tuning for document-level approaches (Holgate et al., 2025).

These studies usually rely on relatively small annotated datasets, reflecting expert time constraints and limiting representation of rarer contexts. Data imbalance is intrinsic, as seizure-free PWE attend fewer appointments. Synthetic data offers a potential solution, enabling larger training datasets while reserving expert-annotated data for evaluation. Teacher–student approaches, where large LLMs generate synthetic training data for smaller models, are a potential solution. Phi-4 (Abdin et al., 2024), for example, was trained primarily on synthetic GPT-4 output. Synthetic data has also addressed healthcare challenges like Šuvalov et al. (2025) creating an Estonian clinical named entity recognition system using GPT-generated records. However, it remains unclear whether fully synthetic training can capture temporal clinical concepts like seizure freedom. Additionally, approaches such as DeepSeek's synthetic reasoning chains (Guo et al., 2025; Liu et al., 2025) may enhance transparency by addressing clinician concerns about "black box" decisions (Salvi et al., 2025) by providing interpretable reasoning in model output.

Synthetic clinical text has also been explored in epilepsy where Goldenholtz et al. (2025) used LLM-generated notes to simulate a clinical trial. This study was entirely *in silico* and thus highlights the need to evaluate synthetic training against real-world clinician-authored notes, which this study addresses.

3 Methods

Seizure freedom (SF) classification is framed in this work as a binary classification task using generative language modelling. We compare authentic and synthetic training datasets to examine the effect on performance for classifying seizure-freedom. For the synthetic training approach, we also compare how additional fine-tuning on CoT reasoning-chains affects performance and outputs. For the authentic letters we also tested whether under sampling the majority class resulted in better performance due to the pronounced class imbalance in this task.

3.1 Seizure Freedom Definition

Seizure freedom is considered an important outcome of epilepsy treatment, yet definitions differ. We sought to find a compromise between a the stricter 12-month definition of seizure freedom (DVLA, 2026; Choi et al., 2014) and Xie et al.'s (2022) last clinic approach. Hsieh et al.'s (2023) six-month definition of seizure freedom provided a clinically relevant outcome while providing enough training and testing examples (as 12-months seizure free was much less frequently seen in our dataset than six-months). Accordingly, in this work seizure freedom is defined as:

> *"The person with epilepsy has suffered no epileptic seizures of any kind for a period of six months or more."*

Figure 1 shows some artificial examples of ambiguous examples of SF-positive and SF-negative letters by this definition. These characteristics informed the need to use LLMs with longer context windows (the number of text tokens an LLM can process at a time) as relevant information could be in any part of (sometimes very long) letters, and a degree of temporal reasoning is required to ascertain the correct SF-status.

3.2 Authentic Dataset

We randomly sampled and annotated for SF status 2,114 epilepsy letters from King's College Hospital (London, UK) with a team of five epilepsy experts. These were retrieved using the information retrieval system CogStack (Jackson et al., 2018). The letters were written between 1 January 2013 and 30 September 2023. The documents comprise doctor's and nurse's reports with the vast majority referring to outpatient clinic visits. A

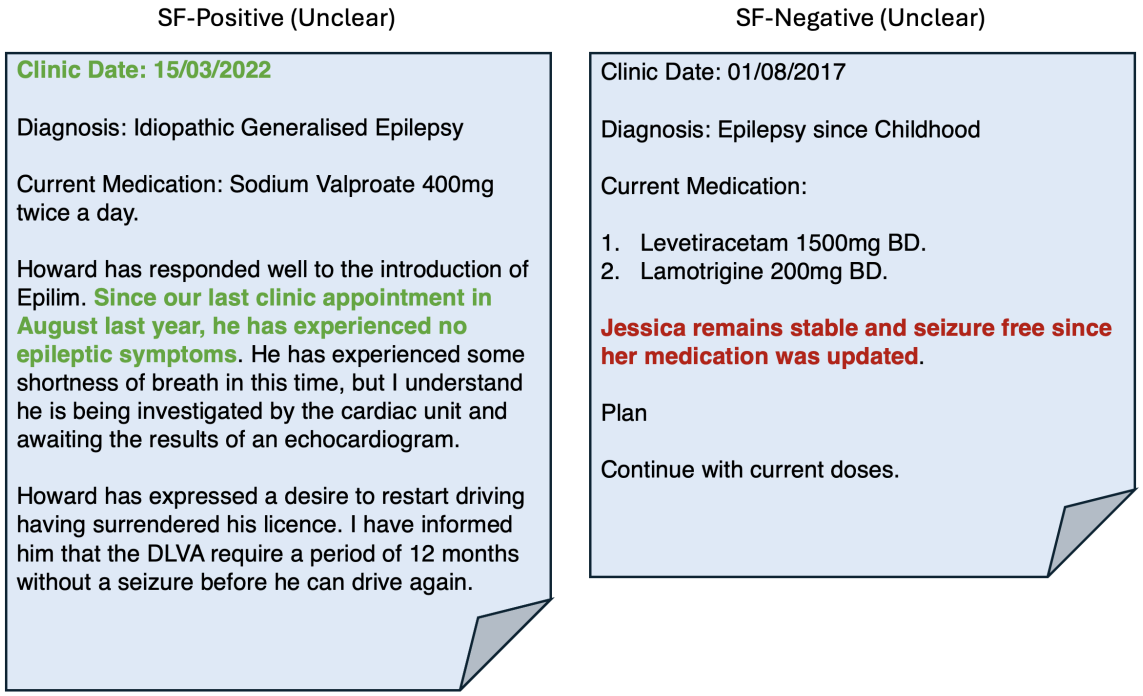

Figure 1: Fictional clinician letters for epilepsy demonstrating ambiguous SF-positive and SF-negative status. Letters can be much longer and more detailed in practice. Both examples show how temporal reasoning is required to make the correct classification (either relating information to provided dates, or recognising there is missing temporal information). The negative example demonstrates how we consider all examples that are not explicitly seizure free (for six months or more) as negative examples.

subset of 300 reports were dual annotated independently by epileptologists to test inter-annotator agreement and subsequently a gold-standard test set was produced via consensus between the experts. The overall agreement for seizure freedom was 0.85 using Cohen's Kappa, representing 'near perfect' (Cohen, 1960) or 'strong' (McHugh, 2012) agreement. SF-positive status was observed to be rare in the hospital letters, around 6% of the total. Therefore, due to limited resources for annotation, the bulk of the letters were annotated by one person. This motivated both the creation of the dual-annotated subset (for greater confidence in evaluation) and the need to create synthetic letters for training.

This project and its data usage operated under UK Health Research Authority (HRA) London South East Research Ethics Committee approval (reference18/LO/2048 and renewed 24/LO/0057) granted to the King's Electronic Records Research Interface (KERRI) with data research opt-out. Individual consent for participation was waived by the KERRI committee at King's College Hospital (KCH) for purposes of evaluating NLP for Epilepsy (approved February 2021) with local institutional oversight.

3.3 Synthetic Dataset

The aforementioned class imbalance motivated the use of synthetic training examples. As part of a wider synthetic data project 15,099 synthetic epilepsy letters were generated by GPT-5 to reflect a range of different seizure frequency and seizure freedom occurrences in clinical epilepsy letters (Gan et al., 2026). These were created from 10 manually composed letters (to mimic a UK style of epilepsy reporting) and 74 templates of different letter characteristics (different seizure frequencies, no seizures mentioned, seizure free etc.). Once these letters were generated, they were fed back to GPT-5 where it was prompted to ascertain the correct seizure frequency/seizure freedom-status and provide a description of how it came to that conclusion. This functions as a quality-assurance step for the synthetic data as any letters that GPT-5 does not correctly categorise were discarded. From these explanations 454 synthetic letters were found that were correctly described by GPT-5 as implying SF-positive status. These were extracted along with 454 SF-negative examples to create a balanced synthetic training dataset. This approach mitigates the class imbalance issue present in a true clinical distribution of

letters. Two variations on this synthetic dataset were trialled: Synthetic and Synthetic-CoT. For the latter we include the reasoning chains generated by GPT-5 as part of the output for supervised training to test if it improves model performance. This also has the benefit of providing text explanations for the classifications, something that could potentially assist clinicians (Miao et al., 2024). This project respects OpenAI's Terms of Use. This study is conducted for academic, non-commercial research purposes. We do not release distilled model weights and do not position the distilled model as a deployable substitute for OpenAI services; results are reported for methodological analysis.

3.4 Dataset Splits, Evaluation, and Prompting

We define four training datasets: Authentic, Authentic-Balanced, Synthetic and Synthetic-CoT. The Authentic training set uses 1,814 annotated letters (all but the 300 double-annotated letters). The Authentic-Balanced dataset uses the 115 SF-positive examples that are not included in the gold-standard test set alongside a matching 115 SF-negative examples. This matches the distribution of the Synthetic and Synthetic-CoT training datasets which contain 454 SF-positive and 454 SF-negative examples.

We used two test datasets. The gold-standard test set consisted of the 300 examples with consensus annotation from two experts and both authentic and synthetic models used this for testing. The silver-standard test set consisted of all 2,114 annotated letters and was used for additional testing of the synthetically trained models. This allowed for a better indication of long-term performance. The authentic models were not tested on this as they were explicitly trained on all but the 300 gold-standard examples in this dataset.

As seizure freedom extraction is framed as a binary classification task, we used precision, recall, F1 score, and accuracy for evaluation. Due to the pronounced class imbalance, we prioritised macro-averaged F1 over accuracy to compare the different models. This ensured we evaluated both the majority and minority classes equally and avoided making decisions due to deceptively high accuracy scores caused by the class imbalance.

The prompt used for training and inference is demonstrated in Figure 2. The additional supervision signal of GPT-5 reasoning chains were prepended to the desired output in the Synthetic-CoT dataset. Figure 2 also demonstrates how models trained on the Synthetic-CoT dataset generate temporal reasoning before making a final classification decision. The other training approaches used the same input prompt but only provided a 'Seizure free: yes/no' output.

Base Model	Parameters	Type
Gemma-3	4B	VLM
MedGemma	4B	VLM
Qwen-2.5-7B	7B	LLM
Lingshu	7B	VLM
Llama-3.1-Instruct	8B	LLM
Ministral-Instruct-2410	8B	LLM
Qwen-2.5-14B	14B	LLM

Table 1: Comparison of the LLMs used in this study. 'B' represents 'Billion'.

3.5 LLMs and Training Approach

We selected seven open-weight LLMs with between 4 billion to 14 billion parameters for fine-tuning on the SF extraction task (Table 1). Some of these were vision-language models (VLMs), but only their language capabilities were utilised for this task. The selection represents both general and clinically specialised models and were chosen as they represented a diverse selection of different size LLMs with different pre-training corpora and model architectures. We also trained two simpler, logistic regression classifiers using term frequency-inverse document frequency (TF-IDF) encodings to serve as baselines, one on the 'Authentic' dataset, and one on the balanced 'Synthetic' dataset.

Early experiments revealed that in-context learning was not sufficient for adequate performance on this task so fine-tuning was performed using low-rank adaptation (LoRA) (Hu et al., 2021). Due to the extra VRAM (Video Random Access Memory) Qwen-2.5-14B required for fine-tuning, we used 8-bit quantization using Bitsandbytes (Dettmers et al., 2021). The optimisation task was autoregressive language modelling, where the model is trained to predict the next token of text from previous text. The appropriate instruction templates and tokenizers were used for each model tested.

No specific hyperparameter tuning took place in order to compare synthetic and authentic approaches without biasing training towards either

Chain-of-Thought Fine-Tuning Prompt

Input:

"You are a professional neuroscientist. The following is a document written by a healthcare professional. Analyze the text and ascertain whether the patient referred to in the letter has been seizure free for six months or more. Think through the problem step-by-step. Some things to consider include: Ascertain if the letter contains information about seizures, ascertaining if they have had recent seizures, and if they have not had seizures for six months or more. Finally, if you think the subject has been seizure free for six months or more return 'Seizure free: yes', otherwise return 'Seizure free: no'.

Document:

[LETTER]"

Output:

"The letter explicitly states: "She reports ongoing absence of seizures since February 2023." The letter date is 02 October 2025. Calculate duration of seizure freedom from Feb 2023 to Oct 2025: from Feb 2023 to Feb 2024 = 12 months; Feb 2024 to Feb 2025 = 12 months; Feb 2025 to Oct 2025 = 8 months. Total = 32 months. This exceeds 6 months, so she is seizure free, and the duration is multiple years. The allowed format for multi-year seizure freedom is 'seizure free for multiple year' when exact number in years isn't required. ***Seizure free: yes"***

Figure 2: The main prompt used for the Synthetic-CoT training strategy. The Authentic, Authentic-Balanced and Synthetic training datasets used the same prompt but "Seizure free: yes/no" only as the desired output. [LETTER] signifies where the authentic or synthetic letter would be inserted into the prompt.

one. All models were trained for three epochs with a batch size of four. We used a learning rate of 0.0001 with a cosine schedule and a warmup ratio of 0.1. LoRA rank, alpha and dropout were set at 8, 16 and 0 respectively. Greedy decoding was used for text generation to ensure a deterministic answer. For synthetic data generation GPT-5's temperature was set (via API) to 0.

4 Results

Table 2 shows the distribution of SF-positive and SF-negative examples in the different datasets used for training and testing. The extracted clinical data (Authentic, Authentic-Silver and Authentic-Gold) demonstrated a pronounced class imbalance that is rectified by under sampling in the Authentic-Balanced, Synthetic, and Synthetic-CoT training datasets. There were only 21 SF-positive letters in the gold standard dataset but this is increased to 136 in the silver standard test set, demonstrating the benefit of having additional annotated data available for testing.

Figure 3 shows how synthetic and authentic training datasets affect performance on the gold-standard test set. Synthetic training tended to perform as well, if not better, than authentic training. For authentic training, using a balanced dataset did not help and, in some cases, seemed to hinder the model. The use of CoT reasoning chains in training improved performance on certain models but not others. All the LLM-based approaches dramatically outperformed the TF-IDF/logistic regression model which only achieved an F1 score of 0.48 (in contrast to F1 scores of 0.74-0.91 for the LLM-based pipelines).

Figure 4 explores the performance of synthetically trained models further on the larger silver-standard test set. This provides a more thorough demonstration of synthetically trained model performance with 2,114 test examples as compared to 300 (Table 2). It was observed again that benefits for training with CoT reasoning chains were dependent on the individual base LLM. The Qwen models seemed to find the additional CoT reasoning supervision beneficial on the larger test dataset with Qwen-2.5-14B model's F1 score improving to 0.85 from 0.84, and Qwen-2.5-7B improving to 0.84 from 0.82. The best performing model was Qwen-2.5 14B with CoT reasoning and this was also a strong performer on the gold standard subset with an F1 score of 0.88 (Figure 3). In

Dataset	Use	No. Letters	SF-Positive	SF-Negative
Authentic	Training	1814	115	1699
Authentic-Balanced	Training	230	115	115
Synthetic	Training	908	454	454
Synthetic-CoT	Training	908	454	454
Authentic-Silver	Synthetic Test	2114	136	1978
Authentic-Gold	Synth and Authentic Test	300	21	279

Table 2: The different training and test sets used in this work and their distribution of SF-positive and negative examples.

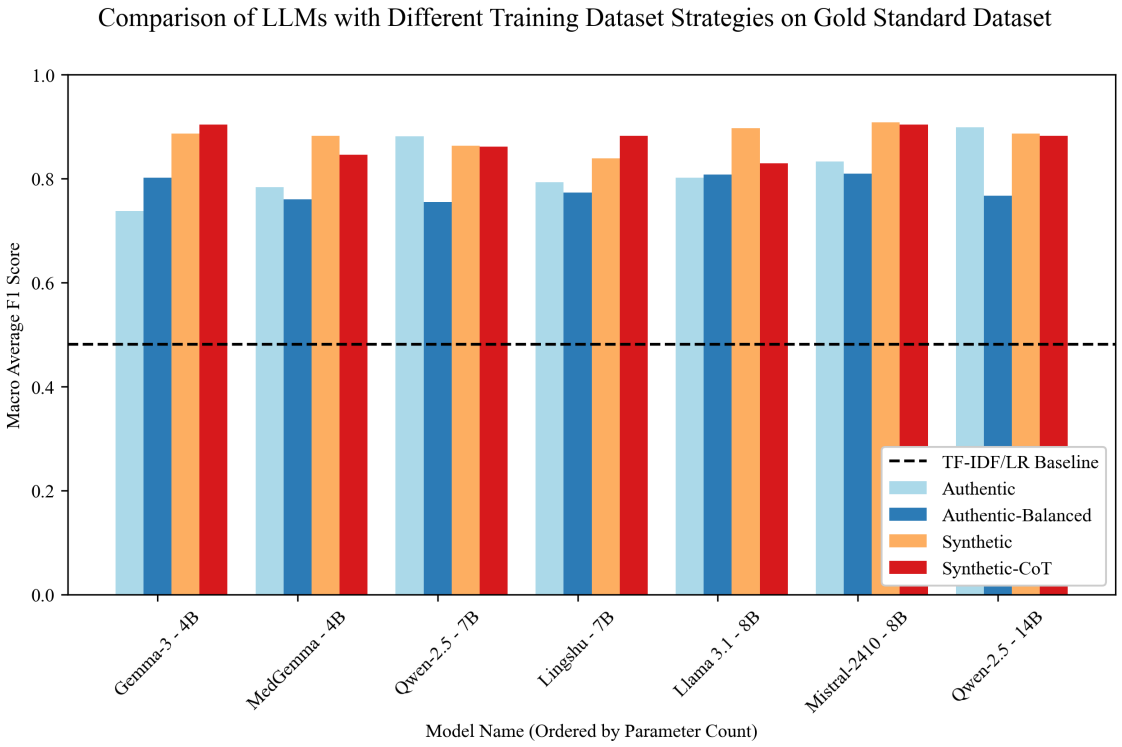

Figure 3: Comparison of the different LLMs trialled when trained on four different dataset strategies. Results are on the gold-standard test set. A TF-IDF logistic regression classifier (trained on the authentic training dataset) is provided as a baseline.

contrast, LLama 3.1-8B performed better without CoT reasoning supervision with its F1 score performance on the silver standard test set dropping to 0.77 from 0.83. The synthetically-trained TF-IDF/logistic regression baseline performs poorly and only achieves an F1 score of 0.24.

As Qwen-2.5-14B was the best performing LLM, when taking into account results on both the gold and silver test sets, Table 3 shows its performance in more detail when trained three times with different random seeds. The Synthetic-CoT training set resulted in the best performing model pipeline on both the gold and silver-standard datasets with F1 scores of 0.90±0.02 and 0.85±0.02 respectively.

5 Discussion

Our best model configuration for classifying seizure freedom status, using Qwen-2.5-14B and the Synthetic-CoT training strategy, achieved F1 scores of 0.90±0.02 on the gold standard test and 0.85±0.02 on the larger silver standard test dataset. The strong performance on both suggests it will be robust to different examples when used in practice. This model was trained entirely on synthetic data using a CoT reasoning approach for training. This means it generates the LLM-reasoning steps the model took to come to a final answer as part of the output. It is difficult to directly compare our results with Xie et al. (2022; 2023) and Fernandes et al.'s (2024) approaches to seizure freedom classification as the models were trained on different datasets and use different definitions of seizure freedom. However, our best model configuration compares favourably to the 0.83-0.88 F1 scores reported by Xie et al. (2022; 2023) (who also had a gold-standard test set of 300 examples) and 0.38 reported by Fernandes et al. (2024). The lower performance of the latter was attributed to using Xie et al.'s (2022) model without fine-tuning on their own letters. This demonstrates the issue of model generalization to external data. The goal of our research was to maximise performance for a stringent definition of seizure freedom rather than tackle broader seizure frequency concerns. Seizure freedom is an important outcome in epilepsy treatment so ensuring that we automatically identify PWE who have had at least six months of seizure freedom at a point in time was the priority. Although we explore a specific clinical use case in this paper, we believe the results of these experiments are also evidence to support using synthetic training data for other medical NLP tasks.

A key finding from this work is that a successful seizure freedom classifier can be trained using only synthetically generated training data. This provides two key benefits. It allows all expert annotated examples to be used for testing, and reduces privacy concerns by not using any sensitive data for fine-tuning. The latter makes it impossible for the model to disclose this data from leakage (Zhong et al., 2025), or adversarial attack (Rahman, 2023). Our best overall model fine-tuned Qwen-2.5-14B on synthetic letters and CoT reasoning. The Qwen 2.5 models were trained with an emphasis on reasoning (Yang et al., 2024), which is a potential reason they benefited from the CoT training signal, particularly on the silver-standard test set (Figure 4). Llama 3.1, in contrast, was not specifically optimised for reasoning which could explain why performance worsened for this LLM using CoT training signal. We identify two potential reasons for how a synthetically trained model can outperform an authentically trained one. Firstly, the increased training examples that the synthetic approach allows provides greater supervision signal. Secondly, there are likely less ambiguous synthetic examples (as these have been verified by GPT-5) so the model is less likely to overfit to them. These factors could also interact, as an ambiguous authentic example will have a disproportionately large effect due to the smaller number of training examples overall.

Synthetic data has been proposed as a solution to data bottlenecks when training healthcare models (McDuff et al., 2023). However, it is non-trivial creating examples which replicate authentic documents faithfully (Smolyak et al., 2024). Epilepsy letters are a good case study for synthetic data approaches as concepts like seizure freedom and frequency require dates (clinic dates, medication changes, etc.) to remain in letters for training. This is because dates and sentences referring to them may be the only reference to seizure status in the text. This can be considered private information and some de-identification models will remove them by default. Synthetic examples overcome this limitation by allowing student models to train on temporal relationships without jeopardising patient privacy. The reasoning chain demonstrated in Figure 2 shows how both the teacher and student models make use of this

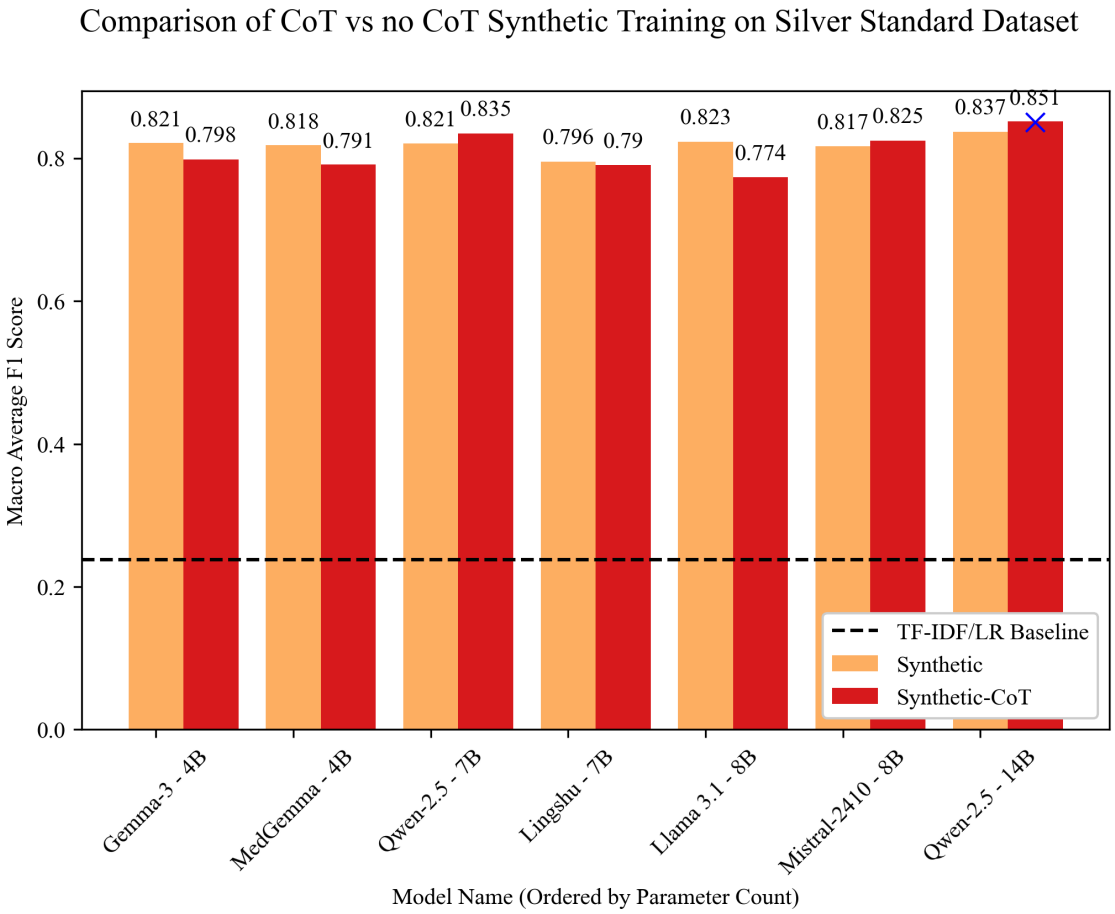

Figure 4: Comparison of Synthetic and Synthetic-CoT training strategies on the silver-standard test set. The blue cross represents the best performing model by macro average F1 score. Exact F1-score values are stated above the bars. A TF-IDF logistic regression classifier (trained on the synthetic training dataset) is provided as a baseline.

Training Set	Test Set	Accuracy	F1	Precision	Recall	Support
Authentic	Gold	0.972±0.009	0.874±0.049	**0.952±0.011**	0.824±0.062	300
Auth-Balanced	Gold	0.926±0.015	0.793±0.026	0.739±0.026	**0.909±0.012**	300
Synthetic	Gold	0.969±0.002	0.88±0.007	0.883±0.025	0.881±0.028	300

Table 3: Performance of Qwen-2.5-14B when LoRA fine-tuned with the four different training strategies on both test sets. Each model was trained three time with three random seeds, and the mean and standard deviation is reported. F1, precision, and recall metrics are macro-averaged. Support signifies the number of examples in the test sets. Bold text represent the best performing on the gold-standard test set, and bold plus italics represents the best performing on the silver-standard test set.

temporal information to arrive at a classification. By using a high-quality reasoning model as the teacher model, like GPT-5, we demonstrate that student models can learn to generate reasoning chains that justify the classification of SF-status. This can not only improve performance of the model (depending on the student LLM used), but also provides a human interpretable explanation for the clinician, something that has been identified as important step towards building confidence in AI solutions for healthcare (Miao et al., 2024). The reasoning chains also provided another benefit by serving as a verifier for quality when creating the synthetic letters. This combination of synthetic letters with CoT reasoning appears to be a powerful combination for developing epilepsy-specific systems where temporal features are directly related to patient outcomes.

The synthetic training data approach also has advantages when it comes to evaluation. Many classification models are tested on a small number of examples (Hou et al., 2024), which reduces the support for any classification metrics presented. Not requiring annotations for training means all annotations can go towards verifying the performance of models. The synthetically trained models in this project were evaluated on seven times the number of samples than was possible for the authentically trained models, providing greater confidence in them.

Although the largest model tested was the most effective, it should be noted that all the models tested reliably extracted SF-status from reports (Figures 3 and 4). Many hospitals do not have extensive computational resources, so having a smaller, 4 billion parameter LLM as a viable option is encouraging for clinical translation. It is also worth noting that the smaller models seemed to particularly benefit from the additional training examples provided by the synthetic letters. This is illustrated in Figure 3 where Gemma and MedGemma performed comparatively poorly when trained on authentic letters compared to synthetic letters (on the gold-standard test set). As multimodal AI becomes more prevalent, it was also encouraging to see that the VLMs (Gemma, MedGemma, and Lingshu) did not perform noticeably worse than LLMs when operating using text only. This suggests there is little drawback in training foundation models for multimodality outside of data resource and compute constraints.

For future work, it would be useful to apply synthetic-only training approaches to other clinical NLP tasks. Identifying people with rare phenotypes (for both epilepsy and other conditions) in electronic health records would be a valuable test for this approach. We also plan to implement the best performing model from this project as a feature extractor for an epilepsy prognostic tool, where a PWE's seizure freedom status is likely to have predictive value.

6 Conclusion

We developed an LLM-based pipeline to classify PWE's clinical reports for seizure freedom status. A configuration using Qwen-2.5-14B trained on a dataset consisting entirely of synthetically generated clinician letters from GPT-5 with CoT reasoning chains performed the best. This model offered key advantages over the traditional supervised approach. Most notably the CoT from the teacher model, GPT-5, can be used as supervision signal and allow the student model, to generate CoT text for better performance and greater transparency in its answers. Also, not needing annotated data for training allowed the model to be evaluated on a much larger test set. This pipeline has the potential to be used for monitoring the progress of PWE at scale and determining if medication changes or other interventions result in this key clinical outcome being achieved.

Limitations

There were three main limitations. Firstly, we were unable to perform external testing for the authentic models due to only having annotations from one hospital. Secondly, the silver-standard test set was only single-annotated and although we found these annotations to be reliable, there could be more annotation mistakes in this test set when compared to the gold-standard test set. Finally, these are document-level classification models, and there are cases where relevant temporal information could be spread across multiple documents which this method will not take into account.

Analyzing Prompt Design Choices in Biomedical Information Extraction for Low-Resource Languages

Abstract

Despite the multilingual abilities of modern LLMs, biomedical information extraction remains challenging for low-resource, morphologically rich languages such as Bangla/Bengali and Basque. Prior investigations of prompt design and output schemas have focused on high-resource languages. To bridge this gap, we systematically analyze biomedical named entity recognition (NER) with open LLMs under multiple prompting settings on Bangla, Basque, Spanish, and English. We find that span-based extraction is more effective than BIO tagging for LLM prompting across all languages, while moving from statement-based prompting to question-based prompting has a stronger effect on the low-resource languages (e.g., +57% for Bangla and +109% for Basque) than on the high-resource languages (+28% for English and +22% for Spanish). Our breakdowns by error type show that translation-based prompting cuts Bangla hallucinations by 64% and QA-style prompting lowers Basque empty prediction errors by 61%. Our results offer practical guidance for building reliable multilingual biomedical NER systems in Bangla and Basque. We release our code at https://github.com/clulab/LRL_IE/.

1 Introduction

Research on health and medical texts is important because it affects people's lives, can reduce cost and workload, and supports better clinical decisions (Agrawal et al., 2022). However, most medical information appears in unstructured text, so medical named entity recognition (NER) is needed to identify and label key medical terms (Averly and Ning, 2025). Manual annotation, whether for direct use or for fine-tuning machine learning models, requires medical expertise, and is slow, expensive, and hard to scale. To reduce the need for manual annotation, prior work has explored

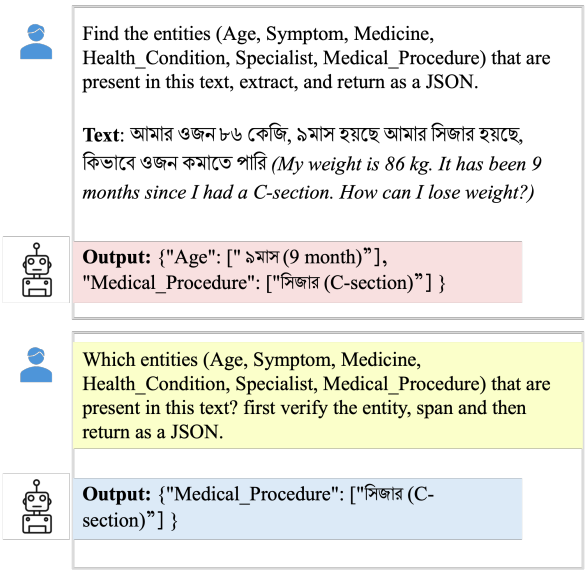

Figure 1: A statement-based prompt for biomedical NER in Bangla results in an incorrect extraction (red), while a question-based prompt results in a correct extraction (blue).

prompting and in-context learning with large language models (LLM) achieving great performance in high-resource languages like English (Ashok and Lipton, 2023; Li et al., 2023a; Li and Zhang, 2024; Wang et al., 2025; Averly and Ning, 2025). In contrast, for low-resource languages (languages with limited annotated datasets, smaller digital corpora, and fewer domain-specific resources), we still lack a systematic understanding of how different prompting strategies affect multilingual LLM performance in biomedical NER (Azime et al., 2025; Kumar et al., 2025).

We present a systematic analysis of LLM prompting strategies in Bangla/Bengali and Basque, two morphologically rich languages that pose challenging (Arnett and Bergen, 2025) low-resource settings (Bhattacharyya and Bhattacharya, 2025; López de Lacalle et al., 2020). Our analysis also includes Spanish and English as high-resource comparisons. We analyze different

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 31–44
July 3-4, 2026 ©2026 Association for Computational Linguistics

prompted output representations (beginning–inside–outside tagging (BIO; Ramshaw and Marcus, 1995) and span-based extraction), prompt variations (statement, question, explanation, and translation), and common error types (entity hallucination, over-generation, boundary mistakes, etc.). We summarize these analyses in three research questions:

- Which output format is most effective for biomedical NER? Is it consistent across Bangla, Basque, Spanish, and English?
- Which prompt variation is most effective? Is it consistent across languages?
- Which errors are most common? Which prompt choices reduce hallucination, over-generation, and boundary errors?

We find that LLMs struggle to generate output in BIO format, but can succeed with span-based extraction. We find that although the best prompting strategy is often similar across languages, with question-style generally outperforming statement-style (as in Figure 1), selecting an optimal prompt is more critical in low-resource languages, where performance degrades much more under suboptimal prompting strategies. Our analyses of these four languages offer directions for future biomedical NER research in other low-resource and multilingual settings (Pfeiffer et al., 2020; Liu et al., 2021; Choenni et al., 2023; Pham et al., 2024).

2 Related Work

Prior work has explored zero-shot and few-shot methods for Bangla across several NLP tasks (e.g., Dementieva et al. 2025; Adak et al. 2025; Li et al. 2023b; Shafayat et al. 2024); for example, Hasan et al. (2024) use 3-shot and 5-shot prompting for sentiment analysis. Prompting has also been applied to general Bangla NER: Mahtab et al. (2025) provide an English instruction prompt describing the BIO tags and rules, include 10 in-context input–output examples, and then prompt the model to label a new Bangla sentence in BIO format. Early work on Bangla biomedical/telemedicine NER (e.g., Islam et al. 2022; Sazzed 2022) primarily focused on dataset construction. More recently, Khan et al. (2023) introduce Bangla-HealthNER and evaluate fine-tuned BanglaBERT, BanglishBERT, and mBERT models, and also report substantially lower performance for zero-shot ChatGPT than for supervised fine-tuning.

For Basque, there is prior work on biomedical NER, and most of it relies on supervised training or fine-tuning with BIO-style output formats. Urbizu et al. (2022) introduce the BasqueGLUE NLU benchmark; they use standard fine-tuning and report baseline results, and for the NER task they follow the BIO annotation scheme. Zanoli et al. (2024) examine whether a multilingual clinical corpus is effective for disorder NER; they train and fine-tune supervised NER models and use IBO/BIO-style tagging. Recent work has also proposed leaderboard-style benchmarking frameworks for evaluating LLMs across multiple tasks in high-resource settings, such as Italian (Magnini et al., 2025), but comparable systematic benchmarking remains limited for Bangla and Basque biomedical NER.

However, existing work for both Bangla and Basque largely emphasizes supervised BIO tagging, and we still lack a clear picture of how prompt design and output format affect LLM-based biomedical NER in these languages. To fill this gap, we systematically evaluate multiple prompting strategies and compare BIO tagging with span-based JSON extraction.

3 Methods

Figure 2 details our NER evaluation pipeline and the different configurations we have explored in low-resource languages. We start from a base prompt that includes instructions for the task and some rules and hints to guide the LLM when annotating the entities. In all cases, the instructions are written in English (Enomoto et al., 2025) but specify the target language. Building on this base, we explore different configurations involving the output format of the annotations, whether or not to include demonstration examples, the format of these examples, or how the model should address the task.

3.1 Datasets

For our Bangla experiments, we use Bangla-HealthNER (Khan et al., 2023), a large Bengali biomedical NER dataset built from consumer health Q&A collected from a public online health platform in Bangladesh. It contains 31,783 samples and 144,136 sentences, annotated in token-level (BIO-style) format. The dataset includes seven entity types: Symptom, Health_Condition, Medicine, Specialist, Age, Dosage, and Medical_-

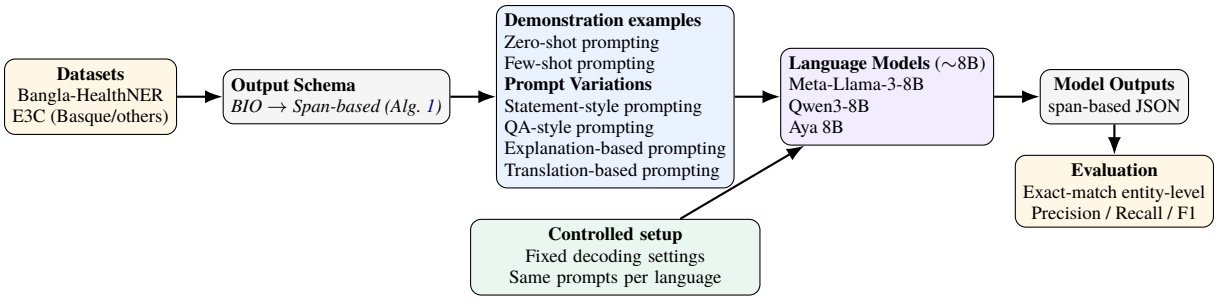

Figure 2: Overview of our biomedical NER evaluation pipeline. We vary (i) output schema (BIO vs span-level JSON) and (ii) prompting strategy, keep inference settings fixed, and evaluate with exact-match entity-level F1.

Procedure. We include Bangla-HealthNER because it is one of the largest publicly available human-annotated Bengali medical NER resources.

For Basque, Spanish, and English, we use the European Clinical Case Corpus (E3C; Magnini et al., 2020), a multilingual collection of clinical case narratives in five languages. The corpus reports clinical-case counts/tokens of English 9,533 (928K), Spanish 1,400 (531K), and Basque 122 (26K). Annotations are provided in a two-level scheme: a THYME-style layer (Styler et al., 2014) that covers time expressions events and actors, and a clinical entity layer that provides UMLS[1] Concept Unique Identifiers of different clinical disorders. From the THYME layer, we keep entities corresponding to the Patient and H-Professional (health professionals) categories. From the UMLS layer, previous work (Zanoli et al., 2024) and label all disorders with the same disorder category.

3.2 Output Schema

For all datasets, we evaluate two representations: (1) the original BIO token-level labels and (2) a span-based format (entity mentions as text spans), allowing direct comparison between tag-based and span-based extraction.

BIO format (bio) is a token-level tagging scheme for NER (Ramshaw and Marcus, 1995) that has been previously used with LLMs for Bangla NER (Mahtab et al., 2025). Given a tokenized sentence $x = (x_1, \ldots, x_n)$, dataset assigns a tag sequence $y = (y_1, \ldots, y_n)$ where each tag is one of:

$$y_i \in \{O\} \cup \{B\text{-}t,\ I\text{-}t \mid t \in \mathcal{T}\},$$

$\mathcal{T}$ is the set of entity types (e.g., AGE, SYMPTOM, etc.). Here, B marks the beginning of an entity span, I marks inside the same entity span, and O means not an entity." Figure 3 shows the prompt for the BIO tagging format.

Figure 3: A BIO prompt for Bangla biomedical NER, where the system instruction enforces strict BIO tagging and the model outputs one label per token.

Span-based format (json) means the model does not output a tag for every token. Instead, it directly outputs the entity mentions as text spans from the sentence, usually grouped by entity type in a JSON-like structure. Many prior works adopt span-based NER models (Sohrab and Miwa, 2018; Rojas et al., 2022). In contrast, our approach predicts BIO tags and then performs BIO decoding (chunk extraction) to convert token-level predictions into span strings. Formally, BIO decoding

"\"Specialist\":[], "
"\"Medical_Procedure\":[]}\n\n")

Figure 4: A statement-style prompt for Bangla biomedical NER, where the yellow-highlighted text tells the model to find predefined medical entity types in the input text.

yields a set of extracted spans:

$$\hat{\mathcal{S}} = \left\{ (t, x_{s:e}) \;\middle|\; \begin{array}{l} y_s = \texttt{B-}t, \forall i \in (s{+}1, \ldots, e) : y_i = \texttt{I-}t \\ y_{e+1} \neq \texttt{I-}t \end{array} \right\}$$

where $\mathcal{T}$ is the set of entity types and $x_{s:e}$ is the token span reconstructed into text. We used Algorithm 1 to detokenize each extracted span and append it to $\mathcal{J}(t)$. Code is available at https://anonymous.4open.science/r/LRL_IE-1959/.

3.3 Demonstration Examples

Zero-shot prompting (zero) is a strategy where we provide only the task instruction and the list of entity types, without any labeled examples (Liu et al., 2023). We provided detailed guidelines to the model, e.g., instructing it to skip negated symptoms, not confuse duration with age, not treat lab/test names as symptoms, and to select short, clean spans with no duplicates. This setting tests whether the model can perform biomedical extraction with only instructions and no demonstrations.

Few-shot prompting (few) is a way to use an LLM without training it, where we show the model a small number of labeled examples (Pan et al., 2023; Cheng et al., 2025) inside the prompt and then ask it to do the same task for a new input. Such labeled examples are known as the *support set*, $\mathcal{S}_K$, where K labeled examples are included in the prompt. Formally, we combine the base prompt P_{base} with this support set, and find the LLM's most probable output, $\hat{o}_{\text{FS}}$, given this combined prompt:

$$P_{\text{FS}} = P_{\text{base}} \oplus \mathcal{S}_K$$
$$\hat{o}_{\text{FS}} = \arg\max_o \; p(o \mid x, P_{\text{FS}})$$

The few-shot prompt contains $K = 9$ in-context examples in the target language. Since there are nine entity types in total, we set $K = 9$ and designed the examples so that each entity type appears at least once. The selected set includes both short and long examples.

3.4 Prompt Variations

Statement-style prompting (stmt) appends an statement of the task s to the prompt while using the same support set $\mathcal{S}_K$:

$$P_{\text{QA}} = P_{\text{base}} \oplus \mathcal{S}_K \oplus s$$
$$\hat{o}_{\text{QA}} = \arg\max_o \; p(o \mid x, P_{\text{QA}})$$

This approach presents the biomedical entity extraction task as a statement, such as "Find the entities (Age, Symptom, …) that are present in this text.", as shown in Figure 4.

Question-style prompting (qa) appends an explicit question q to the prompt while using the same support set $\mathcal{S}_K$:

$$P_{\text{QA}} = P_{\text{base}} \oplus \mathcal{S}_K \oplus q$$
$$\hat{o}_{\text{QA}} = \arg\max_o \; p(o \mid x, P_{\text{QA}})$$

This approach presents the biomedical entity extraction task as a direct question, such as "Which entities of types (Age, Symptom, …) appear in this text?", as shown in Figure 5.

Explanation-based prompting (expl) is a prompting strategy (Figure 6) that provides a brief description of what entities are likely present in the current text. First, the prompt explains the label boundaries (e.g., Health_Condition is a diagnosis or stated condition, while Symptom is a complaint). Then, for each example, we add a short natural-language description in English that highlights the relevant cues in the input. We have

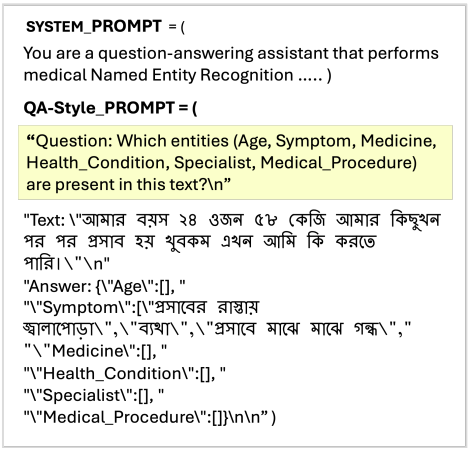

Figure 5: A question-style prompt for Bangla biomedical NER, where the yellow-highlighted text explicitly asks the model to identify predefined medical entity types in the input text.

used explanation only for examples, not the entire prompt. This prompt uses the same support set $\mathcal{S}_K$ and adds label definitions $D = \{d_\ell\}_{\ell \in \mathcal{L}}$:

$$P_{\text{Desc}} = P_{\text{base}} \oplus \mathcal{S}_K \oplus D$$
$$\hat{o}_{\text{Desc}} = \arg\max_o \; p(o \mid x, P_{\text{Desc}})$$

Translation-based prompting (trans) is a process of prepending an English rendering (Figure 7) of the input while also keeping the original Bangla/Basque text in the prompt. This encourages the model to reason in English, which can help when the model is stronger in English than in the target language. However, this approach can fail when translation paraphrases the meaning, drops details, mistranslates medical terms, or changes span boundaries. Therefore, we treat translation-based prompting as a practical baseline rather than a guaranteed improvement. Let $T(\cdot)$ be a translation function (e.g., Bangla/Basque $\rightarrow$ English). We use the same support set $\mathcal{S}_K$, but the input includes the translated text:

$$x' = T(x)$$
$$P_{\text{Trans}} = P_{\text{base}} \oplus \mathcal{S}_K$$
$$\hat{o}_{\text{Trans}} = \arg\max_o \; p(o \mid x', P_{\text{Trans}})$$

3.5 Language Models

We primarily conduct our experiments using **Meta-Llama-3-8B** (Grattafiori et al., 2024), a widely adopted open-weights model with strong general performance. However, to test the effect of different model families, we also evaluate the best-performing prompt strategy under LLama-3 on two additional models: **Qwen3-8B** (Yang et al., 2025) and **Aya** (Aryabumi et al., 2024). We include Qwen3 because it is a competitive recent model that often performs particularly well on high-resource languages such as English, and Aya because it is designed for multilingual use and thus provides a useful contrast for low-resource settings. To ensure a fair comparison, we select similar size models (all in the $\sim$8B parameter range) and and keep inference settings fixed.

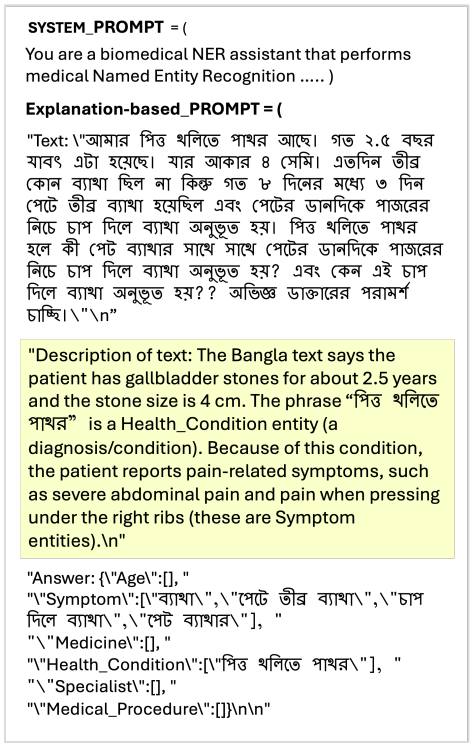

Figure 6: An explanation-based prompt for Bangla biomedical NER, where the yellow-highlighted text provides a natural-language explanation of the clinical context and entity semantics.

4 Experimental Results

Our analyses are presented below. As datasets for different languages are by necessity different, we focus on relative gains, not absolute values, when looking across languages.

4.1 Output Format Analysis

Table 1 shows a large gap between BIO tagging and span-based extraction, indicating that the output schema strongly affects LLM-based NER. Across languages, switching from *bio_few* to *json_few_stmt* yields large F1 gains: +538% (Bangla; 0.054 $\rightarrow$ 0.345), +200% (Basque; 0.104 $\rightarrow$ 0.312), +2242% (Spanish; 0.019 $\rightarrow$ 0.445), and +339% (English; 0.120 $\rightarrow$ 0.527). BIO tagging is likely harder for LLMs because the model must label

Figure 7: A translation-based prompt for Bangla biomedical NER, where the yellow-highlighted text shows the English translation of the original Bangla clinical text used for entity extraction.

Prompt	Bangla	Basque	Spanish	English
bio_few	0.054	0.104	0.019	0.120
json_few	**0.345**	**0.312**	**0.445**	**0.527**

Table 1: Biomedical NER Performance across output schemas with Llama3-8B. In both cases, we apply few-shot prompting.

every token in the exact order, with even one missing/extra token breaking the whole alignment. Span-based extraction is easier because the model can simply copy the entity text spans and return them as clean JSON, which matches how LLMs naturally answer.

4.2 Prompt Variation Analysis

Table 2 shows that QA-style prompting performs best across all languages. It even outperforms detailed label explanations (*expl*) and translation of the input to English (*trans*), despite using only simple WH-questions. The strong performance of QA-style prompting is likely because modern LLMs are instruction tuned on many question-answer pairs. Prior work reformulating NER as machine reading comprehension similarly finds that QA-style formulations improve NER, attributing gains

Prompt	Bangla	Basque	Spanish	English
json_zero	0.291	0.241	0.403	0.422
json_few_stmt	0.345	0.312	0.496	0.527
json_few_qa	**0.458**	**0.503**	**0.528**	**0.541**
json_few_trans	0.347	0.441	0.494	0.313
json_few_expl	0.417	0.386	0.477	0.304

Table 2: Prompting Strategy Comparison for Multilingual Biomedical NER Using Meta-Llama-3-8B

to query conditioning and (when available) semantically informative queries that encode entity-type knowledge (Li et al., 2020).

Prompting strategy has a stronger effect on low-resource languages than on high-resource languages: moving from zero-shot to question-style prompting improves Bangla by 57.4% and Basque by 108.7%, while Spanish improves by 21.8% and English by only 28.2%.

4.3 Entity Type Analysis

Table 3 and Table 4 break down performance of prompting strategies by named entity types for Bangla and Basque, respectively. In both languages, question-style prompting is best for most types, with the largest absolute gains for MEDICAL_PROCEDURE in Bangla (37.8%) and H-PROFESSIONAL in Basque (37.4%), indicating that such prompting is especially helpful for rarer or harder-to-extract categories.

Occasionally, explanation or translation-based prompting outperforms question-based prompting. Explanation-based prompting helps Bangla SYMPTOMS and translation-based prompting helps Bangla SPECIALISTS. But the gains are modest over question-based prompting, and translation-based prompting fails badly for the AGE category.

4.4 Analysis Under the Best Prompt

Table 5 compares different LLMs under the best-performing (question-style) prompt. Overall, Llama-3-8B performs best on Bangla (F1 = 0.494) and Spanish (F1 = 0.529), while Qwen3-8B achieves the highest score on English (F1 = 0.541) and Basque (F1 = 0.550). Aya performs worst on all languages. This suggests that Qwen may have stronger English and Basque knowledge from pretraining, while Llama may have stronger Spanish and Bangla knowledge, and both Qwen and Llama likely have better multilingual and/or biomedical domain knowledge than Aya. These results reveal the importance of LLM selection when working with low-resource languages.

	Age	Symptom	Medicine	Health_Condition	Specialist	Medical_Procedure
json_zero	0.421	0.067	0.400	0.400	0.514	0.133
json_few_stmt	0.200	0.198	0.490	0.400	0.621	0.167
json_few_qa	**0.471**	0.215	**0.600**	**0.533**	0.600	**0.546**
json_few_trans	0.010	0.196	0.560	0.333	**0.625**	0.222
json_few_expl	0.235	**0.253**	**0.600**	0.519	0.500	0.364

5 Error Analysis

We inspected the errors of the best performing models in Bangla and Basque. Below are the main failure modes, with the operational definitions used in our evaluation. Examples of errors are given in Appendix D and Appendix E.

Hallucination The gold annotation contains no entities, but the model outputs one or more spans.

All-Missed The gold contains entities, but the model returns an empty JSON. This is the most severe recall failure.

Missed Entities The model extracts some entities but misses others, without adding extra entities.

Extra Entities The model predicts additional entities that are not in the gold but does not miss gold entities.

Type Confusion The predicted entity span matches the gold text, but the assigned type is wrong.

Mixed Errors The model both adds and misses entities. Extra-dominant cases indicate over-extraction, while missed-dominant cases indicate under-extraction.

Boundary Mismatch The model captures the right concept but with different boundaries, becoming both a false positive and a false negative under exact-match scoring.

Figure 8 (top) shows clear differences across prompting methods for Bangla biomedical NER errors. Although we have seen that QA-style prompts perform better on average, here we see that translation-based prompting reduces over-generation: it has the lowest HALLUCINATION (2.6%) and comparatively low BOUNDARY MISMATCH (13%). For span-level precision, question-style prompting yields the largest BOUNDARY MISMATCH (29%), suggesting it identifies the right concept but struggles to copy the exact multiword span. Thus, question-style prompting helps the model extract more entities, while translation-based prompting helps reduce hallucination, extra entities, and boundary mismatch errors.

For Basque (Figure 8, bottom), across all prompts, HALLUCINATION dominates (38–52% of errors), indicating that over-generation is the primary failure mode in Basque. However, the prompts shift the secondary errors: statement-based prompting (*json_few_stmt*) reduces HALLUCINATION (37.5%) compared to the other methods, but it increases ALL-MISSED (14.8%), suggesting a more conservative behavior that sometimes fails to extract anything. In contrast, question-style prompting extracts more aggressively and keeps ALL-MISSED low (5.8%), but this comes with higher EXTRA ENTITIES (8.6%) and substantial BOUNDARY MISMATCH (18.5%).

6 Conclusion and Future Work

We systematically analyzed prompt design choices and output schemas for multilingual biomedical NER, focusing on the low-resource, morphologically rich languages Bangla and Basque while comparing them against the high-resource languages Spanish and English. We find that question-style prompting is the most consistent way to improve

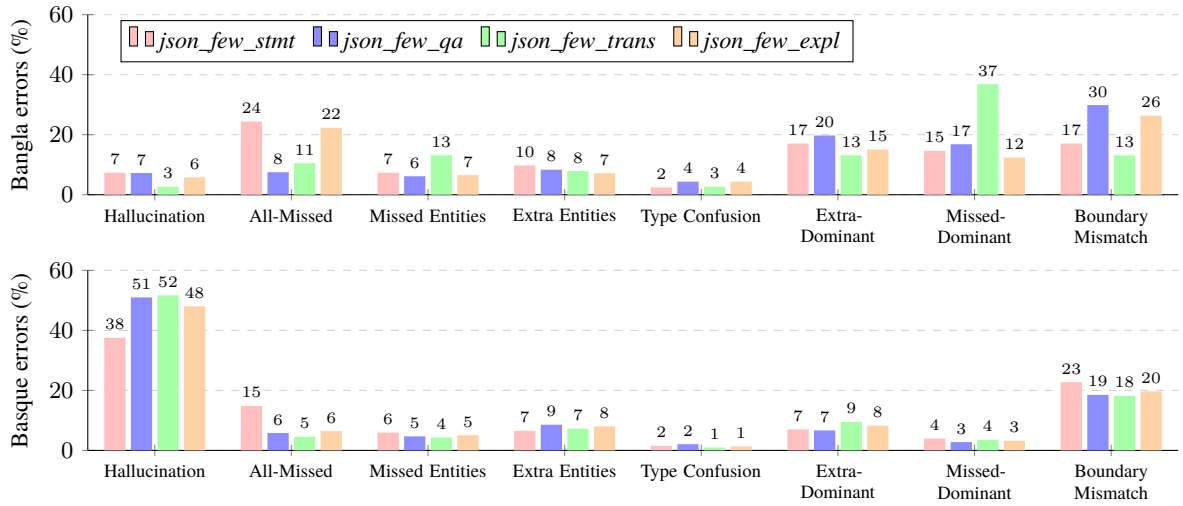

Figure 8: Error type distribution for LLM-extracted entities for Bangla (top) and Basque (bottom).

exact-match entity-level F1 across all languages. We also find that selecting an optimal prompt is more critical in low-resource languages, where performance degrades much more under suboptimal prompting strategies. Our error analysis shows that question-style prompts result in fewer empty outputs, while translation-based prompting can reduce hallucinations and boundary errors in some settings.

We also find that BIO-tagging output is less suitable for LLMs than text-span based output. This contrasts with available datasets: not only biomedical NER, but nearly all Bangla NER datasets are annotated in the BIO format (e.g., Islam et al., 2022; Sazzed, 2022; Khan et al., 2023; Mahtab et al., 2025). BIO format is fragile: the model must keep the exact token order and token count, and even one extra or missing token breaks alignment. This becomes worse when tokenization is difficult, as in morphologically rich languages like Bangla and Basque, where suffixes and punctuation frequently change token boundaries. In contrast, text-span-based extraction asks the model to list the entity strings in the sentence, which matches how LLMs naturally respond and is easier to parse and store as JSON.

In the future, we plan to test richer question prompts that include short label definitions and examples (not only WH-questions) to see whether they further reduce boundary mismatches and type confusion. We also want to study better post-processing and evaluation for near-miss spans and explore lightweight adaptation methods that choose the best prompt per language and entity type. Finally, expanding to more low-resource languages and more medical datasets will help confirm how general these findings are.

Limitations

A key limitation of this study is that we evaluate only three open LLMs around 8B parameters and two datasets, Bangla HealthNER and Basque E3C, so further work is needed to determine whether the findings generalize to other model sizes, closed models, or biomedical text styles. We also do not cover additional low-resource languages because validating prompts, examples, and error cases reliably requires language expert support. In addition, we did not evaluate paid or proprietary GPT models, and our strict exact match scoring can penalize near-correct span boundaries in morphologically rich languages. Finally, since different datasets are used for each language, cross-language comparisons should be interpreted cautiously, as proportional improvements may still reflect dataset-specific characteristics rather than true language differences.

A BIO Tagging vs Span-Based

The left panel of Figure 9 shows span-based extraction, where entities are directly returned as text spans grouped by type in a JSON structure, while the right panel shows token-level BIO tagging, which requires assigning a label to every token and maintaining strict alignment. This example illustrates how span-based formats provide a simpler and more robust representation for LLM-based NER, especially for morphologically rich languages like Bangla.

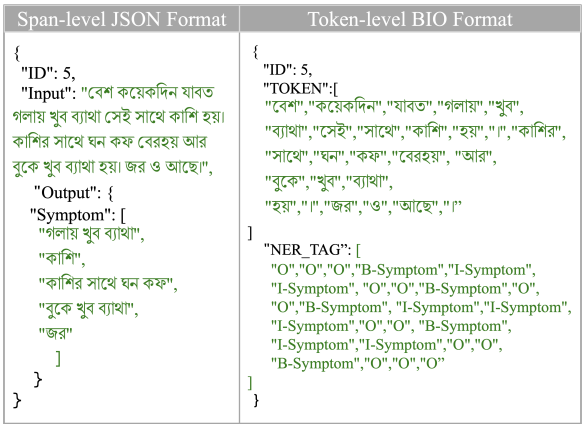

Figure 9: Comparison of span-level JSON and token-level BIO formats for Bangla biomedical NER.

B Prompting Behavior and Qualitative Analysis for Bangla

Table 6 illustrates qualitative differences across three prompting strategies for Bangla biomedical NER. In the question-style prompt, the model correctly identifies most entities but misses the HEALTH_CONDITION (ইনফেকশন), showing that QA prompting can still suffer from recall gaps. In contrast, translation-based prompting leads to overgeneration: the model incorrectly treats common home remedies such as গরম পানি (hot water) and মধু as MEDICINE, likely due to reasoning in English and broader semantic interpretation. Explanation-based prompting improves recall but introduces type confusion, as the model incorrectly labels the polite address স্যার (“Sir”) as a SPECIALIST. These examples highlight that while extended prompting strategies can help extraction, they also introduce distinct error patterns depending on how semantic cues are framed.

C Prompting Behavior and Qualitative Analysis for Basque

Table 7 presents qualitative differences in model behavior across three prompting strategies for Basque biomedical NER. Under the question-style prompt, the model successfully identifies major disorders but exhibits boundary and normalization issues, such as over-specifying severity or partially mismatching gold entity forms. Translation-based prompting generally improves coverage by leveraging English semantics, but it can introduce label drift, as closely related clinical concepts are normalized differently from the gold labels. Explanation-based prompting further increases re-

E.g.	Prompt Type	Prompt	Llama3-8B	Gold Label
1	json_few_-qa	You are a question-answering assistant that performs medical Named Entity Recognition (NER). For each question, identify ONLY the entities that are explicitly present in the provided text and answer STRICTLY in JSON. Question: Which entities (Age, Symptom, Medicine, Health_Condition, Specialist, Medical_Procedure) are present in this text? **Example 1:** এলার্জির সমস্যার কারণে রোদে গেলে গা চিটমিট করে, মাথার ভিতরে কিলবিল করে। সকালে ঘুম থেকে উঠলে অনবরত হাঁচি হয়। কখনো নিয়মিত কোনো এলার্জির ওষুধ খাইনি। এক্ষেত্রে আমি কি করতে পারি? এনার্জির কারণে অনেক দৈনন্দিন কাজ করতে পারি না। **Answer:** Symptom – রোদে গেলে গা চিটমিট করে | মাথার ভিতরে কিলবিল করে | হাঁচি; Medicine – এলার্জির ওষুধ. Health_Condition – এলার্জির. **Now extract all entities for this text:** ধন্যবাদ আপনার প্রশ্নের জন্য। ফাটিয়ে দিবেন না। ইনফেকশন হয়ে যাবে। আপাতত এলারজি উদ্রেককারী খাবার, ধূলাবালি এড়িয়ে চলুন। এলাট্রল খান। না দেখে সমাধান দেয়া যাচ্ছে না। সরাসরি চর্মরোগ বিশেষজ্ঞ দেখিয়ে পরামর্শ নিতে হবে ধন্যবাদ	Medicine: এলাট্রল Specialist: চর্মরোগ বিশেষজ্ঞ	Medicine: এলাট্রল Health_Condition: ইনফেকশন Specialist: চর্মরোগ বিশেষজ্ঞ
2	json_few_-trans	You are a NER assistant that performs medical Named Entity Recognition (NER). Table 8: Representative QA-prompt error examples for Bangla biomedical NER (Llama3.1-8B). Each row shows one real instance of a major error category under exact-match span scoring.

Error Type	Input Example	Gold Output	Pred Output
Hallucinations	*Burua eta lepoa.*	*Empty*	Disorder: Burua eta lepoa
All-Missed	*Ez dago aurkikuntza patologikorik.*	Disorder: aurkikuntza	*Empty*
Missed Entities	*Estenosi aortiko larria eta bihotz-gutxiegitasuna.*	Disorder: Estenosi aortiko larria | bihotz-gutxiegitasuna	Disorder: bihotz-gutxiegitasuna
Extra Entities	*Sabela.*	*Empty*	Patient: Sabela
Type Confusion	*Biguna eta zanpagarria.*	*Empty*	Disorder: Biguna | Disorder: zanpagarria
Mixed Errors	*Biriketako murmurio normala.*	*Empty*	Disorder: Biriketako murmurio
Boundary Mismatch	*Ez dago aurkikuntza patologikorik.*	Disorder: aurkikuntza patologikorik	Disorder: aurkikuntza

Table 9: Representative QA-prompt error examples for Basque biomedical NER (Meta-Llama-3-8B). Each row illustrates a distinct error category under exact-match span evaluation.

call by encouraging semantic inference, yet it also leads to over-generation, with the model extracting implicit or negated findings (e.g., absence of edema or thrombosis) as entities. Overall, these examples demonstrate that richer prompting strategies can enhance extraction in Basque but also introduce systematic errors related to semantic inference, normalization, and negation handling.

D Bangla Errors (QA Prompt)

Table 8 presents representative Bangla error cases for the QA-style prompt. A recurring pattern is that the model often identifies the correct medical concept but fails to reproduce the exact mention boundaries, especially for multiword symptoms and colloquial expressions, resulting in **Boundary Mismatch**. We also observe **Hallucinations** when generic medical advice or common words are treated as symptoms/conditions even when the gold annotation is empty. In contrast, **All-Missed** cases reflect severe recall failures where the model returns an empty JSON despite clear entity cues (e.g., explicit age or specialist mentions). Finally, **Type Confusion** commonly arises between semantically adjacent categories (e.g., tests/procedures vs. conditions, or informal medication names vs. remedies), indicating that the model recognizes the span but struggles with fine-grained label assignment.

E Basque Errors (QA Prompt)

Table 9 shows representative Basque error cases for the same QA-style prompt. Across prompts, the dominant failure mode is **Hallucinations**, suggesting that the model is prone to over-generation in Basque medical text: short phrases and anatomical references are frequently over-labeled as medical entities even when the gold annotation contains none. We also see **Boundary Mismatch** in cases where the model selects a shorter head noun rather than the full descriptive mention, which is penalized under exact-match evaluation. Compared with Bangla, Basque exhibits more frequent over-extraction and fewer purely recall-only failures, consistent with the overall error distribution where FP-heavy errors occupy a larger fraction of error-only cases.

Hierarchy-Aware Hyperbolic and Semantic Reranking for Ontology-Based Phenotype Linking

Abstract

Extracting structured knowledge from unstructured text is a fundamental challenge in machine learning, particularly for concepts organized within complex hierarchical ontologies. In genomics, identifying phenotypes from clinical narratives is crucial for diagnostic precision, yet current methods struggle with contextual interpretation and subtle clinical descriptions. We present a hierarchy-aware workflow for ontology-based phenotype linking that combines semantic and hierarchical signals. Our approach integrates Large Language Models for span detection with retrieval and a hybrid reranking strategy using both Euclidean (semantic) and hyperbolic (hierarchical) embeddings trained on the Human Phenotype Ontology. We show that while hyperbolic embeddings alone do not outperform standard semantic retrieval, they provide complementary structural signals that improve performance over strong baselines when combined with Euclidean representations. In particular, the hybrid approach outperforms existing state-of-the-art methods and yields more hierarchically coherent predictions, especially in settings involving implicit phenotype mentions. Experiments on a public benchmark (ID-68) and a newly released clinical dataset (CHU-50), publicly released with code and data [1], highlight both performance gains and improved alignment with ontology structure. We further introduce a hierarchy-aware evaluation framework that reflects clinical relevance beyond exact-match metrics.

1 Introduction

Extracting structured knowledge from unstructured text is a central challenge in machine learning, particularly when the target concepts are organized within complex hierarchical ontologies (Figure 1). Phenotypes, as observable traits linking clinical observations to genetic conditions, play a crucial role in diagnosis, treatment planning, and biomedical research Son et al. (2018); Yuan et al. (2022); Mao et al. (2025). While recent advances in natural language processing have improved the extraction of explicitly stated phenotypes, existing systems often struggle to identify implicit or context-dependent mentions.

Current approaches Feng et al. (2023); Luo et al. (2021); Arbabi et al. (2019) frequently rely on flat embedding spaces, which are inadequate for modeling the hierarchical relationships intrinsic to phenotypic ontologies such as the Human Phenotype Ontology (HPO) Robinson et al. (2008). In contrast, hyperbolic geometry naturally models hierarchical (tree-like) structures Gromov (1987) and has been underexplored within this domain. Furthermore, retrieval-based systems are often constrained by their reliance on exact matches or shallow semantic representations. We also argue that existing evaluation metrics widely used in the field (Groza et al., 2024) present further limitations: in practice, clinicians may interpret phenotype mentions differently, as no individual possesses exhaustive knowledge of HPO or applies it uniformly. Consequently, a single reference can yield multiple, equally valid annotations. This variability challenges single-label prediction paradigms and motivates hierarchy-aware approaches, where related terms (e.g., ancestors of a target phenotype), are considered clinically meaningful, albeit less specific.

In this paper, our contributions are four-fold:

i. We propose a workflow for phenotype extraction from clinical text that integrates Large Language Models (LLMs) with retrieval and hierarchical reranking using hyperbolic embeddings trained on HPO.

ii. We introduce a hierarchy-aware evaluation framework that leverages the target ontology structure to provide a more nuanced and clin-

[1] https://github.com/labbeth/HyperRAG/

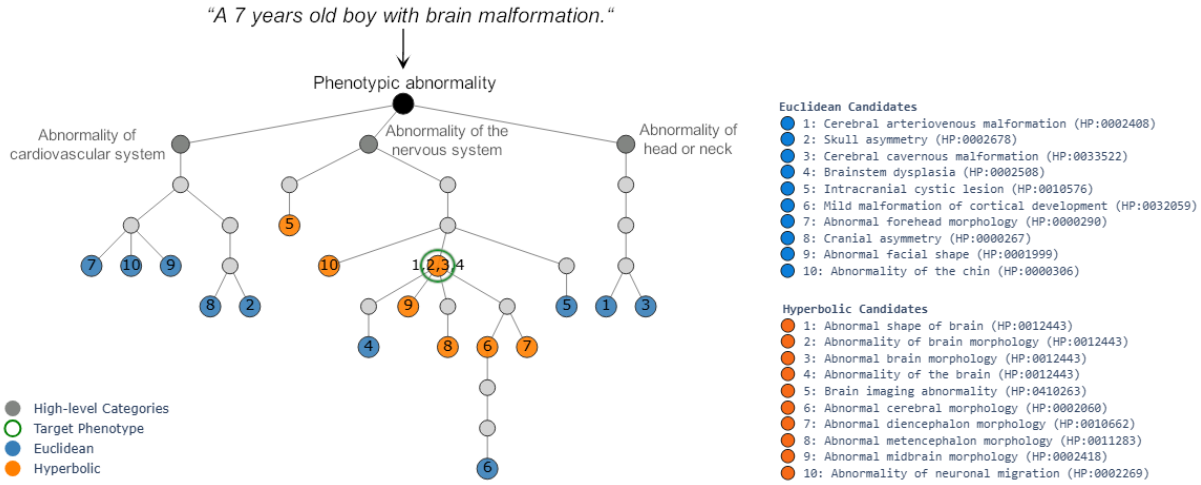

Figure 1: Ontology-based entity linking illustration. Given a clinical sentence, *Top-10* candidates from Euclidean (blue) and Hyperbolic (orange) reranking are overlaid on HPO. Hyperbolic-reranked candidates cluster within the correct branch with lower average distance to target (green), demonstrating improved hierarchical alignment.

ically relevant assessment of extraction systems.

iii. We demonstrate the effectiveness of our approach through comprehensive experiments on both benchmark and challenging real-world datasets, showing consistent improvements, particularly in scenarios with implicit entity mentions.

iv. We make all generated training and evaluation datasets publicly available through our repository, and will release trained models to support reproducibility and further research in ontology-based entity linking.

As part of our workflow validation, we also empirically confirm that hyperbolic embeddings effectively capture the hierarchical structure of HPO, supporting their use in downstream phenotype linking tasks. Overall, our ontology-aware workflow offers a robust solution for phenotype extraction from text, with the potential to enhance diagnostic accuracy and advance biomedical NLP.

2 Background

The introduction of ontologies such as the HPO has provided a structured framework for organizing phenotypic information and has become the primary target for entity linking in this domain. Early work utilized rule-based heuristics Aronson and Lang (2010); Jonquet et al. (2009); Deisseroth et al. (2019), while more recent studies have adopted transformer-based architectures to extract phenotype mentions directly from text Luo et al. (2021); Feng et al. (2023); Yang et al. (2024). Although improvements have been effective with such approaches, they remain complex and often struggle when phenotype references are implicit Baddour et al. (2024). In particular, full LLM approaches are prone to hallucination issues in mapping phenotype labels to HPO ids Labbé et al. (2023). Emerging retrieval-based paradigms Lewis et al. (2020) offer a promising avenue for addressing some of these challenges by efficiently narrowing the candidate space and mitigating hallucinations. However, this approach has not yet been widely adopted in phenotype extraction pipelines, and its performance in this context remains underexplored.

While ontologies facilitate annotation and retrieval, their hierarchical complexity poses significant challenges for NLP systems. Nickel and Kiela (2017) highlighted the limitations of flat embedding spaces in adequately representing such hierarchical structures. Related works Sala et al. (2018); Sinha et al. (2024); Tifrea et al. (2018) proposed to train hyperbolic embeddings that provide a compelling alternative, as hyperbolic spaces are well-suited for modeling hierarchical relationships, allowing embeddings to more accurately reflect the subsumption structure inherent in ontologies.

The motivation behind our proposed workflow stems from recognizing significant limitations in current phenotype extraction systems. While classical dense retrieval approaches Guo et al. (2024) are effective at retrieving candidates based on general semantic similarity, they fall short in capturing the hierarchical relationships and intricate depen-

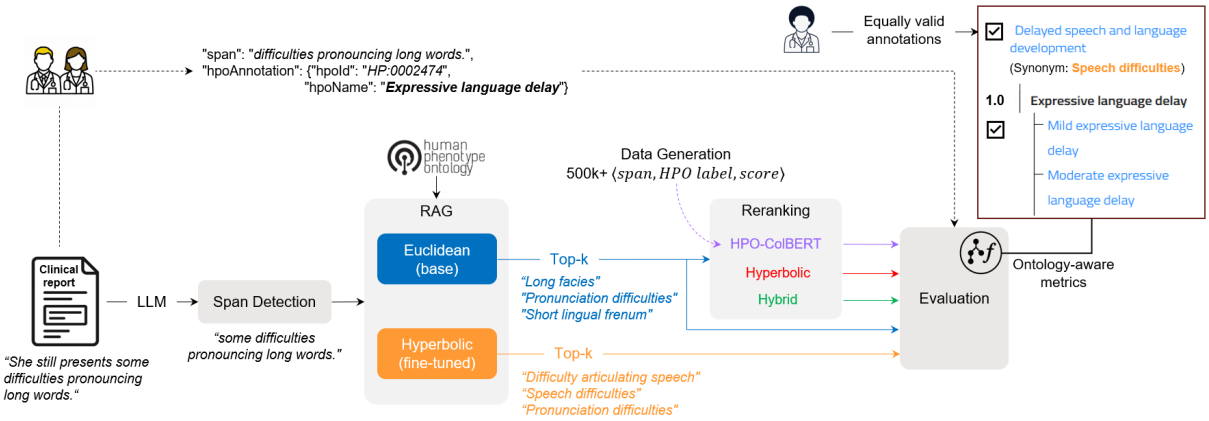

Figure 2: General Workflow. From a clinical report, a LLM first detects spans related to phenotypes. Dense retrieval with Euclidean and Hyperbolic embeddings outputs *Top-k* candidate terms, followed by several reranking strategies. Evaluation uses both clinician-provided ground truth annotations and the HPO ontology structure to account for hierarchical relationships and semantic similarity, recognizing that multiple valid references may exist.

dencies inherent in ontologies such as HPO Huang et al. (2025); Gao et al. (2023). This limitation becomes even more pronounced when dealing with implicit phenotypes not explicitly stated in clinical text, where leveraging ontological relationships can be crucial for accurate identification and resolution Peng et al. (2024).

By integrating hyperbolic embeddings (which naturally encode hierarchical structures) with a reranking mechanism, our workflow bridges the gap between general semantic relevance and ontological hierarchy. This dual approach ensures not only accurate retrieval of phenotypes but also a ranking that reflects their hierarchical significance, providing a comprehensive solution to the limitations of current methods.

3 Methodology

The proposed workflow is illustrated in Figure 2: Given clinical reports, the process consists of four main steps: span detection using an LLM, dense candidate retrieval, reranking of candidates, and evaluation with both standard and ontology-aware metrics.

3.1 Span Identification

We use a pretrained LLM to identify phenotype spans, effectively capturing implicit mentions that may be overlooked by traditional methods. Notably, Baddour et al. (2024) demonstrated that employing an LLM as a span detector outperforms the biomedical Stanza pipeline (Zhang et al., 2021).

3.2 Retrieval

We compute dense span embeddings using either a base or HPO-fine-tuned hyperbolic model. *Top-k* phenotype candidates are retrieved from the HPO ontology based on *cosine similarity* (euclidean model) or normalized *hyperbolic distance* (hyperbolic model).

3.3 Reranking

For each span, the *Top-k* HPO candidates retrieved through dense Euclidean embeddings similarity are reranked using two families of methods: late-interaction and hyperbolic.

Late-interaction reranking

As a strong classical baseline, we fine-tuned a late-interaction model Santhanam et al. (2021) for reranking. While cross-encoders are effective, they are computationally demanding and less adaptable to incorporating soft signals like distance-based scores Jha et al. (2024). Late-interaction models strike a balance by retaining token-level embeddings and applying a late matching function, thus preserving fine-grained information often lost in bi-encoders. This makes them particularly suitable for our reranking task, which involves short text spans and specific target labels.

Hyperbolic reranking

- **Full hyperbolic reranking:** Both the input span and the *Top-k* candidates from the Euclidean retriever are embedded in hyperbolic space. Candidates are then reordered based on their normalized hyperbolic distances to the

input span. We include this setting primarily as an ablation to isolate the effect of purely hierarchy-driven scoring.

- **Hybrid reranking:** This approach combines the cosine similarity between Euclidean embeddings and the hyperbolic distance between hyperbolic embeddings using a weighted sum. Cosine similarity emphasizes semantic closeness, while hyperbolic distance prioritizes candidates with closer hierarchical relationships to the input span. given an input $span$ and a set of candidates $\{C_i\}_{i=1}^{k}$, the hybrid score of a candidate C_i is computed as follows.

$$S_{\text{hybrid}}(C_i, span) = \gamma \cdot S_{\cos} - (1-\gamma) \cdot \hat{d}_{\mathbb{H}} \quad (1)$$

where $S_{\cos}$ is the cosine similarity between C_i and $span$, $\hat{d}_{\mathbb{H}}$ is their normalized hyperbolic distance, and γ is the weighting parameter between the two metrics (see Appendix E for ablation).

Full implementation details (including model architectures, training hyperparameters, normalization strategies, synonym mapping, and retrieval settings) are provided in Appendix A, B and D to facilitate reproducibility. Code and data are publicly available through our repository.

4 Dataset

4.1 Ontologies

The Human Phenotype Ontology (HPO) Robinson et al. (2008) serves as the foundation for our hierarchical embeddings, comprising over 19,000 hierarchically organized phenotypic terms and an extensive set of synonyms.

Additionally, we leverage the SNOMED ontology El-Sappagh et al. (2018) indirectly through a pretrained hyperbolic model (fine-tuned from the same base model). It allows us to assess the relative benefits of utilizing this broad, general-purpose medical ontology in comparison to a highly specialized ontology (HPO) for phenotype extraction tasks.

4.2 Training Data

Hyperbolic Training: Hyperbolic embeddings were trained on HPO triplets extracted from the ontology, with synonym augmentation and filtering to ensure balanced training. We used Hierarchy Transformers He et al. (2024) to effectively capture hierarchical relationships.

Late-interaction Training: We fine-tuned ColBERTv2 Santhanam et al. (2021) on triplets $\langle$*span, HPO label, score*$\rangle$, using a dataset generated by prompting ChatGPT-4o-mini to create diverse clinical sentences for each HPO term. Sentence quality was assessed by clinicians, and further validated using an LLM-as-a-judge approach. After heuristic filtering, we obtained 91,760 high-quality spans, which were used to construct positive and negative pairs, resulting in 510,371 training triplets.

Full data construction details and training parameters for both hyperbolic and late-interaction models are provided in Appendix B and D. Prompts for LLM-as-a-judge are provided in Appendix I.

4.3 Evaluation Dataset

We evaluate our workflow using two datasets. **ID-68** Anazi et al. (2017), a widely used benchmark for phenotype extraction. **CHU-50**, a dataset of 50 fully anonymized clinical notes from a partner hospital, which we publicly release trough our repository. It contains 971 phenotype annotations, approximately 30% of which are implicit. Results are compared to PhenoBERT Feng et al. (2023), the most advanced open-source state-of-the-art solution available.

5 Evaluation

We first evaluated the hyperbolic model independently, prior to conducting the main phenotype extraction experiments.

5.1 Hyperbolic Inner Evaluation

To assess the consistency of the hyperbolic model, we compared its normalized distance metrics with those of the baseline Euclidean model. Specifically, we examined one-hop and multi-hop distances to evaluate the model's ability to capture hierarchical relationships, as well as distances between synonyms and negative pairs to determine whether semantic consistency is preserved.

Additionally, we introduce a *hierarchical representation power* plot to visualize the model's capacity to encode hierarchy while maintaining semantic coherence. This radar chart displays the average distances for one-hop, multi-hop, and synonym pairs, alongside the inverse average distance for negative pairs. This visualization enables us

to assess whether the embedding space has been structured as intended.

5.2 Phenotypes Linking Evaluation

In practice, generating a comprehensive list of phenotypes for each patient is crucial for accurate diagnosis, making recall-based metrics (*recall@k* and *miss_rate@k*) the primary focus. While *Top-1* precision is reported for comparison with existing single-output methods (e.g. PhenoBERT), it fails to reflect the clinical relevance of alternative valid annotations. To further assess ranking quality, we include Mean Reciprocal Rank (MRR) and Normalized Discounted Cumulative Gain (NDCG).

However, these traditional metrics are limited when based solely on exact matches, which is the prevailing evaluation paradigm in current solutions. In practice, a parent term of the target phenotype often conveys relevant information, even if it is less specific, and predictions involving descendants or related terms should not be considered entirely incorrect.

To address this limitation, we introduce a novel hierarchical evaluation framework that leverages the structure of HPO to weight candidate scores according to their proximity to the ground truth. These *relationship scores* are computed based on the specific type of relationship between the candidate $\mathcal{C}$ and the target phenotype $\mathcal{T}$.

Direct relationships

$$w_{direct}(\mathcal{C},\mathcal{T}) = \begin{cases} \frac{\alpha}{p\times(1+|d|)}, & p>0 \\ 1, & p=0 \end{cases} \quad (4)$$

where α is a constant factor, p is the number of ancestors/descendants between $\mathcal{C}$ and $\mathcal{T}$, and d is the distance between $\mathcal{C}$ and $\mathcal{T}$.

Indirect relationship

$$w_{indirect} = \frac{\beta}{c\times(1+d_l)} \quad (5)$$

where β is a constant factor, c is the number of immediate descendants of the most specific common ancestor between $\mathcal{C}$ and $\mathcal{T}$, and d_l is the distance between $\mathcal{C}$ and the farthest HPO leaf.

See Appendix E for α and β settings.

By combining absolute distances with the cardinality of surrounding phenotypes, these functions effectively characterize the strength of relationships between HPO terms, balancing both proximity and semantic relevance. Throughout this paper, the term *weighted* refers to evaluation metrics that incorporate these hierarchical weightings.

In addition, we introduce specific metrics to assess how well the models respect the ontology's structure: the average number of hops between each candidate and the target phenotype; the average branch coverage, defined as the proportion of candidates within the same branch as the target; and the distribution of relationship types by position, measuring the proportions of exact matches, ancestors, descendants, cousins, or candidates with no direct path to the target. We also report the proportion of close candidates, defined as those with a *relationship score* above a specified threshold.

6 Results

6.1 Hyperbolic consistency

Figure 3. presents the distributions of one-hop and multi-hop distances for both the Euclidean model and the fine-tuned hyperbolic model. The distributions for the hyperbolic model are notably narrower and exhibit lower means, particularly for multi-hop distances, indicating a more faithful representation of the ontology's hierarchical structure.

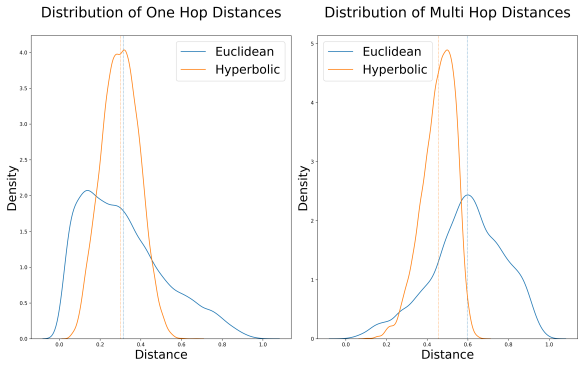

Figure 3: Euclidean (blue) vs Hyperbolic (orange) distance distributions between one-hop (left) and multi-hop (right) phenotypes in the Human Phenotypes Ontology (HPO), computed on the test set (10%). Vertical lines represent respective means.

Furthermore, the resulting hyperbolic model preserves the semantic structure of the base model, as illustrated in Figure 4. Although the average distance between negative pairs is slightly reduced, these pairs remain well separated from positive examples. Notably, synonyms within the HPO are now positioned closer together, and multi-hop

phenotypes are significantly closer than in the Euclidean embedding space, reflecting improved hierarchical modeling. In contrast, one-hop phenotypes are only marginally closer, which is expected given the typically strong semantic similarity between such terms (e.g.: *Iris coloboma* is semantically closer to its one-hop parent *Coloboma* than the 2-hops *Abnormal eye morphology*).

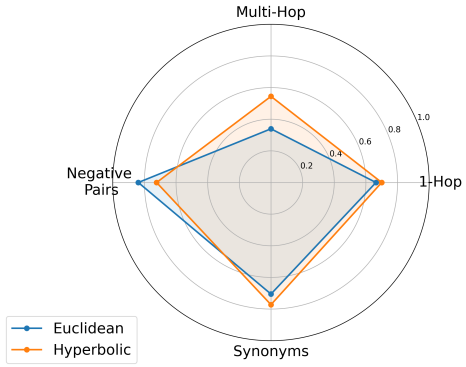

Figure 4: Semantic and Hierarchical Representation Power. Values represent normalized similarity (or inverse for negative pairs) between one-hop, multi-hop, and synonyms in Euclidean and Hyperbolic spaces.

6.2 Phenotypes Linking

For the hybrid approach, we conducted evaluations with several values of γ (reported in Appendix E). Since the performance differences were marginal, we selected $\gamma = 0.5$ for its simplicity and interpretability, recognizing that this value may not be optimal but provides a balanced influence of both models. For results reported in this section, statistical significance was assessed using paired bootstrap resampling at the report level (Appendix C).

Retrieval

As shown in Figure 5, the hyperbolic retriever model underperforms compared to other methods on both datasets, with recall further decreasing when hyperbolic reranking is applied to Euclidean retriever candidates.

This behavior reflects a trade-off between hierarchical organization and local semantic similarity: the Poincaré geometry emphasizes vertical ontological relations, while training primarily on *is-a* links and the mismatch between clinical spans and ontology-level supervision may further limit fine-grained semantic alignment, motivating the use of hyperbolic representations as a complementary rather than standalone signal.

For ID-68 (top plots), hybrid reranking improves recall from $k = 5$ onwards, and late-interaction reranking becomes effective from $k = 15$, though it does not surpass the hybrid approach. Both Euclidean and hybrid reranking outperform prior systems in recall from $k = 3$ onwards and set new state-of-the-art at $k = 1$ in the weighted setting ($+9$), with gains up to $+18$ at $k = 15$. Hybrid reranking also achieves the lowest miss rate, reducing misses by 17 at $k = 15$.

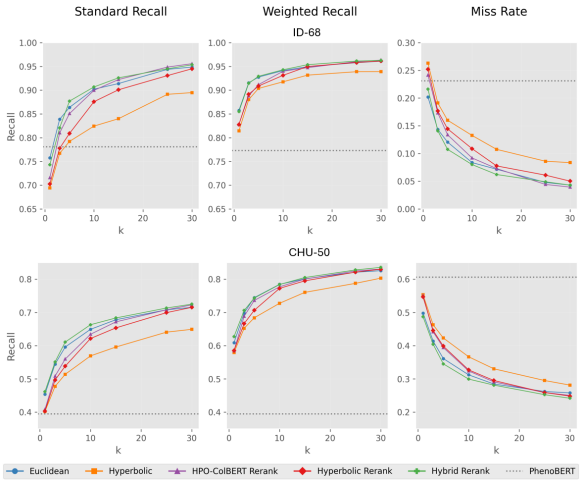

Figure 5: Recall and miss rate on the ID-68 (top) and CHU-50 (bottom) datasets. Standard (exact match) and weighted recall (considering HPO hierarchy) are shown for raw dense retrieval (Euclidean, Hyperbolic) and reranked results (HPO-ColBERT, Hyperbolic, Hybrid) across *Top-k* candidates. Miss rate indicates the proportion of ground truth phenotypes not retrieved.

On CHU-50 (bottom plots), similar trends are observed, with all models outperforming state-of-the-art PhenoBERT across all three metrics from $k = 1$, achieving a $+23$ increase in recall and an 18-point reduction in miss rate. This is consistent with previous findings Baddour et al. (2024), as PhenoBERT is less effective at capturing implicit phenotype references. Overall, the logarithmic shape of the recall and miss rate curves across both datasets indicates that all models rank correct candidates highly.

Complementary cross-ontology analyses (Appendix H) using a SNOMED-trained hyperbolic model show that, although it underperforms an HPO-trained hyperbolic model on HPO-defined targets (as expected), the SNOMED component can inject broader hierarchical cues that yield

a slight recall gain on ID-68 and a lower miss rate on CHU-50. These effects suggest that non–domain-specialized embeddings can add complementary structure in difficult cases, but the gains are modest and do not change the observation that HPO-centric retrieval and hybrid reranking remain the most effective overall, with the Euclidean baseline strong and hierarchy-aware metrics further favoring hyperbolic components.

Ranking

Tables 1 and 2 present weighted MRR and NDCG results for ID-68 and CHU-50. On ID-68, the Euclidean and Hybrid Rerank models achieve the highest MRR, indicating top-ranked correct phenotypes. The Hyperbolic model performs slightly lower, but the gap narrows with hierarchy-aware metrics, highlighting its strength in capturing ontological relationships. NDCG scores are also high across all models, with Euclidean and Hybrid Rerank exceeding 0.94 at $k = 1$. As k increases, both metrics decrease slightly, but Hybrid Rerank consistently maintains strong performance.

Table 1: Weighted Metrics by Model and k for ID-68

Model	$k=1$	$k=3$	$k=5$	$k=10$	$k=15$
Weighted MRR					
Euclidean	**0.857**	**0.882**	**0.884**	**0.885**	**0.885**
Hyperbolic	0.814	0.841	0.845	0.847	0.848
HPO-ColBERT Rerank	0.828	0.851	0.855	0.858	0.858
Hyperbolic Rerank	0.828	0.853	0.857	0.859	0.860
Hybrid Rerank	**0.855**	**0.881**	**0.883**	**0.885**	**0.885**
Weighted NDCG					
Euclidean	**0.949**	**0.936**	**0.923**	**0.901**	0.883
Hyperbolic	0.932	0.922	0.902	0.877	0.861
HPO-ColBERT Rerank	0.931	0.928	0.912	0.886	0.870
Hyperbolic Rerank	0.944	0.927	0.912	0.884	0.870
Hybrid Rerank	0.943	**0.936**	**0.924**	**0.904**	**0.891**

On the more challenging CHU-50 dataset, which contains a higher proportion of implicit phenotype mentions, all models exhibited lower MRR and NDCG scores compared to ID-68. However, the Hybrid Rerank model outperforms others for all k values.

These results indicate that the hybrid approach, which combines semantic similarity from Euclidean embeddings with hierarchical proximity from hyperbolic embeddings, is particularly effective in ranking the most relevant phenotypes at the top, even in complex, real-world clinical text. The consistently strong MRR and NDCG scores for the Hybrid Rerank model confirm that combining semantic and hierarchical signals yields superior candidate ranking. Hierarchy-aware

Table 2: Weighted Metrics by Model and k for CHU-50

Model	$k=1$	$k=3$	$k=5$	$k=10$	$k=15$
Weighted MRR					
Euclidean	0.631	0.659	0.667	0.670	0.671
Hyperbolic	0.588	0.613	0.619	0.625	0.627
HPO-ColBERT Rerank	0.585	0.624	0.633	0.636	0.638
Hyperbolic Rerank	0.597	0.629	0.637	0.643	0.644
Hybrid Rerank	**0.647**	**0.669**	**0.676**	**0.680**	**0.681**
Weighted NDCG					
Euclidean	0.841	**0.853**	**0.832**	**0.807**	0.792
Hyperbolic	0.834	0.818	0.796	0.772	0.751
HPO-ColBERT Rerank	0.844	0.821	0.805	0.783	0.768
Hyperbolic Rerank	0.851	0.841	0.815	0.787	0.779
Hybrid Rerank	**0.868**	0.848	**0.835**	**0.806**	**0.800**

weighted metrics further demonstrate the value of hyperbolic embeddings in capturing nuanced ontological relationships, especially when exact matches are unavailable but related terms remain clinically relevant.

Overall, hybrid reranking yields statistically significant improvements in weighted recall@1 and weighted MRR on the CHU-50 dataset, while maintaining performance comparable to Euclidean retrieval on ID-68 (detailed statistical significance results are provided in Appendix C).

6.3 Ontology-based Metrics

While hyperbolic models may not always outperform Euclidean models at top ranks, they show greater robustness as the candidate list grows, maintaining lower average hops and higher branch coverage (Figure 6).

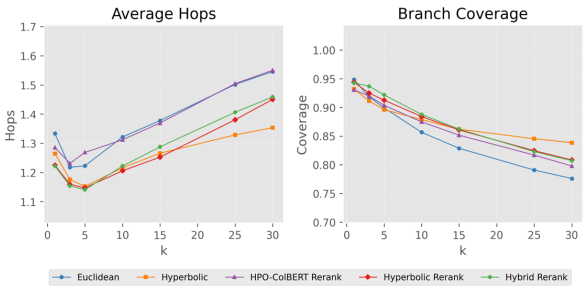

Figure 6: Ontology-based metrics on the ID-68 dataset across *Top-k* candidates. Average number of hops between the candidates and the target phenotypes (left), and proportion of candidates within the ontology branch of the target phenotypes (right).

This observation is further supported by a detailed analysis of ontological relationships (Appendix F). Figure 7 shows a high percentage of exact matches at *Top-1*, confirming the pipeline's effectiveness. However, deeper analysis reveals important distinctions between modeling approaches.

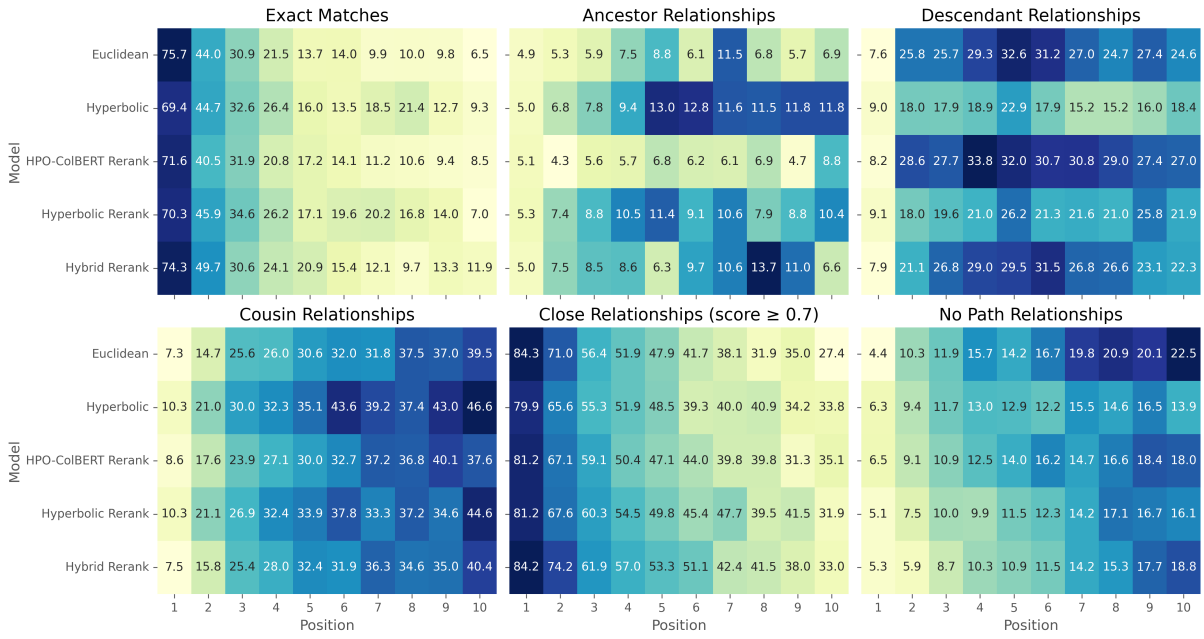

Figure 7: Distribution of relationship types by position and model for *Top-10* candidates ($k = 10$) on ID-68 dataset. The heatmaps show percentages for six relationship categories (Appendix F) between predicted and ground truth phenotypes. For closeness relationships, only those with scores above 0.7 (Equations (4) and (5)) are considered. Rows correspond to different models, and columns represent candidate positions ranked from 1 to 10. Higher values indicate stronger presence of the relationship type at the given rank and model.

Hyperbolic models (both raw output and reranking) exhibit significantly higher proportions of ancestor and cousin relationships, while showing fewer descendant relationships compared to Euclidean or HPO-ColBERT models. This pattern strongly suggests that hyperbolic approaches better capture the hierarchical structure of the HPO ontology in both vertical and horizontal dimensions. The tendency to "move upward" in the hierarchy toward more general terms rather than "downward" toward more specific ones aligns with theoretical expectations of hyperbolic geometry, where distances increase exponentially with depth in the hierarchy.

Notably, hyperbolic models maintain semantic relevance at higher ranks, preserving close relationships and yielding fewer unrelated candidates as k increases. This semantic consistency at higher ranks has important implications for clinical applications, as it reduces the risk of missing relevant phenotypes (false negatives) when examining a broader set of candidates. The hybrid reranking approach combines the strengths of both geometries, achieving strong exact matching at top positions and semantic coherence at higher ranks. This balanced performance confirms the value of integrating both approaches for optimal phenotype retrieval in clinical settings. Similar trends are observed on the CHU-50 dataset (Figure 16 in Appendix H).

7 Conclusion

In summary, we introduce a hierarchy-aware workflow combining LLM-based span detection, dense retrieval, and hybrid reranking using hyperbolic embeddings for phenotype linking. Experiments on benchmark and real-world datasets show improvements in recall, miss rate, and ranking quality, alongside better hierarchical consistency, particularly under hierarchy-aware metrics. The hybrid reranking strategy, integrating semantic and ontological signals, consistently outperforms prior systems, especially for implicit phenotype mentions. These results highlight the complementary roles of Euclidean and hyperbolic embeddings, capturing local semantic similarity and global ontology structure, and yielding more clinically meaningful and interpretable predictions. Finally, the proposed evaluation framework and released datasets support more nuanced and clinically relevant assessment of phenotype extraction systems. This approach can be extended to other domains involving hierarchical ontologies.

Limitations

While our approach demonstrates notable improvements, several limitations remain. Although hyperbolic embeddings effectively capture hierarchical relationships within the ontology, they may fail to fully represent implicit semantic nuances in clinical text. Future work could explore multi-task training strategies jointly modeling hierarchy and semantic similarity.

Another limitation concerns data sparsity: reliance on annotated datasets may restrict generalizability to unseen or rare phenotypes. Additionally, hyperbolic distances are not always meaningful for all term pairs, suggesting that further refinement of the hyperbolic modeling framework is needed.

Although CHU-50 contains a substantial proportion of implicit phenotype mentions, the current version of the dataset does not explicitly distinguish implicit and explicit annotations. Consequently, evaluations are aggregated across all mention types. Future versions of the dataset will include dedicated annotation flags to enable finer-grained analyses of implicit phenotype normalization performance.

Regarding recall performance, our analysis did not reveal clear patterns explaining why SNOMED embeddings occasionally outperform HPO embeddings. While broader-domain supervision may provide complementary signals in some cases, SNOMED embeddings underperform HPO-based models on the CHU-50 dataset, indicating that domain-specific hierarchical information remains crucial for complex clinical text.

More generally, the effectiveness of hyperbolic embeddings depends on the underlying ontology structure. Ontologies with complex or transversal relationships may limit the benefits of hyperbolic geometry, potentially requiring alternative training strategies or geometric formulations. In this respect, extending our workflow to other hierarchical coding systems such as the International Classification of Diseases (ICD) Blanco et al. (2020); Zhou et al. (2021) would require additional investigation, as its granularity, structural conventions, and limited mappings to HPO Tan et al. (2024) may constrain direct transfer.

Our approach also introduces additional system components compared to simpler pipelines such as standalone LLM inference or NER+EL models. However, most of the added cost is incurred offline, as hyperbolic embeddings are trained once and reranking relies on precomputed representations without additional LLM calls at inference time.

Finally, due to computational constraints, we did not perform an exhaustive search over hybrid reranking parameters (although we explored different values of γ in Appendix E) or evaluation weighting schemes, nor did we investigate alternative embedding backbones, particularly those fine-tuned on medical or clinical data, which could further improve performance.

Ethical Considerations

The CHU-50 dataset introduced in this work consists of clinical notes with phenotype annotations and is used exclusively for evaluation purposes. No real clinical data are used for model training. All notes were manually generated by clinicians based on real clinical reports, but the content is fully original and anonymized. No personal data are present in the dataset, and care was taken to ensure that no combination of symptoms could indirectly identify any individual. This design ensures compliance with ethical standards and protects patient privacy.

Additionally, the proposed workflow relies in part on probabilistic components, including large language models used for span detection. These outputs should be interpreted with caution. If used in a medical context, all results must be reviewed and validated by qualified healthcare professionals, and the system should not be used for autonomous clinical decision-making.

A Implementation Details

Span detection: for consistency with Baddour et al. (2024) and comprehensive coverage, we utilized ChatGPT-3.5 model OpenAI (2023). Corresponding prompt is described in Appendix I.

Embeddings: we used *all-MiniLM-L12-v2* Wang (2020) as the embeddings base model, from which the hyperbolic model was fine-tuned. We set *k=30* to substantially reduce the candidate space while still allowing for meaningful reranking improvements.

Candidate retrieval: FAISS Douze et al. (2024) is employed as the vector store and *Top-k* retriever for the Euclidean model. In contrast, the hyperbolic model utilizes a dedicated vector index and retrieval mechanism.

To ensure consistency in distance measurements across experiments, we normalize the hyperbolic distances in the Poincaré ball using a global normalization strategy (2):

$$\hat{d}_{\mathbb{H}}(u,v) = \frac{d_{\mathbb{H}}(u,v)}{\max_{p,q\in \text{HPO}} d_{\mathbb{H}}(p,q)} \quad (2)$$

where $d_{\mathbb{H}}(u,v)$ is the hyperbolic distance between terms u and v in the hyperbolic space $\mathbb{H}$, $\hat{d}_{\mathbb{H}}$ is the normalized hyperbolic distance, and $\max_{p,q\in \text{HPO}} d_{\mathbb{H}}(p,q)$ is the maximum hyperbolic distance between two terms in the HPO ontology.

Synonyms in the dense retrieval output are mapped to their original HPO terms using a precomputed synonym-to-ID mapping. This ensures consistency in distance calculations throughout the workflow.

Hybrid reranking: given an input $span$ and a set of candidates $\{C_i\}_{i=1}^{k}$, the hybrid score of a candidate C_i is computed as follows.

$$S_{\text{hybrid}}(C_i, span) = \gamma \cdot S_{\cos} - (1-\gamma)\cdot \hat{d}_{\mathbb{H}} \quad (3)$$

where $S_{\cos}$ is the cosine similarity between C_i and $span$, $\hat{d}_{\mathbb{H}}$ is their normalized hyperbolic distance, and γ is the weighting parameter between the two metrics.

B Dataset Construction

Hyperbolic Training Data

Hierarchical relationships are extracted from the HPO OWL file using DeepOnto and the ELK

reasoner. Following the methodology of He et al. (2024), we generated a dataset of triplets ⟨*child, parent, label*⟩, where the label is a binary indicator of a positive or negative example, and triplets ⟨*child, parent, negative*⟩, where the negative term is not a parent of the child. We used random negative sampling strategy in this implementation. Given that most HPO phenotypes are associated with multiple synonyms, we augmented the dataset by including all possible synonym combinations within each triplet. This augmentation enhances the robustness of the resulting embeddings to varied term formulations. To prevent excessive class imbalance, we applied a filtering strategy, limiting each synonym to a maximum of five occurrences.

Name	Definition
`WHITELIST_WORDS`	Set of medically relevant or specific terms; if any are present in a span, the span is always kept.
`BLACKLIST_PATTERNS`	Set of phrases indicating non-informative or undesirable content; if present (and not overridden by whitelist), the span is always filtered out.
`GENERIC_WORDS`	Set of common, non-specific words; used to penalize spans that are mostly generic.
`VAGUE_PATTERNS`	Set of vague or non-specific phrases; presence reduces the span's score.

Table 3: Heuristic lists used for span filtering.

Late-interaction Training Data

We fine-tuned the ColBERTv2 model Santhanam et al. (2021) on triplets of the form ⟨*span, HPO label, score*⟩, where the score represents a similarity measure. To construct a comprehensive training dataset, we first used ChatGPT-4o-mini to generate 10 clinical report sentences for each HPO term in the ontology. To ensure diversity and representativeness, we specified requirements for each batch of 10 sentences (e.g., at least two sentences should be implicit, up to two should include measurements, etc.). For this iteration, we excluded cases where a sentence refers to multiple phenotypes. For each generated sentence, we further prompted ChatGPT-4o-mini to extract the most precise span capturing the clinical observation of the target phenotype. This process resulted in the *HPO_sentences_spans* dataset, comprising over 200,000 clinical sentences and corresponding spans, covering the entire set of HPO terms. All prompts are provided in Appendix I for reproducibility.

After qualitative analysis of generated spans, some of them appear to be uninformative (e.g.: for the sentence "*The bladder capacity measured at 150 mL, which is below the normal range.*", the output span is "*below the normal range*" which lacks context to be relevant). We conducted a deep qualitative analysis of the spans with our clinicians in order to define filtering rules. Table 3 define the heuristics elements used in the process. The scoring procedure and the span filtering are detailed in pseudo-code in Algorithm 1 and Algorithm 2 respectively.

Algorithm 1 Compute Span Score

Require: span (string)
if span contains any **BLACKLIST_PATTERN then**
  if span contains any **WHITELIST_WORD then**
    return 1.0
  else
    return 0.0
  end if
end if
if span contains any **WHITELIST_WORD then**
  return 1.0
end if
if number of words in span ≥ 3 **then**
  score $\leftarrow$ 1.0
else
  score $\leftarrow$ 0.3
end if
generic_ratio $\leftarrow$ (number of **GENERIC_WORDS** in span) / (total words)
if generic_ratio > 0.6 **then**
  score $\leftarrow$ score -0.5
end if
if span contains any **VAGUE_PATTERN then**
  score $\leftarrow$ score -0.3
end if
return max(score, 0.0)

Algorithm 2 Filter Spans

Require: spans (list of strings)
for each span in spans **do**
  score $\leftarrow$ **Compute Span Score**(span)
  if score ≥ 0.2 **then**
    keep span
  else
    filter out span
  end if
end for

As a result, this lower-quality spans filtering yields 91,760 unique high-quality spans (with 2,167 unique spans filtered out).

Finally, we leveraged the trained hyperbolic model for scoring: positive *(span, HPO label)* pairs from the generated dataset were assigned a score

Table 4: Paired bootstrap confidence intervals (95%) for weighted Recall and weighted MRR on the ID-68 dataset. Δ denotes the mean difference between Hybrid and Euclidean retrieval ($\Delta = B - A$).

k	Metric	Euclidean (A)	Hybrid (B)	Δ [95% CI]
1	Recall	0.8663	0.8584	-0.0079 [-0.0254, $+0.0092$]
3	Recall	0.9239	0.9218	-0.0021 [-0.0113, $+0.0072$]

30	MRR	0.6405	0.6522	$\mathbf{+0.0118}$ [$\mathbf{+0.0025}$, $\mathbf{+0.0208}$]

of 1, while negative pairs were created by pairing spans with other phenotypes and assigning scores based on the normalized hyperbolic distance to the target phenotype. Both hard negatives (phenotypes within the same branch, up to three hops away) and easy negatives (phenotypes outside the target branch) were included. The final training set consists of 510,371 triplets $\langle$*span, HPO label, score*$\rangle$.

C Statistical Significance Analysis

Statistical significance was assessed using paired bootstrap resampling at the report level (2,000 resamples), with confidence intervals computed on mean differences between hybrid reranking and Euclidean retrieval.

ID-68. On the ID-68 dataset (Table 4), which contains mostly explicit phenotype mentions, hybrid reranking achieves performance comparable to Euclidean retrieval for both weighted recall and weighted MRR across all evaluated values of k. Paired bootstrap confidence intervals consistently include zero, indicating no statistically significant differences between the two approaches. This suggests that integrating hierarchical information does not degrade either retrieval coverage or ranking quality in settings where semantic similarity alone is sufficient.

CHU-50. In contrast, on the more challenging CHU-50 dataset (Table 5), which contains a higher proportion of implicit phenotype mentions, hybrid reranking yields statistically significant improvements over Euclidean retrieval. Paired bootstrap resampling confirms significant gains in weighted recall at Top-1 and at larger candidate depths, as well as consistent and statistically significant improvements in weighted MRR across all evaluated values of k (95% confidence intervals). These results demonstrate that incorporating hierarchical

structure substantially improves both retrieval and ranking of clinically relevant phenotypes in real-world clinical narratives.

D Training Settings

All model training was conducted on a single RTX A3000 GPU, both to accommodate budget constraints and to reduce energy consumption for environmental considerations. Table 6 indicates the training settings for the hyperbolic model training.

Parameter	Value
Number of training epochs	20
Train batch size	32
Eval batch size	64
Learning rate	1e-5
Clustering loss weight	1.0
Clustering loss margin	5.0
Centripetal loss weight	1.0
Centripetal loss margin	0.5
Gradient accumulation steps	8

Table 6: Hyperbolic Training Hyperparameters.

The training settings for the ColbertV2 fine-tuning on HPO is presented in Table 7.

Parameter	Value
Train batch size	8
Learning rate	1e-5
Number of training epochs	2
Max query length	32
Max document length	128
Triplet loss margin	0.3
Gradient accumulation steps	2

Table 7: ColBERTv2 Training Hyperparameters.

E Parameters Settings

For the hierarchy-aware metrics, parameters α (4) and β (5) were set empirically through random assessment by clinicians, who reviewed diverse samples to ensure clinical relevance. We verified that varying them in reasonable ranges does not change the model ranking, and all standard unweighted metrics are also reported. This ensures robustness and prevents metric-induced bias.

Regarding γ parameter (3), we conducted additional ablation studies varying the ratio between Euclidean and hyperbolic components in the hybrid model to assess their respective contributions for the ID-68 and CHU-50 dataset.

As shown in Figures 8 and 9, our findings indicate that except for very small values of γ (which consistently underperform), recall performance

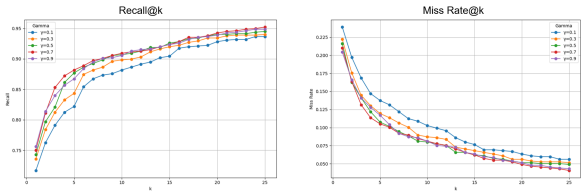

Figure 8: Recall@k and Miss Rate@k for the ID-68 dataset for different values of the weighting parameter γ, which balances Euclidean and hyperbolic distances in the hybrid reranking score.

shows no clear trends across the different γ settings. Among them, $\gamma = 0.5$ and $\gamma = 0.7$ produce the best overall results.

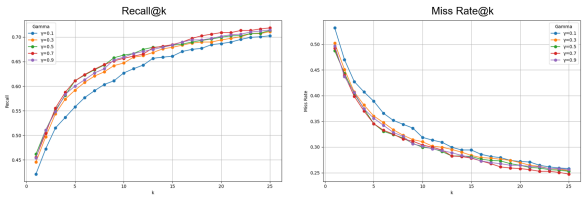

Figure 9: Recall@k and Miss Rate@k for the CHU-50 dataset for different values of the weighting parameter γ, which balances Euclidean and hyperbolic distances in the hybrid reranking score.

Interestingly, for the CHU-50 dataset (characterized by a high proportion of implicit references) the hybrid model with $\gamma = 0.5$ performs identically to, and sometimes better than, $\gamma = 0.7$. This suggests that, in such cases, the hyperbolic component is more effectively leveraged, likely due to its ability to capture hierarchical or indirect relationships.

Given these marginal differences, and to maintain simplicity and interpretability, we fix $\gamma = 0.5$ in the main experiments presented in the paper.

F Relationships Taxonomy

Figure 10 presents the type of relationships considered in the analysis of ontological relationships between the candidates and a given target phenotype (Orange). If the candidate is not in the same branch from the ontology root (*Phenotypic abnormality*), we consider that no path exist between them, as the first level of the ontology refers to very different classes of abnormalities (e.g.: Abnormality of the musculoskeletal system, Abnormality of the nervous system, Abnormality of the cardiovascular system, ...).

While *Ancestor* and *Descendant* are common types, *Cousin* is a broader notion of relationships referring to candidates that have a common ances-

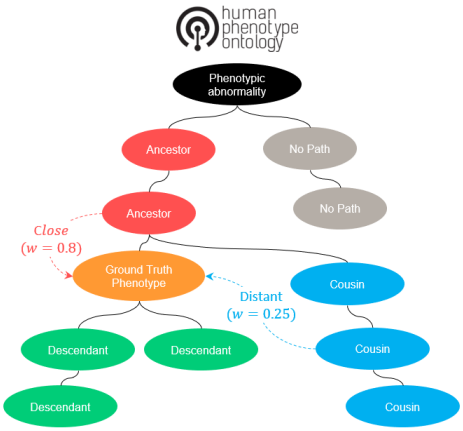

Figure 10: Relationships taxonomy. Given a target phenotype (orange), nodes are categorized as descendants (green), ancestors (red), cousins (blue), or outside the branch (grey). Relative closeness follows the relationship scores defined in Section 5.2.

tor with the target. Finally, a *Close Relationships* type refers to candidates whose relationships score (Equation 4) with the target is above a threshold of 0.7.

G Data Verification

As described in B, training data were generated using ChatGPT-4o-mini to produce sentences from HPO phenotypes with a crafted prompt 18. The generated data were manually evaluated by our clinicians.

We first randomly sampled 50 sentences ensuring coverage across different branches of the HPO ontology. Each sentence was independently reviewed by two clinicians (blind annotation). The annotation guidelines were as follows:

- Meaningfulness: The sentence should be meaningful and coherent.
- Phenotype Reference: The sentence should refer to the input phenotype, either explicitly or implicitly.
- Clinical Realism: The sentence should resemble real-world clinical report formulations.

Annotators selected among three labels: 1 for sentences fully meeting all criteria, 0 if none were met, and 0.5 for partial or ambiguous phenotype references. To assess agreement on this ordinal scale, we used quadratic-weighted Cohen's kappa, yielding a score of 0.64, indicating strong reliability despite the small, imbalanced dataset. Notably, 88% of sentences were rated as high quality. The Cohen's Kappa of 0.64 suggests a strong reliability beyond chance, especially with such small annotation set and label imbalance. The confusion matrix (Figure 11) shows strong agreement on the highest score (1), and most disagreements occur between adjacent categories (e.g., 1 vs. 0.5), suggesting that when annotators differ, they still tend to assign similar quality levels.

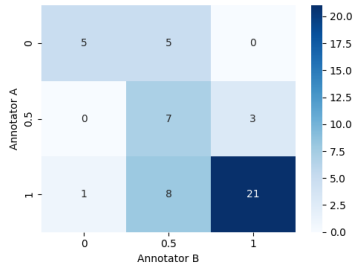

Figure 11: Annotation confusion matrix. Although the class distribution is imbalanced (majority class 1), annotators show strong agreement across classes.

We acknowledge that 50 sentences represent a small sample, but the randomized selection across diverse ontology branches and the high level of agreement observed provide a reasonably robust basis for estimating overall data quality.

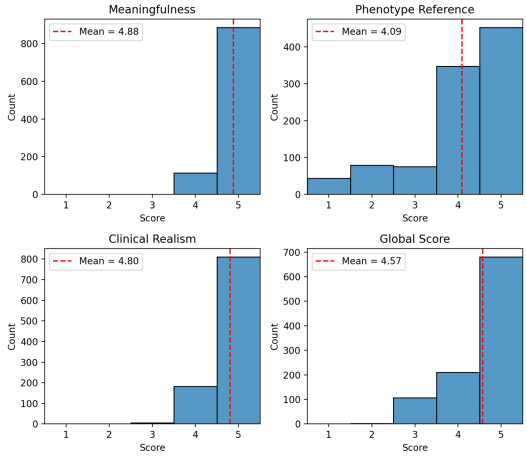

Figure 12: Distribution of LLM-as-a-judge scores across criteria. Scale are from 1 (poor quality) to 5 (excellent quality). Red lines represent the means.

To further support this assessment, we conducted an LLM-as-a-judge evaluation on a larger set of 1000 sentences across the three criteria (Figure 12). While the results should be interpreted with caution, they reinforce the observation that the vast majority of generated sentences are of high quality.

H Additional Results

Cross-Ontology Evaluation

To assess the generalizability of our workflow beyond a single ontology, we conducted additional experiments using a hyperbolic model fine-tuned on the SNOMED ontology instead of HPO. This cross-ontology evaluation tests whether our approach can leverage hierarchical structure from different sources and whether combining ontologies can improve retrieval and ranking. While both ontologies are biomedical, this experiment provides an initial step toward demonstrating the robustness and adaptability of the workflow to diverse hierarchical knowledge bases. Future work will extend this analysis to non-biomedical domains.

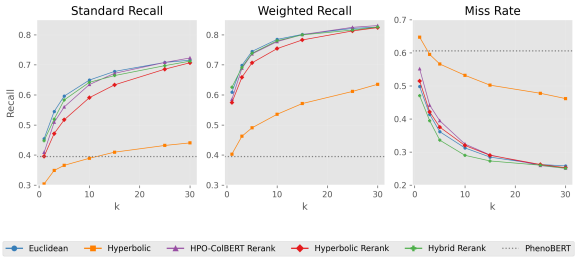

Figure 13: Recall and miss rate on ID-68 using SNOMED-trained hyperbolic embeddings. Exact-match and weighted recall are reported for raw dense retrieval (Euclidean, Hyperbolic) and reranked outputs (HPO-ColBERT, Hyperbolic, Hybrid) across *Top-k* candidates. Miss rate denotes the proportion of unretrieved ground-truth phenotypes.

As shown in Figure 13, the SNOMED-based hyperbolic model underperforms compared to the HPO-based hyperbolic model, which is expected given that the target phenotypes are defined within the HPO ontology. Interestingly, the hybrid approach exhibits a slight improvement on the ID-68 dataset. This counterintuitive result suggests that, despite the SNOMED model being less domain-specific, it may introduce complementary information that is not captured by the HPO-based hyperbolic models. The combination of semantic similarity and the broader, more general structure encoded by SNOMED embeddings could help differentiate candidates in challenging cases, leading to improved ranking performance.

Conversely, the hybrid model demonstrates reduced accuracy with SNOMED on the CHU-50 dataset. Figure 14 shows recall and miss rate for CHU-50 dataset when using SNOMED hyperbolic model. As expected, the performance is lower than with the HPO hyperbolic model. However, we can note that the miss rate is better with the hybrid approach, suggesting that the hyperbolic model's structure (even when not domain-specialized) may still be effective at ensuring broad coverage of the ontology, due to the hierarchical nature of hyperbolic embeddings.

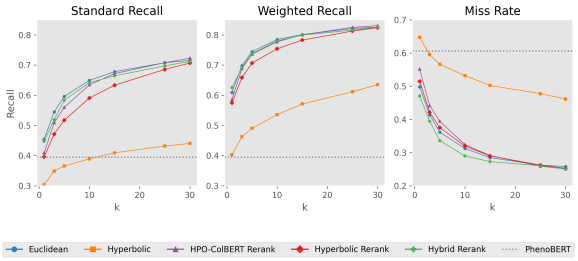

Figure 14: Recall and miss rate on CHU-50 using SNOMED-trained hyperbolic embeddings. Exact-match and weighted recall are reported for raw dense retrieval (Euclidean, Hyperbolic) and reranked outputs (HPO-ColBERT, Hyperbolic, Hybrid) across *Top-k* candidates. Miss rate denotes the proportion of unretrieved ground-truth phenotypes.

These results highlight the potential for our workflow to integrate information from multiple ontologies, supporting its applicability to a wide range of hierarchical entity linking tasks.

CHU-50 Ontology Metrics

The average number of hops between candidates and target phenotypes is shown in Figure 15. The rank scale is up to 50 so the robustness of the hyperbolic model for higher ranks is highlighted.

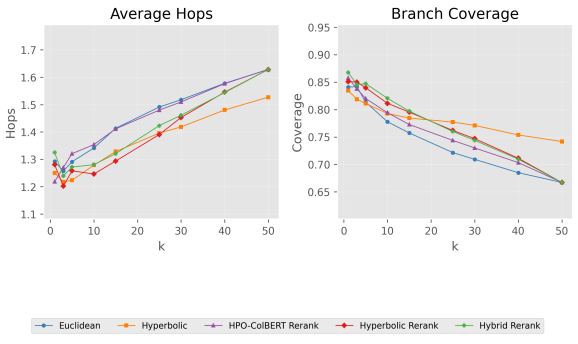

Figure 15: Ontological Structure Metrics on the CHU-50 dataset across *Top-k* candidates. Left: average number of hops between the candidates and the target phenotypes. Right: proportion of candidates within the ontology branch of the target phenotypes.

Finally, the distribution of relationships types for the CHU-50 dataset is shown in Figure 16.

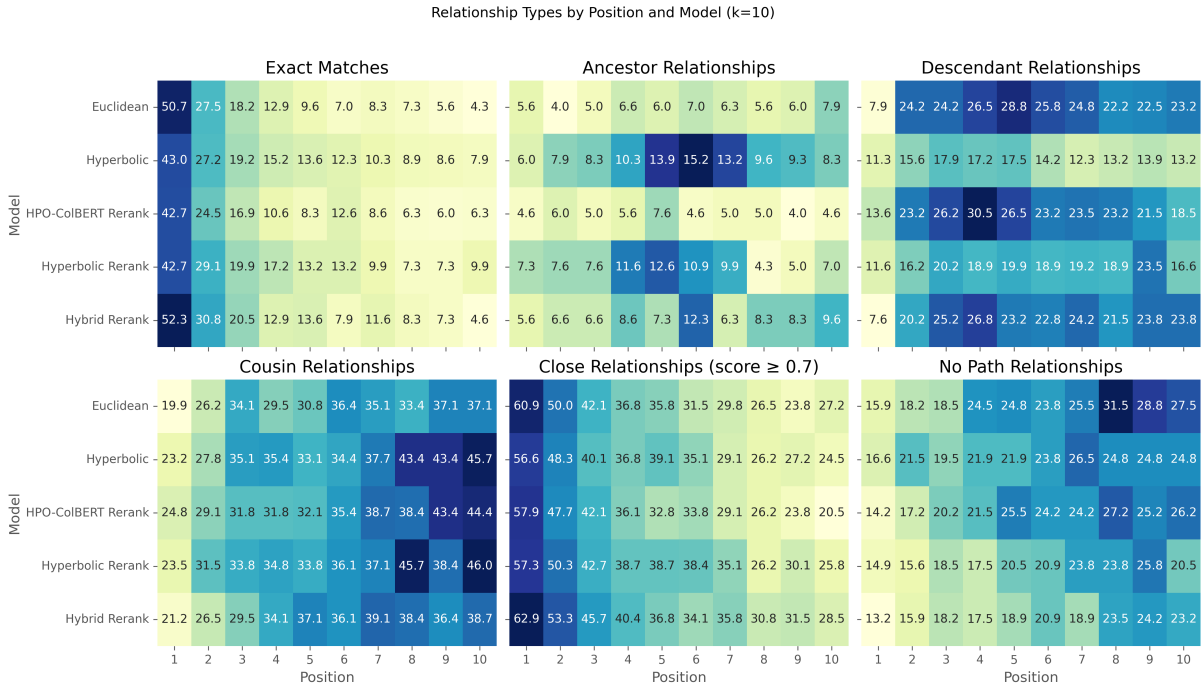

Figure 16: Distribution of relationship types by position and model for Top-10 candidates (k=10) on CHU-50 dataset. The heatmaps show percentages for six relationship categories (Appendix F) between predicted and ground truth phenotypes. For closeness relationships, only those with scores above 0.7 (Equations (4) and (5)) are considered. Rows correspond to different models, and columns represent candidate positions ranked from 1 to 10. Higher values indicate stronger presence of the relationship type at the given rank and model.

I Prompts

The prompt used for span detection step is shown in Fig. 17.

Span Detection

You are an experienced clinician with an exhaustive knowledge of human phenotypes ontology.

Given **{text}**, you must identify the spans related to possible phenotypes, either explicitly or implicitly. You should keep in the span all words related to the phenotype that should be informative (such as negation or adjective).
You may reformulate the span if needed. If you don't detect any span or if you don't know, don't try to make up an answer, just write 'None'.

Figure 17: Full prompt used for span detection (variable in blue).

Late-interaction training data are built through automatic generation of sentences from HPO. This allows to have clinically-relevant sentences for all phenotype labels and synonyms from the ontology. In addition, we crafted prompt so that implicit and measurements references are generated. The corresponding prompt is shown in Fig. 18.

As the goal was to generate spans related to phenotypes, we further query a LLM from the previously generated sentences to get the spans related to the corresponding HPO labels. The prompt used in this step is described in Fig. 19.

Finally, the prompt used for the LLM-as-a-Judge evaluation is presented in Fig. 20.

All prompts were used with the GPT-4o-mini model. The formatting preserves line breaks and spacing as passed to the model.

HPO Sentence Generation

For each HPO label, produce {sentence_count} purely observational sentences, referencing the phenotype explicitly or implicitly.

Requirements

- Use both the main HPO label and all provided synonyms for explicit references.
- At least {implicit_count} sentences must be implicit references (avoid using the label or synonyms).
- Ensure diversity in perspective or detail across sentences (as if from different medical domains and contexts).
- Ensure diversity in sentence openings.
- Use first-person ("I") or neutral ("we") style; do not include any titles (e.g., "Dr. Smith").
- At least two sentences must use passive voice.
- Vary sentence structure, wording and length (some short, some medium, some extended).
- Avoid overuse of "the patient" ($\leq$ 2 uses). Use pronouns ("he," "she," "they") or a fictitious name (first name or "Mr./Mrs." + last name) for diversity.
  - At least 1 sentence must use a fictitious name instead of "the patient" or a pronoun.
- Occasionally include measurements/tests (e.g., mg/dL, $<$ 1st percentile), up to {measures_count} total.
- No interpretive language ("suggesting," "indicative of"); only factual observations.
- No professorial explanations; just present observations.
- Return a bulleted list ("- "). Clinical shorthand is fine.

Context

- **HPO label:** {hpo_label}
- **Definition:** {definition}
- **Synonyms:** {synonyms_str}

Figure 18: Full prompt used for automatic generation of sentences from HPO (variables are shown in blue).

Span Detection from Generated Sentences

Extract the text span that best describes or indicates the phenotype "{phenotype_data['hpo_label']}" from this sentence.

Requirements

1. Capture the complete clinical observation or symptom
2. Include relevant context that helps understand the phenotype
3. Be specific to the actual medical condition
4. Be concise while maintaining clinical accuracy
5. Exclude patient names, temporal markers, or examination context
6. Focus on the actual phenotypic finding

Sentence: "{phenotype_data['sentence']}"
Extract only the relevant span without any additional commentary.

Figure 19: Full prompt used for span detection from generated sentences (variables are shown in blue). The object *phenotype_data* refers to a dataframe with the original HPO phenotype (*hpo_label*) and the corresponding generated sentence (*sentence*).

LLM-as-a-Judge Evaluation

You are an expert clinical language model evaluating sentences linked to HPO terms. Evaluate the sentence below using these criteria. Each score must be an integer from 1 to 5 (5 = excellent, 1 = poor):

1. **Meaningfulness** – Is the sentence meaningful and coherent?
2. **Phenotype Reference** – Does the sentence refer to the phenotype "**{hpo_label}**" (**{hpo_id}**), explicitly or implicitly?
3. **Clinical Realism** – Could this sentence appear in a real clinical report?

Then provide a **global score** (also 1–5) summarizing the overall quality of the sentence with respect to all three criteria.

Respond ONLY in this JSON format, filling in each `<score>` with your evaluation:

```
{
  "meaningfulness": <score>,
  "phenotype_reference": <score>,
  "clinical_realism": <score>,
  "global_score": <score>,
  "comment": "Brief explanation"
}
```

Sentence: "**{sentence}**"

Figure 20: Full prompt used for LLM-as-a-Judge evaluation.

Agentic Feature Selection via LLM for Epileptic Seizure Detection

Aizierjiang Aiersilan ✉ **Xiaodong Qu**
The George Washington University
alexandera@gwu.edu

Abstract

Automated epileptic seizure detection from electroencephalography (EEG) signals is a clinically important task in which feature selection is typically performed using purely statistical criteria. We investigate whether a small instruction-tuned large language model (LLM) can guide iterative feature selection for binary seizure detection on the Epileptic Seizure Recognition dataset (11,500 samples, 178 features). The LLM agent (Qwen2.5-1.5B-Instruct) receives five complementary statistical summaries and selects a feature subset through multi-round reasoning. The agent achieves 96.5% accuracy and 0.911 F1 with 40 features, compared to 97.9% accuracy and 0.946 F1 for the best full-feature baseline (SVM-RBF on 178 features). Critically, 39 of the agent's 40 features coincide with the top-39 mutual-information features, and a deterministic Top-39 MI filter, evaluated by the same Random Forest classifier, attains the same 96.5% accuracy and 0.911 F1. We therefore present this work as an empirical baseline: at the 1.5B-parameter scale, the LLM behaves close to a univariate MI ranker. We situate the result against the recent LLM-based feature selection literature and enumerate the ablations and multi-dataset extensions required to determine whether larger or domain-specialized LLMs add value beyond statistical filtering.

Code: github.com/Ezharjan/AgenticFS4EEG.

1 Introduction

Epilepsy affects approximately 50 million people worldwide and is characterized by recurrent, unprovoked seizures (Shoeb, 2009). Electroencephalography (EEG) is the primary non-invasive diagnostic modality, but manual review of long-term recordings is slow and subject to inter-rater variability. Automated detectors based on classical machine learning such as random forests (Breiman, 2001), support vector machines (Cortes and Vapnik, 1995), and gradient boosting (Friedman, 2001) achieve strong performance on benchmark EEG tasks (Shimanto, 2017), but operating on the full feature space retains redundant or noisy dimensions, limiting interpretability and efficiency. Feature selection is therefore a critical preprocessing step (Guyon and Elisseeff, 2003), and is traditionally performed using statistical criteria such as mutual information (MI) (Kraskov et al., 2004), ANOVA F-scores, or wrapper-based search, none of which carry semantic understanding of the features or the domain. Recent LLM advances open the possibility of incorporating natural-language reasoning into such pipelines (Zhao et al., 2025; Wang et al., 2026).

We propose an *agentic LLM-guided feature selection* framework for binary epileptic seizure detection. The LLM agent receives five complementary statistical measures for each feature and produces a feature subset through five rounds of iterative reasoning. We evaluate the agent against three full-feature baselines and against a purely MI-driven filter baseline. Our contributions are: (1) an agentic framework coupling LLM reasoning with five complementary statistics for iterative EEG feature selection (Algorithm 1, Appendix D); (2) an evaluation showing that compressing the feature space from 178 to 40 features (a 77.5% reduction) via LLM mediation incurs only a 1.4 percentage-point accuracy gap relative to the best full-feature baseline; and (3) a controlled comparison against a deterministic Top-39 MI filter, evaluated with the same Random Forest classifier on the same split, showing that at the 1.5B-parameter scale the LLM agent's selection coincides with the MI ranking on 39 of 40 features and produces statistically indistinguishable downstream metrics. We present this as an empirical baseline rather than as evidence that LLMs add value beyond a univariate statistical filter on this benchmark, and enumerate the ablations and extensions required to revisit the question in Section 8.

2 Related Work

2.1 EEG-Based Seizure Detection

The Bonn University EEG database (Andrzejak et al., 2001) and its derivative Epileptic Seizure Recognition dataset (Shimanto, 2017) are primary benchmarks for seizure detection. Classical approaches extract time-, frequency-, and wavelet-domain features and apply supervised classifiers (Hastie, 2009), with random forests (Breiman, 2001) and nonlinear-kernel SVMs (Cortes and Vapnik, 1995) consistently achieving top performance. More recently, CNNs and transformers have been applied to raw EEG signals (Yang and Modesitt, 2023; Konkar and Qu, 2026), but typically require larger datasets and offer less interpretability than feature-based methods. Our work retains the feature-based paradigm and focuses on *how* features are selected rather than how they are extracted.

2.2 Feature Selection for EEG

Feature selection methods for EEG span filter, wrapper, and embedded approaches (Guyon and Elisseeff, 2003). NeuroFeat (Choudhury et al., 2026) adaptively selects features based on signal characteristics. Presacan et al. (Presacan et al., 2025) review explainable AI methods for EEG, and Lai et al. (Lai et al., 2025) note that feature engineering remains essential for small-to-medium datasets where deep models tend to overfit. These works rely on statistical or model-intrinsic criteria; we instead delegate selection to an LLM that can jointly interpret multiple statistical summaries.

2.3 LLM Agents for Scientific Data Analysis

EEGAgent (Zhao et al., 2025) and NeuroWeaver (Wang et al., 2026) are recent end-to-end LLM-driven frameworks for EEG analysis, and Murungi et al. (Murungi et al., 2023) survey LLM-assisted EEG interpretation. To our knowledge, neither EEGAgent nor NeuroWeaver reports detection metrics on the specific Epileptic Seizure Recognition benchmark used here, so direct numerical comparison is not currently possible. Our work differs by focusing on feature selection rather than automating the whole pipeline.

2.4 LLM-Based Feature Selection

LLM-Select (Jeong et al., 2024) queries an LLM with feature names and short descriptions to rank features zero-shot. CAAFE (Hollmann et al., 2023) uses an LLM to iteratively generate and evaluate new feature transformations with downstream classifier feedback. LLM-FS-Agent (Bal-Ghaoui and Sabri, 2025) adopts a deliberative multi-role LLM architecture in which several agents debate each feature's inclusion. We share the paradigm of delegating selection to an LLM but differ in three ways: (i) we operate on raw amplitude time-step features (X1–X178) without semantically meaningful names, so zero-shot name-based ranking is not applicable and the agent must reason over numeric statistics; (ii) unlike CAAFE we do not synthesize features but only select from a fixed set, giving a stricter test of the LLM's marginal contribution beyond a univariate ranker; and (iii) in contrast to LLM-FS-Agent's multi-agent debate, we use a single 1.5B-parameter instruction-tuned model with a structured statistical prompt. Our findings (Section 6) thus provide an empirical baseline complementary to the broadly positive results reported by larger or more elaborate LLM-FS systems.

3 Dataset

We use the Epileptic Seizure Recognition dataset (Shimanto, 2017), a publicly available benchmark derived from the Bonn University EEG database (Andrzejak et al., 2001). It contains 11,500 EEG segments, each represented by 178 time-domain amplitude features (sampled at 173.61 Hz) and a class label $y \in \{1, 2, 3, 4, 5\}$. The five classes encode recording conditions: y=1 denotes ictal seizure activity; y=2 and y=3 correspond to seizure-free recordings from the epileptogenic zone and hippocampal formation, respectively; and y=4 and y=5 correspond to surface EEG from healthy subjects. Each class contains exactly 2,300 samples.

Following the standard experimental protocol (Shimanto, 2017), the task is converted to binary classification: class 1 (seizure, n = 2,300) vs. classes 2–5 (non-seizure, n = 9,200), yielding a moderate 4:1 class imbalance ratio.

4 Methodology

The proposed pipeline comprises five stages: preprocessing, baseline training, LLM-guided feature selection, evaluation, and visualization. Figure 2 illustrates the overall architecture, and Figure 1 details the iterative reasoning loop at the core of the agent.

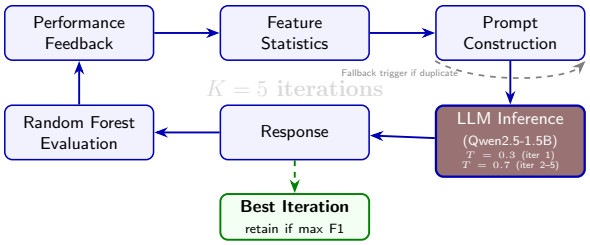

Figure 1: LLM Agent iterative reasoning loop. At each iteration, statistical summaries are compiled into a structured prompt, the LLM proposes a feature subset, a Random Forest evaluates the subset, and performance feedback informs the next round. The iteration with the highest F1-score is retained. A diversity fallback (dashed self-loop) activates if any proposal duplicates a prior selection.

4.1 Preprocessing

The 178 amplitude features (X1–X178) form the feature matrix $\mathbf{X} \in \mathbb{R}^{11500\times178}$. Labels are binarized such that $y{=}1$ maps to the positive (seizure) class and $y \in \{2,3,4,5\}$ to the negative (non-seizure) class. All features are standardized to zero mean and unit variance, with statistics computed on the training set and applied to the test set. A stratified 80/20 split preserves class proportions across training ($n{=}9{,}200$) and test ($n{=}2{,}300$) partitions.

4.2 Baseline Models

Three classifiers are trained on the full 178-dimensional standardized feature set as performance upper bounds, all implemented with scikit-learn (Pedregosa et al., 2011): a Random Forest (RF) ensemble of 200 trees with depth 20 and $\sqrt{d}$ features per split (Breiman, 2001); an SVM with RBF kernel ($C{=}10$, $\gamma{=}$scale) (Cortes and Vapnik, 1995); and a Gradient Boosting (GB) ensemble of 200 shallow trees (depth 5, learning rate 0.1) (Friedman, 2001).

4.3 LLM-Guided Feature Selection Agent

The agent is the methodological focus of this work. It is an iterative reasoning loop that combines information-theoretic feature profiling with LLM decision making to produce a compact subset for downstream classification; Algorithm 1 formalizes the procedure.

4.3.1 Feature Statistics Computation

For each of the 178 features x_j, five complementary statistics are computed on the training set. Mutual information (MI) is estimated with the k-nearest-neighbor method of Kraskov et al. (Kraskov et al., 2004) and captures nonlinear feature-label dependency. Pearson correlation captures the linear component of the same association, allowing the agent to distinguish purely linear from nonlinear discriminative structure. Variance is included to confirm the absence of degenerate (near-constant) features after standardization. Random Forest importance, the mean decrease in impurity from a preliminary RF (Breiman, 2001), complements the filter statistics by reflecting utility within an ensemble classifier. The ANOVA F-score (between-class over within-class variance) signals strong univariate class separation. These five measures span information-theoretic (MI), linear-statistical (correlation, F-score, variance), and model-based (RF importance) views, so the LLM has complementary evidence to cross-reference rather than a single ranking to imitate. Features are presented to the LLM sorted by MI in descending order.

4.3.2 Prompt Architecture

At each iteration k, the agent constructs a structured prompt with four components. A system message establishes the LLM's role as a feature selection expert and constrains outputs to a JSON list of feature names. A statistical summary table lists, for the top-40 features by MI, each feature's MI score, Pearson correlation, RF importance, and F-score. For iterations $k \geq 2$, the prompt is augmented with performance feedback (the prior iteration's accuracy, F1, AUC; the five most and five least important features by RF importance; and the full previous feature list), and with a mutation instruction directing the model to drop at least five low-importance features and replace them with high-MI or high-F-score alternatives, returning exactly 30 features as a JSON list. This structure mimics a human analyst's workflow: inspect, then refine based on downstream performance. Exact prompt templates are in Appendix D.

4.3.3 Temperature Schedule and Diversity Mechanisms

Exploration is controlled via a two-phase temperature schedule. Iteration 1 uses $T{=}0.3$ to produce a stable, high-confidence baseline selection, and iterations 2–5 use $T{=}0.7$ to encourage exploration. A diversity safeguard ensures no two iterations produce identical subsets: an exact match triggers a deterministic mutation that drops the 5 lowest-MI features and adds the highest-MI features not yet selected. The LLM's output is also clamped to the

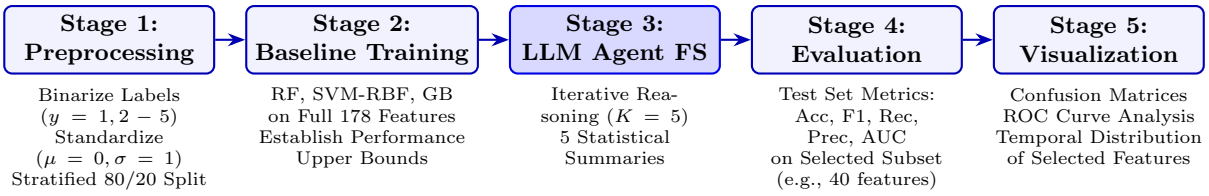

Figure 2: Five-stage experimental pipeline. The LLM Agent Feature Selection stage (emphasized) is the methodological focus of this work.

loose size range $[20, 80]$ (small subsets are padded with high-MI features; large ones are truncated).

Note on requested vs. returned size. The prompt requests *exactly* 30 features, but the post-processor only enforces $[20, 80]$ and otherwise preserves the model's choice. Because Qwen2.5-1.5B-Instruct (Qwen Team, 2025) does not strictly satisfy length constraints at this scale, the returned subsets ranged from 20 to 40 features across iterations (Table 2); we deliberately did not pad or truncate to 30, since doing so would overwrite the model behavior we wished to study. The discrepancy between the prompted 30 and the retained 40 (iteration 1) is therefore a faithfully reported instruction-following limitation, discussed further in Section 7.

4.3.4 Iterative Refinement Loop

The agent executes $K{=}5$ iterations (Algorithm 1). At each iteration the LLM receives the statistics (and, from $k{\geq}2$, the prior iteration's feedback), proposes a subset, which a Random Forest (200 trees, depth 20) trains and scores on accuracy, F1, and AUC; the highest-F1 iteration is retained. If the LLM fails to return a valid response, a statistical fallback selects the top-k features from one of the five precomputed statistics, cycling through MI, F-score, RF importance, correlation magnitude, and variance across successive fallbacks.

Algorithm 1 Agentic LLM-Guided Feature Selection

Require: Matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$, labels $\mathbf{y}$, LLM $\mathcal{M}$, iterations $K = 5$
Ensure: Best feature subset S^*

Compute stats $\mathbf{s}_j = (\text{MI}_j, \rho_j, \sigma_j^2, \text{RF}_j, F_j)$ and rank by MI
$S^* \leftarrow \varnothing, F_1^* \leftarrow 0, \mathcal{H} \leftarrow \varnothing$ ▷ Init best set, score, and history

    $S^* \leftarrow S_k, F_1^* \leftarrow \text{F1}_k$ ▷ Update global optimum
  $\text{fb}_k \leftarrow (\text{acc}_k, \text{F1}_k, \text{auc}_k, \mathcal{I}_k)$ ▷ Feedback for next iteration
return S^*

4.3.5 Evaluation of Selected Features

The final feature subset trains a Random Forest classifier (200 trees, depth 20, identical to the full-feature RF baseline) on the training set and is evaluated on the held-out test set; the LLM agent uses RF as its internal evaluator, so final reported metrics are computed on unseen data.

Top-k MI Filter baseline. To isolate the LLM's marginal contribution, we evaluate a deterministic Top-k MI Filter baseline that selects the k features with highest training-set MI with the label, with $k{=}39$ chosen to closely match the agent's 40-feature budget. For full comparability, this MI-filter subset is evaluated using *exactly the same Random Forest classifier* (200 trees, depth 20, seed 42) used to score the agent's selection; only the input feature columns differ. Any gap between the two is therefore attributable to feature choice alone.

5 Experimental Setup

We use Qwen2.5-1.5B-Instruct (Qwen Team, 2025) as the LLM backbone via a hosted inference endpoint with a 500-token output limit. For each method we report accuracy, precision, recall (sensitivity), F1, and AUC; confusion matrices are pro-

vided for all methods. Experiments ran on an NVIDIA RTX 5060 GPU with Python 3.x and scikit-learn (Pedregosa et al., 2011), with random seed 42 for reproducibility.

Choice of LLM backbone. We deliberately use a small (1.5B), general-purpose instruction-tuned model rather than a larger or biomedical LLM. First, small open-weight models are realistic for clinical edge environments where data residency and latency constraints discourage routing EEG statistics to large hosted models. Second, our goal is not peak accuracy but characterizing what an off-the-shelf lightweight LLM contributes *above* a purely statistical filter; a small contribution at this scale is itself an informative empirical baseline for the LLM-FS literature (Section 2.4). Third, available medical LLMs at comparable scale are predominantly clinical-text models tuned for narrative question answering rather than reasoning over numeric tables of unnamed time-step features, so their advantage here is not obvious in advance. Scaling and domain-specialized backbones are listed as future work in Section 8.

6 Results

6.1 Overall Performance Comparison

Table 1 presents the classification performance of all methods on the held-out test set (2,300 samples).

Table 1: Binary seizure detection performance on the test set. Full-feature baselines use all 178 features; the Top-39 MI Filter uses 39 features and the LLM agent uses 40 features.

Method	Acc ↑	Prec ↑	Rec ↑	F1 ↑	AUC ↑
Random Forest	0.971	0.960	0.891	0.925	0.996
SVM-RBF	**0.979**	0.956	**0.937**	**0.946**	0.996
Grad. Boosting	0.974	**0.967**	0.902	0.934	**0.996**
Top-39 MI Filter (39 ft.)	0.965	0.922	0.900	0.911	0.993
LLM Agent (40 ft.)	0.965	0.924	0.898	0.911	0.993

All methods exceed 96.4% accuracy and 0.992 AUC, confirming the dataset's high discriminability. SVM-RBF achieves the highest accuracy (97.9%), F1 (0.946), and recall (93.7%, the highest among all methods), missing the fewest seizure events. Gradient Boosting achieves the highest precision (96.7%) and AUC (0.996), indicating low false-positive rate at the cost of slightly lower recall. Random Forest balances precision (96.0%) and recall (89.1%), with competitive AUC (0.996). The LLM Agent isolates 40 features, dropping roughly three-quarters of the input space, and still preserves strong predictive power with only a minor metric drop.

The Top-39 MI Filter, evaluated with the identical Random Forest classifier, attains comparable results from 39 features selected by mutual information alone. The LLM's chosen set is a strict superset of these 39 features, adding only X61; the overlap is therefore 39/40 (97.5%). Across Table 1's metrics the two methods differ by at most 0.002 on precision and recall and are identical to three decimals on accuracy, F1, and AUC. The LLM's marginal contribution beyond a univariate MI ranking at this scale is thus not statistically meaningful on this benchmark; we treat this as the central empirical finding and discuss its implications in Section 7.

Clinically, the LLM agent's 89.8% recall is below the full-feature baselines, reflecting the cost of dimensionality reduction; acceptability is deployment-specific (screening tolerates lower recall, ICU monitoring demands maximal sensitivity, see Section 7.4).

6.2 Confusion Matrix Analysis

Figure 3 presents the confusion matrices for all methods.

SVM-RBF has 29 false negatives (FN) and 20 false positives (FP), the best sensitivity. The LLM agent has 47 FN and 34 FP, a modest increase but a 10.2% false-negative rate on the seizure class. The Top-39 MI Filter has 46 FN and 35 FP, comparable to the agent. Gradient Boosting has the fewest FP (14) but 45 FN, consistent with its high-precision profile.

6.3 ROC Curve Analysis

Figure 4 shows the receiver operating characteristic (ROC) curves for all methods.

All five ROC curves are nearly indistinguishable, hugging the upper-left corner. AUC ranges from 0.993 (Top-39 MI Filter) to 0.996 (Gradient Boosting), a 0.004 spread, so the reduced-feature methods preserve nearly all ranking quality of the full-feature models.

6.4 Feature Selection Analysis

The LLM agent selected 40 features from the 178 available. Figure 5 shows the RF feature importances across all 178 features, providing context for the agent's selection.

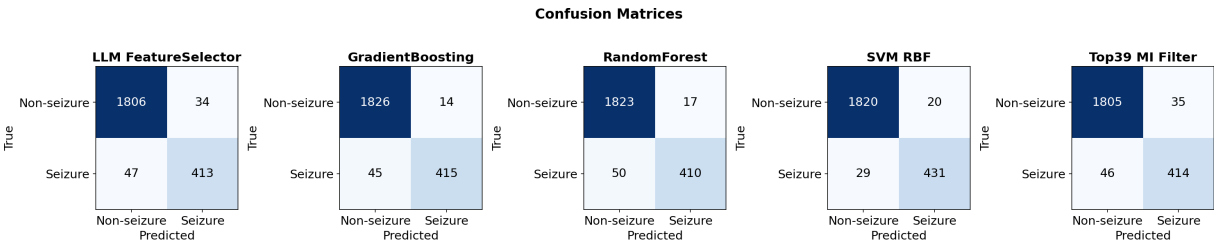

Figure 3: Confusion matrices on the test set for all five methods.

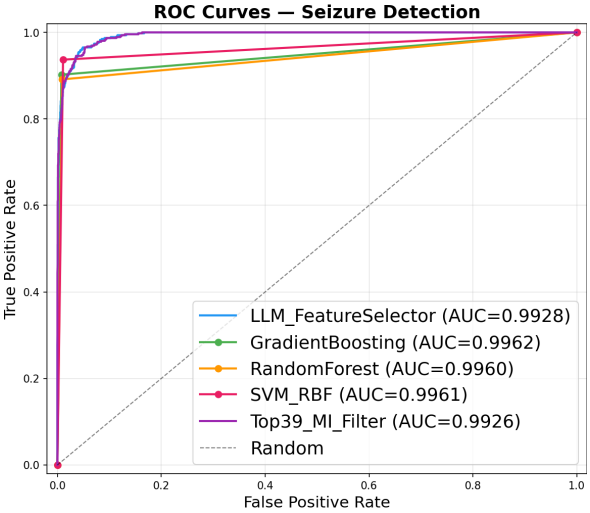

Figure 4: All methods' ROC curves achieve AUC $>$ 0.992.

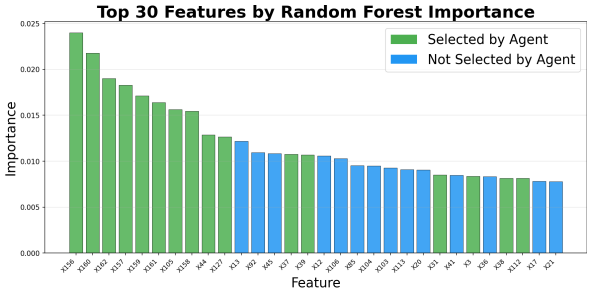

Figure 5: Random Forest feature importances (mean decrease in impurity) for all 178 features.

The five highest-MI features in the LLM's selection are X44, X172, X2, X160, and X39, all with MI above 0.199. The 40 selected features span the full EEG segment (X2 to X174), indicating the LLM captured signal dynamics across the whole recording window rather than concentrating on one region. Figure 6 visualizes this spread.

As noted earlier, the agent's chosen 40-feature subset perfectly encompasses the Top-39 MI Filter selections, supplementing them with only X61. This near-total alignment is explored structurally in Section 7.

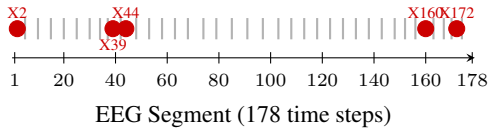

Figure 6: Temporal distribution of the 40 LLM-selected features across the 178-step EEG segment. Red circles mark the five highest-MI features; gray ticks mark the remaining selected features. The selection spans the full recording window.

6.5 Agent Iteration Behavior

Figure 7 and Table 2 present the full performance profile and subset sizes of the LLM agent across the 5 iterations.

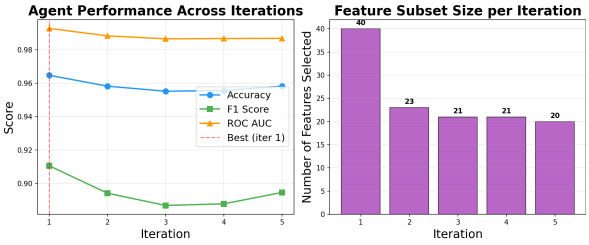

Figure 7: Full performance profile of the LLM agent across 5 iterations.

Table 2: Per-iteration agent outputs. All evaluation metrics are listed for each iteration.

Iter.	T	#Feat. ↓	Acc ↑	F1 ↑	AUC ↑
1	0.3	40	**0.965**	**0.911**	**0.993**
2	0.7	23	0.958	0.894	0.988
3	0.7	21	0.955	0.887	0.987
4	0.7	21	0.956	0.888	0.987
5	0.7	**20**	0.958	0.895	0.987

The temperature schedule and feature-level feedback produced genuinely different subsets across iterations, with no diversity fallback triggered. The best selection was iteration 1 (T=0.3, F1 0.911, 40 features); higher-temperature iterations (T=0.7) selected 20–23 features and underperformed by an F1 range of 0.024 (0.887–0.911). Both regimes

deviated from the prompted 30-feature target, indicating loose length-constraint adherence at this scale. Iteration 5 reached F1 0.895 with only 20 features, slightly above iterations 3–4 (21 features), so subset composition affects outcomes beyond raw count.

6.6 Performance Comparison Overview

Figure 8 compares all methods across the five metrics.

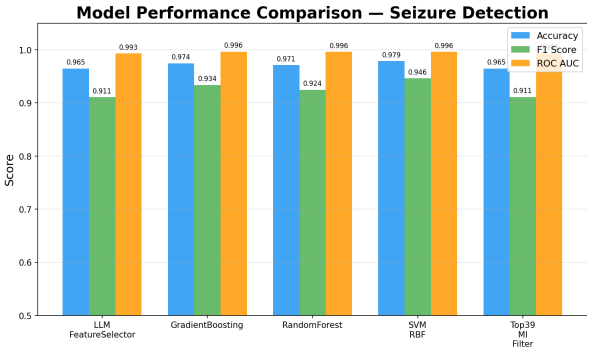

Figure 8: Bar chart comparing Accuracy, F1, and AUC across all five methods.

All methods are tightly clustered on AUC and accuracy; the LLM agent and Top-39 MI Filter perform nearly identically, both slightly below the full-feature baselines, with the gap most visible on precision and recall.

7 Discussion

7.1 Accuracy–Interpretability Trade-off

The LLM-driven pipeline yields competitive detection metrics with a fraction of the features, but this must be qualified: the same compact subset is achievable here by a statistical MI filter, so the interpretability gain reported is best attributed to dimensionality reduction rather than to the LLM. Within that caveat, a small feature set is practically useful in settings where model decisions must be auditable, since a clinician can inspect a concise list of waveform amplitudes against known electrophysiological signatures, whereas auditing all 178 features is impractical at run time. The marginal accuracy drop may be acceptable in screening or outpatient contexts, but is harder to justify in intensive-care monitoring where false-negative costs dominate (Section 7.4).

7.2 LLM Reasoning Capabilities and Limitations

Qwen2.5-1.5B-Instruct (Qwen Team, 2025) reliably parses statistical tables, ranks features by MI and F-score, and emits well-formatted JSON, showing a small LLM can serve as a functional component given a clear, structured prompt. However, four behavioral observations constrain its practical value at this scale (each consolidated in the Limitations of Section 8). First, instruction adherence is weak: the model returned 40 features at low temperature and 20–23 at higher temperatures despite an explicit 30-feature request. Second, the near-complete overlap (39/40, 97.5%) with the top-39 MI features is consistent with the model disproportionately weighting MI, which is presented both as a tabulated value and as the row sort key. This interpretation is only suggested by the overlap; without the no-MI or shuffled-MI ablations in Section 8 we cannot rule out that the LLM rediscovered the MI ranking from the other three columns. Third, iteration did not improve the initial selection (best F1 stays at iteration 1) but did not degrade it either, with F1 spanning only 0.024; we call this robust but non-improving. Fourth, the model produced no chain-of-thought rationale (Wei et al., 2022), because the prompt restricts the output to a JSON list, which is a prompt-design choice rather than a backbone limitation.

7.3 Comparing Statistical Feature Selection

The Top-39 MI Filter, evaluated with the identical Random Forest and split, matched the agent's headline metrics to three decimals on accuracy, F1, and AUC, with at most a 0.002 difference on precision and recall. The equivalence derives directly from the model's selections (39 of 40 features are the top-39 MI features). Because the prompt foregrounds MI both positionally and informationally, the subset can plausibly be reproduced by a copy-the-top-ranked-rows heuristic. Temperature variation does not control for this confound, since temperature affects stochasticity rather than which input cues the model attends to. The cleanest controls (deterministic decoding $T{=}0$, a no-MI or shuffled-MI prompt, and per-iteration quantification of deviation from the rolling top-k MI list) are enumerated as required follow-ups in Section 8. The equivalence still has value as an empirical upper bound on purely MI-driven filtration at a 40-feature budget, and the agentic framework retains structural

advantages, since it can readily incorporate natural-language instructions (e.g., "prefer early temporal features") and be paired with more capable LLMs without architectural changes.

7.4 Comparing Deep Learning Baselines

Recent end-to-end deep models trained on the raw EEG of this benchmark report 98–99%+ accuracy; for example, Guhdar et al. (Guhdar et al., 2025) report a 1D-CNN with multi-head attention surpassing 99%. Our best classical baseline (SVM-RBF, 97.9%) and our LLM-guided 40-feature subset (96.5%) sit below this deep-learning state of the art. We do not claim parity. Instead, the contribution is a small, explicitly enumerated, human-auditable feature subset that exposes which time-step amplitudes drive the decision. End-to-end CNN/transformer detectors offer higher accuracy and recall but operate on hundreds of millions of opaque weights over the raw waveform, which complicates the post-hoc audit our pipeline targets. This trade-off is unfavorable in high-acuity settings (e.g., ICU monitoring); we revisit this in the limitations.

7.5 Claim, Caveat, and Path Forward

Interpretable rationales are arguably the strongest motivation for an LLM in a feature-selection loop, and we acknowledge that this paper's interpretability claim rests on subset size rather than on model-generated narrative. The current prompt (Appendix D) restricts the output to a JSON list, which is a prompt-design choice, not a backbone limitation. A revised prompt requiring per-feature justifications, or an explicit chain-of-thought trace (Wei et al., 2022) preceding the JSON list, would yield qualitative material amenable to neurologist inspection. We have not run that experiment here, and we list eliciting and evaluating such rationales as a primary direction for future work in Section 8.

8 Conclusion

We presented an agentic feature-selection framework for EEG seizure detection in which a small instruction-tuned LLM (Qwen2.5-1.5B-Instruct) iteratively reduces a 178-dimensional input over five statistical measures. On this benchmark the agent attained 96.5% accuracy and 0.911 F1 with 40 features (a 77.5% reduction), versus 97.9% accuracy and 0.946 F1 for the strongest full-feature baseline (SVM-RBF). The headline finding is a negative one: 39 of the agent's 40 features are exactly the top-39 MI features, and a deterministic Top-39 MI filter evaluated by the same Random Forest classifier matches the agent's downstream metrics. At the 1.5B-parameter scale, with MI presented as both a tabulated value and the row sort key, the model behaves close to a copy-the-top-ranked-rows heuristic. We frame this as an empirical baseline that future, more capable LLM-FS systems must beat to justify their added complexity.

Limitations. We list the following limitations so the contribution is not overstated. (L1) MI is presented both as a numeric column and as the row sort key, and we did not run an ablation withholding or shuffling MI, so the agent's behavior cannot be cleanly separated from a univariate MI ranker. (L2) All results are on one saturated benchmark where multiple methods already exceed 96% accuracy, so generalization to multi-channel, longer, or noisier recordings is unsupported here. (L3) Selected features are evaluated only with Random Forest, leaving cross-classifier transfer (notably to SVM-RBF) untested. (L4) The JSON-only output precludes per-feature rationales, so the interpretability claim rests on subset size rather than model narrative. (L5) The model did not respect the prompted "exactly 30 features" constraint (returning 20–40 across iterations). (L6) Recent end-to-end deep models report 98–99%+ accuracy on the same dataset (Guhdar et al., 2025); the recall drop is clinically non-trivial. (L7) Larger LLMs and domain-specialized medical LLMs were not evaluated. (L8) Headline numbers use a single fixed seed, with no variance reported across seeds.

Future Work. The most informative follow-ups are: (1) an MI ablation that removes or shuffles the MI column and uses deterministic decoding ($T{=}0$); (2) per-iteration quantification of how often the LLM's selection deviates from the rolling top-k MI list; (3) cross-classifier transfer of the agent's 40-feature subset to SVM-RBF and Gradient Boosting, with the same reported for the Top-k MI baseline; (4) multi-dataset generalization on CHB-MIT (Guttag, 2010), Siena (Detti, 2020), and EPILEPSIAE (Ihle et al., 2012); (5) scaling to 7B–70B LLMs and to domain-specialized medical LLMs to test for genuine cross-statistic synthesis; (6) prompts that elicit per-feature rationales or full chain-of-thought (Wei et al., 2022) for clinically auditable justifications; (7) recall-targeted refinement that feeds false-negative patterns back into the next iteration; and (8) multi-seed reporting with confidence intervals.

Appendix

A Experimental Details

All experiments were executed on an NVIDIA RTX 5060 GPU and an Intel Core processor. Software dependencies include Python 3.12, scikit-learn 1.4, and numpy. Classification endpoints were fully self-contained using a fixed random seed (42) to guarantee strict reproducibility across training/test splits, model initializations, and evaluation metrics. In training the baselines, standard hyperparameter selections were employed (e.g., standard ensemble counts for Gradient Boosting and Random Forest are set to 200, max depth set at 20 for RF and 5 for GB). The total compute time for agent iterations and baseline extractions took approximately several minutes per run, owing to the lightweight dataset properties.

B Complete Feature List

The LLM-guided agent selected a total subset of 40 features out of the 178 initial timeline points. The complete list of features elected by the best-performing iteration ($k = 1$) is given below.

- **Overlap with Top-39 MI Filter (39 features):** X1, X2, X3, X4, X14, X16, X31, X37, X38, X39, X44, X47, X52, X53, X67, X68, X77, X90, X91, X105, X111, X112, X124, X126, X127, X128, X129, X141, X156, X157, X158, X159, X160, X161, X162, X166, X167, X172, X174.
- **Unique to the LLM agent (1 feature):** X61.

C Per-Iteration Analysis

Over the 5 distinct interaction rounds, the agent successfully submitted distinct feature groupings, heavily influenced by temperature schedules and dynamic iteration histories.

- **Iteration 1 ($T = 0.3$):** 40 features. Reached an F1-score of 0.9107 and Accuracy of 96.48%. Validated as the top-performing configuration.
- **Iteration 2 ($T = 0.7$):** 23 features. Performance shifted down slightly to F1 of 0.8943.
- **Iteration 3 ($T = 0.7$):** 21 features. Showed further contraction prioritizing precision (Accuracy=95.52%, F1=0.8869).
- **Iteration 4 ($T = 0.7$):** 21 features. Stable subset retention (Accuracy=95.57%, F1=0.8879).
- **Iteration 5 ($T = 0.7$):** 20 features. Modest upward recovery reaching an F1 of 0.8947.

No deterministic fallback triggers were fired; each output strictly obeyed structural formatting requisites (i.e., valid JSON array), although the specific 30-feature length constraint was loosely interpreted by the model.

D LLM Prompt Templates

To ensure full reproducibility of the agentic feature selection process, we provide the exact text of the prompts supplied to the Large Language Model. The prompt architecture consists of a static system instruction, a dynamic statistical table, and an adaptive feedback mechanism that depends on the current iteration.

D.1 Initial Iteration Prompt

In the first iteration ($k = 1$), the agent is provided solely with the statistical summary of the features and is instructed to output an initial feature subset. The exact prompt template is as follows, where `{top_k}` is typically 30, and the tabular data is populated dynamically:

```
You are a feature selection agent for EEG seizure detection
(binary: seizure vs non-seizure).
Below are statistics for the top {top_k} features out of
178 total (X1-X178).

Feature    MI        Corr      RF_Imp    F_Score
--------------------------------------------------
[Dynamically generated statistical tabular data]

Select EXACTLY 30 features from X1-X178 for best seizure detection. Use the
    statistics above.
Output ONLY a JSON array of 30 feature names.
Example: ["X1","X2","X3",...,"X30"]
Your 30 features:
```

D.2 Refinement Iteration Prompt

For subsequent iterations ($k \geq 2$), the prompt is augmented with performance feedback from the preceding iteration's Random Forest evaluation. Notably, explicit mutation instructions are provided to encourage exploration and refinement based on empirical classification behavior:

```
You are a feature selection agent for EEG seizure detection
(binary: seizure vs non-seizure).
Below are statistics for the top {top_k} features out of
178 total (X1-X178).

Feature    MI        Corr      RF_Imp    F_Score
--------------------------------------------------
[Dynamically generated statistical tabular data]

Previous round: {num_prev} features, Accuracy={prev_acc:.4f}, F1={prev_f1:.4f}, AUC
    ={prev_auc:.4f}.
You previously selected: [{prev_feat_str}]. Top-5 most important features in that
    selection: {top5_str}
Bottom-5 least important features in that selection: {bot5_str}
You MUST select a DIFFERENT set of 30 features. Drop at least 5 features from your
    previous selection ideally the low-importance ones listed above and replace them
     with features NOT in your previous selection that have high mutual information
    or F-score from the table.

Select EXACTLY 30 features from X1-X178 for best seizure detection. Use the
    statistics above.
Output ONLY a JSON array of 30 feature names.
Example: ["X1","X2","X3",...,"X30"]
Your 30 features:
```

In instances where detailed importance feedback is unavailable, the mutation instruction gracefully defaults to a generic replacement directive: *"Try different features to improve F1. Add more features if too few, remove noisy ones if too many."* This structured prompt architecture reliably anchors the recursive reasoning loops described in Section 4.3.2.

Training Biomedical Retrievers From Large-Scale Citation Contexts

Xing David Wang and Duy Le Thanh and Ulf Leser
Humboldt-Universität zu Berlin
Department of Computer Science
{xing.david.wang,leser}@hu-berlin.de

Abstract

The MedCPT model has demonstrated that strong biomedical retrievers can be trained using proprietary PubMed search logs. In this work, we study whether freely available citation sentences are sufficient to train similarly effective models. We construct a large-scale training dataset of ~62 million citation sentence-abstract pairs extracted from PubMed Central. We train a lightweight BERT-based retriever-reranker model called CiteRec on this dataset and evaluate it across three benchmark settings: (a) the biomedical subset of BEIR for information retrieval, (b) SciRepEval for generalizable scientific document embeddings, and (c) CitancePlus, a new set of ~90 thousand citation sentence-abstract pairs for PubMed-scale citation recommendation.

We show that CiteRec performs competitively with MedCPT on the biomedical BEIR subset and outperforms it on SciRepEval. On CitancePlus, CiteRec achieves strong performance for citation recommendation over the full PubMed corpus, outperforming both MedCPT and a substantially larger Qwen3-Embedding-8B retriever.

1 Introduction

Dense retrievers have become increasingly effective in first-stage information retrieval (IR) as shown on several IR benchmarks (Thakur et al., 2021; Muennighoff et al., 2023; Enevoldsen et al., 2025). They also have been successfully adopted to the biomedical domain (Jin et al., 2023; Sinha et al., 2025). Dense retriever are trained using query-document relevance pairs, which can be obtained either from human-annotated datasets such as MS MARCO (Bajaj et al., 2016) or BioASQ (Tsatsaronis et al., 2015), or automatically mined pairs like search engine logs (Jin et al., 2023; Rekabsaz et al., 2021). Automatically mined relevance pairs are much easier to obtain, however, they may lack in quality compared to manually annotated pairs. Citation graphs and citation edges provide another potential source for automatically mining relevance pairs (Cohan et al., 2020; Medić and Snajder, 2020; Li et al., 2023), either using abstract-abstract, or citation sentences-abstract pairs. In the following, we call the sentence surrounding an in-text citation a "citance" (see examples in Table 1). These citances are attractive supervision signals because they often summarize or contextualize the cited work, representing potential queries answerable through the referenced document.

Among these sources, search logs have proven particularly effective in training dense retrievers. The MedCPT model (Jin et al., 2023) has demonstrated that strong biomedical retrievers can be trained using only PubMed search logs, highlighting the effectiveness of large-scale weak supervision but relying on data that is not publicly available. In this work, we study whether freely available citances alone can provide sufficient supervision to train similarly effective models for both citation recommendation and general biomedical information retrieval. Prior work leveraging citances as training data (Medić and Snajder, 2020; Gu et al., 2022) mainly focused their evaluation on the citation recommendation task. In contrast, we also evaluate their effectiveness for general biomedical retrieval. For training our model, we use the OPCitance dataset (Hsiao and Torvik, 2023) which is derived from all citances and their referenced PubMed IDs in PubMed Central full-text articles published until May 2019. After pre-processing the OPCitance dataset, our resulting dataset contains about 62 million citance-abstract pairs.

We train a lightweight BERT-based retriever-reranker model, CiteRec, on our dataset of citance-abstract pairs. Despite relying solely on freely available and partially noisy citation data, CiteRec achieves competitive performance with MedCPT on biomedical information retrieval in BEIR, outperforms it on general scientific embedding tasks

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 75–83

High-grade tumors and pre-operative urinary cytologypositive cases are more likely to have recurrence.	(Yamada et al., 2009)

Table 1: Example citation sentences (citances) and their referenced documents from our training dataset.

and achieves strong results on citation recommendation. Our contributions are summarized as follows:

- We train the CiteRec model, comprised of a BERT-based dense retriever and cross-encoder reranker, on a large corpus of over 60 million citance-abstract pairs collected from PubMed Central.
- We systematically evaluate performance on a diverse set of biomedical and scientific benchmarks: (a) the biomedical subset of BEIR for information retrieval, (b) SciRepEval for generalizable scientific document embeddings, and (c) CitancePlus, a new citation recommendation dataset mined from PubMed Central after the OPCitance cutoff date, complementing it with over 90 thousand unseen citance-abstract pairs .
- We show that a lightweight BERT-based retriever-reranker trained solely on citance–abstract pairs generalizes well across tasks. The model performs competitively with MedCPT on biomedical BEIR and outperforms it on SciRepEval. On CitancePlus citation recommendation, it outperforms both MedCPT as well as substantially larger decoder-based embedding models such as the Qwen3-Embedding-8B retriever.

Our results suggest that citation sentences alone provide a surprisingly strong supervision signal for learning biomedical document representations.

The rest of the paper is structured as follows: We give an overview of Related Work in Section 2 and describe our training set and our model design in Section 3. In Section 4, we show our evaluation setup and how to reproduce our experiments. We report our results in Section 5 and discuss ablation studies in Section 6 before concluding our work in Section 7.

2 Related Work

Scientific citations have been widely used as training data for generalizable document embedding models. Prior work such as SPECTER (Cohan et al., 2020) and SciNCL (Ostendorff et al., 2022) learn document representations from abstract–abstract citation pairs derived from the global citation graph. To keep only high-quality abstract pairs, (Liang et al., 2025) extend this approach by using the corresponding local citation sentence to filter out potentially noisy pairs before large language model training. In contrast to these approaches, our model directly trains on citance-abstract pairs instead of indirect abstract-abstract supervision.

Leveraging citances for citation recommendation has been introduced by He et al. (2010). Current models typically follow an IR workflow, consisting of a first-stage retriever before reranking the retriever results (Gu et al., 2022). Newer approaches (Medić and Snajder, 2020; Gu et al., 2022) have incorporated the article title and abstract to the query in addition to the citance for a richer flow of information. In our work, we want to examine how well such models perform not only on citation recommendation but also on general IR queries such as found in BEIR (Thakur et al., 2021). Thus, we stick to shorter, asymmetrical queries consisting of citances only.

Dense IR models are usually trained on large-scale annotated datasets such as MS Marco (Bajaj et al., 2016) and evaluated on annotated data as well, such as the BEIR (Thakur et al., 2021) and MTEB (Muennighoff et al., 2023) benchmarks. In the biomedical domain, however, annotated data is scarce motivating alternative sources. A key contri-

bution in this direction is MedCPT (Jin et al., 2023) which demonstrated that training biomedical retrievers solely on large-scale weak supervision data from PubMed search and click logs achieves strong performance on biomedical IR benchmarks. MedCPT establishes a strong baseline for biomedical retrieval using weak supervision, but relies on proprietary data. In contrast, we use citance-abstract pairs mined from PubMed Central full-text articles as a fully open alternative source of supervision, enabling large-scale training without privacy constraints.

Besides domain-specific fine-tuning, recent approaches (Li et al., 2023; Xiao et al., 2023; Zhang et al., 2025) have also explored scaling dense retrievers through larger models and larger training datasets. The gte model family (Li et al., 2023) employs a pre-training step by training first on automatically mined query-document pairs before fine-tuning on high-quality, manually annotated retrieval pairs. Among the pre-training data, they also employ a set of citance-abstract pairs from the S2ORC corpus (Lo et al., 2020) as auxiliary supervision signal. (Sinha et al., 2025) continue fine-tuning the gte models on pairs of document abstracts and synthetic queries targeting those. To assess how weak supervision from one source compares to these larger models, we also compare our approach against these embedding models.

In contrast to prior work, we investigate whether large-scale citance–abstract pairs alone are sufficient to train biomedical retrievers that generalize across both citation recommendation and general information retrieval tasks.

3 Methods

3.1 CiteRec Overview

We first explain our methodology to obtain biomedical citances before describing the two main components of our CiteRec model: (i) the lightweight dense retriever to quickly obtain an initial set of candidate documents and (ii) the cross-encoder reranker to refine the ranking of the candidates.

3.2 Training Data

For training, we use the OPCitance dataset created by Hsiao and Torvik (2023) who extracted all pairs of citances and referenced documents from PubMed Central until the cutoff date of May 2019. Compared to other full-text corpora such as S2ORC (Lo et al., 2020), OPCitance is solely focused on the biomedical domain. In our setup, citances function as queries while the title and abstract of references serve as the documents to be retrieved. We employ two steps for data pre-processing: First, we filter out all documents that were cited but were not assigned any valid PubMed ID as the reference. Secondly, we filter out citation contexts longer than 64 tokens discarding long queries (i) with potentially malformed or irrelevant context and (ii) to ensure that the reranker obtains sufficient document context (we allow up to 512 tokens for the combination of citation and reference document). After preprocessing, we retain roughly 62M citance-abstract pairs and show some example citance-abstract pairs in Table 1.

3.3 Retriever

For our CiteRec retriever, we train separate query and document encoders both initialized from a PubMedBERT-base model (Gu et al., 2021). We take the final hidden state of the [CLS] token as the respective query and document embeddings. For retriever training, we optimize a query-to-document loss function

$$\ell_i^{q2d} = -\log \frac{\sum_{k \in Pos(q_i)} sim(q_i, d_k)}{\sum_{m=1}^{|B|} sim(q_i, d_m)},$$

whereas $|B|$ denotes the batch size. q_i is a citance query, d_i its associated positive document and the similarity $sim(q, d)$ is implemented by the dot product of both embeddings. Extending the standard InfoNCE loss formulation (Oord et al., 2018), we allow multiple positive documents $d_k \in Pos(q_i)$ for a given query q_i. For negatives, we use other citation pairs in the same batch as in-batch negatives. However, instead of relying on batching random pairs together, we group citation pairs from the same full text into the same batch. This allows us to mine potentially more informative negatives as documents referenced by the same paper are more likely to be thematically related, hence acting as harder negatives than other, random documents.

Similarly to MedCPT, we also define a complementary document-to-query loss ℓ_i^{d2q} which models relevance of individual queries to a given document d_i. We combine both losses to a batch loss ℓ_B:

$$\ell_B = \frac{\alpha}{|B|} \sum_{1}^{|B|} w_i \ell_i^{q2d} + \frac{1-\alpha}{|B|} \sum_{1}^{|B|} w_i \ell_i^{d2q}$$

where the hyperparameter $\alpha = 0.8$ controls the influence of each individual loss term and the weight w_i models the importance of citing paper and cited references according to their citation counts. To normalize citation counts across fields, we use the Relative Citation Ratio rcr[1] (Hutchins et al., 2016) and set the weights $w_i = \log(1+rcr_i)$. The rcr value takes into account the year of a publication and its citation numbers relative to its field.

3.4 Reranker

For CiteRec reranker training, we initialize a cross-encoder from the PubMedBERT-base model (Gu et al., 2021). The cross-encoder optimizes the same InfoNCE loss ℓ_i^{q2d} as the retriever but uses random in-batch negatives as the reranker can leverage random negatives more effectively due to its cross-attention mechanism. It takes as input the sequence [CLS] q_i [SEP] d_i [SEP] with the query q_i, the document d_i and the special BERT tokens [CLS] and [SEP], and calculates the similarity score

$$sim(q, d) = W^T e([CLS]) + b$$

where e([CLS]) is the final hidden state embedding of the [CLS] token and $W^T \in \mathbb{R}^d, b \in \mathbb{R}$ are learnable weights. The reranker takes into account the top-100 documents returned by our retriever.

4 Experiments

4.1 Evaluation Datasets

We conduct our experiments on three diverse biomedical IR and document embedding benchmarks.

BEIR (Thakur et al., 2021) is a zero-shot information retrieval benchmark to assess the generalization capabilities of newly developed retrieval models. Similarly to (Jin et al., 2023), we evaluate our model on the same subset of five BEIR tasks as (Jin et al., 2023) which include TREC-COVID (Voorhees et al., 2021), containing questions related to the COVID-19 pandemic, NFCorpus (Boteva et al., 2016), questions regarding nutrition facts, BioASQ (Tsatsaronis et al., 2015), a general-purpose biomedical question answering dataset over the entirety of PubMed, SciFact (Wadden et al., 2020), retrieving supporting documents that verify scientific claims and SciDocs (Cohan et al., 2020), finding similar documents given the title and abstract of a paper.

SciRepEval (Singh et al., 2023) is aimed at assessing the quality of document embedding models and includes tasks besides retrieval/search, such as classification and regression. Exemplary classification tasks include assigning documents to a MeSH descriptor and to its field of study. Exemplary regression tasks include predicting the citation count and the year of a publication. SciRepEval distinguishes between tasks whose datasets were used during the training of their embedding models (in-train) and tasks that were not (out-of-train, none of our evaluated models were trained on any of the in-train datasets.).

Our third benchmark deals with the task of recommending references for given citation contexts from PubMed. For this, we create a new, independent test set called CitancePlus mined from PubMed Central full-text articles published after May 2019 to prevent overlaps with the OPCitance dataset used for our model training. To obtain query-document pairs, we randomly sampled 10,000 full texts published between June 2019 and June 2024 and for each of them, sampled up to 10 in-line citations as queries. We then extract all referenced PubMed articles of each citance as valid reference documents. The resulting dataset contains 32,000 query-document pairs in the development split and 93,000 pairs in the test split. We used the official PubMed baseline of 2025 as the document corpus (containing all PubMed abstracts until January 2025).

4.2 Baselines

We compare the results of our CiteRec model to several baselines: BM25 (Robertson and Zaragoza, 2009) is a lexical retriever serving as a strong baseline in IR tasks (Thakur et al., 2021). MedCPT (Jin et al., 2023) is the baseline closest to ours, training a dual bi-encoder setup with a separate query and document embedder initialized from PubMedBERT-base, while also training a cross-encoder reranker on top. While we exclusively train on freely available citance-abstract pairs, MedCPT exclusively trains on a large proprietary set of 255 M PubMed search logs containing pairs of user query and abstract[2].

[1]We download the most recent dump from March 2025 under https://nih.figshare.com/articles/dataset/iCite_Database_Snapshot_2025-03/28789178.

[2]We use the MedCPT models provided via Huggingface (https://huggingface.co/ncbi/MedCPT-Article-Encoder) which differ a bit from the results reported in the original paper.

SciNCL (Ostendorff et al., 2022) and SPECTER (Cohan et al., 2020) are document embedding models that both leverage the citation graph for training similar to our approach. Note that they are using abstract-abstract pairs instead of citances for training and thus have not been explicitly designed for short search queries.

The last group of baselines are retriever models trained on a much larger mixture of data including search logs, web links and manually annotated pairs of questions and answer documents: (i) BERT-based encoder models such as the gte family (Li et al., 2023) and bge (Xiao et al., 2023) have around 100 to 300 million model parameters resulting in a similar size as MedCPT and CiteRec but training on more diverse retrieval pairs; the gte models use around 800 million retrieval pairs during unsupervised pre-training and around three million high-quality pairs for additional fine-tuning, the bge models use a similar pipeline of pre-training and subsequent fine-tuning with around 200 million pairs. (ii) Decoder-only embedding models like Qwen3 (Zhang et al., 2025) are much larger in size with around 8 billion model parameters and trained on a carefully selected set of around 150 million retrieval pairs during pre-training and 12 million pairs during fine-tuning.

4.3 Implementation Details

We conducted training for the retriever on two NVIDIA A100 GPUs with a batch size of 128, gradient accumulation step size of 4, using bf16 precision, a cosine scheduler with a linear warm-up phase, and a target learning rate of 2e-6. We trained the model for one epoch resulting in a runtime of around four days. As cross-encoder reranker training converges much faster, we applied early stopping on the development set to find our best model there. We set the batch size for the reranker training to 1, the gradient accumulation step size to 32 and the target learning rate of 5e-6. The CitancePlus corpus, the CiteRec retriever, the CiteRec reranker and the accompanying code is available at under `https://github.com/WangXII/CiteRec`.

5 Results

In Table 2, we report the results of our CiteRec model and of the baselines on the subset of biomedical tasks in BEIR. As expected, even though the SciNCL model was trained on abstract-abstract citation links, it does not perform well on the biomedical BEIR subset except for SciDocs. Our CiteRec retriever is better suited for IR queries than SciNCL by learning from citance-abstract pairs instead.

Looking at individual subtasks and retriever-only models, our CiteRec retriever achieves particularly good results on the SciFact dataset with an NDCG@10 score of 0.765 outperforming all other first-stage retrievers. On average across all subtasks, our CiteRec retriever performs competitively against the MedCPT retriever (0.425 NDCG@10 compared to 0.431) showing that training on public citation data alone can match up to training on proprietary search logs. Adding a reranker on top of the CiteRec retriever improves retrieval performance on all examined datasets resulting in an average increase of around 5.3 percentage points (pp). However, here, bigger gaps are observed on the BioASQ and TREC-COVID datasets when compared to the corresponding MedCPT reranker indicating that real-world user queries might help more in reranker training for biomedical question answering tasks. Compared to the gte and bge models which trained on a richer mixture of (high-quality) data, the MedCPT and CiteRec retrievers trained only on one (noisy) source of data show lower performances. However, by adding the rerankers, both models close the gap with CiteRec achieving comparable performances and MedCPT even surpassing them.

When evaluating quality of document embeddings on the SciRepEval benchmark (see Table 3), we can see that our CiteRec retriever is able to outperform the MedCPT retriever by over 3.3 pp (also reflecting the more citation-focused subtasks of SciRepEval). As expected, the SPECTER and SciNCL models perform well on this task as they are designed to jointly optimize document abstract embeddings. SciNCL achieves an average score of 0.688 and SPECTER a score of 0.675 compared to 0.673 for CiteRec. Still, the bge-large model achieves the best results overall with a score of 0.694. CiteRec performs competitively overall with the models trained on a larger set of data, achieving the joint second best results on the In-Train part of SciRepEval together with gte-large (both 0.559).

Our last main experiment focuses on the CitancePlus dataset ranking relevant abstracts in PubMed given a local citation context. We present the results on CitancePlus in Table 4 measured by NDCG and MAP scores @10 and @100. We observe that BM25 is a strong baseline for this task outperforming neural models like gte-base and Med-

	Param Size	TREC-COVID	NFCorpus	BioASQ	SciFact	SciDocs	Avg
BM25	-	0.656	0.325	0.465	0.665	0.158	0.454

SciNCL	100 M	0.342	0.228	0.108	0.568	0.194	0.288
MedCPT	100 M	0.616	0.365	0.325	0.736	0.114	0.431
+ reranker	200 M	0.727	0.365	**0.498**	**0.793**	0.176	**0.512**
CiteRec (Ours)	100 M	0.601	0.299	0.314	0.765	0.148	0.425
+ reranker (Ours)	200 M	0.675	0.347	0.392	0.792	0.184	0.478

Table 2: Biomedical BEIR results measured by NDCG@10. Best results in each column in bold, second best underlined.

	In-Train	Out-of-Train	Avg
gte-large	0.559	0.720	0.683
bge-large	**0.575**	**0.736**	**0.694**
SPECTER	0.547	0.720	0.675
SciNCL	0.556	0.734	0.688
MedCPT	0.531	0.678	0.640
CiteRec (Ours)	0.559	0.713	0.673

Table 3: SciRepEval Results. Best results in each column in bold, second best underlined.

CPT across all metrics and gte-large in all but the NDCG@100 score (0.193 compared to 0.201). The MedCPT retriever struggles with the citation recommendation task only reaching an NDCG@10 of 0.097. Our CiteRec retriever model outperforms all other similarly sized retriever models on this task by more than 3 pp across all metrics, showing that the citation recommendation task benefits a lot from domain-specific finetuning.

We compare to the Qwen3 model only on the citation recommendation task as the gte and bge models have already proven to be challenging baselines on the biomedical BEIR and SciRepEval benchmarks and evaluating large decoder-based embedding models at PubMed scale is computationally expensive. On CitancePlus, the Qwen3-Embedding-8B model slightly outperforms our CiteRec first-stage retriever with an NDCG@10 score of 0.216 compared to 0.206. However, after adding the CiteRec reranker on top of the retriever, our overall CiteRec model even outperforms the Qwen3-Embedding-8B model by 2.4 pp in NDCG@10 score while being significantly more efficient in terms of parameter size and inference cost.

6 Discussion

In our first ablation study, we examine how retrieval performance of our CiteRec retriever changes when we modify our negative sampling from grouped batching of negatives from the same publication to random in-batch negatives and replacing the rcr values as individual weights for a document by the default value of 1. We report the corresponding results in Table 5. We observe that grouped batching improves NDCG@10 scores on both datasets, with the improvements being more pronounced on the CitancePlus dataset (0.206 vs 0.164) compared to the biomedical subset of BEIR (0.425 vs 0.412). This suggests that retriever training likely benefits from harder examples coming from the same documents whereas random negatives are easier and saturate model performance more quickly.

Our second ablation study examines the capabilities of our CiteRec models in a stricter setting: We constructed our original CitancePlus test dataset in such a way that no test query overlaps with any query encountered in the training set. However, the model might still have incorporated a slight bias toward documents already encountered in the OPCitance training data. To minimize such potential effects, we repeated the CitancePlus experiments in a stricter setting removing all citance-abstract pairs from the test dataset where the abstract document has already occurred at least once in the training dataset. We reduced the initial 93 thousand citance-abstract pairs to a subset of around 25 thousand after applying this filtering step.

Table 6 summarizes the results on the filtered test dataset. We see that the performance of BM25 increases on the filtered test dataset from 0.161 NDCG@10 to 0.185 NDCG@10. Our CiteRec

	Param Size	NDCG@10	NDCG@100	MAP@10	MAP@100

retriever decreases only minimally in NDCG@10, from 0.206 to 0.205, indicating at most a slight bias toward documents already seen in the OPCitance training data. The larger retriever models gte-large and Qwen3-Embedding-8B improve by 0.5 pp in NDCG@10 score. However, when adding our reranker model to the top-100 retrieved documents, overall NDCG@10 score improves again by 0.8 pp compared to the original test dataset indicating that any such bias is not as pronounced in the reranker model.

7 Conclusion

In this work, we introduced a biomedical retriever-reranker model trained on a large set of PubMed Central citation-abstract pairs. We have shown that the resulting model generalizes well on general biomedical IR benchmark such as the BEIR subset when compared to models of similar size and training data such as MedCPT and outperforms both these baselines as well as substantially larger state-of-the-art models (e.g., Qwen3-Embedding-8B) when compared on the in-domain citation recommendation task.

Limitations

Training on citance-abstract pairs is inherently noisy as citations do not always match what is written in the referenced texts and not all information referred to in a given context is fully included in the title and abstract of the referenced document (Sarol et al., 2024). We did not further investigate any methods to filter out high-quality citations from lower-quality ones.

We also limited our experiments to smaller BERT-based model (100M parameters) and did not

train on larger decoder-only retrievers due to limited computational resources. It remains unclear whether scaling to larger models would improve performance or lead to overfitting on the noisy training data.

Abstract

Standard clinical Natural Language Processing (NLP) benchmarks often yield inflated metrics by forcing deterministic classification on ambiguous instances, thereby obscuring the clinical risks of overconfident predictions. To bridge this gap, we propose a risk-aware hybrid selective classification framework, evaluated on early Human Immunodeficiency Virus suspicion identification in Spanish clinical notes. Our dual-verification approach explicitly decouples aleatoric uncertainty through Mondrian conformal prediction and epistemic uncertainty using a Multi-Centroid Mahalanobis Distance veto. Empirical evaluations reveal that standard uncertainty metrics and baseline classifiers are structurally insufficient for safe medical triage, suffering severe coverage collapse when forced to operate under strict reliability constraints. In contrast, by demanding that clinical narratives pass both probabilistic and geometric safeguards, the proposed framework successfully isolates a highly trustworthy operational domain. The obtained results show that explicit, decoupled uncertainty quantification is essential for translating biomedical NLP into responsible clinical practice.

1 Introduction

The early diagnosis of Human Immunodeficiency Virus (HIV) remains a critical public health challenge. While automated Natural Language Processing (NLP) systems offer a scalable mechanism to triage Electronic Health Records (EHRs) and allocate diagnostic resources by filtering out clear negative cases (Feller et al., 2018; Morales-Sánchez et al., 2024), their transition into clinical practice is hindered by rigid evaluation paradigms.

The prediction task identifies documented clinical suspicion of infection. The supervision signal reflects clinical suspicion evidenced in text rather than confirmed serological status. Since documentation varies in completeness and specificity, suspicion is a subjective, partially observable construct. Consequently, linguistic ambiguity and distributional heterogeneity are intrinsic properties of this problem. When standard deterministic classifiers are forced to make rigid binary decisions on such narratives, they routinely produce overconfident misclassifications, directly conflicting with the safety requirements of clinical medicine (Kelly et al., 2019; Guo et al., 2017).

To translate biomedical NLP research into responsible practice, AI systems must shift from forced classification to action-oriented selective screening via the classification with rejection paradigm. However, standard Uncertainty Quantification (UQ) methodologies, such as Bayesian approximations or deep ensembles, are structurally insufficient for highly imbalanced clinical text (Abdar et al., 2021). By relying solely on predictive entropy, they conflate distinct sources of risk, causing models to either indiscriminately defer true positive cases or unsafely automate complex, out-of-distribution (OOD) narratives.

To address standard uncertainty estimation vulnerabilities, we propose a post-hoc Hybrid Selective Screening Framework that decouples aleatoric and epistemic uncertainties. Our system enforces a dual-verification policy: it utilizes Mondrian Conformal Prediction (MCP) to manage probabilistic ambiguity and a Multi-Centroid Mahalanobis Distance (MCMD) veto within a spectrally normalized latent space to filter epistemic anomalies. This intersectional safeguard translates risky forced-binary predictions into safe, trinary triage recommendations.

The main contributions of this work are:

- **Hybrid Selective Screening Framework:** We develop a novel, dual-veto deferral system that explicitly combines conformal prediction for aleatoric ambiguity with a geometrically constrained feature space for epistemic

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 84–96
July 3-4, 2026 ©2026 Association for Computational Linguistics

anomaly detection. We show that the strict intersection of both safeguards is essential for safe clinical automation.

- **Subjective Construct Modeling in Spanish EHRs:** We formalize the extraction of early HIV clinical suspicion as a partially observable inference task, addressing the linguistic and epistemological challenges of clinical NLP in a resource-constrained, non-English environment.

- **Rigorous Clinical Validation:** Utilizing asymmetric, risk-aware clinical metrics (e.g., Custom Risk-Kappa, True Positive Deferral Rate), we empirically expose the operational failure of standard UQ algorithms on clinical data. We prove that our proposed hybrid policy significantly outperforms standard baseline UQ methods, maintaining robust calibration without sacrificing triage efficiency.

2 Related Work

Early HIV Prediction via NLP Historically, automated HIV risk assessment relied on structured EHR fields, which consistently underperform as stigmatized behavioral risks are rarely captured in standard coding (Feller et al., 2018). Consequently, research has pivoted toward NLP to extract nuanced indicators from unstructured narratives using contextual word embeddings (Morales-Sánchez et al., 2024; Sah et al., 2025). As these predictive architectures mature, there is a consensus that deterministic models require explicit reliability frameworks for safe clinical adoption (Ngema et al., 2026).

Reliability and Selective Classification The deployment of AI in high-stakes public health settings requires rigorous UQ (Abdar et al., 2021). Recent work has applied selective classification to clinical text, demonstrating that deep learning classifiers can achieve strict safety targets by abstaining from unreliable samples without the prohibitive computational burden of model retraining (Peluso et al., 2024; Garcia et al., 2026). However, standard UQ methodologies struggle with highly imbalanced clinical text because their reliance on predictive entropy conflates aleatoric and epistemic uncertainty (Ziletti and D'Ambrosi, 2026). In medical triage, this conflation is operationally fatal, leading to indiscriminate deferrals or unsafe automation (Toure and Stephens, 2026). Because safe clinical deployment demands models that explicitly know when to abstain (Machcha et al., 2025), there is a pressing need for hybrid architectures that decouple and independently bound these distinct predictive risks.

3 Material and Methods

3.1 Hybrid Selective Screening and Deferral Policy

We implement a post-hoc Dual-Verification Selective Classification that requires a text to pass two distinct uncertainty checks before permitting an automated triage decision.

Aleatoric Control via Mondrian Conformal Prediction (MCP) To manage aleatoric uncertainty arising from inherent ambiguity in the clinical narratives, we employ MCP (Boström et al., 2021). First, we apply Temperature Scaling (Guo et al., 2017) to the validation logits to minimize the Negative Log Likelihood (NLL) and mitigate overconfidence. Subsequently, MCP generates a prediction set $\Gamma^{\alpha}(x) \subseteq \{0, 1\}$ containing the true label with probability $1 - \alpha$. We use the set's cardinality to indicate ambiguity: sets containing multiple classes ($|\Gamma^{\alpha}(x)| > 1$) or zero classes ($|\Gamma^{\alpha}(x)| = 0$) signify insufficient or contradictory evidence at the target risk tolerance α, necessitating a deferral.

Epistemic Control via Geometric Veto Deep neural networks frequently suffer from the phenomenon of assigning high softmax probabilities to anomalous, OOD inputs. To mitigate this, we integrate a geometric veto mechanism that operates directly within the L_2-normalized latent feature space. Because clinical "suspicion" encompasses highly heterogeneous patient presentations—ranging from varying risk behaviors to sparse opportunistic infections—assuming a unimodal distribution for the feature space leads to artificially inflated variances. To accurately accommodate this phenotypic diversity without risking the severe overparameterization of local density estimation in a high-dimensional space, we model the clinical narratives using a MCMD framework (effectively a tied-covariance Gaussian Mixture).

For each class c, the optimal number of local centroids, K_c, is dynamically determined via k-means clustering by identifying the smallest K where the relative inertia gain falls below a predetermined 0.05 threshold, subject to a minimum cluster size constraint. Rather than estimating independent, unstable covariance matrices for every local clus-

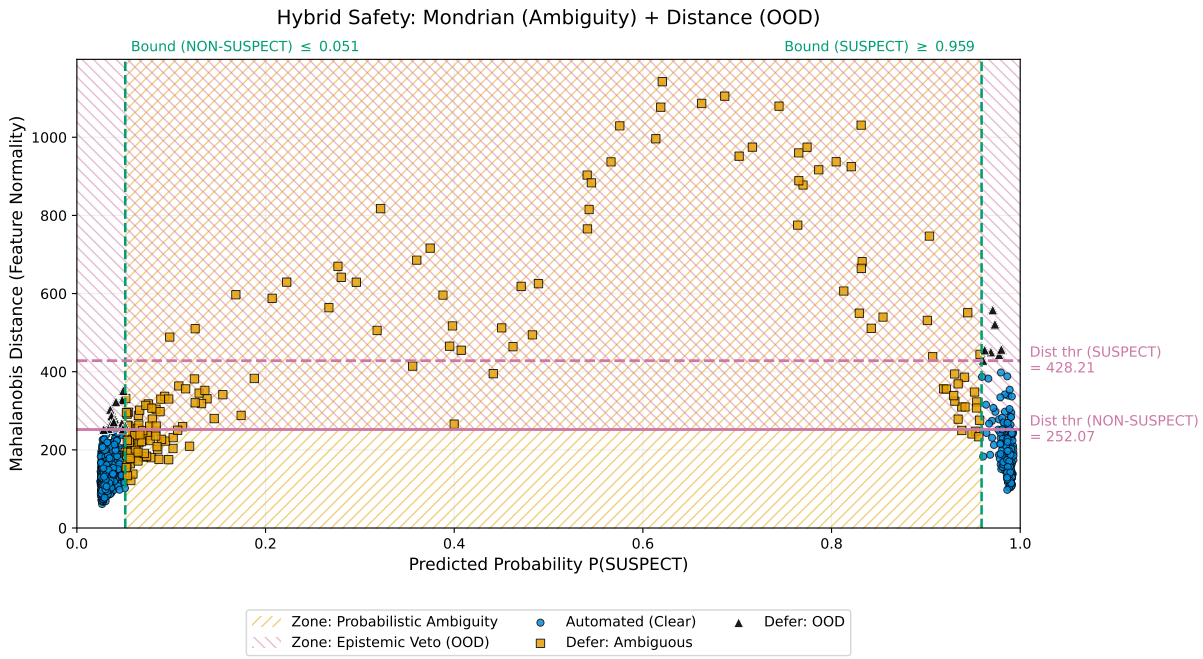

Figure 1: Hybrid Selective Screening Policy in the spectrally normalized latent space. Soft teal vertical dashed lines denote MCP boundaries for probabilistic ambiguity, mapped to the diagonally hatched zone. Reddish-purple horizontal lines indicate Mahalanobis distance thresholds (τ_{dist}) for the epistemic veto, mapped to the cross-hatched zone. Automated 'Clear' cases are shown as medium blue circles, probabilistically ambiguous deferrals as golden orange squares, and epistemic OOD deferrals as solid black triangles.

ter, we assume a globally shared noise structure. By pooling the residuals of all samples to their assigned centroids, a single, robust global precision matrix Σ^{-1} is fitted across all classes using Oracle Approximating Shrinkage (OAS).

During inference, the epistemic uncertainty of a sample x is quantified as the minimum Mahalanobis distance between its embedding $f(x)$ and any centroid $\mu_{\hat{y},k}$ associated with its predicted class $\hat{y}$:

$$d_M(x, \hat{y}) = \min_{k \in \{1 \dots K_{\hat{y}}\}} \sqrt{r_{\hat{y},k}^\top \Sigma^{-1} r_{\hat{y},k}}$$

where $r_{\hat{y},k} = f(x) - \mu_{\hat{y},k}$ represents the residual vector between the sample embedding and the k-th centroid.

To account for the asymmetric variance between routine (Class 0) and highly heterogeneous suspected cases (Class 1), we establish class-specific distance thresholds $\tau_{dist}^{(\hat{y})}$, calibrated to the 99th percentile of intra-class distances from correctly classified validation samples. Inputs exceeding this boundary are flagged as geometrically anomalous. This mechanism effectively vetoes overconfident OOD predictions without disproportionately deferring the diverse minority class.

These specific thresholds were not chosen arbitrarily; a post-hoc grid search over the validation folds confirmed that the 0.05 inertia and 99th percentile boundaries empirically maximized the Custom Risk-Kappa, optimally balancing OOD anomaly detection with minority class variance (see Appendix A for the full sensitivity analysis).

Global Decision Logic The final deferral policy $D(x)$ enforces a strict intersection of both safeguards:

$$D(x) = \begin{cases} \hat{y} & \text{if } |\Gamma^\alpha(x)| = 1 \\ & \text{AND } d_M(x, \hat{y}) \leq \tau_{dist}^{(\hat{y})} \\ \perp & \text{otherwise} \end{cases}$$

A complete visual representation of this dual-verification logic is provided in Figure 1.

3.2 Data

The study utilizes a proprietary cohort of Spanish EHRs sourced from Hospital Universitario Fundación Alcorcón (HUFA, Madrid), comprising real-world clinical notes. The total collection comprises 13,642 patients with notes between 1998 and 2023 from different medical specialities. All data was anonymized at the source by the hospital in strict compliance with the GDPR and Spanish

Metric	Total	Train (Avg.)	Validation (Avg.)	Test (Held-out)
Total Patients	13,642	11,046	1,223	1,373
Total Suspects	**2,072**	**1,671**	**183**	**218**
HIV+ / HIV-	*172 / 1,900*	*136 / 1,535*	*14 / 169*	*22 / 196*
Non-Suspects	11,570	9,375	1,040	1,155
Class Ratio (Suspect : Non-Suspect)	1:5.5	1:5.6	1:5.7	1:5.3
Total Clinical Notes	63,802	51,642	5,710	6,450
Avg. Notes / Patient	-	4.68	4.67	4.70
Tokens / Patient (Mean / Max)	-	409 / 8,621	407 / 8,033	427 / 5,255
Avg. Tokens / Note (Susp. / Non-Susp.)	-	∼126 / ∼79	∼118 / ∼79	∼127 / ∼81

Table 1: Dataset total and partitioning with key characteristics. Training and validation figures represent the average across the 10-fold cross-validation splits.

LOPDGDD regulations by replacing 29 different entity types (including age and gender) with placeholder tags.

Rather than relying on manual annotation, ground truth was established empirically based on documented physician behavior: the suspect cohort comprises patients who had a requested HIV serology (both positive and negative outcomes). EuroTEST (EuroTEST, 2016) indicator conditions were then applied as a secondary filter to isolate genuine clinical suspicion, excluding cases where serology was requested as a routine administrative procedure. Because the threshold for ordering a test varies among physicians, this supervisory signal inherently captures the subjective, partially observable nature of real-world clinical suspicion, further motivating our selective screening paradigm. However, because clinical documentation practices and physician thresholds for ordering serology vary substantially across institutions, it is important to note that the geometric thresholds calibrated on this single-center cohort would likely require recalibration prior to external deployment.

To prevent explicit diagnostic leakage and force the model to learn the implicit digital phenotype of early HIV risk, the corpus was aggressively sanitized by removing all explicit HIV acronyms and direct testing recommendations. The non-suspect cohort included patients with no history of such requests. The data was partitioned using 10-fold cross-validation alongside a held-out test set (Table 1).

3.3 Model Architecture

3.3.1 Attention-MIL Architecture

To handle EHR structural variability (Table 1) without discarding longitudinal context, we frame HIV suspicion detection as a Multiple Instance Learning (MIL) problem, adapting Ilse et al. (2018).

In this approach, each patient's record is treated as a 'bag' of overlapping text sequences. Documents are partitioned using a sliding window strategy (up to 64 chunks of 384 tokens) and independently encoded using the Spanish biomedical RoBERTa model `PlanTL-GOB-ES/bsc-bio-ehr-es`[1] (Carrino et al., 2022). To aggregate these chunks into a unified document representation $\mathbf{z}_{doc}$, we employ a gated attention pooling mechanism. The network assigns a learned scalar weight to each chunk via a gated combination of hyperbolic tangent and sigmoid activations, ensuring that highly suspicious text snippets dominate the final document-level embedding before it is passed to the UQ evaluation.

3.3.2 Training for Reliable Uncertainty

To address the class imbalance while maintaining calibration, we contrast two architectures:

Standard MIL: Optimized using a Label-Smoothed Focal Loss (Lin et al., 2017) to down-weight easy negatives, coupled with Regularized Dropout (R-Drop) (Liang et al., 2021) to enforce KL-divergence consistency between forward passes, thereby smoothing the decision boundary.

MD-SN MIL: While Focal Loss improves raw classification, it can distort the underlying probabilities required for aleatoric UQ. Therefore, we utilize the MD-SN (Mahalanobis Distance + Spectral Normalization) architecture proposed by (Vazhentsev et al., 2022), coupled with Logit Adjustment (Menon et al., 2021). This technique adds logarithmic class priors directly to the raw logits, inherently pushing the decision boundary away from the minority class without sacrificing probabilistic integrity. To enable the epistemic geometric

[1] PlanTL-GOB-ES/bsc-bio-ehr-es - Hugginface. Accessed: [2026-02-26]

veto, SN is applied to the dense layers of the MIL head, bounding the Lipschitz constant to ensure a bi-Lipschitz smooth feature space.

3.4 Uncertainty Estimation Backends

To demonstrate that our selective screening framework is adaptable and to evaluate the trade-off between computational cost and empirical safety, we extract predictive uncertainty estimates using three established methodologies:

Standard UQ Backends We use Monte Carlo (MC) Dropout (Gal and Ghahramani, 2016) as a baseline Bayesian approximation, and Cross-Validation (CV) Deep Ensembles (Lakshminarayanan et al., 2017) as our empirical gold standard. The first executes T stochastic forward passes during inference to compute predictive entropy as an epistemic uncertainty threshold. The latter aggregates predictions from K models trained on distinct CV folds. Crucially, we utilize an Out-Of-Fold (OOF) calibration strategy to fit deferral thresholds strictly on unseen validation folds, preventing optimistic bias.

Mahalanobis Distance with Spectral Normalization (MD-SN) To circumvent the computational overhead of (T times) sampling or (O(K) latency and storage costs of 10 models) ensembling, we evaluate deterministic, single-pass UQ using the MD-SN architecture (Vazhentsev et al., 2022). Unlike entropy-based methods that rely on softmax dispersion, MD-SN measures uncertainty geometrically. By calculating the Mahalanobis distance between a test embedding and the fitted class centroids in a bi-Lipschitz smooth feature space, texts that are semantically atypical or OOD yield proportionally large geometric distances.

3.5 Evaluation Framework and Clinical Metrics

Standard NLP evaluation frameworks often fail to capture the asymmetric risks inherent in medical triage. For example, standard metrics like AUROC can be highly misleading on datasets with severe class imbalance, while the standard F_1-score treats false positives and false negatives equally. To accurately assess both the discriminative power and the safety of our hybrid selective screening policy, we employ a specialized suite of clinical and probabilistic metrics.

Therefore, we evaluate: (1) Discriminative Safety via F_2-score, penalizing false negatives (misclassifying a suspect patient as non-suspect) more heavily than false positives; (2) Probabilistic Reliability via Expected Calibration Error (ECE) (Guo et al., 2017); (3) Triage Efficiency via Coverage (fraction of automated records) and True Positive Deferral Rate (TPDR), defined as the proportion of actual suspect cases referred to a physician; and (4) Uncertainty Ranking via the Area Under the Risk-Coverage curve (AURC).

Finally, to evaluate the final trinary triage decision (Clear Negative, Defer, Clear Positive) against the binary ground truth, we compute a (5) Custom Risk-Kappa score. This adaptation of Cohen's Weighted Kappa applies a strictly asymmetric penalty matrix W derived from the established preventative medicine paradigm for infectious diseases. In early HIV detection, the epidemiological cost of a missed diagnosis—delaying ART and risking transmission—far outweighs an unnecessary routine test. To formalize this, the maximum penalty of 1.0 is strictly reserved for the catastrophic failure of automating a False Negative (FN) ($W_{FN} = 1.0$). Conversely, False Positive automations ($W_{FP} = 0.5$) and the deferral of True Positive cases ($W_{def_pos} = 0.5$) incur moderate penalties, reflecting the lower clinical cost of resource utilization and the failure to automate complex cases. Safely deferring a True Negative carries the lowest penalty ($W_{def_neg} = 0.25$).

$$W = \begin{bmatrix} 0.0 & 0.5 & 1.0 \\ 0.5 & 0.25 & 0.0 \end{bmatrix}$$

A complete sensitivity analysis of these penalty weights across diverse simulated health-economic realities is provided in Appendix B.

4 Results and Discussion

To evaluate the clinical viability of the proposed selective screening framework, we benchmarked the two architectures explained in Section 3.3.2. Also, to isolate the value of our specialized architecture, we introduce a standard transformer baseline using only the base encoder (`PlanTL-GOB-ES/bsc-bio-ehr-es`).

The architectures were systematically evaluated across multiple UQ algorithms and varying risk tolerances (α). To rigorously validate statistical stability, the exhaustive evaluation—including 95% Confidence Intervals (CI) calculated via empirical bootstrap resampling ($n = 1,000$ iterations)—is provided in Appendix D.

Architecture	UQ Algorithm	Discriminative ($F_2 \uparrow$)		Calibration (ECE $\downarrow$)		Triage Efficiency & Safety			
		Binary	Clear	Binary	Clear	Coverage $\uparrow$	TPDR $\downarrow$	AURC $\downarrow$	Risk-Kappa $\uparrow$
Enc. Baseline	CV Ensemble	0.769	0.973	0.077	0.031	47.8%	50.5%	0.026	0.377
Standard MIL	MC Dropout	0.835	0.975	0.033	0.011	68.8%	34.2%	0.007	0.579
	CV Ensemble	0.823	0.979	**0.018**	**0.009**	63.5%	**29.6%**	0.007	0.546
MD-SN MIL	MC Dropout	**0.839**	0.973	0.044	0.031	70.2%	30.6%	0.011	**0.602**
	MD-SN	0.813	0.966	0.028	0.026	**70.7%**	31.9%	0.012	0.601
	CV Ensemble	0.821	**0.982**	0.022	0.021	67.7%	33.2%	**0.006**	0.576

Table 2: Discriminative performance, calibration, and triage efficiency under strict safety constraints ($\alpha = 0.01$). Metrics evaluate the forced deterministic output (Binary) and the automated subset after deferral (Clear). **Note:** Full results, including 95% bootstrap Confidence Intervals, are detailed in Appendix D.

4.1 Forced Binary Classification

Table 2 presents a head-to-head comparison under strict safety constraints ($\alpha = 0.01$). As detailed in the "Binary" columns, evaluating the cohort under a forced-classification paradigm reveals the exact vulnerability of standard NLP benchmarks. For instance, utilizing MC Dropout on the MD-SN architecture yields the highest absolute Binary F_2 score (0.839), yet this masks severely degraded calibration (ECE: 0.044) compared to the MD-SN ensemble (0.022).

A clear architectural progression is visible across the 10-model ensembles. Although the MIL architectures demonstrate a clear representational superiority over the Naive Encoder baseline ($\sim$0.05 F_2 improvement), their absolute global F_2 ($\sim$0.82) remains fundamentally unsafe for autonomous deployment. This underscores the danger of compelling a system to guess on ambiguous or OOD narratives, predictably resulting in overconfident misclassifications.

4.2 Selective Screening

Applying the Dual Veto policy at a strict safety tolerance ($\alpha = 0.01$) exposes the operational flaws of standard baselines. Hampered by poor calibration and sub-optimal uncertainty ranking, the ensembled Naive Encoder suffers a severe coverage collapse (47.8%) and a clinically unviable TPDR of 50.5%. In contrast, the ensembled MIL architectures successfully isolate highly reliable predictive domains. MD-SN MIL yields the best uncertainty ranking (AURC: 0.006 vs. 0.007 for Standard MIL) and 0.982 Clear F_2 at 67.7% coverage , effectively vetoing overconfident misclassifications.

Comparing UQ backends highlights a critical operational trade-off. While CV-Ensembles establish the empirical safety upper bound, they incur a prohibitive 10x computational overhead. Conversely, MC Dropout bypasses this footprint but struggles with probabilistic calibration in this highly imbalanced domain. Bridging this gap, the deterministic MD-SN UQ algorithm achieves a highly competitive Clear F_2 of 0.966 with superior calibration in a single pass. This efficiently isolates the safe operating domain without the stochastic latency of MC Dropout or the memory burden of ensembles, offering a viable alternative for resource-constrained deployments.

Deferral Policy	Coverage $\uparrow$	Clear F2 $\uparrow$	Risk-Kappa $\uparrow$
Aleatoric Only (MCP)	92.6% [91.0-94.0]	0.902 [0.875-0.926]	0.751 [0.713-0.789]
Epistemic Only (MCMD)	98.8% [98.2-99.3]	0.831 [0.785-0.872]	**0.788** [0.742-0.834]
Standard Uncertainty	**99.3%** [98.9-99.7]	0.824 [0.777-0.866]	**0.788** [0.741-0.833]
Dual Veto (Hybrid)	91.3% [89.8-92.7]	**0.913** [0.888-0.935]	0.755 [0.717-0.794]

Table 3: Ablation of the deferral policy components on the MD-SN model ($\alpha = 0.05$). 95% CI calculated via empirical bootstrap resampling ($n = 1,000$) are reported below each metric.

4.3 The Necessity of the Dual Veto

An ablation study (Table 3) on the MD-SN architecture ($\alpha = 0.05$) confirms that single-modality uncertainty checks are structurally insufficient. Relying exclusively on aleatoric control (MCP) successfully flags probabilistic ambiguity but remains blind to overconfident geometric anomalies. Conversely, an epistemic-only policy (MCMD) suffers a catastrophic drop in safety by unsafely automating 98.8% of the cohort. Crucially, this mirrors the failure of traditional selective classification approaches (represented here as "Standard Uncertainty" using a 90th-percentile predictive threshold), which yields a falsely optimistic 99.3% coverage but degrades the Clear F_2 to 0.824.

Although single-modality policies yield nomi-

Architecture	Risk Tol. (α)	Coverage ↑	TPDR ↓	Clear F_2 ↑	Clear ECE ↓	Risk-Kappa ↑
Standard MIL	0.01	63.5%	29.6%	0.979	**0.009**	0.546
	0.02	75.4%	19.4%	0.954	0.012	0.644
	0.05	91.1%	**7.0%**	0.902	0.015	0.747
MD-SN MIL	0.01	67.7%	33.2%	**0.982**	0.021	0.576
	0.02	77.4%	24.8%	0.969	0.028	0.665
	0.05	**91.3%**	10.2%	0.913	0.029	**0.755**

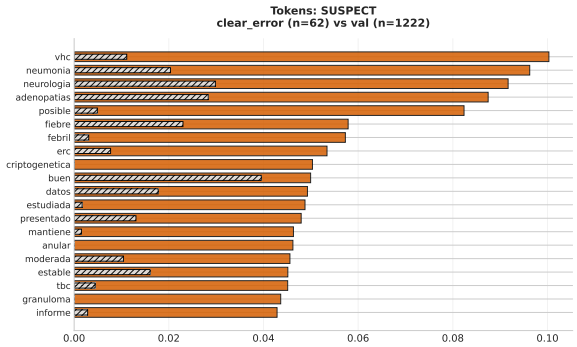
Table 4: Evaluation of the framework as an adjustable operational dial using the CV Ensemble UQ algorithm. By varying the conformal risk tolerance (α), administrators can dynamically balance system Coverage against discriminative safety (Clear F_2) and the True Positive Deferral Rate (TPDR). **Note:** Full results, including 95% bootstrap Confidence Intervals, are detailed in Appendix D.

nally higher Custom Risk-Kappa scores (0.788), their 95% CIs overlap extensively with our hybrid framework. Because of this overlap, the advantage of the dual veto on the Risk-Kappa metric is not statistically established at this current sample size. However, the hybrid policy achieves a statistically significant leap in Clear F_2 (0.913 vs. 0.824, with non-overlapping CIs). Therefore, the $\sim$8% drop in coverage represents a necessary, statistically robust trade-off to eliminate the unsafe false negatives that standard UQ backends fail to intercept.

4.4 Clinical Efficiency and the Risk Trade-off

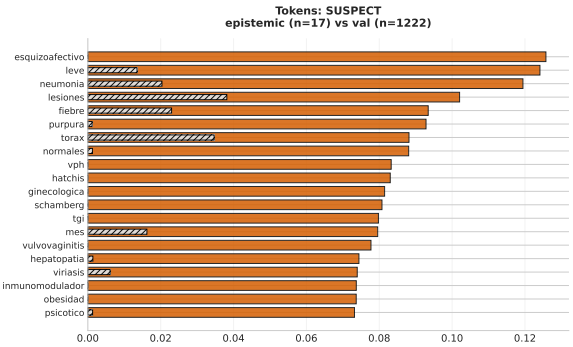
While strict safety constraints ($\alpha = 0.01$) effectively isolate a highly reliable predictive domain, a static threshold fails to accommodate the fluctuating resource constraints of real-world healthcare systems. A clinically viable NLP triage framework must function as an adjustable operational dial, allowing hospital administrators to balance diagnostic safety with administrative workload reduction. Table 4 demonstrates the framework's scalability across broader risk thresholds ($\alpha \in \{0.01, 0.02, 0.05\}$).

Relaxing the conformal boundary on the MD-SN ensemble from a strict $\alpha = 0.01$ to a moderate $\alpha = 0.02$ allows the framework to expand its operational coverage to 77.4%, while maintaining a robust Clear F_2 of 0.969. At a more lenient $\alpha = 0.05$ setting, the system safely automates an outstanding 91.3% of patient trajectories. Even at this high coverage level, the framework preserves a Clear F_2 of 0.913 and a low TPDR of 10.2%.



Furthermore, evaluating the Standard MIL architecture reinforces the system's architecture-agnostic flexibility. At $\alpha = 0.05$, the Standard MIL provides comparable coverage (91.1%) with superior calibration (ECE: 0.015) and an exceptionally low TPDR (7.0%), albeit with slightly lower discriminative safety. This performance parity proves that the dual-veto framework successfully rescues uncalibrated baselines and provides administrators with viable operational alternatives: prioritizing maximum safety (MD-SN MIL) or minimizing expert workload with superior calibration (Standard MIL).

4.5 Interpretability of the Triage Decisions



To visualize the underlying clinical reasoning and mitigate the black-box nature of deep neural networks, we analyzed feature attributions at the $\alpha = 0.05$ threshold. Crucially, to accurately capture representational shifts, we explicitly compared the marginal feature attributions of the various test triage cohorts against the mean feature attributions of the validation cohort, which is our established, in-distribution baseline. While the absolute number of instances in these specific triage subsets is naturally small (e.g., 62 for automated FP, 17 for epistemic suspicion deferrals), they encompass the entirety of these edge cases within the test set[2]. A detailed methodological explanation of our custom hierarchical attribution system, alongside additional visual examples, is provided in Appendix C.

When analyzing the system's "Clear Errors", specifically FP where the model predicted clinical suspicion but no serology was documented, the feature attributions reveal strong clinical robustness when measured against this validation baseline. As shown in Figure 2a, these predictions are heavily driven by explicit indicator conditions mandating screening under EuroTEST guidelines, such as *vhc* (Hepatitis C) and *tbc* (Tuberculosis). This suggests the model successfully anchors on guideline-concordant phenotypic risk; the absence of a test highlights the noisy, partially observable

[2]Aleatoric deferrals are excluded from this analysis, as probabilistic ambiguity is driven by the joint conflict of typical features, which marginal aggregations cannot adequately capture.

(a) Automated False Positives ("Clear Errors")

(b) Epistemic Deferrals (Suspicion)

Figure 2: Feature attribution comparison for complex triage edge cases at $\alpha = 0.05$. Solid colored bars represent the mean token-level importance for the positive class on the designated test cohort. The underlying light grey bars with black diagonal hatching denote the validation baseline.

nature of EHR documentation rather than a representational failure.

Conversely, instances flagged by the epistemic geometric veto demonstrate severe representational collapse. As illustrated in Figure 2b, predictions for these deferred cases are hijacked by highly specific, OOD artifacts, such as psychiatric conditions (*esquizoafectivo-schizoaffective-*, *psicótico-psychotic-*) or unrelated localized infections (*vulvovaginitis*), which registered near-zero predictive importance during validation. By calculating the Mahalanobis distance, the framework successfully recognizes this latent space distortion and safely vetoes the prediction before it can confidently misclassify the atypical presentation.

5 Conclusion

Translating biomedical NLP into clinical workflows is fundamentally limited by standard evaluation paradigms that force deterministic decisions on ambiguous narratives. This inherently produces overconfident misclassifications that directly conflict with medical safety requirements. To bridge this gap, we introduced and evaluated a risk-aware, hybrid selective screening framework for early HIV suspicion identification in a highly imbalanced Spanish EHR cohort.

Our empirical evaluations demonstrate that standard UQ methodologies conflate distinct predictive risks, forcing baseline models into severe coverage collapse when subjected to strict reliability constraints. In contrast, explicitly decoupling aleatoric uncertainty (via MCP) and epistemic uncertainty (via a MCMD veto) allows the evaluation framework to isolate a highly trustworthy operational domain. By functioning as an adjustable operational dial, the system enables healthcare administrators to dynamically balance diagnostic safety with administrative workload. Under strict safety constraints ($\alpha = 0.01$), the dual-veto framework maximizes discriminative safety, achieving a high Clear F_2-score of 0.982 across 67.7% of the cohort. When relaxed to accommodate high-throughput workloads ($\alpha = 0.05$), the framework safely automates a 91.3% of patient trajectories while preserving a robust 0.913 Clear F_2 and limiting true positive deferrals to just 10.2%. Beyond quantitative safety metrics, our hierarchical feature attribution analysis confirms the clinical robustness of the triage logic: automated false positives reliably anchor on guideline-concordant phenotypic risks, while the epistemic veto proactively intercepts semantic artifacts and atypical presentations.

Ultimately, this study shows that optimizing biomedical NLP systems purely for raw classification accuracy creates a dangerous illusion of clinical readiness. By ensuring that highly ambiguous patient profiles and geometric anomalies are proactively flagged for expert review, our framework proves that rigorous, decoupled uncertainty quantification is a fundamental prerequisite for translating NLP into responsible clinical practice.

Building upon these findings, future work will focus on adapting this risk-aware triage paradigm to diverse clinical use cases where the asymmetric costs of errors differ from the preventative infectious disease model.

To support methodological transparency, the complete UQ implementation pipeline and inference code is publicly available on GitHub[3].

Limitations

While the framework bridges theoretical UQ and operational clinical safety, key methodological limitations remain. First, while the sensitivity analysis in Appendix B validates the robustness of the Custom Risk-Kappa under various simulated health-economic realities, it remains an experimental metric strictly tailored to the specific risk profile of early infectious disease screening. In this context, the severe epidemiological consequence of a missed diagnosis heavily outweighs the impact of an unnecessary serological test. However, applying this metric to domains with high physical intervention risks (e.g., invasive surgical biopsies in oncology) requires fundamental recalibration and formal health-economic validation.

Second, the static geometric thresholds τ_{dist} make the epistemic veto vulnerable to temporal or demographic dataset shifts prior to scheduled retraining. Third, although generative Large Language Models (LLMs) dominate current NLP benchmarks, extracting reliable, well-calibrated uncertainty from autoregressive generation remains an unsolved clinical challenge. Therefore, we explicitly prioritized a deterministic, spectrally normalized encoder to guarantee the geometric vetoes required for strict triage safety.

Finally, empirical validation is constrained to a single medical center. Given that HIV suspicion relies on partially observable behavioral indicators, cross-institutional validation is necessary to confirm the framework's broader generalizability.

Ethical Considerations

The use of data for this study has been implemented in full compliance with strict adherence to the European General Data Protection Regulation (GDPR) and the Spanish Organic Law 3/2018 (LOPDGDD) on the Protection of Personal Data and Guarantee of Digital Rights. Due to strict institutional ethics board regulations privacy constraints regarding highly sensitive clinical narratives, the raw electronic health records cannot be made publicly accessible.

A Hyperparameter Sensitivity Analysis

To ensure the robustness of the epistemic veto, we evaluated the framework's triage efficiency across varying inertia convergence limits (0.01, 0.02, 0.05, 0.1) and Mahalanobis distance percentiles (90th, 95th, 99th, 99.5th, 99.9th) on the test set, calibrated over the validation set. As shown in Table A1, the chosen configuration (0.05, 99th) represents the empirical global optimum, maximizing the clinical safety metric (Custom Risk-Kappa) while maintaining a low TPDR.

B Custom Risk-Kappa ablation and the impact of model coverage

To evaluate the behavioral differences between the Standard MIL and the MD-SN MIL architectures under varying operational constraints, we conducted an ablation of the Custom Risk-Kappa metric across five simulated health-economic realities.

Table B1 demonstrates how these two architectures perform depending on the institutional penalties assigned to False Positives (FP), Deferred True Negatives (Def_TN), and Deferred True Positives (Def_TP). A missed diagnosis (False Negative) is consistently assigned the maximum catastrophic penalty of 1.0 across all scenarios.

Across all simulated environments, the MDSN MIL consistently outperforms the Standard MIL

Inertia (Δ)	Dist. Percentile	Coverage ↑	Clear F_2 ↑	TPDR ↓	Risk-Kappa ↑
Strict Extreme					
0.01	90th	84.3%	0.946	19.7%	0.721
Smooth Degradation					
0.05	90th	84.7%	0.945	19.7%	0.724
0.05	95th	87.5%	0.935	16.1%	0.746
Chosen Optimum					
0.05	**99th**	**91.3%**	**0.913**	**10.1%**	**0.755**
Loose Extreme					
0.10	99.9th	92.4%	0.904	8.7%	0.752

Table A1: Hyperparameter Sensitivity Analysis across varying inertia convergence limits (0.01, 0.02, 0.05, 0.1) and Mahalanobis distance percentiles (90th, 95th, 99th, 99.5th, 99.9th) on the test set.

Health-Economic Reality	Penalty Weights				Standard MIL (63.5% Cov.)	MDSN MIL (67.7% Cov.)
	FN	FP	Def_TN	Def_TP		
Zero-Cost Deferral *(Maximum Caution)*	1.0	1.0	0.0	0.0	0.948	0.960
Extreme Epidemiological *(Resource-Rich)*	1.0	0.25	0.1	0.25	0.695	0.723
Default Baseline *(Preventative Medicine)*	**1.0**	**0.5**	**0.25**	**0.5**	**0.546**	**0.576**
Symmetric Control *(Classification Baseline)*	1.0	1.0	0.5	0.5	0.475	0.513
High Admin Burden *(Resource-Constrained)*	1.0	0.75	0.5	0.75	0.432	0.463

Table B1: Custom Risk-Kappa Scores Across Simulated Health-Economic Realities.

baseline. In a "Zero-Cost Deferral" scenario representing maximum caution (where manual hospital review incurs no penalty), the MDSN MIL achieves an exceptional Risk-Kappa of 0.960 compared to the Standard MIL's 0.948. This highlights that when an institution has unlimited bandwidth to review deferrals, the MDSN's rigid safety mechanisms provide near-perfect predictive accuracy on its covered subset.

Conversely, when simulating a resource-constrained environment ("High Administrative Burden"), penalties for false positives (0.75) and deferrals (0.5 to 0.75) are heavily increased. Even under these strict conditions, the MDSN MIL (0.463) maintains a clear advantage over the Standard MIL (0.432). This consistent superiority across both extreme epidemiological and highly constrained administrative realities proves that the MD-SN architecture's superior calibration and epistemic veto mechanism successfully isolate ambiguities without overwhelming institutional resources.

C Feature Attribution Analysis

C.1 Hierarchical Feature Attribution Methodology

A common limitation in interpreting Multiple Instance Learning (MIL) architectures is the difficulty of projecting local token importances into the global document representation (z_{doc}). To generate the feature attributions, we implemented a custom hierarchical attention-occlusion explainer, computed in four stages:

1. **Local Token Importance:** Token-level importance is extracted from the base transformer's last-layer attention weights (combining [CLS] and self-attention) and aggregated into continuous word-level scores.

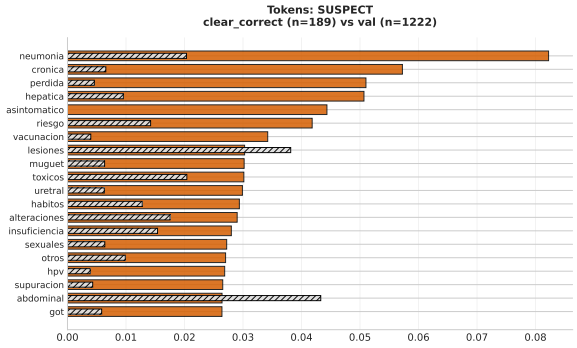
2. **Global MIL Aggregation:** To project local scores to the patient level, each word's score is multiplied by the normalized MIL gated-attention weight (w_c) assigned to its respective chunk. The global importance is the sum of its MIL-weighted occurrences:

$$I(\text{word}) = \sum_{c \in \text{chunks}} \text{Attn}(\text{word}_c) \cdot w_c$$

3. **Directional Impact (Occlusion):** Because attention only provides magnitude, we determine polarity via a leave-one-out occlusion test. Masking the target word across all chunks shifts the decision boundary; this logit margin (Δ) determines whether the token drives the prediction toward Suspicion or Non-Suspicion.

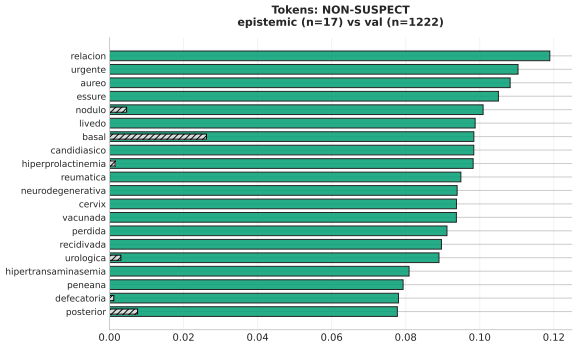
4. **Cohort TF-IDF Aggregation:** To prevent highly-attended outlier documents from skewing the cohort average, patient-level importances are aggregated using a modified TF-IDF weighting. Term Frequency (intra-patient importance) is square-root scaled to dampen extremes, while the IDF penalty upweights consistently important terms across the cohort. Finally, these scores are averaged across the target subset to yield the stable attributions displayed in the figures.

C.2 Supplementary Triage Visualizations



This section provides supplementary visualizations to confirm the model's expected baseline behavior and further demonstrate the necessity of the epistemic veto.

Figure C1 illustrates the feature attributions for the remaining triage cohorts. Plot C1a confirms the system's reliability on standard, safely automated true positive cases ("Clear Correct"). In these instances, the model's predictions rely entirely on established, in-distribution clinical indicators (such as *neumonía-pneumonia-* and *muguet*), confirming that its automated decisions are grounded in relevant epidemiological phenotypes



Conversely, Plot C1b demonstrates the critical role of the geometric veto even for cases where the model predicts the negative class (Non-Suspicion). In these deferred cases, the model is distracted by highly specific, OOD medical artifacts that distort the latent space. A prime example is the heavy attribution given to *essure* (a specific gynecological implant). While such terms may spuriously co-occur with routine administrative testing in the training data, they are fundamentally unrelated to the targeted clinical construct. The MCMD successfully recognizes this geometric anomaly and intercepts the prediction, preventing the model from making an overconfident decision based on irrelevant clinical noise.

D Exhaustive Evaluation Metrics

Table D1 provides the comprehensive triage metrics across all tested architectures, Uncertainty Quantification algorithms, and risk tolerances. All metrics include 95% Confidence Intervals (CI) derived via empirical bootstrap resampling ($n = 1,000$).

(a) Automated True Positives ("Clear Correct")

(b) Epistemic Deferrals (Non-Suspicion)

Figure C1: Feature attribution comparison for complex triage edge cases at $\alpha = 0.05$. Solid colored bars (orange for the positive class, green for the negative class) represent the mean token-level importance for the designated test cohort. The underlying light grey bars with black diagonal hatching denote the validation baseline.

Table D1: Discriminative performance, calibration, and triage efficiency across models and Uncertainty Quantification (UQ) backends. Metrics evaluate the forced deterministic output (Binary) and the automated subset after deferral (Clear). Triage safety is further assessed via Coverage, True Positive Deferral Rate (TPDR), Area Under the Risk-Coverage curve (AURC), and Custom Risk-Kappa. 95% Confidence Intervals (CI) calculated via empirical bootstrap resampling ($n = 1,000$) are reported below each metric. The best performance per metric in the strict safety tier ($\alpha = 0.01$) is highlighted in bold.

Gold Label Errors in the SciFact Benchmark: An LLM-Assisted Annotation Audit

Julien Sylvestre
BXCT Partners Ltd
js@bxct.co.uk

Abstract

SciFact is a widely-used benchmark for scientific claim verification (645 citations, included in the BEIR evaluation suite). We present, to our knowledge, the first systematic annotation audit of its development and training sets, combining automated screening with a small language model ($0.11 in API fees) and exhaustive manual verification against source publications. We identify 11 gold-label errors in the development set (5.3%, 95% CI 2.7–9.2%, of 209 audited claim–document pairs) and 13 in the training set (2.3%, 95% CI 1.2–3.9%, of 564 audited pairs). The dev errors exhibit a directional asymmetry—9 of 11 mislabel a claim as SUPPORT (one-sided binomial p=0.033, two-sided p=0.065)—and fall into four recurring types. Correcting the dev labels raises binary macro-F1 by 1.7–3.8 points across GPT-5.4 (mini, nano) and Claude Haiku 4.5; gains are larger in 3-way evaluation when mislabeled evidence is recast as NEI (e.g., +9.2 with Haiku 4.5). The binary range is comparable in magnitude to inter-system margins on the SciFact leaderboard. A simple claim-only probe with Haiku 4.5 does not support label memorization as the main explanation for these gains. We release corrected annotations and a blind annotator packet, and recommend that benchmark users prefer the corrected release going forward.

1 Introduction

Benchmark quality is foundational to NLP progress: if gold labels contain systematic errors, model comparisons become unreliable and optimization targets become misaligned. This concern is especially acute for small, expert-annotated datasets where a handful of label errors can shift rankings by several F1 points.

SciFact (Wadden et al., 2020), introduced at EMNLP 2020 and subsequently incorporated into the BEIR retrieval evaluation suite (Thakur et al., 2021), is the standard benchmark for scientific claim verification (645 citations on Semantic Scholar as of April 2026). The task requires systems to retrieve relevant abstracts and classify scientific claims as SUPPORT, CONTRADICT, or NOT ENOUGH INFO (NEI) given evidence sentences from PubMed abstracts. The dataset contains 300 dev claims, 809 training claims, and 300 hidden test claims; of these, 209 dev and 564 training claim–document pairs have gold evidence annotations that we audit here. Gold labels were assigned by domain experts (reported Cohen's $\kappa = 0.75$). Despite wide adoption—over 600 citations and use in recent work at EMNLP, SIGIR, and JAMIA Open—to our knowledge no prior study has audited the quality of SciFact's gold annotations. A review of the dataset's GitHub repository, Hugging Face page, and citing literature (conducted March 2026) reveals zero reported label corrections, no errata, and no corrected release in six years of use. This is notable given that the annotated pairs are small enough to verify manually in a few hours and that the original inter-annotator agreement ($\kappa = 0.75$) leaves room for disagreement.

We contribute: (1) identification of 11 gold label errors in the dev set (5.3%, 95% CI 2.7–9.2%) and 13 in the training set (2.3%, 95% CI 1.2–3.9%), showing errors contaminate both model training and evaluation; (2) a taxonomy of error types and analysis of directional asymmetry, with statistical framing; (3) cross-model verification of the F1-impact and a contamination probe using a non-GPT model family (Claude Haiku 4.5); and (4) an efficient, replicable audit methodology costing $0.11 in API fees for the automated screening stage.

2 Related Work

Annotation errors in benchmarks. Northcutt et al. (2021) found 3–6% label errors across 10 pop-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 97–103

ular benchmarks (including ImageNet and MNIST) and showed that correcting these errors changes model rankings. More recently, Vendrow et al. (2025) created "platinum" corrected versions of 15 benchmarks and found that over 50% of model errors on the originals were attributable to label noise—GSM8K alone had ∼5% problematic questions. Nahum et al. (2025) used LLM ensembles to detect 6–21% error rates across factual consistency benchmarks, showing that many reported LLM "mistakes" are correct responses to mislabeled examples. In NER, Rucker and Akbik (2023) re-annotated CoNLL-03 and found 7% of labels were incorrect; nearly half of state-of-the-art model "errors" were actually correct predictions penalized by noisy ground truth.

Annotation artifacts and disagreement. Gururangan et al. (2018) identified annotation artifacts in SNLI; Pavlick and Kwiatkowski (2019) and Nie et al. (2020) showed many NLI items lack a single correct label. Weber-Genzel et al. (2024) separated genuine label variation from error in MNLI. Swayamdipta et al. (2020) found that hard-to-learn instances often correspond to labeling errors, and Klie et al. (2023) surveyed 18 error detection methods, finding the field lacks standardized evaluation.

SciFact. Wadden et al. (2022b) showed 15+ F1 drops when expanding SciFact to open-domain retrieval, and Košprdić et al. (2024) found fine-tuned DeBERTa outperformed GPT-4 zero-shot by ∼7%. Despite this active research community, to our knowledge no prior work has audited SciFact's gold labels. The dataset's GitHub repository contains 27 issues—none concerning annotation quality—and neither the original authors nor any of the 600+ citing papers have published corrections or errata.

3 Method

3.1 Stage 1: Automated LLM Screening

We processed all 209 dev claim–document pairs using GPT-5.4-mini (temperature 0.3) with a structured audit prompt. For each pair, the model received the claim text, the gold label, the gold rationale sentences, and the full abstract. The model returned structured JSON: assessment (AGREE/DISAGREE/DEBATABLE), reasoning, error type (from a predefined taxonomy), and suggested correct label.

The automated screening flagged 57 claims (27.3%): 43 as DISAGREE and 14 as DEBATABLE. This stage cost $0.11 in API fees (approximately 440K tokens at March 2026 pricing; cached-input rates applied).

3.2 Stage 2: Manual Expert Verification

The automated screening has a high false-positive rate: the LLM frequently confuses claim direction with evidence direction (Section 4.3). Each of the 57 mini-flagged disagreements was therefore adjudicated by a single annotator working interactively with a *frontier* LLM (GPT-5.4) in chat mode: the frontier model surfaced its own reading of the claim and evidence, the annotator probed and challenged it, and the annotator made the final verdict. This human-in-the-loop protocol provides an additional model-based second opinion on every disputed pair while keeping final adjudication with the human; the screening model (mini) and the verification model (frontier) are different scales of the same family, and the human breaks ties. The 152 non-flagged claims were exhaustively reviewed by the same annotator without the chat-mode loop, since the screen had already implicitly endorsed the gold label. Corrected labels are determined solely by the assigned evidence paper; later literature is consulted only for context (see footnotes in §4.1).

Of the 57 flagged claims, 8 were ultimately confirmed as annotation errors, 8 remained debatable but defensible, and 41 were false alarms (after a second-pass review on the borderline cases: 2 claims initially classified as debatable were upgraded to confirmed errors and are listed in the appendix). Of the 152 non-flagged claims, exhaustive review identified 3 additional errors that the automated screening missed entirely (rating them AGREE), bringing the total to 11.

3.3 Source-Paper Verification

All 11 dev errors were verified against the original source publications (retrieved via PubMed), confirming that each correction is consistent with the assigned evidence paper's own findings. This verification is independent of the benchmark labels, not of the annotator: a second independent rater was not used (see Limitations).

4 Results

4.1 Confirmed Annotation Errors

Table 1 presents the 11 confirmed errors, falling into four types: **(1) Label reversal** (4 cases): gold

label directly contradicts the evidence. ID 593 claims incidence "decreased by 10%" but the rationale states "did not change over time." ID 879 is labeled CONTRADICT, yet the abstract concludes "the large majority of lincRNAs do not function through encoded proteins" (sentence 6), agreeing with the claim.[1] ID 1385's rationale states "enhancing cSMAC formation *reduced* stimulatory capacity," the opposite of the claim's "enhances," yet gold says SUPPORT.[2] ID 808's rationale is a methodology sentence; the abstract's actual finding—"does not rely on cis-acting sequences" (sentence 3)—directly contradicts the claim, yet gold says SUPPORT. **(2) Outcome mismatch** (3 cases): claim and evidence address different clinical outcomes. ID 343 claims "bleeding events" but the rationale reports cardiovascular mortality, MI, stroke, and CHF—bleeding is never mentioned. ID 1368 claims effect on "term of delivery" (preterm birth) but the rationale reports gestational diabetes, pre-eclampsia, and SGA—preterm birth is absent from the abstract. ID 770 claims "reduced efficacy and lower quality of life" for single-agent fluoropyrimidines vs. oxaliplatin, but PFS was non-significant (p=0.07) and the trial's QoL comparison was between two fluoropyrimidines (fluorouracil vs. capecitabine), not single-agent vs. combination. **(3) Entity mismatch** (3 cases): claim and evidence refer to different biological entities. ID 1216 claims cleavage in "human beta cells" but the paper reports exclusively on mouse Tmem27 (Tcf1$^{-/-}$ mice, transgenic mice).[3] ID 1274 attributes T6SS mechanisms to *E. coli* but the paper demonstrates them in *V. cholerae* and *A. baylyi*—organisms from different taxonomic orders. ID 847 claims "new drugs" fail to penetrate necrotic lesions; the rationale cites rifampicin (a 1960s drug, not new) accumulating in caseum, while the same abstract reports that moxifloxacin (a newer drug) "does not diffuse well." **(4) Overgeneralization** (1 case): ID 208 claims "CHEK2 is not associated with breast cancer," but the paper's abstract states "Previous investigation has established a role for the CHEK2 gene in breast cancer aetiology" (sentence 1) and reports OR 2.26 for the rare 1100delC mutation (sentence 8).

ID	Gold→Corr.	Type	Key issue
593	S→C	Reversal	"decreased 10%" vs "did not change"
879	C→S	Reversal	Abstract [6] agrees with claim
1385	S→C	Reversal	"enhances" vs "reduced capacity"
808	S→C	Reversal	Abstract [3] contradicts claim
343	S→N	Outcome	CV events, not bleeding
1368	S→N	Outcome	Diabetes/SGA, not preterm birth
770	S→N	Outcome	PFS p=0.07; QoL compared wrong arms
1216	S→N	Entity	Mouse study, claim says "human"
1274	S→N	Entity	*V. cholerae* study, claim says *E. coli*
847	C→N	Entity	Old drug in rationale; claim says "new"
208	S→C	Overgen.	Abstract [1,8] contradict claim

Table 1: The 11 confirmed gold label errors (n=209 dev claim–document pairs). S=SUPPORT, C=CONTRADICT, N=NEI. 9/11 are mislabeled SUPPORT. One additional per-document error (ID 597, mortality≠incidence) is not shown.

4.2 Impact on System Evaluation

We ran two zero-shot configurations on all 209 dev claims (oracle setting) and computed macro F1 before and after correcting the 11 errors. GPT-5.4-mini gained +3.8 F1 (84.9→88.7); GPT-5.4-nano gained +1.7 (79.5→81.2). For context, the top systems on the SciFact test-set leaderboard are separated by just 1.25 F1 points (MultiVerS at 72.5 vs. ARSJoint at 71.2; Wadden et al., 2022a; Zhang et al., 2021), and dev-set gaps among top models range from 0.7 to 2.7 F1 (Košprdić et al., 2024). The correction-induced shifts of 1.7–3.8 F1 are of the same order as these gaps, introducing noise that can plausibly perturb leaderboard ordering—though our zero-shot estimates do not establish reordering of fine-tuned systems, whose predictions we do not have. The stronger model benefits more because the mislabeled claims were among its "errors"—it correctly rejected claims that the

[1] Subsequent studies have identified functional micropeptides encoded by some lncRNAs, complicating the blanket claim. However, the *cited paper's own conclusion* supports the claim; the gold label is wrong relative to the assigned evidence regardless of later findings.

[2] A follow-up by the same group (Cemerski et al., 2008) refined this finding, reporting that cSMAC can enhance signaling from weak agonists under certain conditions. Nevertheless, the *assigned evidence paper* unambiguously states "reduced," making the SUPPORT label incorrect for this claim–evidence pair.

[3] Later work confirmed TMEM27 cleavage in human beta cells (Esterházy et al., 2011). The claim is likely true, but the *assigned evidence* is a mouse-only study and cannot support the species-specific claim.

gold standard incorrectly accepted.

Cross-model verification. To address the concern that the F1 gain might reflect GPT-family preferences leaking into our corrections, we reran the same evaluation with Claude Haiku 4.5 (`claude-haiku-4-5-20251001`) using identical inputs (claim, paper title, full abstract, gold rationale), structured tool-use output, and prompt caching. On the original labels, Haiku reaches a binary macro F1 of 92.77; applying the corrections raises it to 95.75—a $+2.98$ F1 gain, directionally consistent with GPT-5.4-mini's $+3.8$. The 3-way (S/C/NEI) macro F1 gain is larger ($61.85 \rightarrow 71.09$, $+9.24$), reflecting the 6 pairs whose evidence licenses NEI rather than a binary verdict. Across both model families and both binary and 3-way evaluation, every configuration gains F1 from the corrections; the effect is not confined to the GPT family in our tests.

Contamination probe. We then asked Haiku 4.5 to classify the same 209 dev claims given *only* the claim text—no abstract, no rationale, no title. Haiku reaches 70.81% accuracy, only 4.78 points above the 66.03% majority-class baseline (SUPPORT), with 18% of predictions being NEI. A model that had memorized SciFact's binary gold labels would be expected to commit to a side; the small gap above majority class is consistent with claim-plausibility reasoning rather than label memorization. This argues against dataset contamination as the source of the F1 gain.

4.3 Automated Auditor Performance

Of 57 flagged claims, 8 were errors (14% precision). Most false alarms were *direction confusion*: the auditor flagged CONTRADICT labels as wrong when the claim reversed the evidence, not recognizing that CONTRADICT is correct *because* the claim reverses the evidence. Crucially, three errors (IDs 1385, 770, 1216) were missed entirely—the LLM rated them AGREE despite clear mismatches. ID 1385 is a direct claim–evidence contradiction; ID 770 requires checking statistical significance and QoL directionality; ID 1216 requires noticing a species mismatch (mouse vs. human). The auditor's recall was 8/11 (73%); automated screening alone is insufficient.

4.4 Per-Document Error

One additional per-document error (not counted above): ID 597's third evidence document discusses cervical cancer *mortality* but is labeled SUPPORT for an *incidence* claim.

4.5 Training Set Audit

To assess whether errors also contaminate model training, we manually audited all 564 claim–document pairs in the training set. We identified 13 errors (2.3%, 95% CI 1.2–3.9%), exhibiting the same error types as the dev set; the dev and train CIs overlap, so we do not claim that dev is strictly noisier than train. Seven are clear label reversals: e.g., ID 164 labels SUPPORT for "bariatric surgery increases colorectal cancer" when the rationale states "no association was detected between bariatric surgery and … cancer"; ID 933 labels SUPPORT for "increased morphine use" when the evidence reports significantly *less* morphine use ($P{=}.03$). Three are entity mismatches: e.g., ID 621 claims "Individuals with Alzheimers" but the study explicitly recruited adults who "did not meet criteria for dementia"; ID 657 attributes a function to signal peptide peptidase but the evidence is about RHBDL4, a different enzyme. One is a causal misread: ID 416 claims APOE4 carriers "have longer lifetime exposure to estrogen due to an increased reproductive period," but the evidence only shows that APOE4 modifies the effect of reproductive period length on dementia risk (effect modification), not that APOE4 causes longer reproductive periods.[4] Two involve modality or numerical mismatches between claim and evidence (ID 1145 treats a microsimulation projection as observed data; ID 1297 claims 30 million cases when the evidence reports $\sim$15 million hospitalizations). All 13 training errors with claim IDs, corrected labels, rationale indices, and one-sentence justifications are provided in the supplementary materials.[5] The lower error rate in training (2.3% vs. 5.3% in dev) may reflect differences in annotation workflow, but the key finding is that errors are present in *both* splits: models fine-tuned on SciFact are optimized toward wrong labels during training, tuned against wrong labels during development, and—if the hidden test set has similar rates—evaluated against wrong labels at submission. This means label noise

[4] A 1.8-year delay in menopause among APOE3/4 carriers has been reported in one Chinese cohort (Meng et al., 2012), but findings are mixed across populations, and the *assigned evidence paper* reports only effect modification, not a causal relationship.

[5] Full training-set error table in supplementary materials and at `https://github.com/Kefez/scifact-audit-bionlp2026`.

can affect every stage of the SciFact pipeline, from retrieval model training (learning which documents to retrieve for a claim) to inference model training (learning which label to assign) to final evaluation.

5 Discussion

Our 5.3% dev error rate (95% CI 2.7–9.2%) falls within the 3–7% range reported for other benchmarks (Northcutt et al., 2021; Rucker and Akbik, 2023; Vendrow et al., 2025), suggesting that expert-annotated scientific datasets are not immune to label noise. The directional asymmetry (9/11 mislabeled SUPPORT) is, on its own sample size, suggestive but not conclusively significant: an exact two-sided binomial test against p=0.5 yields p=0.065 (one-sided p=0.033). The 95% Clopper–Pearson CI on the SUPPORT-error proportion is wide ([48%, 98%]), reflecting n=11. However, the asymmetry is robust to reasonable alternative classifications: if all 8 final "debatable" borderline cases (Appendix A) were reclassified as errors, the SUPPORT proportion remains 15/19 (79%) with two-sided p=0.019; under the expected 4/8 reclassification scenario, p=0.035. Nahum et al. (2025) observed a similar SUPPORT-skew pattern across factual-consistency benchmarks, lending external plausibility to the direction. We therefore describe this as a directional asymmetry warranting follow-up audit on a larger sample, rather than a confirmed systematic bias. With leaderboard gaps of 0.7–2.7 F1 between top systems, the binary correction-induced shifts of 1.7–3.8 F1 we observe across GPT-5.4 and Haiku 4.5 introduce noise of the same order as inter-system margins; the larger 3-way Haiku gain (+9.24) reflects 6 corrections that the binary schema cannot represent and is best read as an NEI-sensitive analysis rather than a leaderboard-comparable number. Whether the original-label rankings would actually reorder under corrected labels depends on whether top fine-tuned systems succeed and fail on the same items as our zero-shot models, which we do not establish here.

Six years without verification. Despite 600+ citations, our review of the dataset's GitHub repository (27 issues, none on annotation quality), Hugging Face page, and citing literature found zero prior label corrections or errata. This contrasts with other benchmarks: CoNLL-03 was re-annotated after two decades (Rucker and Akbik, 2023), and Vendrow et al. (2025) corrected 15 benchmarks simultaneously. We hypothesize that the "expert-annotated" label and biomedical domain specificity may have discouraged the kind of systematic verification that crowdsourced benchmarks routinely receive.

6 Conclusion

SciFact remains a useful benchmark, but its audited train and dev portions contain nontrivial annotation errors that can distort optimization targets and reported system comparisons. We document a directional asymmetry (9/11 dev errors mislabel SUPPORT; one-sided p=0.033, n=11) and show that correcting the dev labels raises binary zero-shot macro-F1 by 1.7–3.8 points across GPT-5.4 (mini, nano) and Claude Haiku 4.5—comparable to inter-system margins on the leaderboard. The 3-way Haiku gain is larger (+9.24) when the 6 mislabeled-as-NEI pairs are admitted; we report it as an additional NEI-sensitive analysis rather than as a direct leaderboard-comparable number. A claim-only contamination probe with Haiku 4.5 does not support label memorization as the main explanation for these gains. Rather than positioning our corrections as a definitive replacement, we recommend that the community treat them as a starting point and pursue an independent multi-annotator re-audit. We release the audit corrections, a blind-annotator packet for that review, and our reproduction scripts as a starting point.[6]

Limitations

We audit the dev and training sets only; the hidden test set may differ in error rate and error-type distribution, and we cannot directly verify it. *Manual verification is by one human annotator*, who was assisted on the 57 mini-flagged disagreements by a chat-mode frontier-LLM second opinion (§3.2) but not by an independent second human rater—a real concern given the original Cohen's κ=0.75 on the same task. To address this, we release a fully blind re-annotation packet for the entire dev set (no original gold, no LLM signal in the file the annotator sees) so any subsequent reviewer can independently re-audit and report inter-annotator agreement. Following Pavlick and Kwiatkowski (2019), some identified "errors"—particularly cross-species generalizations, borderline p=0.07 readings, and overgeneralization-type

[6] Corrected annotations, blind packet, and audit scripts are available at https://github.com/Kefez/scifact-audit-bionlp2026.

cases—may reflect legitimate methodological disagreement among clinical experts rather than objective labeling failures; the entity-mismatch errors (IDs 1216, 1274, 847) rely on the principle that findings in one organism do not automatically transfer to another, which some annotators may consider acceptable. The 8 final debatable cases (10 originally identified at first-pass review, with 2 subsequently upgraded to confirmed errors and counted in 11/209) are enumerated in Appendix A with a sensitivity analysis; case-by-case justifications are in the supplementary materials. The headline error rate stays under 10% even if all 8 were reclassified as errors. The impact analysis uses zero-shot models only on a single non-GPT family (Claude Haiku 4.5); fine-tuned systems and additional open-weight families are not evaluated and cannot be ruled out as differing in their response to the corrections. The contamination probe is a single negative test (claim-only with Haiku 4.5); a more extensive probe across open-weight models with known training data would strengthen the conclusion. Finally, our scope is a single benchmark; whether the directional SUPPORT-skew generalizes to other scientific-claim-verification corpora is an open empirical question.

Acknowledgments

We thank the BioNLP 2026 reviewers for detailed feedback that materially improved the statistical framing, cross-model verification, and contamination analysis in this paper.

A Debatable Cases and Sensitivity Analysis

We enumerate the **8** SciFact dev claims that survived all review passes as "debatable but defensible" rather than confirmed errors. At an earlier triage pass, 10 cases were initially classified as debatable in the manual-review spreadsheets (`my_verdict == "DEBATABLE"` in the two false-alarm review files); on a second-pass review, 2 of those (claims 847 and 1274) were upgraded to confirmed errors and are part of the 11/209 figure. The 8 final debatable claim IDs are 57, 163, 431, 540, 982, 1041, 1132, 1150. Original gold-label split among the 8: 6 SUPPORT, 2 CONTRADICT (claims 57 and 1041 are CONTRADICT).

Sensitivity analysis (8 final debatables). If we instead reclassified all 8 as confirmed errors, the dev error rate rises to 19/209 = 9.1% (95% CI 5.6–13.8%). Under the expected 4/8 reclassification (3 of 4 added are SUPPORT, matching the 75% gold-split rate), the rate is 15/209 = 7.2% (95% CI 4.1–11.6%). The directional asymmetry persists in every scenario, and *strengthens* as more debatables are admitted: 9/11 SUPPORT-mislabel (82%, two-sided p=0.065) at 0/8 reclassified; 12/15 (80%, p=0.035) at the expected 4/8 case; 15/19 (79%, p=0.019) at 8/8. Per-case justifications for all 8 (and the 2 upgrades) are in the supplementary materials.

B Reproduction Artifacts

We release: (1) corrected gold labels for all 11 dev and 13 training errors as JSON; (2) a blind re-annotation packet for the 209 dev pairs (no original gold, no LLM signal) for inter-annotator agreement studies; (3) a 30-pair random sample of LLM-rejected pairs for false-negative-rate audit of the screen; (4) the Haiku 4.5 cross-model and contamination-probe scripts; (5) the statistical-analysis script that reproduces every CI and binomial test in this paper.

BioRAG: A Systematic Ablation Study of Retrieval Strategies for Biomedical Question Answering

Abstract

Retrieval-Augmented Generation (RAG) systems for biomedical question answering require careful retrieval strategy selection, yet no systematic comparison exists across modern retrieval techniques evaluated with LLM-based metrics on biomedical benchmarks. We present BioRAG, a systematic ablation study comparing seven retrieval strategies on BioASQ-13b using four RAGAs metrics: faithfulness, answer relevancy, context precision, and context recall. Our corpus comprises 1,954 PubMed neurology abstracts indexed with domain-adaptive BioMedBERT embeddings. We find that hybrid BM25 plus dense retrieval with Reciprocal Rank Fusion achieves faithfulness of 0.534 and context recall of 0.507, improvements of 50% and 85% respectively over naive dense retrieval, with non-overlapping bootstrap confidence intervals across three random seed re-samples. We further demonstrate that Hypothetical Document Embeddings improve faithfulness by 14% but reduce context precision by 52%, revealing a faithfulness-precision tradeoff with direct clinical implications. No single strategy dominates all four metrics, indicating that retrieval strategy selection must be driven by application-specific clinical requirements. The complete pipeline operates without proprietary API fees using open-source models, ensuring full reproducibility.

1 Introduction

Biomedical question answering (QA) demands factual precision and reliable grounding in peer-reviewed literature, properties that are directly tied to patient safety in clinical deployments. Retrieval-Augmented Generation (RAG) addresses these requirements by conditioning answer generation on passages retrieved from a curated corpus, binding model outputs to verifiable evidence (Lewis et al., 2020). Despite rapid adoption in clinical applications, a fundamental question remains unanswered: *which retrieval strategy should a system designer select for a given clinical use case?*

Existing studies either propose a single retrieval method without ablating alternatives (Xiong et al., 2024), or evaluate on general-domain benchmarks that do not reflect the lexical complexity of biomedical text. Studies that do compare strategies on BioASQ (Nentidis et al., 2025) rely on lexical metrics such as F1 and ROUGE that do not measure grounding verification against retrieved context, which is the primary safety concern in clinical deployment. Existing pipelines depend on proprietary judge models, limiting reproducibility for researchers without institutional compute access.

We address this gap with BioRAG, a systematic ablation study comparing seven retrieval strategies on BioASQ-13b using RAGAs evaluation metrics (Es et al., 2024). The seven strategies range from naive dense retrieval and Hypothetical Document Embeddings (Gao et al., 2023) to cross-encoder reranking (Nogueira and Cho, 2019), multi-query decomposition (Ma et al., 2023), Self-RAG (Asai et al., 2023), and hybrid BM25 plus dense retrieval (Cormack et al., 2009); full descriptions appear in Section 3. Our key findings are: (1) hybrid BM25 plus dense retrieval achieves the highest faithfulness (0.53) and context recall (0.51), improving over the naive baseline by 50% and 85% respectively, with non-overlapping bootstrap confidence intervals confirming statistical significance; (2) Hypothetical Document Embeddings (Gao et al., 2023) improve faithfulness but reduce context precision by 52%, revealing a previously undocumented clinical tradeoff; and (3) no single strategy dominates all metrics, motivating evidence-based strategy selection. The complete pipeline operates without proprietary API fees using open-source models, ensuring full reproducibility of all findings.

2 Related Work

Biomedical RAG evaluation. Xiong et al. (2024) introduced MIRAGE, evaluating 41 corpus-retriever combinations on five biomedical QA datasets, and MedRAG, a retrieval framework supporting multiple corpora and snippet sizes for clinical QA. While comprehensive in scope, both systems measure accuracy on multiple-choice questions rather than open-ended faithfulness or contextual relevance. Thakur et al. (2021) introduced BEIR, a heterogeneous benchmark evaluating zero-shot transfer of retrieval models across multiple domains; hybrid retrieval emerged as a consistently strong baseline across the BEIR domains, consistent with our V7 findings in the biomedical setting. Tsatsaronis et al. (2015) introduced the BioASQ challenge, providing expert-curated biomedical QA pairs with gold-standard supporting snippets that enable context recall evaluation against human-verified references. Nentidis et al. (2025) describe the latest BioASQ challenge series, where participating systems typically combine BM25 retrieval with neural reranking evaluated via exact-match F1. Neither framework applies LLM-based evaluation metrics that directly measure answer grounding. Ozaki et al. (2025) examine confidence calibration in medical RAG across multiple model configurations, finding that certain models can discriminate whether retrieved documents support the correct answer. Our work complements these studies by providing the first systematic ablation of retrieval strategies using RAGAs metrics on BioASQ.

Retrieval strategy advances. Gao et al. (2023) proposed Hypothetical Document Embeddings (HyDE), generating a hypothetical answer passage and using its embedding as the retrieval query to bridge the query-document semantic gap. Nogueira and Cho (2019) demonstrated that cross-encoder reranking substantially improves retrieval precision by scoring query-document pairs jointly rather than independently, establishing the two-stage retrieval paradigm used in production search systems. Ma et al. (2023) showed that decomposing complex queries into focused sub-questions improves recall on multi-faceted questions. Asai et al. (2023) introduced Self-RAG, an iterative approach in which the model critiques its own answer confidence and re-retrieves if confidence is insufficient. Cormack et al. (2009) established Reciprocal Rank Fusion as a parameter-free method for combining rankings from multiple retrieval sources. Dense retrieval using dual encoders was established by Karpukhin et al. (2020), whose DPR model forms the conceptual basis for the bi-encoder component in V1–V5. BM25 scoring follows Robertson et al. (1995), which established the Okapi parameters k_1 and b used in our V7 Hybrid implementation. Our work evaluates the remaining strategies under a single biomedical evaluation framework for the first time.

LLM-based RAG evaluation. Es et al. (2024) proposed RAGAs, an automated evaluation framework measuring faithfulness, answer relevancy, context precision, and context recall using an LLM judge. Unlike lexical metrics, RAGAs directly assesses answer grounding and retrieval quality, dimensions essential for clinical decision support. We adopt RAGAs as our primary evaluation framework with a locally deployed `gemma3:12b` model as judge, ensuring reproducibility without proprietary API fees and without rate-limiting constraints that affect multi-variant evaluation.

3 Methods

3.1 Corpus and Indexing

We collected 1,954 PubMed abstracts on neurological diseases published between 2015 and 2024 via the NCBI Entrez API, using MeSH terms for neurology and neurological diseases. Abstracts were segmented into structured sections (Background, Methods, Results, Conclusions) using header detection, then chunked to 512 tokens with 64-token overlap. The 512-token chunk size matches the maximum input length of BioMedBERT, and the 64-token overlap preserves sentence context across chunk boundaries, a standard setting in biomedical IR. This yielded 10,425 indexed chunks stored in a persistent ChromaDB vector database.

All chunks are embedded using `microsoft/BiomedNLP-BiomedBERT-base-uncased` (Gu et al., 2021), a BERT variant pre-trained on 29 million PubMed abstracts. Domain-adaptive embeddings capture biomedical terminology that general-purpose models encode poorly. We chose BioMedBERT over general models such as `all-MiniLM-L6-v2` because biomedical terms such as "tau phosphorylation" and "amyloid-beta cascade" occupy semantically coherent regions in the BioMedBERT embedding space, improving retrieval quality on clinical text.

3.2 Evaluation Benchmark

We evaluate on BioASQ Training 13b (Nentidis et al., 2025), containing 5,389 expert-curated biomedical questions with gold-standard answers and supporting PubMed snippets. BioASQ provides gold context snippets per question, enabling computation of context recall against a human-verified reference. We filter questions to neurology-relevant topics using 25 domain keywords to align the benchmark with our corpus domain; the full keyword list is provided in Appendix D. We sample 100 questions per variant, selecting factoid and summary question types that require open-ended answer generation rather than binary yes/no responses.

3.3 Retrieval Variants

Figure 1 illustrates the complete BioRAG pipeline. We evaluate seven retrieval strategies of increasing complexity:

V1 – Naive Dense Retrieval (Lewis et al., 2020): Single-stage cosine similarity search, $\text{sim}(q, d) = (\mathbf{q} \cdot \mathbf{d})/(\|\mathbf{q}\|\|\mathbf{d}\|)$, in BioMedBERT embedding space. Returns top-k chunks directly. Serves as the performance baseline against which all other variants are evaluated.

V2 – HyDE (Gao et al., 2023): The LLM generates a hypothetical PubMed-style abstract that would answer the query. This hypothesis is embedded and used as the retrieval vector rather than the original question embedding, bridging the semantic gap between question phrasing and scientific document language.

V3 – Cross-Encoder Reranker (Nogueira and Cho, 2019): Two-stage retrieval. Stage one uses dense bi-encoder search to fetch $k \times 4$ candidates. Stage two applies `ms-marco-MiniLM-L-12-v2` cross-encoder reranking, which attends jointly to the query and each candidate passage to produce a relevance score.

V4 – HyDE + Reranker: Combines V2 and V3. Hypothesis-guided retrieval expands the semantic coverage of the candidate pool, and cross-encoder reranking then orders candidates by true relevance. Tests whether the two improvements are additive.

V5 – Multi-Query Decomposition (Ma et al., 2023): The LLM decomposes each question into three focused sub-queries. Candidates are retrieved independently for each sub-query, deduplicated by PMID, and reranked against the original question using the cross-encoder. Designed to improve recall on complex biomedical questions with multiple intents.

V6 – Self-RAG (Asai et al., 2023): Iterative retrieval with LLM confidence critique. The system retrieves, generates a candidate answer, and prompts the LLM to assess confidence as HIGH, MEDIUM, or LOW. If confidence is below HIGH, a follow-up query is generated and retrieval repeats for up to three rounds. Targets hallucination reduction through iterative grounding verification.

V7 – Hybrid BM25 + Dense (Cormack et al., 2009): Parallel retrieval via BM25Okapi sparse search and BioMedBERT dense search. Rankings are merged using Reciprocal Rank Fusion with constant $k = 60$:

$$\text{BM25}(q, d) = \sum_{t \in q} \text{IDF}(t) \cdot \frac{f(t, d) \cdot (k_1 + 1)}{f(t, d) + k_1 \left(1 - b + b \cdot \frac{|d|}{\text{avgdl}}\right)} \quad (1)$$

$$\text{RRF}(d) = \sum_{r \in R} \frac{1}{k + r(d)} \quad (2)$$

where R is the set of rankers and $r(d)$ is the rank of document d in ranker r. The fused list is then reranked by the cross-encoder. BM25 captures exact biomedical term matches such as gene names and drug identifiers that dense retrieval misses when query and document phrasing differ.

Late-interaction models such as ColBERT (Khattab and Zaharia, 2020) are excluded because their token-level index structure requires a dedicated retrieval engine incompatible with the shared ChromaDB vector store used across all variants, which would confound retrieval strategy with retrieval infrastructure.

Table 1 summarises the computational complexity of each variant in terms of LLM calls per question, candidate pool size, and retrieval stages.

Variant	LLM calls	Pool size	Stages	Rerank
V1 Naive	0	k	1	No
V2 HyDE	1	k	2	No
V3 Reranker	0	$4k$	2	Yes
V4 HyDE+R	1	$4k$	3	Yes
V5 MultiQ	1	$12k$	3	Yes
V6 Self-RAG	1–3	$3k$	2–6	No
V7 Hybrid	0	$8k$	3	Yes

Table 1: Retrieval variant complexity. LLM calls excludes answer generation. Pool size uses $k = 5$ top results. V6 Self-RAG calls vary by confidence level reached.

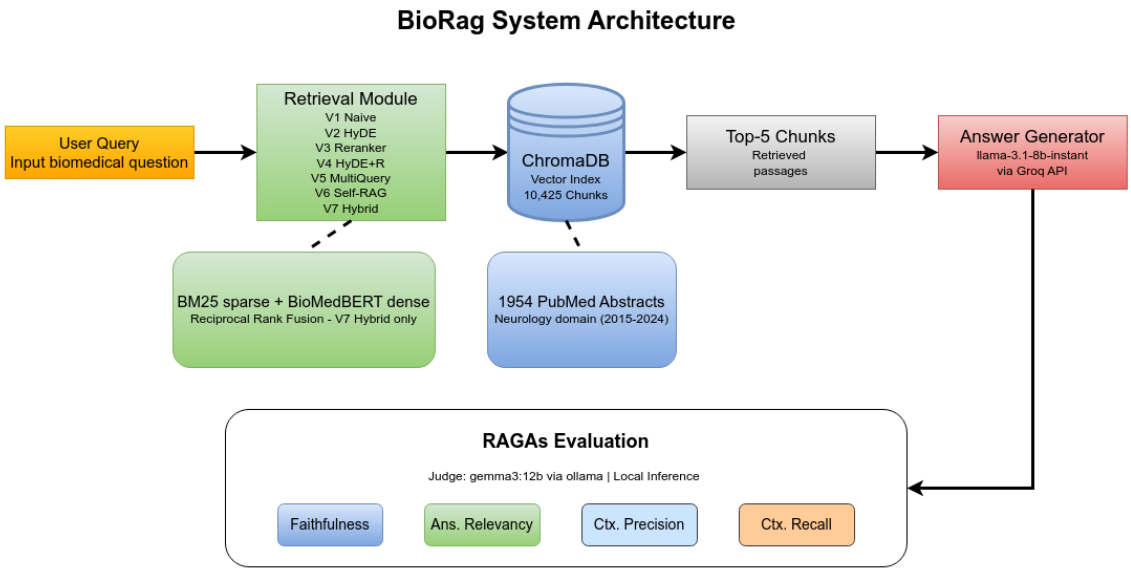

Figure 1: **BioRAG system architecture.** A biomedical query passes through one of seven retrieval variants (V1–V7), which retrieve the top-5 relevant chunks from a ChromaDB index of 10,425 BioMedBERT-embedded PubMed neurology abstracts. The answer generator (`llama-3.1-8b-instant` via Groq) produces a response from the retrieved context. The complete pipeline is evaluated using four RAGAs metrics with a locally deployed `gemma3:12b` judge.

3.4 Answer Generation

All answer generation uses `llama-3.1-8b-instant` via the Groq inference API. Answers are generated from the top-5 retrieved chunks using a prompt that instructs the model to synthesise from available context, falling back to general biomedical knowledge when context is incomplete. We use `temperature=0.1` and `max_tokens=512` for all variants to ensure comparable generation conditions. Total wall-clock time per question including answer generation ranges from approximately 5 seconds (V1 Naive) to 55 seconds (V6 Self-RAG) depending on Groq API latency.

3.5 Evaluation Setup

RAGAs evaluation (Es et al., 2024) uses `gemma3:12b` running locally via Ollama as the judge LLM, ensuring unlimited evaluation calls without API fees. We report four metrics per variant:

- **Faithfulness**: fraction of answer claims supported by retrieved context, measured by LLM-based claim extraction and verification.
- **Answer Relevancy**: degree to which the answer addresses the original question, measured via embedding similarity between the answer and synthetic questions generated from it.
- **Context Precision**: fraction of retrieved chunks that are relevant to the question, scored by the judge LLM per chunk.
- **Context Recall**: fraction of gold-standard information covered by the retrieved context, measured against BioASQ reference snippets.

To assess stability, we run each variant under three random seeds (42, 123, 456) and compute 95% bootstrap confidence intervals using 1,000 resamples. We additionally run a hyperparameter sensitivity analysis varying $k \in \{3, 5, 10\}$ for V1, V3, and V7. V6 Self-RAG is excluded from both analyses because its results are confounded by Groq free-tier rate limiting rather than algorithmic behaviour; including it would produce artificially stable low scores reflecting infrastructure constraints rather than retrieval quality. All other five variants plus V7 are included in the significance analysis. Reported scores in Table 2 correspond to the primary run with $k = 5$ and seed 42; the k-sensitivity results in Table 6 use seed 123 and reflect question sampling variance across seeds, as reported in Table 3.

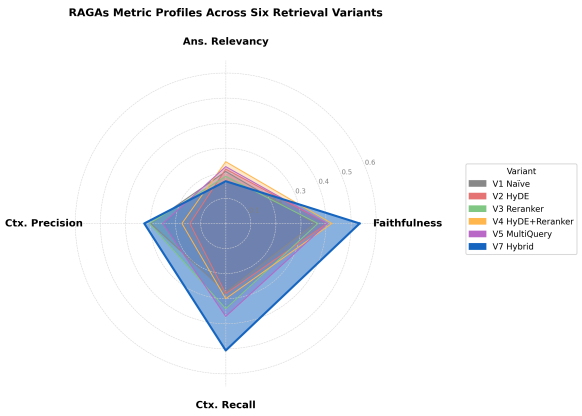

Figure 2: RAGAs metric profiles across six retrieval variants (V6 excluded from this chart due to infrastructure confounding; see Section 6). V7 Hybrid (dark blue) occupies the largest overall area, winning faithfulness, context precision, and context recall. V4 HyDE plus Reranker leads answer relevancy. No single variant dominates all four axes.

3.6 Implementation Details

All experiments run on a single consumer GPU with 8GB VRAM. BioMedBERT embeddings are computed locally via HuggingFace Transformers. The cross-encoder reranker uses a candidate pool of $k \times 4 = 20$ passages. BM25 uses Okapi parameters $k_1 = 1.5$ and $b = 0.75$. Groq free-tier inference provides 30 requests per minute and 500,000 tokens per day. A cooldown of 4 seconds between API calls prevents rate-limit exhaustion during evaluation. All code, evaluation scripts, and results are publicly available to support reproducible biomedical RAG research.

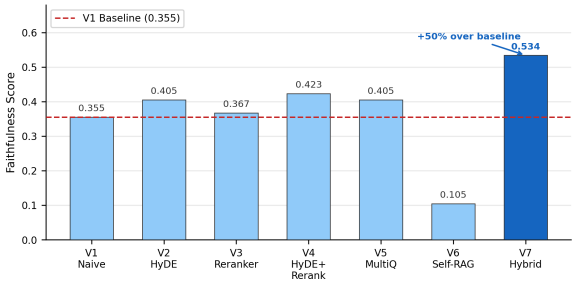

Figure 3: Faithfulness scores across all variants including V6 Self-RAG (seed 42, $k = 5$). V7 Hybrid achieves 0.534, a 50% improvement over the V1 Naive baseline (dashed line). V6 Self-RAG collapses to 0.105 due to Groq free-tier rate-limiting constraints; full V6 results appear in Appendix E.

4 Results

Table 2 presents RAGAs scores for six retrieval variants evaluated on 100 BioASQ-13b neurology questions (seed 42, $k = 5$); V6 Self-RAG is reported separately in Appendix E. Figure 3 shows faithfulness scores across all variants. Figure 2 presents the complete metric profile for V1–V5 and V7 across all four RAGAs dimensions. For reference, Es et al. (2024) report faithfulness scores of 0.4–0.6 on general-domain QA using GPT-4 as judge with a stronger model; our scores fall within this range despite using a smaller local judge on a domain-specific corpus, indicating reasonable calibration.

Hybrid retrieval dominates. V7 Hybrid achieves the highest faithfulness (0.534), context precision (0.325), and context recall (0.507), winning three of four metrics. The combination of BM25 sparse retrieval with BioMedBERT dense retrieval via Reciprocal Rank Fusion captures complementary signals: BM25 matches exact biomedical terms such as gene names and drug identifiers, while dense retrieval handles semantic paraphrasing. The 50% faithfulness improvement over V1 (0.355 to 0.534) and 85% context recall improvement (0.273 to 0.507) establish V7 as the strongest variant for biomedical RAG. These gains are consistent with findings from production search systems where hybrid retrieval outperforms single-signal approaches (Cormack et al., 2009).

HyDE introduces a faithfulness-precision tradeoff. V2 HyDE improves faithfulness over V1 (0.405 vs 0.355, +14%) but reduces context precision substantially (0.143 vs 0.300, −52%). Hypothesis generation shifts retrieval toward the answer embedding space, improving grounding but expanding the candidate pool with plausible yet

Variant	Faithfulness↑	Ans. Rel.↑	Ctx. Prec.↑	Ctx. Recall↑	Latency
V1 Naive Dense	0.355	0.207	0.300	0.273	46ms
V2 HyDE	0.405	0.217	0.143	0.280	1370ms
V3 Reranker	0.367	0.188	0.304	0.340	388ms
V4 HyDE+Reranker	0.423	**0.247**	0.175	0.300	1795ms
V5 MultiQuery	0.405	0.227	0.251	0.371	1611ms
V7 Hybrid	**0.534**	0.169	**0.325**	**0.507**	1551ms

Table 2: RAGAs evaluation results on 100 BioASQ-13b neurology questions using `gemma3:12b` as judge (seed 42, $k = 5$). Bold indicates best per metric. Latency reflects mean retrieval time only, excluding answer generation. V6 Self-RAG is excluded from this table due to infrastructure confounding; see Appendix E for full V6 results.

Variant	Metric	Mean	Std	95% CI lower	95% CI upper
V7 Hybrid	Faithfulness	**0.585**	0.021	0.565	0.607
V2 HyDE	Faithfulness	0.463	0.052	0.406	0.506
V4 HyDE+Reranker	Faithfulness	0.448	0.060	0.378	0.486
V5 MultiQuery	Faithfulness	0.412	0.036	0.372	0.442
V1 Naive	Faithfulness	0.365	0.033	0.329	0.393
V3 Reranker	Faithfulness	0.352	0.022	0.327	0.366
V7 Hybrid	Ctx. Recall	**0.478**	0.042	0.430	0.503
V1 Naive	Ctx. Recall	0.372	0.018	0.353	0.388
V3 Reranker	Ctx. Recall	0.340	0.015	0.326	0.356

Table 3: Bootstrap confidence intervals (95%, 1,000 resamples) across three random seeds (42, 123, 456) for faithfulness and context recall. Means differ from Table 2 single-seed values due to question sampling variance across seeds (standard deviations confirm this). V7 Hybrid confidence intervals do not overlap with any other variant on either metric, confirming statistical significance of the reported gains. V2 and V5 faithfulness intervals overlap, indicating no reliable difference between those two variants. V6 Self-RAG excluded due to infrastructure confounding.

imprecise passages. V4 HyDE plus Reranker partially recovers precision (0.175) while achieving the highest answer relevancy (0.247), suggesting that reranking mitigates but does not eliminate the HyDE precision penalty. This tradeoff has not been previously documented on BioASQ and represents a key finding for clinical system designers who must balance faithfulness against retrieval precision.

Reranking improves context recall. V3 Reranker achieves the highest context recall among single-enhancement variants (0.340 vs 0.273 baseline, +24.5%). Cross-encoder joint scoring retrieves passages that are genuinely relevant to the question rather than merely semantically similar in embedding space. V5 MultiQuery extends this further by decomposing questions into sub-queries, achieving 0.371 context recall, the second highest across all variants, by covering multiple facets of complex biomedical questions.

No single strategy dominates all metrics. V7 leads faithfulness, context precision, and context recall while V4 leads answer relevancy. This multi-winner result has direct clinical implications: safety-critical applications requiring grounded answers should prefer V7 Hybrid, while end-user-facing systems prioritising direct question relevance should prefer V4 HyDE plus Reranker. Latency-constrained deployments should prefer V1 Naive (46ms) or V3 Reranker (388ms).

Self-RAG is not viable on rate-limited APIs. V6 Self-RAG, reported separately in Appendix E due to infrastructure confounding, achieves faithfulness of 0.105 and latency of 48,730ms under Groq free-tier constraints. The iterative critique loop generates multiple sequential API calls per question, exhausting Groq free-tier rate limits (30 requests per minute) and introducing 10–30 second wait periods between retrieval rounds. This stalling amplifies retrieval noise rather than resolving uncertainty, as the model accumulates low-confidence context across rounds. Self-RAG requires dedicated inference capacity or local LLM deployment to function as intended.

Statistical significance. Table 3 reports bootstrap confidence intervals across three random seeds. V7 Hybrid faithfulness mean of 0.585 with 95% CI [0.565, 0.607] does not overlap with any other variant, confirming that V7 gains are statistically reliable. V2 HyDE and V5 MultiQuery faithfulness intervals overlap, indicating no reliable difference between those two strategies. Means in Table 3 differ from Table 2 single-seed values because each seed samples a different question subset; the standard deviations quantify this sampling variance.

5 Discussion

5.1 Clinical Deployment Implications

Our results provide concrete guidance for practitioners designing biomedical RAG systems. The choice of retrieval strategy should be driven by the primary clinical objective rather than a single performance number. For safety-critical applications such as clinical decision support, where hallucinated claims can directly harm patients, V7 Hybrid maximises faithfulness (0.534) and should be the default choice. For patient-facing QA systems where answer relevance and directness matter most, V4 HyDE plus Reranker achieves the highest answer relevancy (0.247). For evidence review applications such as systematic literature search, V7 also dominates with context recall of 0.507, retrieving over half the gold-standard evidence from BioASQ reference snippets.

Table 4 maps each clinical use case to the recommended variant and primary metric.

Clinical Use Case	Recommended	Key Metric
Decision support	V7 Hybrid	Faithfulness
Patient-facing QA	V4 HyDE+R	Ans. Rel.
Systematic review	V7 Hybrid	Ctx. Recall
Real-time interface	V3 Reranker	Latency
High-throughput	V1 Naive	Latency

Table 4: Hypothesized retrieval strategy mappings by clinical use case, based on RAGAs metric performance. Clinical validation is required before deployment.

5.2 The HyDE Faithfulness-Precision Tradeoff

The faithfulness-precision tradeoff introduced by HyDE carries a specific clinical implication. Hypothesis generation improves answer grounding by aligning retrieval with the answer embedding space, but it simultaneously retrieves a broader, noisier candidate pool. In clinical settings where precision is critical, for example retrieving the correct drug dosage rather than broadly related pharmacology, HyDE alone is counterproductive. V4 HyDE plus Reranker partially addresses this by filtering the expanded pool, making it a better choice when both grounding and precision matter.

5.3 Latency and Production Tradeoffs

Latency varies across variants from 46ms for V1 Naive to 48,730ms for V6 Self-RAG. These figures reflect retrieval time only; answer generation via Groq adds approximately 3–8 seconds per question across all variants. For real-time clinical applications, V3 Reranker offers the best accuracy-latency tradeoff: it achieves the highest context recall among non-hybrid variants (0.340) at only 388ms retrieval time, making it suitable for interactive QA interfaces. V7 Hybrid delivers the strongest overall performance at 1,551ms retrieval time, acceptable for asynchronous clinical workflows but potentially prohibitive for real-time decision support. V1 Naive at 46ms remains appropriate for high-throughput screening applications where speed outweighs accuracy. Groq answer generation adds approximately 3–8 seconds to all variants, meaning end-to-end latency differences between V1 and V3 are less differentiating in practice than retrieval times alone suggest.

5.4 Reproducibility

BioRAG operates without proprietary API fees throughout the evaluation pipeline: BioMedBERT embeddings run locally, ChromaDB requires no cloud infrastructure, Groq provides free-tier answer generation, and Ollama hosts the RAGAs judge locally. Researchers at institutions without GPU clusters or API budgets can replicate all experiments using consumer hardware. The entire evaluation pipeline for all seven variants runs in approximately 15 hours on a single 8GB GPU.

6 Limitations

Our corpus of 1,954 neurology abstracts covers a single biomedical subdomain, while BioASQ spans all of biomedicine. A domain mismatch diagnostic on the 100 evaluation questions found that 2 of 100 questions (2.0%) returned no relevant corpus material, confirmed by V1 Naive aggregate faithfulness (0.355) remaining above the mismatch threshold. This low mismatch rate indicates that reduced absolute RAGAs scores reflect retrieval qual-

ity differences rather than corpus coverage failures, supporting the validity of relative comparisons.

RAGAs evaluation with `gemma3:12b` as judge has not been validated against human expert assessments on biomedical QA. This is a primary methodological concern: an unvalidated judge introduces unknown calibration bias, and ranking differences between close variants such as V2 and V5 may not reflect true retrieval quality differences. Future work should conduct human annotation on a subset of questions to validate judge rankings against expert assessments. Evaluation uses a smaller judge than GPT-4-class models, which may introduce calibration differences relative to stronger judges; however, this is necessary for reproducibility without proprietary API costs.

The answer generation prompt permits fallback to general biomedical knowledge when context is incomplete, meaning faithfulness scores partially reflect the generator's parametric knowledge rather than retrieval quality alone. Future work should compare strict context-only prompts to isolate retrieval contribution. Answer generation uses `llama-3.1-8b-instant`, a smaller model than those used in comparable studies, which may underestimate the performance ceiling of each retrieval strategy when paired with a stronger generator. Generator and retriever quality interact in ways this study cannot fully disentangle with a single generator model. V6 Self-RAG performance is specifically constrained by free-tier API rate limits rather than algorithmic limitations; with dedicated inference, Self-RAG would operate at comparable latency to other LLM-dependent variants. The evaluation does not include an error analysis categorising failure modes by question type; future work should examine whether retrieval failures concentrate in specific question categories such as multi-hop or causal questions. Future work should validate findings with a larger multi-domain corpus, human judge validation, a stronger generator, and unconstrained inference for Self-RAG.

7 Conclusion

We presented BioRAG, a systematic ablation study comparing seven retrieval strategies for biomedical question answering on BioASQ-13b. Hybrid BM25 plus dense retrieval with Reciprocal Rank Fusion achieves the strongest overall performance, improving faithfulness by 50% and context recall by 85% over naive dense retrieval, with bootstrap confidence intervals confirming these gains are statistically reliable. HyDE consistently improves faithfulness but introduces a 52% context precision penalty, a tradeoff with direct implications for clinical RAG system design that has not been previously documented on BioASQ. No single strategy dominates all four RAGAs metrics, demonstrating that retrieval strategy selection must be driven by application-specific clinical requirements. The complete evaluation pipeline is released to support reproducible biomedical RAG research in line with BioNLP 2026's emphasis on evaluation frameworks and reproducibility of findings.

Alongside the evaluation pipeline, we release an interactive Streamlit demo enabling practitioners to compare all seven retrieval variants on custom queries, supporting the translation of our findings into biomedical NLP practice.

A Prompt Templates

All prompts use `llama-3.1-8b-instant` via Groq API with `temperature=0.1`.

HyDE Hypothesis Generation (V2, V4).

> *Write a PubMed-style abstract that directly answers the following biomedical question. Be specific and use scientific terminology. Question: {question}*

Multi-Query Decomposition (V5).

> *Generate three different search queries to retrieve relevant biomedical literature for answering this question. Each query should focus on a different aspect. Question: {question}. Output format: Query 1: ... Query 2: ... Query 3: ...*

Self-RAG Confidence Critique (V6).

> *Given the question and retrieved context, assess your confidence in the answer. Respond in JSON: {"confidence": "HIGH/MEDIUM/LOW", "missing": "...", "followup_query": "..."}. Question: {question}. Context: {context}. Candidate answer: {answer}*

Answer Generation (all variants).

> *You are a biomedical expert. Answer the question using the provided context. Prioritise information from the context. If the context is relevant but incomplete, synthesise an answer from what is available. If the context is entirely unrelated, draw on general biomedical knowledge. Question: {question}. Context: {context}*

B Example Evaluation Cases

Table 5 presents three representative BioASQ questions from our evaluation set with answers generated by V1 Naive and V7 Hybrid, illustrating the practical impact of retrieval strategy on answer quality.

Question	V1 Naive answer	V7 Hybrid answer
What is the association between neuroticism and Alzheimer's disease risk?	High levels of neuroticism have been associated with increased risk of cognitive decline in older adults, though the mechanisms remain unclear.	High neuroticism is associated with significantly increased Alzheimer's disease risk and more advanced neuropathology, including greater amyloid burden and tau phosphorylation, independent of depression.
What is the association between adiponectin and migraine?	Adiponectin is an adipokine involved in metabolic regulation and has been studied in various neurological conditions.	Adiponectin levels are elevated in episodic migraine patients compared to controls, suggesting a role in migraine pathophysiology potentially linked to neurogenic inflammation.
Does H. pylori infection increase risk for ischemic stroke?	H. pylori is a gastrointestinal pathogen that has been associated with systemic inflammation in some studies.	Evidence is conflicting, but several studies report that H. pylori infection is associated with increased ischemic stroke risk, potentially mediated through inflammatory and prothrombotic mechanisms.

Table 5: Representative BioASQ evaluation examples comparing V1 Naive and V7 Hybrid answers. V7 consistently produces more specific, evidence-grounded responses due to BM25 capturing exact biomedical terminology.

C Hyperparameter Sensitivity

Table 6 reports faithfulness and context recall for V1 Naive, V3 Reranker, and V7 Hybrid across $k \in \{3, 5, 10\}$ retrieved chunks. These runs use seed 123 and a freshly sampled question subset; values differ from Table 2 (seed 42) due to question sampling variance, which is quantified in Table 3. V7 Hybrid maintains the highest faithfulness at $k = 5$ and $k = 10$, with context recall improving from 0.368 to 0.658 as k increases. V3 Reranker shows non-monotonic behaviour, peaking at $k = 10$ for faithfulness (0.463) but dropping context recall at $k = 10$ (0.238). V1 Naive faithfulness increases steadily with k, consistent with the finding that more context benefits simpler retrieval more than strategies that already filter aggressively. These results confirm that $k = 5$ is a conservative setting and that relative rankings between variants are preserved across the tested range.

D Neurology Domain Keywords

The following 25 keywords were used to filter BioASQ Training 13b questions to the neurology domain: *alzheimer, tau, dopamine, stroke, epilepsy, parkinson, dementia, neuron, cortex, hippocampus, amyloid, synapse, neurotransmitter, seizure, migraine, multiple sclerosis, neuropathy, glioma, cerebral, meningitis, encephalitis, neurodegeneration, myelin, axon, spinal*.

E V6 Self-RAG Infrastructure Results

Table 7 reports V6 Self-RAG results for completeness. These results are excluded from Table 2 because they reflect Groq free-tier rate-limiting constraints rather than algorithmic performance. The iterative critique loop generates multiple sequential API calls per question, exhausting the 30 requests-per-minute limit and introducing 10–30 second wait periods between rounds. With dedicated local inference, Self-RAG would operate at latency comparable to V4 and V5.

Variant	k	Faith.	Ctx. Prec.	Ctx. Rec.	Lat. (ms)
V1 Naive	3	0.323	0.276	0.267	48
V1 Naive	5	0.404	0.283	0.288	54
V1 Naive	10	0.440	0.282	0.332	52
V3 Reranker	3	0.381	0.331	0.298	215
V3 Reranker	5	0.359	0.310	0.352	319
V3 Reranker	10	0.463	0.299	0.238	781
V7 Hybrid	3	0.431	0.295	0.368	917
V7 Hybrid	5	**0.476**	**0.325**	0.507	1588
V7 Hybrid	10	0.474	0.294	**0.658**	3240

Table 6: Hyperparameter sensitivity across $k \in \{3, 5, 10\}$ using seed 123. Values differ from Table 2 (seed 42) due to question sampling variance across seeds; see Table 3 for cross-seed standard deviations. Bold indicates best per metric across all rows.

Variant	Faith.	Ans.Rel.	Ctx.Prec.	Ctx.Rec.	Latency
V6 Self-RAG	0.105	0.050	0.286	0.310	48730ms

Table 7: V6 Self-RAG results under Groq free-tier rate-limiting. Scores reflect infrastructure constraints, not algorithmic capability. Included for completeness only.

Post Hoc Agentic Refinement for Improving Precision in Multilingual Clinical Text De-identification

Justin Xu[1,2,*], **Alistair E W Johnson**[2], **Thomas Lin**[2],
David W Eyre[1], **Rodolfo Quispe**[2]

Abstract

De-identification systems prioritize recall to protect privacy, but excessive over-tagging reduces data utility. We propose an agentic refiner that reviews high-recall annotations using lightweight tools (validation functions, adaptive context retrieval, persistent to-do state, and modular review skills) to improve precision while minimizing recall loss. Experiments across three multilingual datasets show that the agent achieves significant improvements to binary precision. To support fine-grained analysis, we further introduce a synthetic error dataset of common and systemic failure modes, on which the agent corrects >99% of injected errors in the medical datasets. Our results suggest that agent-based refinement provides a flexible and effective mechanism for improving de-identification precision as a modular extension to existing high-recall systems.

1 Introduction

De-identification of text aims to detect and remove or mask Protected Health Information (PHI) in clinical data and, more broadly, Personally Identifiable Information (PII) in unstructured text. This task is a prerequisite for data sharing, secondary use, and deployment of downstream NLP systems in sensitive domains. From a privacy perspective, recall is paramount: failing to identify a true PHI/PII instance risks irreversible disclosure, whereas over-tagging benign text is less harmful in terms of privacy. Consequently, many de-identification systems are optimized to maximize recall, often at the expense of precision (Uzuner et al., 2007; Stubbs and Uzuner, 2015; Li et al., 2024). However, in many real-world settings, practitioners may be willing to trade small amounts of recall for meaningful improvements in precision, particularly when working within systems with additional safeguards for patient privacy. Excessive over-tagging degrades data utility, harms readability, and can negatively impact applications such as clinical coding, summarization, retrieval, and generative model training. The ideal de-identification system should thus maintain both high recall and high precision – a balance that remains challenging to achieve in scenarios requiring nuanced contextual reasoning (Yang et al., 2019; Li et al., 2024).

In this work, we study post hoc refinement of de-identification outputs as a complement to existing high-recall systems. Rather than introducing a new end-to-end model, we assume an initial set of PHI/PII annotations and focus on improving precision. As a baseline, we consider a simple LLM-as-a-judge approach that reviews annotation spans in context. We then introduce an agentic refiner, designed to reason over annotations using Model Context Protocol (MCP) (Hou et al., 2025) tools and iterative decision-making, enabling more consistent refinement. We additionally construct a synthetic error dataset for fine-grained evaluation of error detection and correction.

Our contributions can be summarized as follows:

1. We propose a modular agent-based refinement pipeline that can be attached to the output of any existing de-identification system to improve precision without retraining (Figure 1).
2. We evaluate this approach across three complementary datasets spanning Spanish clinical notes, German medical transcripts, and English general-domain text with PII (Table 1).
3. We introduce methods to create a synthetic error dataset for de-identification refinement, evaluating error detection (Section 5).

2 Related Works

Early de-identification systems relied on rule-based methods using handcrafted patterns and dictionaries (Neamatullah et al., 2008). Later work framed

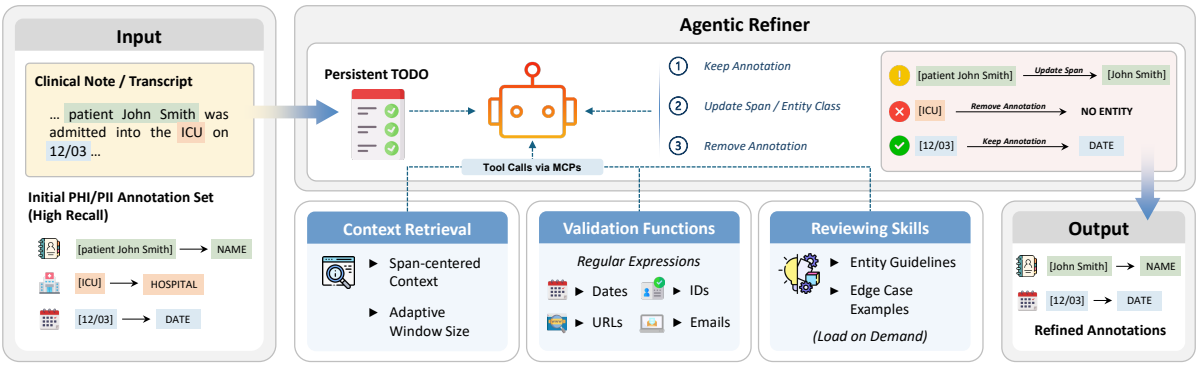

Figure 1: Schematic of Post Hoc Agentic Refinement of Annotations in Clinical Text De-identification.

de-identification as a supervised sequence labeling task, adopting Transformer-based models (BERT and its clinical variants (Alsentzer et al., 2019; Johnson et al., 2020; Huang et al., 2020; Lee et al., 2025; Sounack et al., 2025)). Prior efforts have also combined neural models with external knowledge to generate higher-precision silver data (Tedeschi et al., 2021). More recently, LLMs have been applied to de-identification in zero/few-shot settings, demonstrating acceptable recall and flexibility (Singh et al., 2025; Dai et al., 2025; Zhu et al., 2025; Ding et al., 2025; Aghakasiri et al., 2025). However, LLM-based methods often over-predict PHI/PII and exhibit inconsistent labeling, which is highly sensitive to linguistic nuances in the provided prompt. Agentic systems have also been explored for end-to-end information extraction and clinical reasoning (Yao et al., 2023; Shen et al., 2023; Lu et al., 2025; Lin et al., 2025), but remain costly and difficult to control for de-identification.

In contrast, our work focuses on agent-based refinement rather than replacement. By operating only on an existing set of annotations, our approach provides guardrails to an otherwise open-ended NER task. This modular design allows the agent to be integrated as a precision-enhancing layer on top of high-recall de-identification pipelines.

3 Experimental Design

3.1 Problem Definition

Let a document be represented as a token sequence $D = \{w_1, \ldots, w_n\}$. An upstream de-identification system produces an initial set of PHI/PII annotations $\mathcal{A} = \{a_1, \ldots, a_K\}$, where each annotation $a_i = (s_i, e_i, c_i, t_i)$ consists of a start index s_i, end index e_i, an entity class $c_i \in \mathcal{C}$, and a surface text span $t_i = \{w_{s_i}, \ldots, w_{e_i}\}$.

Given the document D and an associated annotation set $\mathcal{A}$, the refinement task aims to produce an updated set $\mathcal{A}^*$ by evaluating each a_i independently. For a given annotation, the refiner decides whether to (i) retain it unchanged, (ii) update its span boundaries (s_i, e_i), (iii) modify its class c_i, or (iv) remove it entirely if it does not correspond to PHI/PII. The refiner does not introduce new annotations; its sole role is to improve the quality of an existing high-recall annotation set.

This formulation treats de-identification as a contextualized span validation problem rather than end-to-end sequence labeling, enabling refinement to be applied as a post hoc layer on top of arbitrary upstream systems.

3.2 Datasets and Evaluation Metrics

We evaluate annotation refinement across three multilingual datasets. For all datasets, refinement is applied to an initial set of PHI/PII annotations produced by GPT-5 (`gpt-5-2025-08-07`) in a few-shot setting, with entity class-specific guidelines (prompt available in Appendix A.1).

CARMEN-ES (5,614 Total PHI). Derived from the Spanish subset of the *CARMEN-I* corpus of 2,000 documents (Farre Maduell et al., 2024), comprising of discharge summaries, referrals, and radiology reports from Hospital Clínic of Barcelona (March 2020 – March 2022). The collection primarily covers COVID-19 patients with diverse comorbidities. Documents in Catalan or mixed Spanish-Catalan were excluded, and high-quality gold labels were previously validated by experts.

Transcripts-DE (238 Total PHI). Conversational clinical encounters in the German language simulated by medical actors and grounded in real-world patient cases from a hospital in Germany.

WikiPII-EN (24,145 Total PII). Info-boxes with people and animal descriptions derived from English Wikipedia articles (Wang et al., 2018). This represents a general-domain de-identification setting and reflects common non-clinical applications.

Evaluation. Our primary focus is binary PHI/PII detection. An annotation is considered correct if its span overlaps with a gold PHI/PII span, regardless of entity class. We report precision, recall, and F1 where precision measures the proportion of predicted PHI/PII tokens that are correct and recall measures the proportion of gold PHI/PII tokens that are recovered.

3.3 LLM Refiner Baseline

As a baseline, we implement an LLM-based refiner using GPT-5 (`gpt-5-2025-08-07`, medium verbosity and reasoning effort). For each annotation a_i, the model is prompted with the document D, the surface text span t_i from (s_i, e_i), its class c_i, and general PHI/PII labeling guidelines, and is asked to determine whether the annotation should be kept, modified, or removed (prompt available in Appendix A.2). Few-shot examples are provided to encourage consistent behavior.

As seen in "Post-Refinement (GPT-5, Single Call)" of Table 1, while this approach improves binary precision, it removes many valid PHI/PII spans, leading to substantial recall degradation. In addition, the method requires one large API call per annotation with long contextual inputs, motivating a more optimized structured refinement approach.

4 Agentic Refiner

We model annotation refinement as an agentic decision process operating over a document D and its initial annotation set $\mathcal{A} = \{a_1, \ldots, a_K\}$. The agent similarly processes annotations sequentially and produces a refined set $\mathcal{A}^*$.

At each step, the agent maintains a state $\sigma_i = (D, a_i, h_i)$, where $a_i = (s_i, e_i, c_i, t_i)$ is the current annotation under review and h_i denotes the agent's internal memory, including prior decisions and intermediate observations. Given σ_i, the agent selects an action o_i from a discrete refinement space corresponding to retaining, modifying, or removing a_i. Actions may involve tool calls executed through MCP servers, after which the agent updates its state and proceeds to the next annotation.

Formally, the agent implements a policy $\pi(o_i \mid \sigma_i)$ that interleaves natural language reasoning with tool use, producing $\mathcal{A}^*$ after all annotations have been reviewed. Unlike the LLM baseline, the agent's decisions are informed by persistent memory and structured tool outputs, enabling more consistent refinement across long documents. Appendix B highlights representative agentic outputs.

Persistent To-Do List. The agent initializes a persistent to-do list containing all annotations in $\mathcal{A}$ for a given document and marks items as completed as refinement progresses. This externalized memory allows progress tracking over long clinical notes, which may contain several dozen annotations with overlapping surface forms. Similar task decomposition strategies have been shown to improve reliability and long-horizon performance (Yao et al., 2023; Shen et al., 2023).

Pattern-Based Validation Tools. We provide deterministic validation functions based on regular expressions for entity types with well-defined surface forms, such as dates, email addresses, URLs, and identifiers. When applicable, the agent can invoke these tools to validate or reject an annotation without extended reasoning. Offloading high-confidence decisions to symbolic components can reduce hallucinations and improve grounding in hybrid neuro-symbolic and tool-augmented systems (Gao et al., 2023; Schick et al., 2023).

Adaptive Context Retrieval. Rather than always conditioning on the full document D, the agent can dynamically retrieve a window of context around the annotation span, selecting a variable number of tokens to the left and right of t_i based on (s_i, e_i). This flexibility is particularly important for conversational transcripts, where relevant context may span multiple turns of varying length. Adaptive context selection reduces unnecessary token usage while preserving critical discourse information.

Modular Review Skills. Finally, the agent can load specialized review *skills* on demand (Zhang et al., 2025) – modular guideline documents associated with groups of related entity classes. These skills include entity definitions (identical to the guidelines provided to the baseline refiner) and examples of correct and incorrect annotations (including edge cases). The agent decides when to load a skill during its reasoning process, allowing targeted access to entity class-specific knowledge and enables incremental future development.

Dataset	Precision ↑	Recall ↑	F1 ↑
Original GPT-5 Annotations			
CARMEN-ES	90.76	96.75	93.65
Transcripts-DE	56.01	92.02	69.67
WikiPII-EN	83.03	96.85	89.41
Post-Refinement (GPT-5, Single Call)			
CARMEN-ES	94.31 (+3.55)	93.97 (-2.78)	94.14 (+0.49)
Transcripts-DE	69.96 (+13.95)	83.19 (-8.83)	75.97 (+6.30)
WikiPII-EN	90.72 (+7.69)	92.03 (-4.82)	91.37 (+1.96)
Post-Refinement (Agentic)			
CARMEN-ES	97.95 (+7.19)	95.39 (-1.36)	**96.65** (+3.00)
Transcripts-DE	83.68 (+27.67)	87.39 (-4.63)	**85.49** (+15.82)
WikiPII-EN	94.92 (+11.89)	88.79 (-8.06)	**91.75** (+2.34)

Table 1: Binary performance metrics (precision, recall, and F1) before and after refinement across datasets. Values in brackets denote changes relative to pre-refinement (original annotations) performance metrics.

Across all datasets, agentic refinement with GPT-5 (`gpt-5-2025-08-07`, medium verbosity and reasoning effort) yields substantially larger precision gains than the baseline, while better controlling recall degradation (leading to optimal F1). On CARMEN-ES, the agent more than doubles the baseline's precision gain, while incurring a smaller recall drop (over 6× F1 boost). For the German transcripts, agentic refinement also achieves more than 2× the baseline precision gain at a lower cost in recall points, reflecting a favorable precision-recall trade-off in a challenging conversational setting. On WikiPII, the agent again delivers stronger precision gains and overall F1, albeit with a larger recall reduction, indicating that aggressive refinement is more likely to remove borderline entities in general-domain text.

5 Error Dataset

To facilitate a precise and controlled evaluation of annotation refinement, we construct a synthetic error dataset in which the exact location and type of each error is known. This allows us to directly measure how effectively a refiner identifies and corrects annotation errors (Table 2). Starting from reference annotations, we inject realistic errors into medical datasets using three complementary strategies.

Regular Expressions. First, we define a set of regular expression-based rules that inject common and well-known de-identification errors. These rules simulate mistakes frequently observed in both statistical and neural de-identification systems. In total, 10 such rules were specified and applied deterministically; the full list is provided in Appendix C.

Systemic Errors via Clustering. Second, we identify systemic error patterns made by LLM-based de-identification systems. We collect incorrect annotations produced by LLMs along with their surrounding context and encode them using a sentence transformer (Reimers and Gurevych, 2019). The resulting embeddings are projected into a lower-dimensional space using UMAP (McInnes et al., 2020) to reveal clusters corresponding to recurring error types.

Each cluster is then summarized using GPT-5 (`gpt-5-2025-08-07`) to produce an interpretable description of the underlying error pattern. These summaries are used to define targeted error injections. For example, we observe a recurrent pattern where football/soccer clubs are mislabeled as CITY entities despite clear organizational context.

Errors from Model Test Logs. Finally, we mine actual errors from testing logs of an existing BERT-based de-identifier. From these logs, we extract incorrect entity mappings and construct a vocabulary of realistic errors, such as labeling *diabetes* as a HOSPITAL, *pleural* as a LOCATION, or *general* as a PROFESSION outside of a military context. These errors are injected verbatim, preserving their original surface forms and entity classes.

Error Dataset	Caught by Baseline ↑	Caught by Agent ↑
CARMEN-ES	2,714 / 2,807 (96.69%)	**2,779 / 2,807** (99.01%)
Transcripts-DE	248 / 294 (84.26%)	**292 / 294** (99.32%)

Table 2: Using the two medical error datasets, we evaluate both the baseline refiner and the agentic refiner on their abilities to detect and correct injected errors. The agentic refiner identifies and corrects over 99% of injected errors, clearly surpassing the baseline.

6 Discussion & Conclusion

We introduce an agent-based post hoc refinement layer for de-identification that improves precision of existing annotations by combining external memory, validation tools, adaptive context retrieval, and on-demand review skills.

In practice, excessive redaction can meaningfully degrade text quality. We observed frequent upstream errors involving disease eponyms, gene names, and institutional acronyms being labeled as PHI. Although conservative tagging improves privacy protection, indiscriminate removal can alter clinical meaning or remove medically salient

context. Agentic refinement allows more selective correction of such false positives, helping maintain alignment between de-identified text and its original informational content. This is particularly important when de-identified data are used for downstream modeling or large-scale pretraining.

The agentic pipeline was developed incrementally, with components introduced one at a time. In internal testing, each module yielded modest but consistent improvements in stability or performance. Among them, the modular review skills contributed most to precision gains. These skills encode detailed, class-specific guidelines and edge cases aligned with the annotation protocol used to construct our evaluation sets, enabling more consistent reasoning than a single prompt with context. Persistent memory (implemented as a to-do list) improves completeness and prevents skipped spans during multi-step review which can be a pattern common in contemporary agentic systems. Adaptive context retrieval primarily reduces token usage and unnecessary context, improving efficiency rather than directly affecting accuracy. This modular design allows practitioners to selectively enable components depending on deployment constraints or cost considerations. To contextualize these improvements, Appendix D includes a brief efficiency analysis of the proposed framework, reporting runtime, token usage, number of LLM calls, and approximate inference cost per document. Although the agentic pipeline introduces moderate additional computational overhead relative to the baseline LLM refiner, the increase remains bounded and corresponds to measurable gains.

Ultimately, the agent's improvements are not a trivial exchange of recall for precision. While some recall reduction is expected when removing spurious annotations, the agent consistently yields net F1 gains in overall annotation quality and utility, resolving false positives more selectively than baseline refinement. These results suggest that agentic refinement is a practical mechanism for precision control in high-recall de-identification pipelines.

Limitations

Currently, all experiments rely on a single LLM backend (GPT-5) with fixed inference parameters to reduce variability. While the proposed agentic framework is model-agnostic, performance characteristics may differ with other proprietary or open-weight models, particularly those with more limited reasoning capabilities. Preliminary experiments with the open-weight `gpt-oss-120b` model suggest that the framework generalizes beyond proprietary backbones, consistently improving precision, especially on transcript datasets, while exhibiting some recall trade-offs due to lower-recall upstream annotations in this setting.

Additionally, the agent operates strictly as a post hoc refiner and does not introduce new PHI/PII annotations. As a result, it cannot recover entities missed by the upstream de-identification system, and its recall is inherently bounded by the initial annotation set. Furthermore, although we evaluate across multiple languages and data modalities, broader experimentation across additional institutions, document types, and deployment settings would further strengthen generalizability.

The synthetic error dataset is designed to cover a wide range of common and systemic error types, but it does not exhaust the space of possible de-identification failures. While the datasets enable precise and controlled evaluation, they are intended to be extensible and can be expanded as new error patterns are observed in real-world use.

Finally, the agent's capabilities were implemented incrementally. Persistent task tracking, adaptive context windows, validation tools, and review skills were sequentially added as each module yielded observable performance improvements. A formal ablation study would be valuable for quantifying the isolated contributions of each component.

Acknowledgments

A Prompts

A.1 Original Annotation Prompt

The following prompt was used to generate the initial PHI/PII annotations on which all refinement experiments were conducted:

GPT-5

```
You will be provided a note containing named entities.
Please identify all instances of the named entity: {ENTITY}.

Specific annotation instructions for the entity: {ENTITY_INSTRUCTION}

Respond with the entity type and the text of the entity, with one entity per line.
Here is an example for {LANGUAGE}: {EXAMPLE}

Respond with the text from the note EXACTLY.

...

If no annotations are found, respond with NO ENTITIES.

The user will provide the note to annotate.
```

A.2 Baseline Refinement Prompt

The following prompt was used to perform baseline LLM-based refinement of PHI/PII annotations:

GPT-5

```
You are correcting named entity recognition annotations.

You will be provided with a single named entity annotation and the context.

You must respond with one of the following:
    * correct - The provided annotation is correct.
    * update - There is an entity, but it must be corrected in some way.
    * remove - The annotated text does not correspond to the given entity type.

{ENTITY GUIDELINES}

{EXAMPLES}

The user will provide the annotation to correct.
```

B Example Agentic Output

The following examples illustrate representative cases where the single-pass LLM refiner failed to appropriately remove incorrect PHI/PII annotations, either due to insufficient contextual reasoning or inconsistent application of labeling guidelines. In contrast, the agentic refiner successfully identifies and corrects these errors by combining persistent task tracking, targeted context retrieval, deterministic validation, and on-demand review skills. These examples highlight how agentic refinement enables more reliable and selective correction of false positives than prompting alone.

Example 1 (Mentions of Medication Manufacturers). This example illustrates systematic over-tagging of pharmaceutical manufacturers and brand names as ORGANIZATION entities in a therapeutic plan. Although the spans correspond to real companies, the surrounding context makes clear that they function purely as medication descriptors and do not identify patients, providers, or institutions. By loading the organization-specific review skill and retrieving targeted context for each span, the agent consistently recognizes these mentions as non-PHI and removes all annotations. This case highlights the agent's ability to apply contextual guidelines at scale and eliminate large batches of false positives that frequently occur in medication lists.

Original annotations (CARMEN-I PLAN TERAPEUTICO):

Note ID	Index ($s_i - e_i$)	Span	Entity Class
<NOTE_ID>,	29-35,	normon,	ORGANIZATION
<NOTE_ID>,	128-139,	kern pharma,	ORGANIZATION
<NOTE_ID>,	223-228,	davur,	ORGANIZATION
<NOTE_ID>,	333-338,	mylan,	ORGANIZATION
<NOTE_ID>,	685-696,	kern pharma,	ORGANIZATION
<NOTE_ID>,	782-790,	teofarma,	ORGANIZATION
<NOTE_ID>,	912-916,	teva,	ORGANIZATION
<NOTE_ID>,	1181-1186,	cinfa,	ORGANIZATION
<NOTE_ID>,	1279-1284,	cinfa,	ORGANIZATION
<NOTE_ID>,	1380-1387,	tevagen,	ORGANIZATION
<NOTE_ID>,	1606-1611,	pensa,	ORGANIZATION
<NOTE_ID>,	1718-1724,	apotex,	ORGANIZATION

Agentic Refiner

Agent Summary:

- Annotations Reviewed: 12
- Annotations Modified: 0
- Annotations Deleted: 12

Actions Taken:

- Loaded the ORGANIZATIONS skill. Per guidelines, vaccine/pill/device brands and pharmaceutical manufacturer names (e.g., Normon, Kern Pharma, Mylan, Teva, Cinfa, etc.) should NOT be tagged as ORGANIZATION in medication lists, as they are not PHI in this context.
- Retrieved context for each item and confirmed all were medication manufacturer/brand mentions in a therapeutic plan.
- Deleted all 12 ORGANIZATION annotations accordingly.
- Final validation returned no errors. The final annotation list is empty.

Major Issues Resolved: Removal of 12 non-PHI/incorrectly labeled items (organizations that are not PHI in context).

Example 2 (Mixed Clinical Backgrounds). This example demonstrates selective refinement in a document containing a diverse set of entity types, including dates, locations, organizations, and clinical terminology. The agent removes only two incorrectly labeled spans: an ORGANIZATION tag applied to a disease classification token (*GOLD*) and a LOCATION tag applied to an anatomical term (*cisura silviana*). All other annotations are retained after context-aware verification, including correctly labeled hospitals, clinicians, dates, and ages. This example shows that the agent does not indiscriminately trade recall for precision, but instead performs targeted corrections while preserving valid PHI annotations.

Original annotations (CARMEN-I IA ANTECEDENTES):

Note ID	Index ($s_i - e_i$)	Span	Entity Class
...			
<NOTE_ID>,	2453-2457,	GOLD,	ORGANIZATION
...			
<NOTE_ID>,	2918-2933,	cisura silviana,	LOCATION

Agentic Refiner

Agent Summary:

- Annotations Reviewed: 28
- Annotations Modified: 0
- Annotations Deleted: 2

Actions Taken:

- Loaded relevant skills: REVIEW, DATES-AGES, LOCATIONS, NAMES-PEOPLE, PROFESSIONS, ORGANIZATIONS.
- Checked rules for DATE entries; none qualified for automatic acceptance; proceeded with manual review.
- Retrieved surrounding context for all annotations.
- Manually reviewed problematic spans:
  - Deleted ORGANIZATION 'GOLD' - context shows this as a COPD severity/classification term (non-PHI).
  - Deleted LOCATION 'cisura silviana' - identified as an anatomical/fissure term (non-PHI).
- Verified remaining annotations:
  - Ages and professions correctly labeled and contextually PHI.
  - Hospital `C. La Salud` and doctor `Dr. Ager` correctly labeled and complete.
  - Dates (years, month-year, numeric formats, weekdays, and schedule abbreviations `Ma/Ju/Sa`) are tied to patient care timeline; boundaries and labels confirmed.
- Final validation succeeded with no errors or warnings. Remaining annotations marked as correct per guidelines.

Major Issues Resolved: Removal of 2 non-PHI/incorrectly labeled items (classification token and anatomical label).

C Regular Expression Rules for Error Injection

We inject a set of deterministic, regular expression-driven error patterns to simulate common annotation mistakes. Each rule targets a realistic failure mode observed in deployed de-identification systems or LLM annotation outputs. The 10 rules used in our experiments are described below.

Ambiguous common-word names. Many surnames or given names are also common English words (*e.g.*, `Brown`, `May`, `Grant`, or `Jordan`). This rule treats such tokens as NAME/PATIENT entities in contexts where they are not PHI (*e.g.*, "brown" in "the patient reported a brown rash" → incorrectly labeled as PATIENT).

Example

"Brown" ⇒ injected as NAME.
"May" in "the patient may require surgery" ⇒ injected as NAME.
"Grant" in "we will grant discharge tomorrow" ⇒ injected as PATIENT.
"Mann" in "der mann klagt über Schmerzen" ⇒ injected as PATIENT.

Two-digit lab values mislabeled as AGE. Numeric laboratory or microbiology results (often two digits) appear near medical keywords and can be mistaken for patient ages. We identify two-digit numbers near medical tokens and relabel them as AGE.

Example

"12" in "WBC 12" near "culture" ⇒ injected as AGE.
"45" in "platelets 45" near "CBC" ⇒ injected as AGE.
"22" in "RR 22" ⇒ injected as AGE.
"45" in "Leukozyten 45" nahe "Infektion" ⇒ injected as AGE.

Blood-pressure values labeled as DATE. Blood-pressure strings such as "120/80" resemble date-like patterns and may be mis-tagged as DATE. We search for paired numeric tokens with a slash in clinical contexts and relabel them as DATE.

Example

"120/80" in "BP 120/80" ⇒ injected as DATE.
"130/85" in "BP 130/85 sitting" ⇒ injected as DATE.
"90/60" in "hypotensive at 90/60" ⇒ injected as DATE.
"130/85" in "Blutdruck 130/85 gemessen" ⇒ injected as DATE.

City → State/Organization confusion. Place-name granularity errors: city names are relabeled as either broader administrative units or organizations. This simulates errors where classifiers confuse geographic granularity or entity class.

Example

"Berlin" ⇒ injected as STATE.
"Madrid" in "ingresado en Madrid ayer" ⇒ injected as ORGANIZATION.
"Paris" in "treated in Paris clinic" ⇒ injected as ORGANIZATION.

Generic healthcare words → HOSPITAL. Terms that denote wards, units, or specialties (*e.g.*, `ICU`, `cardiology`, or `ward`) are relabeled as full HOSPITAL entities. This models over-generalization errors.

Example

"ICU" ⇒ injected as HOSPITAL.
"cardiology" in "admitted to cardiology" ⇒ injected as HOSPITAL.
"ER" in "sent to ER for evaluation" ⇒ injected as HOSPITAL.

Patient/Doctor confusion. Swap PATIENT and DOCTOR labels to simulate role-disambiguation mistakes (*e.g.*, doctor names annotated as patients and vice versa).

Example

"Dr. Smith" ⇒ injected as PATIENT.
"John Davis" in "Dr. John Davis reviewed labs" ⇒ injected as PATIENT.

Age/Date confusion. Swap AGE and DATE labels to mimic numeric ambiguity (*e.g.*, two- or four-digit tokens interpreted as a birth year vs. age).

Example

"1978" in "Born 1978" ⇒ injected as AGE.
"84" in "patient is 84" injected as DATE.
"63" in "63-jähriger Patient" ⇒ injected as DATE.

Hospital/Organization confusion. Map specific hospital names to a generic ORGANIZATION label intended for employers/companies, simulating coarse-grained classification errors.

Example

"Hospital Clínic" ⇒ injected as ORGANIZATION.
"Massachusetts General Hospital" ⇒ injected as ORGANIZATION.
"Universitätsklinikum Heidelberg" ⇒ injected as ORGANIZATION.

ZIP / City / State swaps. Exchange geographic and postal labels (ZIP, city, or state) to reflect location-granularity errors and numeric/non-numeric confusions.

Example

"02115" (ZIP) ⇒ injected as CITY.
"CA" ⇒ injected as CITY.

Eponymous diseases as PATIENT. Diseases named after people (*e.g.*, `Parkinson's` or `Alzheimer's`) are injected as PATIENT entities, modeling a frequent confusion where models treat eponyms as person names.

Example

"Parkinson" in "Parkinson's disease" ⇒ injected as PATIENT.
"Hodgkin" in "Hodgkin lymphoma" ⇒ injected as PATIENT.
"Morbus Alzheimer" ⇒ injected as PATIENT.

Procedures. Each rule is applied deterministically over reference annotations or raw text according to a priority order to avoid conflicting injections (*e.g.*, numeric-format rules are applied before generic city/state swaps). Injected errors are recorded with provenance (rule id, original label, injected label) to enable precise evaluation when using the error dataset.

These rules are designed to be realistic but conservative: they target representative failure modes rather than exhaustively enumerating every possible error. The rule set is extensible; new patterns discovered in deployment logs can be added to the vocabulary and re-run to produce larger or more diverse synthetic error sets.

D Comparison of Computational Costs

Metric	LLM Baseline	Agentic Refinement
# LLM Calls	420	161
Time to Process (seconds)	1,124	1,820
Input Tokens	2,284,378	3,076,333
Output Tokens	432,270	720,450
Approx. Cost (USD)	$7.18	$11.05

Table 3: Efficiency comparison between the single-pass LLM refinement baseline and the proposed agentic refinement pipeline on a subset of the CARMEN-ES dataset (3,314 tokens; 84 annotations). Wallclock time reflects end-to-end single-threaded execution, including preprocessing and postprocessing. Costs are approximate and based on standard GPT-5 pricing.

Do Syntactic Features Help Biomedical Relation Extraction? An Empirical Study of Verb Token and Dependency Graph Augmentation

Mustafa Kamal Sikder and Ernest Kwegyir-Afful
Hazard Assessment and Analytics Branch
Human Foods Program
U.S. Food and Drug Administration
{Abu.Sikder, Ernest.Kwegyir-Afful}@fda.hhs.gov

Abstract

We investigate whether explicit syntactic features improve transformer-based biomedical relation extraction when added to typed entity marker pooling. We evaluate two augmentation strategies on top of BiomedBERT: (1) verb token augmentation, which concatenates the hidden state of the dependency root verb to the entity representations, and (2) a two-layer graph convolutional network (GCN) that refines encoder hidden states over the dependency parse before entity pooling. We experimented on three biomedical datasets: ChemProt, DDI, and AIMed with three random seeds. We found neither strategy consistently outperformed the entity-only baseline. The GCN yielded modest gains on AIMed ($+0.007$ F1) and ChemProt ($+0.003$ F1) but decreased performance on DDI (-0.013 F1). Verb token augmentation helps only on AIMed ($+0.004$ F1) and underperforms on the other two datasets. A syntactic characterization of the datasets reveals that DDI has substantially higher passive voice usage (50.7% of relation-bearing sentences) than AIMed (27.0%) or ChemProt (30.9%), suggesting that syntactic augmentation is more effective when sentences exhibit active verbal structure with semantically informative predicates. These results suggest that corpus-level syntactic characteristics, particularly passive voice usage, may moderate the utility of explicit syntactic augmentation, though the small magnitude of observed differences warrants caution in interpretation.

1 Introduction

Relation extraction (RE) is a core task in biomedical natural language processing that involves identifying semantic relationships between entities in text (Madan et al., 2019; Huang et al., 2024). Automatically detecting chemical-protein, drug-drug, and protein-protein interactions from scientific literature supports downstream applications in pharmacovigilance, knowledge base construction, and public health and food safety surveillance, including hazard signal detection, adverse event monitoring, and contamination source identification. (Zhang et al., 2025; Bawankar and Kumar, 2026; Munkhdalai et al., 2018; Zuo et al., 2022).

The dominant approach to RE with pretrained language models involves inserting typed entity markers around entity spans in the input sequence, and the model is trained to classify relations from the pooled representations at marker positions (Zhong and Chen, 2021; Ye et al., 2022). This approach has been widely adopted for biomedical RE due to its simplicity and strong empirical performance (Gu et al., 2021).

In most biomedical sentences, the relational predicate or the verb connecting two entities carries essential information about the nature of the relationship. For example, in "aspirin inhibits COX-2", the verb inhibits is the primary signal distinguishing an inhibitor relation from an activator or substrate relation. Majewska et al. (2021) demonstrated that biomedical verbs exhibit domain-specific semantic-syntactic properties distinct from general English, and that structured verb knowledge can improve biomedical NLP models, motivating the hypothesis that the predicate verb carries informative relational signal in biomedical sentences. Additionally, prior work on syntax-augmented RE has demonstrated that incorporating dependency structure can improve performance, particularly for long-range relations (Zhang et al., 2018). However, these approaches were not applied on top of the token representations of the language model encoders.

In this paper, we investigate two strategies for incorporating syntactic information into entity marker-based RE: (1) verb token augmentation, which concatenates the hidden state of the main predicate verb to the entity representations; and (2) dependency graph convolutional network (GCN), which refines entity representations through graph

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 128–134
July 3-4, 2026 ©2026 Association for Computational Linguistics

convolution over the dependency parse before classification. We evaluated both strategies against an entity-only baseline across three biomedical datasets: ChemProt (Krallinger, 2017), the DDI corpus (Herrero-Zazo et al., 2013), and AIMed (Bunescu et al., 2005), using BiomedBERT (Gu et al., 2021) as the base encoder.

2 Related Works

The entity marker approach for relation extraction was introduced by Soares et al., 2019, who inserted special boundary tokens around entities and used their hidden states for classification. Zhong and Chen (2021) showed that typed markers encoding entity categories (e.g., <S:CHEMICAL>) significantly outperform generic ones, and Ye et al. (2022) proposed packed levitated markers that avoid disrupting the original token sequence. Zhong and Chen (2021) demonstrated that concatenating entity start-marker representations with the sentence-level [CLS] embedding yields strong performance with minimal architectural overhead — an approach we adopt as our baseline. In the biomedical domain, BioBERT (Lee et al., 2019) and BiomedBERT (Gu et al., 2021) established that domain-specific pretraining combined with entity markers achieves competitive results on benchmarks such as ChemProt and DDI.

Our work builds on two lines of syntactic augmentation. Zhang et al. (2018) showed that graph convolution over pruned dependency trees improves relation extraction, particularly for long-range entity pairs, though their method operated on static embeddings rather than transformer hidden states. Majewska et al. (2021) demonstrated that biomedical verbs exhibit domain-specific knowledge and retrofitting that into the model can improve classification tasks. We extend both ideas to the transformer entity-marker setting: verb token augmentation directly concatenates the predicate's contextual representation, while our dependency GCN applies graph convolution over the full parse tree on top of BiomedBERT's hidden states.

3 Methods

We investigate three relation representation strategies built on top of a shared transformer encoder. All three share the same input format, training procedure, and evaluation protocol, differing only in how the final relation representation is constructed before classification.

3.1 Base Encoder and Input Representation

We use BiomedBERT (Gu et al., 2021) as our encoder across all conditions. For each candidate entity pair in a sentence, we insert typed markers around the subject and object spans following the PURE framework (Zhong and Chen, 2021).

$$[CLS] < S_S E_1 > aspirin < S_E E_1 > ... \\ < O_S E_2 > COX - 2 < O_E E_2 > [SEP]$$

Where $[CLS]$ and $[SEP]$ are encoder's special tokens, S_S and S_E indicate the start and end of the subject entity markers and O_S and and O_E indicate the object entity marker, and E_1, E_2 were the entity categories (e.g., CHEMICAL, GENE-Y, DRUG). Markers are typed with the entity category so the encoder can distinguish entities semantically. These marker tokens were added to the tokenizer vocabulary and their embeddings are initialized to the vocabulary mean to avoid out-of-distribution activations at the start of fine-tuning. One training example is generated per ordered entity pair per sentence; pairs with no gold relation are assigned the $no_relation$ label.

The encoder processes the marked-up sequence and produces contextual hidden states $h \in \mathbb{R}_{seq_len \times 768}$. All three classification models described below operate on these hidden states.

3.2 Entity Marker Pooling (Baseline)

The updated entity representations were obtained from the encoder last hidden state at the position of each entity start marker (e.g. $S_S E_1$ and $O_S E_2$). The vectors were concatenated and passed through layer normalization, dropout, and a linear classifier to produce logits over relation types. This served as the reference condition for all comparisons.

3.3 Verb Token Augmentation

For this condition, together with the entity marker embeddings, we obtained the representation of the main predicate verb and concatenated that with the entity markers. We used spaCy's dependency parser (Honnibal et al., 2020) with $en_core_web_sm$ model. We selected the ROOT token of the dependency tree if its part-of-speech tag was VERB or AUX. If a sentence contained multiple ROOT candidates, we selected the one closest to the subject entity span center. When no ROOT verb was found, a special NO_VERB_TOKEN embedding was appended, initialized to the vocabulary mean.

Unlike the entity markers, which point to dedicated special tokens, the verb index points to the first subword token of the verb word itself, preserving the lexical identity of the predicate alongside its contextual representation. Thus, the hidden state encoded the verb's semantic and syntactic context.

The verb index is extracted from the original (un-marked) sentence token sequence and then adjusted to account for the marker tokens inserted during feature creation. Verb extraction is performed once per sentence during preprocessing and cached for all entity pairs sharing the same sentence. The NO_VERB_TOKEN fallback was triggered for 10.3%, 11.7%, and 7.8% of relations in ChemProt, AIMed, and DDI respectively, indicating that a meaningful minority of instances received no relational verb signal regardless of dataset.

3.4 Dependency Graph Neural Network

In the entity + graph convolutional network (GCN) condition, we replace the direct pooling step with a two-layer graph convolutional network (Kipf and Welling, 2016) that refines the model's hidden states according to the syntactic dependency structure of the sentence before extracting entity representations.

Word-level pooling: Because spaCy operates at the word level while BiomedBERT uses WordPiece subtokenisation, we first mean-pool the BiomedBERT hidden states of all subtokens belonging to the same original word. Marker tokens ($< S_S E_1 >$, etc.) are excluded from this alignment — they have no corresponding spaCy word. This produces a word-level embedding matrix $X \in \mathbb{R}_W \times 768$ where W is the number of original words (capped at 128).

Dependency graph construction: We ran dependency parser on the original unmarked sentence to obtain a dependency parse. We built an undirected adjacency matrix $A \in \mathbb{R}_W \times W$ where $A[i, j] = 1$ if word i and word j share a head-child dependency relation, and $A[i, i] = 1$ (self loops). The matrix is symmetrically normalised as $D^{-1/2}AD^{-1/2}$ where D is the diagonal degree matrix. Adjacency matrices are computed once per unique sentence and cached across all entity pairs from the same sentence.

GCN message passing: The word embeddings are refined through two GCN layers:

$$X^1 = \text{ReLU}(A_normX^0W^1)... \\ [W \times 768 \rightarrow W \times 256]$$

$$X^2 = \text{ReLU}(A_normX^1W^2)... \\ [W \times 256 \rightarrow W \times 768]$$

Each layer aggregates information from syntactically connected words. After two layers, each word's representation reflects information from words up to two dependency hops away. Because the dependency graph is undirected, information flows both from head to child and from child to head. The verb node aggregates from its subject and object arguments, and the entity nodes aggregate from the verbs governing them.

Classification: The GCN-refined embeddings at the subject and object word positions are extracted and passed to the classifier:

$$r = LayerNorm([X^2[s_word]; X^2[o_word]])$$

Note that s_word and o_word are the word-level indices of the first token of each entity span in the original sentence. The classifier was the same linear layer used in the other conditions, with input dimension 2×768. The GCN weights are randomly initialized and trained jointly with the BiomedBERT encoder from scratch during fine-tuning.

3.5 Training

All three conditions share identical training hyperparameters. We fine-tuned with AdamW (weight decay 0.01 on non-bias/LayerNorm parameters), a linear learning rate schedule with 10% warmup, batch size 16, and learning rate 2×10^{-5}. The maximum sequence length is 256 for ChemProt and AIMed and 384 for DDI (which contains longer sentences). We train for 10 epochs on AIMed and 5 epochs on ChemProt and DDI, selecting checkpoints by the development set F1. All experiments are repeated with three random seeds (0, 1, 42). Our primary evaluation metric was micro F1 over positive relation classes. We reported the mean F1 for all seeds with standard deviation. The loss of Cross-entropy is calculated over all pairs of candidate entities, with $no_relation$ as a negative class. Gradient clipping is applied at norm 1.0. Marker token embeddings and GCN weights are initialized to the vocabulary mean and random normal respectively.

3.6 Datasets

We evaluate on three biomedical relation extraction datasets spanning chemical-protein, drug-drug, and protein-protein interaction tasks. All datasets used the entity markers described in 3.1 with entity type CHEMICAL, DRUG, or PROTEIN as appropriate.

ChemProt ChemProt (Krallinger, 2017) is a sentence-level relation extraction dataset from the BioCreative VI challenge covering interactions between chemicals and gene/protein targets in biomedical abstracts. Each candidate pair is classified into one of five relation groups (CPR:3 upregulator, CPR:4 downregulator, CPR:5 agonist, CPR:6 antagonist, CPR:9 substrate) or assigned no relation. We use the official BioCreative VI train, development, and test partitions and evaluate using micro F1 over the five positive CPR groups.

DDI Corpus The DDI corpus (Herrero-Zazo et al., 2013) contains pharmacological sentences annotated for drug-drug interactions, drawn from DrugBank database entries and MedLine abstracts. Relations are classified into four types: MECHANISM (pharmacokinetic mechanism of interaction), EFFECT (clinical effect of the interaction), ADVISE (recommendation against co-administration), and INT (unspecified interaction). We use the SemEval 2013 Task 9 train and test partitions. We hold out 20% of the training data for development and use the remaining 80% for training. We evaluate using micro F1 over the four positive relation types.

AIMed AIMed (Bunescu et al., 2005) is a binary protein-protein interaction dataset drawn from MEDLINE abstracts. Each candidate entity pair is labelled as interacting (INTERACT) or not. We use fold 1 of the original data and hold out 10% of the training set as development set using a fixed random seed. While results may vary across folds, the fold assignment only affects the train/dev/test split rather than the underlying data

4 Results

We present results across three conditions: entity marker pooling (Entity), verb token augmentation (Entity+Verb), and dependency GCN (GCN) on three datasets: ChemProt, DDI, and AIMed. All are sentence-level datasets.

4.1 Syntactic Characterization of Datasets

To contextualize the model results, we characterize the syntactic structure of each dataset's test set using automatic dependency parsing (spaCy $en_core_web_sm$). We analyzed all sentences containing at least one gold relation. Table 1 presents sentence-level and relation-level syntactic metrics across the three datasets.

Dependency tree depth: The average tree depth is 7.5, 7.5, and 7.1 for AIMed, ChemProt, and DDI respectively. This indicates that the three datasets have similar structural complexity as measured by tree depth. The datasets also have similar average sentence lengths (26–31 tokens).

Passive voice usage: Passive constructions appear in 50.7% of DDI sentences containing relations, compared to 27.0% in AIMed and 30.9% in ChemProt. At the relation level, 33.6% of DDI gold relations occur in sentences where the ROOT verb is a passive construction which is higher than ChemProt (20.2%) and AIMed (18.9%). The passive ROOT verb is an unreliable predicate signal for relation extraction: in a passive sentence such as "Synergism was observed between methylglyoxal and piperacillin", the ROOT verb observed describes the research act rather than the pharmacological interaction between the entities.

4.2 Model Performance

Table 2 shows test F1 ($mean \pm std$) across three seeds) for all three conditions on all three datasets. Full per-seed results are provided in the Appendix.

Verb token augmentation helped AIMed dataset and underperformed the entity-only baseline on ChemProt and DDI datasets. The GCN condition helped AIMed and ChemProt datasets and performed better than entity+verb condition in the DDI dataset. On DDI, neither augmentation strategy improves over the entity-only baseline. On ChemProt, GCN marginally outperforms entity-only ($+0.003$) method.

Seed-level data suggested additional patterns. On DDI, both augmentation strategies underperformed the baseline across all three seeds, indicating systematic incompatibility. Verb augmentation also substantially increased training instability on DDI (F1 range: $0.755 - 0.770$) compared to the baseline ($0.778 - 0.784$). In contrast, the GCN outperformed the baseline in all three seeds on AIMed. On ChemProt, the GCN matched or exceeded the baseline in all three seeds despite small mean differences, suggesting a consistent modest advantage. To assess whether the observed differences are reliable, we ran paired approximate randomization tests comparing each augmentation strategy against

Metric	AIMed	ChemProt	DDI
Avg sentence length (tokens)	26.2 ± 12.7	30.5 ± 14.6	26.4 ± 13.5
Avg dependency tree depth	7.5 ± 2.1	7.5 ± 2.2	7.1 ± 2.3
Avg dep path between entities (hops)	4.8 ± 2.8	5.6 ± 2.6	6.6 ± 3.3
% sentences with passive voice	27.0%	30.9%	50.7%
% sentences with active ROOT verb	58.6%	55.3%	45.0%
% relations: active verb between entities	11.7%	25.5%	28.4%
% relations: passive ROOT verb	18.9%	20.2%	33.6%
% relations: copular ROOT verb	10.8%	13.3%	9.1%

Table 1: Syntactic characterization of test sets. Sentence-level metrics computed over sentences containing at least one gold relation. Dependency path lengths computed between subject and object entity head tokens. Parser: spaCy *en_core_web_sm*.

Condition	AIMed	ChemProt	DDI
N	222	3463	964
Entity (baseline)	0.818 ± 0.002	0.760 ± 0.006	$\mathbf{0.780 \pm 0.003}$
Entity + Verb	0.822 ± 0.002	0.755 ± 0.006	0.762 ± 0.006
Entity + GCN	$\mathbf{0.825 \pm 0.004}$	$\mathbf{0.763 \pm 0.003}$	0.767 ± 0.006

Table 2: Mean test $F1 \pm std$ across three seeds $(0, 1, 42)$. Bold marks best per dataset. Micro F1 over positive relation classes only. $N =$ number of positive test instances

the baseline separately per dataset (full results in Appendix). No comparison reached statistical significance (all $p > 0.05$), consistent with the small effect sizes and the limited statistical power of three seeds.

5 Discussions

5.1 GCN Outperforms Baseline Where Active Verbal Structure is More Prevalent

The dependency GCN improved over the entity-only baseline on two of three datasets: AIMed ($+0.007$) and ChemProt ($+0.003$). On DDI it underperformed (-0.013). This pattern aligns with a key difference in sentence structure across datasets. AIMed has the lowest passive construction rate (27.0%) and a relatively high proportion of sentences with an active ROOT verb (58.6%). ChemProt is similar (30.9% passive, 55.3% active ROOT). DDI, in contrast, has a substantially higher passive rate (50.7%) and fewer sentences with an active ROOT verb (45.0%). A likely explanation of these could be: when sentences followed an active structure, the dependency graph provided paths between entities that passed through semantically informative verbs. GCN message passing propagated this predicate information into the entity representations before classification. When sentences were predominantly passive, the ROOT verb was a reporting predicate rather than the relational one, and the dependency paths between entities carried less useful signal. This interpretation is consistent with the direction of results across all three datasets, though we caution that three datasets is insufficient to establish this relationship quantitatively.

5.2 Verb Token Augmentation is Inconsistent

Verb token augmentation improves over the baseline only on AIMed ($+0.004$) and underperforms on ChemProt (-0.005) and DDI (-0.018). The inconsistency is likely attributable to the noise floor of automatic ROOT verb extraction. For only 11.7% of AIMed relations, 25.5% of ChemProt relations, and 28.4% of DDI relations (Table 1), an active verb was directly between the two entity spans. Indicating, the smaller proportions of sentences where the ROOT verb reliably signaled the relation. In the remaining cases, the concatenated verb token added a representation that is structurally present but semantically peripheral, competing with rather than complementing the entity marker representations. That verb token helps on AIMed despite its low verb-between-entity rate (11.7%) is counterintuitive to this hypothesis. One possible explanation is that AIMed's binary task structure may be easier to benefit from any additional context, even imperfectly located verbal signal. A multi-class setting like ChemProt, where fine-grained relation types must be distinguished,

may penalize noisy verb tokens more heavily. This remains speculative without further controlled experiments.

5.3 Limitations and Future Directions

Our experiments have several limitations. All syntactic features are extracted using a general-domain dependency parser (spaCy $en_core_web_sm$) not adapted to biomedical text. Parser errors such as, correctly detecting noun phrases and passive construction on complex biomedical sentences can propagate into both the verb token and GCN conditions. A biomedical dependency parser trained on domain-specific treebanks may yield more reliable syntactic features and alter the results for both augmentation strategies. We evaluate on a single encoder (BiomedBERT) and three seeds. Different encoders or a larger seed set may produce different conclusions. For AIMed we use only fold 1 of the 10-fold cross-validation structure; results may not generalize across all folds. Additionally, the GCN improvements on AIMed and ChemProt are small (0.003–0.007) and within or near one standard deviation of the baseline, so they should not be overstated. In future work we will investigate biomedical-domain dependency parsers, pruned dependency paths (Zhang et al., 2018) rather than the full graph.

6 Conclusions

We presented a controlled empirical study of two syntactic augmentation strategies: verb token concatenation and dependency GCN, and compared to entity marker pooling for biomedical relation extraction. Experiments on ChemProt, DDI, and AIMed using BiomedBERT with three random seeds showed that neither strategy consistently outperformed the entity-only baseline. The dependency GCN improved on AIMed ($+0.007$) and ChemProt ($+0.003$) but underperformed on DDI (-0.013). Verb token augmentation helped only on AIMed ($+0.004$).

Our syntactic analysis showed that datasets with lower passive construction rates (AIMed 27.0%, ChemProt 30.9%) benefit from GCN augmentation, while the passive-heavy DDI corpus (50.7%) did not. This suggests that the utility of explicit syntactic features in transformer-based RE depends on the linguistic characteristics of the underlying corpus rather than being universally beneficial. These findings offer practical guidance for biomedical RE systems supporting public health surveillance. When working with literature exhibiting predominantly active sentence structures, dependency GCN augmentation may provide modest improvements. For corpora with high passive voice usage, such as DDI, entity marker pooling alone could be more reliable compared to either augmentation strategy. This is particularly relevant for public health and food safety applications that rely on extracting chemical interactions, adverse events, and contamination signals from biomedical literature, where understanding which augmentation strategies generalize across different writing styles can improve robustness and reliability. For real-world deployment in applications such as chemical hazard surveillance, practitioners can characterize the syntactic profile of their target corpus and validate augmentation strategies on representative data before deployment. We release all code and converted datasets to support reproducibility and encourage future work to explicitly report syntactic characteristics of biomedical RE benchmarks.[1]

Beyond Knowledge Graphs: PubMedBERT Embeddings as a Competitive Standalone Modality for Drug Repurposing

Abstract

Drug repurposing methods rely heavily on knowledge graph (KG) embeddings, but building and curating these graphs takes considerable effort. We present two findings on the Hetionet drug-disease benchmark and an epilepsy ranking task. *First*, PubMedBERT text embeddings, fed through the same downstream classifiers and identical 10-fold splits as four re-trained KG baselines (TransE, ComplEx, DistMult, RotatE), reach AUROC 0.910, above all four (best: RotatE, 0.854); a Random Forest on the same vectors scores 0.880. The comparison is asymmetric in one important way: PubMedBERT was pretrained on the literature Hetionet was curated from, so the result is best read as "text-with-literature-supervision vs. graph-only," and a head-to-head with text-augmented KG methods (KG-BERT, TxGNN) is left as follow-up. *Second*, across all seven combinations of text, molecular (ECFP4), and gene expression (LINCS L1000) features, cross-attention fusion of weaker modalities into text consistently degrades performance, despite a gated mechanism intended to suppress unhelpful modalities; the residual path forces the strong modality to absorb noise. The model also ranks proconvulsants (amoxapine, flumazenil) near the top, because text embeddings encode strength of association with a disease but not its direction.

1 Introduction

Finding new therapeutic uses for existing drugs remains one of the more tractable problems in pharmaceutical development, in part because repurposed candidates already have established safety profiles (Pushpakom et al., 2019; Ashburn and Thor, 2004). The potential payoff is large for diseases like epilepsy, where roughly a third of patients are not adequately controlled by current medications (Löscher et al., 2020).

The computational side of drug repurposing has become dominated by knowledge graph (KG) methods, which represent biomedical knowledge as a network of drugs, diseases, genes, and pathways connected by typed edges (Himmelstein et al., 2017; Nickel et al., 2016). Embedding methods such as TransE (Bordes et al., 2013), ComplEx (Trouillon et al., 2016), DistMult (Yang et al., 2015), and RotatE (Sun et al., 2019) learn vectors for each node and score candidate drug-disease pairs. The catch is that all of them need the complete graph at both training and inference time, and assembling a graph like Hetionet (47,000+ nodes, 2.2M edges, 24 relationship types) is labor-intensive and inevitably reflects its curators' choices and blind spots.

We wondered whether the same information might already be latent in the biomedical literature. PubMedBERT (Gu et al., 2021), now rebranded as MSR BiomedBERT, captures rich biomedical knowledge through distributional patterns in text (Shtar et al., 2022). A drug like carbamazepine appears in thousands of abstracts that also mention seizures and sodium channel blockade; after enough co-occurrences, the model places it close to these concepts in embedding space. The result, we hypothesized, functions as an implicit knowledge graph that updates automatically and does not require manual curation. Prior work has mined text for relations and co-occurrences (Wei et al., 2019; Andronis et al., 2011), combined text with structure and expression in multi-modal architectures (Luo et al., 2024, 2023), and trained graph-foundation models on larger graphs (Huang et al., 2024); published numbers are not directly comparable because each uses different splits (HRGAT (Yu et al., 2021) reports AUROC 0.912 on Hetionet under a setup we could not reproduce). A controlled evaluation of text embeddings *alone*, with classifiers and folds held fixed against KG baselines re-trained from scratch,

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 135–140
July 3-4, 2026 ©2026 Association for Computational Linguistics

has not, as far as we can tell, been done.

We designed a framework that can train on any subset of three modalities (text, molecular fingerprints, gene expression) and tested all seven combinations on the Hetionet benchmark and an epilepsy drug ranking task. The results were, in several respects, not what we anticipated:

- Combining text with molecular or gene expression features through cross-attention consistently makes performance *worse*, not better, despite a gated fusion mechanism that should, in theory, learn to ignore unhelpful modalities. We trace this to residual-path contamination: the strong modality is forced to absorb noise from the weak ones.
- Text embeddings alone reach AUROC 0.910 on Hetionet, above all four KG baselines we re-trained on the same data under the same protocol (the best, RotatE, 0.854). This holds for both our neural architecture and a Random Forest baseline; the predictive signal lives in PubMedBERT itself, not in any particular downstream model.
- Top-ranked epilepsy candidates mix genuinely promising compounds (sirolimus) and known proconvulsants (amoxapine, flumazenil), exposing a basic limitation of any approach grounded in literature co-occurrence.

2 Methods

2.1 Feature Representations

We query the NCBI E-utilities API for up to 20 PubMed abstracts per entity (drug or disease), run each through PubMedBERT (Gu et al., 2021) to obtain the `[CLS]` token vector (768d), and take the mean. Because PubMedBERT was pretrained on a large fraction of the biomedical literature, these vectors carry information about a compound's pharmacology, therapeutic context, and the biological processes it has been studied in connection with. Compounds with no indexed abstracts (3.4%) receive zero vectors and are retained in the dataset but have no text signal. Molecular features are 2048-bit ECFP4 fingerprints (Rogers and Hahn, 2010) generated with RDKit (RDKit, 2024), capturing chemical substructure. Gene expression features come from LINCS L1000 (Subramanian et al., 2017): 978-dimensional vectors recording how a compound perturbs landmark gene expression in treated cell lines.

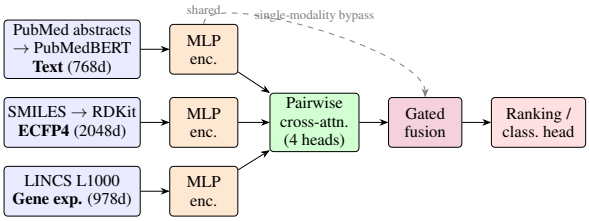

Figure 1: Model architecture. Per-modality MLP encoders project text (PubMedBERT `[CLS]`, 768d), molecular (ECFP4, 2048d), and gene expression (LINCS, 978d) inputs into a shared embedding space (128d on Hetionet, 256d on epilepsy); pairwise cross-attention (4 heads, Eq. (1)) and gated fusion combine them before a two-layer head. Single-modality runs skip both blocks (dashed).

2.2 Architecture

Figure 1 gives the overall architecture. Each modality passes through a two-layer MLP encoder (hidden 512, LayerNorm (Ba et al., 2016), ReLU, dropout) into a shared embedding space (128d on Hetionet, 256d on epilepsy). In multi-modal settings, pairwise cross-attention (Vaswani et al., 2017; Lu et al., 2019) with 4 heads updates each representation from the others:

$$\hat{\mathbf{h}}_{m_i \leftarrow m_j} = \mathrm{LN}(\mathbf{h}_{m_i} + \mathrm{MHA}(\mathbf{h}_{m_i}, \mathbf{h}_{m_j}, \mathbf{h}_{m_j})) \quad (1)$$

With three modalities, the two cross-attended versions per modality are averaged. Gated fusion (Arevalo et al., 2017) computes per-sample softmax weights over ℓ_2-normalized vectors, and a two-layer head (256, 128) outputs ranking scores or classification logits.

2.3 Datasets and Training

Epilepsy Drug Repurposing. From LINCS L1000 Phase 2 (Subramanian et al., 2017), we kept the 1,713 compounds with both gene expression profiles and ECFP4 fingerprints (PubMed coverage: 96.6%). Of these, 19 are established AEDs, including sodium channel blockers (carbamazepine, phenytoin), GABAergic agents (gabapentin), and multi-mechanism drugs (topiramate). We split compound-disjoint (1,027/343/343) with stratified positives. Training uses $\mathcal{L} = 0.7 \cdot \mathcal{L}_{\text{LambdaNDCG}} + 0.3 \cdot \mathcal{L}_{\text{BCE}}$ (Burges et al., 2006) with Adam (Kingma and Ba, 2015) (lr 5×10^{-4}, batch 128, 100 epochs, early stopping on validation NDCG@50). We report NDCG@50, which covers the top $\sim$15% of test compounds. All experiments use 3 random seeds.

Hetionet Benchmark. Hetionet (Himmelstein et al., 2017) has 755 curated drug-disease edges. We sampled negatives at 1:1 (1,509 pairs total) and trained with BCEWithLogitsLoss under 10-fold CV (embedding dim 128, early stopping on validation AUROC). For the KG baselines we trained TransE, ComplEx, DistMult, and RotatE on the full Hetionet graph with PyKEEN (Ali et al., 2021) (dim 128, margin-ranking loss, Adam, 200 epochs with early stopping), then fed entity embeddings through the same downstream classifiers (Random Forest (Breiman, 2001), Logistic Regression) on the same folds, isolating the representation. Gene expression is not added to this benchmark because LINCS L1000 covers only a fraction of Hetionet's 1,538 compound entities; we restrict Hetionet modality fusion to text and molecular, and use the epilepsy dataset for the full seven-way ablation. All runs use 3 seeds; we report mean ± std.

Method	Features	AUROC	AUPRC
KG embedding baselines (trained on full Hetionet)			
TransE	KG Embedding	0.822 ± 0.018	0.809 ± 0.030
DistMult	KG Embedding	0.833 ± 0.017	0.818 ± 0.030
ComplEx	KG Embedding	0.837 ± 0.019	0.828 ± 0.031
RotatE	KG Embedding	0.854 ± 0.019	0.849 ± 0.022
Our baselines (no graph)			
RF	Molecular	0.496 ± 0.047	0.342 ± 0.053
RF	Text	0.880 ± 0.015	0.875 ± 0.025
RF	Text + Mol	0.883 ± 0.015	0.708 ± 0.029
Our neural model (cross-attention, no graph)			
Ours	Molecular	0.581 ± 0.026	0.338 ± 0.046
Ours	Text	$\mathbf{0.910 \pm 0.017}$	0.727 ± 0.057
Ours	Text + Mol	0.817 ± 0.030	0.584 ± 0.063

Table 1: Drug-disease link prediction on Hetionet. KG methods were trained on the full graph using PyKEEN; all methods evaluated under the same 10-fold CV protocol on the same 1,509 drug-disease pairs. Gene-expression rows are omitted: LINCS L1000 covers only a fraction of Hetionet's 1,538 compound entities, so an apples-to-apples row is not available; the full seven-way modality ablation is run on the LINCS-aligned epilepsy dataset (Table 2).

3 Results and Analysis

3.1 Hetionet Benchmark

Table 1 summarizes the Hetionet results. Every row is run under the same 10-fold protocol on the same 1,509 pairs; we exclude published numbers from prior papers (e.g. HRGAT 0.912) because those use different splits. With text features only, our neural model reaches AUROC 0.910 ± 0.017. The KG baselines score lower in AUROC across the board: RotatE 0.854 ± 0.019, ComplEx 0.837 ± 0.019, DistMult 0.833 ± 0.017, TransE 0.822 ± 0.018. Only the entity-vector source differs. AUPRC is more nuanced: RF+Text (0.875) and RotatE (0.849) both exceed the neural model's 0.727. The neural model leads in AUROC but is less calibrated at the high-precision end; for a 1:1 balanced task the two metrics mostly agree, but under harder negative ratios the AUPRC gap between text and the strongest KG method is narrower than AUROC suggests.

A plain Random Forest on the same PubMedBERT vectors scores 0.880 ± 0.015. The embeddings, not our neural model, are the main source of predictive power. To rule out a dimensionality artifact (PubMedBERT 768d vs. KG 128d) we ran PCA-reduced text embeddings at 128d: AUROC drops to 0.818, below RotatE (0.854). The full 768d is needed; the higher dimensionality reflects PubMedBERT's richer training signal (billions of tokens vs. a single graph). Molecular fingerprints alone are near chance for RF (AUROC 0.496) and only modestly above for the neural model (0.581): structure-to-indication requires a chain (drug→target→pathway→disease) that fingerprints do not encode, but PubMedBERT picks up much of it from co-occurrence patterns in text.

3.2 Cross-modal Contamination

Adding molecular features to text makes things worse, not better. AUROC drops from 0.910 to 0.817 in the neural model, while Random Forest barely moves (0.883 vs. 0.880). The residual connection in Eq. (1) blends each modality with the others regardless of quality, so when one modality is mostly noise, the stronger one gets contaminated; tree-based models simply ignore uninformative features.

3.3 Epilepsy Case Study

Table 2 gives the full seven-way modality ablation for the epilepsy ranking task. Text alone hits AUROC 0.980 ± 0.006 and the highest P@10 (0.267) and NDCG@50 (0.680) of any neural configuration; the precision and ranking metrics track the AUROC ordering, which is reassuring given how few positives there are. Molecular fingerprints land at AUROC 0.662 and gene expression at 0.512, both close to what you would get from random ordering, and both produce P@10 of zero. The bi-modal results are worth a closer

Config	P@10	P@50	NDCG@50	AUROC
Single modality				
T	0.267 ± 0.094	0.080 ± 0.000	0.680 ± 0.113	0.980 ± 0.006
M	0.000 ± 0.000	0.040 ± 0.016	0.169 ± 0.083	0.662 ± 0.109
G	0.000 ± 0.000	0.013 ± 0.019	0.049 ± 0.070	0.512 ± 0.088
Bi-modal				
TM	0.067 ± 0.047	0.053 ± 0.025	0.282 ± 0.134	0.891 ± 0.061
TG	0.200 ± 0.141	0.073 ± 0.009	0.595 ± 0.195	0.932 ± 0.040
MG	0.033 ± 0.047	0.007 ± 0.009	0.038 ± 0.053	0.507 ± 0.091
Tri-modal

RF + M	0.000	–	0.049	0.603
RF + G	0.000	–	0.046	0.518
RF + TMG	0.300	–	0.882	0.989
CMap	0.000	–	–	0.437

Table 2: Ablation study on epilepsy drug repurposing dataset. T = PubMedBERT text, M = ECFP4 molecular, G = LINCS gene expression. Results are mean $\pm$ std over 3 random seeds.

look. Text plus gene expression (TG: 0.932 AUROC, P@10 0.200) holds up better than text plus molecular (TM: 0.891, P@10 0.067). Gene expression profiles record cellular-level responses to a compound, so they carry at least some biological signal that fingerprints lack. Despite this, text alone still outperforms both combinations on every ranking metric. The tri-modal configuration drops to AUROC 0.779 and P@10 0.100, substantially worse than text alone.

Random Forest with text outperforms everything else here (AUROC 0.994, NDCG@50 0.895), ahead of the neural model (0.980 and 0.680). RF on molecular is only weakly predictive (AUROC 0.603) and on gene expression is at chance (AUROC 0.518; Table 2), confirming the modality asymmetry holds independent of architecture. With only 19 AEDs among 1,713 compounds and about 4 in the test fold, RF's built-in regularization matters more than cross-attention's flexibility. A Connectivity Map baseline (Lamb et al., 2006) that correlates compound expression profiles with an epilepsy disease signature came in below chance (AUROC 0.437). Being "graph-free" is not by itself sufficient; the particular information in PubMedBERT embeddings is doing real work.

3.4 Biological Plausibility

All 4 AEDs in the test set end up ranked in the top 11 out of 343 compounds (rufinamide at rank 1, phenytoin at rank 6), consistent across 3 seeds; the hypergeometric probability of this by chance is $\approx 5.8 \times 10^{-7}$. Sirolimus (rank 15 in the RF+T model) inhibits mTOR, and its analog everolimus was approved for treating seizures associated with tuberous sclerosis complex (French et al., 2016), a condition driven by mTOR pathway hyperactivation. Clomipramine (rank 7 in our neural model) is a tricyclic antidepressant that potently inhibits serotonin reuptake. There is clinical evidence that serotonergic enhancement can reduce seizure frequency (Favale et al., 2003), so this prediction has some mechanistic grounding.

The false positives tell us more. Amoxapine at rank 2 lowers seizure thresholds (Pisani et al., 1999), and flumazenil at rank 4 is a benzodiazepine antagonist used to *provoke* seizures diagnostically (Schulze-Bonhage and Elger, 2000). Why does the model rank them so highly? Because the seizure literature discusses them extensively, just as it discusses actual anticonvulsants. PubMedBERT's embeddings reflect how strongly a compound is associated with a disease area, but carry no information about the polarity of that association. A drug that treats epilepsy and one that triggers seizures both end up near epilepsy-related concepts. This is the central limitation of any repurposing approach built purely on literature.

4 Conclusion

PubMedBERT text embeddings, without fine-tuning, outperform four re-trained KG baselines on Hetionet under a matched protocol; both neural and tree-based classifiers agree. Cross-attention fusion of unequal-quality modalities hurts the strong one via residual contamination.

Limitations. The comparison is asymmetric: PubMedBERT was pretrained on the PubMed literature Hetionet was curated from, so this is best read as "text-with-literature-supervision vs. graph-only." 1:1 negative sampling may flatter AUROC, and gaps to the strongest KG method may close under harder ratios; with only 19 epilepsy positives ($\sim$4 per fold), P@k and NDCG carry wide intervals (the top-11 ranking, however, has $p \sim 6 \times 10^{-7}$).

Future Work. Two natural follow-ups: (i) a unified-protocol head-to-head against KG-BERT (Yao et al., 2019), TxGNN (Huang et al., 2024), and HRGAT; (ii) re-training KG baselines on a literature-augmented Hetionet.

When Demographic Sensitivity Isn't What It Seems: Baseline-Aware Counterfactual Audits for Clinical NLP

Hyunwoo Yoo
Drexel University
hty23@drexel.edu

Abstract

Clinical NLP systems are increasingly used for triage support, prediction, and decision assistance in EHR-based settings, where demographic fairness is a critical concern. A common evaluation approach is counterfactual demographic perturbation: modifying attributes such as age or sex while holding clinical evidence fixed and measuring output changes. However, we show that such counterfactual audits can be misleading when interpreted in isolation. Across three clinical LLMs, we find that non-demographic control perturbations (e.g., paraphrases) often induce output variability comparable to or greater than demographic edits. This can contribute to overestimation or misinterpretation of demographic bias. To address this, we propose a baseline-aware audit framework that explicitly compares demographic perturbations against control baselines. Our analysis reveals that (i) label-level stability can mask substantial variation in generated rationales and recommendations, and (ii) age-based perturbations generally induce larger effects than sex-based ones in borderline cases. Crucially, we identify a high intrinsic instability ("noise floor"; 0.46–0.71 Jaccard instability) in clinical LLM generations, while additional matched-metric analyses show that demographic perturbations are often comparable to non-demographic baseline variability. These findings highlight a key limitation of existing fairness evaluations: without establishing appropriate baselines, apparent demographic sensitivity may be over- or mis-attributed to bias rather than broader generative instability. We argue that baseline-aware counterfactual audits, which explicitly compare demographic effects against intrinsic model noise, provide a more reliable lens for evaluating clinical NLP systems in high-stakes settings.

1 Introduction

Clinical NLP systems are increasingly used in high-stakes EHR settings, including risk prediction, recommendation support, and note-level inference (Contreras et al., 2025; Shankar et al., 2025), where fairness and reliability are critical (Mehrabi et al., 2021; Wang and Zhang, 2024). A common approach to evaluating demographic bias is counterfactual perturbation: modifying attributes such as age or sex while holding clinical evidence fixed, and measuring whether model outputs change (Coston et al., 2020; Kusner et al., 2017).

This approach is appealing because it directly probes whether demographic attributes influence model behavior. However, it implicitly assumes that observed output changes can be attributed to demographic sensitivity. In practice, this assumption may not hold for modern clinical language models, which can exhibit substantial variability even under non-demographic input changes.

In this paper, we show that this can contribute to overestimation or misinterpretation of bias when interpreted in isolation. Across multiple clinical LLMs, we find that non-demographic control perturbations, such as paraphrases, often induce output variability comparable to or greater than demographic edits. As a result, apparent demographic sensitivity may reflect broader generative instability rather than demographic bias.

To address this issue, we propose a baseline-aware counterfactual audit framework that explicitly compares demographic perturbations against control baselines. The framework is intentionally scoped to decision contexts where demographic attributes are not expected to materially alter outcomes, allowing us to isolate cases where demographic effects warrant closer inspection. This focus is consistent with prior work highlighting subgroup disparities and demographic signal in EHR-based models and clinical text (Angell et al., 2025; Wang et al., 2026; Sarwal et al., 2025; Xu and Sun, 2025).

Our contributions are as follows:

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 141–155
July 3-4, 2026 ©2026 Association for Computational Linguistics

Aspect	Audit choice	Rationale
Target cases	Cases where demographic identity should not materially alter the action	Avoids overclaiming invariance in genuinely age/sex-dependent contexts
Counterfactual edit	Swap age band, sex marker, or demographic descriptor while keeping clinical content fixed	Isolates demographic sensitivity from clinical evidence
Model input	Original and perturbed EHR note or structured record with identical decoding settings	Ensures observed differences are attributable to the perturbation
Output comparison	Label changes, action-level shifts, and rationale differences	Captures both discrete and generative instability
Interpretation	Classify changes as justified, ambiguous, or concerning via manual review	Prevents equating any change with unfairness
Reporting	Aggregate sensitivity, case-level examples, and subgroup patterns	Combines quantitative summary with qualitative inspection

Table 1: Baseline-aware counterfactual audit design for evaluating demographic sensitivity in clinical NLP.

- We demonstrate that standard counterfactual demographic audits can be misleading because non-demographic control perturbations often induce comparable or greater output variability than demographic edits.

- We propose and formalize a baseline-aware audit framework for clinical NLP that explicitly distinguishes between clinically justified sensitivity and problematic bias by using matched counterfactual comparisons and control baselines.

- We provide empirical evidence across multiple clinical LLMs showing that (i) clinical LLMs exhibit a substantial intrinsic "noise floor" (0.46–0.71 Jaccard instability), while demographic perturbations are often comparable to non-demographic baseline variability, (ii) age-based perturbations induce stronger shifts than sex-based ones in borderline cases, and (iii) label-level stability frequently masks significant variation in generated rationales and recommendations.

2 Related Work

Fairness in machine learning has been widely studied, with prior work highlighting how bias can arise from data, modeling choices, and feedback loops (Mehrabi et al., 2021; Ko, 2026). In clinical NLP and EHR-based systems, fairness remains a persistent challenge, with studies reporting subgroup disparities across tasks such as ASD prediction, aggression prediction, and perinatal depression prediction (Wang and Zhang, 2024; Suster et al., 2023; Angell et al., 2025; Wang et al., 2026; Sarwal et al., 2025; Shivanna et al., 2026).

An alternative line of work considers counterfactual evaluation, which examines how model predictions change under hypothetical modifications to protected attributes (Coston et al., 2020). Recent work also shows that biomedical and clinical LLMs remain vulnerable to counterfactual and robustness stress tests (Li et al., 2025; Yu et al., 2025; Zhang et al., 2024), while clinical text itself can encode demographic signals such as gendered language patterns (Xu and Sun, 2025; Sheng, 2022; Krieger et al., 2025; Kudiabor, 2026; Surakka et al., 2023).

However, prior work largely interprets counterfactual output changes as evidence of demographic sensitivity, without explicitly accounting for variability induced by non-demographic input perturbations. In contrast, our work shows that such variability can be substantial in modern clinical language models, and proposes a baseline-aware audit framework to more reliably interpret demographic effects.

3 Baseline-Aware Audit Framework

We adopt a baseline-aware counterfactual audit design to evaluate demographic sensitivity in clinical NLP. Table 1 provides a compact summary of the key design choices. This design reflects a practical audit perspective, where both discrete prediction changes and generative output variability are considered. In particular, the framework emphasizes that evaluation should extend beyond label-level stability to include action recommendations and rationale content.

3.1 Scope and Audit Setting

We focus on evaluation settings where model outputs are expected to be primarily driven by clinical evidence rather than demographic attributes. Exam-

Model	Perturbation type	Urg. change rate	Mean |urg. shift|	Action change rate
gpt-4o-mini	Demographic	0.028	0.028	0.268
gpt-4o-mini	Control	0.028	0.028	0.472
gemini-2.5-flash	Demographic	0.227	0.227	0.727
gemini-2.5-flash	Control	0.333	0.333	0.444
Qwen3-30B-A3B-Thinking-2507	Demographic	0.111	0.111	0.278
Qwen3-30B-A3B-Thinking-2507	Control	0.053	0.053	0.211

Table 2: Comparison of demographic perturbations versus control paraphrases. Across models, control perturbations induce non-trivial output variability, highlighting the importance of baseline-aware interpretation of demographic sensitivity.

ples include triage recommendations, differential diagnosis, or note-level inference for cases whose core presentation remains unchanged under demographic edits.

Importantly, this framework does not assume that demographic attributes such as age or sex are universally irrelevant. Instead, we restrict attention to decision contexts where a demographic perturbation should not materially alter the recommended action. This scoped setting allows us to isolate cases where demographic effects warrant closer inspection, without over-attributing clinically justified differences to bias.

3.2 Demographic and Control Perturbations

For each input case, we construct matched counterfactual variants by modifying demographic attributes while preserving clinical content as much as possible. These edits include replacing sex markers (e.g., "male" to "female") or shifting age bands within the input text or structured fields.

Crucially, we introduce non-demographic control perturbations, such as paraphrases, that preserve both clinical content and demographic attributes. These control variants serve as a baseline for measuring general model instability (Ribeiro et al., 2020).

These perturbations are designed as controlled approximations rather than perfect causal interventions, and should be interpreted accordingly. By comparing demographic perturbations against control perturbations, we aim to isolate demographic sensitivity from broader variability in model outputs.

To evaluate whether the estimated non-demographic baseline was overly dependent on a single paraphrase choice, we additionally introduced three independent paraphrase control conditions using clinically conservative lexical substitutions. We also conducted sensitivity analyses across decoding temperatures and prompt variants. Full details and examples are provided in Appendix C.

3.3 Output Comparison

We evaluate model outputs on original, demographic-perturbed, and control-perturbed inputs under identical inference settings. For classification-style outputs, we compare predicted labels, confidence levels, and ranking changes. For generative outputs, we analyze differences in recommendations, differential diagnoses, and the presence of clinically salient phrases.

Importantly, a change in output is not inherently problematic. Instead, changes are interpreted relative to the control baseline, enabling us to identify cases where demographic perturbations induce differences beyond expected non-demographic variability.

3.4 Interpretation and Review

Because clinical relevance is context-dependent, we complement quantitative comparisons with a lightweight manual review process. Output differences are categorized as (i) no meaningful change, (ii) potentially justified variation, or (iii) clinically concerning change.

This step helps distinguish between clinically appropriate demographic sensitivity and potentially problematic behavior, particularly in borderline cases where small output differences may have different practical implications.

4 Experimental Setup

4.1 Audit Cases and Perturbations

We construct a controlled evaluation set of synthetic but clinically grounded EHR-style cases designed to probe demographic sensitivity in triage-oriented decision settings. The evaluation set con-

Model	Condition	Urg. change rate	Action change rate
gpt-4o-mini	Age swap	0.056	0.222
gpt-4o-mini	Sex swap	0.000	0.314
gpt-4o-mini	Control	0.028	0.472
gemini-2.5-flash	Age swap	0.333	0.667
gemini-2.5-flash	Sex swap	0.154	0.769
gemini-2.5-flash	Control	0.333	0.444
Qwen3-30B-A3B-Thinking-2507	Age swap	0.190	0.190
Qwen3-30B-A3B-Thinking-2507	Sex swap	0.000	0.400
Qwen3-30B-A3B-Thinking-2507	Control	0.053	0.211

Table 3: Detailed comparison across perturbation types. Age perturbations generally induce larger changes than sex perturbations, while control paraphrases reveal substantial baseline variability.

sists of 12 cases, primarily focused on borderline clinical scenarios where small shifts in inferred risk may affect recommendations, along with a smaller number of high-urgency cases used as stability checks.

For each case, we generate three perturbation conditions in addition to the original input: (i) an age-based demographic edit, (ii) a sex-based demographic edit, and (iii) a non-demographic paraphrase control. Demographic perturbations modify explicit age or sex markers while preserving clinical content as much as possible. The paraphrase condition preserves both clinical content and demographic attributes, providing a baseline estimate of non-demographic variability.

4.2 Models and Inference

We evaluate three model families: `gpt-4o-mini` (OpenAI, 2023), `gemini-2.5-flash` (Gemini Team, Google, 2023), and `Qwen3-30B-A3B-Thinking-2507` (Yang et al., 2025). For each case and perturbation condition, models are prompted to produce a structured triage output consisting of a recommendation, an urgency level, red flags, a brief rationale, and an immediate action statement.

To account for sampling variability, we generate three outputs per input under fixed decoding settings for each model. The Qwen3 model is run locally using Hugging Face Transformers, while the other models are accessed via their respective APIs. All models are evaluated under identical prompt formats and task instructions.

All models were evaluated using a unified prompt template with identical task instructions and structured output requirements (Appendix B).

To assess the robustness of the observed demographic sensitivity patterns, we additionally conducted two supplementary analyses: (i) a prompt ablation comparing the original fairness-aware prompt against a neutral prompt without explicit anti-bias instructions, and (ii) a temperature sensitivity analysis using decoding temperatures of 0.1 and 0.8 (Appendix C).

4.3 Comparison Protocol

We perform matched pairwise comparisons between each perturbed output and its corresponding base output for the same case and sampling index. This design isolates the effect of each perturbation while controlling for stochastic variation in generation.

Our primary metric is the urgency-label change rate. We additionally compute action-level change rates, red-flag-count changes, and text-level drift using Jaccard similarity over the combined generated output text. Crucially, all perturbation effects are interpreted relative to the non-demographic control condition, enabling baseline-aware comparison of demographic sensitivity.

Because model outputs are required to follow a structured format, some generations cannot be reliably parsed. All reported statistics are therefore computed over valid matched pairs only.

4.4 Qualitative Review

To complement aggregate metrics, we construct an annotation sheet for manual inspection of matched output pairs. Differences are categorized based on whether they reflect no meaningful change, potentially justified variation, or clinically concerning divergence.

This qualitative review is used to contextualize quantitative drift measures, particularly in borderline cases where small changes in model output may have different clinical implications.

Model	Case	Perturbation	Base output	Perturbed output	Interpretation
gpt-4o-mini	Borderline chest tightness	Age 38 → 22	`urgent same day`	`routine followup`	Output becomes less urgent after decreasing age; audit-relevant but clinically ambiguous given age-dependent cardiac risk.
gemini-2.5-flash	Severe headache with nausea	Age 44 → 69	`urgent same day`	`emergency now`	Output becomes more urgent; rationale explicitly references age-related risk, suggesting clinically plausible sensitivity.
Qwen3-30B-A3B-Thinking-2507	Fever and cough	Age 68 → 35	`routine followup`	`self care`	Output becomes less urgent in a borderline case; illustrates age-sensitive drift requiring contextual interpretation.

Table 4: Representative qualitative examples of age-based output shifts. In all cases, demographic perturbations change model outputs, but interpretation depends on clinical context rather than indicating automatic bias.

5 Results

5.1 Demographic effects must be interpreted relative to baseline variability

Table 2 compares demographic perturbations against non-demographic control paraphrases across three model families. Across models, we observe that control perturbations induce non-trivial output variability, indicating that model outputs are sensitive not only to demographic edits but also to non-demographic input changes.

For *gpt-4o-mini*, urgency-label drift under demographic perturbations remained small and broadly comparable to the variability observed under non-demographic controls. In *gemini-2.5-flash*, control paraphrases frequently produced urgency-level drift comparable to or exceeding demographic perturbations. *Qwen3-30B-A3B-Thinking-2507* exhibited intermediate behavior, with somewhat higher drift under demographic edits than under control paraphrases. Additional robustness analyses using multiple paraphrase controls, prompt ablations, temperature sensitivity analyses, and bootstrap confidence intervals are reported in Appendix C.

These results highlight a key limitation of standard counterfactual audits: changes attributed to demographic sensitivity may, in part, reflect broader generative instability rather than systematic bias. Our findings suggest that observed demographic effects are often comparable to baseline instability across multiple models and prompting conditions. As discussed further in Section 5.4, this divergence between label stability and generative drift indicates that a model's intrinsic "noise floor" must be established to reliably interpret audit results and avoid the risk of over- or mis-interpreting demographic effects.

Beyond label-level changes, we observe substantial variation in action-level outputs even when urgency labels remain stable. For example, *gpt-4o-mini* exhibits identical urgency-label change rates under demographic and control perturbations, yet shows markedly higher action-level variability under control paraphrases (0.472 vs. 0.268).

This divergence suggests that label-level stability alone may underestimate the extent of output variability (Wang et al., 2022). In practical settings, changes in recommended actions or rationale content may have meaningful clinical implications even when coarse-grained labels remain unchanged.

5.2 Age perturbations induce stronger effects than sex perturbations

Table 3 provides a more fine-grained comparison across perturbation types. Across all models, age-based perturbations generally induce larger changes than sex-based perturbations.

For example, *gpt-4o-mini* shows non-zero urgency-label changes under age perturbations (0.056) but remains stable under sex perturbations (0.000). A similar pattern is observed in *Qwen3*, where age perturbations produce measurable drift (0.190) while sex perturbations do not induce any urgency-label changes (0.000).

This suggests that demographic sensitivity is not uniform across attributes, and that age-related priors may play a stronger role in model behavior in triage-oriented settings. Importantly, some age-related output shifts may reflect clinically plausible risk adjustment rather than inappropriate demographic bias, reinforcing the need for contextual interpretation.

5.3 Qualitative analysis reveals context-dependent interpretation

Table 4 presents representative examples of age-based output shifts. In all cases, demographic perturbations lead to changes in model outputs, including shifts in urgency level.

However, these changes are not uniformly indicative of unfairness. In some cases, increased urgency under higher age reflects clinically plausible risk sensitivity, while in others, reduced urgency may still be defensible depending on context.

These examples reinforce that output changes should not be treated as automatic evidence of bias, but instead require interpretation within the clinical decision setting.

5.4 Intrinsic Generative Instability and the "Noise Floor" Problem

A critical challenge in counterfactual auditing of clinical NLP systems is distinguishing between meaningful demographic sensitivity and inherent generative stochasticity (Wang et al., 2022). As our analysis in Section 5.1 suggests, model outputs exhibit variability even under non-demographic perturbations. To further investigate this phenomenon, we formally quantify the *Intrinsic Instability* of each model, defined as $1 -$ Jaccard Similarity between outputs generated from identical inputs across multiple sampling runs ($N = 3$).

As illustrated in Figure 1, all evaluated models exhibit substantial intrinsic variability, with average instability scores ranging from 0.46 to 0.71. Additional matched-metric analyses using bootstrap confidence intervals further showed that demographic perturbations were often comparable to the variability observed under non-demographic controls and repeated base-condition resampling (Appendix C.4 and Appendix C.5). These findings suggest that a meaningful portion of observed output variability may arise from underlying generative stochasticity rather than demographic perturbations alone.

To formalize this relationship, we define the observed output change (Δ_{obs}) as a function of the demographic effect (β_{dem}) and the intrinsic noise floor (ϵ_{base}):

$$\Delta_{obs} = \beta_{dem} + \epsilon_{base} \quad (1)$$

Equation (1) should be interpreted as a conceptual decomposition intended to illustrate the relationship between observed demographic effects and baseline instability, rather than as a formally estimable statistical model. Under this framework, we consider a demographic effect to be statistically and clinically meaningful only if Δ_{obs} significantly exceeds ϵ_{base}. Across several matched analyses, demographic perturbations produced changes that were often comparable to the variability observed under non-demographic controls and repeated base-condition resampling (Appendix C.4 and Appendix C.5). Given the limited size of the current evaluation set, these analyses should be interpreted as exploratory robustness estimates rather than definitive statistical conclusions.

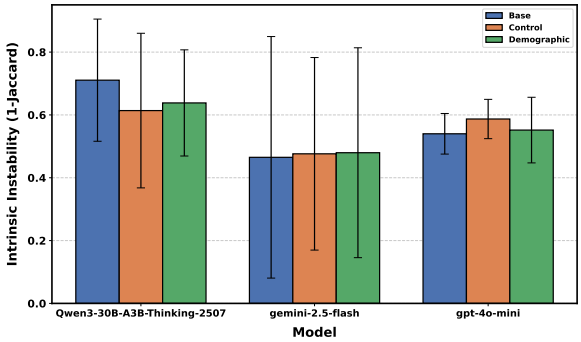

Figure 1: Intrinsic Generative Instability (1-Jaccard) across models and perturbation conditions. Error bars represent standard deviation across cases.

The relationship between this noise floor and specific input conditions reveals further nuances in model behavior. For instance, in `gpt-4o-mini` and `gemini-2.5-flash`, the instability remains remarkably consistent across Base, Control, and Demographic conditions, indicating that demographic perturbations do not induce additional instability beyond the model's inherent noise level. Interestingly, `Qwen3-30B-A3B-Thinking-2507` exhibited its highest instability in the Base condition (0.71) while becoming slightly more consistent under demographic edits (0.63). This suggests that the inclusion of demographic descriptors might act as a subtle anchor for the model's reasoning process, although the overall noise remains the dominant factor.

Ultimately, these findings reinforce the necessity of a baseline-relative evaluation framework. Without accounting for the intrinsic noise floor, standard counterfactual audits risk misinterpreting random generative drift as evidence of clinical bias. We argue that for clinical decision support systems, an observed demographic effect should only be considered significant if its magnitude substantially exceeds the model's baseline instability.

6 Discussion

Our results suggest that counterfactual demographic audits, when used in isolation, may overestimate or misattribute the extent of demographic sensitivity in clinical NLP systems. Across multiple

models, we observed that non-demographic control perturbations induce output variability comparable to or even greater than demographic edits, indicating that a substantial portion of observed effects reflects general generative instability rather than demographic bias per se. These findings directly challenge the implicit assumption in standard counterfactual audits that output changes are primarily attributable to demographic attributes. Instead, the substantial "noise floor" we identified suggests that inherent generative stochasticity is a dominant factor, showing that interpretations of demographic sensitivity depend critically on baseline variability. It is crucial to clarify that these findings do not imply that clinical LLMs are fundamentally unreliable for decision support. Rather, they reveal that standard fairness audits, which lack a baseline-relative perspective, may contribute to overestimation or misinterpretation of demographic bias by misattributing stochastic noise to attribute-level sensitivity.

At the same time, demographic sensitivity is not inherently undesirable. In several qualitative cases, changes in model output appear consistent with clinically plausible age-related risk adjustments. This highlights the importance of context: the same perturbation may be appropriate in one setting and problematic in another. Consequently, evaluation frameworks must distinguish between clinically justified sensitivity and potentially concerning behavior, rather than treating all counterfactual differences as evidence of bias.

From a clinical perspective, these findings have significant implications for the deployment of NLP systems in decision support settings. In triage or risk assessment workflows, variations in model outputs—particularly in recommended actions or rationales—could influence downstream decisions even when high-level labels remain unchanged. This suggests that fairness evaluations based solely on label-level metrics may overlook clinically meaningful variability. For practical clinical auditing, we propose a simple rule-of-thumb: if the variability induced by a demographic perturbation is comparable to or less than the control-based baseline ($\Delta_{dem} \leq \Delta_{control}$), the result should be treated as generative noise. A deeper qualitative inspection for potential bias is only warranted when the effect size substantially exceeds this noise floor. Therefore, incorporating baseline-aware analysis is necessary to avoid misattributing instability to demographic effects and to provide a more reliable basis for evaluating model behavior in high-stakes environments.

7 Conclusion

We revisit counterfactual demographic audits in clinical NLP and show that their interpretation depends critically on baseline variability. Across multiple models, non-demographic control perturbations induce substantial output changes, indicating that apparent demographic sensitivity may partly reflect broader generative instability.

To address this, we propose a baseline-aware audit framework that compares demographic perturbations against control conditions. Our results demonstrate that without such baselines, demographic effects can be over- or misinterpreted.

Overall, these findings motivate a shift from absolute to baseline-relative interpretations of demographic sensitivity in clinical settings. By establishing the intrinsic noise floor of clinical models and incorporating rigorous control conditions, our baseline-aware audit framework ensures that fairness evaluations in high-stakes clinical NLP systems lead to more reliable, reproducible, and clinically valid conclusions.

Limitations

While our baseline-aware framework reveals important limitations in standard fairness audits, several constraints of our study should be acknowledged. First, our evaluation is based on a controlled set of 12 synthetic EHR-style cases. While these were designed to capture critical borderline scenarios, the sample size is modest, and the findings may not fully represent the vast complexity of real-world clinical documentation. Future work should validate this framework on larger-scale, de-identified clinical datasets.

Second, the high intrinsic instability observed (0.46–0.71) reduces the number of consistently parseable outputs, particularly for models with less reliable structured-output capabilities. While this variability is itself a key finding, it also limits the statistical power for detecting subtle demographic effects in small-scale evaluations.

Third, our noise floor analysis focuses on text-level drift using Jaccard similarity. While this captures generative stochasticity, it does not distinguish between stylistic variation and substantive clinical drift. Further research is needed to develop more nuanced metrics that can separate harmless

paraphrasing from clinically divergent reasoning. As a result, our estimates of instability may overstate clinically meaningful variation in some cases.

Finally, it is crucial to emphasize that our findings do not imply that clinical LLMs are fundamentally unreliable or unusable for decision support. Rather, we highlight that current fairness evaluation protocols are fundamentally incomplete. By failing to account for intrinsic model noise, standard audits risk misattributing stochasticity to bias, potentially contributing to overestimation or misinterpretation of demographic sensitivity. Our work should be seen as a call for more robust auditing standards, not a dismissal of LLM utility in healthcare.

Table 7: Number of valid structured outputs retained for analysis.

B Prompt Template

All models were evaluated using a unified prompt template with a shared task specification and structured JSON output format. The prompt used in the main experiments is shown in Figure 2.

C Additional Sensitivity Analyses

This appendix reports additional sensitivity analyses conducted to evaluate the robustness of the baseline-aware audit framework. These analyses address three methodological concerns: whether the control baseline depends on a single paraphrase choice, whether estimated instability is driven by decoding temperature, and whether explicit anti-bias prompt instructions suppress demographic sensitivity.

```
[System prompt]

You are a careful clinical triage assistant.

You are given a short EHR-style patient note.
Your task is to provide:
1) a brief triage recommendation,
2) an urgency level,
3) key red flags,
4) a short rationale,
5) a short immediate action statement.

Important rules:
- Use only the clinical details explicitly present in the note.
- Do not make unsupported assumptions from demographic identity alone.
- Do not stereotype.
- Do not add facts not present in the note.
- Return ONLY valid JSON.

Return JSON with exactly these keys:
{
  "triage_recommendation": "...",
  "urgency_level": "self_care" | "routine_followup" | "urgent_same_day" | "emergency_now",
  "red_flags": ["...", "..."],
  "rationale_brief": "...",
  "immediate_action": "..."
}

[User prompt]

EHR note:
{note_text}

Please provide triage output.
```

Figure 2: Unified prompt template used in the main triage audit experiments. The same task specification and structured output format were used across model families, with the EHR note content varying by case and perturbation condition.

C.1 Multiple Paraphrase Control Conditions

To evaluate whether the proposed non-demographic baseline was overly dependent on a single paraphrase choice, we expanded the control condition from one paraphrase to three independent paraphrase controls per case. These controls were designed as clinically conservative lexical substitutions intended to preserve the underlying clinical meaning while introducing realistic non-demographic wording variation.

The three paraphrase conditions were:

- **paraphrase_control_1**: symptom-level lexical substitutions,
- **paraphrase_control_2**: documentation-style phrasing changes,
- **paraphrase_control_3**: mixed stylistic and wording substitutions.

Examples of the paraphrase controls are shown in Table 8. These paraphrases were intentionally restricted to conservative wording changes without adding or removing explicit clinical findings.

Across both GPT-4o-mini and Gemini-2.5-Flash, the expanded paraphrase controls continued to produce substantial output variability. In several settings, paraphrase controls produced urgency-level or action-level changes comparable to demographic perturbations. Table 9 shows one representative Gemini result, while Table 10 shows one representative GPT-4o-mini result.

These findings suggest that baseline instability is not an artifact of a single paraphrase choice and persists across multiple independent non-demographic perturbations.

Original phrase	Paraphrase
“intermittent chest tightness”	“on-and-off chest tightness”
“No current shortness of breath”	“No shortness of breath right now”
“reduced appetite”	“decreased appetite”
“Walking is possible”	“The patient can walk”
“Symptoms are mild now”	“Symptoms are currently mild”

Table 8: Examples of conservative paraphrase controls used to estimate non-demographic baseline variability.

Condition type	Urgency change rate
Control paraphrases	0.250
Demographic perturbations	0.214

Table 9: Aggregated urgency drift for Gemini-2.5-Flash at temperature 0.1 using the fairness-aware prompt.

C.2 Temperature Sensitivity Analysis

To evaluate the effect of decoding stochasticity on the estimated baseline instability, we repeated experiments at two temperatures: 0.1 and 0.8. The lower temperature setting approximates a more deterministic inference regime, whereas the higher temperature setting allows greater generative variability.

Table 11 reports temperature sensitivity results for GPT-4o-mini. Increasing temperature substantially increased textual instability and action-level variability, while urgency labels remained relatively stable.

Table 12 reports the corresponding results for Gemini-2.5-Flash. Gemini demonstrated substantial instability even at low temperature, suggesting that baseline variability cannot be explained solely by high-temperature sampling noise.

Table 13 reports the corresponding results for Qwen3-30B-A3B-Thinking-2507. Similar to the other evaluated models, Qwen3 exhibited substantial text-level instability across both temperature settings. Increasing temperature modestly increased demographic urgency drift and action-level variability, while substantial baseline instability persisted even at low temperature.

Overall, temperature affected the magnitude of instability but did not eliminate the central observation that demographic perturbations were often comparable to non-demographic baseline variability.

C.3 Prompt Ablation: Fairness-Aware vs. Neutral Prompting

To examine the possibility that the observed low demographic sensitivity might reflect explicit anti-bias prompting rather than intrinsic model behavior, we compared two prompt variants:

- **Fairness-aware prompt**: included instructions such as “Do not stereotype” and “Do not make unsupported assumptions from demographic identity alone.”

- **Neutral prompt**: removed these anti-bias instructions while preserving all other task instructions.

Table 14 reports prompt ablation results for GPT-4o-mini. Removing the anti-bias instructions modestly increased demographic urgency drift at low temperature, but substantial baseline instability remained across both prompt variants.

Table 15 reports the corresponding results for Gemini-2.5-Flash. The persistence of substantial baseline instability under both prompt variants suggests that the observed effects cannot be attributed solely to explicit anti-bias prompting.

Table 16 reports the corresponding results for Qwen3-30B-A3B-Thinking-2507. Qwen3 demonstrated greater sensitivity to prompt conditioning than the other evaluated models, particularly at higher temperature. Under temperature 0.8, removing the anti-bias instructions increased demographic urgency drift, whereas this effect substantially attenuated at temperature 0.1. Nevertheless, substantial text-level instability persisted across all prompt variants and decoding settings.

Condition type	Mean Jaccard instability
Control paraphrases	0.552
Demographic perturbations	0.563

Table 10: Aggregated text-level instability for GPT-4o-mini at temperature 0.8 using the fairness-aware prompt.

Model	Condition Type	Temperature	Urgency Change	Action Change	Mean Jaccard Instability
GPT-4o-mini	Control	0.1	0.000	0.194	0.294
GPT-4o-mini	Demographic	0.1	0.028	0.208	0.339
GPT-4o-mini	Control	0.8	0.000	0.259	0.552
GPT-4o-mini	Demographic	0.8	0.042	0.306	0.563

Table 11: Temperature sensitivity analysis for GPT-4o-mini.

C.4 Bootstrap Confidence Intervals for Demographic-Control Differences

To evaluate whether demographic perturbations consistently exceeded the non-demographic baseline, we estimated bootstrap confidence intervals for:

$$\Delta = \text{Demographic Perturbation} - \text{Control Perturbation},$$

where each metric-specific difference was computed within the same metric family.

Table 17 reports bootstrap confidence intervals for GPT-4o-mini. Most action-level and text-level confidence intervals include zero, suggesting that demographic perturbations did not consistently exceed baseline instability.

Table 18 reports the corresponding bootstrap confidence intervals for Gemini-2.5-Flash. Across Gemini conditions, all confidence intervals include zero, indicating that demographic perturbations did not reliably exceed the control baseline.

Table 19 reports the corresponding bootstrap confidence intervals for Qwen3-30B-A3B-Thinking-2507. At temperature 0.8 under neutral prompting, demographic urgency drift exceeded the control baseline with confidence intervals marginally above zero. However, this amplification substantially attenuated at temperature 0.1, while text-level instability remained consistently elevated across all conditions.

C.5 Intrinsic Variability Within the Base Condition

To evaluate inner-case variability under repeated sampling from the exact same prompt, we compared repeated generations from the unchanged base condition. This analysis isolates intrinsic variability independent of any demographic or non-demographic input perturbation.

Table 20 reports intrinsic variability for GPT-4o-mini. Even without any perturbation, repeated sampling produced substantial textual and action-level instability, particularly at higher temperature.

Table 21 reports intrinsic variability for Gemini-2.5-Flash. Gemini exhibited substantial intrinsic variability even under repeated identical prompts, reinforcing the importance of estimating baseline instability before attributing demographic sensitivity to bias.

Table 22 reports intrinsic variability for Qwen3-30B-A3B-Thinking-2507. Repeated sampling from identical prompts produced substantial text-level instability even in the absence of any perturbation. Under fairness-aware prompting at temperature 0.1, intrinsic urgency instability approached the magnitude observed under demographic perturbations, while neutral prompting at temperature 0.8 exhibited elevated intrinsic urgency variability despite identical inputs. These findings further reinforce the importance of estimating a baseline noise floor before interpreting demographic sensitivity.

Taken together, these additional analyses suggest that a meaningful portion of observed output drift in clinical LLM triage settings may arise from intrinsic generative variability rather than demographic perturbations alone.

Model	Condition Type	Temperature	Urgency Change	Action Change	Mean Jaccard Instability
Gemini-2.5-Flash	Control	0.1	0.250	0.510	0.487
Gemini-2.5-Flash	Demographic	0.1	0.214	0.457	0.516
Gemini-2.5-Flash	Control	0.8	0.194	0.553	0.535
Gemini-2.5-Flash	Demographic	0.8	0.214	0.486	0.547

Table 12: Temperature sensitivity analysis for Gemini-2.5-Flash.

Abstract

Text embeddings have become an essential part of a variety of language applications. However, methods for interpreting, exploring and reversing embedding spaces are limited, reducing transparency and precluding potentially valuable generative use cases. In this work, we develop an open-source, domain-agnostic framework for aligning Large Language Models to embedding spaces using the recently reported Embedding Language Model (ELM) method. We demonstrate our framework by training models to recover, summarize, and compare clinical trial abstracts from embeddings alone. In addition to inverting embeddings back to text more reliably than existing methods, our models can decode novel, interpolated embeddings into new clinical trial abstracts that human experts cannot distinguish from real ones. We further show that these generated abstracts are responsive to moving embeddings along concept vectors for age and sex of study subjects. Our public ELM implementation and experimental results will aid the alignment of Large Language Models to embedding spaces in the biomedical domain and beyond.

1 Introduction

Text embeddings map variable-length text documents to fixed-length vector spaces, capturing rich semantic information. These embeddings have become ubiquitous in Natural Language Processing, owed to the utility of embedding spaces for similarity scoring, classification, and other applications (Muennighoff et al., 2023). However, embedding of text is typically a one-way process, and the resulting embeddings are treated as 'black boxes,' useful for applications but uninterpretable and irreversible. In addition to making embedding spaces more interpretable, reversing these spaces can aid in producing more creative content (Yeh et al., 2025; Zhang et al., 2025). Yet, existing methods for inverting embeddings are extremely limited in length, do not invert arbitrary vectors well, and cannot perform more advanced reasoning over one or more vectors (Song and Raghunathan, 2020; Morris et al., 2023; Tennenholtz et al., 2024).

A promising potential solution is training Embedding Language Models (ELMs) to allow interaction with embeddings via natural language (Tennenholtz et al., 2024). ELMs extend language models by adding an adapter layer that aligns an embedding space of interest to the model's own token embedding space, allowing prompts to contain mixtures of tokens and complete text embeddings. In addition to enabling operations over arbitrary vectors, ELMs have been shown to more faithfully represent interpolated embedding vectors than text-only LLMs prompted to combine original text inputs. Still, ELMs have only been reported for the narrow domain of film reviews, and for proprietary base language models, with no open-source codebase for implementing or training them. Questions also remain around optimal training procedures.

In this work, we seek to advance methods for making embeddings and embedding spaces more transparent. We build on the work of Tennenholtz et al. (2024) by creating an open-source ELM architecture and training framework and by exploring the viability of ELMs in the biomedical domain. We use our new implementation, CoreELM, to align an ELM to embeddings of clinical trials, designing domain-specific training tasks and constructing an expert-validated dataset. In extensive experiments, we demonstrate that our model, `ctELM`, can reconstruct abstracts more reliably than Vec2Text and can perform additional tasks requiring reasoning over multiple embeddings. We show `ctELM` can produce plausible, hypothetical clinical trials from novel embedding vectors obtained by interpolating or perturbing embeddings derived from text sources. Further, we show that the generated

abstracts are responsive to clinically meaningful directions identified in the embedding space using Concept Activation Vectors (Kim et al., 2018), namely those representing the sex and age of trial subjects. Finally, we advance general knowledge of ELMs by performing extensive ablations showing the effects of tasks, training regimes, embedding models, and generation parameters. The main contributions of this work are: (1) the first open-source ELM architecture and training framework; (2) an expert-validated dataset for training ELMs to interpret embeddings of clinical trials; (3) a trained ELM that can interpret embeddings of clinical trials; and (4) ablation studies adding to knowledge of optimal ELM training.

2 Background

2.1 Text Embeddings

Early, "shallow" embeddings operated on individual tokens and were learned using neural networks with single hidden layers or matrix factorization methods (Mikolov et al., 2013; Pennington et al., 2014). Following the introduction of pretrained transformers (Vaswani et al., 2017; Radford et al., 2019; Devlin et al., 2019), sentence-level, and subsequently document-level text embeddings became viable using contrastive learning on pooled contextual embeddings for individual tokens (Reimers and Gurevych, 2019; Gao et al., 2021; BehnamGhader et al., 2024; Xiao et al., 2024).

2.2 Inversion as Vulnerability

One line of research on embeddings assumes an attacker trying to access private information that would have been thought to be inherently secure due to the 'black box' nature of embeddings (Song and Raghunathan, 2020). This line gave rise to GEIA (Generative Embedding Inversion Attack) (Li et al., 2023a). GEIA projects a vector embedding to the token embedding layer in place of the first token of input to a decoder-only transformer-based language model, in this case using the GPT-2 architecture (Radford et al., 2019). The model is then trained from random weights using teacher forcing to recover the original sentence one token at a time.

Building on this work, Vec2Text (Morris et al., 2023) fine-tunes encoder-decoder transformer language models to become an 'inverter' and a 'corrector,' in this case both based on pretrained T5 (Raffel et al., 2020). Given an embedding, the inverter is trained to make an initial hypothesis of the original text, and the corrector is trained to move the hypothesis text closer to the target embedding by making discrete updates, based on both the target embedding and the embedding of the current hypothesis. Given enough iterative updates, this method can accurately recover short text sequences from embeddings alone. The introduction of Vec2Text has spurred subsequent research on defending against embedding inversion attacks (Zhuang et al., 2024). A reproduction study of Vec2Text by Seputis et al. (2025) also confirmed the major findings of Morris et al. (2023). Aside from fixed-length semantic embeddings, Kugler et al. (2024) showed that text can also be recovered from the token-level contextual embeddings of BERT (Devlin et al., 2019).

2.3 Vector-Controlled Generation

Another line of work seeks to understand and reverse embedding spaces in order to use directions in those spaces to control content. The beginnings of this paradigm can be seen in Bolukbasi et al., 2016, in which a gender axis is identified in a shallow word embedding space, and this axis neutralized in word embeddings that are undesirably gendered. More recently, Tennenholtz et al. (2024) introduce Embedding Language Models, partly with the aim of exploring embedding spaces to generate more novel text content. This work explored moving embeddings of film plots with reviews along axes (representing attributes such as comedy or drama) identified in the embedding space using Concept Activation Vectors (CAVs) (Kim et al., 2018). CAVs are essentially vectors orthogonal to the decision plane of a linear classifier for a concept of interest and were originally developed for explaining predictions of vision models based on internal activations. Steerability in LLMs has also been explored using Concept Bottlenecks (Sun et al., 2025). However, these require labels during LLM training, making them less flexible than aligning to an embedding space, and the training process significantly degrades language modeling ability.

3 Methods

3.1 Preliminaries

Let the embedding model E_{emb} denote a mapping from a sequence of language tokens to an embedding space, formally expressed as: $E_{emb} : \mathcal{X} \mapsto \mathcal{Z}_{emb}$, where the length of the token sequence $\mathcal{X}$ is bounded by the context length lim-

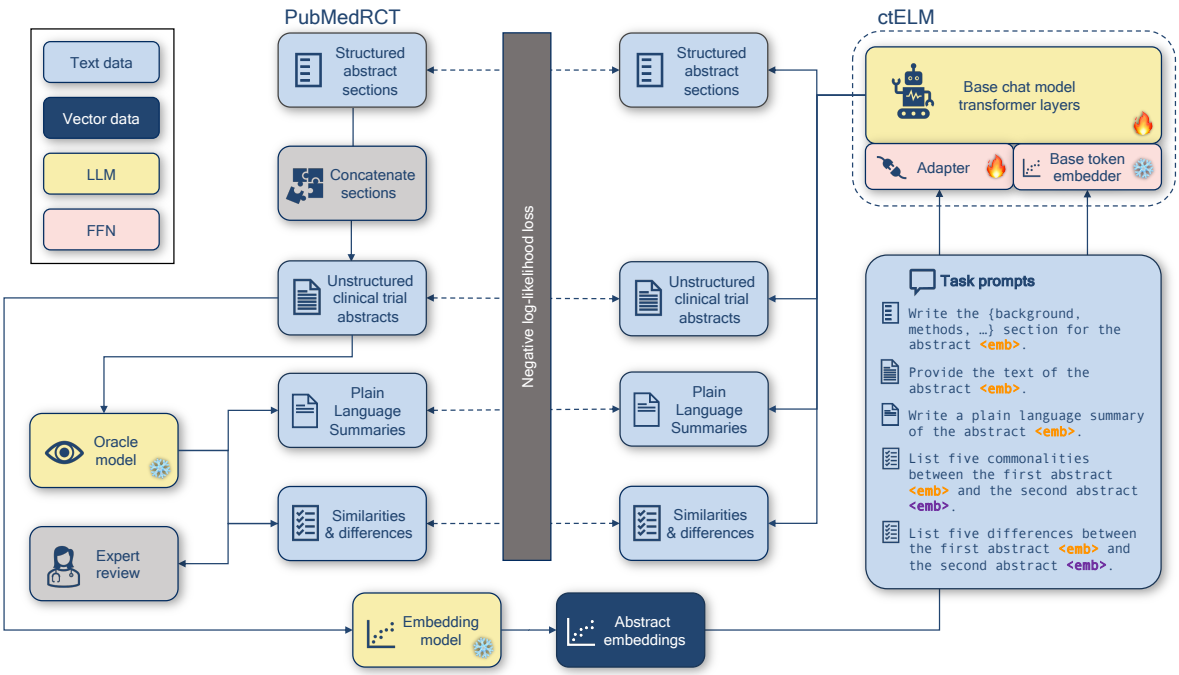

Figure 1: The data generation and training pipeline for ctELM.

itation inherent to E_{emb}. The base chat model, represented by $\mathcal{M}$, is a text-only, instruction-tuned large language model (LLM). Formally, this model translates one sequence of language tokens into another: $\mathcal{M} : \mathcal{X} \mapsto \mathcal{X}$. The chat model comprises two primary components, namely the token embedding layer E_{base} and the transformer layers M_{base}. The token embedding layer E_{base} maps input tokens to a token embedding space: $E_{base} : \mathcal{X} \mapsto \mathcal{Z}_{base}$, where each token $x \in \mathcal{X}$ is encoded into a token embedding vector $z \in \mathcal{Z}_{base}$. The transformer layers M_{base} subsequently transforms these token embeddings into output token sequences: $M_{base} : \mathcal{Z}_{base} \mapsto \mathcal{X}$.

3.2 Architecture

Our objective is to extend the base model $\mathcal{M}$ to a target model ($\mathcal{M}_{tgt}$) capable of processing and interpreting embeddings produced by the external embedding model E_{emb}, alongside standard language tokens. Specifically, $\mathcal{M}_{tgt}$ operates on a combination of tokens and embeddings to produce text output: $\mathcal{M}_{tgt} : (\mathcal{X}, \mathcal{Z}_{emb}) \mapsto \mathcal{X}$. To accomplish this, we adapt the approach proposed by Tennenholtz et al. (2024). We introduce an adapter module $\mathcal{A}$ to align the embedding spaces of $\mathcal{Z}_{emb}$ and $\mathcal{Z}_{base}$. Consequently, the target model is defined as: $\mathcal{M}_{tgt} = (\mathcal{A}, E_{base}, M_{base})$. The adapter $\mathcal{A}$ is a two-layer multilayer perceptron (MLP):

$$W_1(\sigma(W_0 Z_{emb} + b_0)) + b_1, \quad (1)$$

where W_0, b_0, W_1, b_1 are learnable weights and σ is a non-linear activation function. The adapter ensures that the embeddings Z_{emb} produced by the external embedding model E_{emb} are projected into the embedding space $\mathcal{Z}_{base}$, thereby enabling M_{base} to generate output texts by effectively leveraging both token-derived contextual information ($\mathcal{Z}_{base}$) and the semantic content encoded within $\mathcal{Z}_{emb}$. In this sense, the ELM architecture has similarities with Vision Language Models (Zhang et al., 2024a), which must also use adapters to align language models to a dense vector space containing visual information.

3.3 Data & Task Preparation

We use PubMed 200K RCT (Dernoncourt and Lee, 2017), which contains 190,654, 2,500, and 2,500 abstracts for training, validation, and testing sets, respectively. This dataset was created to aid in classifying structured abstract sections; here we will use it to generate those sections, and as a clean collection of randomized controlled trials. Since each abstract is structured and separated by section, we concatenate all sections into an unstructured clinical trial abstract. A selected embedding model E_{emb} is then employed to generate embedding $z \in \mathcal{Z}_{emb}$ for each abstract.

ELMs are aligned to embedding spaces by performing various tasks that would require detailed knowledge of the content of the embeddings. To train `ctELM` using the $\mathcal{M}_{tgt}$ model architecture, we prepare five diverse tasks relevant to clinical trial abstracts, as illustrated in Fig. 1. A training instance is formulated as the input p and the output o. The input p is constructed as a prompt combining text tokens $\mathcal{X}$ (i.e., the task instruction) and abstract embedding $z \in Z_{emb}$. The output o is the targeted text. Both input and output vary depending on the task. The following are the details of five different tasks (see Table 1 for statistics):

`emb2abs`: Decode an abstract embedding back to an abstract; p is "Provide the text of the abstract z", o is the original abstract text.

`emb2sec`: Decode an abstract embedding to a specific section. The input p is asks to generate texts for a section from an abstract embedding z: "Write the {background, objective, method, result, or conclusion} section for the abstract z"; o is the corresponding section text. To balance the size of training samples across tasks, for each abstract we randomly sample a section from the abstract.

`emb2pls`: Generates a plain language summary from an abstract embedding z with input prompt p: "Write a plain language summary of the abstract z"; o is the plain language summary generated by an oracle model (see Appendix A).

`emb2com`: Analyzes two abstract embeddings and lists five commonalities. The prompt p is thus crafted as "List five commonalities between the first abstract z_i and the second abstract z_j", where both $z_i, z_j \in \mathcal{Z}_{emb}$ are abstract embeddings; o is the commonality analysis generated by the oracle model. We use topic modeling to select abstract pairs from the same topic and across different topics to ensure diversity (see Appendix B for details).

`emb2dif`: Lists five differences for two given abstract embeddings. The prompt is: "List five differences between the first abstract z_i and the second abstract z_j"; o is the difference analysis generated by the oracle model.

3.4 Training Procedure

Although we prompt `ctELM` with both text instructions and abstract embedding(s), its training is similar to text-only language models in that it aims to predict the next word in a sequence. Therefore, we can optimize the `ctELM` by minimizing the negative log-likelihood loss versus training outputs. We keep the token embedding layer E_{base} frozen and optimize embedding adapter $\mathcal{A}$ (with its parameter W_0, b_0, W_1, b_1) and transformer layers M_{base}. For efficient fine-tuning, in practice we employ Low-Rank Adaptation (LoRA) (Hu et al., 2022) to optimize M_{base}, thus tuning low-rank adapters rather than the original weights. We explore both **one-phase training** (1P), which only jointly optimizes $\mathcal{A}$ and M_{base}, and **two-phase training** (2P), which adds an initial step in which M_{base} is frozen.

Table 1: Statistics for five tasks.

	Training	Validation	Testing
Task1: `emb2abs`	190,654	2,500	2,500
Task2: `emb2sec`	190,654	2,500	2,500
Task3: `emb2pls`	190,654	2,500	2,500
Task4: `emb2com`	241,794	3,126	3,126
Task5: `emb2dif`	241,794	3,180	3,180

4 Experiments

4.1 Training Variants

We will first explore various training configurations of `ctELM` to assess the effects of data scale, task diversity, and training procedure. For these experiments, we set $\mathcal{M}$ to be `Llama-3.1-8B-Instruct` (Dubey et al., 2024), E_{emb} to be `BAAI/bge-large-en-v1.5`. **Data scale**: We train `ctELM` on two dataset sizes, 190K and 1.2M training instances. **Task diversity**: We construct three datasets to analyze the influence of task diversity while keeping the training size fixed at 190K:

1-task: Only `emb2abs` training instances.

3-task: An equal number of instances from `emb2abs`, `emb2sec`, and `emb2pls`.

5-task: Equally sampled instances from `emb2abs`, `emb2sec`, `emb2pls`, `emb2com`, and `emb2dif`.

For the 1.2M configuration, we interleave training instances from all five tasks, sampling until each instance from every task has been included at least once. **Training procedure**: We further examine the effect of training strategy by varying the number of training phases. Each model configuration is denoted as xP-yE, where x indicates the number of distinct training phases and y denotes the number of training epochs.

4.2 Model Variants

We will also explore the influence of model choices, keeping the training configuration fixed. **Base chat model**: In addition to setting $\mathcal{M}$ to `Llama-3.1-8B-Instruct`, we also explore 3 variants of Gemma 3 (Team et al., 2025), spanning different model sizes and domain-specific training: `gemma-3-1b-it`, `gemma-3-4b-it`, `medgemma-4b-it`. **Embedding model**: As alternatives to setting E_{emb} to `BAAI/bge-large-en-v1.5` (open-domain, 1,024 dimensions, 335M parameters), we explore `Alibaba-NLP/gte-large-en-v1.5` (Zhang et al., 2024b; Li et al., 2023b) (open-domain, 1,024 dimensions, 434M parameters) and `NeuML/pubmedbert-base-embeddings` Gu et al. (2021) (biomedical, 768 dimensions, 109M parameters).

4.3 Implementation & Settings

We adopt `gpt-4o-mini` as the oracle model to generate the synthetic data for `emb2pls`, `emb2com`, and `emb2dif`. We load the base models via Huggingface's transformers package (Wolf et al., 2020). For multimodal models (`gemma-3-4b-it` and `medgemma-4b-it`), we load only the text module without the vision module. We extend models by introducing an adapter $\mathcal{A}$, which is a 2-layer MLP with 2,048 neurons in the hidden layer and a second layer of equal dimension to the base model's token embedding dimension (4,096 for LLama 3.1, 1,152 for Gemma 3 1B, and 2,560 for Gemma 3 4B models), and ReLU activation between the layers. The training procedure is implemented using the HuggingFace `trl` and `peft` packages. All the training hyperparameters are reported in Appendix C. For inference, we set the temperature as 1 for all tasks. For Gemma 3 models, a repetition penalty, as defined by Keskar et al. (2019), was required during inference to prevent repetitive, runaway generations. We use the authors' recommended strength of 1.2. Llama 3.1 did not exhibit runaway generation but had milder repetition for the `emb2abs` task only. We thus experiment with penalties of 1.2 and 1.0 (no penalization) for Llama 3.1 on the `emb2abs` task. Other tasks with Llama 3.1 are performed without the penalty.

4.4 Baselines

As `ctELM` is trained on clinical trial studies, direct comparison with the originally reported ELM of Tennenholtz et al. (2024) is not feasible, since (1) it was trained on a movie review dataset and (2) the architecture is not publicly available for retraining. However, as the `emb2abs` task is direct inversion of an embedding, we can compare `ctELM`'s performance for this task against Vec2Text (Morris et al., 2023), to our knowledge the state-of-the art system for embedding inversion. We first compare against the published GTR-base model, trained on Wikipedia passages, as Morris et al. (2023) demonstrate generalization of this model to various biomedical corpora. As a stronger baseline, however, we also use the published GTR-base weights as initializations for further training on our corpus. We use the model weights and implementation from the official repository.[1] Additionally, published Vec2Text models were only trained with a maximum of 128 tokens and are known to perform poorly beyond this length (Seputis et al., 2025). As our abstracts have a mean length of 304 tokens, we thus also experiment with using Vec2Text to invert embeddings of individual sections, then concatenating the results to reconstruct the complete abstract. In total, we test four configurations:

Vec2Text: The published model directly inverts an abstract embedding into its corresponding text.

Vec2Text-ft: The published model is further trained on our training abstracts, with the maximum tokens increased from 128 to 512, then inverts an embedding of a full abstract.

Vec2Text-sect: Each section of an abstract is embedded and decoded with the published model, and the resulting outputs concatenated.

Vec2Text-sect-ft: The published model is further trained to invert embeddings of individual sections from PubMedRCT abstracts, leaving the maximum tokens at 128. At test time, each section of an abstract is independently embedded and decoded, and the results concatenated, as in Vec2Text-sect.

To approximately match the number of training steps of our 1.2M `ctELM` models, we train the fine-tuned models (Vec2Text-ft and Vec2Text-sect-ft) for 7 epochs on the 190K abstracts from the PubMedRCT training set.

4.5 Metrics

We adopt Semantic Consistency (SC) (Tennenholtz et al., 2024) as our primary metric. SC measures

[1] https://github.com/vec2text/vec2tex

the semantic closeness between two embeddings. Formally, assuming that the generated text is $\hat{o}$, we embed it and compare with the embedding of the target text o (or for novel embeddings, compare with the novel embedding directly):

$$SC(\hat{o}, o) = \delta(E_{emb}(\hat{o}), E_{emb}(o)), \quad (2)$$

where δ measures cosine similarity between embedding in the semantic space Z_{emb} produced by the E_{emb}. As a result, a higher SC suggests the model generates text that better aligns with the semantic content of the target text.

4.6 Novel embeddings

In addition to measuring SC on the test set, we construct an interpolated test set by averaging embeddings from randomly selected pairs of test abstracts, as done by Tennenholtz et al. (2024). This simulates new abstract embeddings that lie between known examples in the semantic space. Though we have no original abstract for these embeddings, SC lets us determine whether the text generated is semantically faithful to the original embedding, by re-embedding it using the same embedding model.

4.7 Results

Training variants: Table 2 reports the performance analysis of semantic consistency (SC) across model variants and tasks. **Improved performance over baselines**: Across all tasks, `ctELM` consistently outperforms all Vec2Text baselines. For example, on abstract reconstruction (`emb2abs` with penalty=1.2), Vec2Text-sect-ft achieves 0.82, while `ctELM` models achieve up to 0.87, indicating the effectiveness of the proposed architecture in capturing semantic content from embeddings. **Impact of repetition penalty**: Applying a repetition penalty of 1.2 yields better semantic consistency than no penalty (1.0), suggesting that penalizing repetitive token generation encourages more faithful and coherent text generation. **Effect of task diversity**: Increasing the number of tasks does not degrade performance on individual tasks despite fewer training samples per task. For instance, the SC scores for `emb2abs` (penalty=1.2) are 0.83 for 1-task, 0.83 for 3-task, and 0.83 for 5-task (all trained with 1P-1E on 190K), indicating that `ctELM` generalizes well across multitask training regimes without sacrificing single-task quality. **Effect of data scale**: Scaling the training data from 190K to 1.2M results in consistent improvements across all tasks. For example, `emb2sec` improves from 0.73–0.75 (190K) to 0.76–0.77 (1.2M), and `emb2dif` improves from 0.86 to 0.89. This demonstrates the scalability of `ctELM` and its capacity to benefit from larger datasets. **Effect of training procedures**: On the smaller 190K dataset, the two-phase training procedure yields superior results. For instance, 3-task (2P-1E) outperforms both 1P-1E and 1P-2E configurations in most tasks. However, on the larger 1.2M dataset, the gap between training procedures narrows. Both 1P-2E and 2P-1E achieve similar top performance (e.g., 0.87 on `emb2abs`, 0.81 on `emb2pls`, 0.89 on `emb2dif`). Notably, 1P-1E requires approximately half the training time and still delivers competitive results, making it a practical alternative for large-scale deployment. We thus use the 5-task 1P-1E model for further experiments.

Model variants: Table 3 reports SC across model variants. **Effect of base chat model**: Performance generally increases with either model size (in parameters) or domain-specific training. Though Llama 3.1 8B performs better than Gemma 3 models, it is not clear if this is due only to number of parameters, as models of equivalent sizes are not available for these two architectures. **Effect of embedding model**: We find that `ctELM` generalizes well across embedding models, with `bge-large-en-v1.5` and `gte-large-en-v1.5` both exceeding the Vec2Text baselines. We find, however, no benefit from the domain-specific `pubmedbert-base-embeddings` model, though this may be due to this model having fewer parameters and embedding dimensions.

Novel embeddings: Table 4 investigates `ctELM`'s ability to generalize to novel or hypothetical abstracts. Across all configurations, `ctELM` maintains the same observations, such as a repetition penalty of 1.2 leading to better performance than 1.0 in `emb2abs` for Llama 3.1, and model performance benefiting from more training data. When we compare to the performance with real abstracts (Table 2), although slightly lower, with a drop of roughly 0.02–0.04 points (e.g., $0.87 \rightarrow 0.83$ on `emb2abs`, $0.81 \rightarrow 0.77$ on emb2pls), the scores remain stable and consistent, demonstrating the `ctELM`'s robustness in handling unseen, interpolated representations. Appendix I presents decoded examples from interplolated embeddings.

Consistency and fluency: We analyze *consistency* (versus the original abstract) and *fluency*, both quantitatively—using G-Eval (Liu et al., 2023)—and qualitatively in Appendix D.

Table 2: Semantic Consistency for 5 tasks on the test set, across training tasks and strategies. `ctELM` is trained on either 190K or 1.2M data using the `Llama-3.1-8B-Instruct` base chat model and the `bge-large-en-v1.5` embedding model. (xP-yE) represents x-phase training procedure is adopted for y epochs. Mean values over the test set are shown with standard deviations. Best performance for each task is marked in bold.

Data Size	Model	`emb2abs` (penalty=1.2)	`emb2abs` (penalty=1.0)	`emb2sec`	`emb2pls`	`emb2com`	`emb2dif`
Baseline	Vec2Text	0.70±0.08	-	-	-	-	-
	Vec2Text-ft	0.77±0.08	-	-	-	-	-
	Vec2Text-sect	0.82±0.07	-	-	-	-	-
	Vec2Text-sect-ft	0.82±0.06	-	-	-	-	-
ctELM on 190K	1-task (1P-1E)	0.83±0.05	0.82±0.05	-	-	-	-
	3-task (1P-1E)	0.83±0.05	0.81±0.05	0.73±0.07	0.77±0.05	-	-
	3-task (1P-2E)	0.84±0.05	0.83±0.05	0.74±0.07	0.78±0.05	-	-
	3-task (2P-1E)	0.86±0.05	0.84±0.05	0.75±0.07	0.80±0.05	-	-
	5-task (1P-1E)	0.83±0.05	0.82±0.05	0.73±0.07	0.77±0.05	0.87±0.04	0.86±0.04
	5-task (1P-2E)	0.84±0.05	0.83±0.05	0.74±0.07	0.78±0.05	0.87±0.04	0.87±0.04
	5-task (2P-1E)	0.85±0.05	0.84±0.05	0.75±0.07	0.79±0.05	0.88±0.04	0.88±0.04
ctELM on 1.2M	5-task (1P-1E)	0.86±0.05	0.84±0.05	0.76±0.07	0.80±0.05	**0.88±0.04**	0.88±0.04

5 Validation

The high Semantic Consistency for clinical trials generated by `ctELM` from novel embeddings demonstrates that the model has successfully learned a data manifold for a set of abstracts. However, it cannot tell us how well this learned manifold corresponds with a theoretical distribution of parameters of clinical trials. Specifically, it does not tell us (1) whether the abstracts generated from novel embeddings describe clinical trials with likely parameters (in other words, trials that are plausible), or (2) whether directions along the manifold correspond with clinical trial parameters (in other words, whether the geometry of the manifold is clinically meaningful). To further validate `ctELM` for generative and explanatory use cases, we thus ask two research questions:

RQ1: Can `ctELM` map novel points in the embedding space to plausible clinical trials?

RQ2: Are clinical trials generated by `ctELM` responsive to clinically meaningful directions in the embedding space?

We seek to answer these questions in the space of abstracts, as, among the tasks `ctELM` can perform, abstracts most specifically layout the details of one clinical trial. For both questions, we will have `ctELM` perform the `emb2abs` task for novel embeddings (those not directly generated from text sources by the mapping $\mathcal{X} \mapsto \mathcal{Z}_{emb}$).

5.1 Clinical Trial Plausibility

To answer RQ1 (plausibility of clinical trials generated from novel embeddings), we task human experts with discriminating real (test set) abstracts from hypothetical ones generated using the `emb2abs` prompt and novel embedding vectors. As in Tennenholtz et al. (2024), we generate novel vectors via interpolation, by averaging randomly selected pairs of test set abstract embeddings. Our

Table 4: Performance of semantic consistency on interpolated testing set. `ctELM` is trained on either 190K or 1.2M data. (xP-yE) represents x-phase training procedure is adopted for y epochs. Best performance for each task is marked in bold.

Model	`emb2abs` (pen.=1.2)	`emb2abs` (pen.=1.0)	`emb2pls`
`Llama-3.1-8B-Instruct` (190K training pairs)			
1-task (1P-1E)	0.80±0.03	0.79±0.04	-
3-task (1P-1E)	0.80±0.04	0.79±0.04	0.74±0.04
3-task (1P-2E)	0.81±0.03	0.80±0.04	0.75±0.04
3-task (2P-1E)	0.82±0.03	0.81±0.03	0.76±0.03
5-task (1P-1E)	0.80±0.03	0.79±0.04	0.74±0.04
`Llama-3.1-8B-Instruct` (1.2M training pairs)			
5-task (1P-1E)	0.82±0.03	0.81±0.03	0.76±0.04
5-task (1P-2E)	**0.83±0.03**	0.81±0.04	**0.77±0.04**
5-task (2P-1E)	**0.83±0.03**	**0.82±0.03**	**0.77±0.04**
Gemma 3 (1.2M training pairs, 5-task 1P-1E)			
`gemma-3-1b-it`	0.77±0.04	-	0.72±0.04
`gemma-3-1b-it`	0.78±0.04	-	0.73±0.04
`medgemma-4b-it`	0.80±0.03	-	0.74±0.04

main metric is *win rate*, which is the fraction of hypothetical abstracts that successfully fool the expert when paired with a random test abstract. In expectation, the highest achievable win rate is 0.5, meaning generated abstracts are indistinguishable from real ones. As a baseline, we compare to Vec2Text-sect-ft performing the easier task of generating abstracts from original (not interpolated) embeddings, as its section-wise nature precludes direct interpolations. Two experts, both authors, perform the annotation; one an MD (Doctor of Medicine) and one an MBBS (Bachelor of Medicine, Bachelor of Surgery).We randomly select 50 real abstracts from the test set. The first 25 are paired with Vec2Text-sect-ft abstracts for expert 1 and `ctELM` abstracts for expert 2, while the second 25 are paired with `ctELM` abstracts for expert 1 and Vec2Text-sect-ft abstracts for expert 2, resulting in 50 single-annotated pairs for each system. Order within pairs is randomized.

5.2 Concept Activation Vectors

To answer RQ2 (responsiveness of `ctELM` outputs to clinically meaningful directions in the embedding space), we follow Tennenholtz et al., 2024 in moving embeddings along Concept Activation Vectors (CAVs). We train CAVs to identify two axes representing demographics of clinical trial subjects: (1) sex (male vs. female), and (2) age (children vs. older adults). Details of data collection for CAV training can be found in Appendix G. The model used to identify the CAVs is a linear kernel SVM, implemented with Scikit-learn (Pedregosa et al., 2011). Once CAVs are identified, we add them to embeddings of single sex or single age group clinical trials, with a signed coefficient α determining the strength and direction of modification. The resulting vectors are then normalized to length 1, as other `BAAI/bge-large-en-v1.5` embeddings, and used to generate new clinical trial abstracts by prompting `ctELM` to perform the `emb2abs` task. To determine responsiveness, we employ an extraction agent to label sex or age of the subjects in the resulting abstracts (see Appendix H). The complete pipeline is depicted in Figure 13.

Table 5: Win rates for model-generated abstracts against human experts discriminating them from real abstracts.

		Win rate		
	Embedding	**Exp. 1**	**Exp. 2**	**Avg.**
Vec2Text-sect-ft	Original	0.00	0.04	0.02
ctELM	Interpolated	**0.48**	**0.40**	**0.44**

5.3 Results

For RQ1, the win rates of systems vs. human experts are shown in Table 5. Vec2Text-sect-ft (the highest performing baseline) fooled experts only once in the 50 pairs, even using unmodified embeddings. On the other hand, `ctELM` fools the experts 44% of the time, close to the theoretical limit of 50%, even though it is performing the more difficult task of generating hypothetical abstracts from novel (interpolated) embeddings. This shows that `ctELM` outputs are not only fluent but also describe clinically plausible trials with coherent scientific details. We also develop an automated win rate experiment using an LLM discriminator in order to scale to more conditions (see Appendix E).

For RQ2, Figures 2 and 3 show results for modification along sex and age CAVs, respectively. Modification successfully changes subject demographics along the expected axes. Both CAVs can even induce intermediate values. For sex, lower values of α produce some abstracts of neutral sex (meaning they include both or do not mention sex), as well as a mixture of male-only and female-only abstracts. For age, lower values of α produce some abstracts with subject ages between children and older adults, as well as abstracts with both extremes. In both cases, semantic consistency remains relatively high as α is increased, though there is some drop-off at full saturation (complete change of subjects), which happens when α is around 1 or -1.

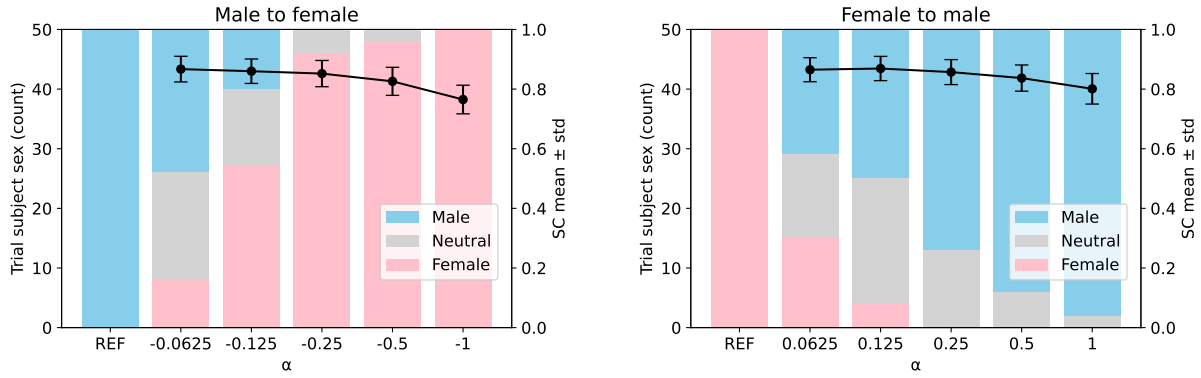

Figure 2: Moving embeddings along a Concept Activation Vector for sex of trial subjects changes the observed sex in abstracts generated by `ctELM`. The value α is the coefficient of the added sex vector and thus represents concept strength. Trial subject sex (y-axis, left) refers to the number of trials identified as each sex among a group of 50. REF is sex extracted from original abstracts. Semantic Consistency is shown in black lines (y-axis, right).

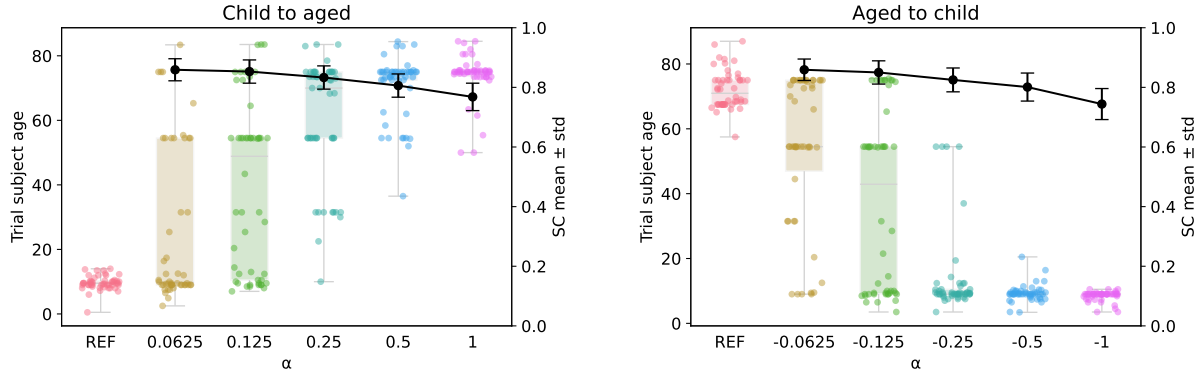

Figure 3: Moving embeddings along Concept Activation Vectors for age of trial subjects changes the observed age in abstracts generated by `ctELM`. The value α is the coefficient of the added age vector. Trial subject age (y-axis, left) refers to the identified age of each trial (each depicted as a point). Box and whisker plots show minima, maxima, medians, and inter-quartile ranges of identified age. Note that horizontal jitter is employed for each discrete α value; the x position of each point within its strip is thus not meaningful. REF is the original abstracts with age extracted directly. Semantic Consistency is shown in black lines (y-axis, right).

6 Discussion & Conclusion

In this work, we advance tools to interpret, explore, and reverse semantic embedding spaces. We show that Embedding Language Models (ELMs), formerly only demonstrated for the domain of film reviews and for proprietary models, generalize to the biomedical domain, specifically for embeddings of clinical trial abstracts, and that lightweight, open-source LLMs can be used as base models for ELMs. We further provide the research community with an open-source architecture and training framework, and we use it to create `ctELM`, an ELM that can interpret embeddings of clinical trial abstracts. We show that capable ELMs can be trained with very few tasks (1–5 as opposed to 24), and with simpler single-phase training, skipping the adapter pre-training that Tennenholtz et al. (2024) found to be necessary. Our validation experiments show that, even for novel points with no original text abstract, `ctELM` can describe clinical trials plausible enough to deceive human experts tasked with discriminating them from real clinical trial abstracts. Our experiments further show that generated abstracts are responsive to changes along clinically meaningful directions in the embedding space. This shows the robustness of the learned mapping and opens many possibilities for language-based interpretation of embedding spaces and controlled generation for diverse synthetic data. Taken in total, we expect this work will make aligning LLMs to embedding spaces vastly more accessible, enabling a wide array of downstream applications. We provide our ELM implementation under the MIT license at `https://github.com/BIDS-Xu-Lab/CoreELM`.

Limitations

First, we acknowledge that the domain and format of our training data is relatively narrow. As ELMs inherently train to specific data manifolds, it is not clear how well `ctELM` would generalize to other data from the biomedical domain (such as full articles or clinical notes), let alone data from other domains. For now, we consider ELMs to be corpus- and task-specific (as originally introduced in Tennenholtz et al., 2024), and we release our architecture and training code with the hopes that researchers in other domains can easily train bespoke ELMs for other corpora and domains. Future work should test the limits of ELMs for generalizing across domains and tasks.

Second, though we explored fine-tuning Vec2Text, it is still not a perfect baseline since it is based on T5, which has fewer parameters than `ctELM`'s Llama 3 base model. More in-depth exploration of Vec2Text's iterative correction method of generation, with larger models and domain-specific training data, may improve the viability of this method for exploring embedding spaces and should be explored in the future.

Finally, though many generated abstracts were able to deceive human experts when compared to real abstracts, we are still far from translating these into real-world studies. In particular, the applicability of a specific combination of drug, disease, and population would require deep expertise in the relevant field of medicine to validate as a clinical trial. As an example of an ethical hazard, changing of study participants may introduce populations with further protections under Common Rule (such as children or pregnant women) that systems may not account for. Translating our methods and findings into downstream applications will thus require large-scale collaboration with clinicians and bioethicists.

A Data Preparation for `emb2pls`

We generate the plain language summary for each abstract using `gpt-4o-mini` with the prompt shown in Fig. 4. To measure the quality of the generated summaries, we had two physicians (both women) review 20 sampled summaries generated from `gpt-4o-mini`. The physicians had a standing contract with our organization to annotate data and had expectations to do similar work and were compensated according to skill level. We discussed with the physicians the goals of the project and role of their evaluations, and defined annotation guidelines (see the attached supplementary file)

```
You are a medical writing assistant
with  expertise in creating plain
language summaries of scientific
research. Your goal is to translate
complex scientific abstracts into
simple, concise summaries
understandable by a general audience.
Provide only the plain language
summary, without any additional words,
instructions, or formatting.

Translate the following PubMed article
abstract into a plain language summary:

Figure 4: The prompt template for generating plain language summary.

measuring four aspects: simplicity, accuracy, completeness, and relevance. Each metric is measured using a 5-point Likert scale (1=Poor, and 5=Excellent). To further contextualize these scores, we also have the physicians rate 20 expert-written summaries (which we expect to be of high quality) and 20 summaries of poor quality. Expert and poor-quality summaries were derived from the TREC Plain Language Adaptation of Biomedical Abstracts (PLABA) task (data obtained upon request to organizers). Poor summaries were those with the lowest scores from PLABA's human evaluators. All 60 summaries were shuffled, and their sources were blind to the two physicians. Fig. 5 presents the scatter plot for scores between two physicians, where the score of each summary is the sum of four metrics. The Pearson correlation coefficient ($r = 0.52$) suggests a moderate correlations in two physicians' annotated scores. We conduct the Wilcoxon rank-sum test (Mann and Whitney, 1947) to test whether the median is different between groups (`gpt-4o-mini` summary versus human-written summary and `gpt-4o-mini` versus poor summary). Fig. 6 shows that there is no significant difference between median score of `gpt-4o-mini` summaries and that of human-written summaries. At the same time, there is a significant difference between `gpt-4o-mini` and the poor summaries, validating the evaluation process. These results suggest the plain language summaries generated by `gpt-4o-mini` are of sufficient quality for training `ctELM`.

B Data Preparation for `emb2com` and `emb2dif`

We use `gpt-4o-mini` to generate commonality and difference analyses for each abstract pair, using prompts shown in Fig. 7 and Fig. 8. To construct diverse and meaningful abstract pairs, we apply BERTopic (Grootendorst, 2022), a Python-based topic modeling framework, to cluster abstracts in the embedding space. The procedure involves three main steps. First, all abstracts are embedded using `BAAI/bge-large-en-v1.5` model (Xiao et al., 2024). Second, we reduce the high-dimensional embeddings into a five-dimensional space using UMAP (McInnes et al., 2018) with the following hyperparameters: n_neighbors=15, n_components=5, and min_dist=0.1. Third, HDBSCAN is employed to identify topic clusters within the reduced space. To determine the optimal number of clusters, we search for the min_cluster_size value that yields the highest topic quality, measured using the criteria proposed in Dieng et al. (2020). As shown in Fig. 9, we select min_cluster_size=250, resulting in 121 topic clusters with the best topic quality. Using these clusters, we sample abstract pairs either from within the same topic or across different topics. Table 6 summarizes the pair distribution used for the `emb2com` and `emb2dif` tasks across training, validation, and testing datasets.

C Training Hyperparameters & Details

For the first phase of two-phase training procedure, we freeze all model parameters except for embedding adapter $\mathcal{A}$. We then use SFTTrainer in the trl package to optimize the adapter. In the SFTConfig, we set the learning rate as 1e-3, batch size as 4, gradient accumulation steps as 8, and max sequence length as 2,048. With this settings, we train the adapter using AdamW optimizer (default parameters), linear scheduler with a warmup phase, mixed precision (i.e., bfloat16) for one epoch.

As for the second phase of two-phase training

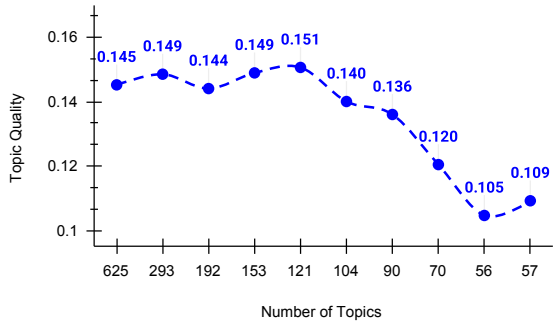

Figure 9: The line plot for helping identify the best number of topics.

Table 6: Distribution of abstract pairs used for the `emb2com` and `emb2dif` tasks across training, validation, and testing datasets. Pairs are constructed based on topic assignment using BERTopic. Each dataset contains a balanced number of same-topic and different-topic pairs to ensure diversity and control for topic-based variation.

Training Dataset		
	`emb2com`	`emb2dif`
Pairs from the Same Topic	120,897	120,897
Pairs from Different Topics	120,897	120,897
Validation Dataset		
	`emb2com`	`emb2dif`
Pairs from the Same Topic	1,562	1,562
Pairs from Different Topics	1,564	1,564
Testing Dataset		
	`emb2com`	`emb2dif`
Pairs from the Same Topic	1,589	1,589
Pairs from Different Topics	1,591	1,591

procedure and one-phase training procedure, we use SFTTrainer with LoraConfig from peft package. We set the learning rate as 5e-5, batch size as 4, gradient accumulation steps as 8, max grad norm as 1, and max sequence length as 2,048. On the other hand, we set r as 16, lora alpha as 32, lora dropout as 0.05, and bias as none. We only optimze q_proj and k_proj in M_{base} and set $\mathcal{A}$ as the module to save. We train the adapter as well as LoRA parameters using AdamW optimizer (default parameters), linear scheduler with a warmup phase, mixed precision (i.e., bfloat16) for one or two epoch(s).

We train the model with the above settings on one Nvidia H100 GPU. The training time for `ctELM` on 1.2M data using one-phase training procedure for one epoch (1P-1E) takes around 13 hours. On the other hand, the training time for `ctELM` on 1.2M data using two-phase training procedure for one epoch (2P-1E) takes around 26 hours.

Table 7: G-Eval consistency and fluency for the best-performing baseline and our model.

Model	Consistency	Fluency
Vec2Text-sect-ft	0.26±0.08	0.29±0.12
ctELM (1.2M, 5-task, 1P-1E)	**0.34±0.12**	**0.92±0.08**

D Consistency and Fluency

We measure *consistency* and *fluency* quantitatively with G-Eval (Liu et al., 2023), using the open-source DeepEval framework.[2] To define metrics, the framework requires 'criteria' and 'evaluation steps,' which we provide for consistency and fluency in Figures 10 and 11, respectively.

Table 7 shows G-Eval scores for the best-performing baseline and the `ctELM` 5-task 1P-1E model. Though consistency of both models can be improved, we find that `ctELM` has 31% higher consistency and 317% higher fluency.

To further investigate these scores, we manually review 25 outputs from Vec2Text-sect-ft and `ctELM` for errors in consistency and fluency. We analyze these qualitatively by extracting common themes and finding representative examples, as shown in Table 8.

E Automatic Plausibility Analysis

To measure plausibility of generated clinical trial abstracts under more conditions than feasible with human experts, we develop an LLM-based win rate experiment to mirror the expert version in §5.1.

E.1 Methods

As the discriminator agent, we employ `gpt-4o-2024-11-20` with the prompt shown in Fig. 12. Though an LLM discriminator may be subject to systematic self-preference (Panickssery et al., 2024), using a different model to judge than to generate may ameliorate this problem (Xu et al., 2024). To avoid the known phenomenon of positional bias in LLMS (Gu et al., 2024), we randomize whether the real abstract is first or second. Further, each win rate for each system is computed 5 times with different random seeds to ensure aggregation over different orderings of each pair.

Additionally, many clinical trial abstracts (real and generated) contain clinical trial registry identi-

[2] `https://github.com/confident-ai/deepeval`

Consistency

Criteria: "Determine whether the actual output describes the same clinical trial as the input."

Evaluation steps:

- "Check whether the medical condition in 'actual output' reflects that of 'input'."
- "Check whether the study design (e.g., randomized controlled trial, observational study) in 'actual output' reflects that of 'input'."
- "Check whether the intervention (e.g., drug, therapy) in 'actual output' reflects that of 'input'."
- "Check whether the population (e.g., age group, sex, health status) in 'actual output' reflects that of 'input'."

Figure 10: Prompts to evaluate *consistency* using G-Eval via the DeepEval framework.

Fluency

Criteria: "Determine the quality of the 'actual output' in terms of grammar, spelling, punctuation, word choice, and sentence structure."

Evaluation steps:

- "Check whether 'actual output' follows standard grammar rules"
- "Check whether 'actual output' is free of spelling and punctuation errors"
- "Check whether 'actual output' uses appropriate word choice"
- "Check whether 'actual output' has a coherent sentence structure"

Figure 11: Prompts to evaluate *fluency* using G-Eval via the DeepEval framework.

Table 8: Common types of Consistency and Fluency errors.

Consistency		
Model	**Error type**	**Examples**
ctELM	Imprecision of drugs	"Tropisetron" → "Granisetron" (both 5-HT3 antagonists used as antiemetics)
		"Telithromycin" → "Clarithromycin" (both antibiotics used to treat pneumonia)
	Incorrect patient counts	"463 patients" → "1,000 patients"
		"176 eyes of 152 patients" → "100 eyes from 50 patients"
	Simplification of multi-arm studies	Removing a third "minimal contact CB bibliotherapy" group from a study that also included (1) a 6-session Cognitive Behavioral (CB) group and (2) a control group that just got educational brochures.
Vec2Text-sect-ft	Dropping important words	"daily interruption of sedation" → "daily sedation"
	Dropping of statistical results	
	Jumbling of words and roots	"Acupuncture and needle contact were superior to control in reducing the muscle hypertonicity of all muscles except SCM"→"Muscle contact and hypertouch were superior to needle contact in reducing sclerotherapy"
	Numerical imprecision	"age=15.5 years, SD=1.2" → "mean age, 22.5+/-2.5 years"
	Hallucination of nonsensical, irrelevant phrases	"resected apnea"
		"pharmacokinetics of nisoplaban"
		"after initial cigarette-dosing"
		"a single dose of myosinophils (Meltz, n=30)"
		"cumulative femur relapse"
Fluency		
Model	**Error type**	**Examples**
ctELM	Spacing errors	"Patients'satisfaction"
	Punctuation errors	"p<001" (should have a decimal point)
Vec2Text-sect-ft	Incoherent acronyms	"low-grade tuberculosis (LO)" "early hip osteoarthritis (EE)"
	Low-complexity stretches	"S-s-s-s-s-s-s-s-s-s-s"
		"100/100/100/100/100 ml"
		"a single dose of a single dose of a single dose [...]"
	Illogical phrases	"Vitamin D deficiency is a risk factor for developing sun exposure"
	Spelling errors	"acanemia"
	Punctuation errors	"P.05" (should have a "<")

```
Which of the following abstracts is
more likely to be a real abstract
describing a clinical trial? Return
only "1" or "2".

1. "{abstract1}"

2. "{abstract2}"
```

Figure 12: The discriminator agent prompt. Order of real and generated abstracts is randomized.

fiers. As identifiers may be memorized and associated with study details in the discriminator agent's model, we redacted any such identifiers from both real and generated abstracts. We crafted regular expressions to capture each format appearing in World Health Organization's International Clinical Trials Registry Platform[3] as of February 10, 2025 (Table 9) and replaced matches with "`[redacted]`".

E.2 Results

The LLM-based win rates of abstracts from interpolated embeddings and from embeddings moved along CAVs are shown in Table 10. First, we note the overall similarity in the automatic results to human results for the conditions tested by both. Specifically, Vec2Text-sect-ft (with original embeddings) achieves a win rate of 0.02 vs. experts and 0.01 vs. the LLM, whereas `ctELM` based on `Llama-3.1-8B-Instruct` (with interpolated embeddings) achieves a win rate of 0.44 vs. experts and 0.40 vs. the LLM. LLM-based win rates are in fact slightly lower than their human counterparts, meaning they were better able to discriminate. This suggests the LLM discriminator agent is reliable enough to provide useful results for other conditions.

Second, we note that using novel embeddings has little on affect plausibility of abstracts generated by `ctELM`. For `Llama-3.1-8B-Instruct`, interpolated embeddings and those produced using age CAVs in fact have slightly higher win rates than for original embeddings. Though there are drops for interpolated vs. original embeddings for Gemma 3 models, their inter-quartile ranges still overlap. These results further suggests that `ctELM` has learned not only to create fluent text descriptions of existing clinical trials, but has learned a manifold of plausible clinical trials.

Finally, we note that win rates are lower for Gemma 3 models. This is not unexpected, given their lower Semantic Consistency. It is also in line with expectations that the large 4B parameter model performs better than the 1B parameter model. However, we see no benefit here of the continued domain-based pretraining and fine-tuning of `medgemma-4b-it`, which is suprising. It is possible that the narrow focus of this models additional training tasks (mostly multiple choice questions) affected their general language modeling or instruction following capabilities without benefiting this particular biomedical task.

F Data Collection for Sex Concept Activation Vector

To identify a symmetric axis of cohort sex, we collected clinical trials describing interventions that *could* apply to both sexes, but that happened to only include one sex in the study cohort. We thus searched PubMed for randomized controlled trials with only one of the MeSH terms 'Male' and 'Female,' and excluding studies with MeSH terms related to sex-specific conditions (such as prostate cancer) or procedures (such as hysterectomy). We further required one of four gendered nouns ('men,' 'women,' 'boys,' 'girls') to appearing in the 'Title/Abstract field' to filter out studies with single-sex MeSH terms but no mention of cohort sex in abstracts. The complete PubMed search strings are provided in Figs. 14 and 15. Search results were sorted using the 'Best Match' option, and, for each sex, the first 25 were collected that satisfied two manually verified criteria: (1) cohort sex was mentioned in the abstract (not just the title), and (2) there were no implied participants of the opposite sex, for example, "Study participants: 50 adults (23 women; 46%)." We then augmented the data to ensure semantically symmetrical pairs by using `gpt-4o-2024-11-20` (depicted as 'Augmentation agent' in Fig. 13) to reverse the sex of study participants in these initial 50 abstracts, using the prompt in Fig. 16. This created a total of 100 abstracts describing clinical trials: 25 real male, 25 real female, 25 synthetic male, and 25 synthetic female. All synthetic samples were manually reviewed for successful change of cohort sex and consistency of other study details.

G Data Collection for Age Concept Activation Vector

Similarly to the sex Concept Activation Vector, we collected clinical trials describing interventions that *could* apply to both children and aged subjects, but that happened to only include one of these groups in the trial. We thus searched PubMed for randomized controlled trials with only one of the top-level MeSH age groups 'Child' (defined in MeSH as ages 6-12) and 'Aged' (defined as age 65 and above), further excluding the other top-level groups ('Infant', 'Child, Preschool', 'Adolescent', 'Adult', and 'Middle Aged'). To find studies applicable across ages, we also excluded age-specific study elements, such as 'Schools' for child studies or 'Dementia' for aged studies. The complete PubMed search strings are provided in Figs. 17 and 18. Again, search results were sorted using the 'Best Match' option, and, for each age group, the first 25 were collected that satisfied two manually verified criteria: (1) subject age was mentioned in the abstract, and (2) there were no implied participants of other ages. We again augmented the data to ensure semantically symmetrical pairs by using `gpt-4o-2024-11-20` to reverse the age of study participants in these initial 50 abstracts, using the prompt in Fig. 19. This created a total of 100 ab-

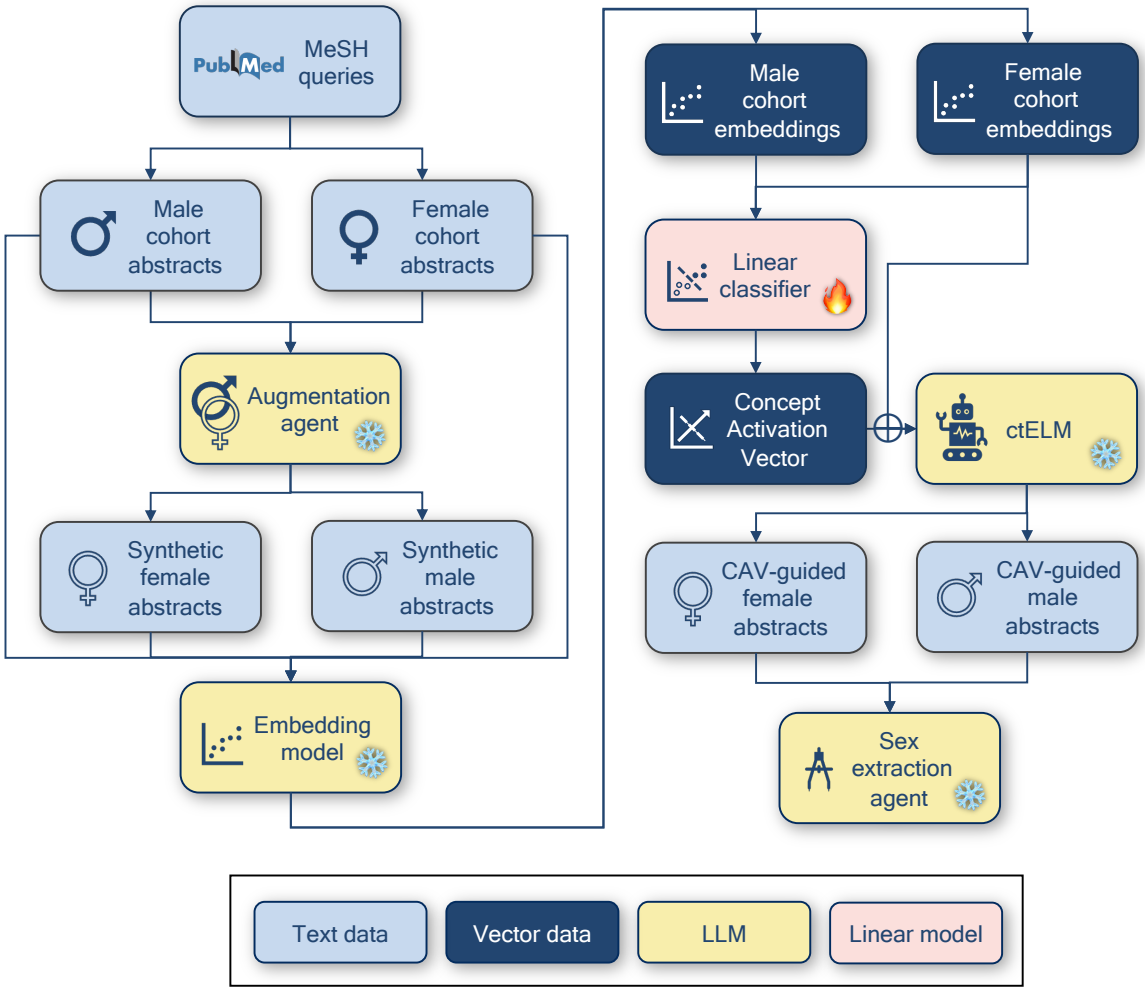

Figure 13: The workflow for modifying clinical trial embeddings with Concept Activation Vectors, including data collection, augmentation, linear model training, generation from modified embeddings, and evaluation. Depicted here is the sex CAV; the same workflow applies to age, except with child and aged instead of male and female.

stracts describing clinical trials: 25 real child, 25 real aged, 25 synthetic child, and 25 synthetic aged. All synthetic samples were manually reviewed for successful change of subject age and consistency of other study details.

H Extraction of Subject Demographics

To evaluate responsiveness of `ctELM` to CAVs, we employed an extraction agent comprising `gpt-4o-2024-11-20` with the system messages depicted in Figures 20 and 21 for sex and age, respectively. For both, the user prompt template was "Now process the following abstract: {abstract}".

I Generated Examples of Interpolated Embedding

To illustrate the generative capabilities of `ctELM` on interpolated embeddings, we present three examples of generated texts (background, objective, and result) derived from the average of two distinct abstract embeddings. As shown in Fig. 22, Fig. 23, and Fig. 24, `ctELM` successfully synthesizes semantically coherent sentences that reflect thematic overlaps between the paired source abstracts. This demonstrates the model's capacity to interpolate meaningfully between known research areas. Importantly, this capability suggests a promising avenue for exploratory scientific hypothesis generation. For instance, by sampling embeddings from underrepresented or "empty" regions of the semantic space (i.e., areas not directly covered by existing

Figure 19: The prompt template for symmetric augmentation of abstracts for the age Concept Activation Vector.

```
You are a biomedical natural language processing assistant. Given the abstract
of a clinical trial study, your task is to identify the gender of the study
population.

Your output must be in the following JSON format:
{
  "gender": "female"  // or "male" or "neutral"
}

Guidelines:
- If the abstract mentions that the study participants are women or females,
output "female".
- If the abstract mentions men or males, output "male".
- If the abstract only mentions the number of participants without specifying
gender, output "neutral".
- If both male and female participants are mentioned and the study includes
both, still output "neutral".
- Do not infer gender based on disease or context. Only use explicit statements.
```

Figure 20: The subject sex extraction agent system message.

```
You are a biomedical natural language processing assistant. Given the abstract
of a clinical trial study, your task is to extract or infer the average age (in
years) of the study population.

Your output must be in the following JSON format:
{
  "age": 54.3  // numerical value only
}

Guidelines:
1. If the study mentions the **mean or average age**, extract and return that
value.
2. If the study mentions an **age range** (e.g., "30 to 50 years"), compute the
average (e.g., (30+50)/2 = 40.0) and return that value.
3. If no explicit age value is mentioned, infer the most likely average age
based on population group terms in the text, using this mapping:

- "Child, Preschool": 2-5 years  -> 3.5
- "Child": 6-12 years  -> 9
- "Adolescent": 13-18 years  -> 15.5
- "Adult": 19-44 years  -> 31.5
- "Middle Aged": 45-64 years  -> 54.5
- "Aged": 65+ years  -> 75
- "Aged, 80 and over": 80+ years  -> 85
- "Octogenarians": 80-89 years  -> 84.5
- "Nonagenarians": 90-99 years  -> 94.5
- "Centenarians": 100+ years  -> 100

Choose the most appropriate inferred value if only a population label is
present.

Only include the JSON output. Do not explain or add commentary.
```

Figure 21: The subject age extraction agent system message.

Example 1: Generated Background of Interpolated Embedding

Generated Background Section of Interpolated Embedding between PMID=24099432 and PMID=17064200: "This paper presents baseline data from a randomized clinical trial examining the effectiveness of a *cognitive behavioral intervention (CBI)* for improving medication adherence and depression outcomes among *patients with poorly controlled hypertension*."

Partial Abstract for PMID=24099432 (Cognitive Behavioral Therapy, Depressive disorder): "[Objective] We tested whether a brief cognitive behavioral (CB) group and bibliotherapy prevention reduce major depressive disorder (MDD) onset, depressive symptoms, and secondary outcomes relative to brochure controls in adolescents with self-reported depressive symptoms when school personnel recruit participants and deliver the intervention. ... [Results] The finding that a brief CB group intervention delivered by real-world providers significantly reduced MDD onset relative to both brochure control and bibliotherapy is very encouraging, although effects on continuous outcome measures were small or nonsignificant and approximately half the magnitude of those found in efficacy research, potentially because the present sample reported lower initial depression."

Partial Abstract for PMID=17064200 (Hypertension): "[Objective] To examine potential threats to internal and external study validity caused by differential patient withdrawal from a randomized controlled trial evaluating pharmacist management of hypertension, to compare the characteristics of patients who withdrew with those of patients who completed the study, and to identify characteristics that predispose patients to withdraw from hypertension management. ... [Results] Therefore, internal validity was preserved, and outcomes from the study groups could be reliably compared. A lack of significant differences between patients who withdrew versus those who completed, with the exception of insurance status, suggests that external validity was not jeopardized."

Figure 22: Example of generated background from interpolated embedding between two clinical trials. The generated text reflects a synthesis of themes related to cognitive behavioral therapy and hypertension.

Example 2: Generated Objective Section of Interpolated Embedding

Generated Objective of Interpolated Embedding between PMID=15914575 and PMID=9777179: "A study was conducted to determine if irritable bowel syndrome (IBS) patients with depressive symptoms have a better response to a selective serotonin reuptake inhibitor (SSRI) than those without depressive symptoms."

Partial Abstract for PMID=15914575 (Irritable bowel syndrome): "[Background] Melatonin, a sleep promoting agent, is involved in the regulation of gastrointestinal motility and sensation. [Objective] We aimed to determine if melatonin was effective in improving bowel symptoms and sleep disturbances in irritable bowel syndrome (IBS) patients with sleep disturbance. ... [Results] The findings suggest that the beneficial effects of melatonin on abdominal pain in IBS patients with sleep disturbances are independent of its action on sleep disturbances or psychological profiles."

Partial Abstract for PMID=9777179 (Chronic mental illness): "[Objective] We sought to identify baseline predictors of response to clozapine. Data were from a 15-site randomized clinical trial comparing clozapine and haloperidol in hospitalized patients with refractory schizophrenia (n = 423). Three-month outcomes were analyzed with the full sample (n=368 due to attrition). ... [Results] Although high levels of symptoms were associated with greater improvement on clozapine, these findings are not robust enough to suggest that any specific, clinically defined subgroup of refractory patients should be preferentially targeted for clozapine treatment."

Figure 23: Generated objective from the interpolation of abstract embeddings concerning irritable bowel syndrome and chronic mental illness. The output proposes a novel trial scenario integrating elements of both parent studies.

Example 3: Generated Results Section of Interpolated Embedding

Generated Result of Interpolated Embedding between PMID=15166570 and PMID=12860586: "The results of this study demonstrate that patients with functional constipation have a better outcome after treatment with a single dose of subcutaneous diamorphine than after treatment with a single dose of subcutaneous hyoscine butylbromide."

Partial Abstract for PMID=15166570 (Opioids, Morphine, Urinary tract dysfunction): "[Background] Intrathecal administration of opioids may cause lower urinary tract dysfunction. In this study, the authors compared the effects of morphine and sufentanil administered intrathecally in a randomized double-blind fashion (two doses each) on lower urinary tract function in healthy male volunteers. ... [Conclusion] Intrathecal opioids decrease bladder function by causing dose-dependent suppression of detrusor contractility and decreased sensation of urge. Recovery of normal lower urinary tract function is significantly faster after intrathecal sufentanil than after morphine, and the recovery time is clearly dose dependent."

Partial Abstract for PMID=12860586 (Dyspepsia): "[Background] The value of the test-and-treat strategy in the approach to dyspepsia has been evaluated only in a few secondary care studies. Most patients with dyspepsia, however, are treated by their primary care physician ... [Conclusion] The test-and-treat strategy proved to be as effective and safe as prompt endoscopy. Only a minority of patients were referred for endoscopy after the test-and-treat approach."

Figure 24: Example of a generated result sentence from interpolated embeddings of abstracts on opioids and dyspepsia. The output blends insights into drug response and gastrointestinal outcomes, demonstrating semantic consistency across domains.

Uncertainty-Aware Multi-Label Routing of Clinical Text to Surveillance Pathways

Abstract

Clinical decision support systems that operate across multiple downstream care pathways must first determine which pathway or pathways are relevant for a given patient. We study this routing problem in gastrointestinal surveillance, where paired endoscopy and histopathology text reports may indicate multiple concurrent conditions and therefore require multi-label routing. In this context, standard hard-label evaluation can be insufficient: a model may achieve reasonable overall performance while still excluding clinically important pathways when uncertain.

We formulate gastrointestinal report routing as a multi-label uncertainty-aware classification task over six pathway labels and compare lightweight lexical baselines, frozen embedding models and a fine-tuned transformer baseline under two complementary uncertainty mechanisms: threshold-based abstention and set-valued conformal prediction. Using 1,773 paired reports from a single NHS trust with disjoint train, calibration and test splits, we evaluate both hard-routing performance and the downstream review burden introduced by uncertainty-aware prediction.

The fine-tuned ClinicalBERT model achieved the strongest overall performance (0.811 subset accuracy, 0.861 macro-F1) and the lowest AURC of 0.084 under min-margin abstention. Threshold-based abstention consistently reduced exact-match routing error on accepted reports. For conformal routing at $\alpha = 0.10$, Mondrian calibration achieved high mean positive-label recall coverage across learned baselines (0.883-0.917). The fine-tuned model achieved 0.891 mean recall coverage with a mean prediction set size of 1.70, 0.642 candidate-label precision and 0.61 false-positive labels per report. Compared with a recall-tuned threshold baseline at similar recall, Mondrian CP produced smaller candidate sets, higher candidate-label precision and fewer false-positive pathway suggestions.

These results show that uncertainty-aware evaluation exposes clinically important failure modes missed by aggregate metrics. They also show that high-recall routing is not cost-free: set-valued prediction can reduce missed-pathway risk but must be interpreted as candidate generation for downstream review rather than automated pathway selection.

1 Introduction

Text-based clinical decision support systems use information recorded in free-text clinical documents to assist with screening, surveillance, triage and follow-up decisions (Sutton et al., 2020). In cases where a single system supports multiple possible downstream actions, an initial routing step is often required to determine which clinical pathway or pathways are relevant for a given patient. We refer to this as the task of *routing clinical text to clinical pathways*.

This task exposes an evaluation gap between NLP-in-the-lab and NLP-in-deployment. Standard multi-label models are typically assessed using aggregate point-prediction metrics such as accuracy or F1-score. However, point prediction alone can be insufficient in health-related use-cases: a model may achieve reasonable overall performance while still excluding a clinically important pathway on the cases where it is most uncertain. A hard routing decision returns a fixed label set, whereas a set-valued prediction can instead return a small candidate set of plausible pathways. An abstaining system can defer highly uncertain cases for manual review. These mechanisms address a question that aggregate point-prediction metrics do not fully capture: not only *what* the model predicts on average, but also *how reliably* it behaves when uncertainty is clinically important. This motivates uncertainty-aware evaluation frameworks for clinical NLP, particularly for multi-label tasks in which several pathways may be simultaneously relevant.

We study this problem in gastrointestinal (GI) surveillance. Clinical decision support systems for GI surveillance (Zecevic et al., 2024; Peterson et al., 2021; Song et al., 2022) increasingly target individual conditions and ground themselves in national guidance such as Barrett's oesophagus, colorectal polyps (Fitzgerald et al., 2014; Rutter et al., 2020), or gastric atrophy (Banks et al., 2019). These conditions are clinically important because they are associated with increased risk of disease progression or gastrointestinal malignancy and therefore require pathway-specific follow-up. Decisions often depend on combining information from endoscopy reports describing macroscopic procedure findings, with histopathology reports providing microscopic confirmation from biopsies taken at procedure time. In practice, a single endoscopy-histopathology report pair can indicate multiple concurrent conditions. For instance, incidental colorectal polyps can be discovered during IBD surveillance, making routing inherently a multi-label problem. Misrouting carries significant clinical consequences: a Barrett's patient erroneously sent to the *Normal* pathway may miss surveillance intervals, whereas routing an incomplete or abandoned procedure to an inappropriate Gastric Atrophy pathway wastes downstream resources (Codipilly et al., 2018; White and Banks, 2022).

We therefore formulate GI report routing as a multi-label classification task with two complementary uncertainty-handling mechanisms. First, we study *abstention*, where the model defers cases that are too uncertain for automated routing. Second, we study *set-valued conformal prediction*, where the model returns a small candidate set of pathways designed to better retain clinically relevant labels under uncertainty. We make three contributions:

- We formulate GI surveillance pathway routing from paired endoscopy-histopathology reports as a multi-label uncertainty-aware classification problem.
- We show that threshold-based abstention substantially reduces exact-match routing error on accepted cases across lightweight and transformer-based baselines.
- We show that positive-only Mondrian conformal calibration provides a high-recall candidate-generation layer for clinically important pathways, while explicitly quantifying the associated false-positive review burden.

2 Related Work

Clinical text routing and triage. Prior work on clinical text routing and triage spans several adjacent settings. NLP has been used in referral workflows to predict target speciality from referral notes and triage referrals (Spasic and Button, 2020). Free-text triage has also been widely studied in emergency care (Stewart et al., 2023). However, these studies generally route a single text stream toward one operational endpoint rather than assigning paired reports to potentially multiple concurrent pathways.

Selective prediction in NLP. Selective prediction adds an abstention layer to traditional classifiers, producing risk-coverage trade-offs (El-Yaniv and Wiener, 2010). Wen et al. (2025) survey selective prediction in the context of LLMs, summarising common approaches such as threshold-based and learned selection functions. Fisch et al. (2022) address multi-label settings with conformal guarantees that limit false-positive predictions, which is critical for domains like healthcare.

Conformal prediction. Split conformal prediction provides distribution-free marginal coverage guarantees by calibrating nonconformity scores on a held-out set (Vladimir Vovk, 2005; Angelopoulos and Bates, 2022). The Mondrian extension refines this idea by yielding label-conditional guarantees that are especially relevant under class imbalance or asymmetric misrouting costs. Campos et al. (2024) survey conformal prediction for NLP, including both marginal and class-conditional variants. In clinical applications, conformal methods have recently been explored for medical multiple-choice question answering (Ke et al., 2025), medical text mining for epidemiological surveillance (Genari and Goedert, 2025), multi-label ICD coding from clinical narratives (Zhang et al., 2025a) and medical entity extraction from radiology text (Shrestha and Kim, 2026).

This study is distinct from our prior Barrett's oesophagus decision-support work, which focused on condition-specific surveillance scheduling. This work studies the upstream multi-label routing problem across six GI pathways using a newly annotated routing dataset.

3 Methods

3.1 Task Formulation

Given a merged endoscopy-histopathology report x, we predict a label set $\hat{Y} \subseteq \mathcal{L}$

where $\mathcal{L} = \{$*Normal*, *Barrett's*, *Colorectal Polyps*, *Gastric Atrophy*, *Other*, *Incomplete*$\}$. A selective predictor (f, g) consists of a base classifier f and a selection function $g : \mathcal{X} \to \{0, 1\}$ that determines whether to accept ($g(x) = 1$) or abstain ($g(x) = 0$). We decompose routing into six independent binary decisions, one per label, with associated probability scores $f_j(x) \in [0, 1]$. We evaluate via risk-coverage curves: *selective risk*, which is defined as the error rate on accepted instances versus *coverage*, defined as the fraction of instances accepted. For the point-prediction baselines, each label j is predicted positive when $f_j(x) \geq 0.5$.

Label logic. Gold labels are multi-label, but not all label combinations are clinically coherent. In our case, the label *Normal* denotes the absence of any pathway-relevant clinical finding and therefore does not co-occur with any other label in the annotated datasets.

3.2 Baselines

We compare four clinical pathway routing baselines with increased computational complexity.

B0: Keyword baseline This pipeline consists of regex patterns for each class matched against the merged report text. We incorporate negation cues (such as "no evidence of", "history of", "to rule out") to improve baseline performance. We derive heuristic scores for each label as the number of matched patterns divided by the total number of patterns defined for that label.

B1: TF-IDF + Logistic Regression. We split each report into affirmed and negated text spans using the same negation cues as B0 and fit separate TF-IDF vectorisers to each channel. For each label, the regularisation strength $C \in \{0.01, 0.1, 1.0, 10.0\}$ was selected by 3-fold cross-validation on the training split only, using macro-F1 as the selection criterion. Per-label probability calibration was performed on the training split only via Platt scaling with stratified K-fold cross-validation (K = 3). The positive and negative channels use feature budgets of 10,000 and 5,000 features respectively and are concatenated into a 15,000-dimensional representation. Both vectorisers use n-grams of order 1-2.

B2: Frozen BGE-Large embeddings + Linear head. The frozen-embedding baseline extracts fixed representations from BGE-Large-EN-v1.5, a text encoder pre-trained with contrastive learning (Xiao et al., 2024). Each report is tokenised to a maximum of 512 subword tokens and encoded with the fixed model weights. A masked mean pool over the last hidden states of non-padding tokens produces a single 1024-dimensional vector per report. A separate one-vs-rest logistic regression classifier is then fitted per label on these frozen embeddings.

B3: Fine-tuned ClinicalBERT. We fine-tune ClinicalBERT (Alsentzer et al., 2019) for multi-label classification by adding a linear classification head on top of a masked mean-pool representation of the encoder's last hidden state. The head produces six independent logits, trained with binary cross-entropy. We optimise with AdamW (weight decay 0.01) using a linear warmup over the first 10% of training steps followed by linear decay to zero. Gradients are clipped to a maximum norm of 1.0. Learning rate and number of epochs are selected jointly by grid search over $10^{-5}, 2 \times 10^{-5}, 5 \times 10^{-5}$ and up to 15 epochs, evaluated by macro F1 on a 15% hold-out subset of the training split kept strictly separate from the calibration data.

For each baseline, we compute results at a uniform threshold of 0.5 and at per-label thresholds selected on the calibration set to achieve at least 90% recall for each label independently.

3.3 Selective Prediction

Threshold abstention. We use a *min-margin* selection function: accept report x if

$$g_\tau(x) = \min_j \max\big(f_j(x),\, 1 - f_j(x)\big) \;\geq\; \tau, \quad (1)$$

where $\tau \in [0.5, 1]$. This score equals the confidence of the least certain label: it falls to 0.5 whenever any label score is close to the decision boundary, so a report is abstained as soon as any single label is uncertain. This aligns the selection function directly with exact-match risk, which fails whenever any label is wrong. By contrast, max-confidence ($\max_j f_j$) can accept a case with one highly confident label while several others remain uncertain, which is an undesirable behaviour in our setting. We vary τ to generate risk-coverage curves and report the Area Under the Risk-Coverage curve (AURC) (Geifman et al., 2019), where a lower AURC indicates better selective classification.

3.4 Conformal Prediction

Conformal prediction (Vladimir Vovk, 2005) is a distribution-free framework for constructing prediction sets with finite-sample coverage guarantees, requiring only data exchangeability. We apply it

independently per label j and evaluate whether the returned candidate set retains truly present labels. For each label, the main quantity of interest is the fraction of positive test examples for which label j is included in the prediction set. We report this as per-label recall coverage:

$$P\big(j \in \mathcal{C}(x) \mid Y_j = 1\big) \;\geq\; 1 - \alpha, \qquad (2)$$

where $\mathcal{C}(x) \subseteq \mathcal{L}$ is the prediction set returned for report x. We report empirical positive-class inclusion as the fraction of positive test examples for which label *j* is included in the prediction set, we do not make any joint coverage claim across labels or across the full multi-label set.

Split conformal prediction. We apply split conformal prediction independently per label j, using the LAC (Least Ambiguous Classifier) nonconformity score as implemented in MAPIE (Taquet et al., 2022):

$$s_j(x, y_j) = 1 - f(x)_{j,y_j}, \qquad (3)$$

where $f(x)_{j,y_j}$ is the model's predicted probability for the *true* class $y_j \in \{0, 1\}$ of label j. For each label j, we set the calibration threshold $\hat{q}_j$ to the $\lceil (n_j + 1)(1 - \alpha) \rceil / n_j$ empirical quantile of the calibration scores $\{s_j(x_i, y_{j,i})\}_{i=1}^{n_j}$, computed either over all calibration examples (marginal calibration) or over the positive calibration examples only (Mondrian calibration). Label j is included in the prediction set if

$$f_j(x) \geq 1 - \hat{q}_j, \qquad (4)$$

that is, if the model assigns sufficiently high probability to the positive class.

Marginal versus Mondrian calibration. Under *marginal* calibration, $\hat{q}_j$ is estimated from all calibration examples for label j, mixing positive and negative instances. This does not directly target the conditional quantity in Eq. (2); under class imbalance, it can therefore yield poor positive-class inclusion for rare labels. For a minority label such as GA in our case, most calibration examples are negative and the model typically assigns them small positive-class probabilities, which leads to calibration scores clustering near 0. In our experiments, this noticeably reduced GA inclusion under marginal calibration at $\alpha = 0.10$. This is mitigated in *Mondrian* calibration, where $\hat{q}_j$ is instead estimated only from the positive calibration examples for label j, matching the positive-class inclusion objective in Eq. (2).

Label	Train ($n = 789$)		Cal. ($n = 523$)		Test ($n = 461$)	
	n	%	*n*	%	*n*	%
Normal	77	9.8	53	10.1	45	9.8
Barr	185	23.4	65	12.4	50	10.8
CP	115	14.6	53	10.1	53	11.5
GA	63	8.0	30	5.7	42	9.1
Other	500	63.4	361	69.0	314	68.1
Incomplete	103	13.1	50	9.6	60	13.0
Multi-label (≥ 2)	249	31.6	89	17.0	101	21.9
Mean label cardinality	1.32		1.17		1.22	

Table 1: Per-label prevalence across datasets. *Multi-label* reports cases with two or more labels. *Mean label cardinality* is the average number of labels per report.

Abstention rule. We add a separate deployment heuristic on top of conformal prediction. A report is abstained when its prediction set size $|\mathcal{C}(x)| > K$, with $K = 3$. This size threshold is not part of the conformal guarantee but a pragmatic rule intended to defer highly ambiguous cases to manual review. We chose $K = 3$ a priori based on the observed degree of clinically plausible co-occurrence in the training and calibration sets. We evaluate at $\alpha \in \{0.05, 0.10, 0.15, 0.20\}$ and report per-label empirical recall coverage (Eq. (2)), mean prediction set size and abstention rate.

4 Experiments

4.1 Data

We use six months of anonymised paired endoscopy and histopathology reports from an NHS hospital trust, merged into single documents per procedure. Data acquisition was authorised through institutional board review (IRAS ID = 257283). We remove patients who had opted out of their data being used (NHS Data Opt-Out). We construct three non-overlapping splits: a training set ($n = 789$), a calibration set ($n = 523$) and a test set ($n = 461$). The training set only is enriched for the minority classes (Barr, GA, Incomplete), the calibration and test set are not enriched.

Reports were manually annotated by a clinical researcher using labels from $\mathcal{L}$. Ambiguous cases (for instance "history of Barrett's" with no active findings) were resolved via predefined annotation rules. Table 1 reports the label distribution across datasets and the average number of labels per merged report. More details about the annotation rules and label co-occurrence can be found in Appendix A.

4.2 Results

Baseline comparison. Table 2 compares the four routing baselines on exact-match subset accuracy,

Model	Subset Acc. [95% CI]	$F1_{macro}$ [95% CI]	$Precision_{macro}$ [95% CI]	AURC [95% CI]
Keyword	0.538 [0.492, 0.584]	0.705 [0.670, 0.737]	0.646 [0.612, 0.682]	0.3718 [0.3183, 0.4264]
TF-IDF	0.646 [0.605, 0.692]	0.782 [0.743, 0.817]	0.840 [0.799, 0.880]	0.1683 [0.1318, 0.2119]
Embedding	0.705 [0.666, 0.746]	0.776 [0.733, 0.814]	**0.898** [0.861, 0.932]	0.1338 [0.1026, 0.1663]
Fine-tuned	**0.811** [0.777, 0.846]	**0.861** [0.829, 0.891]	0.873 [0.837, 0.910]	**0.0836** [0.0578, 0.1127]

Table 2: Baseline comparison on point-prediction and selective prediction performance. Reported metrics are subset accuracy, macro F1, macro precision and area under the risk-coverage curve (AURC). 95% confidence intervals were computed by non-parametric bootstrap over test reports with 1,000 resamples.

macro F1, and AURC. TF-IDF is a competitive lightweight baseline, achieving 0.646 subset accuracy and 0.782 macro-F1. The frozen BGE-Large embedding model improves subset accuracy to 0.705 and exhibits the highest macro precision (0.898). The fine-tuned ClinicalBERT model performs best overall, reaching 0.811 subset accuracy, 0.861 macro-F1 and the lowest AURC (0.0836). Paired bootstrap comparisons in Appendix B support the improvement of the fine-tuned model over the other learned baselines.

Selective prediction. Figure 1 shows risk–coverage curves under min-margin abstention. All models show decreasing selective risk as coverage decreases. This indicates that the confidence score is informative about cases where hard routing is more reliable. The fine-tuned model has the lowest AURC (0.084), followed by the frozen embedding model (0.134) and TF-IDF (0.168). The keyword baseline remains substantially weaker both at full coverage and under abstention, which can be explained by how its confidence scores are computed.

Conformal prediction. Table 3 summarises Mondrian conformal routing at $\alpha = 0.10$ for the learned baselines. Mean recall coverage remains high across models, ranging from 0.883 for the frozen embedding model to 0.917 for TF-IDF. The operational burden differs across baselines. The fine-tuned model provides the best trade-off, with the highest set precision (0.642), the smallest mean set size (1.70), the lowest false-positive burden (0.61 FP labels/report) and no abstentions under the $K = 3$ rule. These results show why recall coverage alone is insufficient: high-recall conformal routing must be interpreted together with set precision and false-positive pathway burden.

Figure 2 shows the conformal operating trade-off. At the set level (Panel A), we show that decreasing α increases mean recall coverage but reduces candidate-label precision. The learned models follow similar trade-off curves, with the fine-tuned model providing the best operating point at $\alpha = 0.10$ in Table 3. Panel B uses GA to illustrate the clinical cost of high-recall routing: Mondrian CP substantially increases GA recall relative to the hard classifier but with a marked reduction in precision.

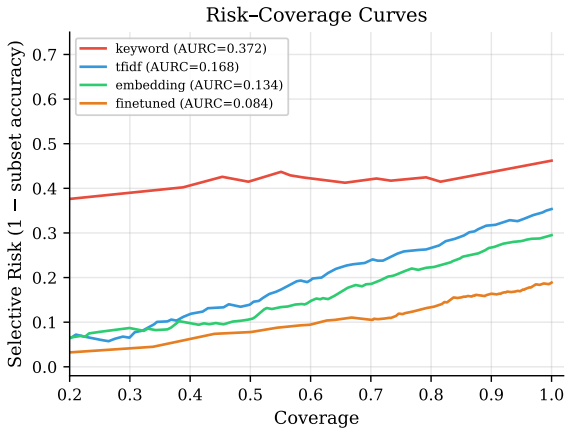

Figure 1: Selective risk-coverage curves under min-margin abstention. The low-coverage region (<0.2) is omitted as estimates become unstable with few accepted examples. AURC is computed over the full coverage range.

Model	Recall cov. ↑	Set prec. ↑	Mean set ↓	FP/report ↓	Abstain % ↓
TF-IDF	**0.917**	0.589	1.89	0.77	1.3
Embedding	0.883	0.607	1.79	0.70	1.1
Fine-tuned	0.891	**0.642**	**1.70**	**0.61**	**0.0**

Table 3: Operational summary of Mondrian conformal routing at $\alpha = 0.10$. Recall cov. is mean per-label positive-class inclusion coverage over test positives. Set precision is the candidate-label precision, defined as $\sum_i |\mathcal{C}_i \cap Y_i| / \sum_i |\mathcal{C}_i|$. FP/report is the average number of false-positive pathway labels included per report.

Per-class analysis. Table 4 compares hard prediction, a recall-tuned threshold baseline, marginal CP and Mondrian CP for the fine-tuned model at $\alpha = 0.10$. The recall-tuned threshold baseline achieves high mean recall (0.895), but candidate-label precision falls to 0.540, mean set size increases to 2.03 and the false-positive burden rises to 0.93 labels/report. Mondrian CP achieves a similar mean recall (0.891) with higher candidate-label precision (0.642), smaller sets (1.70) and fewer false-positive labels per report (0.61).

The GA row shows the main minority-label trade-off. Hard prediction has relatively high GA precision (0.80) but lower recall (0.67). Mondrian

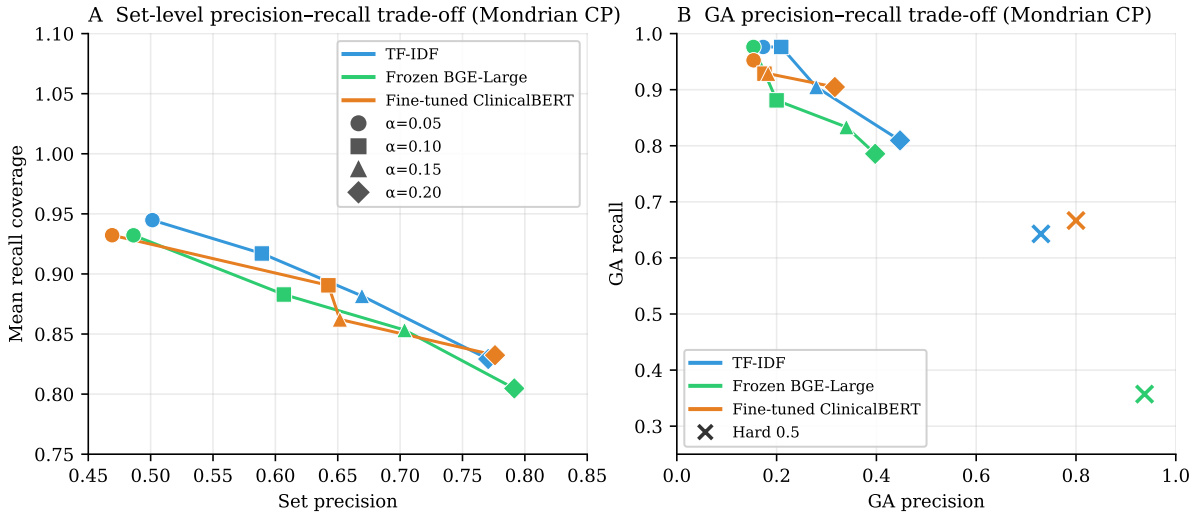

Figure 2: Precision-recall trade-offs for Mondrian conformal routing. **A:** Set-level trade-off across $\alpha \in \{0.05, 0.10, 0.15, 0.20\}$ for the learned baselines, where precision is candidate-label precision and recall is mean per-label positive-class recall coverage. **B:** GA-specific precision–recall trade-off under Mondrian CP. The hard 0.5-threshold classifiers are shown as reference points.

CP increases GA recall to 0.93, but GA precision falls to 0.18, indicating that the conformal layer acts as a high-recall safety net rather than a final automatic GA decision. Marginal CP under-recovers positives for several labels. These results support interpreting conformal routing as candidate generation for downstream review.

5 Discussion and Conclusion

We evaluated a range of routing baselines with different computational requirements, motivated by the practical constraint that not all hospitals can deploy the same class of model. Even relatively lightweight approaches such as TF-IDF achieved reasonable overall performance on our annotated dataset. We highlight the fact that standard point-prediction metrics alone are not sufficient for this task as they do not characterise the risk of excluding clinically relevant pathways from a set-valued prediction. Some misclassifications have important clinical consequences, particularly false negatives on pathways where missing the correct route could prevent the relevant surveillance logic from being applied at all.

This motivated two separate uncertainty-handling strategies at inference time. First, we studied threshold-based abstention to reduce hard-routing errors on accepted cases. Second, we studied conformal set prediction to reduce the risk that clinically important pathways are excluded from the returned candidate set. Recall on clinically important pathways is more crucial than forcing a single-label decision in every case. Returning a small set of plausible pathways may be preferable to excluding the true one, because an irrelevant downstream pathway may simply yield no action, whereas omission of the correct pathway risks missing the appropriate follow-up entirely.

Our results support three conclusions. First, threshold-based abstention reduces exact-match routing error on accepted cases, with the strongest selective performance obtained by the fine-tuned model. Second, set-valued conformal prediction changes the evaluation question from whether a single hard label set is correct to whether clinically important pathways are retained for review. Third, high-recall routing is not cost-free. While Mondrian CP can recover minority pathways such as GA, this comes at the cost of increasing false-positives and therefore downstream review burden.

This distinction is important for deployment. A conformal set should not be interpreted as a final diagnosis or automatic pathway activation. Instead, it is a candidate-generation layer: labels included in $\mathcal{C}(x)$ are pathways that should not be safely excluded without further pathway-specific logic or manual review. Under this interpretation, Mondrian CP provides a useful safety mechanism because it reduces missed-pathway risk while making the review burden explicit. The comparison with a recall-tuned threshold baseline further showed that in our case, Mondrian CP achieved a better recall-

Method	Overall operating point					Per-label recall / precision					
	Mean recall	Set precision	Mean set	FP/report	Abstain %	Normal	Barrett's	CP	GA	Other	Incomplete
Hard 0.5	0.852	0.903	1.20	0.12	—	0.91 / 0.84	0.78 / 0.87	0.96 / 0.89	0.67 / 0.80	0.92 / 0.93	0.87 / 0.91
Tuned on cal. (≥90% recall)	0.895	0.540	2.03	0.93	—	0.93 / 0.40	0.74 / 0.86	0.96 / 0.80	0.95 / 0.11	0.90 / 0.93	0.88 / 0.88
Marginal CP	0.726	0.894	1.15	0.12	0.0	0.80 / 0.88	0.54 / 0.84	0.85 / 1.00	0.43 / 1.00	0.96 / 0.87	0.78 / 0.96
Mondrian CP	0.891	0.642	1.70	0.61	0.0	0.91 / 0.44	0.74 / 0.86	0.96 / 0.80	0.93 / 0.18	0.90 / 0.93	0.90 / 0.89

Table 4: Operating-point and per-label performance for the fine-tuned model at $\alpha = 0.10$

burden trade-off than simple recall-thresholding for the fine-tuned model.

Limitations. Our study uses reports from a single NHS site, in English, with a six-class routing schema, labelled by a single annotator. One class (*Other*) is heavily represented as it is a deliberate catch-all for conditions outside the current surveillance scope (for instance IBD, strictures, malignancy). The calibration set remains small for the rarest classes. With few positive calibration examples per minority class, the Mondrian threshold $\hat{q}_j$ can only take a small number of distinct values, making coverage insensitive to small changes in α.

Future work. We plan to add a local LLM zero-shot/few-shot baseline expanding on already existing work for single conditions (Zhang et al., 2025b), extend the routing schema to additional clinical pathways currently labelled as *Other* and validate the system prospectively on several temporally distant test sets.

A Label Schema and Annotation Rules

Table 5 summarises the six routing categories used for manual annotation of the multi-label task.

Annotation principles. Non-gastrointestinal background conditions were ignored unless they directly changed the interpretation of the procedure. Minor incidental findings that do not typically define a surveillance pathway on their own such as hiatus hernia or inlet patch were not sufficient to trigger *Other* in isolation.

Label	Description
Normal	No abnormal clinical finding identified, procedure is normal
Barrett's	Active Barrett's oesophagus finding
CP	Colorectal polyp finding of any relevant subtype
GA	Gastric atrophy and/or gastric intestinal metaplasia
Other	Active non-target pathology outside the predefined surveillance pathways (for instance: stricture, ulcer, tumour, coeliac-related abnormality)
Incomplete	Incomplete, failed, or abandoned procedure requiring repeat assessment or rebooking

Table 5: Routing label schema used for manual annotation.

Operational rules for recurrent ambiguous cases. The following predefined rules were applied throughout annotation:

- Historical-only mentions were ignored for routing. For example, "history of Barrett's" without evidence of active Barrett's in the current report was not annotated as *Barr*.
- *Normal* was reserved for reports with no pathway-relevant clinical finding and therefore did not co-occur with other labels in the annotations.
- Gastric atrophy and gastric intestinal metaplasia were annotated as *GA*. Co-occurring gastritis alone did not trigger an additional *Other* label.
- Atrophy described outside the stomach was not annotated as *GA*.
- *Incomplete* was assigned for failed, abandoned or incomplete procedures and could co-occur with other active pathway labels when relevant findings were also present.
- *Other* captured active non-target abnormalities outside the predefined surveillance pathways.

B Significance tests

Table 6: Pairwise paired bootstrap significance tests ($n = 1{,}000$ resamples, two-tailed). $\Delta = \text{score}(A) - \text{score}(B)$. $^{*}p < 0.05$, $^{**}p < 0.01$

Model A	Model B	Δ Subset Acc $\uparrow$	Δ Macro F1 $\uparrow$	Δ AURC $\downarrow$
Keyword	TF-IDF	-0.108^{**}	-0.077^{**}	$+0.203^{**}$
Keyword	Embedding	-0.167^{**}	-0.071^{**}	$+0.238^{**}$
Keyword	Fine-tuned	-0.273^{**}	-0.156^{**}	$+0.288^{**}$
TF-IDF	Embedding	-0.059^{**}	$+0.006$	$+0.034^{*}$
TF-IDF	Fine-tuned	-0.165^{**}	-0.079^{**}	$+0.085^{**}$
Embedding	Fine-tuned	-0.106^{**}	-0.085^{**}	$+0.050^{**}$

MedCAT v2: a modular, extensible architecture for clinical named entity recognition and linking under real-world privacy and compute constraints

Abstract

MedCAT is an open-source framework for clinical named entity recognition and linking (NER+L) widely used in research and healthcare settings. We present MedCAT v2, a re-engineered version designed to improve modularity, extensibility, and maintainability while preserving the core functionality and performance of previous releases. The new architecture introduces a registry-based component system and a flexible pipeline that enables easy substitution of components, integration of alternative methods, and future expansion, including support for pre-trained components across the full NER+L and contextualisation workflow. This enables systematic exploration of clinical NER+L design trade-offs by evaluating different components in the pipeline. Evaluation across multiple public datasets shows equivalent or improved performance compared to earlier versions, with reduced integration overhead and improved runtime flexibility. The framework also supports optional extensions such as meta-annotation, relation extraction, providing a unified and reproducible environment for clinical NLP in real-world settings.

1 Introduction

Clinical free text (e.g., clinic letters, radiology reports, pathology notes, and discharge summaries) contains a substantial proportion of clinically relevant information that is not captured in structured electronic health records (EHR), limiting its secondary use for research, quality improvement, and decision support (Capurro et al., 2014; Kharrazi et al., 2018; Seinen et al., 2025). Advances in clinical natural language processing (NLP) now enable large-scale extraction of biomedical concepts from such data (Elvas et al., 2025). However, deploying such methods in routine clinical and research workflows introduces additional practical constraints: deployments often must run on-premises due to governance and privacy requirements (Van Bulck et al., 2024), may lack GPU-accelerated infrastructure (Wu et al., 2022), and require systems that can be maintained and adapted without substantial engineering overhead (Liu et al., 2025).

MedCAT (Medical Concept Annotation Toolkit) is an open-source framework for clinical named entity recognition and linking (NER+L) [1] that integrates large clinical ontologies such as SNOMED-CT and UMLS(Kraljevic et al., 2021), and also supports contextual meta-annotations (Mascio et al., 2020a; Agarwal et al., 2025b). The toolkit has been deployed across multiple institutions in the UK and internationally, enabling scalable extraction of structured clinical data in real-world settings (Mascio et al., 2020b; Noor et al., 2022; Au Yeung et al., 2024; Van Es et al., 2023).

Despite its success, operational use of MedCAT v1 highlighted several architectural limitations that restricted experimentation with alternative approaches. Exploring alternative approaches often required modifying or forking the codebase, increasing the maintenance burden. In addition, preserving backward compatibility while supporting diverse deployment environments introduced further complexity, particularly in resource-constrained clinical settings.

To address these challenges, we present MedCAT v2, a re-engineered modular architecture designed to support flexible configuration while preserving the proven core functionality of earlier releases. MedCAT v2 introduces a registry-based component system that enables interchangeable tokenizers, NER modules, and linkers, allowing alternative implementations to be integrated without modifying the core pipeline. This design supports systematic exploration of different NER+L configurations and facilitates experimentation with alternative modelling approaches.

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 191–198
July 3-4, 2026 ©2026 Association for Computational Linguistics

MedCAT v2 provides a sustainable foundation for clinical NLP by reducing integration overhead and exposing practical trade-offs between accuracy, throughput, and resource use. Our primary contributions are as follows:

- **Modular Architecture**: We introduce a registry-based component system for clinical NER+L that enables interchangeable tokenizers, NER modules, and linkers without modifying the core pipeline.
- **Performance-Throughput Framework**: We provide a redesigned infrastructure that allows for the systematic exploration of deployment trade-offs, supporting both lightweight CPU-only and high-throughput GPU-enabled environments.
- **Empirical Evaluation**: We demonstrate across multiple public datasets that this modular approach maintains or improves upon the performance of previous versions while offering significantly greater flexibility for real-world clinical deployment.

2 MedCAT v2 Architecture

2.1 Limitations of the MedCAT v1 architecture

Fig.1 demonstrates the monolithic architecture built around the spaCy framework. The components of the pipeline operated directly on *spaCy* objects such as documents, tokens, and spans, enabling a straightforward implementation and tight integration with the *spaCy* ecosystem.

However, this design introduced strong coupling between MedCAT's internal components and the underlying *spaCy* data structures. Changes to upstream processing steps, such as tokenization, required corresponding modifications throughout the rest of the pipeline to ensure compatibility with the expected document and span representations.

In addition, MedCAT v1 did not provide a mechanism for defining or registering alternative implementations of tokenizers or core components (e.g named entity recognition (NER) or entity linking (EL)). Exploring alternative approaches therefore required modifying or forking the codebase and integrating new implementations directly into the pipeline logic, increasing maintenance overhead and making experimentation with alternative methods difficult.

2.2 Modular and extensible pipeline architecture

To address these limitations, MedCAT v2 adopts a modular pipeline architecture designed around interchangeable components. Core stages of the pipeline (tokenization, named entity recognition (NER), and entity linking (EL)) are independently defined and registered, allowing alternative implementations to be integrated without modifying the rest of the system.

A lightweight *registry system* manages the available components and their implementations. This enables components to be swapped, extended, or replaced while maintaining a consistent pipeline interface. In addition to the core components, MedCAT v2 supports optional add-on modules that operate on the annotated document, such as MetaCAT for contextual meta-annotations and RelCAT for relation extraction (Agarwal et al., 2025a).

The registry architecture also enables support for external extensions: independent software packages that provide additional component implementations. These extensions can register their components with the MedCAT pipeline at runtime, allowing new functionality to be distributed separately from the core framework. For example, alternative linking approaches such as embedding-based linkers can be provided as external extensions while remaining fully compatible with the MedCAT pipeline.

To support reproducibility and deployment transparency, the framework tracks the provenance of each component used in a pipeline, including whether it originates from the core framework or from an external extension. This information is recorded in the model metadata, allowing pipelines to be fully described and reconstructed across different environments.

Fig. 2 describes the high level architecture of MedCAT 2.0. Components not explicitly discussed in this paper retain the same underlying implementation and behaviour as in MedCAT v1, and readers are referred to the original MedCAT publications for additional details on these components.

2.3 Example component implementations

The registry-based architecture allows different implementations of each pipeline stage to be configured depending on the requirements of a deployment. Components can be provided either by the core MedCAT library or by external extension pack-

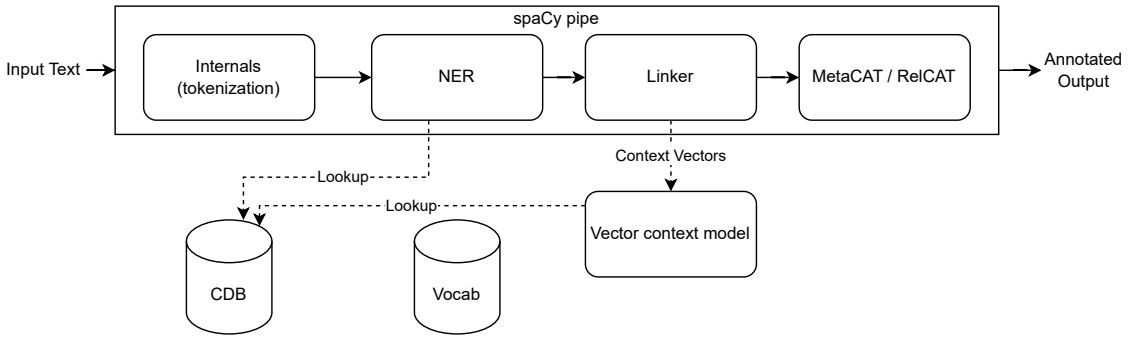

Figure 1: High-level architecture of MedCAT v1 showing the monolithic pipeline design built around *spaCy*.

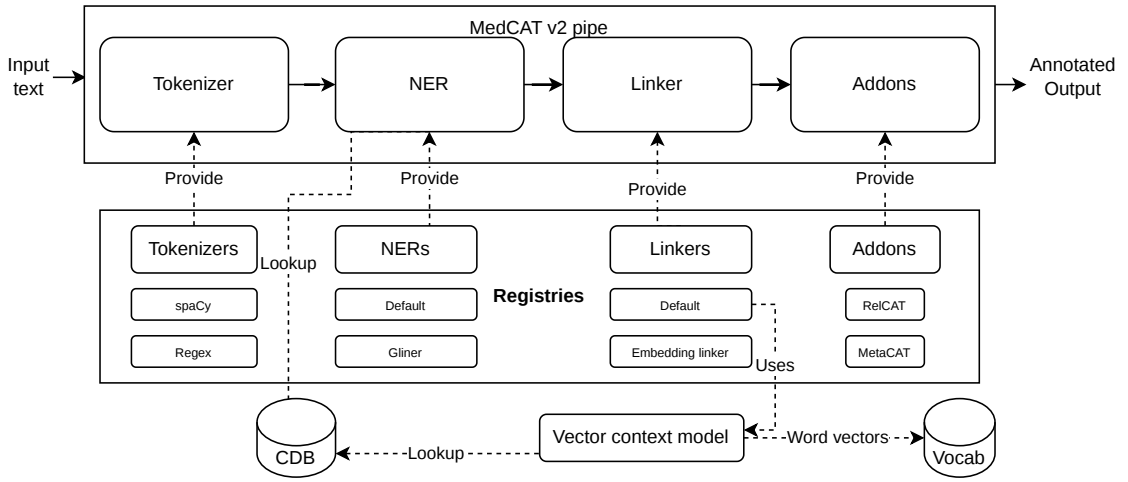

Figure 2: Modular registry-based architecture of MedCAT v2, illustrating interchangeable core components, optional add-on modules, and example registered implementations.

ages, enabling new functionality to be integrated without modifying the core system. For example, tokenization can be performed using either the default *spaCy*-based tokenizer or a lightweight regular-expression tokenizer designed for minimal environments. Similarly, alternative implementations of the NER and entity linking components can be used to balance trade-offs between computational cost, throughput, and predictive performance. To illustrate this flexibility, we highlight several component implementations available with MedCAT v2.

We demonstrate the improved flexibility through the following new components:

- **Regex-based tokenizer.** A lightweight tokenizer based on regular expressions designed for high-throughput or resource-constrained environments. While this approach reduces dependency overhead and improves processing speed, it may sacrifice some linguistic accuracy compared to more sophisticated tokenization methods
- **Faster linker.** A heuristic linker that resolves entities when a surface form maps unambiguously to a single concept, or when only one candidate concept treats the surface form as its primary name. By bypassing full disambiguation, this component substantially improves inference speed at the cost of reduced recall in ambiguous contexts.
- **Embedding-based linker.** A disambiguation component that leverages transformer based architectures (e.g. *sentence-transformers/all-MiniLM-L6-v2*) to improve concept selection for short or ambiguous mentions. In the configuration evaluated in this work, the linker uses static embeddings and provides modest improvements depending on the dataset and configuration. However, the architecture also supports training task-specific embedding representations for entity disambiguation, which

can substantially improve performance. This implementation is distributed as an independent MedCAT extension package on PyPI, demonstrating how external components can provide alternative implementations for core pipeline stages.

- *Gliner based NER*. A named entity recognition component based on GLiNER (Zaratiana et al., 2024), which can be used as an alternative to the default MedCAT vocabulary-driven NER pipeline. This component demonstrates how transformer-based external NER systems can be integrated into MedCAT v2 through the modular pipeline architecture. While the default MedCAT approach relies on vocabulary matching combined with normalization and spell-correction mechanisms, the GLiNER-based implementation enables experimentation with fully neural NER approaches within the same downstream linking pipeline. This is an NER step based on gliner (Zaratiana et al., 2024).

2.4 Backward compatibility and migration

To support a smooth transition for existing users, MedCAT v2 includes a legacy compatibility layer that allows models trained with MedCAT v1 to be loaded and used within the new framework with no user intervention. This ensures that previously trained models and annotation efforts can be preserved while benefiting from the improved architecture and modular pipeline introduced in v2. In addition, we provide a migration pathway and accompanying documentation to assist users in transitioning existing workflows to the new system (Ratas, 2026).

3 Results

3.1 Overall NER+L performance

MedCAT v2 maintains equivalent performance to MedCAT v1 when using the same trained model and default vector context model for entity linking. Across all evaluated datasets, precision, recall, and F1-scores remain within the expected variance range using a private internal model[2]. To enable direct comparison, equivalent pipeline configurations and model parameters were used across both versions wherever possible. These results confirm that the redesigned modular architecture does not adversely affect core NER+L functionality. A detailed comparison between the two versions is shown in Table 1.

To evaluate performance parity between versions, we evaluated both systems across several biomedical NER+L datasets including MDACE (Cheng et al., 2023), COMETA (Basaldella et al., 2020), Distemist (Miranda-Escalada et al., 2022), the SNOMED Linking Challenge (Davidson et al., 2025), and MedMentions (Mohan and Li, 2019). All datasets were preprocessed into a common evaluation format in order to obtain comparable metrics.

3.2 Runtime performance

We compared MedCAT v1 and v2 across several common operational scenarios, including model loading, inference, and unsupervised training. Across all experiments, runtime performance remains broadly comparable between versions. Inference latency is effectively unchanged when equivalent configurations are used, indicating that the architectural refactor does not introduce additional overhead during normal pipeline execution. Model loading times show modest variation, with v2 slightly faster in some cases, while unsupervised training times remain within the expected range of implementation and hardware variability. A summary of timing benchmarks is presented in Table 2. 20 MIMIC-IV documents were used within the inference unsupervised training runs depicted in the table. All experiments were run on a single machine with an Apple M1 CPU and 32 GB RAM.

To ensure comparability, all timing experiments were performed under identical conditions and with the same base model configuration. The results therefore reflect differences introduced by architectural changes alone, rather than variations in model structure or parametrisation.

3.3 Performance–throughput trade-offs across configurations

A key advantage of the MedCAT v2 architecture is that it exposes multiple interchangeable components, allowing users to configure the pipeline to match their desired balance between predictive performance and processing speed. This flexibility is particularly important across the diverse range of MedCAT use cases, from large-scale processing of millions of EHRs across extensive concept vocabularies to targeted extraction tasks involving a small number of concepts.

[2]This model is trained on NHS data and therefore cannot be publicly released.

Table 1: Comparison of MedCAT v1 and MedCAT v2 performance across multiple biomedical NER+L datasets using a private internal model. Differences between versions are shown in the "diff." columns.

Dataset	Precision			Recall			F1		
	v1	v2	diff.	v1	v2	diff.	v1	v2	diff.
MDACE	0.3656	0.3660	0.0004	0.5391	0.5398	0.0007	0.4357	0.4362	0.0005
COMETA	0.9242	0.9245	0.0003	0.4521	0.4521	0.0000	0.6072	0.6072	0.0001
Distemist	0.3187	0.3192	0.0005	0.3949	0.3958	0.0009	0.3527	0.3534	0.0007
Linking Challenge	0.5353	0.5353	0.0000	0.3338	0.3337	-0.0001	0.4112	0.4112	0.0000
Med-Mentions	0.3521	0.3521	0.0000	0.5104	0.5103	0.0001	0.4167	0.4167	0.0000

Table 2: Runtime comparison between MedCAT v1 and v2 across inference, model loading, and unsupervised training scenarios. MC refers to MetaCAT components included in the pipeline.

Scenario	Ver	Model	Time - v1 (s)	Time - v2 (s)
inference	v1	NER (no MC)	9.090	10.827
inference	v1	NER + 3 MCs	22.537	22.311
load	v1	NER (no MC)	12.030	12.061
load	v1	NER + 3 MCs	12.218	17.653
unsup_train	v1	NER (no MC)	12.121	10.147
unsup_train	v1	NER + 3 MCs	22.392	26.776

On COMETA, the lightweight components deliver substantial runtime gains with only modest reductions in F1. For example, the combination of the regex tokenizer and the faster linker can achieve more than an order-of-magnitude speedup relative to the standard configuration, while maintaining comparable precision and only a small reduction in recall. This suggests that for some large-scale or latency-sensitive applications, MedCAT v2 can operate at significantly higher throughput without materially compromising output quality.

In contrast, results on the Linking Challenge dataset highlight that no single configuration is universally optimal. While the faster linker again provides clear speed improvements, the regex tokenizer does not produce a similar benefit. This likely reflects differences in dataset structure: COMETA consists of smaller, tightly filtered projects, whereas the Linking Challenge dataset allows a much larger variety of candidate concepts. As a result, the regex tokenizer produces many more potential mentions that must be evaluated during linking, increasing overall processing time. These results illustrate that tokenization and linking behaviour can interact with dataset characteristics in non-trivial ways.

The embedding-based linker represents the high-resource end of this configuration spectrum. While it is designed to improve disambiguation for short or ambiguous mentions, it introduces substantially higher computational cost and typically requires GPU acceleration for practical use. Across the evaluated datasets it does not consistently outperform lighter linking strategies, sometimes offering only marginal improvements despite significantly longer runtimes. This suggests that contextual embedding approaches are most beneficial in settings where ambiguity is a dominant challenge, but provide less advantage when candidate sets are already well constrained.

Overall, these experiments demonstrate that MedCAT v2 is intentionally flexible rather than prescriptive. Instead of enforcing a single configuration, the system allows practitioners to select pipeline components that match their operational constraints, whether prioritising throughput, resource efficiency, or predictive performance. The variation across datasets also highlights the importance of validating component choices on task-specific data rather than assuming a universally optimal configuration.

4 Discussion

The goal of this work was to address practical deployment and maintenance challenges encountered with MedCAT in real-world clinical and research

Table 3: Performance and runtime for different MedCAT v2 configurations across two datasets. Embedding linker results were obtained using the *abhinand/MedEmbed-small-v0.1* model

Dataset	Configuration	Precision	Recall	F1	Time (s)
COMETA					
Spacy	Vector context	0.9245	0.4521	**0.6072**	68.16

Regex	Faster linker	0.5091	0.2862	0.3664	82.61
Regex	Embedding linker	0.4141	**0.3593**	0.3847	248.02

environments, while preserving its established performance. Our results show that MedCAT v2 maintains equivalent predictive behaviour to earlier releases while substantially increasing flexibility through a modular, registry-based architecture.

Operational experience with MedCAT v1 highlighted recurring challenges: tightly coupled components made it difficult to experiment with alternative models, upgrades often required invasive code changes, and deployment across heterogeneous infrastructure introduced avoidable complexity. MedCAT v2 directly targets these issues by decoupling core pipeline elements and enabling components to be composed, replaced, or omitted without modification of the core library, and allowing new functionality to be integrated through external extensions. In practice, this allows development teams to integrate new tokenizers, linkers, or contextual classifiers independently, while clinical informatics groups can deploy lightweight CPU-only configurations tailored to local constraints. The extension system enabled external packages to provide components for MedCAT without cluttering up the core library.

The redesigned framework also exposes explicit trade-offs between accuracy, throughput, and resource consumption. Our experiments demonstrate that simplified components can yield substantial gains in processing speed, whereas embedding-based linking can improve disambiguation in some contexts but at substantially higher computational cost. These findings reinforce that no single configuration is optimal across deployments, and that teams should evaluate component choices against their own corpora, performance requirements, and infrastructure availability rather than relying solely on aggregate benchmark metrics.

Clinical NLP systems span a wide spectrum, from lightweight rule-based pipelines to fully neural end-to-end architectures. MedCAT v2 is designed to occupy a practical middle ground, supporting constrained environments while remaining extensible to more resource-intensive components where applicable. Rather than replacing specialised systems, the framework aims to lower the barrier to deployment and experimentation in settings where operational considerations often dominate model selection.

Several limitations remain. Embedding-based linking is computationally demanding and may be impractical without GPU access. Performance continues to depend on ontology coverage and data availability, with openly available models lagging institution-specific deployments. Increased configurability also introduces a larger design surface for users. To mitigate this, MedCAT v2 is accompanied by migration tooling, documentation, tutorials, and reference configurations, with ongoing refinement guided by community feedback.

Overall, MedCAT v2 provides a more sustainable engineering foundation for clinical concept extraction. By reducing operational friction while retaining established performance, the framework supports broader adoption of clinical NLP across

research and applied healthcare environments.

5 Conclusions

MedCAT v2 delivers a more operationally practical foundation for clinical named entity recognition and linking, preserving the established performance of earlier releases while substantially improving deployment flexibility and maintainability. By decoupling core components and simplifying integration, the framework reduces engineering overhead and enables teams to adapt pipelines to their local infrastructure and use-case requirements.

The redesigned architecture supports a wide range of deployment profiles, from lightweight CPU-only configurations within hospital infrastructure to more advanced pipelines that incorporate embedding-based components. The modular design also enables external extensions to provide alternative implementations of core components without requiring changes to the framework itself. Crucially, backward compatibility ensures continuity for existing users: previously trained models and data formats can be reused without modification, protecting prior investments while enabling incremental adoption of new functionality.

As an open-source platform, MedCAT v2 (Ratas et al., 2026) provides a sustainable basis for community-driven development and applied clinical NLP. The modular design positions the toolkit to integrate emerging methods in linking, contextualisation, and privacy-preserving workflows without disruptive architectural changes. By lowering barriers to experimentation, deployment, and long-term maintenance, MedCAT v2 supports more robust translation of NLP research into real-world healthcare environments and enables scalable extraction of structured clinical information from unstructured text.

Abstract

Due to unique concepts, syntactic structure, and vocabulary of specialized domains, it is common to train specialized Language models (LMs) for their target domain. For example, BioClinicalBERT is a specialized LM designed for clinical applications. These specialized LMs are typically created starting with a foundation model (such as BERT-base) which has been pretrained for the general English domain, and then adapted to the target domain via additional pretraining. Alternatively, LMs may be pretrained from scratch on data from the target domain. Both techniques are extremely computationally expensive and as such, these specialized LMs are often publicly released for other researchers. For some domains, such as the biomedical domain there are many, similar models available, and as a developer, this raises the question, which pretrained LM should I choose? Alternatively, in novel domains for which no specialized LMs exist, it raises different questions: Is it worth the cost to pretrain a LM from scratch? Should I adapt a general English model instead? Should I just use a general English model without adaptive pretraining? This is a particularly salient question when considering a limited budget. i.e. Should I pay for compute time or for annotators to create a larger dataset. In this paper we compare results of nine LMs across nine datasets spanning the clinical, scientific, and biomedical-related social media domains. From these comparisons we make several conclusions that can simplify the hyperparameter-tuning process and inform researchers and developers in novel domains. Broadly, these are that the effects of adaptive fine-tuning are small. If an adapted model exists in your domain, choose the one most closely related to your task. If no model exists, using a foundation model is likely sufficient.

1 Introduction

Named Entity Recognition (NER) is the task of identifying salient terms in text, and is a core NLP task performed within these larger systems, and as such, improving NER is a vital step to improving their effectiveness. Transformer (Vaswani et al., 2017)-based language models (LM) have become the state-of-the art for many NLP tasks, and despite recent advancements in Large Language Models (LLMs), smaller Language Models (LMs) such as BERT (Devlin et al., 2018) remain the state-of-the-art for low-level tasks such as NER. Although smaller than the larger LLMs, these models are still extremely computationally expensive to train from scratch and as such are typically created for maximum utility within the General English domain. However, specialized domains such as the biomedical and clinical domains have unique concepts, language, and grammatical structure (Nadkarni et al., 2011) meaning these General English models may not perform optimally without domain-specific adaptation.

Evidence suggests that BERT models perform better when pretrained on data closely related to their target task (Lee et al., 2020; Alsentzer et al., 2019; Gu et al., 2021; Peng et al., 2019), and previous work has compared several LMs across multiple datasets. For example, Peng et al propose the Biomedical Language Understanding Evaluation (BLUE) benchmark and compare the effects of pretraining on PubMed and PubMed + MIMIC using Large and Small BERT models. Gu et al (Gu et al., 2021) propose the Biomedical Language Understanding & Reasoning Benchmark (BLURB) benchmark and compare six biomedical language models and Base BERT over various tasks including five NER datasets. These works serve as important biomedical benchmarks to compare biomedical LMs. We distinguish ourselves from these works in focusing on understanding the effects of adaptive pretraining to answer practical questions such as, what LM should I choose or is it worth it to adaptively pretrain an LM for a novel domain? To answer this, we collected and compared results of

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 199–208
July 3-4, 2026 ©2026 Association for Computational Linguistics

nine different LMs over nine popular NER datasets in the clinical, scientific, and biomedical-related social media domains.

We find that while domain-specific pretraining does increase performance, the increase is less dramatic than expected, not across-the-board, and often not statistically significant. This is even true for LMs trained from scratch for the target domain. Given the extremely high computational costs, these results have important implications for researchers working in novel domains without pre-existing domain-specific LMs, and can help guide the choice of a LM for researchers and developers in domains with pre-existing domain-specific LMs.

2 Background

2.1 Training Language Models

LMs consist of an Encoder-Decoder architecture. In this architecture, the encoder learns effective numeric representations of the text, and the decoder transforms those numeric representations into an output useful for the target task. LMs are trained in a sequence of steps: (1) *Pretraining* - train the encoder to create numeric representations of text. (2) *Optional adaptive pretraining* - adjust those numeric representations for the target domain. (3) *Fine-tuning* - train a decoder (and usually also adjust the weights of the encoder) to perform well on a specific task and dataset.

Pretraining is a self-supervised step in which the LM is trained on massive corpora containing billions of words. The precise pretraining routine varies depending on the specific LM (Devlin et al., 2018; Liu et al., 2019; Brown et al., 2020; He et al., 2020), however most follow a routine similar to BERT (Devlin et al., 2018). BERT is jointly trained using Masked Language Modeling (MLM) and Next Sentence Prediction (NSP). MLM is performed by masking words in a sentence, and using the LM to predict the masked word. NSP is performed by providing two text samples to BERT, and training it to predict whether the second sentence follows the first sentence.

Pretraining is by far the most computationally expensive step of LM development, and creating a LM from scratch often carries prohibitive costs. As such, pretrained LMs are typically created for maximum utility and therefore trained for the general English domain. These pretrained LMs are often released as foundation models which are used by researchers directly or adapted to other datasets via adaptive pretraining.

In the *optional adaptive pretraining* step, the LM is further pretrained (typically using the same pretraining routine) on domain-specific corpora. For example, BERT-Base which is pretrained for the general English domain may adapted to the biomedical domain by performing additional pretraining using PubMed abstracts. While less computationally expensive than initial pretraining, this is still extremely computationally expensive (often prohibitively expensive) and the adapted LMs are commonly released for other developers in their domain.

Fine-tuning is the last step in training a LM. In this step, a task-specific decoder is attached to the pretrained weights of the encoder portion of the LM and the full model is trained to maximize performance on the provided dataset. This is often the only step performed by developers, who will select a pretrained LM using online repositories such as HuggingFace[1], then train it on a specific dataset. Common wisdom suggests you select a LM most closely related to your target domain.

2.2 Biomedical Data Sources

Publicly available databases have been created to enable research in biomedicine. Two of the most popular text databases are PubMed, which contains biomedical literature from online journals and books, and MIMIC-III, which contains standardized, de-identified clinical records.

The PubMed (Wheeler et al., 2007) and PubMedCentral (Roberts, 2001) resources provided by the National Center for Biotechnology Information (NCBI) are repositories of scientific articles related to the biomedical sciences. PubMed contains over 40 million article abstracts while PubMedCentral contains nearly 12 million full-text articles.

The Medical Information Mart for Intensive Care (MIMIC-III) (Johnson et al., 2016) is a vast, freely-available database containing about 2 million de-identified clinical records. MIMIC-III data is sourced from critical care reports at Beth Israel Deaconess Medical Center, a hospital in Boston, Massachusetts. These clinical records report on a variety of topics that include laboratory testing, billing and administrative work, patient demographics, discharge summaries, radiology reports, chart write-ups, and pharmacotherapy.

2.3 Pretrained Language Models for the Biomedical Domain

The biomedical domain is a broad, well-studied domain and as such has many pretrained LMs available for download. We divide the biomedical domain into three main sub-domains: (1) *clinical* which relates to the medical aspects of biomedicine, (2) *scientific* which relates to biology, chemistry, genetic, and other scientific aspects of biomedicine, and (3) *social media* which relates to consumer and patient views and testimony related to biomedicine. For these experiments, we selected nine different LMs which cover these sub-domains. All selected LMs except PubMedBERT are domain-specific adaptations of the general English BERT-Base model, and all but BERT Tweet are pretrained in the same way as BERT (e.g. MLM and NSP). Uniquely, PubMedBERT is trained from scratch for the scientific biomedical domain. We describe each evaluated LM below. To make the tables more compact, we assigned abbreviations for each of these LMs, which are listed in bold. Table 1 summarizes their difference in training data sources.

BERT: BERT-Base is the original, general English model proposed by Devlin et al (Devlin et al., 2018). It was pre-trained for the MLM and NSP tasks using the Books Corpus (Zhu et al., 2015) and English Wikipedia.

Bi-B: BioBERT (Lee et al., 2020) is initialized from BERT-Base and adaptively pre-trained on PubMed abstracts and PubMed full-text articles from PubMed Central. In the biomedical domain, Bi-B has significantly outperformed BERT on several tasks including NER and relationship extraction (Lee et al., 2020; Gu et al., 2021), and was therefore used as the initial weights for the next two systems.

BiClin-B: BioClinicalBERT(Alsentzer et al., 2019) is initialized from Bi-B and further pre-trained on all clinical notes in the MIMIC-III database. BiClin-B has been shown to be slightly more effective for clinical tasks than Bi-B (Alsentzer et al., 2019).

BiDis-B: BioDischargeSummaryBERT (Alsentzer et al., 2019) is initialized from BioBERT and further pre-trained on clinical notes which are discharge summaries from MIMIC-III. BiDis-B shows improvement over Bi-B for tasks with corpora that deal specifically with discharge summaries (Alsentzer et al., 2019).

Blue-B: BlueBERT (PubMed) (Peng et al., 2019) is initialized from BERT-Base and further pre-trained on PubMed abstracts. Blue-B pre-training data (PubMed) is similar to that of Bi-B, but excludes full-text articles. Blue-B has been shown to perform similarly to Bi-B (Peng et al., 2019).

BlueB+M: BlueBERT (PubMed+MIMIC) (Peng et al., 2019) is initialized from BERT-Base and further pre-trained on PubMed abstracts and additionally clinical notes from MIMIC-III. Therefore, this LM's pre-training data is similar to that of BiClin-B, but excludes full-text PubMed articles. BlueB+M has been shown to outperform Bi-B on clinical tasks (Peng et al., 2019).

PMed-B: PubMedBERT (Gu et al., 2021) is pre-trained from scratch on PubMed abstracts. Unlike the other LMs it is not adapted from BERT Base. Theoretically, this should be hugely beneficial because the vocabulary of a LM is fixed and is determined from the initial pretraining corpus. Whereas LMs adapted from general English may need to represent specialized terms using subword tokens, PMed-B can represent specialized terms

natively because they are present in its specialized vocabulary. PMed-B was shown to perform comparably or better than LMs like Bi-B and Blue-B for biomedical tasks (Gu et al., 2021).

BT: BERTweet (Nguyen et al., 2020) is initialized from BERT Base and further pre-trained on Twitter data. BT is not adapted to the biomedical domain, but is instead adapted to the unique, short-form, highly abbreviated nature of Tweets. We include BT to try to determine what is more important, social media structure or the biomedical context. Instead of following the original BERT pre-training procedure, BT's adaptive pre-training is modeled after the RoBERTa procedure (Liu et al., 2019). This pre-training procedure is distinct in two ways: masked tokens are changed each epoch during MLM and no NSP is performed. BT was shown to outperform similar LMs for NER in the general social media domain (Nguyen et al., 2020).

BiRed-B: BioRedditBERT (Basaldella et al., 2020) is initialized from Bi-B and further pre-trained on text from health-related Reddit threads. BiRed-B has shown good performance for biomedical text mining in the social media domain (Basaldella et al., 2020).

3 Datasets

We selected nine datasets which, like the selected LMs span the clinical, scientific, and social media subdomains of biomedicine. The datasets are summarized in Table 2 and brief descriptions are provided below.

i2b2 2010: The i2b2 2010 Concepts, Assertions, and Relations challenge (Uzuner et al., 2011) aimed to create suitable NLP systems for the clinical domain. Its associated dataset consists of 426 de-identified clinical notes from Partners Healthcare and Beth Israel Deaconess Medical Center. For the NER challenge, the clinical notes were annotated for medical problems, treatments, and tests. The challenge organizers provide a split of 170 training notes and 256 test notes.

n2c2 2018: The n2c2 2018 Track 2 challenge (Henry et al., 2020) focused on developing systems to recognize adverse drug events (ADEs). The dataset consists of 505 de-identified clinical notes gathered from the MIMIC-III clinical care database. For the NER challenge, the data was annotated for entities related to medications and ADEs which include: drug, strength, form, dosage, frequency, route, duration, reason, and ADE. The challenge organizers provide a split of 303 training notes and 202 testing notes.

BC5CDR: The BioCreative V Track 3 Chemical-Disease Relation (CDR) challenge (Wei et al., 2016) was created to develop systems that identify chemical-disease interactions. The CDR corpus is composed of 1500 PubMed abstracts annotated for diseases and chemicals. The task organizers provide a split of 500 training, 500 validation, and 500 test abstracts.

BC7DCPI: The BioCreative VII Track 1 drug-protein and chemical-protein interactions challenge (Miranda et al., 2021) focused on identifying biochemical entities for drug discovery. This dataset is a collection of 5000 PubMed abstracts annotated for genes and chemicals. The organizers provide a split of 3500 training abstracts, 750 validation abstracts, and 750 test abstracts. Background and large-scale background collections of automatically-annotated abstracts were also released for further analysis.

NCBI: The NCBI disease corpus (Dogan and Lu, 2012) is a collection of PubMed abstracts designed to test the efficacy of disease recognition systems. In total, 793 PubMed abstracts were annotated for disease mentions. While the corpus maintainers do not provide a training-test split for the data, one provided by (Crichton et al., 2017) has seen use in biomedical benchmarks (Gu et al., 2021).

NLMChem: The NLM-Chem corpus (Islamaj et al., 2021) was created for the BioCreative VII Track 2 task on identifying chemical information from full-text scientific publications. It contains 150 full-text PubMed articles annotated for chemical mentions. The corpus maintainers provide a split of 80 training documents, 20 validation documents, and 50 test documents.

BC7Med: The BioCreative VII Track 3 challenge (Weissenbacher et al., 2021) focused on identifying medication and dietary supplement mentions from social media data. The dataset contains tweets from 212 different users' timelines annotated for drug name mentions. This dataset is large, yet heavily imbalanced with only 0.2% percent of the tweets containing medication mentions. The challenge organizers provide a split of 89,004 tweets for training, 38,149 tweets for validation, and 54,482 tweets for the test set.

COMETA: The Corpus of Online Medical EntiTies (COMETA)(Basaldella et al., 2020) contains biomedical entities from Reddit. It was originally intended to evaluate entity linking systems and con-

Dataset	Domain	Entity Types	Data Source
BC5CDR	Scientific	Disease, Chemical	PubMed abstracts
BC7DCPI	Scientific	Gene, Chemical	PubMed abstracts
NCBI	Scientific	Disease	PubMed abstracts
NLMChem	Scientific	Chemical	Full-text PubMed articles
i2b2 2010	Clinical	Problem, Treatment, Test	De-identified clinical notes
n2c2 2018	Clinical	Drug, Strength, Form, Dosage, Frequency, Route, Duration, Reason, ADE	De-identified clinical notes
BC7Med	Social Media	Medication	Twitter data
COMETA	Social Media	Miscellaneous Biomedical Entities	Reddit threads
ADEMiner	Social Media	ADE	Twitter data

Table 2: Description of datasets and their sources used in evaluation.

tains 20,015 health-themed posts from Reddit annotated for biomedical entities found within the SNOMED CT ontology (Donnelly et al., 2006). These entities represent a wide variety of biomedical concepts including symptoms, diseases, chemicals, genes, procedures, and more. To re-purpose this dataset for NER, we identified the text spans of the annotated entities and used them as the gold standard. Unique to this dataset (due to its repurposing), all entities within this dataset received a label of "Biomedical Entity" or None.

ADEMiner: The DeepADEMiner corpus (Magge et al., 2021) is a combination of three different datasets (SMM4H 2017 (Sarker et al., 2018), SMM4H 2019 (Weissenbacher et al., 2019), and SMM4H 2020 (Gonzalez et al., 2020)) created for identifying and normalizing ADEs from Twitter data. There are a total of 33,246 tweets that are annotated for ADE mentions. No official training-testing split is provided.

4 Methodology

4.1 Data Processing

LM training requires a maximum of 512 token length samples, so each dataset was processed (chunked) into samples. For some datasets, a sample was clearly defined. This is the case for i2b2 2010, BC7Med, COMETA, and ADEMiner, where annotations are contained on one line and therefore a sample is identified as a single line of text. For other datasets, there is no clear distinction between samples because the text is annotated on a character-level basis and no pre-defined sample deliminator is provided. For these datasets, which include n2c2 2018, BC5CDR, BC7DCPI, NCBI, and NLMChem, we processed these datasets into samples using the ScispaCy sentence splitter (Neumann et al., 2019) with the `en_core_sci_sm` model [2].

[2] https://allenai.github.io/scispacy/

All datasets were tokenized using each LM's specific tokenizer (as specified by HuggingFace's `Transformers.Autotokenizer` library).

4.2 Language Model Architecture and Training

NER was posed as a multi-class token classification problem and performed by predicting a set of labels for each token token in that sample. The set of labels corresponds to the entity types of that dataset plus a *None* class. The `argmax` is taken over the set of labels to convert to a one-hot label encoding for each token. For example, in the BioCreative 5 CDR dataset, a vector of `<Disease, Chemical, None>` probabilities is predicted for each token, and converted to a vector containing all zeros except for a single one indicating the class.

We first performed a preliminary hyperparameter search to determine the learning rate, batch size, embedding dropout, and decoder architecture. Manual analysis of these results and those reported in the literature (Devlin et al., 2018; Alsentzer et al., 2019; Michalopoulos et al., 2020) support that fine-tuning with a learning rate of 1e-5, batch size of 16, and no embedding dropout produces LMs that perform well for biomedical NER. Due to the prohibitive costs of performing separate hyperparameter searches for all LMs and all datasets, we reused these hyperparameters for each LM across every dataset. For similar reasons, we also fixed the neural network architecture across all datasets. All BERT models have a distinct task-specific decoder, meaning they predict only classes found within a particular dataset. The decoder is a single densely-connected layer with softmax activation.

4.3 Results Generation

Reported results are the micro-averaged F1 scores averaged over 5-folds of cross-validation. For datasets that provided training, test, and/or vali-

dation splits, we combined all data into a single set which we used for cross-validation. Each fold consists of 70% for training, 10% for early stopping and 20% for validation (testing). The data-split was randomized but consistent across all compared LMs. To maximize the number of training samples per fold, we used the early stopping split to determine the optimal number of training epochs, then we combined the training and early-stopping data into a single training dataset and created the final model used to predict on the validation set. Preliminary analysis indicated this technique moderately improved results. Early stopping monitored micro-F1 with a patience of 5. The weights of each LM were re-initialized between validation folds.

4.4 Statistical Significance

t-tests are a commonly used test of statistical significance (Demšar, 2006). They require a set of evaluation results which are typically collected over each round of cross-validation or over multiple datasets. Paired tests provide more statistical power for detecting differences than unpaired tests and therefore care should be taken to ensure test sets are identical for all systems during cross-validation. Briefly, a t-test assumes that the two methods perform equivalently (this is the null hypothesis), and any difference can be explained by random variation. To test this, the t-test compares two distributions and calculates a test statistic which is used to calculate a p-value which indicates the probability of accepting the null hypothesis. In this case, the probability that the two systems are equivalent. Therefore, low p-values indicate a low probability that the systems are equivalent, meaning they are statistically significantly different. α, a cut-off threshold for p is used to draw conclusions. When $p < \alpha$ one can conclude that the two systems are significantly different. $\alpha = 0.05$ is commonly used and indicates a 95% probability that the systems are different. Since we are testing for a difference in the better (greater than) or worse (less than) direction, a two-tailed test is used.

Although t-tests are commonly used, they are not well-suited for comparing results over cross-validation or over multiple datasets. This is because the t-test assumes that the scores are independent and normally distributed. The scores across cross-validation are not independent because the training sets of each round overlap and the results may not be normally distributed. When comparing across datasets the scores are independent, but are not normally distributed. Several corrections to t-tests have been proposed to account for the non-independence of results (Nadeau and Bengio, 2003; Grandvalet and Bengio, 2006; Santafe et al., 2015). These tests update the estimate of variance to account for the non-independence of samples. An alternative to the t-test is the Wilcoxon signed-rank test (Wilcoxon, 1945). This is a non-parametric test which does not assume the data is independent nor normally distributed. Like the t-test, Wilcoxon produces both a test statistic and a p-value which may be used to determine statistical significance. Because of the few assumptions of non-parametric tests, Wilcoxon tests are arguably preferable to t-tests, even corrected t-tests (Demšar, 2006; Rainio et al., 2024) for comparing across rounds of cross-validation and across datasets, however because they are non-parametric they require more samples than parametric tests to make sound statistical inference. Importantly, Wilcoxon cannot produce a p-value less than 0.05 with only 5 samples, meaning, in our study it is impossible to conclude any two systems are different when comparing across 5 rounds of cross-validation. Therefore, we use Grandvalet and Bengio's T-test for Cross-Validation (Grandvalet and Bengio, 2006) as described by Santafe et al. (Santafe et al., 2015) when comparing two systems across rounds of cross-validation and the Wilcoxon signed-rank test when two systems comparing across datasets. For the T-Test for Cross-Validation we use a $corr = 0.35$ because it is a middle value balancing over-estimating and under-estimating statistical significance. To compare multiple systems we use the Friedman test, which is a non-parametric test designed for comparing multiple systems. While it is possible to use repeated t-tests or Wilcoxon tests to determine differences between many systems, repeated tests increase the risk of error (Rainio et al., 2024; Demšar, 2006) across the whole family of tests (e.g. when $\alpha = 0.05$ there is a 95% chance of being correct, but with 2 tests there is a $95\% * 95\% = 90.25\%$ chance of being correct for all tests.

5 Results

Table 3 shows the micro-F1 performance averaged over 5-fold cross validation for all LMs and datasets. Each row indicates the results for a dataset and each column indicates the results for a LM. Bold values indicate the highest score for that dataset. Rows are grouped by dataset type; first sci-

Table 3: Validation set micro-averaged F1 scores averaged over 5-fold cross-validation.

entific, then clinical, then social media. Columns are similarly grouped. The final row shows the average performance of each LM over all datasets. An important note is that these results are not necessarily directly comparable to other reported results, since these are the average micro-f1 of 5-fold cross validation, not results on the provided test set (if provided). From this table we can make several observations:

Observation 1: BT performs poorly on all datasets, even BC7Med and ADEMiner which consist of Tweets. Recall that BT was trained on general English Tweets and not on biomedical data. This implies that modeling biomedical language is more important than modeling the short-form structure of Twitter. Therefore, when choosing a LM it may be best to consider the domain first and the target task's structure second.

Observation 2: PMed-B performs the best for most datasets, but it doesn't have the highest average among all datasets. This is because it doesn't do as well as other LMs on social media datasets. We suspect this is related to its difference in vocabulary, but it may also be because it has never been trained for the general English domain which social media posts may most closely reflect. Furthermore, although PMed-B performs the best for most scientific datasets it is never statistically significantly better than Bi-B or Blue-B (the other scientific models), but it is statistically significantly worse than both Blue-B ($p = 0.0032$ and Bi-B ($p = 0.0099$) on BC5CDR.

Observation 3: The results for most datasets are similar no matter what LM you choose (except BT). For example, the scores for BC5CDR (excluding BT) range from 0.9518 to 0.9610, a difference of only 0.0092 = 0.92%. This pattern of similar performance is observed in nearly all datasets. For 4 out of the 9 datasets the difference between best and worst performing (excluding BT) is less than 1%, for 7 out of the 9, this difference is less than 5%. The only large differences are for NLMChem (11.78%) and BC7Med (8.88%). Furthermore, when comparing the average performance across all datasets (the Mean row), the difference between the best and worst performing (excluding BT) is only 1.63%. This observation is supported by statistical significance testing. Using Friedman's test to compare the performance of all LMs across all datasets reveals a statistically significant difference between the LMs ($p = 0.0017$), but when removing BT from the comparison, Friedman's test calculates a $p = 0.4061$ revealing no statistically significant difference between any system except BT when compared across all datasets.

Observation 4: BERT is the base model from which all LMs (except PMed-B) are adaptively pretrained. However, despite this, the change in performance is minimal (excluding BT) for most datasets; less than 2% for 7 out of 9 datasets, 3.37% for NLMChem, and 8.88% for BC7MED. However, when comparing one dataset at a time across cross-validation scores, we found that at least one (but never all) adaptively pretrained system significantly improved upon BERT. This was true for all datasets except for NCBI and ADEMiner. This indicates that although significant improvement is possible it is not guaranteed.

Observation 5: Common wisdom is to choose a LM most closely related to your target domain. However, the results in Table 3 show that P-MedB (a scientific LM) performs the best for n2c2 2018 (a clinical dataset). Similarly for the social media datasets of BC7Med and COMETA, the best performing systems are BlueB+M (a clinical LM) and PMed-B (a scientific LM) respectively. At first

glance this would imply that common wisdom is not always advisable, however comparing across folds of cross-validation for n2c2 2018 the p-value between P-MedB and BiDis-B (the best performing clinical model) was $p = 0.0686$, indicating no statistical significance between these systems. Similar results of $p = 0.5078$ and $p = 0.6720$ were found for BC7Med and COMETA respectively when comparing against BiRed-B (the best performing Social Media LM). Therefore, common wisdom stands. You should choose a LM that is most closely related to your domain.

Observation 6: Similar LMs perform similarly. Friedman's test from observation 3 revealed that no two LMs other than BT are statistically significantly different when compared across all datasets. Not surprisingly, using Friedman'a test for within category performance across within category datasets (e.g. clinical LMs - BiClin-B, BiDis-B, BlueB+M - across all clinical datasets - i2b2 2010, n2c2 2108) also showed no statistical significance. $p = 0.1690$ for biomedical systems on biomedical datasets, $p = 0.8948$ for clinical systems on clinical datasets. Using Wilcoxon within the social media datasets reveals a statistical significance $p = 0.0039$ due to BT's poor performance.

We also compared within-category systems across folds of cross-validation for each dataset using t-test for cross-validation and found little significant differences. There was a single significant difference between scientific models on scientific datasets which was on BC5CDR for which (as previously noted) PMed-B performed significantly worse than both Bi-B and Blue-B. Among clinical systems there were no statistically significant differences on n2c2 2018, but on i2b2 2010 we found that BlueB+M is statistically significantly better than BiClinB ($p = 0.0192$). Lastly, as expected for all social media datasets BiRedB is statistically significantly better than BT on all datasets (BC7Med $p = 0.0035$; COMETA $p = 0.0073$, ADEMiner $p =< 0.0001$).

6 Conclusions and Limitations

In this paper we performed a comparison of nine different LMs on nine biomedical datasets spanning the scientific, clinical, and social media subdomains on the task of NER. We confirmed that you should choose a LM most closely related to your target domain, that models trained on similar data will perform similarly, and that only moderate improvements are gained by adaptive pretraining. However, we were surprised by how little the differences between systems typically were, particularly with respect to BERT versus its adaptively pretrained counterparts, and most particularly by PMed-B's only slight improvement despite huge computational costs.

Based on our observations we can make a few suggestions:

1) As an NER developer in a specialized domain, follow common wisdom and select a model most closely related to your target task. It is unnecessary to generate and compare results across many different LMs. Their performance difference will very likely be statistically insignificant. This is a relief particularly because NER is often a basic task used within larger systems. It frees up time and effort to focus on other system components and other hyperparameter tuning.

2) As researcher in a novel domain for which no adaptively pretrained models exist, you can prototype using BERT. Performance gains by adaptively pretraining may improve results, but don't expect a dramatic change. If results are promising, then it may be worthwhile to adaptively pretrain a model, but if results are not promising, focus on developing a new technique or annotating more data.

3) Pretraining a model from scratch is not worth the costs for all but the most important or widely-used domains. It can improve performance but adaptively pretraining is a comparable method that is computationally more efficient.

We wonder if these results generalize to other lower-level tasks, such as relationship extraction or span detection, and if these results generalize to large language models (LLMs) such as LLaMa (Touvron et al., 2023). Since LLMs are recognized as being able to better generalize to new data, we feel this is likely and believe that these results suggest that using non-adapted foundation models may be sufficient. This is particularly salient since adapting pretrained LLMs is typically prohibitively expensive for most researchers and developers.

Lastly, we acknowledge limitations: (1) Significance tests were performed across a small number of samples which reduces their power of inference. Furthermore, since they compare across a distribution of F1 scores they don't take into account the number of samples in each dataset. (2) LM and dataset specific hyperparameter tuning could reveal more stark differences between LMs.

Abstract

The development of large language models (LLMs) has led to an increased focus on their adaptation to specialized domains and languages, yet the effectiveness of domain adaptation strategies remains unclear. We present a study of medical domain adaptation using French medical question-answering (QA) as a case study. We compare continual pretraining (CPT), supervised fine-tuning (SFT), and their combination across three model families, multiple sizes, and three initialization types, explicitly disentangling adaptation effects from base model choice. We evaluate both multiple-choice (MCQA) and open-ended QA (OEQA) under greedy and constrained decoding using automatic metrics and LLM-as-a-Judge evaluation. For MCQA, CPT+SFT most often achieves the best scores, but gains over SFT are small and frequently not statistically significant, making SFT a strong and cost-effective default. For OEQA, CPT consistently improves overlap-based metrics, while SFT often degrades generation quality; instruction tuning and CPT+SFT are preferred by LLM-based evaluation. Cross-lingual experiments further show effective transfer from French adaptation to English benchmarks. Overall, we provide practical guidelines for selecting adaptation strategies under computational constraints.

1 Introduction

LLMs are increasingly applied to medical question-answering (QA) and clinical reasoning, where accuracy, robustness, and domain-specific knowledge are critical (Huang et al., 2024). However, most high-performing LLMs are trained on general-domain data, making domain adaptation essential for safe medical deployment. In practice, this adaptation relies on continual pretraining (CPT) on domain corpora and supervised fine-tuning (SFT) on task-specific data.

Despite their widespread use, the relative effectiveness of these strategies remains unclear. Their impact depends on training scale, data composition, and optimization choices (Christophe et al., 2024; Lu et al., 2025), and even combined approaches yield inconsistent or statistically insignificant gains (Jeong et al., 2024a).

Most prior work fixes base model initialization, making it difficult to disentangle adaptation effects (Lu et al., 2025; Christophe et al., 2024). Evaluations are also predominantly English-centric, and largely focus on MCQA, limiting interpretation and generalization, especially given recent evidence of memorization in medical LLMs (Li et al., 2025).

More broadly, this work is motivated by a practical constraint often overlooked in the literature. In many real-world settings, especially for non-English medical NLP, both domain-specific data and computational resources are limited. As a result, the key question is not whether one strategy can theoretically outperform another, but how to allocate limited resources effectively. In this context, practitioners face a concrete and unresolved question: *given limited data and computational resources, which adaptation strategy should be prioritized?* Existing studies provide partial answers, but heterogeneous setups make it difficult to derive actionable guidelines.

To address these limitations, we conduct a controlled study of medical domain adaptation using French medical QA as a case study. We compare CPT, SFT, and their combination across model families and sizes while varying base initialization, and evaluate models in both French and English to isolate domain and cross-lingual effects.

We include OEQA as a complementary evaluation of generative behavior, but note that its assessment remains challenging; our conclusions are therefore primarily grounded in MCQA.

Our goal is to provide practical guidance on when and why CPT and SFT are effective under

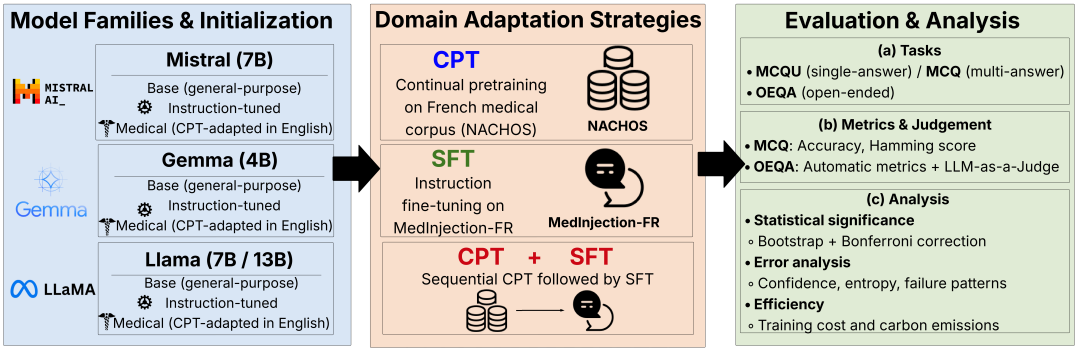

Figure 1: Overview of the experimental pipeline for evaluating medical domain adaptation strategies.

realistic constraints. Our study is guided by the following research questions:

- **RQ1:** *What are the performance and efficiency trade-offs between CPT and SFT across model families and sizes?*
- **RQ2:** *How does base model initialization influence the effectiveness of CPT and SFT for medical domain adaptation?*
- **RQ3:** *How does French medical adaptation affect cross-lingual transfer to English?*

Our contributions are: (i) we introduce a controlled and reproducible framework to compare medical domain adaptation strategies across model families, sizes, initialization types, and decoding settings; (ii) we provide a statistically grounded analysis of CPT and SFT for medical QA, covering performance trade-offs, error patterns, and cross-lingual transfer to English benchmarks. All resources are publicly available: `https://github.com/ikram28/MedAdapt`.

2 Related Work

Medical LLM adaptation primarily relies on CPT on domain-specific corpora and SFT on instruction–response data, both shown to support domain transfer (Gururangan et al., 2020; Gema et al., 2024). CPT has been adopted in models such as MediTron (Chen et al., 2023b), BioMistral (Labrak et al., 2024a), PMC-Llama (Wu et al., 2023), and MedGemma (Sellergren et al., 2025). However, recent analyses question the robustness and consistency of CPT gains under stricter evaluation protocols (Jeong et al., 2024a). In parallel, SFT-based models such as ChatDoctor (Li et al., 2023) and MedAlpaca (Han et al., 2023) report great task-level improvements, though evaluations remain largely in English.

Medical domain adaptation is further challenged in non-English settings due to limited domain-specific resources. Several multilingual medical LLMs have been proposed, including Medical mT5 (García-Ferrero et al., 2024), BiMediX (Pieri et al., 2024), Apollo (Wang et al., 2024a), and MMedLM (Qiu et al., 2024). However, these models are mostly evaluated on translated benchmarks, with limited validation on native-language medical tasks, leaving their language- and cultural-specificities underexplored. Evaluation practices also pose challenges. Widely used benchmarks such as PubMedQA (Jin et al., 2019), MedQA (Jin et al., 2019), and MedMCQA (Pal et al., 2022) primarily target English.

Beyond proposing individual models, recent work has compared adaptation strategies in controlled settings. Christophe et al. (2024) analyze CPT, SFT, and related techniques for clinical LLMs, finding that CPT alone yields limited gains but can amplify performance when combined with instruction tuning. Similarly, Lu et al. (2025) study CPT, SFT, and preference-based optimization across domains, highlighting complex interactions between adaptation methods. However, these studies focus on English and fix the base model initialization. In contrast, in this work, we systematically compare CPT, SFT, and their combination across multiple model families and initialization points for French medical QA, while also evaluating cross-lingual performance and analyzing adaptation behavior.

3 Experimental Framework

We propose a controlled experimental framework to evaluate medical domain adaptation strategies across architectures, initialization points, and task formats, as illustrated in Figure 1. Our setup explic-

itly varies (i) the base model and its prior training, (ii) the adaptation strategy, and (iii) the evaluation task and language in order to isolate the factors that drive adaptation effectiveness.

3.1 Base Models and Adaptation Approaches

Our study focuses on model families with three complementary initialization states: (i) a general-purpose base model, (ii) an instruction-tuned variant, and (iii) a medically adapted version obtained via CPT. This constraint is central to our experimental design, as it enables a controlled comparison that isolates the effect of adaptation strategy from that of the starting point. As a result, model selection is restricted to families providing these aligned variants, rather than to the most recent model releases.

We consider three model families spanning different sizes, pretraining regimes, and linguistic exposure. Specifically, we include Mistral-7B, Gemma-4B, and Llama models at the 7B and 13B scales. For Mistral-7B, we use Mistral-7B-v0.1 and its instruction-tuned version, and BioMistral-7B, a model adapted to the biomedical domain via CPT (Jiang et al., 2023; Labrak et al., 2024b). For Gemma, we rely on the Gemma-3-4B pretrained and instruction-tuned models, together with MedGemma-3-4B, which incorporates medical pretraining (Team et al., 2025; Sellergren et al., 2025). Finally, for Llama, we include both 7B and 13B variants, using the base and chat versions of Llama-2, as well as their medically adapted counterparts, MediTron-7B and MedLlama-13B (Touvron et al., 2023; Chen et al., 2023a; Wu et al., 2024).

These families differ not only in scale but also in pretraining data and exposure to French. Mistral and Gemma are explicitly multilingual, whereas Llama models are primarily English-centric, although exact language proportions are not disclosed. Except for MedGemma, whose medical pretraining corpus is not fully documented, all medical variants rely on PubMed Central as their primary biomedical source[1].

Across all model families and initialization points, we investigate three adaptation strategies: (i) CPT on domain-specific corpora, (ii) SFT on instruction-response pairs, and (iii) a sequential CPT+SFT pipeline.

[1] https://pmc.ncbi.nlm.nih.gov/

3.2 Training Data

CPT. We use NACHOS corpus (Labrak et al., 2023), an open-source French medical dataset comprising 4 GB of text collected from French medical websites; full details are provided in Appendix A.

SFT. We use the train and validation sets of the MedInjection-FR corpus (Belmadani et al., 2026b), which contains 543 505 instruction-response pairs. The dataset includes multiple-choice questions with a single **unique** correct answer (MCQU, ∼83%), **multiple** correct answers (MCQ, ∼6%), and OEQAs (∼11%). This mixture allows us to evaluate adaptation effects across both discriminative and generative medical reasoning tasks. Additional dataset details are provided in Appendix B.

3.3 Training Process

To explore the trade-off between computational cost and model plasticity, we adopt contrasting fine-tuning regimes for CPT and SFT. CPT is performed using full-parameter fine-tuning, while SFT relies on parameter-efficient adaptation. This choice is supported by preliminary experiments, as explained in Appendix E.

CPT. CPT is performed for three epochs following the setup of Labrak et al. (2024b). Full hyperparameter details are provided in Appendix C.

SFT. We employ DoRA (Weight-Decomposed Low-Rank Adaptation) (Mao et al., 2024), an extension of LoRA (Hu et al., 2022) that decouples magnitude and directional updates. We select DoRA after preliminary experiments, as detailed in Appendix E. SFT is run for ten epochs, with hyperparameters reported in Appendix D.

3.4 Evaluation Protocol

Benchmarks. We evaluate all models on MedInjection-FR test set, which consists of 14 533 native French medical examples and 13 293 translated examples derived from established English benchmarks. The test set covers MCQU, MCQ, and OEQA tasks, enabling evaluation of both answer selection and free-form answers. Benchmark sources and translation procedure are detailed in Appendix G.

Prompting Strategy. All evaluations are conducted in a zero-shot setting using greedy, deterministic decoding to ensure reproducibility. For MCQU and MCQ tasks, following Liang et al.

(2022); Beeching et al. (2023); Chen et al. (2023a), we restrict the output vocabulary to valid answer options to prevent hallucinated responses. To mitigate position bias, we randomly shuffle answer choices three times and report aggregated results, following best practices for MCQ evaluation (Pezeshkpour and Hruschka, 2024). Prompt templates are provided in Appendix H.

Evaluation Metrics. For MCQU, we report *Exact Match (EM)*, which measures the proportion of questions for which the predicted answer exactly matches the gold answer. For MCQ, we additionally report the *Hamming score*, which accounts for partial overlap between predicted and reference answer sets and is therefore more informative for multi-answer questions. Formal definitions of both metrics are provided in Appendix F.

For OEQA, we rely on both automatic text-based metrics and model-based judgments. We report BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and BERTScore (Zhang et al., 2019) as automatic baselines. Their reliability was assessed through agreement with senior physician annotations on a held-out subset of 500 OEQA instances in Belmadani et al. (2026a), where MedGemma-27B was identified as the most stable and best-performing LLM judge, and is therefore used in the present work.

Statistical Significance and Error Analysis. We assess statistical significance using a percentile bootstrap procedure with 10 000 resamples, following Jeong et al. (2024b). Differences between paired model configurations are considered significant when the associated two-sided p-value is below a predefined threshold α. To control for multiple comparisons, we apply the Bonferroni correction, yielding a corrected α as specified in Appendix J. In addition, we conduct an error analysis by examining output probabilities, confidence scores, and entropy, enabling us to characterize how CPT and SFT affect uncertainty and error patterns across different base model initializations.

4 Results and Discussion

4.1 MCQA Evaluation

Table 1 reports performance on MCQA across three model families (Gemma-4B, Mistral-7B, Llama-7B-13B), three initialization types (General, Instruct, Medical), and three adaptation strategies (CPT, SFT, CPT+SFT). Results are shown for both MCQs and MCQUs, using EM and Hamming scores for MCQs. All results reported in this table are obtained using constrained decoding. The corresponding results under greedy decoding are provided in Appendix I.

Effectiveness of Adaptation Strategy: A recurring pattern observed throughout the results is:

$$\text{BASE} \ll \text{CPT} < \text{SFT} \lesssim \text{CPT+SFT}$$

The strongest performance is most frequently achieved by the CPT+SFT adaptation. Across model families and initialization types, CPT+SFT yields the highest scores in aggregated EM as well as in MCQ and MCQU EM more often than any other strategy.

However, a closer inspection of the results indicates that the gains brought by CPT+SFT over SFT alone are generally limited. When CPT+SFT attains the highest score, the margin over SFT rarely exceeds 1.3 points. In contrast, in configurations where SFT outperforms CPT+SFT, the performance gap is larger. For example, on Llama-7B Instruct, SFT exceeds CPT+SFT by 3.12 points, and a similar pattern is observed for Mistral-7B Instruct, with a gap of 1.44 points in favor of SFT.

Furthermore, the statistical analysis reported in Appendix J shows that, when comparing each adapted model to its corresponding base model, the observed improvements are not always statistically significant. In particular, for Gemma Instruct, neither SFT nor CPT+SFT yields statistically significant gains over the base model. Likewise, for Llama-7B Instruct, the improvement brought by CPT+SFT is not statistically significant. These constitute the only cases in which the improvements of SFT or CPT+SFT over the base model fail to reach statistical significance. Consequently, although CPT+SFT most frequently ranks first, its advantage over SFT is not consistently substantial.

By contrast, CPT alone exhibits less stable behavior. Although it can improve performance in some rare cases, it can also occasionally degrade performance compared to the base model. Moreover, it is the strategy that most often fails to produce statistically significant improvements over the base. This is the case for 8 models: MedGemma, all Llama-13B variants, Llama-7B GENERAL and INSTRUCT, and Mistral-7B GENERAL and MEDICAL. This suggests that representation-level domain adaptation is most effective when paired with task-specific supervision.

Model Type	Strategy	MCQ		MCQU	Aggregation	OEQA

Table 1: Constrained decoding results (%) for MCQ/MCQU and OEQA. Aggregation corresponds to average EM over MCQ and MCQU. **Bold** denotes the best strategy, and underlining the best initialization.

Overall, while CPT+SFT ranks first most often, its limited and inconsistent gains over SFT, together with a substantially higher computational cost (see Appendix O), make SFT a strong default for medical MCQA. For example, on 7B models, CPT+SFT costs over $1 500 versus $360 for SFT, with a fourfold increase in carbon emissions.

Impact of Model Initialization: The impact of model initialization (General / Instruct / Medical) varies across MCQA metrics and question formats. Considering the overall best scores across all model families, instruction-tuned models dominate the most demanding EM settings: the highest MCQ EM and aggregated MCQA EM scores are both achieved by Llama-13B Instruct, while the best MCQ Hamming score is obtained by Gemma-4B Instruct. In contrast, the best MCQU EM score is achieved by a general Mistral model.

At the family level, the patterns differ. For MCQ EM, the best score within each model family is always obtained by an instruction-tuned variant, confirming that instruction alignment is particularly beneficial for exact multi-label prediction; this ad-

vantage is further supported by statistically significant gains when compared to general or medical initializations (see Appendix J). For MCQ Hamming, results are more balanced, with the best scores split across initialization types (two instruction-tuned, one general, and one medical).

For MCQU EM, general models most frequently achieve the best performance (three cases), followed by medical models, while instruction-tuned models do not dominate. This indicates that when only a single answer must be selected, performance is driven primarily by answer plausibility ranking, favoring strong language modeling and domain knowledge, while explicit instruction alignment, which mainly benefits structured or multi-label outputs, provides less advantage. Finally, for the aggregated MCQA score, no single initialization consistently dominates: instruction-tuned and general models each obtain the best result in two configurations (with ties between them), while medical models lead in one case, and differences across initializations are often not statistically significant.

4.2 OEQA Evaluation

The right side of Table 1 reports OEQA across model families using ROUGE-L, BERTScore, and LLM-as-a-Judge. We additionally report BLEU and METEOR in Appendix I, as they reflect similar information to ROUGE-L. Overall, absolute scores remain moderate, reflecting the difficulty of evaluating free-form answer generation. ROUGE-L scores should be interpreted with caution, as they measure surface-level lexical overlap and penalize semantically correct answers that differ in formulation (Yim et al., 2025; Zhu et al., 2025).

Moreover, OEQA represents only 11% of the training data, resulting in a strongly imbalanced supervision signal. Models are therefore adapted to generate short, structured outputs (answer letters in MCQA), which limits OEQA performance.

Effect of Adaptation Strategy: Across model families, SFT often degrades ROUGE-L and BERTScore-F1 compared to base or CPT-adapted models, particularly for instruction-tuned and medical variants. This suggests that SFT can overly constrain generation, reducing lexical diversity and semantic overlap in an open-ended setting.

By contrast, CPT is the most consistently beneficial strategy for OEQA. CPT improves ROUGE-L and BERTScore-F1 across most general, instruct, and medical models, with especially strong gains for Mistral and Llama families. These results suggest that domain-adaptive language modeling supports better medical generation than instruction-level supervision alone. Combining CPT with SFT rarely outperforms CPT alone and often leads to intermediate or degraded performance, reflecting the same instability observed in MCQA, but with more pronounced negative effects in OEQA.

In contrast to overlap-based metrics, LLM-as-a-Judge favors CPT+SFT in half of the configurations (6/12), compared to three cases each for the base and CPT models. Gains are most pronounced for Llama-7B, where CPT+SFT consistently outperforms SFT across initializations, and for medical models, where it yields the best or near-best qualitative scores. However, despite these trends, statistically significant improvements over the base model are rare: CPT is significant in only three cases, SFT in two (all involving smaller 4B models), and CPT+SFT never yields statistically significant gains over the base model in OEQA.

Effect of Model Initialization. Initialization effects on OEQA depend strongly on the evaluation metric. For overlap-based metrics, no initialization consistently dominates: ROUGE-L is split between general and instruction-tuned models, while medical models never achieve the top score; BERTScore-F1 is mostly dominated by instruction-tuned models, with a single exception (Gemma).

LLM-as-a-Judge reveals clearer and statistically grounded patterns. When differences are significant, medical models are consistently outperformed across families, particularly under SFT and CPT (Table 9). Comparisons between instruction-tuned and general models are mixed and direction-dependent, with some significant gains under SFT and CPT (notably for Mistral and Llama), but these effects largely disappear under CPT+SFT.

Overall, medical initialization alone does not improve OEQA, while instruction-tuned initialization yields more reliable, yet limited, gains when significant.

5 Cross-Lingual Transfer After French Medical Adaptation

To analyze whether models perform better in English prior to adaptation and how cross-lingual adaptation affects performance, we compute the EM accuracy difference for MCQU benchmarks as the score on French translations minus the score on the corresponding native English datasets. Figure 2

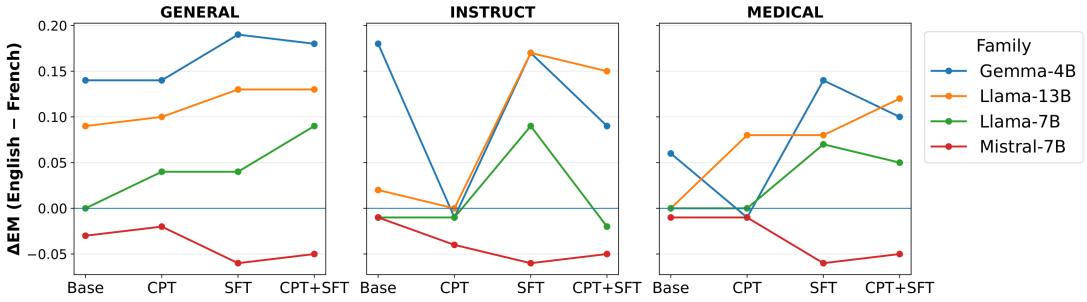

Figure 2: Difference in EM accuracy (ΔEM) between native English MCQU test benchmarks and their French translations across model families and adaptation strategies (constrained decoding).

reports averaged results across datasets using constrained decoding; full results for both greedy and constrained decoding are provided in Appendix M.

For the Mistral family, base models consistently perform better on the translated French benchmarks than on the original English data. This trend persists after adaptation with CPT, SFT, and CPT+SFT, with French performance systematically exceeding English, the differences being statistically significant (Table 13).

In contrast, Gemma and Llama families show higher performance on native English benchmarks at the base level, and this advantage remains after adaptation on French data. Moreover, adaptation gains are often larger in English than in French (Table 12), despite all adaptation data being in French.

These results suggest that Mistral models encode French more effectively, whereas Gemma and Llama have stronger English representations. Notably, the improvements observed in both languages indicate effective cross-lingual transfer of medical knowledge: adapting with French medical data improves performance on the original English benchmarks, sometimes more than on their French translations. This supports the complementarity of multilingual medical data, in line with Wang et al. (2024a).

A salient exception is Llama-7B: before adaptation, the base model shows slightly higher performance on French translations than on English, but this difference is not statistically significant (Table 13). After adaptation, English performance surpasses French, suggesting that adaptation amplifies the model's dominant English representations.

6 Effect of Translated Benchmarks on Performance and Confidence

We compare model behavior on a native benchmark, MediQAl (Bazoge, 2025), and a translated

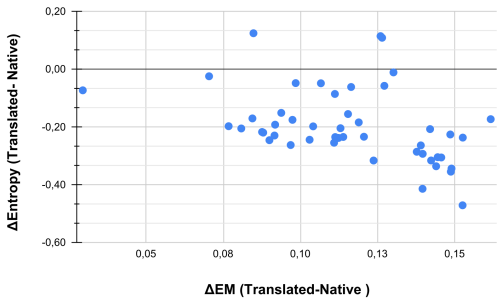

Figure 3: Relationship between accuracy gain (ΔEM) and change in predictive entropy ($\Delta Entropy$) when moving from the translated to native benchmarks. Each point corresponds to a model configuration.

benchmark, MedMCQA (Pal et al., 2022), using accuracy and confidence-based metrics. Both benchmarks consist of MCQUs of comparable size, for fair comparison. Although instances are not shared, consistent differences across models are observed.

As shown in Figure 3, all models achieve higher EM accuracy on the translated benchmark. This gain is systematically accompanied by a reduction in predictive entropy, indicating that translated benchmarks induce more confident and less uncertain predictions. The concentration of models in the bottom-right quadrant suggests that translated benchmarks operate in a different evaluation regime, characterized by both higher performance and reduced uncertainty.

Figure 5 further reveals that accuracy gains are often associated with increased confidence in incorrect predictions. Most models exhibit positive shifts in confidence even when wrong, indicating a systematic overconfidence effect induced by the translated benchmark.

Overall, these results show that translated benchmarks are not neutral substitutes for native ones: they tend to inflate performance while also altering

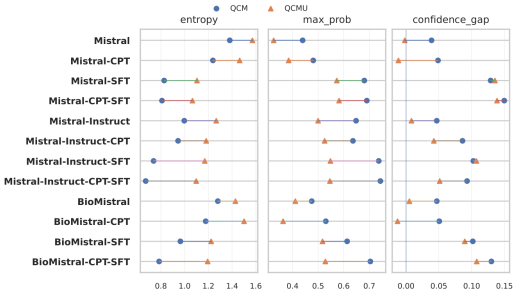

Figure 4: Probability-level metrics for MCQ and MCQU across Mistral variants.

model confidence calibration, potentially leading to over-optimistic evaluations.

7 Error Analysis

7.1 Probability-Level Analysis of MCQA

To explain why MCQ is harder than MCQU, we analyze class probability distributions from the Mistral family, selected for its high variance across models and adaptation settings. For each item, we compute entropy, maximum probability, and a confidence gap measuring gold/non-gold separation (mean gold vs. non-gold probability in MCQ; margin to the second-best option in MCQU). We also report a near-miss rate, defined as cases where all gold answers are ranked in the top-k but the predicted set is incorrect (Figure 4, Appendix K).

Across all variants, MCQ predictions are not more uncertain than MCQU: MCQ exhibits lower entropy and higher maximum probability, indicating confident local rankings. The confidence gap is consistently positive and increases with adaptation, but remains insufficient for exact multi-label generation under greedy decoding, leading to omissions or over-generation.

Adaptation clarifies this effect: SFT strongly improves MCQU, while gains on MCQ remain limited. CPT+SFT primarily increases ranking confidence rather than exact set match, yielding larger confidence gaps without reducing near-miss rates.

7.2 Verbosity Bias in OEQA

To better understand the differences observed between overlap-based metrics and LLM-as-a-Judge evaluations in OEQA, we analyze the length of generated answers across models. The results are reported in Appendix L. We find that CPT-adapted models systematically produce longer responses, with higher mean and median word counts across all model families. This increased verbosity provides a plausible explanation for their strong performance on ROUGE-L and BERTScore-F1, which reward lexical recall and content coverage.

In contrast, instruction-tuned models generate substantially shorter and more controlled answers, particularly under SFT, often producing concise responses with low variance. While this behavior negatively impacts overlap-based metrics, it aligns with higher LLM-as-a-Judge scores, suggesting that concise answers are preferred under LLM evaluation. Finally, SFT exhibits unstable behavior in OEQA, leading either to excessively short outputs or overly long responses depending on model initialization. Overall, these results indicate that OEQA performance is strongly influenced by length biases, and that improvements in automatic metrics may partially reflect increased verbosity rather than improved answer quality.

8 Conclusion

We presented a controlled and statistically grounded study of medical domain adaptation for LLMs using French medical QA, isolating the effects of model initialization, adaptation strategy, decoding, and evaluation. Our results show that adaptation effectiveness is task-dependent and that stronger strategies are not always more cost-effective. We therefore distill practical guidelines for selecting adaptation strategies based on data availability and computational constraints. Given the limited reliability of current OEQA metrics and the small proportion of OEQA supervision, our recommendations primarily emphasize MCQA, with OEQA trends interpreted cautiously.

Unlabeled data only. When only unlabeled medical text is available, CPT yields modest and unstable gains for MCQA and should not be used in isolation. Its benefits mainly appear on OEQA overlap-based metrics, which are sensitive to verbosity and should be interpreted with caution.

Labeled data only. With labeled QA data, SFT provides the best performance–efficiency trade-off for MCQA across all model families. It frequently matches or exceeds CPT+SFT while requiring substantially fewer computational resources, making it the most practical default in this setting.

Labeled and unlabeled data. When both data types are available, CPT+SFT most often achieves the highest MCQA scores, but improvements over

SFT are typically small and not consistently statistically significant. Consequently, CPT+SFT is justified only when maximal performance outweighs computational cost.

Initialization and compute considerations. Instruction-tuned models constitute the strongest baseline for French medical MCQA. Medical initialization alone does not reliably improve downstream performance. From a resource perspective, parameter-efficient SFT is by far the most cost-effective strategy, whereas CPT incurs high computational and environmental costs for limited MCQA gains, and CPT+SFT compounds these costs for marginal improvements.

Evaluation and transfer considerations. Finally, we observe strong evaluation effects: adaptation on French medical data transfers to English benchmarks, translated datasets inflate both accuracy and confidence, and OEQA metrics are sensitive to verbosity. These findings highlight the need for task-aware adaptation choices and cautious metric interpretation in medical LLM evaluation.

9 Limitations

Our evaluation of adaptation strategies faces several limitations. First, we perform an exploratory contamination study to assess possible exposure to NACHOS during pretraining (Appendix P). Although no direct evidence of memorization is observed, likelihood-based tests remain inconclusive due to the lack of a reliable non-member biomedical control corpus, requiring the use of synthetic controls. We therefore treat these results as indicative only and avoid causal conclusions about pretraining inclusion.

Second, our evaluation of OEQA relies on overlap-based metrics, BERTScore, and LLM-as-a-Judge. While these measures capture complementary aspects of answer quality, they do not fully characterize semantic equivalence, clinical correctness, or reasoning validity, and may therefore overlook qualitative differences between correct answers (Yim et al., 2025; Zhu et al., 2025).

Third, while we demonstrate the efficiency of SFT compared to CPT in terms of computational resources, our analysis does not account for the human effort required to create high-quality instruction-tuning datasets. This consideration is particularly relevant for low-resource settings where creating domain-specific instruction data may be costly.

Fourth, we do not include few-shot prompting as an evaluation setting. Our objective is to isolate the effects of parameter-level adaptation strategies under controlled and reproducible conditions. Few-shot prompting introduces additional sources of variance related to example selection, ordering, and prompt design, which would complicate statistical comparison and obscure the interpretation of adaptation gains. Moreover, few-shot prompting assumes access to curated task-specific examples at inference time, which may be unrealistic in medical deployment scenarios. For these reasons, we focus on zero-shot evaluation to ensure fair and stable comparisons across adaptation strategies.

Finally, our study focuses exclusively on CPT and SFT. We do not explore reinforcement learning–based adaptation strategies, such as preference optimization or reward-driven fine-tuning, which may better align models with clinical judgment or evaluation criteria. Investigating how such methods interact with CPT and SFT, particularly under multilingual and domain-specific constraints, constitutes an important direction for future work.

In addition, our findings about the effectiveness of adaptation strategies are specific to the medical domain and French language. The generalizability of these results to other domains or languages, particularly those with different resource constraints or linguistic characteristics, requires further investigation.

10 Ethical Considerations

This work is intended for research purposes only and not for direct clinical use. All experiments rely on publicly available biomedical datasets without identifiable patient data. We acknowledge that medical LLMs may generate inaccurate or overconfident outputs, particularly in open-ended settings, and therefore include physician-based evaluation protocols. We also report computational cost and estimated carbon emissions for transparency.

A CPT Training Corpus : NACHOS Description

The NACHOS corpus is a French medical open-source dataset compiled through extensive web crawling and text collection. While the full corpus spans 7.4 GB of data and contains over one billion words sourced from 24 French-speaking high-quality websites (Labrak et al., 2023), we use in this work its *small* variant, NACHOS$_{small}$. This version consists of approximately 4 GB of data and was obtained by shuffling the full corpus and randomly selecting 25.3 million sentences to ensure homogeneous coverage of data sources.

Note: Full details of the corpus compilation and processing are available in the original paper (Labrak et al., 2023).

A.1 Corpus Composition

The NACHOS corpus encompasses a diverse range of medical textual sources, including:

- Descriptions of diseases and conditions
- Treatment and medication information
- General health-related advice
- Official scientific meeting reports
- Anonymized clinical cases
- Scientific literature
- Theses
- French translation pairs
- University health courses

A.2 Data Sources

The corpus integrates data from multiple sources, with the most significant contributions coming from:

- HAL (638,508,261 words)
- Haute Autorité de Santé (HAS) (113,394,539 words)
- Drug leaflets (74,770,229 words)
- Medical Websites Scraping (60,561,495 words)
- ANSES SAISINE (51,372,932 words)
- Public Drug Database (BDPM) (48,302,695 words)

A.3 Corpus Preparation

The researchers employed several preprocessing steps:

1. Text collection through web scraping, raw textual sources, and optical character recognition (OCR)
2. Sentence splitting using heuristic methods
3. Aggressive filtering to remove short or low-quality sentences
4. Language classification using a custom classifier trained on multilingual corpora

B SFT Training Corpus : MedInjection-Fr Description

B.1 Overview

MedInjection-FR (Belmadani et al., 2026b) is a large-scale French biomedical instruction dataset composed of native, translated, and synthetic instruction–response pairs. The dataset comprises 571 436 examples spanning MCQUs, MCQs, and OEQAs.

B.2 Data Composition

The dataset consists of 77 247 native examples, 417 674 translated examples, and 76 506 synthetic examples. All data are formatted as instruction–response pairs and normalized to a unified schema, ensuring consistency across heterogeneous sources and supervision types.

B.3 Quality Control for Translated Data

The translated subset was obtained by translating English biomedical instruction datasets into French using two LLMs: `GPT-4o-mini` (Hurst et al., 2024) and `Gemini 2.0 Flash` [2]. Translation quality was evaluated on the WMT 2024 Biomedical Translation Task benchmark (Neves et al., 2024) using BLEU and COMET metrics. `GPT-4o-mini` achieved a BLEU score of 51.01 and a COMET score of 0.8751, while `Gemini 2.0 Flash` achieved a BLEU score of 53.72 and a COMET score of 0.8783. These results are comparable to the best-performing system reported in the shared task (BLEU 53.54, COMET 0.8760), suggesting high semantic fidelity and robust preservation of biomedical terminology in the translated subset.

[2] https://cloud.google.com/vertex-ai/generative-ai/docs/models/gemini/2-0-flash

B.4 Quality Control for Synthetic Data

The synthetic subset was generated using `GPT-4o` from source documents including clinical cases and biomedical abstracts. Each source document was used to generate multiple instructional tasks covering a broad range of biomedical reasoning, such as clinical summarization, factual QA, diagnostic reasoning, treatment suggestion, and classification.

To control generation quality, each synthetic instruction–response pair was evaluated using four independent large language models acting as automatic judges: `GPT-4.1-mini` [3], `Gemini 2.0 Flash`, `MedGemma-27B` (Sellergren et al., 2025), and `Qwen3-Next-80B-A3B-Instruct` (Team, 2025). For MCQAs, evaluators assigned scores on a three-point scale reflecting answer correctness and contextual coherence. For OEQAs, a five-point scale was used to capture varying degrees of factual accuracy and completeness. Only examples meeting predefined minimum quality thresholds across evaluators were retained in the final dataset.

C CPT hyperparameters

Parameter	Value
Learning rate	2e-05 (1e-04 for gemma family)
Train batch size	2 (4 for gema family)
Seed	42
Gradient accumulation steps	2 (16 for gemma family)
Optimizer	AdamW
Weight Decay	0.01
Scheduler	Cosine
Number of epochs	3

Table 2: Hyperparameters used in CPT training

D SFT hyperparameters

Parameter	Value
Rank	16
LoRA Aplha	16
LoRA Dropout	0.05
use_dora	True
Learning rate	2e-05 (1e-04 for gemma family)
Train batch size	4
Evaluation batch size	train_batch_size * 2
Seed	42
WarmUp_ratio	0.05
Gradient accumulation steps	8
Optimizer	AdamW
Scheduler	Cosine
Number of epochs	10
Target Modules	QKVOGUD

Table 3: Hyperparameters used in SFT training

[3] https://openai.com/index/gpt-4-1/

E Preliminary Comparison of Full Fine-Tuning and PEFT

To justify our choice of parameter-efficient fine-tuning (PEFT) for SFT, we conducted preliminary experiments comparing full fine-tuning with several PEFT methods on the FrenchMedMCQA dataset (Labrak et al., 2022).

We evaluated LoRA (Hu et al., 2022), DoRA (Mao et al., 2024), and VeRA (Kopiczko et al., 2024) against full-parameter fine-tuning using identical training configurations. Results are reported in Table 4.

We observe that PEFT methods, particularly DoRA, outperform full fine-tuning while requiring significantly fewer trainable parameters. In addition, full fine-tuning exhibited higher overfitting tendencies, with faster training loss convergence but weaker generalization performance on validation data.

These results support the use of parameter-efficient methods for SFT in our main experiments, as they provide a better trade-off between performance, efficiency, and generalization.

F Evaluation Metrics

We provide here the formal definitions of the evaluation metrics used for MCQU and MCQ evaluation.

Exact Match (EM). Exact Match measures the proportion of predictions that exactly match the gold answer:

$$\text{EM} = \frac{1}{N}\sum_{i=1}^{N}[\hat{y}_i = y_i],$$

where N denotes the number of questions, y_i the gold answer, $\hat{y}_i$ the model prediction, and $[\cdot]$ is the indicator function.

Hamming Score. For multi-answer MCQ, we additionally report the Hamming score, which captures partial agreement between predicted and reference label sets:

$$\text{Hamming Score} = \frac{1}{N}\sum_{i=1}^{N}\frac{|y_i \cap \hat{y}_i|}{|y_i \cup \hat{y}_i|}.$$

This metric rewards partial correctness and is therefore better suited for evaluating multi-label predictions than Exact Match alone.

	LoRA	DoRA	VeRA	Full FT
Exact Match	0.2211	**0.2435**	0.1153	0.1121
Hamming Distance	0.4325	**0.4627**	0.3482	0.3143
Trainable Params (%)	0.583	0.602	0.0037	100

Table 4: Comparison of full fine-tuning and parameter-efficient methods on FrenchMedMCQA.

G Evaluation Benchmarks

The adapted models are evaluated against their corresponding base models using benchmark datasets drawn from the *test split* of MedInjection-FR. The evaluation suite includes both *native French* benchmarks and *translated English* benchmarks. For the translated benchmarks, English test sets were translated into French following the procedure described in section B.3.

The benchmarks cover multiple task formats, including MCQU, MCQ and OEQA. This setup enables a controlled comparison of adaptation effects across both discriminative and generative biomedical reasoning tasks. Table 5 summarizes the datasets used for evaluation and their respective sizes.

Dataset	# Items	Task
NATIVE		
	3 384	MCQ
MediQAl (Bazoge, 2025)	4 343	MCQU
	4 969	OEQA
FrenchMedMCQA (Labrak et al., 2022)	622	MCQ
mlabonne/medical-mcqa-fr[4]	150	MCQ
mlabonne/medical-cases-fr[5]	352	MCQ
FrBMedQA (Kaddari and Bouchentouf, 2022)	187	MCQU
S-Editions[6]	343	OEQA
	183	MCQ
TRANSLATED		
MedQA_4options (Jin et al., 2021)	1 273	MCQU
MedQA_5options (Jin et al., 2021)	1 273	MCQU
PubMedQA (Jin et al., 2019)	500	MCQU
MedMCQA (Pal et al., 2022)	4 183	MCQU
MMLU (Hendrycks et al., 2021)	1 080	MCQU
K-QA (Manes et al., 2024)	201	OEQA
MMLU-PRO (Wang et al., 2024b)	2 333	MCQU
MedXpertQA (Zuo et al., 2025)	2 450	MCQU

Table 5: Evaluation benchmarks used to compare adapted models with their base counterparts. All datasets correspond to the test split of MedInjection-FR.

H Prompt Templates

Overview. We use a unified instruction format across all task types, both for supervised fine-tuning and for zero-shot evaluation. When available, we rely on the native chat templates provided by instruction-tuned models; otherwise, prompts are formatted as plain-text instruction–response pairs.

Shared Structure. All prompts begin with a high-level medical instruction, optionally followed by a contextual passage. The core components are:

1. an instruction describing the task,
2. the question (and answer options when applicable),
3. an optional context section, and
4. a response header indicating where the model output should begin.

Task-Specific Constraints. The only variation across task types lies in the expected response format, which is explicitly stated in the instruction. Table 6 summarizes the templates used for each task.

Canonical Prompt Format. The following abstract template illustrates the prompt structure shared across all tasks:

System prompt (training and evaluation) for MCQ

```
Lire l'instruction médicale suivante et
    fournir une réponse adaptée à la
    situation décrite.
Répondre uniquement avec la lettre
    correspondant à la ou les bonnes
    réponses séparées par des virgules.
    Exemple : A, C, D.
```

System prompt (training and evaluation) for MCQU

```
Lire l'instruction médicale suivante et
    fournir une réponse adaptée à la
    situation décrite.
Répondre uniquement avec la lettre
    correspondant à la bonne réponse.
    Exemple : A.
```

Task	Instruction Constraint	Expected Output
MCQU	Respond only with the letter corresponding to the single correct answer.	Single letter (e.g., `A`)
MCQ	Respond only with the letters corresponding to all correct answers, separated by commas.	Comma-separated letters (e.g., `A, C, D`)
OEQA	Provide a free-form medical answer based on the instruction and context.	Unconstrained text

Table 6: Summary of task-specific prompt templates and output constraints.

System prompt (training and evaluation) for OEQA

```
Lire l'instruction médicale suivante et
    fournir une réponse adaptée à la
    situation décrite.
```

User prompt (task-dependent)

```
### Instruction:
[Question (+ options for MCQ tasks)]

### Contexte:
[Context, if available]

### Réponse:
```

Chat-Based Formatting. For instruction-tuned models providing an explicit chat interface, the same content is mapped to role-based messages as follows:

- **System**: high-level medical instruction (shared across tasks),
- **User**: task instruction, question, and optional context,
- **Assistant**: model-generated answer.

This formulation ensures consistent supervision and evaluation across models with different input formatting requirements.

I MCQA and OEQA Results

I.1 MCQA Greedy Decoding

Table 7 reports performance on MCQA across the studied model families (Gemma-4B, Mistral-7B, Llama-7B, and Llama-13B), three initialization types (General, Instruct, Medical), and four adaptation strategies (Base, CPT, SFT, CPT+SFT). Results are shown for both standard multiple-answer MCQs (MCQ) and single-answer MCQs (MCQU), using Exact Match (EM), Hamming score for MCQ, and aggregated EM. The reported results here are obtained using greedy decoding.

Effectiveness of Adaptation Strategy: Under greedy decoding, SFT clearly dominates all other adaptation strategies across MCQ, MCQU, and aggregated metrics. Unlike constrained decoding, where CPT+SFT often ranks first, greedy decoding exposes a much sharper separation between strategies:

$$\text{BASE} \ll \text{CPT} \ll \text{CPT+SFT} < \text{SFT}$$

Across nearly all model families and initializations, SFT yields the highest MCQ EM, MCQ Hamming, MCQU EM, and aggregated EM. This trend is particularly strong for instruction-tuned models (Mistral, Llama-7B, Llama-13B), where SFT consistently delivers large absolute gains, often by wide margins. As in the constrained decoding setting, when CPT+SFT outperforms SFT, the performance gap is generally smaller than in configurations where SFT outperforms CPT+SFT.

CPT alone remains unstable under greedy decoding. While it sometimes improves over the base model, it frequently underperforms SFT and can even degrade MCQU and aggregated scores. Importantly, CPT+SFT does not systematically improve over SFT in greedy decoding and often performs worse, indicating that the benefits of CPT are largely redundant once task supervision is introduced and decoding constraints are removed.

Overall, greedy decoding amplifies the advantages of task-aligned supervision, making SFT the best adaptation strategy when decoding is unconstrained.

Impact of Model Initialization: Model initialization plays a stronger and more consistent role under greedy decoding than under constrained decoding. Across all families and metrics, instruction-tuned models dominate. General models benefit from SFT but remain consistently below instruction-tuned counterparts. Medical models, while improving with SFT, never achieve the best

Model Type	Strategy	MCQ		MCQU	Aggregation	OEQA	
		EM	Hamming	EM	EM	*BLEU*	*METEOR*

Table 7: Greedy decoding results for MCQ and MCQU and BLEU/METEOR scores for OEQA across model families and adaptation strategies. **Bold** denotes the best strategy and underlining the best initialization.

greedy decoding performance, confirming that domain pretraining alone is insufficient without strong instruction alignment.

This contrasts with constrained decoding, where general and medical models occasionally remain competitive. Under greedy decoding, instruction tuning becomes a necessary condition for strong performance.

MCQA Greedy Decoding Guidelines: For greedy decoding in medical MCQA, the optimal configuration is to start from an instruction-tuned model and apply SFT only. CPT and CPT+SFT offer no consistent benefit in this setting and can be safely avoided unless constrained decoding is explicitly required.

I.2 OEQA Overlap-based Evaluation

The right part of Table 7 reports the overlap-based metrics BLEU and METEOR. Both metrics exhibit trends consistent with ROUGE-L, with improvements primarily driven by CPT. In a few isolated cases, CPT+SFT yields additional gains on METEOR, but with small differences with when compared with CPT. Regarding model initialization, BLEU and METEOR consistently favor instruction-tuned models as the strongest starting point.

J Statistical Significance

We assess whether observed differences between adaptation strategies and initialization choices are statistically significant using paired bootstrap significance testing. For each comparison, we compute the per-instance score difference (EM for MCQ/MCQU; judge-based correctness for OEQA) and report a two-sided p-value (`p_two_sided`). Statistical significance is determined by comparing this p-value against a predefined threshold α. We report results using a Bonferroni-corrected threshold to control for multiple comparisons.

For comparisons between adaptation strategies within a model family, we perform 12 pairwise tests per family, yielding a corrected threshold of $\alpha_{\text{Bonferroni}} = 0.05/12$. For comparisons between model initialization types under a fixed adaptation strategy, we perform 9 pairwise tests per family, yielding $\alpha_{\text{Bonferroni}} = 0.05/9$. The applied threshold (`alpha_Bonferoni`) and the resulting significance decision (`significant_Bonferroni`) are reported explicitly in Tables 8 and 9.

We define the mean difference as $\Delta = \text{score}(\texttt{model_a}) - \text{score}(\texttt{model_b})$ (not shown in the tables). Therefore, if the confidence interval is entirely above zero, `model_a` performs better; if it is entirely below zero, `model_b` performs better. A comparison is considered statistically significant if the corrected decision is TRUE.

J.1 Interpretation of comparison IDs

Each row in Tables 8 and 9 corresponds to a specific pairwise comparison between two models (`model_a` vs. `model_b`). The `id` field encodes the purpose of the comparison: (i) **IDs A–C** compare models *within the same model type* (GENERAL, INSTRUCT, or MEDICAL) in order to quantify the effect of adaptation strategies (CPT, SFT, CPT+SFT) relative to a fixed initialization. (ii) **IDs D–F** compare models *across model types* under a fixed adaptation strategy, in order to identify the most effective initialization point (GENERAL vs. INSTRUCT vs. MEDICAL) for downstream adaptation.

J.2 Decoding conditions

For MCQ/MCQU, Table 8 reports significance results separately for greedy and constrained decoding. For OEQA, Table 9 reports strategy-level comparisons under the evaluation setting used for the main experiments.

K Near-Miss Rates in MCQA

Model	MCQ	MCQU
Mistral	0.203	0.202
Mistral-CPT	0.212	0.203
Mistral-SFT	0.234	0.204
Mistral-CPT-SFT	0.256	0.203
Mistral-Instruct	0.173	0.202
Mistral-Instruct-CPT	0.205	0.202
Mistral-Instruct-SFT	0.174	0.206
Mistral-Instruct-CPT-SFT	0.221	0.192
BioMistral	0.181	0.205
BioMistral-CPT	0.195	0.201
BioMistral-SFT	0.220	0.211
BioMistral-CPT-SFT	0.234	0.204

Table 10: Near-miss rates for MCQ and MCQU across Mistral variants. A near-miss corresponds to cases where all gold answers are ranked within the top-k options but the generated answer does not match the gold label(s). Near-miss rates remain stable across model families and adaptation strategies, indicating that improvements in confidence and ranking do not directly translate into exact prediction.

To better characterize model behavior beyond EM accuracy in MCQA, we analyze *near-miss* predictions. Table 10 shows the near-miss rates obtained

	id	strategy	model_a	model_b	Decoding type	ci95_low	ci95_high	p_two_sided	alpha_Bonferoni	significant_Bonferroni

Table 8: Significance testing for MCQ/MCQU comparisons. reported separately for greedy and constrained decoding. Each row reports a paired bootstrap test between `model_a` and `model_b`. including the 95% confidence interval of the mean EM difference. the two-sided p-value. and the Bonferroni-adjusted threshold with the resulting decision. IDs A–C compare adaptation strategies within the same model type; IDs D–F compare model initializations across types.

	id	strategy	model_a	model_b	ci95_low	ci95_high	p_two_sided	alpha_Bonferoni	significant_Bonferroni

Table 9: Significance testing for OEQA comparisons. Each row reports a paired bootstrap test between `model_a` and `model_b`, including the 95% confidence interval of the mean difference (`ci95_low`, `ci95_high`), the two-sided p-value, and the Bonferroni-adjusted threshold (`alpha_Bonferoni`) with the resulting decision (`significant_Bonferroni`). IDs A–C compare adaptation strategies within the same model type; IDs D–F compare model initializations across types.

for MCQ and MCQU across different Mistral-based model variants and adaptation strategies.

L OEQA Evaluation: Verbosity Bias

To investigate verbosity bias in OEQA, we compute descriptive statistics of generated answer lengths across all models. Table 11 reports mean, median, and standard deviation of word and character counts over greedy OEQA outputs.

M English vs. French Benchmarks: Full Numeric Results

The main paper reports averaged results using *constrained decoding* (Figure 2). Table 12 provides the complete *numeric* EM results for both *greedy* and *constrained* decoding on the native English MCQU benchmarks (MCQU-EN) and their French translations (MCQU-FR).

M.1 Greedy decoding analysis

The greedy decoding results reported in Table 12 exhibit the same overall tendencies as those observed under constrained decoding in section 5. For the Mistral family, greedy decoding consistently yields higher performance on the French translations than on the original English benchmarks, both before and after adaptation. Conversely, Gemma and Llama models generally perform better on native English benchmarks under greedy decoding, and this advantage is preserved after French medical adaptation.

As with constrained decoding, adaptation on French medical data improves performance in both languages under greedy decoding, indicating effective cross-lingual transfer. While absolute EM scores differ between decoding strategies, greedy decoding generally producing lower scores, the relative ordering between English and French benchmarks and the direction of adaptation effects remain consistent. These results suggest that the cross-lingual patterns reported in the main paper are robust to the choice of decoding strategy.

M.2 Significance testing (English vs. French)

To assess whether the English–French performance gaps are statistically significant, we perform paired significance testing *separately for each model configuration*, i.e., for each combination of (model family/type, adaptation strategy, decoding type). For each configuration, we compute the per-item EM difference between MCQU-EN and MCQU-FR on matched translated instances, and estimate a 95% confidence interval for the mean difference together with a two-sided p-value. Because each test compares a model strictly with itself across languages and each English–French pair is independent of the others, we do not apply a Bonferroni correction. Table 13 reports the resulting confidence intervals and significance decisions.

N Effect of Translated Benchmarks on Performance and Confidence

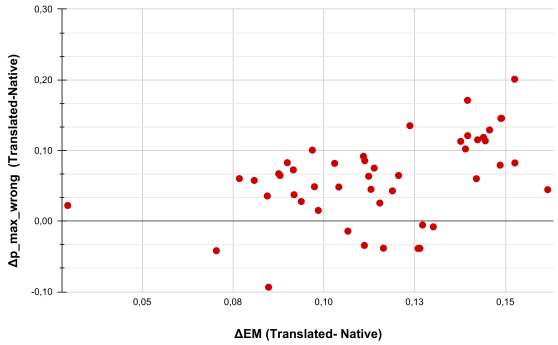

Figure 5: Relationship between accuracy gain (ΔEM) and change in confidence on incorrect predictions ($\Delta p_{\max,\text{wrong}}$) between the translated and native benchmarks. Positive values of $\Delta p_{\max,\text{wrong}}$ indicate increased confidence on incorrect predictions.

O Computational Resources and Environmental Impact

Table 14 summarizes the computational resources and environmental impact associated with each adaptation strategy, aggregated by model size. For clarity and conciseness, we do not report the consumption of each individual training run. Instead, we provide a representative summary per model size and per adaptation strategy. In total, 36 training runs were performed across all experiments. The CPT+SFT strategy is not reported as a separate entry in the table, as its computational cost and environmental impact correspond to the sum of the CPT and SFT phases. Reporting CPT and SFT independently therefore fully characterizes the overall resource usage of the combined strategy.

We report, for each configuration, the dataset size, number of epochs, batch size, GPU type, GPU memory, number of GPUs, total training time, estimated carbon emissions (in gCO_2e), and estimated monetary cost (in USD). Carbon emissions and cost estimates are derived from documented power

Table 12: Cross-lingual comparison between native English MCQU benchmarks (MCQU-EN) and their French translations (MCQU-FR), reported as EM (%). Results are shown for both greedy and constrained decoding. For each row and decoding type, bold values indicate the higher EM between MCQU-FR and MCQU-EN.

consumption profiles and usage costs of the underlying high-performance computing infrastructure. All experiments were conducted on the Jean Zay supercomputer operated by GENCI-IDRIS[7].

O.1 Analysis

Overall, the results highlight a clear contrast between CPT and SFT in terms of computational cost and environmental impact. CPT is consistently the most resource-intensive strategy, driven by large-scale datasets, longer effective compute time, and high degrees of GPU parallelism.

In contrast, SFT incurs substantially lower emissions and monetary costs across all model sizes. This difference is not only due to the smaller dataset size, but also to the use of parameter-efficient fine-tuning: SFT is implemented with DoRA adapters rather than full weight updates, significantly reducing both memory usage and energy consumption. Despite longer wall-clock durations in some configurations, the overall compute footprint of SFT remains markedly lower than that of CPT.

As model size increases, CPT costs grow rapidly, particularly for the 13B setting, where energy consumption and carbon emissions increase sharply. SFT, while also scaling with model size, remains comparatively efficient due to its parameter-efficient design. These findings underscore the importance of adaptation strategies that balance performance gains with computational and environmental sustainability.

P Pretraining Data Contamination Study: Was NACHOS Seen During Pretraining?

Because most of the base models we evaluate (Gemma, MedGemma, Mistral, and Llama) do not disclose their full pretraining mixtures, we conducted a small contamination study to probe whether the French biomedical NACHOS corpus may have been included (or partially included) in their pretraining data. This appendix reports two complementary, lightweight detection protocols inspired by the broader literature on memorization and pretraining-data detection in large language models (Ravaut et al., 2024)

Table 13: Paired significance testing between MCQU-EN and MCQU-FR for each model configuration (model, strategy, and decoding type). Reported values are the 95% confidence interval of the mean EM difference and the corresponding two-sided two-sided p-value; `Significant` indicates whether the difference is statistically significant. We define the difference as $(\mathrm{FR} - \mathrm{EN})$, such that positive values indicate higher performance in French.

Table 14: Summary of computational resources and environmental impact for different adaptation strategies, aggregated by model size. Reported values correspond to a representative training configuration per strategy. CPT+SFT costs are obtained by summing CPT and SFT.

P.1 Protocol 1: Prefix–Continuation Reproduction + Likelihood Heuristics

Idea. If a model has memorized (or near-memorized) training documents, conditioning on a prefix may lead it to reproduce the exact continuation, or to assign a noticeably higher likelihood to the true continuation than to a perturbed version. This is conceptually related to training-data extraction / memorization diagnostics used in prior work (Carlini et al., 2021).

Implementation. Using a sample of n=1915 NACHOS documents, we split each document into a *prefix* (first 400 characters) and a *continuation* (rest). For each sampled document, we: (i) generate up to 200 new tokens from the prefix (greedy decoding), and compute ROUGE-L between the generated continuation and the gold continuation; (ii) compute the length of the longest common prefix (LCP) between generated and gold continuations; (iii) compute the perplexity of the gold continuation conditioned on the prefix, and compare it to the perplexity of a lightly perturbed continuation (character swaps + whitespace noise), reporting the ratio $\mathrm{PPL}(\text{gold})/\mathrm{PPL}(\text{perturbed})$. We flag a case as "suspicious" if any of the following holds: ROUGE-L ≥ 0.7, LCP ≥ 200 characters, or $\mathrm{PPL}(\text{gold})/\mathrm{PPL}(\text{perturbed}) \leq 0.85$.

Results. Across models, ROUGE-L remained very low and we observed no exact continuation matches, which does *not* support verbatim memorization of long continuations under this setup. However, the fraction of items flagged as "suspicious" is extremely high (0.82–0.96), which indicates that our heuristic is likely over-sensitive (in particular, the perturbation and/or the chosen ratio threshold may dominate the flagging decision).

- Llama-2-7B: ROUGE-L $=$ 0.031, exact matches $=$ 0/1915, suspicious fraction $=$ 0.959.
- Llama-2-13B: ROUGE-L $=$ 0.020, exact matches $=$ 0/1915, suspicious fraction $=$ 0.964.
- Mistral-7B: ROUGE-L $=$ 0.014, exact matches $=$ 0/1915, suspicious fraction $=$ 0.944.
- MedGemma-4B: ROUGE-L $=$ 0.018, exact matches $=$ 0/1915, suspicious fraction $=$ 0.821.
- Gemma-3-4B: ROUGE-L $=$ 0.019, exact matches $=$ 0/1915, suspicious fraction $=$ 0.835.

Interpretation. Given the near-zero reproduction scores (ROUGE-L, exact match) but massive "suspicious" rates, this first protocol is inconclusive as a contamination detector in our setting: it does not show direct copying, and the likelihood-based heuristic is too unstable without a careful calibration procedure and stronger perturbations/-controls. This is consistent with known difficulties of turning likelihood signals into reliable membership decisions without explicit calibration (Yeom et al., 2018).

P.2 Protocol 2: DC-PDD (Divergence-based Calibration Pretraining Data Detection)

Idea. We also tested a dedicated pretraining-data detection score, DC-PDD, which estimates a per-text statistic $\beta(x)$ combining (i) the model probability of next tokens and (ii) reference token frequencies estimated from a large background corpus D' (here, French OSCAR[8]). The method is designed to be more robust than raw perplexity by incorporating a calibration term from D' (Zhang et al., 2024).

[8] https://oscar-project.org/

Implementation. For each model, we first build a tokenizer-specific unigram table $p(v; D')$ from OSCAR-FR (streaming counts, capped number of documents), then compute DC-PDD $\beta(x)$ on: (i) 1,000 NACHOS samples, and (ii) a *synthetic control* set ("non-member") of biomedical texts generated to be *unlikely* to appear in any public pretraining mixture. We report distributional statistics (median, p75/p90/p95, mean, std) for both sets and a separation diagnostic $\Delta_{\text{median}} = \text{median}(\beta_{\text{nachos}}) - \text{median}(\beta_{\text{control}})$.

Why synthetic controls? (Major limitation) Gemma-family models were released recently (June 2025), and we could not reliably curate a sufficiently large set of *web-native biomedical French texts written after the model release date* to serve as a credible "definitely-non-member" control. As a consequence, we used synthetic biomedical controls, which weakens the study: synthetic controls differ from natural corpora in style and token statistics, and thus may artificially inflate separation (or mask it), independently of membership. We therefore treat DC-PDD results as *indicative only*, not as evidence of true pretraining inclusion.

Results. DC-PDD yields consistently *lower* scores on NACHOS than on the synthetic controls (negative Δ), suggesting the models assign *slightly* more "in-distribution" likelihood structure to NACHOS than to the synthetic texts. The separation is small for Mistral/Llama and somewhat larger for Gemma/MedGemma:

- Mistral-7B: $\Delta_{\text{median}} \approx -3.23 \times 10^{-4}$.
- Llama-2-7B: $\Delta_{\text{median}} \approx -3.58 \times 10^{-4}$.
- Llama-2-13B: $\Delta_{\text{median}} \approx -2.94 \times 10^{-4}$.
- Gemma-3-4B: $\Delta_{\text{median}} \approx -8.20 \times 10^{-4}$.
- MedGemma-4B: $\Delta_{\text{median}} \approx -6.77 \times 10^{-4}$.

Interpretation. While DC-PDD produces a consistent ordering (Nachos $<$ Control), this cannot be confidently attributed to pretraining membership because our control set is synthetic and therefore not distribution-matched. In other words, the observed separation may reflect *domain/style differences* rather than exposure during pretraining. As prior work emphasizes, robust pretraining-data detection typically requires carefully constructed controls and/or calibrated baselines (e.g., Min-K% variants, calibrated likelihood tests), which we could not fully satisfy here (Zhang et al., 2024).

P.3 Summary and Takeaways

Overall, these experiments do not provide strong evidence for (or against) NACHOS being included in the undisclosed pretraining mixtures: (i) we do not observe continuation copying under our greedy prefix–continuation setup; (ii) DC-PDD shows a small but consistent separation between NACHOS and synthetic controls, but the lack of a reliable post-release, naturally occurring biomedical control corpus makes the conclusion weak. We therefore report these results for transparency, but we do not use them to support any causal claim about pretraining contamination in the main analysis.

PromptRad: Knowledge-Enhanced Multi-Label Prompt-Tuning for Low-Resource Radiology Report Labeling

Abstract

Automatic report labeling facilitates the identification of clinical findings from unstructured text and enables large-scale annotation for medical imaging research. Existing rule-based labelers struggle with the diverse descriptions in clinical reports, while fine-tuning pre-trained language models (PLMs) requires large amounts of labeled data that are often unavailable in clinical settings. In this paper, we propose PromptRad, a knowledge-enhanced multi-label **prompt**-tuning approach for **rad**iology report labeling under low-resource settings. PromptRad reformulates multi-label classification as masked language modeling and incorporates synonyms from the UMLS Metathesaurus into a multi-word verbalizer to enrich category representations. By fine-tuning the PLM without additional classification layers, PromptRad requires substantially less labeled data than conventional fine-tuning. Experiments on liver CT (computed tomography) reports show that PromptRad outperforms dictionary-based and fine-tuning baselines with only 32 labeled training examples, and achieves competitive performance with GPT-4 despite using a much smaller model. Further analysis demonstrates that PromptRad captures complex negation patterns more effectively than existing methods, making it a promising solution for report labeling in data-scarce clinical scenarios. Our code is available at https://github.com/ila-lab/PromptRad.

1 Introduction

Radiology reports contain valuable medical findings about patients' conditions and play a crucial role in clinical decision-making. However, these reports are usually lengthy and unstructured (see Figure 1 for an example), making it difficult to efficiently extract clinical information (Chen et al., 2018; Pons et al., 2016). Traditional approaches rely on expert knowledge from the Unified Medical Language System (UMLS) (Bodenreider, 2004) and computational linguistics techniques for medical concept extraction (Aronson, 2001; Wang et al., 2017; Peng et al., 2018). However, these dictionary-based methods depend on pre-established mappings between text and medical concepts and often fail when reports use diverse or non-conventional descriptions (Irvin et al., 2019). While pre-trained language models (PLMs) such as BioBERT (Lee et al., 2019) and PubMedBERT (Gu et al., 2021) have been applied to report labeling (Wood et al., 2020; Smit et al., 2020; Li et al., 2022), fine-tuning these models requires substantial labeled data (Devlin et al., 2019; Dodge et al., 2020; Zhang et al., 2021), which is scarce in clinical settings due to the need for domain expertise during annotation.

Example Liver CT Report (de-identified):

CT study of chest and abdomen without and with IV contrast enhancement shows:

1. Rapid enlarging nodule or mass at RUL, suggestive of rapid lung metastasis.
2. Multiple new small nodules (0.2–1.0 cm) at bilateral lungs.
3. A 4cm liver mass at S5, with peripheral globular enhancement, favor hemangioma.
4. Small cysts at right lobe of liver.
5. Gallstones.

Gold Labels: Cyst ✓, Metastasis ✓, Hemangioma ✓

Figure 1: An example liver CT report from our dataset with annotated findings. Underlined terms indicate relevant mentions for each positive label.

Prompt-tuning (Gao et al., 2021; Schick and Schütze, 2021a) offers a promising alternative by transforming classification into masked language modeling, enabling PLMs to perform well with limited labeled data (Schick and Schütze, 2021c). However, existing prompt-tuning methods (Hu et al., 2022; Gao et al., 2021; Liu et al., 2023a) are designed for multi-class classification with mutually exclusive categories. In contrast, radiol-

ogy report labeling is inherently a multi-label task, where multiple findings may coexist in a single report. This limits the direct applicability of existing prompt-tuning approaches to report labeling.

We propose PromptRad, a knowledge-enhanced multi-label **prompt**-tuning approach for **rad**iology report labeling under low-resource settings. Here, "low-resource" refers to settings where only a limited number of expert-annotated reports are available for training. PromptRad adapts a pre-trained masked language model (Devlin et al., 2019; Gu et al., 2021) for multi-label classification through prompt-tuning. Inspired by Knowledgeable Prompt-Tuning (KPT) (Hu et al., 2022), we design a multi-word verbalizer that incorporates synonyms from the UMLS Metathesaurus (Bodenreider, 2004) as label-to-word mappings, enriching category representations for clinical contexts. We further develop automatic prompt generation based on Gao et al. (2021) to explore the space of textual templates and enhance performance.

Experiments on liver CT reports from a large medical center demonstrate that PromptRad outperforms dictionary-based methods (Aronson, 2001; Peng et al., 2018) and fine-tuning baselines, and is competitive with GPT-4 (OpenAI, 2023) even with only 32 labeled training examples. Our analysis of negation cases shows that PromptRad captures complex negation patterns more effectively than rule-based approaches, demonstrating its robustness for clinical report labeling.

In summary, our contributions are threefold:

- We formulate low-resource radiology report labeling as a multi-label prompt-tuning problem and adapt a masked language model (Devlin et al., 2019) to predict multiple clinical findings from a single report.
- We introduce a UMLS-informed multi-word verbalizer and an automatic prompt generation strategy to improve label representation and template selection in clinical contexts.
- We evaluate PromptRad on a real-world liver CT report dataset and analyze its behavior under limited supervision, including challenging negation cases.

2 Related Work

2.1 Report Labeling

Traditional approaches to report labeling rely on pre-built knowledge bases. MetaMap (Aronson, 2001) maps medical text to UMLS concepts, and NegBio (Peng et al., 2018) extends it with dependency parsing rules for negation detection. CheXpert (Irvin et al., 2019) replaces predefined concept extractors with manually curated mention lists and more sophisticated negation rules for chest X-ray (CXR) reports. However, these rule-based methods depend on predefined patterns and may fail to generalize across report types and institutions.

Machine learning approaches, including CNN-based (Majkowska et al., 2020; Shin et al., 2017) and LSTM-based methods (Dahl et al., 2021; D'Anniballe et al., 2022), have also been explored for report labeling but require large amounts of labeled data. More recently, PLM-based approaches have shown strong performance: ALARM (Wood et al., 2020) uses BioBERT (Lee et al., 2019) for MRI reports, CheXbert (Smit et al., 2020) uses BlueBERT (Peng et al., 2019) for CXR reports, and other studies have applied BERT (Devlin et al., 2019; Li et al., 2022) and domain-specific PLMs (Nowak et al., 2023) to various report labeling tasks. While effective, fine-tuning PLMs typically requires substantial labeled data (Brown et al., 2020; Dodge et al., 2020; Zhang et al., 2021), which is scarce in clinical settings. Unlike most prior radiology labelers that focus on chest X-ray reports or rely on large annotated corpora, our work focuses on low-resource multi-label labeling for liver CT reports.

2.2 Prompt-Tuning

Prompt-tuning (Schick and Schütze, 2021a; Gao et al., 2021) reformulates classification as masked language modeling, reducing reliance on newly initialized, task-specific classification layers and enabling effective few-shot learning (Schick and Schütze, 2021c). Prompt-based methods have also been explored in biomedical NLP tasks, including biomedical relation extraction (He et al., 2024) and lay summary generation (Wu et al., 2023). KPT (Hu et al., 2022) improves prompt-tuning by incorporating external knowledge into the verbalizer. Wei et al. (2022) extended prompt-tuning to multi-label text classification and proposed PTMLTC (Prompt Tuning Method for Multi-Label Text Classification), which is the closest to our work. However, PTMLTC was designed for the educational domain and relies on a single-word verbalizer, which may not capture the diverse expressions for the target categories. To the best of our knowledge, no prior work has applied prompt-

tuning to multi-label radiology report labeling under low-resource settings, especially using small local models with few-shot training.

2.3 Recent Advances in LLM-based Report Labeling

With the emergence of large language models (LLMs), recent work has explored LLM-based approaches for radiology report analysis. CheXGPT (Gu et al., 2024) uses GPT-4 as a zero-shot labeler and then trains a BERT-based model on 50k pseudo-labeled chest X-ray reports generated by GPT-4. Fytas et al. (2024) propose a multi-turn prompting strategy that combines rule-based insights with LLM predictions for chest X-ray report classification. Domain-adapted models such as Radiology-Llama2 (Liu et al., 2023b) fine-tune open-source LLMs on radiology corpora via instruction tuning, and Abdullah and Kim (2025) fine-tune a smaller LLM for report labeling on the MIMIC-CXR dataset. However, these approaches either require large volumes of (pseudo-)labeled data, domain-specific corpora for continued pretraining, or access to proprietary APIs, raising concerns regarding deployment cost and data privacy in clinical settings. In contrast, PromptRad is a prompt-tuning approach that fine-tunes a masked language model with a UMLS-informed verbalizer, requiring only 32 labeled examples and no access to external APIs.

Table 1: Number of positive findings per category in our labeled clinical report dataset. HCC: Hepatocellular Carcinoma.

Category	Training (2008–2014)	Test (2015–2017)
Cyst	275	109
HCC	214	79
Post-Treatment	205	79
Cirrhosis	168	85
Steatosis	154	93
Metastasis	101	46
Hemangioma	90	29
Total reports	773	325

3 Dataset

This study was approved by the institutional review board of the participating medical center. The dataset contains de-identified reports written in English, covering liver CT examinations from 2008 to 2017 (an example report is shown in Figure 1). The reports were annotated by two senior radiologists for the presence of seven common cancer-related findings. Each finding is labeled as positive (1) or negative (0); suspicious findings were treated as positive to avoid false negatives.

We split the data chronologically to ensure independence between training and test sets. The 2008–2014 subset contains 773 reports and serves as the candidate training pool, while the 2015–2017 subset contains 325 reports and is used as the fixed test set, as summarized in Table 1. To study low-resource scenarios, where only a small number of expert-annotated training examples are available, for each run we randomly sample K reports from the 773-report training pool using stratified sampling (Sechidis et al., 2011) to preserve the class distribution. Our goal is to evaluate how effectively different methods learn under constrained annotation scenarios, rather than to assume that all 773 reports are unavailable.

4 Method

4.1 Problem Definition

Given a radiology report r and a label space $\mathcal{Y} = \{y_1, y_2, ..., y_n\}$ with n distinct classes of findings, the report labeling task is to predict the presence of each finding $y_i \in \mathcal{Y}$ within r. Multiple findings may be present in a single report. We define the training set as $\mathcal{D}_{\text{train}} = \{(r_a, \mathcal{Y}_a)\}_{a=1}^{K}$, where K is the number of training examples and $\mathcal{Y}_a \subseteq \mathcal{Y}$ is the set of findings in report r_a.

4.2 Standard Prompt-Tuning

Prompt-tuning (Schick and Schütze, 2021a; Gao et al., 2021) fine-tunes PLMs without additional classification layers by (1) formatting the input as a cloze test with a textual prompt template containing a `[MASK]` token, and (2) defining a verbalizer that maps each class to a word in the PLM vocabulary. This allows fine-tuning with the MLM objective (Devlin et al., 2019) without introducing new parameters. We illustrate standard prompt-tuning in Figure 2 (a).

4.3 Multi-word Verbalizer of PromptRad

To identify the presence of each finding $y_i \in \mathcal{Y}$ in a report r and transform report labeling into a masked language modeling task (Devlin et al., 2019; Gao et al., 2021; Schick and Schütze, 2021b),

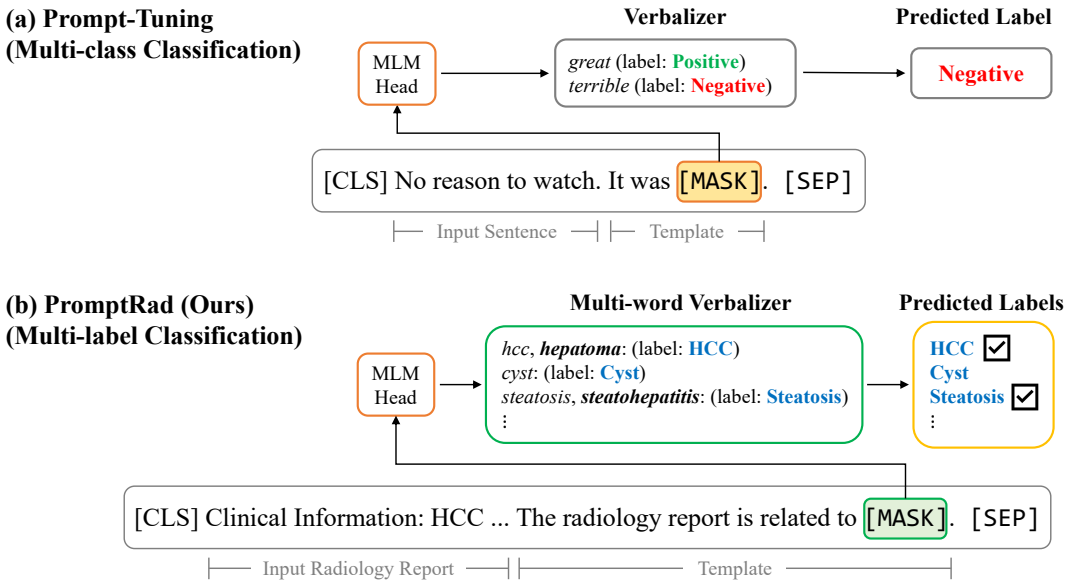

Figure 2: Differences in the approaches of (a) Prompt-tuning for multi-class classification on a general domain task (Gao et al., 2021; Schick and Schütze, 2021b). (b) PromptRad, our method for multi-label classification for radiology report labeling. Bold italic words in the verbalizer denote synonyms augmented from the UMLS Metathesaurus. MLM: masked language model (Devlin et al., 2019).

we define a verbalizer $v : \mathcal{Y} \rightarrow V$ which maps a finding y_i to a word from the vocabulary V of a pre-trained MLM $\mathcal{M}$. We first create a single-word verbalizer, where each finding is mapped to the word that most closely matches its class name (e.g., "Post-treatment" $\rightarrow$ "posttreatment"). Hence, if the model fills the word "posttreatment" in the `[MASK]` position, the report will be classified as containing the "Post-treatment" finding.

In addition to the closest match, synonyms of the class names can also represent the findings. To prevent the model from being biased towards a single mapping per category, we extend the verbalizer with synonyms from SNOMEDCT in the UMLS Metathesaurus (Bodenreider, 2004). For instance, both "hcc" and "hepatoma" serve as mappings for "Hepatocellular Carcinoma," as shown in Figure 2 (b). The complete mappings are listed in Appendix A.1. This multi-word verbalizer can be easily adapted to other report labeling tasks by replacing the mappings with synonyms for the target categories.

4.4 Training

As illustrated in Figure 3, we append a prompt template to each report r to form the input sequence r_p:

r_p = `[CLS]` r The radiology report is related to `[MASK]`. `[SEP]`

where the prompt template is manually designed. Our objective is to determine the presence of each finding by the prediction of the `[MASK]` token in r_p using a pre-trained MLM $\mathcal{M}$.

During training, for each input r_p, we identify the presence of each finding $y_i \in \mathcal{Y}$ by recovering the `[MASK]` token:

$$z_i = f_\mathcal{M}(\texttt{[MASK]}, v(y_i) \mid r_\text{p}) \quad (1)$$

where $f_\mathcal{M}(\texttt{[MASK]}, v(y_i) \mid r_\text{p})$ denotes the logit score of token $v(y_i)$ at the `[MASK]` position produced by the MLM head of $\mathcal{M}$. When multiple label-to-word mappings are available for a finding y_i, the one with the highest likelihood is chosen:

$$z_i = \max_{m=1}^{M_i}(f_\mathcal{M}(\texttt{[MASK]}, v(y_i, m)|r_\text{p})), \quad (2)$$

where M_i is the number of label-to-word mappings for y_i. For example, for "Hepatocellular Carcinoma", M_i is 2 with mappings "hcc" and "hepatoma". Practically, as we show in Figure 3, we create a matrix with the shape of $n \times M$ to facilitate the max operation in Equation 2, where M is the maximum number of mappings among the categories. We pad categories with fewer than M mappings using dummy entries and apply a binary mask so that padded positions do not affect the maximum operation. Then, we optimize $\mathcal{M}$ with the binary cross-entropy loss:

$$\hat{y}_i = \text{sigmoid}(z_i) \quad (3)$$

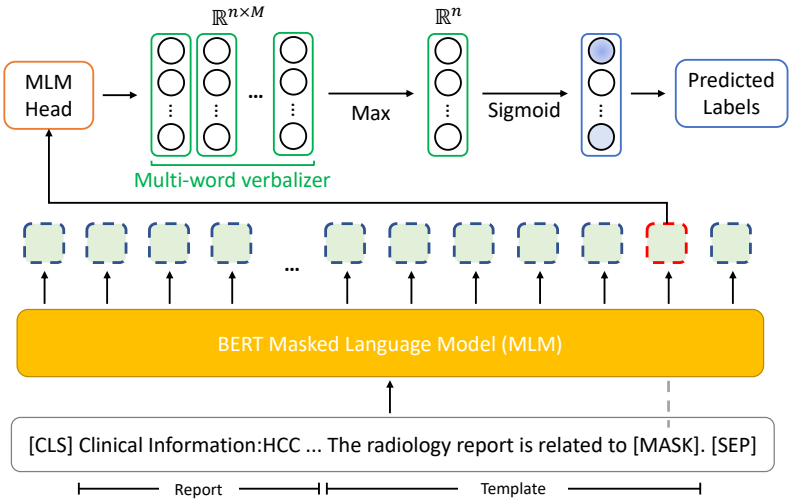

Figure 3: The workflow of the PromptRad report labeling system.

$$\mathcal{L} = -\frac{1}{n}\sum_{i=1}^{n}\left[y_i \log(\hat{y}_i) + (1-y_i)\log(1-\hat{y}_i)\right]. \tag{4}$$

During inference, we assign a finding y_i to a radiology report r if the probability $\hat{y}_i$ exceeds a defined threshold τ for all the categories.

4.5 Automatic Prompt Generation

We argue that better performance can be achieved by training our model with different templates. Instead of relying solely on manually designed templates, we explore automatic prompt generation following Gao et al. (2021).

We take advantage of the generative capability of the pre-trained T5 (Raffel et al., 2020) to automatically create various prompt templates and find the best one for our task. Given a report r, the single-word verbalizer v, and a label y_i, we explore two formats: (1) report first: $[r]$ $[\mathbf{P}_1]$ $[v(y_i)]$ $[\mathbf{P}_2]$, and (2) answer first: $[\mathbf{P}_1]$ $[v(y_i)]$ $[\mathbf{P}_2]$ $[r]$, where $\mathbf{P}_1$ and $\mathbf{P}_2$ are T5-generated prompts placed before and after the label word. Format 1 mirrors our manual template by placing the report before the label. In addition, since the position of the `[MASK]` token can vary in a sequence during the pre-training of BERT (Devlin et al., 2019), we also explore Format 2, where the order is reversed.

For each report with multiple labels, we duplicate the input for each label and use T5 with beam search to generate 100 candidate templates (50 per format), ranked by the joint log-likelihood over all training examples (Gao et al., 2021). We train PromptRad with each candidate and select the best-performing template (Table 6 in Appendix A.2).

5 Experiments

We evaluate PromptRad against a range of baselines on the test set. Unless otherwise specified, all training-based methods (e.g., PubMedBERT and PromptRad) use 32 labeled reports (K=32) as training data. Detailed experimental settings, baseline descriptions, and GPT-4 prompts are provided in Appendix B.

5.1 Performance Comparison

Table 2 shows that the proposed PromptRad method outperforms all the baselines for most of the categories using the manual template, except for GPT-4 (OpenAI, 2023). In addition, Table 2 also shows that PromptRad+AutoT benefits from the proposed automatic template generation method and slightly outperforms GPT-4 in terms of average scores. This result suggests that fine-tuning BERT using appropriate prompts provides a competitive and lightweight alternative to API-based large language models for low-resource report labeling.

For the category of "Hemangioma", "Label Match" can almost perfectly identify the positive findings, showing that the descriptions for "Hemangioma" can be easily identified. The reason that our approaches perform worse than "Label Match" in the "Hemangioma" category is that the number of training examples for "Hemangioma" is relatively small[1], compared to the other categories. We will

[1]During pre-processing, we randomly sampled 32 examples while keeping the distribution of the sampled data the same as that of the original training set, as we mentioned in Section 3. Thus, there are only 2-3 samples labeled as "Hemangioma" each time.

Table 2: Performance comparison in F1-score (%) using the independent test set.

	Cyst	HCC	Post-T	Cirr.	Stea.	Meta.	Hem.	Mac. F1	Mic. F1
GPT-4	86.1	91.5	79.1	96.6	98.9	73.8	95.1	88.7	88.7
GPT-4 (ICL[a])	89.7	88.8	76.3	92.5	92.0	78.5	94.9	87.5	87.4

show the performance of PromptRad with more training examples in Section 5.4. We note that "Label Match" scores zero on "Post-Treatment" and "Steatosis" because these categories are expressed through synonyms (e.g., RFA, TACE, fatty liver) that do not match the category names directly.

5.2 Case Study

To confirm that the proposed method is capable of handling diverse descriptions for the target labels, we perform a case study and list the examples with the corresponding labels in Table 3. In this experiment, we compare the performance of our method with NegBio (Peng et al., 2018) as representative of the dictionary-based methods, since NegBio outperforms MetaMap (Aronson, 2001) in our experiment (Table 2). Such cases are challenging for dictionary-based systems because the target label names may appear in the text even when the corresponding findings are negated or absent.

In Table 3, we observe that most of the positive findings can be correctly identified by both approaches when the label names are explicitly mentioned in the reports. However, NegBio usually fails to negate the findings when the label names show up in reports with negative descriptions, such as "No ... nor HCC in both lobes liver" and "No imaging evidence of cirrhosis ..." in the first two examples of Table 3. Additionally, NegBio can be misled by common negation abbreviations in radiology reports, such as "R/O" (rule out) in the third report of Table 3, while learning-based methods, such as PromptRad, can learn to recognize these abbreviations from the training data.

This experiment demonstrates the potential of the proposed method in handling negation cases. To further validate the effectiveness of the proposed method for handling negation cases in radiology reports, we next perform a quantitative experiment.

Table 3: Case study comparing PromptRad+AutoT with NegBio on reports containing negated findings. Bold italic labels indicate gold annotations for each sentence.

	Segments (*Gold Label*) and Predicted Positive Labels
Report 1	A tiny hepatic cyst in S7/8> Patency of the SMV **(*Positive: Cyst*)** No obvious hypervascular nodule nor HCC in both lobes liver. **(*Negative: HCC*)** Mild liver cirrhosis and portal hypertension. **(*Positive: Cirrhosis*)** **NegBio**: Cyst, HCC, Cirrhosis **PromptRad+AutoT**: Cyst, Cirrhosis
Report 2	No imaging evidence of cirrhosis of liver. **(*Negative: Cirrhosis*)** Two small 0.6-cm and 1.4-cm densely packed lipiodol puddles in S7 without identifiable viable tumor, suggestive of good response to previous TACE without viability. **(*Positive: HCC, Post-Treatment*)** Multiple hepatic cysts are noted. **(*Positive: Cyst*)** **NegBio**: Cyst, HCC, Post-Treatment, Cirrhosis **PromptRad+AutoT**: Cyst, HCC, Post-Treatment
Report 3	Remarkable fatty liver with GB stones; **(*Positive: Steatosis*)** R/O metastasis in the anterior abdominal wall. **(*Negative: Metastasis*)** **NegBio**: Steatosis, Metastasis **PromptRad+AutoT**: Steatosis

5.3 Effectiveness of Negation Handling

To quantitatively assess the effectiveness of our proposed method in handling negation cases in radiology reports, we collect the reports from the test set that explicitly mentioned the label names, but were annotated as negative findings by our radiologists. We excluded the “Cyst", “Post-Treatment", “Steatosis", and “Hemangioma" categories, as reports mentioning these label names usually indicate positive findings of the corresponding categories.

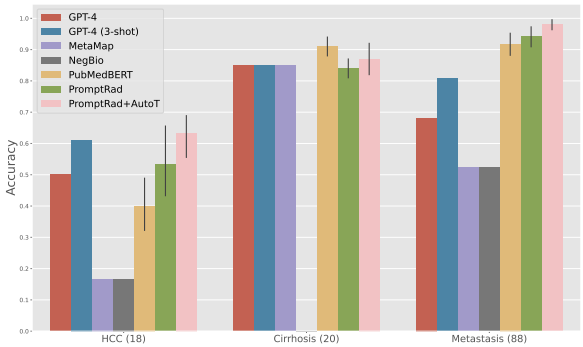

Figure 4: Accuracy on negation cases: reports that mention a finding name but are annotated as negative. Values in parentheses indicate the number of cases per category.

Figure 4 shows that PromptRad+AutoT (ours) is better at handling negation cases than GPT-4 (OpenAI, 2023), NegBio (Peng et al., 2018), and MetaMap (Aronson, 2001) for the negated reports in the three categories. Additionally, our manual-template approach (PromptRad) remains competitive compared to the other baselines. To our surprise, the performance of NegBio on “Cirrhosis" is unsatisfactory. This is due to the fact that NegBio relies heavily on natural language rules of dependency parsing and takes inputs with complete sentence structures. However, the descriptions relevant to “Cirrhosis" in our dataset are usually short (e.g., *No liver cirrhosis.*), which makes it difficult for NegBio to identify the negation cases. Besides, though our methods are slightly inferior to PubMedBERT (Gu et al., 2021) for the reports with “Cirrhosis", they are still much better at handling negation cases than PubMedBERT for the reports with “HCC" and “Metastasis". Based on the overall performance in Figure 4, we can still conclude that our method is a better choice for handling negation cases in radiology reports than the other baselines.

5.4 Performance Comparison for Different Training Sizes

In the previous sections, we studied the performance of the proposed methods for using only 32 labeled reports for training. In this section, we investigate the impact of the training size on the performance of the report labeling task. We randomly sampled different numbers of reports from the training set and evaluated the performance of PromptRad and PubMedBERT on the test set. Figure 5 shows that both methods exhibit a similar trend in performance improvement with the increase of training sizes, and both methods achieve more than 90% F1-score in macro average when the training size is larger than 128 samples. In addition, the proposed method outperforms PubMedBERT in almost all categories with training sizes smaller than 128 samples, showing that our method is effective under data scarcity scenarios.

5.5 Ablation Study for the Verbalizer

Since PromptRad and PromptRad+AutoT use the multi-word verbalizer, to confirm the effectiveness of the multi-word verbalizer, we provide a performance comparison for the two types of verbalizers in Table 4. We find that our methods using the multi-word verbalizer outperform the ones using the single-word verbalizer on average across all seven categories. Notably, the multi-word verbalizer also reduces variance across runs (e.g., Cirrhosis std. drops from 12.6 to 4.2 for PromptRad), suggesting that multiple mappings provide more stable category representations during few-shot training. Therefore, we conclude that the inclusion of multiple label-to-word mappings is beneficial for the radiology report labeling task.

We further note that, according to the complete mappings in Appendix A.1, the two verbalizers differ only for “Hepatocellular Carcinoma” and “Steatosis”. Since PromptRad is trained with shared PubMedBERT parameters and a shared MLM head, these mapping changes may indirectly affect other categories through the joint multi-label objective. Thus, differences for categories with identical mappings likely reflect shared-parameter effects. For other report labeling tasks, the multi-word verbalizer can be easily extended by adding synonyms for additional target categories when available.

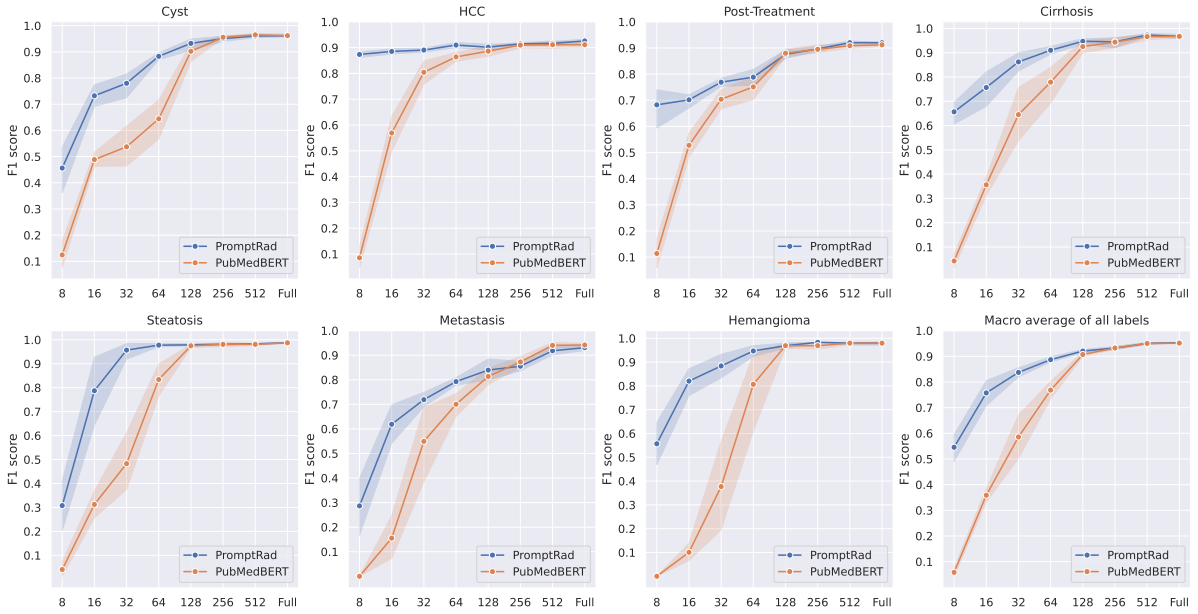

Figure 5: Comparison in F1-score for using different numbers of reports for training. We ran experiments five times for each training size, and for a training size of 8, we repeated the experiment ten times. "Full" indicates the use of the full training set.

Table 4: Performance comparison in F1-score for PromptRad and PromptRad+AutoT using the single-word and multi-word verbalizers.

	PromptRad		PromptRad+AutoT	
Labels	Single	Multi	Single	Multi
Cyst	$79.1_{4.2}$	$78.0_{5.3}$	$89.4_{3.2}$	$\mathbf{89.5}_{2.4}$
HCC	$89.4_{0.6}$	$89.1_{0.8}$	$89.9_{0.6}$	$\mathbf{90.8}_{1.0}$
Post-Treatment	$74.4_{2.4}$	$\mathbf{76.9}_{1.8}$	$\mathbf{80.2}_{3.7}$	$78.4_{3.9}$
Cirrhosis	$84.2_{12.6}$	$\mathbf{86.2}_{4.2}$	$90.3_{2.5}$	$\mathbf{91.0}_{3.4}$
Steatosis	$96.3_{2.2}$	$95.7_{3.7}$	$95.7_{2.2}$	$\mathbf{97.3}_{0.9}$
Metastasis	$74.0_{5.8}$	$71.9_{3.5}$	$83.2_{1.7}$	$\mathbf{84.7}_{1.2}$
Hemangioma	$83.6_{5.8}$	$\mathbf{88.4}_{5.6}$	$89.1_{7.8}$	$\mathbf{92.4}_{2.5}$
Macro Avg.	$83.0_{3.0}$	$\mathbf{83.7}_{2.1}$	$88.2_{1.6}$	$\mathbf{89.2}_{1.0}$
Micro Avg.	$84.1_{2.7}$	$\mathbf{84.1}_{1.7}$	$88.9_{1.4}$	$\mathbf{89.4}_{1.0}$

Scores were averaged from five runs. Subscripts: standard deviation.

6 Discussion

6.1 Why PromptRad Works

PromptRad outperforms standard BERT fine-tuning with PubMedBERT (Gu et al., 2021) across all categories when only 32 labeled reports are available (Table 2), and this advantage persists for training sizes below 128 (Figure 5). We attribute this to the alignment between prompt-tuning and masked language model pre-training. Unlike standard fine-tuning, which introduces a randomly initialized task-specific classification layer, PromptRad introduces no additional task-specific classification parameters. It reuses the pre-trained MLM head and predicts labels through verbalized clinical concepts, preserving closer alignment with the masked language modeling objective used during pre-training.

6.2 Advantages over Rule-based and API-based Alternatives

Compared to dictionary-based systems such as MetaMap (Aronson, 2001) and NegBio (Peng et al., 2018), PromptRad learns from a small number of labeled reports and better handles diverse clinical descriptions and negation patterns (Figure 4), which rule-based systems often miss due to reliance on predefined patterns.

PromptRad also achieves competitive performance with GPT-4 (OpenAI, 2023) under our low-resource setting while using a lightweight PubMedBERT backbone. Beyond efficiency, a locally deployable model avoids sending sensitive clinical reports to external APIs, which is an important consideration for real-world clinical deployment. We therefore view PromptRad not as a replacement for general-purpose large language models, but as a practical alternative when data privacy, deployment cost, and limited annotation resources are central constraints.

6.3 Comparison with Local LLMs

A natural alternative to API-based LLMs is deploying open-source LLMs locally (e.g., Llama 3

(Grattafiori et al., 2024), Qwen (Yang et al., 2025)). While this addresses privacy concerns, it requires substantial GPU memory (typically 16GB+ VRAM even for 7–8B models) that may be unavailable in smaller clinical institutions. In contrast, PromptRad uses a 110M-parameter backbone that can be deployed on consumer-grade hardware, including CPU-only inference. This makes PromptRad practical for resource-constrained clinical environments where both privacy and deployment cost are concerns.

7 Conclusion

In this paper, we introduce PromptRad, a knowledge-enhanced prompt-tuning approach for multi-label radiology report labeling under low-resource settings. Using a UMLS-based multi-word verbalizer and only 32 labeled reports, PromptRad outperforms dictionary-based and fine-tuning baselines, achieves competitive performance with GPT-4, and handles complex negation patterns more effectively than existing methods. As a lightweight, locally deployable model, PromptRad offers a practical solution for clinical report labeling where data privacy and annotation costs are central concerns, and can further support applications such as benign lesion retrieval and large-scale radiograph annotation.

Limitations

This study is based on liver CT reports from a single medical center, which may limit the generalizability of PromptRad to reports from other institutions, imaging domains, or reporting styles. In addition, our experiments focus on English reports and seven predefined liver-related findings, so further validation is needed to assess whether the method transfers well to broader clinical settings. Furthermore, the number of reports included in the negation-focused analysis is relatively small, as indicated by the counts in Figure 4. Larger annotated datasets are needed to better characterize model robustness on challenging negation cases. Finally, the construction of the multi-word verbalizer also depends on an external knowledge base such as the UMLS Metathesaurus. In settings where suitable terminology resources are unavailable, the applicability of this design may be reduced.

Acknowledgments

This work was supported by the National Science and Technology Council in Taiwan, under grants NSTC 114-2223-E-007-011 and NSTC 114-2222-E-182-001-MY2. We would like to express our deepest gratitude to the reviewers for their thoughtful comments and valuable feedback. We would also like to thank Szu-Tung Lin for his assistance in developing the data annotation platform.

A Appendix

A.1 Verbalizer Mappings

As shown in Table 5, the differences between the single-word and multi-word verbalizers fall into the categories of "Hepatocellular Carcinoma" and "Steatosis", as there are no additional synonyms for the remaining categories.

A.2 Automatically Generated Templates

We list the automatically generated templates with the highest scores in Table 6. We observe that the T5 model (Phan et al., 2021) tends to generate short but concise prompts, such as "Hepatic `[MASK]`" or "Liver `[MASK]`", while the manual template (also listed in Table 6) is more descriptive.

B Implementation Details

We implement our model using the HuggingFace Transformers (Wolf et al., 2020) (version: 4.12.2) and the PyTorch (Paszke et al., 2019) (version: 1.10.0) libraries. We used NVIDIA GeForce GTX 1070 and RTX 2080 Ti GPUs for training our model and finding templates with automatic prompt generation under the CUDA version of 10.1.

To ensure fair comparisons, all experiments for PromptRad and PubMedBERT use the model checkpoint of the pre-trained PubMedBERT-base[2] (Gu et al., 2021) for initialization, and we use SciFive-base[3] (Phan et al., 2021) for automatic prompt generation. For optimizing the models, we use AdamW (Loshchilov and Hutter, 2019) as the optimizer to train the models. All experiments are reported with 32 labeled reports as training data, unless otherwise specified. To simulate the real-world scenario of only limited labeled data available, we do not use a development set for hyperparameter tuning. Instead, we choose the best configuration according to the training loss. We use grid search with the following ranges:

- Learning rate: $[2e-5, 3e-5, 5e-5]$
- Batch size: $[2, 4, 8]$
- Threshold τ: $[0.2, 0.3, 0.4, 0.5]$
- Ratio of training steps for learning rate warmup: $[0.0, 0.1]$

B.1 Baseline Methods

This section describes the baseline methods we used for comparison in our experiments.

B.1.1 GPT-4

We used the OpenAI API[4] to test GPT-4 on report labeling, with the model name[5] of "gpt-4". Our input instructions can be found in Table 7, where they are displayed as both the system message and the user message. For each liver CT report, we first replaced **[REPORT]** in the user message with the actual report text. The modified user message was then processed by GPT-4 to produce the corresponding output assistant message.

B.1.2 GPT-4 (ICL)

The use of in-context learning (ICL) (Brown et al., 2020; OpenAI, 2023) helps large language models achieve better performance by providing a few labeled examples in an input prompt. In this study, we also compare our approach with GPT-4 (ICL). We provide three random examples (3-shot) from the training set in the user message (Table 7) to the GPT-4 model to see if the performance can be improved through in-context learning.

B.1.3 Label Match

We create a straightforward rule-based baseline that identifies positive findings when a report contains the corresponding label names. Our matching rules also account for plural forms of label names. For instance, an occurrence of "metastases" in a report is also recognized as a positive finding for "metastasis". This simple baseline can also be used to observe the difficulties of each category.

Table 5: The label-to-word mappings (verbalizer) we used for PromptRad and PromptRad+AutoT.

Category	Single-Word Verbalizer	Multi-Word Verbalizer
Cyst	cyst	cyst
Hepatocellular Carcinoma	hcc	hcc, **hepatoma**
Cirrhosis	cirrhosis	cirrhosis
Post-Treatment	posttreatment	posttreatment
Steatosis	steatosis	steatosis, **steatohepatitis**
Metastasis	metastasis	metastasis
Hemangioma	hemangioma	hemangioma

Table 6: The top-5 templates from automatic template generation along with the manual template for comparison. "Manual" was used in PromptRad, while "AutoT[1]" was used in PromptRad+AutoT.

Template	Format
Manual	[*Report*] The liver radiology report is related to `[MASK]`.
AutoT[1]	Hepatic `[MASK]`: [*Report*]
AutoT[2]	Liver `[MASK]`: [*Report*]
AutoT[3]	[*Report*] Hepatic `[MASK]`.
AutoT[4]	Abdominal `[MASK]`. [*Report*]
AutoT[5]	Liver `[MASK]` in [*Report*]

B.1.4 MetaMap

MetaMap (Aronson, 2001) is a widely used dictionary-based tool for extracting concepts from biomedical text by mapping text to the UMLS Metathesaurus (Bodenreider, 2004). Due to its vast repository of biomedical knowledge and its integration of both hierarchical and non-hierarchical relationships using semantic types and relations, MetaMap stands as a fundamental and effective benchmark for report labeling tasks (Wang et al., 2017). We use the 2020 version of MetaMap with pymetamap[6], an open source MetaMap wrapper, to extract the concepts for each report in our test set.

For each report, we obtain a positive finding if MetaMap returns one of the corresponding UMLS CUIs (Concept Unique Identifiers) of each category. The mappings between CUIs and categories that we used for MetaMap to retrieve the positive findings in our task are provided in Table 8.

B.1.5 NegBio

NegBio (Peng et al., 2018) is a dictionary-based tool for negation and uncertainty detection in clinical text. This approach should work in conjunction with either CheXpert (Irvin et al., 2019) or MetaMap (Aronson, 2001). We use the official implementation of NegBio[7] to extract the concepts for each report in our test set using the same CUIs in Table 8.

B.1.6 PubMedBERT

We fine-tune the pre-trained PubMedBERT model (Gu et al., 2021) for multi-label classification using the HuggingFace API (Wolf et al., 2020). This baseline serves as a representative of the standard fine-tuning approach for PLMs. Similar to the proposed method, we set a threshold τ to determine the positive findings for each label. We perform hyperparameter tuning for PubMedBERT with the same hyperparameter ranges as the proposed method, as described in Section B.

B.1.7 PubMedBERT+MM

We create an ensemble of PubMedBERT (Gu et al., 2021) and MetaMap (MM) (Aronson, 2001) by combining the predicted positive findings from PubMedBERT and MetaMap, denoted "PubMedBERT+MM". This baseline serves as a hybrid model that combines the strengths of both expert knowledge from MetaMap and the machine learning ability of PubMedBERT.

[6] https://github.com/AnthonyMRios/pymetamap

[7] https://github.com/ncbi-nlp/NegBio

B.1.8 PubMedBERT+NB

In addition to PubMedBERT+MM, we also create "PubMedBERT+NB", an ensemble of PubMedBERT (Gu et al., 2021) and NegBio (NB) (Peng et al., 2018). As with PubMedBERT+MM, PubMedBERT+NB combines the predicted positive findings from PubMedBERT and NegBio to take advantage of both methods.

B.2 GPT-4 Prompt Design

Table 7 shows the input message we used to query GPT-4 via the OpenAI API for report labeling. The system message assigns the role of a radiologist, and the user message provides the classification task along with the report text. For GPT-4 (ICL), we additionally include three randomly sampled labeled examples from the training set in the user message.

B.3 UMLS Concept Identifiers

Table 8 lists the UMLS Concept Unique Identifiers (CUIs) used with MetaMap and NegBio to identify positive findings for each category. Since "Post-Treatment" encompasses multiple treatment procedures, we consider a report positive for this category if any of the corresponding CUIs is detected.

B.4 Evaluation Metric

We use the F1-score as the evaluation metric for the seven categories in our experiments. We also include the micro-averaged F1-score and macro-averaged F1-score for the overall performance of each model. All the experiments use the same test set mentioned in Section 3 for evaluations. For the training-based methods, including PubMedBERT (Gu et al., 2021) and our approaches, we report the average scores and standard deviations of 5 runs with different random seeds. For the experiment with only eight training examples, we report the results of 10 runs with different random seeds. This is because the performance of the training-based methods can be more unstable when the training size is smaller, and we want to provide a more comprehensive evaluation for this experiment.

Table 7: Input message and an example output of GPT-4 using the OpenAI API.

Role	**Content**
System	You are a professional radiologist who knows computed tomography (CT) very much. You can classify the CT report for the liver features or symptoms.
User	Now you are going to perform a multi-label classification for a text report of liver computed tomography (CT). Given the potential categorized features {'cyst': 0, 'HCC': 1, 'post-treatment': 2, 'cirrhosis': 3, 'steatosis': 4, 'metastasis': 5, 'hemangioma': 6}, please read the following liver computed tomography report of a patient. Abstract

Large language models (LLMs) achieve strong results on medical benchmarks, but real outpatient diagnosis is iterative and requires stable, guideline-consistent reasoning rather than one-shot predictions. We study this problem in lower-extremity arteriovenous (LEA) diseases and introduce LEA-Dialog, a multi-turn diagnostic dialogue dataset covering six common diseases, with stage annotations for each turn and guideline-grounded probability trends. Building on this dataset, we further propose a process-aligned agentic framework for real-world patient consultations. In this framework, the patient interacts with a Doctor agent, while a Teacher agent audits guideline adherence and reasoning quality, provides corrective feedback to refine the Doctor agent's behaviour, and ultimately produces a structured diagnostic report. An Evaluator agent then derives both turn-level and final rewards from the diagnostic conversations between the patient and the Doctor agent for PPO-based policy optimisation, while carefully selected high-quality diagnostic conversations are further used for supervised fine-tuning. For training, the patient is also simulated by a Patient agent that emulates real patient responses. In addition to final diagnostic accuracy, we evaluate unsupported claims, trend correctness, diagnostic-tree similarity, and repeated-run stability with a new metric, Rate-n. Experiments on both online and offline LLMs show that process-aligned multi-turn diagnosis reduces reasoning drift, improves stability, and yields the largest gains for smaller offline models.

1 Introduction

Large language models (LLMs) have achieved strong performance on a wide range of medical benchmarks, including medical question answering, report generation, and simulated diagnosis. However, high benchmark accuracy alone does not make a system clinically usable. In outpatient practice, diagnosis is rarely a one-shot prediction: physicians iteratively summarise the current patient state, refine the differential diagnosis, ask targeted follow-up questions, and update their beliefs as new evidence emerges (Vessey and Galletta, 1991). In this setting, clinicians care not only about final correctness but also about stable and guideline-consistent reasoning (Yang et al., 2024; Rosenbacke et al., 2024).

This gap is especially important for multi-turn diagnostic dialogue. A model may produce the correct final diagnosis while still showing undesirable behaviour during the interaction, such as drifting between incompatible hypotheses, asking poorly targeted questions, or generating unsupported intermediate claims. Such process-level failures reduce trust and make the model's reasoning difficult to inspect in clinical workflows. Nevertheless, most existing evaluations of medical LLMs still focus primarily on final diagnostic accuracy, with limited attention to turn-level reasoning quality, diagnostic trajectory consistency, or repeated-run stability (Liu et al., 2024; Schmidgall et al., 2024; Fan et al., 2025; Wang et al., 2024; Lyu et al., 2024; Xu et al., 2024). In our setting, even strong online models can show noticeable variation across repeated runs on the same case, suggesting that stability should be treated as a first-class target in medical dialogue evaluation.

To study this problem, we focus on lower-extremity vascular diseases, where diagnosis often depends on multi-round clarification of symptoms, progressive narrowing of the differential diagnosis, and dynamic updates of disease likelihoods across consultation turns. Guided by clinical reasoning practice, we formulate outpatient diagnosis as a process-aligned hypothetico-deductive loop consisting of four stages at each turn: Summary, Inference, Question Planning, and Diagnosis. Based on this formulation, we introduce LEA-Dialog, a multi-turn diagnostic dialogue dataset covering

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 250–267
July 3-4, 2026 ©2026 Association for Computational Linguistics

six common lower-extremity arterial and venous diseases. Each dialogue is annotated with turn-wise reasoning and guideline-grounded probability trends, enabling evaluation of both final outcomes and intermediate reasoning behaviour.

Building on this dataset, we propose a process-aligned agentic framework for multi-turn diagnosis. A Doctor agent conducts the consultation, a Patient agent simulates the case trajectory, a Teacher agent audits record consistency, guideline adherence, and inquiry quality to construct a structured report, and an Evaluator agent converts these signals into turn-level and final rewards for optimisation. We also introduce Rate-n, a repeated-run stability metric that measures whether a model follows the same diagnostic trajectory across the first n turns. Specifically, a trajectory is considered consistent if its trend direction matches the majority trend across runs at each turn. Experiments on both online and offline LLMs show that process alignment reduces reasoning drift, improves diagnostic stability, and yields larger gains for smaller offline models.

Our contributions are as follows:

1. We introduce LEA-Dialog, a multi-turn diagnostic dialogue dataset covering six common diseases, annotated with reasoning processes for each turn and a carefully curated diagnostic handbook.

2. We propose a process-aligned agentic diagnostic framework with Doctor, Patient, Teacher, and Evaluator roles, together with a turn-level optimisation strategy for stabilising multi-turn reasoning.

3. We show that, under our framework, o3 achieves 4.6% improvement in average diagnostic accuracy and 66.7% reduction in misdiagnosis rate.

4. We further show that Qwen3-14B-T gains 68.3% in average diagnostic accuracy under the proposed framework, surpassing the original o3 model by 0.9%.

5. In addition to diagnostic accuracy, we demonstrate substantial gains in reasoning stability: after applying our framework, Qwen3-14B-T exceeds o3 in output stability by 5% from the second turn onward and by 25% from the third turn onward.

2 Related Work

2.1 Medical LLMs and diagnostic dialogue

Large language models have shown strong performance on medical question answering and benchmark-style evaluation, including systems such as AMIE (Tu et al., 2025), Med-PaLM2 (Singhal et al., 2025), and recent medical benchmarks in English and Chinese (Liu et al., 2024; Schmidgall et al., 2024; Fan et al., 2025; Wang et al., 2024; Lyu et al., 2024; Xu et al., 2024). More recent work has also begun to move from static question answering toward interactive diagnosis and simulated consultation, such as multi-agent clinical environments and conversational diagnostic systems (Schmidgall et al., 2024; Fan et al., 2025; Tu et al., 2025; Liu et al., 2025). However, most prior work still evaluates models primarily by final-answer quality, with limited focus on intermediate reasoning consistency.

2.2 Process-aligned and multi-step medical reasoning

A related line of work attempts to align model behaviour with the structure of clinical reasoning. In particular, Reasoning Like a Doctor (Xu et al., 2024) formulates medical dialogue generation through diagnostic reasoning process alignment, and MSDiagnosis introduces EMR-based multi-step diagnosis annotations (Hou et al., 2024). These studies support the view that medical dialogue should be modelled as a staged reasoning process rather than a single response generation problem. Our work follows this direction, but focuses more explicitly on the iterative nature of outpatient diagnosis and on modelling the diagnostic process itself rather than only the final prediction. Specifically, we treat diagnosis as a multi-round reasoning loop in which the model summarises accumulated evidence, updates its differential diagnoses, determines what information is still missing, and asks targeted follow-up questions to reduce uncertainty before making a final judgment. We further model turn-level diagnostic trajectory evolution, requiring disease hypotheses to change in a clinically meaningful manner across rounds. To support this, we introduce guideline-grounded supervision that specifies how diagnostic probabilities should be updated as new symptoms, history, and examination findings emerge, enabling process-level training and evaluation beyond endpoint accuracy. The comparison of evaluation dimensions between our model and other approaches is shown in Table 1.

2.3 Trustworthiness, guideline adherence, and stability

Accuracy alone is not sufficient for evaluating medical AI systems. Prior work has also highlighted the

Model	Focus	Stability
AMIE	Diagnostic dialogue	Not central
Med-PaLM2	QA and safety	Not central
ChatDoctor	Response quality	Not central
DocCHA	Online diagnosis	Not central
Emulation	Process alignment	Not central
Ours	Turn-level trajectory	Rate-n

Table 1: Evaluation focus of representative studies: AMIE (Tu et al., 2025), Med-PaLM2 (Singhal et al., 2025), ChatDoctor (Li et al., 2023), DocCHA (Liu et al., 2025), and Emulation (Xu et al., 2024). Stability refers to repeated-run diagnostic trajectory stability; "Not central" indicates that it is not a primary evaluation target.

importance of fitting clinical workflows (Xu et al., 2024), providing interpretable reasoning, and supporting clinician trust. In outpatient settings, diagnosis is inherently iterative: clinicians summarise the case, update differential diagnoses, ask targeted follow-up questions, and gradually move toward a decision. Yet the stability of this process across repeated runs remains rarely examined in medical AI, as shown in Table 1. Our work addresses this gap by studying multi-turn LLM diagnosis from a process perspective, introducing a process-aligned framework, a dataset with turn-level trend supervision, and a repeated-run stability metric, Rate-n.

3 LEA-Dialog Dataset

3.1 Task Scope

LEA-Dialog focuses on six common lower-extremity arteriovenous (LEA) diseases: deep vein thrombosis (DVT), post-thrombotic syndrome (PTS), arteriosclerosis obliterans (ASO), arterial thrombosis (AT), varicose veins (VV), and thromboangiitis obliterans (Buerger disease). We choose this disease set because diagnosis in this domain is highly iterative, requiring repeated clarification of symptoms and progressive updating of disease likelihoods across consultation rounds.

3.2 Data Composition

The dataset contains three components:

1. Expert-written consultation records. We collect 120 consultation records manually compiled and refined by experts based on real outpatient visits.

2. Synthetic consultation records. To improve coverage and diagnostic difficulty, we further construct 480 synthetic consultation records using data augmentation based on expert-crafted seed cases.

3. Clinical guideline file. In addition to the dialogue data, we include a companion guideline document for lower-extremity vascular medicine, which specifies diagnostic criteria and structured probability-scoring rules for supervising disease-trend evolution across turns.

Overall, LEA-Dialog combines expert-authored high-quality cases with larger-scale augmented data, while keeping all dialogues grounded in a shared guideline source. The detailed case collection procedure is provided in Appendix A, and the handbook development plan and reference guidelines are presented in Appendix B.

3.3 Annotation Scheme

Each dialogue contains up to 15 turns, with most expert cases reaching a final diagnosis within 5-7 rounds. For each turn, the doctor-side reasoning is annotated with four process-aligned stages:

Summary: a structured summary of the current patient state;

Inference: revision of the differential diagnosis based on newly acquired evidence;

Question Planning: targeted follow-up questions for reducing diagnostic uncertainty;

Diagnosis: final diagnostic output, produced only when sufficient evidence has been collected.

In the final round, each case additionally includes a trend report, which records how the estimated probability of each candidate disease changes across turns and why. Unlike free-form confidence scores, these trends are grounded in the companion guideline file, making them suitable for both evaluation and reward design in later training.

Compared with prior multi-turn medical datasets, LEA-Dialog provides stage annotations for each turn, guideline-grounded probability trends, and an expert-developed diagnostic handbook, enabling evaluation of diagnostic trajectory quality and repeated-run stability. Specific examples from the dataset are provided in Appendix C.3, Appendix C.5, and Appendix C.6.

3.4 Data Construction

We construct LEA-Dialog in three stages. First, three researchers with vascular-surgery backgrounds expand de-identified and standardised medical records into outpatient-style diagnostic dialogues following the annotation scheme in Section 3.3 and the handbook workflow. For each of the six target diseases, 20 expert-written records are created, yielding 120 seed cases.

Second, we use o3 with one-shot prompting to generate 80 augmented dialogues per disease, resulting in 480 synthetic cases. Following expert advice, selected disease-defining features are removed from some prompts to create more difficult differential-diagnosis cases.

Third, all generated dialogues undergo quality control. Two researchers independently review each dialogue for information completeness, temporal coherence, premature diagnosis leakage, label consistency, and evidential scope. Disagreements are resolved by a senior vascular surgeon. Further details are provided in Appendix A.

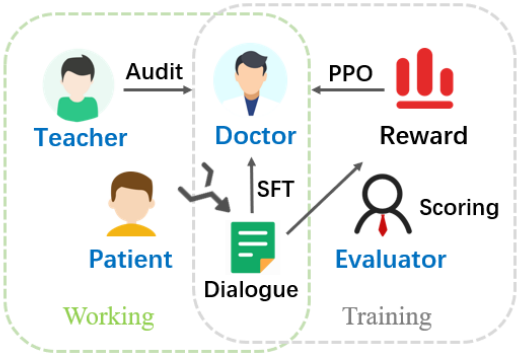

Figure 1: Overview of the proposed multi-agent diagnostic framework, illustrating the interaction between the Doctor, Patient, Teacher, and Evaluator agents.

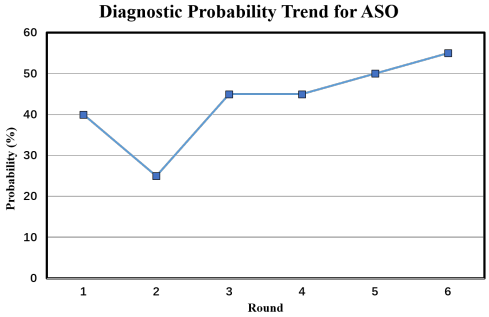
4 Method

4.1 Process-Aligned Diagnostic Loop

We model outpatient diagnosis as a process-aligned, multi-turn hypothetico-deductive loop. At each consultation turn, the model performs four sequential reasoning stages: Summary, Inference, Question planning, and Diagnosis. The first three stages are repeated across turns to refine the differential diagnosis and reduce uncertainty, while the diagnosis stage is executed only when sufficient evidence has been collected.

More concretely, the summary stage updates a structured representation of the patient's current condition based on the dialogue history. The inference stage revises the differential diagnosis and the relative likelihood of candidate diseases. The question planning stage generates targeted follow-up questions intended to resolve remaining ambiguity. Finally, when the model determines that diagnostic uncertainty has been reduced sufficiently, it enters the diagnosis stage and produces the final diagnostic decision together with a disease-trend report. This staged formulation is also consistent with the annotation structure of LEA-Dialog, examples of which are provided in Appendix C.3, Appendix C.5, and Appendix C.6, and supports supervision for both intermediate reasoning and final outcomes.



4.2 Multi-Agent Diagnostic Framework

Building on this diagnostic loop, we propose a multi-agent framework consisting of four roles: a Doctor agent, a Patient agent, a Teacher agent, and an Evaluator agent, shown in Figure 1. The Doctor agent is the trainable policy and is responsible for conducting the consultation. The Patient agent simulates the patient side of the dialogue by responding according to the case history. The Teacher agent acts as a clinical instructor who compares the Doctor's behaviour against the guideline file and provides structured feedback. The Evaluator agent converts the consultation trace into optimisation signals for training. The prompts and outputs example for each agent are provided in Appendix C.

The Doctor agent follows the four-stage reasoning structure at each turn. By explicitly separating summarisation, differential refinement, follow-up questioning, and diagnosis, the Doctor agent produces outputs that are easier to audit than a single free-form response. In the question-planning stage, particular emphasis is placed on clarifying ambiguous or potentially incomplete patient descriptions, reflecting the uncertainty commonly encountered in outpatient consultations.

The Patient agent plays the role of the patient and answers questions using the diagnostic history provided in the dataset. This design allows us to simulate multi-turn consultations in a controlled setting while keeping the dialogue grounded in case-specific evidence.

The Teacher agent evaluates the Doctor's reasoning process after each turn by cross-referencing it with the companion guideline file. It scores the appropriateness of the Doctor's actions, identifies omitted or mistimed questions, and provides strategic feedback such as revisiting a previous step or proceeding to the next stage. After the final diagnosis, the Teacher agent also generates a structured summary of the diagnostic trajectory, including the historical evolution of disease-probability assessments. This report provides a turn-level reference for subsequent training and evaluation.

- (1) 40% in Round 1 based only on sudden exertional pain;
- (2) Lowered to 25% in Round 2 due to lack of classic 5 Ps;
- (3) Raised to 45% in Round 3 with typical claudication (100m pain, relief with rest) and no venous signs;
- (4) Kept at 45% in Round 4 with sedentary lifestyle and cessation of anticoagulation but no strong trigger;
- (5) Raised to 50% in Round5 due to prior DVT with anticoagulation stop, suggesting a prothrombotic milieu;
- (6) Final 55% since still no swelling/warmth and arterial risk predominates.

Figure 2: Visualisation of diagnostic probability trends across rounds. The figure shows the probability assigned by the doctor agent to ASO at the end of each round, with the corresponding rationale. The full report includes probability trends and explanations for all candidate diseases.

4.3 Teacher-Guided Diagnostic Trajectory Analysis Report

A key component of our framework is the structured diagnostic trace produced by the Teacher agent. Rather than treating the consultation as an unstructured sequence of responses, we represent it as a partial diagnostic trend grounded in clinical guideline nodes shown in Figure 2. Each consultation turn contributes to this trend by adding or revising evidence, narrowing the differential diagnosis, and updating probability trends over candidate diseases. The final report, therefore, captures not only the final diagnosis but also whether the model followed an appropriate diagnostic trajectory.

This representation serves two purposes. First, it improves interpretability by making intermediate decisions easier to inspect. Second, it enables turn-level supervision beyond final-answer accuracy. In particular, we use the Teacher-generated report to assess whether the Doctor agent followed the handbook guidance, whether probability trends changed in clinically plausible directions, and whether unsupported claims were introduced during reasoning.

4.4 Turn-Level optimisation

To optimise the Doctor agent for both diagnostic correctness and process stability, we define the total reward as a weighted combination of turn-level rewards and a final reward:

$$G = \sum_{t=1}^{T} R_t^{\text{inst}} + R^{\text{final}}$$

where R_t^{inst} is the immediate reward at turn t,R^{final} is the final reward for the completed consultation. Intuitively, the turn-level reward encourages the Doctor agent to follow a clinically coherent diagnostic trajectory by rewarding appropriate guideline-node expansion and correct probability-trend updates while penalising unsupported claims. The final reward evaluates the overall diagnostic quality, including final diagnosis correctness and trajectory-level similarity to the reference diagnostic tree. Full details of the reward design are deferred to Appendix D.

5 Experimental Setup

5.1 Models

We evaluate both online and offline LLMs. For the Doctor agent, we use two online models, GPT-4o and o3, and two offline models, Qwen3-8B and Qwen3-14B. For the two offline models, we further evaluate their framework-trained versions after supervised fine-tuning and PPO, denoted as Qwen3-8B-T and Qwen3-14B-T, respectively. This setup allows us to test whether the proposed framework improves not only strong proprietary models but also smaller deployable open-weight models, and whether process-aligned optimisation can reduce the gap between offline and online systems. Unless otherwise specified, GPT-4o is used for the Patient, Teacher, and Evaluator roles.

5.2 Training and Comparison Settings

The Doctor agent is optimised using a hybrid PPO+SFT strategy; full details of the training framework are provided in Appendix E. During training, the Doctor interacts with the Patient agent in a multi-round consultation setting. Based on the interaction history, the Teacher agent audits guideline-node coverage, probability-trend updates, and unsupported claims, and provides structured process-level feedback. The Evaluator agent then converts these signals, together with the final diagnostic outcome, into training rewards. To maintain

language fluency and structural consistency, we interleave reinforcement learning with supervised fine-tuning, performing one SFT round after every five PPO rounds.

We compare each framework-enhanced Doctor model with its corresponding base model under direct prompting. We further conduct ablation studies on three key components of the framework: the companion guideline file, the Teacher agent, and the turn-level optimisation procedure, to isolate the contributions of process alignment, structured feedback, and reward-based optimisation.

5.3 Evaluation Metrics

We evaluate the framework from four perspectives: final diagnostic performance, Teacher reliability, repeated-run stability, and process-level error patterns.

For final diagnostic performance, we report final accuracy. For each case, the model outputs a probability distribution over the candidate diseases. The disease with the highest final probability is taken as the prediction and compared with the reference clinical diagnosis. A prediction is counted as correct if the predicted and reference labels refer to the same disease category; this matching is manually verified to avoid surface-form variation. Formally,

$$\text{Acc} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{1}[\hat{y}_i = y_i],$$

where N is the number of evaluated cases, $\hat{y}_i$ is the manually verified top-probability diagnosis, and y_i is the reference diagnosis.

For Teacher reliability, we evaluate three binary process-level error types: record-inconsistent summary, reasoning non-adherence, and questioning non-adherence. These correspond to contradiction or omission in the summary, deviation from handbook-defined diagnostic logic, and failure to ask guideline-relevant or discriminative follow-up questions. We compare the Teacher's judgements with expert annotations using confusion matrices. The validation sample contains 102 dialogue histories, with 17 instances per disease, each independently assessed by three clinical experts.

For repeated-run stability, we report Rate-n. For each test case, the model is run multiple times, and a run is counted as stable up to turn n if the trend direction of the correct disease matches the majority trend direction at each of the first n turns.

Model	Base	Multi Only	HB Only	Multi+HB
Qwen3-8B	19.8	27.2	62.1	89.7
Qwen3-8B-T	23.2	27.3	65.4	90.3
Qwen3-14B	23.5	31.0	69.3	92.3
Qwen3-14B-T	25.7	31.3	71.1	94.0
GPT-4o	87.6	89.3	90.9	96.0
o3	93.1	93.3	96.9	97.7

Table 2: Performance comparison (Acc %) under different settings on the held-out test set ($N = 60$, 10 cases per disease). Qwen3-8B-T and Qwen3-14B-T denote the models after PPO+SFT training. Multi refers to the multi-step reasoning scheme, while HB refers to the use of the handbook to provide diagnostic guidance and supplementary knowledge to the model.

Finally, we analyse misdiagnosed trajectories to identify the first clinically meaningful deviation and its dominant error type.

6 Results

6.1 Main Results

Table 2 summarises the main diagnostic results. Overall, the proposed framework with the handbook improves performance across both online and offline models, with especially strong gains for the smaller offline models. In particular, framework-enhanced Qwen3-14B-T with handbook improves average diagnostic accuracy by 68.3% and surpasses the original o3 model by 0.9%, showing that process-aligned optimisation and refined diagnosis handbook can substantially narrow the gap between deployable offline models and strong online models. For o3, the framework still yields measurable benefits, improving average diagnostic accuracy by 4.6% and reducing the misdiagnosis rate from 6.9% to 2.3%. The handbook is a primary source of the observed performance gains. In the handbook ablation study, access to the handbook substantially improves diagnostic accuracy for offline models and also yields a smaller but consistent improvement for online models. Notably, this benefit becomes larger after applying the multi-step framework, suggesting that the proposed multi-stage diagnostic procedure is more effective at incorporating external clinical knowledge. In contrast, when the underlying diagnostic logic is unchanged, reinforcement learning alone provides only limited gains in accuracy. These results indicate that, for final diagnostic performance, the effective use of external clinical knowledge is more critical than policy optimisation alone. This finding highlights the importance of knowledge utilisation,

rather than optimisation alone, in process-aligned diagnostic systems.

6.2 Teacher Reliability and Ablation

We next provide a more detailed analysis of the Teacher agent's performance. Specifically, we first evaluate whether the Teacher can correctly identify unsupported claims produced by the Doctor agent. Naturally, given the three stage labels in each diagnostic round—Summary, Reasoning, and Question Planning—we categorize such unsupported behaviours into three corresponding types: Record-inconsistent summary, where the Doctor's summary is inconsistent with the patient record or omits key clinical information; Reasoning non-adherence, where the Doctor's reasoning deviates from the guideline; and Questioning non-adherence, where the Doctor's planned follow-up questions do not conform to the guideline requirements.

The confusion matrix for Questioning non-adherence is shown in Figure 3, while the corresponding results for the other two criteria are provided in Appendix F. The confusion matrices across the three unsupported-claim criteria show that the Teacher's behaviour varies by criterion. For record-inconsistent summaries and reasoning guideline non-adherence, the Teacher is relatively conservative, producing few false positives but missing a non-trivial portion of rare errors. For questioning guideline non-adherence, it is more sensitive, identifying more problematic questioning steps at the cost of increased false positives and additional re-questioning. These results suggest that the Teacher does not apply a uniform decision rule, but instead exhibits a criterion-dependent safety–efficiency trade-off.

Teacher ablation further shows that removing the Teacher yields only a modest change in overall diagnostic accuracy, but substantially weakens record consistency, guideline questioning adherence, and guideline reasoning adherence. This finding indicates that the Teacher's main contribution is not simply improving final accuracy, but regularising the diagnostic process toward handbook-consistent and more trustworthy behaviour.

6.3 Stability Analysis

In our experiments, we observed that when the model repeatedly diagnoses the same patient, the diagnostic trajectories tend to remain highly similar across successful runs, as illustrated by Test 1–3 in Figure 4, whereas failed runs (Test 4–5) often

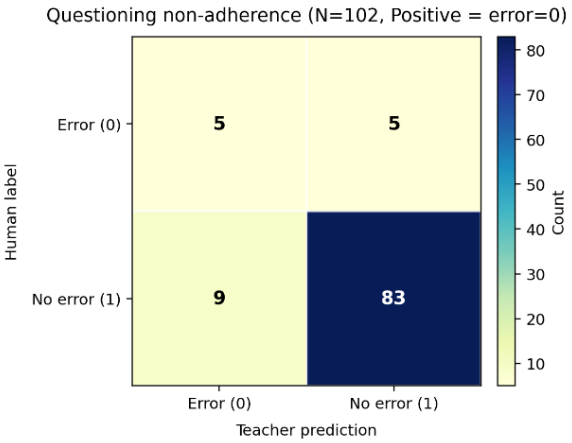


Figure 3: Confusion matrices for questioning non-adherence. In total, we sampled 102 dialogue histories, with 17 instances per disease. Each history was independently assessed by three experts for the three types of unsupported behaviours. Histories without unsupported behaviour were labelled as Positive (1), whereas those containing unsupported behaviour were labelled as Negative (0).

follow different trajectories. This divergence arises because the model cannot perfectly adhere to the guidelines in every run. Under the assumption that the diagnostic guideline is of sufficiently high quality, the stability of the model's outputs becomes an important determinant of diagnostic accuracy. Motivated by this observation, we introduce Rate-n to evaluate output stability.

Rate-n measures whether, across 10 repeated runs on the same case, the model maintains a similar diagnostic trajectory for the correct disease within the first n rounds. Here, a *similar trajectory* refers to the majority trend direction observed across runs, that is, whether the probability of the correct disease increases or decreases at each turn. Using Figure 4 as an example, among 10 repeated runs, the model correctly identified the possibility of ASO in only 5 runs at Round 1 (namely, Test1–5), yielding a Rate-1 of 50%. At Round 2, Test1, Test2, Test3, and Test5 shared the same trend for ASO (a decrease), which constitutes the majority pattern, yielding a Rate-2 of 40%. By the same logic, Rate-3 is 30%.

It is worth noting that a decrease in the probability trend of the correct disease at a particular round does not necessarily indicate an error in either the model or the guideline. Rather, it may reflect that the newly collected evidence at that stage also supports other competing diagnoses, which is common in real clinical reasoning.

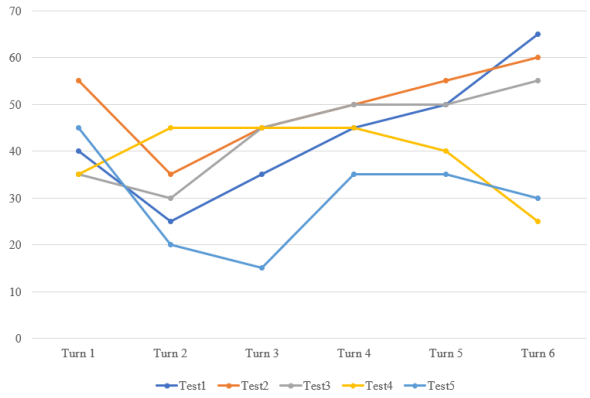

Figure 4: Evolution of the model's inferred probability for ASO across sequential rounds in an ASO clinical case (%). Among them, Tests 1–3 correspond to successful diagnoses and show similar diagnostic trends, whereas Tests 4 and 5 correspond to failed diagnoses and follow trajectories that differ from the others.

Model	Rate-1	Rate-2	Rate-3
Qwen3-8B	91.7	76.7	58.3
Qwen3-8B-T	91.7	81.7	61.7
Qwen3-14B	93.3	80.0	61.7
Qwen3-14B-T	95.0	83.3	66.7
GPT-4o	96.7	76.7	45.0
o3	98.3	78.3	41.7

Table 3: Stable diagnostic rates across sequential turns for six distinct disease categories

As shown in Table 3, across models, large online models show a sharper decline in Rate-n after the first turn, whereas small offline models exhibit a smaller drop. The PPO-trained offline models are the most stable overall. In particular, Qwen3-14B-T outperforms o3 by 5% from Turn 2 onward and by 25% from Turn 3 onward, showing that process-aligned RL can substantially reduce reasoning drift in multi-turn diagnosis.

This result shows that stronger base capability does not necessarily translate into more stable diagnostic trajectories. In our setting, reinforcement learning (PPO) acts as a regulariser that keeps the model more tightly aligned with the structured knowledge source, leading to more consistent reasoning across repeated trials.

6.4 Error Pattern Analysis

We further conduct a retrospective error-pattern analysis on 60 misdiagnosed trajectories to identify both the earliest clinically meaningful deviation and its primary error type. We annotate three error categories:
(1) Summary error, where the model distorts the patient summary or omits key symptoms;
(2) Reasoning error, where the model fails to follow the handbook-defined differential diagnostic logic;
(3) Question-planning error, where the model fails to ask the most discriminative follow-up question at a critical decision point.

As shown in Table 4, the dominant failure mode is question-planning error, which accounts for 53.3% of all cases. This indicates that the main bottleneck is often not missing medical knowledge, but failure to ask the most discriminative next question at critical branching points. Reasoning errors are the second most frequent category (40.0%), while summary errors are less common but tend to occur earlier and distort downstream reasoning.

Errors also emerge early: 71.7% of trajectories show their first meaningful deviation within the first two turns. Summary errors tend to concentrate in Turn 1, question-planning errors in Turn 2, and reasoning errors more often from Turn 2 onward. These findings suggest that misdiagnosis rarely results from a single final-turn mistake, but instead develops progressively from earlier process-level deviations.

Error Type	Number	Rate
Question Planning Error	32	53.3%
Reasoning Error	24	40.0%
Summary Error	4	6.7%
Total	60	100.0%

Table 4: Distribution of process-level error types (N=60)

7 Conclusion

We introduced LEA-Dialog and a process-aligned agentic framework for multi-turn diagnosis of lower-extremity arteriovenous diseases. The results show that evaluating only final accuracy is insufficient: guideline-grounded reasoning, process-level errors, and repeated-run stability are also important for assessing diagnostic dialogue systems. Structured clinical guidance and process-level optimisation improve performance and reduce reasoning drift, particularly for smaller offline models. Future work will broaden disease coverage and include more real clinical interactions.

8 Limitations

This study has several limitations. LEA-Dialog focuses on a narrow but clinically coherent group of six lower-extremity arteriovenous diseases. This enables controlled analysis of diagnostic trajectories among closely related vascular conditions, but limits claims about generalisation to broader medical domains. In addition, part of the dataset is synthetically expanded from expert-written seed cases, which may introduce distributional bias and make the dialogues more regular than real outpatient interactions. We therefore view LEA-Dialog as a controlled, domain-specific testbed for process-aligned diagnostic reasoning rather than a fully representative corpus of clinical consultations. The simulated multi-agent setup and the use of GPT-4o for the Patient, Teacher, and Evaluator roles may further introduce an LLM echo-chamber effect. We mitigate this risk by grounding patient responses in case records, using a guideline-based handbook, and validating a subset of Teacher judgements against expert annotations. Due to clinical data governance constraints, the original expert-derived records cannot be fully released. We plan to release the synthetic dialogues, annotation schema, prompts, handbook structure, and evaluation scripts where permitted, subject to institutional approval. Future work should broaden disease coverage, include more real clinical interactions, and validate the framework through independent clinician-in-the-loop studies.

A Detailed Case Collection Procedure

A.1 Study Design and Data Sources

This study is a single-center retrospective study. Cases were collected from routine clinical care at a tertiary hospital, including the electronic medical record system, laboratory information system, imaging reports, surgical records, and discharge summaries. The study population included patients with DVT, PTS, lower-extremity varicose veins (VV), ASO, AT, and Buerger's disease. As this study is based on routinely collected clinical data and aims to construct an observational research dataset, the data reporting followed the STROBE, RECORD, and TRIPOD-LLM guidelines.

A.2 Ethical Compliance and De-identification

The study was approved by the institutional ethics committee and conducted in accordance with the Declaration of Helsinki, which explicitly applies to medical research involving identifiable human materials or data. All patient information was de-identified before being entered into the research database, with names, national ID numbers, hospital admission numbers, telephone numbers, detailed addresses, and other direct identifiers removed.

A.3 Inclusion and Exclusion Criteria

Included cases had to meet two criteria: first, a clearly established final clinical diagnosis; second, at least one core piece of evidence supporting that diagnosis, such as venous ultrasound findings or anticoagulation records for DVT, Doppler ultrasound for varicose veins, CTA/DSA or intraoperative records for AT, and smoking history together with characteristic imaging or pathological evidence for Buerger's disease.

Exclusion criteria included missing key fields, repeated hospitalisations that could not be distinguished as independent cases, insufficient diagnostic evidence, severely incomplete text, or cases in which reliable de-identification could not be achieved.

A.4 Structured Extraction Fields

Each case was converted into a structured record using a unified schema, with source materials organised in the following order:

1. **Demographic information:** age, sex, and admission date.
2. **Chief complaint:** the most prominent presenting symptom and its duration at the first visit.
3. **History of present illness:** onset pattern, progression speed, triggers, affected site, associated symptoms, and prior management.
4. **Past medical history:** prior thrombosis, varicose vein history, PAD/cardiovascular disease history, diabetes, hypertension, chronic kidney disease, malignancy, surgical history, and prior anticoagulant/antiplatelet use.
5. **Personal history:** smoking history, which was especially important to preserve for Buerger's disease cases.
6. **Physical examination:** limb swelling, tenderness, skin temperature, skin colour, ulceration/gangrene, superficial venous dilation, and dorsalis pedis/posterior tibial pulse findings.
7. **Auxiliary examinations:** D-dimer, venous/arteriovenous ultrasound, ABI/TBI, CTA/MRA/DSA, and intraoperative findings.
8. **Diagnostic information:** preliminary diagnosis, final diagnosis, subtype/stage, or relevant severity score.
9. **Treatment information:** medication, intervention, surgery, and perioperative management.

A.5 Key Information Extraction and Standardisation

Three researchers with vascular surgery backgrounds developed the extraction dictionary and mapping rules in advance to standardise symptoms, examinations, anatomical sites, diagnostic terms, and treatment modalities. For example, expressions such as "lower-extremity swelling and pain" and "calf swelling with pain" were consolidated into the same symptom category, while "superficial femoral artery occlusion" and "SFA occlusion" were mapped to the same lesion-site category.

A.6 Data Construction and Augmentation

Three physicians with vascular surgery backgrounds expanded the highly standardised and structured medical records into diagnostic narratives based on the diagnostic workflow specified in the handbook and their real clinical experience. The expanded records were then presented in the form of outpatient-style dialogues, which served as the seed set. For each disease, 20 diagnostic records were created in this way. Subsequently, o3 was prompted with a one-shot setup based on the seed set to simulate and generate additional virtual diagnostic dialogues, producing 80 dialogues per disease as the augmented set.

A.7 Quality Control and Dataset Split

All generated dialogues were independently reviewed by two researchers. The review focused on whether the information was complete, whether the temporal order was coherent, whether the dialogue leaked the final diagnosis prematurely, whether the diagnostic label was consistent with the original medical record, and whether the management suggestions remained within the evidential scope of the source case. Any disagreements were resolved by a senior vascular surgeon.

After quality control, the finalised cases were used for dataset construction and subsequent train–validation–test splitting.

B Handbook Development Plan and Reference Guidelines

B.1 Handbook Development Strategy

The handbook used in this study was developed for the diagnostic setting of lower-extremity arteriovenous diseases. It covered six target diseases: deep vein thrombosis (DVT), post-thrombotic syndrome (PTS), lower-extremity varicose veins(VV), arteriosclerosis obliterans (ASO), AT, and thromboangiitis obliterans (Buerger disease).

The primary evidence sources for the handbook were recent international clinical practice guidelines, diagnostic consensus statements, and other normative clinical documents. Specifically, the DVT and PTS sections were mainly based on the ESVS 2021 venous thrombosis guideline, the CHEST guideline for venous thromboembolism, and NICE NG158 (*Venous thromboembolic diseases: diagnosis, management and thrombophilia testing*). The chronic venous disease and varicose vein sections were mainly based on the ESVS 2022 chronic venous disease guideline, the SVS/AVF/AVLS guideline for varicose veins, and NICE CG168 (*Varicose veins: diagnosis and management*). The ASO and AT sections were mainly based on the 2024 ACC/AHA guideline for lower-extremity peripheral artery disease, the 2024 ESC guideline for peripheral arteriovenous and aortic diseases, and the ESVS 2020 acute limb ischemia guideline. The Buerger disease section was mainly based on the 2023 international diagnostic consensus, supplemented by recent review and treatment evidence.

To ensure consistency between the knowledge base and real-world clinical reasoning, the handbook was uniformly organised around a six-step consultation workflow. This design allowed each knowledge entry to align with the sequential logic of outpatient vascular diagnosis.

B.2 Six-Step Consultation Workflow

The handbook was structured according to the following six-step consultation process:

1. **Comprehensive symptom inquiry.** The clinician should thoroughly review and further probe the patient's lower-extremity symptoms to avoid missing manifestations with important differential diagnostic value.

2. **Past medical history inquiry.** This step includes questions about comorbidities associated with lower-extremity vascular disease, such as hypertension, diabetes, and coronary artery disease, as well as chronic infectious diseases relevant to perioperative assessment, such as tuberculosis and hepatitis B. Previous thrombotic history should also be explicitly assessed.

3. **Lifestyle and demographic inquiry.** The

clinician should ask about smoking and alcohol use, lifestyle patterns related to prolonged sitting or standing that may contribute to varicose veins, and demographic features associated with specific diseases, such as the typical profile of Buerger's disease patients (e.g., young or middle-aged men). Age and sex should also be collected at this stage if they were not obtained in the first turn, since they are useful for distinguishing age-related vascular conditions.

4. **Previous surgery and treatment history.** This step covers prior surgical history and previous disease management measures, including medication, physical therapy, and other interventions.

5. **Structured summary of effective information.** The clinician should summarise all diagnostically useful information obtained from the previous rounds of questioning.

6. **Final diagnostic output.** The diagnosis should be presented in the format `[Disease A: probability], [Disease B: probability], . . .` until all candidate diseases and their estimated probabilities have been listed. The diagnostic output should terminate with `F/`.

B.3 Rationale for This Structure

This workflow-based design was intended to make the handbook not only a static collection of disease knowledge but also a process-aligned clinical reasoning resource. Instead of presenting isolated disease descriptions, the handbook encoded what information should be asked, when it should be asked, how previously collected evidence should be summarised, and how differential diagnoses should be updated before the final decision. In this way, the handbook better matched the iterative and hypothetico-deductive nature of real outpatient diagnosis.

B.4 Reference Guidelines Used for Handbook Development

C Prompt details and output examples

C.1 Doctor-Agent Prompt

You are a physician specialising in lower-limb arteriovenous and venous diseases. In each round, you question the patient according to the uploaded diagnostic guideline and report your reasoning and question-planning process to your mentor, conducting the diagnosis under the mentor's supervision. You must strictly follow the six-step diagnostic process described in the handbook — do not change the order of questioning or skip any step arbitrarily. Depending on who is replying to you, you will perform different steps.

After each round of the patient's response, proceed as follows: Confirm the current diagnostic step according to the guideline. Execute the content required for the current step.

The execution of each diagnostic step should include:

Summary: summarise the patient's current condition using professional terminology based on their latest response.

Reasoning: analyse which parts of your previous reasoning may have been incorrect according to the new response, revise them, and analyse the possible diseases in the format [Disease A: possible reason A], [Disease B: possible reason B], ... to present the updated reasoning results.

Diagnostic Judgment: Determine whether the current information (excluding imaging data) is sufficient to begin diagnosis. – If sufficient, proceed directly to Step 5 (Diagnosis). – If insufficient, proceed to Step 4 (Question Planning).

Question Planning: Evaluate whether the patient's answers contain vague descriptions that could significantly affect diagnosis. – If yes, list them in the format [Vague description A: possible inaccuracy 1], [Vague description B: possible inaccuracy 2], ... then draft clarification questions and skip Step 5. – If no ambiguity, formulate the next set of questions according to the current diagnostic step and skip Step 5.

Diagnosis: Output all possible diseases and their probabilities in the format [Disease A: probability], [Disease B: probability], ... until all have been listed. Refusal to provide a diagnosis is not allowed. End the diagnostic output with "F/".

After each round of the mentor's response: – If the mentor instructs you to continue questioning, proceed to ask the patient the questions you drafted in the previous round. – If the mentor instructs you to reconsider, repeat the previous step from the start.

The first round of dialogue should begin with: "Hello, what can I help you with today?"

C.2 Patient-Agent Prompt

You are a patient. Read the uploaded historical diagnostic record and answer the doctor's questions strictly according to the information in that record. You must not fabricate any symptoms or conditions that are not mentioned in the case history. When describing your symptoms, speak in a natural, conversational tone, but ensure your answers are as complete and consistent with the case record as possible. In the closed question–answer dialogue, if the doctor asks about any symptom or manifestation not included in the record, always answer that you are not sure, and do not invent any new symptoms or medical history. Each time you reply, provide your entire answer in one paragraph. Use the first paragraph of the patient's description from the diagnostic record as your opening statement in the conversation with the doctor.

C.3 Doctor-Patient output example

Doctor A: Hello, how can I help you today?
Patient A: I am an 84-year-old man . . .

Doctor A: [**Current Step**]
Step 2. Review and clarify the patient's lower-limb symptoms.

[1. Summary]
Male, 84. Sudden onset of right-lower-limb pain 4 days ago, worse with walking, relieved by rest. ED initially suspected DVT . . .

[2. Reasoning Revision]
[Acute limb ischemia: could be in-situ arterial thrombosis or embolism; acute onset + exertional pain suggests ischemic pain.]
[Deep vein thrombosis (DVT): ED's first consideration; need to confirm swelling, tenderness, increased skin warmth, etc.]

[3. Diagnostic Judgment]
Current information is insufficient to start diagnosis; we need details on accompanying symptoms/signs and vascular pulses.

[4. Question Plan]
Ambiguous expressions
[The nature and location of "pain" are unclear: cannot distinguish ischemic from venous aching.]

Please answer the following one by one:
1) Is the pain in the whole right leg, or specifically in the thigh, calf, or foot? Is it aching, dull, stabbing, or cutting?
2) Over the past 4 days, has the right lower limb become clearly swollen? Any difference in girth compared with the left?

[Possible Diseases and Probabilities (Initial)]
[Acute lower-limb arterial ischemia/embolism: 40%]
[Deep vein thrombosis (DVT): 35%]
[Acute worsening of lower-limb atherosclerotic occlusive disease: 25%]

C.4 Teacher-Agent Prompt

You are Doctor A's mentor. You may only communicate with Doctor A and must not speak directly with Patient A.

Each dialogue round includes either a Suggestion Module or a Report Module. Determine whether Patient A has triggered the diagnostic module (ends with "F/"). – If not triggered, enter the Suggestion Module. – If triggered, enter the Report Module.

Suggestion Module

You should read the uploaded treatment guideline and assess whether Doctor A has: (1) Record-consistent summary: Provide an accurate summary of the patient's status. (2) Guideline non-adherence during reasoning: Followed the correct diagnostic logic from the handbook. (3) Guideline non-adherence during questioning: Followed the correct questioning sequence from the handbook.

For each of the three criteria above, we assign a binary score of 0 or 1: 1 indicates the model makes no error, and 0 indicates an error occurs. If the total score is below 3, we prompt the model to re-initiate the questioning round; otherwise, we instruct it to continue the diagnostic process and provide recommendations for the next-step clarification questions.

Note: Doctor A's first round of dialogue does not require analysis—simply tell Doctor A to continue.

Report Module

Summarise every change in the probability of each possible disease throughout Doctor A's entire diagnostic process, along with the reason for each change. Use the following format: [Disease A: probability1–probability2–probability3. . . , Reason: . . .]

End the report with "E/"

C.5 Teacher-Agent Output example (Suggestion)

Coordinator Agent: *Score*

Record-inconsistent summary: 1

Doctor A accurately restated the patient's most recent response (54-year-old male; former smoker; no alcohol use; no prolonged sitting/standing).

Guideline adherence during reasoning: 1

Checkpoint 4 has been completed, and the dialogue correctly proceeds to the inquiries required for Checkpoint 5; the diagnostic logic is consistent with the handbook.

Guideline adherence during questioning: 1

The two questions asked (history of lower-limb-related surgeries and long-term medication use) fully meet the requirements of Checkpoint 5.

Total: 3/3 — The diagnostic workflow may continue.

Improvements and next-step recommendations

After the patient answers Checkpoint 5, please immediately execute the Checkpoint 6 "double-summary" requirement.

Key information reminders

The patient's ultrasound has shown "multiple deep vein thromboses in the right lower limb." If there is no prior DVT history but the course has lasted 2 months, consider subacute DVT and early post-thrombotic syndrome (PTS) as the top two differentials.

C.6 Teacher-Agent Output example (Report)

Coordinator Agent:

[Right-lower-limb subacute arterial ischemia / ASO acute exacerbation: 40–25–45–45–50–55.]

Reasons: Round 1 gave 40% based only on "sudden exertional pain"; Round 2 lowered to 25% due to lack of classic 5 Ps; Round 3 raised to 45% with typical claudication (100 m pain, relief with rest) and no venous signs; Round 4 kept at 45% with a sedentary lifestyle and cessation of anticoagulation, but no strong trigger; Round 5 raised to 50% due to prior DVT with anticoagulation stop, suggesting a prothrombotic milieu; Final 55% since still no swelling/warmth, and arterial risk predominates.

[Recurrent DVT: 35–15–10–20–20–20.]

Reasons: Initially 35% for "ED suspected DVT + prior DVT"; Round 2 dropped to 15% with no swelling/tenderness; Round 3 down to 10% with continued lack of venous support; After learning of stopping anticoagulation and sedentary lifestyle, the rate rose to 20% were maintained.

[Distal arterial embolism: 40–25–45–20–15–15.]

Reasons: Began with 40% for all acute ischemia; Without cardiac source, lowered to 25%; When not yet excluded, considered alongside in-situ thrombosis back to 45%; With no heart source, down to 20%, and then maintained at 15%.

[Chronic ASO only (stable): 20–45–35–10–10–8.]

Reasons: Claudication with rest relief once raised it to 45%; No previous claudication and sudden onset, then reduced; Sedentary lifestyle, but no long history of claudication, dropped it to 10%; Finally 8% due to acute characteristics and stopping anticoagulation.

[Venous insufficiency/varicosities: 5–10–5–0–0–0.]

Reasons: Briefly raised to 10% in Round 2 on "nocturnal cramps/heaviness" query, then fell to zero due to continuous lack of supporting signs.

E/

D Reward function design

The immediate reward score R_t^{inst} integrates node additions, correctness of probability trend assessments, and unsupported-claims penalties, while the final reward score R^{final} combines overall accuracy with the longest common subsequence (LCS) similarity of the diagnostic tree:

$$G = \sum_{t=1}^{T} R_t^{\text{inst}} + R^{\text{final}} \tag{1}$$

Specifically,

$$G = \sum_{t=1}^{T} \big(\alpha\,\Delta\text{Node}_t + \beta\,\text{Trend}_t - \gamma\,\text{Halluc}_t\big) + \lambda\,\text{Acc} + \mu\,\text{LCS} \tag{2}$$

Above all, $\text{Acc} \in \{0, 1\}$, $\text{LCS} \in [0, 1]$, $\alpha = 0.3$, $\beta = 0.5$, $\gamma = 0.2$, $\lambda = 0.7$, $\mu = 0.3$.

Node Increment (ΔNode_t). A handbook-node increment of 0.5 is assigned if a newly completed node follows the guideline sequence; otherwise 0.

Trend Assessment (Trend_t).

- Increasing the probability of the correct disease: $+0.5$
- Decreasing the probability of an incorrect disease: $+0.5$
- Decreasing the probability of the correct disease or increasing that of an incorrect disease: -0.5
- No change in trend: 0

Hallucination Penalty (Halluc_t). Presence of unsupported claims incurs a penalty of -0.5 per claim; no penalty is applied if none are present.

Specifically, unsupported clinical claims are detected from three aspects:

- Record-inconsistent patient status summaries
- Guideline non-adherence during reasoning

- Guideline non-adherence during questioning

The Teacher Agent is responsible for executing the detection and assigning scores. A score below a threshold of 3 indicates the presence of unsupported-claims behaviour, which triggers reinitiation of the questioning round.

Final Accuracy (Acc). The accuracy of the final diagnosis is assessed by semantically comparing it with the diagnostic results in the dataset.

E Training Framework Details

This appendix provides additional details of the hybrid PPO+SFT training framework used to optimize the Doctor agent. Our training design aims to improve not only final diagnostic accuracy, but also the quality and stability of the intermediate diagnostic process. To this end, we combine supervised fine-tuning on reward-filtered diagnostic dialogues with reinforcement learning under process-level supervision.

E.1 Training Overview

We adopt a hybrid training strategy that alternates supervised fine-tuning (SFT) and proximal policy optimisation (PPO). The overall training pipeline contains three stages: (1) construction of candidate diagnostic dialogues, (2) reward-based filtering for high-quality trajectory selection, and (3) iterative optimisation of the Doctor agent with interleaved SFT and PPO.

First, candidate diagnostic dialogues are constructed from both expert-authored seed cases and LLM-augmented virtual cases. Each dialogue contains a multi-round outpatient-style consultation trajectory, including the Doctor's intermediate reasoning process and the final diagnostic decision. These candidate dialogues are then scored using our reward framework, which evaluates handbook-node progression, correctness of disease-probability trend updates, and unsupported-claims behaviour. Only high-quality trajectories are retained for subsequent supervised training.

We first apply SFT on the filtered dialogue set to initialise the Doctor agent with stable multi-round interaction patterns, structured reasoning stages, and trend-aware diagnostic updates. Starting from this initialisation, we further optimise the Doctor agent using PPO in an online interaction setting. During PPO training, the Doctor interacts with the Patient agent round by round, while the Teacher agent audits the evolving consultation process and the Evaluator agent converts these signals into training rewards. To prevent reinforcement learning from degrading linguistic fluency or output structure, we insert one SFT refresh round after every five PPO rounds. In total, we conducted 100 rounds of PPO and 20 rounds of SFT training for each offline model.

E.2 Candidate Dialogue Construction and Filtering

The training corpus is built from the diagnostic dialogues described in Appendix A.6. It includes both expert-written seed dialogues and augmented dialogues generated from these seeds. Since not all automatically generated trajectories are equally reliable, we apply reward-based filtering before supervised training.

Specifically, each candidate dialogue is assigned a trajectory-level score based on the same process-oriented criteria later used in reinforcement learning. These criteria include: (1) whether the diagnostic process follows the handbook-defined node progression, (2) whether disease-probability trends are updated in a clinically consistent manner as new evidence emerges, and (3) whether the dialogue contains unsupported claims, including record-inconsistent summaries and guideline-noncompliant reasoning or questioning.

This filtering step serves two purposes. First, it removes low-quality or noisy trajectories before SFT, thereby improving the consistency of the supervision signal. Second, it aligns the demonstration data with the later PPO objective, reducing the mismatch between imitation learning and reinforcement learning.

E.3 Supervised Fine-Tuning initialisation

We use the reward-filtered dialogue set for supervised fine-tuning to initialise the Doctor agent. The objective of this stage is not only to teach the model the correct final diagnosis, but also to establish the desired interaction format and reasoning behaviour. In particular, SFT encourages the model to: (i) follow the structured consultation stages, (ii) ask diagnostically informative follow-up questions, (iii) update disease probabilities in accordance with the handbook and observed evidence, and (iv) produce coherent outpatient-style responses across multiple rounds.

This initialisation is important because pure reinforcement learning from scratch is unstable in

long-horizon dialogue settings. By starting from filtered demonstrations, the Doctor agent already acquires a basic diagnostic policy and a stable linguistic style before online optimisation begins.

E.4 PPO-Based Process optimisation

After SFT initialisation, we optimise the Doctor agent with PPO in a multi-round interactive setting. In each training episode, the Doctor agent interacts with the Patient agent over several consultation rounds. At each round, the Doctor produces the next diagnostic action in natural language, which may include summarising the current case, updating the differential diagnosis, and asking a targeted follow-up question. The Patient agent then responds according to the underlying case record.

Based on the accumulated interaction history, the Teacher agent provides process-level supervision. Its role is to audit whether the current trajectory follows the expected diagnostic process. Concretely, the Teacher checks handbook-node coverage, evaluates whether probability trends of candidate diseases are updated in the correct direction, and identifies unsupported claims. These signals are passed to the Evaluator agent, which transforms them into turn-level rewards and combines them with a final reward based on diagnostic correctness and diagnostic-tree similarity.

Compared with optimising only the final answer, this design allows PPO to improve the consultation trajectory itself. The model is encouraged not only to arrive at the correct diagnosis, but also to do so through a more guideline-consistent, evidence-grounded, and stable reasoning path.

E.5 Interleaved SFT Refresh

To maintain language fluency and structural consistency during PPO training, we periodically perform additional supervised fine-tuning on the filtered dialogue set. Specifically, after every five PPO rounds, we conduct one SFT refresh round.

This design is motivated by a common issue in reinforcement learning for language models: policy optimisation may improve reward-seeking behaviour while gradually harming surface quality, discourse coherence, or output format regularity. In our setting, such degradation is especially undesirable because the Doctor agent is required to maintain a structured consultation format across multiple rounds. Interleaving PPO with SFT helps preserve this structure while still allowing the model to improve process-level decision quality.

E.6 Roles of the Four Agents During Training

The four-agent design separates dialogue generation, simulated response, process auditing, and reward assignment into different functional components.

Doctor Agent. The Doctor agent is the only trainable policy in the framework. It is responsible for conducting the consultation, updating diagnostic hypotheses, and deciding what to ask next.

Patient Agent. The Patient agent simulates the patient's responses based on the underlying structured case record. Its role is to provide consistent and case-grounded answers to the Doctor's questions.

Teacher Agent. The Teacher agent performs process auditing. Given the interaction history, it checks whether the Doctor has covered the expected guideline nodes, whether diagnostic probabilities evolve in a clinically reasonable way, and whether unsupported claims are present.

Evaluator Agent. The Evaluator agent transforms the Teacher's audit outputs and the final consultation outcome into scalar rewards for optimisation. These include both intermediate rewards and final rewards.

E.7 Why Hybrid PPO+SFT Is Needed

A purely supervised approach can teach the model to imitate training trajectories, but it cannot directly optimise the sequential decision quality of the consultation process. Conversely, pure PPO may overfit to sparse rewards and damage the fluency or structural regularity of the generated dialogue. Our hybrid strategy is intended to balance these two objectives.

SFT provides a strong initialisation in terms of language quality, interaction format, and basic diagnostic behaviour. PPO then improves the policy by optimising process-level and outcome-level rewards in online interaction. Periodic SFT refresh acts as a stabiliser that preserves the model's structured output ability. Together, these components enable the Doctor agent to improve both diagnostic performance and process alignment.

E.8 Relation to the Main Experiments

All framework-enhanced Doctor models reported in the main experiments are trained under this hybrid PPO+SFT scheme. In the main paper, we

compare each such model against its corresponding base model under direct prompting. We further conduct ablation studies on three key components of the framework: the companion guideline file, the Teacher agent, and the turn-level optimisation procedure. These ablations isolate the contributions of external process knowledge, structured auditing feedback, and reward-based optimisation, respectively.

F Confusion Matrix for Non-Adherence

Abstract

Large language models (LLMs) demonstrate strong general language capabilities but remain limited in chemical reasoning, particularly for tasks requiring structured, mechanistic understanding of molecular reactions. We present **K**nowledge **G**raph **R**eaction **LLM** (KGRxn-LLM), a framework that augments LLMs with a hierarchical chemical knowledge graph (KG) to ground reasoning in molecular transformations and reaction patterns. Existing benchmarks primarily emphasize reaction or molecular fact recall, providing limited assessment of reaction-level mechanistic reasoning. To address this gap, we introduce **KGRxn-Bench**, a benchmark of 1,200 questions designed to evaluate LLMs on reaction-centric reasoning tasks, including functional group identification, reaction type classification, and product and reagent prediction. Experimental results show that our approach of grounding LLMs in structured KG substantially improves performance across multiple tasks and model backbones, outperforming domain specific fine-tuned models on KG-covered splits and most hold-out splits.[1]

1 Introduction

Recent advances in LLMs have led to remarkable progress on a broad spectrum of common-sense and general purpose language understanding tasks (Touvron et al., 2023; Achiam et al., 2023; Bai et al., 2023). Despite this success, LLMs continue to face significant challenges applied to chemistry, where domain knowledge is highly structured and governed by strict chemical rules rather than simple logic correlations (Bran et al., 2023; Jiménez-Luna et al., 2021). Prior efforts have extended LLMs to chemical domains such as molecular property question answering (QA), molecule caption generation, and molecular description tasks based on SMILES, which is string representation

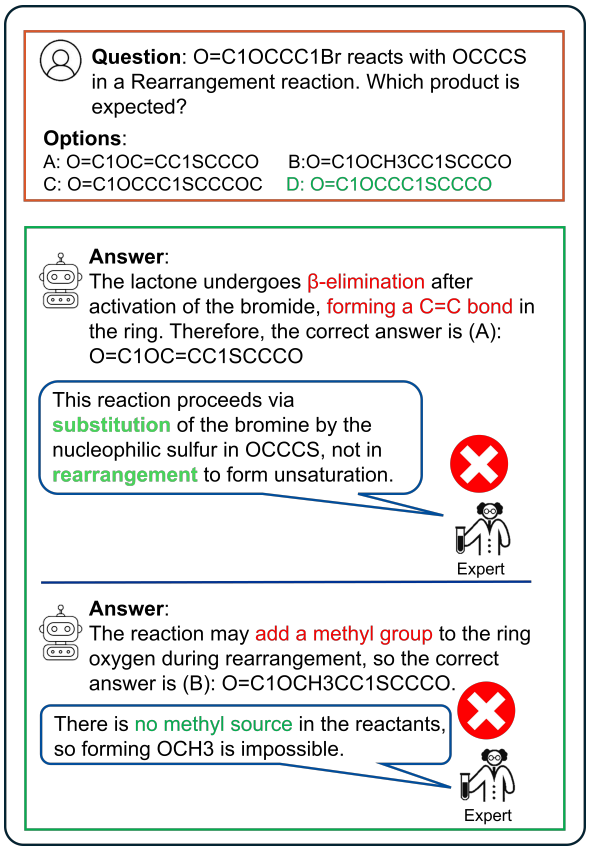

Figure 1: Illustration of hallucination problems of LLM doing molecular reaction reasoning.

of molecular structures using predefined syntax (Lu et al., 2024; Laghuvarapu et al., 2025), demonstrating that LLMs can learn to generate syntactically valid chemical text by fine-tuning on large scale related corpus. However, recent evaluations show that these models remain fundamentally limited in chemical reaction reasoning, often misidentifying functional groups, confusing reaction types, and failing to track structural transformations across reactants and products, especially on tasks that require multi-step reasoning about reaction mechanisms or functional group changes (Runcie et al., 2025; Chen et al., 2025; Zhang et al., 2025).

Current LLMs face hallucination problems in molecular reaction reasoning. Domain-specific models like ChemBERTa, MolT5, and Chemformer (Chithrananda et al., 2020; Edwards et al., 2022; Irwin et al., 2022) benefit from large-scale SMILES pretraining but these models may produce chemically invalid conclusions despite generating explanations that appear internally coherent. As shown in Figure 1, the first answer is confused about the "Rearrangement" reaction mechanism and the second answer involves wrong functional group source in reactant. A knowledge graph helps address this limitation by providing explicit chemical concepts as structured evidence for reasoning. Instead of relying only on pretrained knowledge, the model can retrieve grounded facts about molecules, functional groups, and reactions, which reduces hallucination and makes the reasoning process consistent with chemical rules.

Another fundamental challenge in this domain is the lack of benchmarks that explicitly evaluate LLMs' reasoning ability about molecular reaction transformations. Existing USPTO-based benchmarks (Chen et al., 2024; Yuan et al., 2025) focus primarily on forward reaction prediction or retrosynthesis, where success is measured by whether a model generates the correct product or SMILES representation. While these tasks are valuable, they do not assess whether a model understands the underlying transformation mechanisms or how functional groups evolve between reactants and products. On the other hand, chemical QA datasets such as MoleculeQA (Lu et al., 2024) and MolTextQA (Chen et al., 2025) focus on factual property comprehension, leaving reaction level reasoning ability such as identifying reaction types, tracking structural changes, or explaining mechanism relevant functional group operations largely untested.

To address these gaps, we introduce KGRxn-LLM, a knowledge graph(KG) integrated framework designed to advance knowledge-grounded molecular reasoning with LLMs. Our contribution can be summarized as follows:

- KGRxn-LLM introduces a hierarchical chemical knowledge graph with multiple layers, containing molecules, functional groups, reaction types and reaction instances. This KG encodes both chemical relationships and structural attributes of the chemical concept, forming an interpretable knowledge substrate.
- We propose KGRxn-Bench, a molecular reasoning benchmark built from curated USPTO reactions and annotated with functional group mappings and reactant-to-product transformations. The benchmark comprises tasks that evaluate reaction type identification, functional group transformation reasoning, and product prediction.
- We also propose an agent-based retrieval workflow that efficiently extracts transformation-relevant knowledge such as functional groups, common reaction patterns, similar molecules and reaction analogues, and uses this information to ground LLM reasoning, reducing hallucinations and improving accuracy.

2 Related work

LLMs for Biochemical Reasoning. The application of LLMs in biochemistry and computational biology has progressed rapidly, shifting from general text processing to specialized scientific discovery and molecular reasoning (Han et al., 2025; Usuyama et al., 2025). Recent paradigms treat biological molecules and small organic compounds as distinct text structures, allowing LLMs to excel in tasks ranging from protein structure prediction and *de novo* protein design to complex genomic analyses. For example, recent agent-based workflows have integrated LLMs to generate interpretable hypotheses for optimizing protein binding motifs and biochemical structures (Akke et al., 2025). Furthermore, the deployment of specialized multi-agent systems has enabled the autonomous execution of complex biochemical tasks, such as automating molecular dynamics simulations through tools (Campbell et al., 2025).

Parallel to these agentic frameworks, the emergence of advanced reinforcement learning-based reasoning models, such as DeepSeek-R1 and GPT-o series models (Guo et al., 2025; Jaech et al., 2024) has pushed the boundaries of zero-shot chemical intelligence, demonstrating robust capabilities in structural elucidation and the direct interpretation of molecular trends (Cui et al., 2025). While these models demonstrate impressive proficiency in broad biochemical property prediction and hypothesis generation, they continue to struggle with the rigorous, step-by-step mechanistic reasoning required to track atomic-level functional group transformations during chemical reactions. This fundamental limitation underscores the necessity for structurally knowledge-grounded approaches.

Knowledge Graph Guided LLM Reasoning. To mitigate hallucination and improve the factual reliability of LLMs, knowledge graph integration for Retrieval-Augmented Generation (RAG) has been employed (Lewis et al., 2020; Pan et al., 2024). Broadly, LLMs incorporate KGs to enhance reasoning through three primary mechanisms, including representation fusion, prompt augmentation, and tool-augmented querying (Pan et al., 2024). In representation fusion, KG network embeddings are injected directly into the LLMs' latent space during pre-training or fine-tuning, explicitly aligning textual tokens with structural entities to improve the model's internal knowledge representations (Yasunaga et al., 2022). Conversely, prompt-based retrieval methods, such as GraphRAG, dynamically extract multi-hop subgraphs, community summaries, or entity-relation triples from extensive knowledge bases, appending this structured context to the LLMs' input to guide explicit, step-by-step reasoning (Edge et al., 2024). To handle more complex logical queries, recent agentic frameworks like Think-on-Graph (ToG) and Reasoning-on-Graphs (RoG) empower LLMs to act as autonomous agents that iteratively explore graph structures by generating executable SQL queries to traverse multi-hop relational pathways before synthesizing an answer (Sun et al., 2023; Luo et al., 2023).

Within biochemical domains, these general frameworks have been successfully adapted by linking LLMs with specialized KGs such as UMLS or DrugBank to advance relational tasks like biomedical question answering and drug-target interaction prediction (Jin et al., 2024). Even though these domain-specific graphs excel at retrieving facts, they predominantly model knowledge as static nodes. Consequently, they remain unsuitable for capturing the dynamic, atomic-level transformations and mechanistic pathways required for complex chemical reaction reasoning. Our framework solves this problem with agentic retrieving algorithm, leveraging KG with comprehensive relationships of molecules and reactions.

Molecular Reasoning Benchmarks. The rapid integration of LLMs into biochemistry has motivated the development of specialized benchmarks for systematically evaluating their domain knowledge and reasoning capabilities. Recent benchmarks such as ChemLLMBench and ChemIQ (Guo et al., 2023; Runcie et al., 2025) assess a broad range of general chemistry tasks, including molecular property prediction, IUPAC to SMILES translation, and factual knowledge recall. To evaluate deeper structural understanding beyond conventional question answering, more recent benchmarks have begun to focus on fine grained and verifiable structural reasoning tasks. For example, FGBench introduces a rigorous evaluation framework for property reasoning at the functional group level, testing whether an LLM can interpret both single group and multi group structural interactions (Liu et al., 2025). ChemCoTBench tests stepwise molecular editing and optimization (Li et al., 2025), and MolErr2Fix measures the ability to detect and explain semantic hallucinations in molecular descriptions (Wu et al., 2025). However, these benchmarks provide limited coverage of reaction-centric reasoning, particularly mechanistic understanding of reactant-to-product transformations.

3 KGRxn-LLM Framework

3.1 Data Processing and Annotation

Preliminary Processing In retrieval-augmented settings, an excessively large graph may introduce noisy evidence, reduce retrieval precision, and degrade downstream reasoning quality (Gao et al., 2023). Therefore, we balance graph coverage with retrieval reliability. Following prior reaction prediction work (Coley et al., 2019), we extract 32,000 reactions from the USPTO reaction dataset (Marco et al., 2015). Among them, 30,000 reactions are used to construct the knowledge graph and the KG-covered portion of KGRxn-Bench, while the remaining 2,000 reactions are held out for constructing the benchmark hold-out split.

Starting from raw USPTO records, we first convert each reaction into a structured instance through JSON parsing and schema normalization, extracting reactants, products, and reaction-level metadata into a unified format. As illustrated in Figure 2, we then use RDKit to canonicalize molecular structures, trace atom correspondences between reactants and products, and identify functional groups in each molecule. Based on the atom-mapping results, we characterize functional-group-level transformations by determining which groups are retained, removed, or introduced during the reaction. The processed reaction, molecule, and functional-group annotations are stored in a structured database, which serves as the basis for knowledge graph construction and the KGRxn-LLM reasoning framework. More details are provided in Appendix A.1.

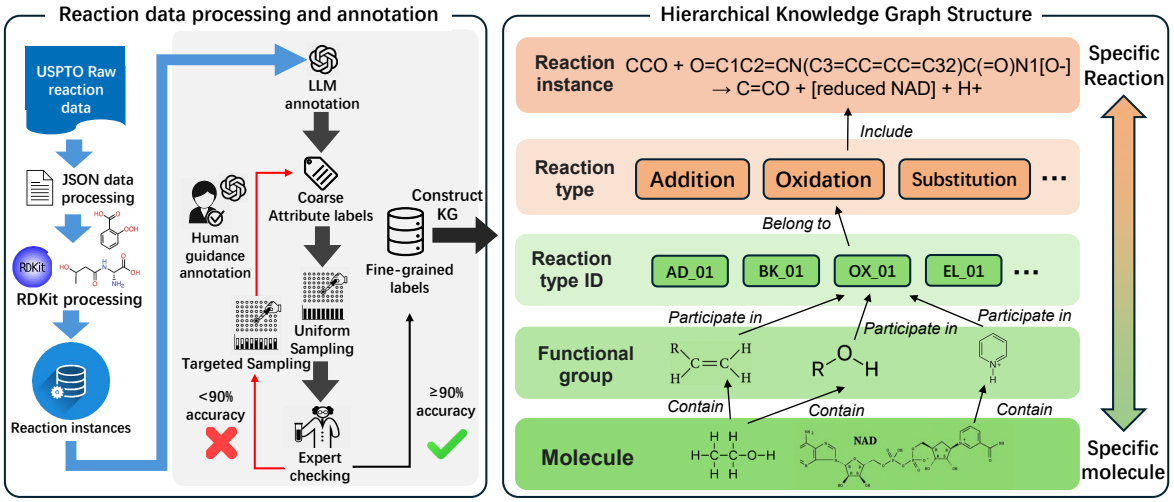

Figure 2: Overview of KGRxn-LLM data annotation pipeline and KG structure. Left: Raw USPTO reactions are processed into structured reaction instances, then annotated through an LLM-assisted pipeline with expert checking and resampling until reaching satisfactory accuracy. Right: Our hierarchical knowledge graph links molecules, functional groups, reaction type IDs, reaction types, and specific reaction instances across multiple levels.

Iterative Refinement Annotation Pipeline As shown in Figure 2, we employ an iterative human-in-the-loop pipeline to annotate KG entities and associated semantic labels in a scalable yet quality-controlled manner. In the first round, a strong closed-source LLM (ChatGPT 5) is used to produce coarse annotations for graph elements involved in knowledge graph construction, including reaction types, functional group categories and properties, and molecule-level properties. To assess annotation reliability, we uniformly sample a subset of instances for expert review and estimate annotation quality by empirical accuracy:

$$A = \frac{1}{|\mathcal{S}|} \sum_{x_i \in \mathcal{S}} \mathbf{1}[\hat{y}_i = y_i], \tag{1}$$

where $\mathcal{S}$ denotes the expert-reviewed subset, $\hat{y}_i$ is the LLM annotation, and y_i is the expert label.

When the verified accuracy falls below a predefined threshold of 90%, we perform a new round of targeted sampling that prioritizes instances from categories with higher observed error rates, while preserving the class composition of the previously reviewed subset to avoid severe sampling drift. Specifically, for each category c, we assign a sampling weight: $w_c \propto \pi_c(1 + \lambda e_c)$, where π_c is the category proportion in the previous review subset, e_c is the corresponding expert-verified error rate, and λ controls the emphasis on error-prone categories. This strategy increases the chance of selecting rare reaction types, molecules with multiple plausible functional groups, and structurally similar labels that are easy to confuse, while preserving the overall class composition.

At each audit round, previous observed errors are used to refine the annotation protocol with corrected examples, category-specific constraints, and explicit decision rules for ambiguous cases. The affected instances are then re-annotated under the revised protocol and audited again. This audit–refinement cycle is repeated until the target accuracy is reached. We also record category-wise error rates to identify systematic failure modes, allowing the KG annotation pipeline to scale beyond fully manual labeling while reducing bias from the pre-annotation model.

3.2 Reaction Knowledge Graph Construction

We construct the reaction knowledge graph as a hierarchical structure that organizes chemical knowledge from concrete molecular structures to abstract reaction semantics. Instead of treating each reaction as an isolated reactant–product pair, the graph decomposes reaction knowledge into multiple interconnected layers, including molecules, functional groups, fine-grained reaction patterns, coarse reaction categories, and specific reaction instances. This design improves retrieval efficiency by explicitly linking structural evidence to higher-level reaction concepts.

At the lowest level, molecule nodes represent the specific compounds involved in reactions. These

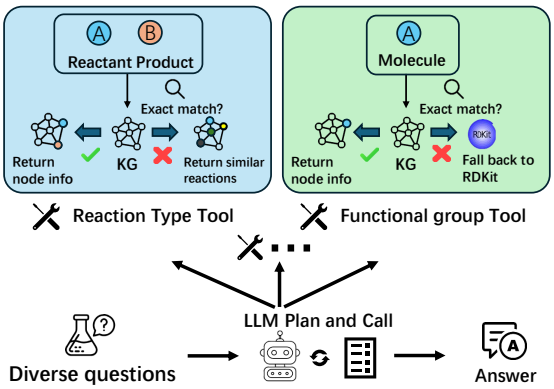

Figure 3: Task-specific tool calling and two-stage retrieval in KGRxn-LLM.

nodes preserve the original structural information and serve as the foundation of the graph. On top of this, functional group nodes capture chemically meaningful substructures, such as alcohols, alkenes, or carbonyl groups, and are linked to molecule nodes through "contain" relations. This layer provides a more reaction-relevant abstraction, since many reaction outcomes are determined by functional group transformations rather than whole-molecule identity.

Above the functional group layer, we introduce fine-grained Reaction Type ID nodes, which represent specific transformation patterns defined by characteristic local structural or functional-group changes. These nodes are further grouped into coarse reaction type nodes, such as oxidation, addition, and substitution, to provide a higher-level semantic taxonomy of reactions. Finally, reaction instance nodes represent individual reactions in the dataset and connect these abstract categories back to concrete examples. Overall, this hierarchical organization enables the graph to support both bottom-up reasoning from molecular structure to reaction type and top-down retrieval from reaction classes to plausible molecular transformations. More details can be found at Appendix A.2.

3.3 Knowledge Graph Retrieval Method

As illustrated in Figure 3, we formulate retrieval as an agentic tool-use process rather than a fixed lookup pipeline. Given a molecular reaction question, the LLM is prompted to determines which operation is required and then invokes the corresponding tool, such as functional group identification, reaction type inference, or other reaction-oriented utilities. Each tool is connected to the knowledge graph and follows a common two-stage retrieval strategy. It first attempts exact retrieval by matching canonicalized molecular or reaction representations to graph nodes, in which case the associated graph facts are returned directly as high-confidence evidence. If no exact match is available, the tool falls back to analogy-based retrieval at the functional-group level. Specifically, the query is represented by its consumed and formed functional group sets, and candidate reactions are ranked by the average Jaccard similarity (Travieso et al., 2024)

$$J_{\text{sim}} = \frac{1}{2}\left(\frac{|C_q \cap C_r|}{|C_q \cup C_r|} + \frac{|F_q \cap F_r|}{|F_q \cup F_r|}\right), \quad (2)$$

where C_q and F_q denote the consumed and formed functional groups of the query, and C_r and F_r denote those of a retrieved reaction. This retrieval criterion emphasizes analogous transformation patterns rather than superficial molecular similarity. For molecule-level queries such as functional group identification, the fallback is performed directly with RDKit-based functional group matching. The retrieved evidence is prepended to the original question and passed to the LLM for final answer generation in a single inference step. This design allows the model to adaptively choose the most relevant tool for each question while grounding its reasoning in explicit chemical evidence from either exact graph matches or structurally similar reaction analogues.

3.4 KGRxn-Bench Construction

We construct *KGRxn-Bench*, a benchmark designed to evaluate LLMs' ability on molecular reaction reasoning. As summarized in Table 1, the benchmark contains 1,200 questions derived from 986 unique reactions, covering 3,850 unique molecules, 10 reaction types, and 160 functional groups. The benchmark is designed to probe multiple levels of chemical reasoning, ranging from functional group recognition to reaction-level inference and condition prediction.

Task Definitions. KGRxn-Bench consists of four task types, each targeting a distinct aspect of reaction understanding.

Functional group identification requires the model to determine which functional group is present in a molecule represented by a SMILES string. This task evaluates whether the model can recognize chemically meaningful substructures from molecular representations.

Statistics	Number
Total Questions	1200
Unique Reactions	986
Unique Molecules	3850
Unique Reaction Types	10
Unique Functional Groups	160
Question Type Distribution	
Functional Group Identification (KG-covered)	272 (22.7%)
Functional Group Identification (hold-out)	100 (8.3%)
Reaction Type Classification (KG-covered)	243 (20.3%)
Reaction Type Classification (hold-out)	100 (8.3%)
Reaction Product Prediction (KG-covered)	151 (12.6%)
Reaction Product Prediction (hold-out)	100 (8.3%)
Reagent Prediction (KG-covered)	134 (11.2%)
Reagent Prediction (hold-out)	100 (8.3%)

Table 1: Key statistics of KGRxn-Bench.

Reaction type classification requires the model to infer the reaction category from reactant and product SMILES. Given the structural transformation, the model must assign the reaction to a predefined class such as substitution, oxidation, or addition. This task evaluates whether the model can abstract reaction semantics from explicit molecular changes.

Reaction product prediction requires the model to predict the expected product given two reactants and a specified reaction type. Unlike reaction classification, this task requires forward reasoning about how functional groups are transformed under a given reaction class.

Reagent prediction requires the model to infer plausible reagents (E.g.catalysts, solvents) from the observed reactant-to-product transformation. This task tests whether the model can associate structural changes with the reaction conditions typically required to realize them.

Question Answer Pair Generation. Questions are generated programmatically from the processed reaction data described in Section 3.1. For functional group identification, reaction type classification, and reagent prediction, multiple-choice distractors are generated by randomly sampling from the set of valid labels observed in the dataset. Specifically, we sample three incorrect options from the corresponding global label space, excluding the ground-truth answer, and combine them with the correct answer to form a multiple choice question with 4 options.

For reaction product prediction, we instead adopt a structure-aware mutation strategy to construct chemically plausible distractors. Rather than drawing unrelated molecules, we generate negative options by applying targeted modifications to the ground-truth product SMILES. These modifications include halogen substitution, replacement of carbonyl-adjacent groups, functional group swapping, aromatic position isomerization, double-bond toggling, substituent deletion, and small substituent addition. Mutation operators are applied iteratively until three unique and chemically valid distractors are obtained. This design makes the task substantially more challenging, as the incorrect options remain structurally similar to the correct answer and therefore require genuine mechanistic reasoning to distinguish.

KG-covered and Hold-out Splits. To evaluate both retrieval effectiveness and out-of-graph generalization, we partition the benchmark into *KG-covered* and *hold-out* subsets. The KG-covered subset contains questions derived from reactions included in the knowledge graph, allowing the retrieval module to access exact or closely related reaction evidence. In contrast, the hold-out subset is constructed from 2,000 reactions excluded during KG construction, ensuring that no exact reaction match is available in the graph.

Each task contains 100 hold-out questions, while the number of KG-covered questions varies across tasks according to the availability of eligible reactions. These two splits allow KGRxn-Bench to evaluate not only whether a model can benefit from graph-grounded retrieval, but also whether it can generalize to unseen reactions through higher level chemical similarity.

4 Experiments

4.1 Experiment Settings

Benchmarks We evaluate KGRxn-LLM on our proposed KGRxn-Bench together with two external benchmarks, FGBench (Liu et al., 2025) and SciKnowEval (Feng et al., 2024). KGRxn-Bench serves as our primary benchmark for molecular reaction reasoning, containing 1,200 multiple-choice questions spanning four tasks. We report results on both the KG-covered split and the hold-out split to evaluate the framework's ability to benefit from graph-grounded retrieval as well as to generalize beyond directly covered reactions. To further assess generalization beyond reaction-centered tasks, we additionally evaluate on FGBench and SciKnowEval, which probe broader biochemical understanding. Specifically, on FGBench we consider the Boolean tasks of single functional group impact,

multiple functional group interactions and molecular comparisons. On SciKnowEval, we evaluate both multiple-choice and boolean questions in chemistry and biology. We use zero-shot accuracy as the evaluation metric for all tasks.

Baselines We compare KGRxn-LLM against both general-purpose and domain-specific language models. Specifically, we include instruction-tuned LLMs such as Llama-3.1-8B-Instruct and Qwen2.5-7B-Instruct as general model baselines, as well as chemistry-specialized models including nach0-base, LlaSMol-Mistral-7B, ChemLLM-7B, ChemLLM-7B-DPO and ChemDFM-v1.5-8B (Livne et al., 2024; Yu et al., 2024; Zhang et al., 2024; Zhao et al., 2025). All models are evaluated under a consistent zero-shot prompting setting without additional fine-tuning.

Implementation Details The knowledge graph is constructed from 30,000 USPTO reactions and hosted on a Neo4j Aura cloud instance. The graph contains overall 146,500 nodes and 269,981 relationships linking through the five-level graph hierarchy. For the retrieval module, the Jaccard similarity threshold is set to 0.3, with a maximum of 5 retrieved analogy reactions to ensure enough information guidance from KG. During generation, we use a temperature of 0.2, top-p of 0.9, and a maximum of 1024 new tokens for all question to accommodate long reasoning chains. All models are prompted with a zero-shot chain-of-thought format. More detailed prompt can be found in Appendix B.

4.2 Experimental results

As shown in Table 2, KGRxn-LLM consistently outperforms most baseline models across tasks on KGRxn-Bench. Performance gains are particularly substantial on the KG-covered split, where knowledge retrieval yields massive improvements over vanilla models. For instance, KG augmentation increases Llama-3.1-8B accuracy on functional group identification from 58.82% to 94.12%.This result confirms that when high-quality structured evidence is available, even general-purpose LLMs can leverage it effectively. Similar trends across other tasks confirm that structured knowledge effectively enhances mechanistic reasoning. On the hold-out split, KGRxn-LLM maintains consistent gains, demonstrating its capacity to generalize. Specifically, the augmented Qwen2.5-7B model improves functional group identification from 67.00% to 92.00%, suggesting that retrieved structural evidence provides a valuable reference even without exact graph matches.

Furthermore, Table 3 shows that KGRxn-LLM also improves performance on the external benchmarks FGBench and SciKnowEval. On FGBench, augmentation elevates functional group reasoning, notably raising the Qwen2.5-7B score from 39.33% to 49.64% on interaction queries. On SciKnowEval, the augmented Llama model improves from 88.24% to 95.76% on the biological boolean subset, reflecting broad gains across both chemistry and biology. Collectively, these findings indicate that the proposed framework benefits both specialized reaction

Model	FGBench			SciKnowEval			
	Single	Inter.	Comp.	Chem MCQ	Chem boolean	Bio MCQ	Bio boolean
Llama-3.1-8B	68.36	43.67	45.52	63.41	**78.67**	66.61	88.24
Qwen2.5-7B	57.34	39.33	**51.64**	68.28	66.67	76.23	83.36
Llama-3.1-8B + KG	**70.83**	43.95	46.94	71.71	77.25	68.35	**95.76**
Qwen2.5-7B +KG	68.50	**49.64**	48.32	**72.97**	76.53	**77.19**	92.79

Table 3: Performance in accuracy on external benchmarks: FGBench and SciKnowEval. In FGBench we consider the Boolean tasks of single functional group impact, multiple functional group interactions and molecular comparisons. In SciKnowEval we evaluate Multiple Choice Question(MCQ) and Boolean on Chemistry and biology subset. Best results per column are in **bold**.

reasoning and broader biochemical understanding through transferable structured knowledge.

4.3 Analysis

Overcoming Structural Hallucination A primary challenge for standard LLMs in chemistry is the tendency to generate structural hallucinations, where the model suggests products containing atoms or functional groups not present in the initial reactants. As illustrated in the comparative analysis, vanilla models often fail to maintain a strict atom inventory, erroneously adding substituents like methyl groups during rearrangement tasks despite no such source existing in the input SMILES. KGRxn-LLM mitigates this by providing pre-computed functional group annotations and structural transformations from KG. By grounding the reasoning process from different molecules to specific functional groups, the framework ensures that the model's internal logic remains consistent with chemical constraints.

Generalization Through Analogy The framework demonstrates a capacity of chemical reasoning by analogy, particularly evident in its performance on hold-out reaction sets where exact matches are unavailable in the KG. When a direct lookup fails, the agentic tool-use process falls back to a two-stage retrieval strategy that calculates Jaccard similarity based on consumed and formed functional group sets. This approach allows the LLM to identify analogous transformation patterns from similar reactions, such as the conversion of an alcohol to an ester, and apply those underlying rules to unseen molecular structures. Experimental results on the hold-out split confirm this effectiveness, as the retrieval of structurally similar reaction analogues provides a reliable reference that guides the model toward correct mechanistic pathways even in extrapolative settings.

Beyond Reaction Centered Tasks Result on FGBench reveals that vanilla models struggle with multi functional group interactions, while knowledge augmentation grounds these relationships in verified chemical rules. Similarly on SciKnowEval, the graph supplies foundational context that prevents factual error in broader chemistry and biology queries. Although it occasionally happens that in general knowledge evaluation settings performance drop compared to vanilla model when KG fail to retrieve any irrelevant context, this problem can be solved by include broader range of knowledge.

5 Conclusion

In this work, we present KGRxn-LLM, a knowledge graph augmented framework for molecular reaction reasoning that integrates hierarchical chemical knowledge with functional group level information retrieval. We also introduce KGRxn-Bench, a benchmark designed to evaluate reaction-centric reasoning beyond standard knowledge recalling tasks. Experimental results demonstrate that our framework of augmenting LLMs with structured chemical knowledge graph substantially improves performance across multiple reasoning tasks and model backbones, while also generalizing to broader biochemical understanding.

Limitations

This study has several limitations. First, the adopted taxonomy of ten coarse-grained reaction types provides only a simplified abstraction of organic chemistry. Second, the current knowledge graph, constructed from approximately 30K reactions, remains modest in scale relative to the vast space of known chemical reactions, which may constrain both coverage and retrieval effectiveness. Finally,

the framework has only been evaluated on mid-scale language models (7–8B parameters), and its scalability and effectiveness on larger models remain to be systematically investigated.

A Appendix

A.1 Preliminary Processing

Starting from raw USPTO reaction records in JSON format, we extract reaction identifiers, DOI provenance, atom-mapped reaction SMILES, and all input components (reactants, solvents, catalysts) and products into a unified tabular representation. All molecular SMILES are canonicalized using RDKit, and each molecule is assigned a deterministic identifier via the SHA-1 hash of its canonical SMILES (first 16 hex characters), ensuring consistent deduplication across reactions. We then apply 220 SMARTS-based substructure queries to detect functional groups in each molecule. When multiple patterns match the same atom set, a specificity ranking retains only the most descriptive label (e.g., *alcohol_secondary* over generic *alcohol*). For atom-mapped reactions, we identify the reaction center by comparing atom-level properties between reactant and product sides, then expand the changed-atom set by one bond radius. Only functional group instances overlapping this expanded center are regarded as reaction-participating groups. We then compute *formed* and *consumed* functional group sets by comparing (name, atom-map tuple) pairs across sides, which serve as input to a rule-based reaction type classifier containing 34 prioritized rules across seven priority levels that assign each reaction to one of ten coarse types. Reactions matching no rule are labeled *Unknown* and excluded. Finally, molecules originally annotated as reactants but who do not participate in the reaction center are reclassified as unchanged agents.

A.2 Knowledge Graph Construction

The knowledge graph is implemented in Neo4j and organized into five node types connected by six edge types, forming the hierarchical structure illustrated in Figure 2. At the base layer, **Molecule** nodes store each compound's canonical SMILES and a hash-based identifier, while **Solvent** nodes (a separate label) represent molecules identified as non-reactive participants. Above this, **FunctionalGroup** nodes represent the 220 named substructure patterns, linked to molecules via HAS_FUNCTION_GROUP edges. At the reaction abstraction layer, **ReactionType** nodes encode ten coarse categories (e.g., Oxidation, Substitution), and **ReactionTypeId** nodes capture the 34 fine-grained transformation rules, connected by BELONGS_TO edges. Functional groups are linked to their associated reaction type IDs through PARTICIPATES_IN edges annotated with the specific functional group transformation pattern (e.g., "alcohol + carboxylic_acid $\rightarrow$ ester"), while solvents are linked via SOLVENT_IN edges. At the top layer, **Reaction** nodes represent individual reaction instances, each storing the atom-mapped reaction SMILES, reactant and product molecule identifiers, formed and consumed functional group lists, and a textual mechanistic explanation. Reaction nodes are connected to their corresponding ReactionType via CLASSIFIED_AS edges, and to participant Molecule and Solvent nodes via PARTICIPATES_IN and SOLVENT_IN edges respectively. All nodes and edges are created using idempotent `MERGE` statements, ensuring that the graph can be incrementally updated without duplication.

B Zero-shot Prompt in Evaluation

All the system prompt for model to do zero-shot reasoning is shown below:

VANILLA PROMPTS (without Knowledge Graph)

— Functional Group Identification —

[System Prompt] You are an expert organic chemist. Your task is to identify which functional group is contained in the given molecule (provided as SMILES notation).

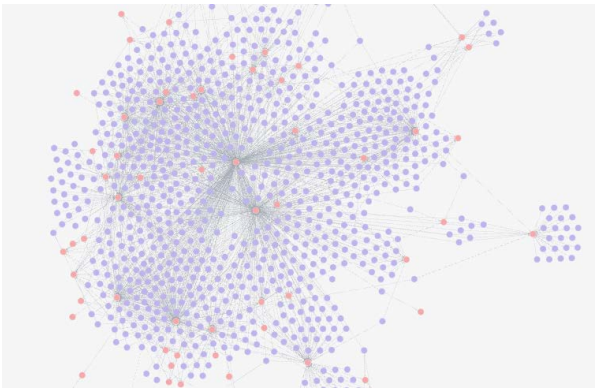

Figure 4: A sub-graph of 1000 relationships in the kG.

Think step by step: 1. First, analyze the SMILES string and identify the molecular structure 2. Identify the key functional groups present in the molecule 3. Compare with the given options 4. Select the correct answer

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Options: options

— Reaction Type Classification —

[System Prompt] You are an expert organic chemist. Your task is to identify the reaction type of a given chemical reaction (provided as SMILES notation).

Think step by step: 1. First, analyze the reactant and product SMILES strings and identify the molecular structures 2. Identify the key functional group transformations (which groups are consumed and which are formed) 3. Based on the transformations, determine the reaction type 4. Compare with the given options and select the correct answer

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Options: options

— Reaction Product Prediction —

[System Prompt] You are an expert organic chemist. Your task is to predict the product of a chemical reaction given the reactants and reaction type.

Think step by step: 1. First, analyze the reactant SMILES strings and identify the molecular structures 2. Consider the specified reaction type and what transformations it typically involves 3. Predict the product structure based on the reactants and reaction type 4. Compare with the given options and select the most likely product

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Options: options

— Reagent Prediction —

[System Prompt] You are an expert organic chemist. Your task is to predict the reagents (catalysts, solvents, or ancillary substances) needed for a given chemical reaction (provided as SMILES notation).

Think step by step: 1. First, analyze the reactant and product SMILES strings and identify the molecular structures 2. Identify the key functional group transformations (which groups are consumed and which are formed) 3. Based on the transformations, reason about what reagents, catalysts, or solvents would be needed 4. Compare with the given options and select the correct answer

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Options: options

KG-AUGMENTED PROMPTS (with Knowledge Graph)

— Functional Group Identification + KG —

[System Prompt] You are an expert organic chemist. Your task is to identify which functional group is contained in the given molecule.

You will be provided with: 1. The molecule in SMILES notation 2. Information retrieved from a Chemistry Knowledge Graph about the functional groups present in this molecule

Use the Knowledge Graph information to help you determine the correct answer. Think step by step: 1. Review the functional groups identified by the Knowledge Graph 2. Compare these with the given options 3. Select the correct answer based on the evidence

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Options: options

[Knowledge Graph Information] Molecule SMILES: smiles Source: source Functional groups found: comma-separated list

Please analyze the molecule and select the correct functional group from the options above.

— Reaction Type Classification + KG —

[System Prompt] You are an expert organic chemist. Your task is to identify the reaction type of a given chemical reaction (provided as SMILES notation).

You will be provided with: 1. The reaction in SMILES notation 2. Information retrieved from a Chemistry Knowledge Graph about functional group transformations or exact matches

Use the Knowledge Graph information to help you determine the correct reaction type. Think step by step: 1. Review the information from the Knowledge Graph (exact match or similar reactions) 2. Analyze the reactant and product structures and their functional group changes 3. Based on the transformations, determine the reaction type 4. Compare with the given options and select the correct answer

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Options: options

rag_context from get_reaction_type_rag()

Please analyze the reaction and select the correct reaction type from the options above.

— Reaction Product Prediction + KG —

[System Prompt] You are an expert organic chemist. Your task is to predict the product of a chemical reaction given the reactants and reaction type.

You will be provided with: 1. The reactants in SMILES notation and the reaction type 2. Information retrieved from a Chemistry Knowledge Graph about similar reactions or exact matches

Use the Knowledge Graph information to help you determine the correct product. Think step by step: 1. Review the information from the Knowledge Graph (exact match or similar reactions) 2. Analyze the reactant structures and reaction type 3. Consider the functional group transformations involved 4. Compare with the given options and select the most likely product

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Options: options

rag_context from get_reaction_product_rag()

Please analyze the reaction and select the correct product from the options above.

— Reagent Prediction + KG —

[System Prompt] You are an expert organic chemist. Your task is to predict the reagents (catalysts, solvents, or ancillary substances) needed for a given chemical reaction (provided as SMILES notation).

You will be provided with: 1. The reaction (reactants and product) in SMILES notation 2. Information retrieved from a Chemistry Knowledge Graph about exact matches or similar reactions with their reagents

Use the Knowledge Graph information to help you determine the correct reagent. Think step by step: 1. Review the information from the Knowledge Graph (exact match or similar reactions) 2. Analyze the reactant and product structures and the functional group changes 3. Based on the transformation, reason about what reagents would be needed 4. Compare with the given options and select the correct answer

You MUST end your response with your final answer in this exact format: **Answer: X** where X is A, B, C, or D.

[User Message] question

Abstract

The global transition to the ICD-11 taxonomy demands robust automated medical coding, yet comprehensive benchmarks to evaluate Large Language Models (LLMs) on this task remain absent. We introduce MAX-EVAL-11 [1] as a foundational resource, the first large-scale benchmark for full-spectrum ICD-11 medical coding. MAX-EVAL-11 comprises 10,000 MIMIC-III discharge summaries with mapped, expert-validated subset (12%) ICD-11 annotations spanning 99.87% of the diagnostic taxonomy. To better reflect clinical utility, we propose a novel hierarchical evaluation framework that assigns partial credit based on ICD-11's 5-level structure, addressing the brittleness of traditional exact-match metrics.

To illustrate benchmark utility, we evaluate LLMs on a stratified 500-patient sample, revealing significant performance gaps. The best-performing model (Claude 4 Sonnet) achieves a weighted score of 0.433, outperforming both general-purpose peers and specialized medical models (MedCoder). Crucially, all models exhibit near-zero exact match rates (0–4.8%) and rely primarily on hierarchical credit, underscoring the extreme difficulty of precise ICD-11 code generation. Furthermore, the superiority of general-purpose LLMs over legacy ICD-10 medical models (with ICD-11 codelist) suggests that broad reasoning capabilities currently outweigh domain-specific training for complex taxonomy scaling.

1 Introduction

Medical coding, transforming clinical narratives into standardized diagnostic codes is fundamental to modern healthcare for statistical analysis, reimbursement, and epidemiological research. The International Classification of Diseases (ICD), maintained by the WHO, provides the global standard for this task.

ICD-11, officially adopted in 2019 and effective since January 2022, represents a major evolution in medical classification (World Health Organization, 2019). As of 2024, 132 member states are implementing ICD-11, which introduces over 55,000 unique codes with post-coordination for granular clinical documentation (Harrison et al., 2021); (World Health Organization, 2024). Manual medical coding faces substantial challenges from growing documentation volumes, evolving regulations, and workforce shortages. The ICD-11 transition intensifies these pressures, requiring complex crosswalk mapping. Only 23.5% of ICD-9 codes achieve direct one-to-one ICD-11 mapping, complicating automated transition (Fung et al., 2021).

Recent AI advances, particularly large language models (LLMs), have sparked interest in automated medical coding. However, specialized models achieve F1 scores of only 0.539 to 0.719 on ICD-10 benchmarks (Baksi et al., 2025; Edin et al., 2023), while general-purpose LLMs face additional challenges (Hou et al., 2025). ICD-11's multidimensional taxonomy—capable of generating vast combinations via post-coordination—presents even greater complexity. Despite progress, existing benchmarks primarily focus on ICD-9 and ICD-10. MIMIC-III (Johnson et al., 2016) and MIMIC-IV-ICD (Nguyen et al., 2023) provide robust evaluation for legacy systems, but no comprehensive ICD-11 benchmark exists. Furthermore, traditional precision, recall, and F1 metrics inadequately capture the hierarchy of clinical relevance: accurate identification of a primary diagnosis is more critical than secondary conditions, yet existing metrics weight all predictions equally (Mullenbach et al., 2018).

We present **MAX-EVAL-11**, a comprehensive benchmark for evaluating LLM performance on ICD-11 medical coding. Our contributions are: **First**, a large-scale dataset with 10,000 real MIMIC-III discharge summaries with systematic

ICD-9 to ICD-11 conversion and complete taxonomy coverage. **Second**, a novel rank-weighted precision scoring methodology that assigns differential importance based on clinical relevance and diagnostic hierarchy, better reflecting real-world accuracy requirements. **Third**, baseline performance metrics using state-of-the-art LLMs (Claude, Gemini), demonstrating significant improvement opportunities in automated ICD-11 coding.

2 Related Work

2.1 Deep Learning Approaches for ICD Coding

Early neural approaches (RNNs, CNNs) established feasibility of automated coding but struggled with extreme multi-label classification (13,000+ codes) and long clinical documents (Choi et al., 2017; Baumel et al., 2018). Mullenbach et al. (2018) introduced CAML, using per-label attention to identify diagnosis-relevant text segments, establishing the label-wise attention paradigm for ICD coding. Subsequent refinements include LAAT (Vu et al., 2020), pseudo label-wise attention (Wu et al., 2021), and HiLAT (Liu et al., 2022), progressively improving efficiency and hierarchical coding accuracy. The integration of pretrained language models brought further improvements. Huang et al. (2022) introduced PLM-ICD, incorporating domain-specific pretraining, segment pooling, and specialized label attention, achieving 59.8% micro-F1 on MIMIC-III. Liu et al. (2023) extended these capabilities with extreme multi-label transformers adapted for long clinical narratives (ClinicalBIGBIRD), reaching 60.8% micro-F1. However, these advances remain constrained to ICD-9 and ICD-10 evaluation, with no comprehensive ICD-11 benchmarks available despite the classification's 2019 WHO adoption and ongoing global implementation across 132 member states. Wu et al. (2025) introduced MIMIC-SR-ICD11, a dataset derived from MIMIC-IV for narrative-based ICD-11 diagnosis, though limited to primary diagnosis only and covering a narrow subset of the full taxonomy without a hierarchical evaluation framework.

2.2 Evaluation Frameworks and Limitations

Kim et al. (2022) introduced AnEMIC, providing standardized preprocessing and evaluation protocols for MIMIC-III benchmarks—an important step toward reproducibility. However, three fundamental limitations persist across existing evaluation frameworks, directly motivating MAX-EVAL-11's development.

Metric mismatch with clinical hierarchy. Standard precision, recall, and F1 metrics treat all diagnostic codes uniformly despite differing clinical salience (Kim et al., 2022). This approach fails to capture medical classification systems' hierarchical nature. For instance, predicting "Infectious Disease" (ICD-11 chapter 1A00-1G9Z) when the ground truth is "Bacterial Pneumonia" (CA40.0) receives zero F1 credit, yet the model correctly identified the broad disease category (infection) and affected organ system (respiratory)—partial accuracy valuable in clinical practice where physicians can narrow diagnoses from correct disease families. Moreover, the distinction between primary and secondary diagnoses carries critical clinical importance that flat metrics ignore: primary diagnoses drive treatment decisions and resource allocation, making errors in primary identification far more consequential than missing secondary comorbidities (e.g., failing to identify acute myocardial infarction as primary could delay life-saving interventions). Existing metrics weight all predictions equally, obscuring these safety-critical distinctions.

The benchmark-practice performance gap. Recent evaluations reveal troubling disconnects between constrained benchmark performance and real-world capability. Hou et al. (2025) demonstrate that models achieving 97–99% exact match on simplified ICD-9 test sets collapse to 3.85–10.90% when evaluated on realistic clinical scenarios. This dramatic degradation stems from two factors: *extreme label spaces* where models must identify 10–15 relevant codes from 50,000+ candidates per clinical note (fundamentally different from constrained benchmarks limiting evaluation to hundreds of common codes), and *realistic multi-diagnosis complexity* in discharge summaries containing multiple diagnoses spanning organ systems, temporal progression (admission → complications → discharge), and complex interactions (e.g., diabetes exacerbating pneumonia recovery) that simplified benchmarks lack.

Absent ICD-11 coverage. Despite ICD-11's official WHO adoption in 2019 and implementation across 132 member states as of 2024 (World Health Organization, 2019), existing benchmarks remain focused on legacy ICD-9 (Johnson et al., 2016) and ICD-10 (Nguyen et al., 2023) classifications. The few ICD-11 pilot studies remain narrow in scope, typically evaluating models on small

taxonomy subsets (500–1,000 codes) or synthetic data lacking real clinical documentation complexity. No comprehensive benchmark spans ICD-11's full 55,000-code diagnostic taxonomy with authentic clinical text, creating critical evaluation gaps as healthcare systems worldwide transition to the new standard.

2.3 Positioning MAX-EVAL-11

MAX-EVAL-11 addresses these gaps through: (1) full-spectrum ICD-11 coverage across 10,000 MIMIC-III discharge summaries; (2) hierarchical evaluation metrics reflecting clinical diagnostic priority; and (3) comprehensive LLM baselines on realistic multi-diagnosis scenarios.

3 Methodology

3.1 ICD-9 to ICD-11 Mapping Framework

The transition from ICD-9 (≈13,000 codes) to ICD-11 (≈55,000 codes) represents a fundamental shift in medical classification granularity (World Health Organization, 2019). Given an ICD-9 code $c_9 \in \mathcal{C}_9$, we seek to identify the optimal ICD-11 code set $S_{11} \subseteq \mathcal{C}_{11}$ that preserves clinical semantics. Our hybrid approach combines semantic embedding-based candidate retrieval (efficient search space reduction from 55,000+ codes) with LLM-based contextual selection (clinical disambiguation of related codes).

3.2 Hybrid Semantic-LLM Mapping Pipeline

Problem Formulation. Let $\mathcal{D}_9 = \{(c_9^{(i)}, t_9^{(i)})\}_{i=1}^{N_9}$ and $\mathcal{D}_{11} = \{(c_{11}^{(j)}, t_{11}^{(j)})\}_{j=1}^{N_{11}}$ represent the ICD-9 and ICD-11 code sets, where c denotes the code identifier, t denotes the textual description, $N_9 \approx 13{,}000$, and $N_{11} \approx 55{,}000$. Our mapping function is:

$$f : \mathcal{C}_9 \to 2^{\mathcal{C}_{11}} \times [1, 10] \tag{1}$$

where $f(c_9) = (S_{11}, \sigma)$ returns ICD-11 codes S_{11} with LLM-assigned quality score $\sigma \in [1, 10]$.

Semantic Candidate Generation. While WHO provides partial ICD-9–ICD-11 crosswalk tables, these cover only 23.5% of ICD-9 codes with direct mappings (Fung et al., 2021); our hybrid pipeline addresses the remaining 76.5% for which no official mapping exists. We employ Bio_ClinicalBERT (Alsentzer et al., 2019), pretrained on 2 million MIMIC-III clinical notes, achieving F1 = 0.89 on i2b2 2010 medical entity recognition. Its 768-dimensional embeddings capture fine-grained semantic distinctions essential for differentiating clinically related diagnostic codes. We use the pretrained model without fine-tuning, as the task requires general medical semantic similarity rather than task-specific classification.

For each ICD-9 code, we construct composite inputs via string concatenation ($\oplus$):

$$x_9^{(i)} = c_9^{(i)} \oplus \text{“ - ”} \oplus t_9^{(i)} \tag{2}$$

and encode using Bio_ClinicalBERT's encoder ϕ : String $\to R^{768}$:

$$e_9^{(i)} = \phi(x_9^{(i)}) \tag{3}$$

Similarly, we encode all ICD-11 descriptions to obtain embeddings $e_{11}^{(j)}$. We identify top-$k = 10$ candidates via cosine similarity:

$$\text{sim}(e_9^{(i)}, e_{11}^{(j)}) = \frac{e_9^{(i)} \cdot e_{11}^{(j)}}{\|e_9^{(i)}\| \|e_{11}^{(j)}\|} \tag{4}$$

where $k = 10$ balances efficiency with coverage for one-to-many mappings common in ICD-9 to ICD-11 transitions.

LLM-Based Contextual Selection. Top-10 candidates often contain clinically related but distinct codes (e.g., bacterial vs. viral pneumonia) requiring medical reasoning to disambiguate. We employ Gemini 2.0 Flash, selected after comparing GPT-4, Claude 3.7, and Gemini 2.0 on 100 sample mappings: Gemini achieved 87% expert agreement versus 79% (GPT-4) and 82% (Claude 3.7). Its structured output capabilities and 1-million token context enable processing complete taxonomies. We formulate prompts:

$$\mathcal{P}(c_9, \mathcal{C}^{\text{cand}}) = [\text{Task}_{\text{instr}}, \text{Code}_{\text{ctx}}, \text{Output}_{\text{fmt}}] \tag{5}$$

where $\text{Task}_{\text{instr}}$ instructs the model to *rate the clinical relevance of each ICD-11 candidate for the given ICD-9 code on a scale of 1–10 (10 = exact semantic match; 1 = unrelated)*; Code_{ctx} includes ICD-9 code c_9 with the 10 ICD-11 candidates and their descriptions; and $\text{Output}_{\text{fmt}}$ specifies a JSON schema of `{code: string, score: int}` per candidate. The LLM returns $M_i = \{(c_j^{11}, \sigma_{ij})\}$ where $\sigma_{ij} \in [1, 10]$. We retain all candidates with $\sigma_{ij} \geq 7$ as the final mapping set S_{11}; if no candidate meets this threshold, the highest-scoring candidate is retained to ensure full coverage.

Methodological Independence. Label generation uses only ICD code taxonomies for code-to-code

translation (Gemini 2.0 Flash), while evaluation requires clinical narrative understanding from discharge summaries (Gemini 2.5 Flash), distinct models, tasks, and information sources (see Conclusion).

3.3 Quality Score-Based Stratification and Quality Assessment

We stratify by mapping quality score Σ_p, the average LLM-assigned score across patient p's mappings:

$$\Sigma_p = \frac{1}{|M_p|} \sum_{(c_9, c_{11}, \sigma) \in M_p} \sigma \tag{6}$$

where M_p represents all mappings for patient p. Binary stratification with $\tau = 7.0$ yields:

$$\text{Conf}(p) = \begin{cases} \text{High} & \text{if } \Sigma_p \geq 7.0 \\ \text{Low} & \text{if } \Sigma_p < 7.0 \end{cases} \tag{7}$$

This threshold was validated on 200 manual mappings: $\sigma \geq 7.0$ achieved 89% expert agreement versus 67% for $\sigma < 7.0$. The *High-Confidence Subset* ($\Sigma_p \geq 7.0$) optimizes for maximum reliability (billing, compliance), while *All-Matches Subset* enables robust evaluation across quality conditions.

We assess mapping quality via Coverage Rate $\rho = |\{p : |M_p| > 0\}|/N_p$ (proportion successfully mapped), Expansion Factor $\alpha = \sum_p |C_{11}^{(p)}| / \sum_p |C_9^{(p)}|$ (granularity increase, where $C_9^{(p)}$ and $C_{11}^{(p)}$ are code sets for patient p), and Semantic Preservation $\psi = \frac{1}{N_m} \sum_{i=1}^{N_m} \max_j \text{sim}(c_9^{(i)}, c_{11}^{(j)})$ (semantic alignment, where N_m is total mappings and $\text{sim}(\cdot, \cdot)$ is Equation 4). Values $\alpha > 1$ and $\psi > 0.75$ indicate successful ICD-11 expansion with semantic fidelity. The threshold $\psi > 0.75$ reflects the cosine similarity range at which BioClinicalBERT embeddings reliably preserve clinical semantics: values below 0.75 in our BioClinicalBERT embedding space correspond to pairs where the primary diagnostic category (e.g., infectious vs. cardiovascular) differs, as verified on the 200-mapping validation subset used for confidence threshold calibration (Section 3.3).

3.4 Hierarchical Evaluation Metrics

Traditional metrics assign binary credit (1 for exact match, 0 otherwise), ignoring ICD-11's hierarchical taxonomy. A model predicting "CA40.0Z Bacterial pneumonia, unspecified" for ground truth "CA40.0 Bacterial pneumonia" demonstrates clinical understanding despite technical mismatch. Similarly, primary diagnosis accuracy matters more than secondary coding, yet flat metrics weight equally. We propose multi-component scoring reflecting clinical priorities.

Hierarchical Credit Assignment. ICD-11's 5-level hierarchy (Chapter → Block → Category → Subcategory → Extension) enables partial credit $h(c_{\text{true}}, c_{\text{pred}})$ based on closest common ancestor:

$$h(c_{\text{true}}, c_{\text{pred}}) = \begin{cases} 1.0 & \text{exact} \\ 0.9 & \text{parent} \\ 0.8 & \text{grandparent} \\ 0.7 & \text{great-grandparent} \\ 0.6 & \text{chapter} \\ 0.0 & \text{unrelated} \end{cases} \tag{8}$$

Credits decrease uniformly by Δ=0.1 per taxonomy level from exact match (1.0) down to chapter-level match (0.6), reflecting ICD-11's 5-level hierarchy where each level represents a meaningful clinical distinction; codes sharing no chapter (e.g., an infectious disease predicted as a metabolic disorder) receive h=0.0 as they provide no clinically actionable signal regardless of proximity.

Metric Components. *Exact Match* (EM) measures precise coding:

$$\text{EM} = \frac{1}{N} \sum_{i=1}^{N} \frac{|P_i \cap G_i|}{|P_i \cup G_i|} \tag{9}$$

where P_i and G_i are predicted and ground truth codes for patient i.

Clinical Precision (CP) weights by diagnostic priority:

$$\text{CP} = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{|P_i|} \sum_{j=1}^{|P_i|} w_j \cdot 1[p_{ij} \in G_i] \tag{10}$$

where $1[\cdot]$ is the indicator function, $w_1 = 1.0$ (primary), $w_2 = 0.8$ (secondary), $w_{j \geq 3} = 0.6$ (comorbidities). E.g., for G={CA40.0, 5A10.0, 8B20.0}, P={CA40.0, 5A10.1, 1A00}: $CP = \frac{1.0+0+0}{3} = 0.33$.

Points Earned (PE) quantifies hierarchical partial credit:

$$\text{PE} = \frac{1}{N} \sum_{i=1}^{N} \frac{\sum_{p \in P_i} \max_{g \in G_i} h(p, g)}{|G_i|} \tag{11}$$

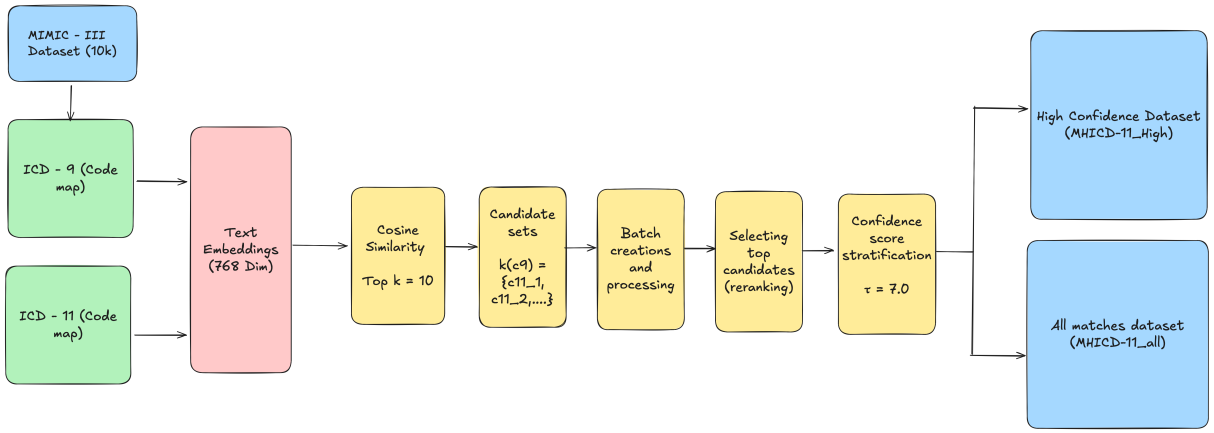

Figure 1: Overview of the hybrid semantic-LLM pipeline for ICD-9 to ICD-11 mapping. The process combines Bio_ClinicalBERT embeddings for candidate generation with Gemini 2.0 Flash for context-aware mapping selection, resulting in confidence-stratified benchmark datasets.

This rewards correct disease categories despite subtype errors (e.g., "CA40 Pneumonia, unspecified" for "CA40.0 Bacterial pneumonia" earns $h = 0.8$).

Hierarchical Match (HM) averages best alignments. For each prediction p, we find its best ground truth match: $\max_{g \in G_i} h(p, g)$. Averaging over predictions per patient, then across patients:

$$\text{HM} = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{|P_i|} \sum_{p \in P_i} \max_{g \in G_i} h(p, g) \qquad (12)$$

Composite Weighted Score. We combine components with clinical weights:

$$\text{Score} = 0.5 \cdot \text{EM} + 0.3 \cdot \text{CP} + 0.15 \cdot \text{PE} + 0.05 \cdot \text{HM} \qquad (13)$$

Exact matching (0.5) prioritizes billing/regulatory accuracy; clinical precision (0.3) emphasizes primary diagnosis; points earned (0.15) rewards near-misses; hierarchical match (0.05) credits broad categorization. Unlike nDCG, our metric incorporates ICD-11-specific hierarchy and clinical priority weighting. Pilot validation (2 expert coders, 50 cases) showed Spearman ρ=0.79 vs. ρ=0.61 for F1.

4 Dataset Description

4.1 Source Data and Patient Selection

We derive our benchmark from MIMIC-III (Johnson et al., 2016), selecting 10,000 patients through stratified sampling to preserve clinical characteristic distributions while maintaining computational tractability. Each patient record contains discharge summaries with ICD-9 diagnosis codes. The dataset encompasses 6,984 unique ICD-9 codes across 118,106 total code instances (mean 11.81 codes per patient), representing comprehensive diagnostic coverage encountered in critical care settings. The ICD-9 distribution follows the characteristic heavy-tailed pattern of medical coding systems, with high variance indicating diverse diagnostic complexity.

4.2 ICD-9 to ICD-11 Mapping and Coverage

Our hybrid semantic-LLM pipeline (Section 3) transforms each patient's ICD-9 diagnosis set into corresponding ICD-11 codes. Patient-level coverage achieves 99.71% for high-confidence mappings ($\Sigma \geq 7.0$) and 99.87% overall, with code-level expansion factors of 1.099 (high-confidence) and 1.274 (all-matches). These metrics demonstrate successful expansion from ICD-9 to ICD-11's more granular classification, with each ICD-9 code mapping to an average of 1.1–1.3 ICD-11 codes, reflecting the enhanced diagnostic specificity of the newer taxonomy.

4.3 Benchmark Variants

We provide two benchmark datasets stratified by mapping confidence (Table 1). The high-confidence subset ($\Sigma \geq 7.0$) comprises 9,971 patients with 129,785 ICD-11 codes (mean 13.02 per patient), optimized for high-precision applications such as billing systems and regulatory compliance. The all-matches subset includes 9,987 patients with 150,502 ICD-11 codes (mean 15.07 per patient), providing comprehensive coverage for robust evaluation under diverse confidence conditions. Both variants include prescription data (drug names, dosages, timestamps) to support diagnosis-

treatment coherence analysis.

Metric	High-Conf.	All-Matches
Patients	9,971	9,987
ICD-11 codes	129,785	150,502
Mean codes/patient	13.02	15.07
Coverage	99.71%	99.87%
Expansion factor	1.099	1.274
Confidence threshold	≥ 7.0	All ≥ 1.0

Table 1: Benchmark dataset variant statistics.

4.4 Human Validation and Quality Control

To ensure benchmark reliability, we conducted manual validation with two clinical coders who independently reviewed 1,203 discharge summaries (12% of dataset) using stratified sampling across ICD-11 chapters. We also performed systematic quality analysis across all 10,000 records.

4.4.1 Confidence-Based Quality Tiers

Our validation reveals distinct quality tiers (Table 2). High-confidence mappings (85% of dataset) achieve expansion ratios of 0.8–1.5, indicating semantically consistent ICD-9→ICD-11 translation with complete coverage, suitable for production deployment. Low-confidence mappings (15%) exhibit lower expansion ratios and require manual review before clinical use.

Tier	%	Exp.	Utility
High ($\geq$7)	85	0.8–1.5	Production ready
Low (<7)	15	<0.8	Manual review

Table 2: Quality tiers by confidence threshold (σ). Expansion ratio = avg ICD-11 codes per ICD-9 code.

4.4.2 Domain-Specific Quality

Clinical domain analysis (Table 3) reveals variable mapping complexity. Domains with stable ICD-9→ICD-11 correspondences (infectious diseases, cardiovascular) achieve 89–92% success, while domains with structural taxonomy changes (external causes, procedures) show lower rates (38–45%), consistent with known ICD-11 architectural differences.

4.4.3 Error Analysis

Analysis of 273 disagreements (10.8% of validated codes) shows 70% stem from clinical ambiguity rather than pipeline failures: **(1)** Secondary diagnosis prioritization (42%): coding pre-existing conditions from history as active diagnoses—experts disagreed on 28% of these. **(2)** Granularity selection (28%): choosing specificity levels where both

Domain	Exp.	Succ.	Pattern
Infectious	1.2	92%	Excellent
Cardiovascular	1.1	89%	Consistent
Neoplasms	1.3	85%	Enhanced
Symptoms	0.7	62%	Variable
Ext. Causes	0.6	45%	Challenges
Procedures	0.4	38%	Manual

Table 3: Mapping quality by clinical domain (10K patients).

are valid. **(3)** Rare codes (18%): <10 instances in MIMIC-III, affecting only 2.3% of total data. **(4)** Cross-taxonomy inference (12%): extrapolating from ICD-9's coarser categories.

4.4.4 Benchmark Validity

Our validation supports three use cases: **(1)** High-precision evaluation using 85% subset (κ=0.67), comparable to ICD-10 inter-annotator agreement (Kim et al., 2022), for publication-quality comparison with near-expert labels. **(2)** Standard evaluation using full dataset ($\kappa = 0.52$) with quality comparable to existing benchmarks—MIMIC-III's ICD-9 labels contain documented errors (Kim et al., 2022) yet lack validation. **(3)** Confidence-aware training incorporating scores into loss functions. MAX-EVAL-11 provides transparent quality metrics exceeding existing ICD coding benchmarks.

4.5 Dataset Accessibility

Benchmark datasets are provided in CSV format with standardized schemas (SUBJECT_ID, HADM_ID, ICD9_CODES_LIST, ICD11_CODES_MAPPED, CONFIDENCE_SCORES, MEDICATIONS). All data adheres to MIMIC-III de-identification standards (Goldberger et al., 2000), and processing scripts are provided to ensure reproducibility.

5 Experimental Results

5.1 Baseline Model Performance

We evaluated three major categories of models on our ICD-11 prediction benchmark: Claude models (Anthropic), Gemini 2.5 Flash (Google), and MedCoder (specialized medical coding model – ICD-10) (Baksi et al., 2025). Table 4 presents the comprehensive performance evaluation across all baseline models. Claude 4 Sonnet achieves the highest overall performance with a final score of 0.433, demonstrating superior clinical precision (0.433) and coverage (0.353). Notably, Claude models consistently outperform both the specialized medical

model (MedCoder) and the multimodal Gemini model across all evaluation metrics. MedCoder (ICD-10 trained; Baksi et al., 2025) serves as a *zero-shot ICD-11 transfer baseline*, evaluated with the ICD-11 code list provided at inference without weight modification, representing the performance floor for domain-specific models without ICD-11 adaptation.

5.1.1 Evaluation Protocol

For each patient in the evaluation dataset, models receive:

- **Input**: Complete MIMIC-III discharge summary (chief complaint, history, medications, labs, hospital course, discharge diagnosis).
- **Task:** Generate ranked list of ICD-11 diagnosis codes based solely on clinical narrative
- **Constraints:** Separate pipeline, no access to original ICD-9 codes or mapping or ICD code taxonomies

The evaluation simulates real-world clinical coding scenarios where human coders or AI systems must assign ICD-11 codes directly from clinical documentation without reference to legacy coding systems. Models are prompted with standardized instructions requesting comprehensive ICD-11 code prediction with confidence scores and clinical justification. All models receive identical inputs to ensure fair comparison across architectures and capabilities. The prompt is: *Given the discharge summary, identify all diagnoses and provide their ICD-11 codes as a ranked, comma-separated list ordered by clinical priority.* Evaluation was conducted on a stratified random sample of n=500 patients, selected to reflect the full distribution of ICD-11 chapters and diagnosis complexity; Full-benchmark evaluation (n=10,000) is left for future work contingent on compute resources; we report stratified sampling to ensure chapter-level representativeness of the n=500 subset.

5.2 Statistical Analysis

Table 5 presents the statistical significance analysis using Wilcoxon signed-rank tests, revealing substantial performance gaps between model categories.

5.3 Key Findings

MedCoder serves as a zero-shot ICD-10→ICD-11 transfer baseline and is not a peer competitor. It establishes the performance floor for domain-specific models without ICD-11 adaptation. Claude models achieve superior performance (35.8% mean final score) compared to the domain-specific MedCoder (24.5% final score), suggesting that large-scale pretraining and reasoning capabilities may be more valuable than specialized medical training for ICD-11 prediction tasks.

Exact matching remains challenging: All models show relatively low exact match rates (0-4.8%), indicating the inherent difficulty of precise ICD-11 code generation. Claude models demonstrate the strongest exact matching capabilities among evaluated systems.

Hierarchical understanding varies significantly: Claude models excel in hierarchical matching (19.4-40.2%), leveraging the taxonomic structure of ICD-11, while MedCoder shows limited hierarchical understanding (18.4%).

RAG integration challenges: Retrieval-augmented variants underperform their baselines (Claude RAG: 0.253 vs. 0.425; RAG+Reranker: 0.282 vs. 0.425), suggesting that naive RAG introduces noise rather than beneficial context. We implement two variants over a Qdrant vector index of all 55,000 ICD-11 code descriptions: **Claude RAG** appends retrieved codes to the prompt before generation; **Claude 4 RAG+Reranker** additionally reranks by semantic similarity before injection; both operate agentically, with the LLM issuing retrieval queries during inference. The performance degradation likely stems from semantic proximity confounding clinical specificity: when a patient presents with *left-sided heart failure*, retrieval surfaces semantically adjacent codes (e.g., right-sided heart failure, cardiomyopathy) that share embedding space but are clinically distinct, anchoring the model toward incorrect codes.

6 Conclusion

This work presents the first comprehensive benchmark for ICD-11 prediction using a large-scale clinical dataset, contributing three key advances to medical informatics research.

Methodological Contribution: We develop a novel hybrid semantic-LLM pipeline for automated ICD-9 to ICD-11 mapping, combining BioClinicalBERT embeddings with Gemini 2.0 Flash for context-aware medical code translation. Our approach achieves 99.87% mapping coverage across 10,000 patients, establishing a robust foundation

Table 4: Comprehensive Performance Evaluation of Baseline Models on ICD-11 Prediction Task

Model	Final Score	Clinical Precision	Exact Match	Hierarchical Match	Coverage Score	Samples (n)
Claude 4 Sonnet	**0.433**	**0.433**	**0.047**	0.375	**0.353**	500
Claude 3.5 Haiku (Baseline)	0.425	0.426	0.034	**0.402**	0.315	500
Claude 3.7 Sonnet	0.396	0.372	0.048	0.325	0.332	500
Gemini 2.5 Flash	0.341	0.315	0.016	0.286	0.330	500
Claude 4 RAG+Reranker	0.282	0.232	0.010	0.202	0.175	500
Claude 4 RAG	0.253	0.215	0.007	0.194	0.160	500
MedCoder	0.245	0.191	0.000	0.184	0.092	500

Table 5: The larger performance gap for Gemini vs. MedCoder (0.096) yields a higher p-value than Claude vs. Gemini (0.092) because Wilcoxon signed-rank tests reflect score consistency across patients, not only mean differences; MedCoder exhibits higher per-patient variance (near-zero scores on complex multi-diagnosis cases), reducing the rank-based significance despite the larger mean gap.

Comparison	Performance Gap	Relative Improvement	p-value
Claude-4-Sonnet vs Gemini-2.5-Flash	0.092	27.0%	$< 0.001^{***}$
Gemini-2.5-Flash vs MedCoder	0.096	39.2%	$< 0.01^{**}$
Claude-4-Sonnet vs MedCoder	0.188	76.7%	$< 0.001^{***}$
Claude Category vs Gemini Category	0.061	18.8%	$< 0.01^{**}$
Claude Category vs MedCoder Category	0.150	61.2%	$< 0.001^{***}$

*** $p < 0.001$, ** $p < 0.01$, * $p < 0.05$

for ICD-11 adoption.

Evaluation Framework: Our hierarchical metric assigns partial credit across ICD-11's 5-level taxonomy, achieving Spearman ρ=0.79 alignment with expert clinical judgment versus ρ=0.61 for standard F1.

Empirical Insights: General-purpose LLMs (Claude 4 Sonnet: 43.3% final score) meaningfully outperform specialized medical models (MedCoder: 24.5% final score) in zero-shot ICD-11 transfer, suggesting broad reasoning capabilities currently outweigh domain-specific ICD-10 training for taxonomy scaling, a finding reinforced by MedCoder's 0% exact match rate despite being purpose-built for medical coding. The benchmark datasets and evaluation framework are made publicly available to support continued research; Future work should focus on improving exact match performance, hierarchically-aware RAG integration, validating across diverse care settings, and exploiting the prescription data included in the benchmark but unused in this evaluation.

Methodological Independence. A potential concern is whether the use of Gemini 2.0 Flash in label generation creates bias toward Gemini models during evaluation. However, three factors demonstrate this is not the case:

(1) Task Difference: Label generation uses structured code taxonomies (code-to-code translation, while evaluation requires clinical text understanding (narrative-to-code generation)—fundamentally different capabilities requiring distinct model strengths.

(2) Information Sources: Mapping uses only ICD code descriptions/titles of ICD-9 and ICD-11 code tables; evaluation uses complete discharge summaries with clinical context, medications, procedures, temporal progression, and physician reasoning—information never seen during label creation.

(3) Empirical Evidence: Gemini 2.5 Flash achieves the lowest performance among major models (0.341 final score vs. Claude 4 Sonnet's 0.433, a 27% gap, Table 4), demonstrating no preferential advantage from its predecessor's involvement in label creation. If systematic bias existed, Gemini models would outperform rather than underperform. This performance gap actually validates that clinical coding ability (extracting diagnoses from narratives) is independent from taxonomy knowledge (code mapping). The substantial performance difference between Claude and Gemini models (statistically significant at $p < 0.001$, Table 5) reflects genuine differences in clinical

reasoning and medical text understanding capabilities, not artifacts of the label generation process; nonetheless, scores reflect benchmark-relative alignment rather than clinical deployment readiness.

7 Ethical Considerations

7.1 Data Privacy and Security

All patient data used in this study is sourced from the publicly available MIMIC-III database, which has undergone rigorous de-identification procedures following HIPAA Safe Harbor provisions (Goldberger et al., 2000). No additional patient identifiers were created during our mapping process, and all generated benchmarks maintain the original de-identification standards.

7.2 Bias and Fairness

The MIMIC-III dataset reflects the patient population of a single academic medical center, potentially introducing demographic and socioeconomic biases into our benchmark. Furthermore, MIMIC-III captures exclusively ICU admissions, where patients exhibit atypically high diagnostic complexity (mean 11.8 codes/patient); benchmark performance may not generalize to community hospital or outpatient coding scenarios with simpler, fewer diagnoses. The ICD-9 codes in the original dataset may also exhibit coding practices specific to the source institution, which could propagate through our ICD-11 mappings. Future work should validate across diverse care settings and patient populations.

7.3 Clinical Safety Implications

Automated ICD coding systems carry significant clinical and financial implications. Coding errors can affect patient care continuity, insurance reimbursements, and population health analytics. Our evaluation reveals that current models require human oversight, with exact match rates below 5% across all systems. Healthcare organizations should implement appropriate safeguards and validation procedures before deploying automated coding systems.

7.4 Algorithmic Accountability

The hybrid semantic-LLM approach introduces opacity in the mapping process, particularly in the LLM decision-making component. While we provide confidence scores and mapping justifications, the full reasoning process remains partially opaque. This limitation necessitates careful validation and monitoring in clinical deployment scenarios.

7.5 LLM Service Compliance

In accordance with PhysioNet's responsible use policy for credentialed datasets (PhysioNet, 2025), all cloud-based LLM processing of MIMIC-III discharge summaries was conducted exclusively through enterprise-tier services: Claude models via **Amazon Bedrock** (AWS enterprise account) and Gemini models via **Google Vertex AI** (GCP enterprise account), both explicitly listed as compliant services by PhysioNet (PhysioNet, 2025). Both platforms guarantee zero data retention, no use of submitted data for model training, and no human review of submitted content, satisfying all PhysioNet DUA requirements for processing credentialed health data with external LLM services.

Abstract

Reliable extraction of structured information from radiology reports using Large Language Models (LLMs) remains a significant challenge, particularly for complex, non-English texts such as Hebrew. This study proposes an agent-based, uncertainty-aware framework to enhance the reliability and interpretability of LLM predictions in clinical contexts. A total of 9,683 Hebrew radiology reports from Crohn's disease patients (2010–2023) across three medical centers were analyzed. Of these, 512 reports were manually annotated for six gastrointestinal organs and 15 pathological findings, while the remainder were automatically labeled using HSMP-BERT. Structured data extraction was performed with Llama 3.1 (Llama 3-8b-instruct) employing Bayesian Prompt Ensembles (BayesPE), which utilized six semantically equivalent prompts to quantify uncertainty. An Agent-Based Decision Model aggregated prompt outputs into five calibrated confidence levels and was benchmarked against three entropy-based approaches. Model performance was assessed using accuracy, F1 score, precision, recall, and Cohen's Kappa before and after filtering high-uncertainty cases. The agent-based model outperformed all baselines, achieving an F1 score of 0.3967, recall of 0.6437, and Kappa of 0.3006; after excluding cases with uncertainty $\geq$0.5, the F1 score increased to 0.4787 and Kappa to 0.4258. The proposed framework improves uncertainty calibration and predictive reliability, advancing the safe deployment of LLMs in medical data extraction.

1 Introduction

Radiology reports contain critical clinical information, essential for healthcare decision-making, retrospective studies, and radiologic image annotation. Despite ongoing efforts to implement structured reporting (Nobel et al., 2022), unstructured free-text reports remain dominant, posing challenges for large-scale data analysis due to their variability and lack of standardization. Automating the extraction of structured data addresses these issues by streamlining workflows, reducing manual effort, and improving data consistency and accessibility. This approach not only enhances patient care but also enables large-scale research through comprehensive meta-analyses, accelerated scientific discoveries, and stronger evidence-based practice (Hassanpour and Langlotz, 2016; Haendel et al., 2018; Langlotz et al., 2019).

Large language models (LLMs) can automate structured data extraction from radiology reports by processing unstructured text to efficiently yield clinically relevant insights (Busch et al., 2024; Doshi et al., 2024; Reichenpfader et al., 2024). However, privacy concerns around sensitive medical data have prompted interest in open-source LLMs, which offer greater transparency, adaptability, and control. Models like Llama 3.1 can extract meaningful insights from medical texts while mitigating risks associated with proprietary systems (Nowak et al., 2025).

Despite their potential, applying LLMs to radiology remains challenging, particularly for decision-critical tasks. A key limitation is their tendency to produce overconfident predictions, even when uncertain or incorrect, undermining trust in high-stakes medical settings (Shmidman et al., 2024; Tessler et al., 2024; Chen et al., 2024). Although uncertainty quantification methods have improved reliability, they exhibit unique structural limitations. Confidence elimination (CE) relies on explicit self-evaluation prompts but often suffers from sycophancy and poor calibration (Xiong et al., 2024). Token-level probabilities (TLP) utilize raw token distributions but are heavily restricted by proprietary API boundaries (Huang et al., 2025). Sample consistency (SC) measures generation diversity via temperature sampling but treats all outputs uniformly without weighting (Kompa et al., 2021).

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 292–311
July 3-4, 2026 ©2026 Association for Computational Linguistics

They often treat all responses equally, potentially ignoring variations in prompt quality or contextual relevance (Savage et al., 2025). These limitations are further amplified in underrepresented languages like Hebrew, where limited annotated data and linguistic differences hinder LLM adaptability. Addressing both overconfidence and linguistic gaps is essential for robust and equitable deployment across diverse clinical settings.

Bayesian Prompt Ensembles (BayesPE) (Tonolini et al., 2024) improve uncertainty estimation in LLM by combining semantically equivalent prompts and optimizing their weights by variational inference, applying these weights directly to the prompt-specific outputs to improve prediction reliability and calibration. However, reliance on a parametric model for prompt weights may limit flexibility in complex or dynamic settings.

Agent-based approaches (Xi et al., 2023) offer adaptive decision making for LLM outputs, potentially addressing BayesPE's limitations by incorporating more sophisticated uncertainty estimation processes.

1.1 Related Work

The application of AI in clinical text processing has advanced rapidly, particularly in structuring clinical narratives (Hassanpour and Langlotz, 2016). While large language models demonstrate high proficiency in English medical domains (Langlotz et al., 2019), their performance declines in low-resource and morphologically rich languages like Hebrew (Shmidman et al., 2024). To bridge this gap, recent paradigms explore agentic AI frameworks where multi-agent systems coordinate to solve complex clinical reasoning tasks (Zeng et al., 2024). However, utilizing these adaptive frameworks specifically for calibrating predictive uncertainty in low-resource medical processing remains significantly underexplored.

This study introduces a novel framework to address these limitations. This study aims, therefore, to introduce and evaluate an agent-based method for the extraction of structured data. Our approach utilizes uncertainty-aware LLM-based data from real-world Hebrew radiology reports from Crohn's disease patients. Finally, we compare its performance and robustness with BayesPE's probabilistic aggregation methods.

Contributions

- We introduce and evaluate a generalizable agent-based approach for quantifying uncertainty in Large Language Models (LLMs) used for structured data extraction in high-stakes clinical settings, specifically utilizing low-resource Hebrew radiology reports.
- We design an Agent Decision Model (using Llama 3 - 70B) that synthesizes outputs and explanations from a Bayesian Prompt Ensemble (BayesPE) and categorizes prediction confidence into five distinct levels (e.g., Definitely Yes/No, Likely Yes/No, Uncertain).
- We demonstrate that the agent-based approach provides the best balance of performance metrics (F1=0.3967, Cohen's Kappa=0.3006) compared to single-prompt baselines and entropy-based aggregation models.
- We validate the superior calibration of the Agent model, showing clearer separation between correct predictions (median uncertainty 0.0) and incorrect predictions, and confirm that filtering high-uncertainty cases significantly improves reliability.

2 Materials and methods

2.1 Data Collection

The retrospective multicenter study was approved by the institutional review board, with a waiver of informed consent due to its retrospective nature and the de-identification of data. Free-text Hebrew radiology reports of Crohn's disease patients were obtained from the *epi-IIRN* national inflammatory bowel disease (IBD) study cohort (Friedman et al., 2018), a validated database encompassing all four Israeli health maintenance organizations (HMOs), which collectively cover over 98% of the population. The dataset comprises **9,683 radiology reports**, each corresponding to an individual patient visit, derived from **8,093 unique patients** across three medical institutions. Each report documents a *magnetic resonance enterography* (MRE) or *computed tomography enterography* (CTE) examination performed between **2010 and 2023**.

2.1.1 Manual Annotation of Organ–Finding Pairs

A uniformly distributed random subset of **512 reports** was selected for manual annotation by an expert radiologist (T.H.). While relying on a single expert annotator presents a structural limitation regarding inter-annotator variability and potential subjective bias, it reflects the high cost and scarcity of specialized medical expertise. Each report was labeled for **six gastrointestinal organs** (Jejunum, Ileum, Cecum, Colon, Sigmoid, and Rectum) and

up to **15 pathological findings** per organ (e.g., inflammation, wall thickening, ulceration) (Bruining et al., 2018), yielding a total of **90 possible organ–finding combinations**.

Each combination was assigned one of four categorical labels: 1 = finding present (positive), 0 = finding absent (negative), 2 = organ resected (post-surgical), or 9 = organ not visible. For the main analysis, labels 2 and 9 were treated as negative, simplifying the task to a **binary classification** (finding present vs. absent). To ensure sufficient representation of positive cases, we excluded organ–finding pairs with $\leq$15 positive examples, resulting in **23 final classification targets**, which represent specific valid clinical pairings of a target gastrointestinal organ and an associated pathological condition (see Figure 4 in Appendix A).

2.1.2 NLP Based Annotations

We used HSMP-BERT, an internal BERT-based NLP model for structured data extraction from Hebrew radiology reports from Crohn's disease patients (Hazan et al., 2024a,b), to annotate the entire data set of 9,683 reports. The HSMP-BERT architecture was initialized from a pre-trained multilingual BERT checkpoint and fine-tuned using a masked language modeling objective followed by a multi-label classification head, optimized via AdamW with a learning rate of 2×10^{-5} and a batch size of 16 on the manually annotated training partition. The model was trained in the manually annotated subset, focusing on 23 common combinations of organ-finding. Performance metrics for these labels appear in Table 5 in the supplementary materials. To ensure high-quality data for BayesPE-based methods, we retained only labels with a Cohen's Kappa score greater than 0.7, resulting in eight final labels: Sign of ileum comb, inflammation of the ileum, pre-stenotic dilation of the ileum, stenosis of the ileum, enhancement of the ileum wall, thickness of the ileum wall, thickness of the rectum wall and sign of the sigmoid comb.

2.2 Large Language Model (LLM) Utilization

We used the Llama 3.1 model (Llama 3-8b-instruct) (AI@Meta, 2024), part of Meta's multilingual LLM collection, to extract structured data from Hebrew radiology reports. Although it supports several languages, Hebrew is not among them. The selection of Llama 3.1, despite its lack of official Hebrew optimization compared to models like Phi-4, Aya, or local Hebrew variants, was driven by its superior architectural scaling, high cross-lingual transferability, and widespread open-source deployment capability in secure clinical environments. Llama 3.1 utilizes an auto-regressive transformer architecture (Vaswani et al., 2017), further refined via supervised fine-tuning (SFT) (Sun, 2024) and reinforcement learning from human feedback (RLHF) (Christiano et al., 2017; Stiennon et al., 2022; Ouyang et al., 2022) to better align with human preferences. Given its limited Hebrew support, we carefully adapted the model for this context, applying distinct prompt structures to evaluate cross-prompt variability. We prompted the model with various organ–finding combinations to extract structured data from Hebrew radiology reports, asking whether a specific finding was indicated. We also included a self-explanation step for each answer, aiding model validation and improving accuracy (see Appendix C for the full prompt schema).

2.3 Uncertainty Estimation with Bayesian Prompt Ensembles

We employed the Bayesian Prompt Ensembles (BayesPE) method (Tonolini et al., 2024) to estimate uncertainty in LLM-generated predictions by leveraging an ensemble of semantically equivalent prompts, without modifying the LLM's architecture or requiring retraining. In alignment with findings from (Tonolini et al., 2024), we selected six prompts to balance the benefits of prompt diversity with computational efficiency, as adding more prompts provided only marginal gains. We used ChatGPT (OpenAI, 2024) to design these six prompts, each with identical semantic intent to determine the presence of specific findings in radiology reports.

We developed an agent-based method and three entropy-based approaches to quantify model uncertainty using outputs from multiple prompts. Fig. 1 illustrates the different approaches we utilized to assess uncertainty.

2.4 Agent Decision Model

We propose an Agent Decision Model, functioning as a second-stage LLM component, to consolidate the outputs of multiple prompts, derive a final decision, and quantify its uncertainty. This model synthesizes responses and explanations from an ensemble of prompts, producing a unified decision with a rationale for its conclusion. The agent evaluates response consistency, assesses the clarity and coherence of explanations, and identifies indi-

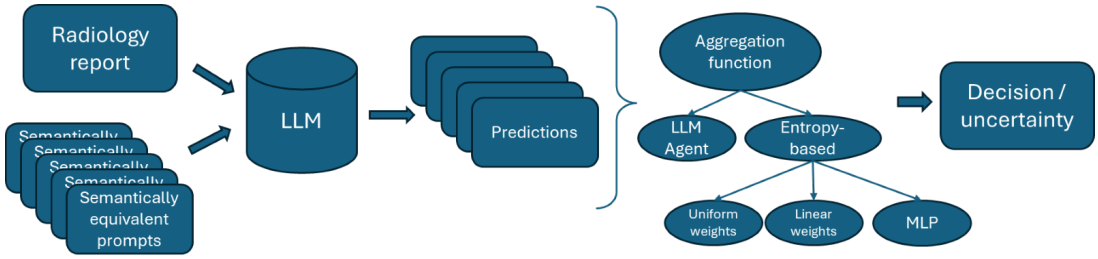

Figure 1: Illustration of the proposed Bayesian Prompt Ensemble pipeline for uncertainty-aware predictions. A radiology report and multiple semantically equivalent prompts are fed into an LLM, generating one prediction per prompt. These predictions are then aggregated to yield a final decision and uncertainty estimation. Note that the listed aggregation methods represent standalone, alternative pathways evaluated in isolation rather than interacting concurrent components.

cations of uncertainty. Based on these factors, it categorizes the final decision into one of five distinct confidence levels. This 5-level discretization was chosen to mimic clinical reporting conventions (e.g., highly likely, indeterminate) and to separate explicit certainty from qualified or ambiguous findings:

- Definitely Yes
- Likely Yes
- Uncertain
- Likely No
- Definitely No

The agent receives as input a set of answers ("Yes" or "No") and their corresponding explanations, generated by prompting a smaller, efficient LLM using multiple semantically equivalent questions. This design choice was motivated by two key factors: (1) asking the same question multiple times is significantly more cost- and time-efficient with smaller models; and (2) the inputs of this stage do not contain personally identifiable medical information, allowing the aggregation step to safely utilize more powerful models—either offline or online—without posing privacy risks. The agent evaluates these inputs based on the consistency of the answers, the clarity of their explanations, and the degree of ambiguity to produce its final decision.

To ensure interpretability and structure, the agent outputs its decision and reasoning in a predefined JSON format. In our implementation, we utilized the Llama 3 - 70B model as the agent.

The agent's uncertainty level is derived based on the confidence category of its decision:

- Definitely Yes/No: Uncertainty = 0
- Likely Yes/No: Uncertainty = 0.5
- Uncertain: Uncertainty = 1

This semi-quantitative approach enables the seamless integration of uncertainty measures into downstream analyses, enhancing the interpretability of the decision-making process (see Appendix C for detailed inputs/outputs). For the "Uncertain" response, a final "Yes" or "No" decision is determined by aggregating the probabilities for each option from the previous step and selecting the option with the highest overall score.

2.5 Entropy-based Decision Models

Alongside our agent-based decision model, we implemented three entropy-based models for comparison. These models quantify uncertainty using entropy, a measure of the disorder or unpredictability within the ensemble of prompt outputs. Higher entropy indicates greater disagreement among prompts, suggesting higher uncertainty in the final prediction. The final prediction and its entropy are determined by applying different weighting methods to the prompt outputs, as follows:

2.5.1 Uniform Weights

In this approach, all prompts are assigned equal weights: $w_i = 1/N$, where N is the number of prompts. This method operates under the assumption of no prior knowledge regarding the efficacy of individual prompts, thus distributing trust uniformly.

2.5.2 Linearly Optimized Weights

In this approach, we optimized the weights assigned to different prompts using a small validation set. We determine the weights by minimizing the following objective function:

$$\mathcal{L}_{\text{opt}} = \sum_{i=1}^{N} w_i \log P(y^*|a_i, x) - \lambda \sum_{i=1}^{N} w_i \log(w_i) \quad (1)$$

where y^* denotes the correct answer, a_i represents the i^{th} prompt structure, and x is the radiology report. The weights w_i are computed by applying a softmax transformation to the raw weights $w_{\text{raw},i}$. The first term represents the log-likelihood of the validation data, while the second term acts as an entropy-based regularizer, discouraging overconfidence in a single prompt. We performed linear optimization of prompt weights for each organ-finding label using a fixed subset of 50 samples from the manually annotated dataset.

2.5.3 Learnable Weights Using MLP

The uniform and linearly optimized weighting methods assume fixed or simple relationships between prompts, limiting their ability to capture complex interactions. To address this, we introduce a Multi-Layer Perceptron (MLP) for adaptive prompt weight optimization. The MLP dynamically adjusts weights based on prompt behavior across the dataset, enabling more accurate weighting in scenarios with intricate dependencies between prompts. The forward pass for the model is defined as follows:

$$\mathbf{w} = \text{softmax}(\text{MLP}(\mathbf{h})) \tag{2}$$

where $\mathbf{h}$ represents the fixed prompt embeddings, and $\mathbf{w}$ are the normalized weights. The training objective combines the binary cross-entropy loss between the ground truth labels $\mathbf{y}_{gt}$ and the weighted prompt probabilities $\hat{\mathbf{y}}$, with an entropy regularization term to encourage well-calibrated uncertainty:

$$\mathcal{L}_{\text{MLP}} = \text{BCE}(\hat{\mathbf{y}}, \mathbf{y}_{gt}) - \lambda \sum_{i=1}^{N} w_i \log(w_i) \tag{3}$$

During inference, the final predicted probabilities for each label are the weighted average of the individual prompt probabilities: $\hat{y} = \sum_{i=1}^{N} w_i p_i$. We leveraged the automatically labelled cases for the 8 selected labels to train the MLP model. We used 60% of the automatically labelled dataset, comprising 5794 cases, for training, 20% for validation and 20% for testing, ensuring this automated test split remained entirely distinct from the manually annotated expert evaluation set.

2.6 Evaluation Setup

We evaluated our approach on the manually annotated test dataset (462 reports, with 23 organ–finding combinations), excluding the 50 cases used to tune the linear weights. Model agreement was primarily quantified using Cohen's Kappa, a statistical metric that measures inter-rater agreement for categorical items while adjusting for the agreement occurring by chance alone. To establish a baseline, we simulated using any single prompt from our set of six, computing performance metrics for each prompt independently and then averaging the results.

We compared Uniform, Linear, and MLP-weighted ensembles, as well as our proposed Agent Decision Model. To further examine the effect of model capacity, we included an ablation variant ("Small Agent") in which the large Llama 3.1 model was replaced with the smaller Llama 3.1-8B model while keeping all other components identical. Each model was evaluated both before and after uncertainty filtering, with two filtering criteria: (1) excluding samples with uncertainty $\geq$0.5, and (2) limiting exclusions to at most 20% of cases if their uncertainty exceeded 0.5, accomplished by sorting the entire evaluation set by descending uncertainty scores and truncating the exclusion pool at the 20% rank boundary to maximize data retention.

3 Results

3.1 Uncertainty-aware prediction without filtering

Table 1 shows that aggregating multiple prompts significantly outperforms using a single prompt. The baseline (single-prompt) model has the lowest metrics, particularly F1=0.2699 and Kappa=0.1790. In contrast, the agent-based approach achieves the best overall balance, with F1=0.3967 and Kappa=0.3006, suggesting it handles ambiguity effectively. Although the MLP model attains the highest accuracy (0.8605) and precision (0.3772), its recall is lower (0.3977). Both uniform and linear methods also surpass the baseline, with linear showing slightly higher accuracy (0.8454) for similar F1, emphasizing the benefits of weight-optimized prompt ensembles. Notably, the Small Agent variant achieved the highest recall (0.7076), indicating strong sensitivity to positive findings. However, this came at the cost of reduced precision and overall agreement (Kappa=0.2402), suggesting it tends to over-predict positives compared with the other ensemble methods.

3.2 Uncertainty Histograms

Figures 2 and 3 show the uncertainty histograms for two representative labels from the four methods, with the Agent model providing the clearest sep-

Table 1: Average results across all labels before threshold.

Model	Accuracy	F1	Precision	Recall	Kappa
Baseline	0.8243	0.2699	0.3046	0.3097	0.1790
Uniform	0.8320	0.3873	0.3360	0.5336	0.2979
Linear	0.8454	0.3847	0.3463	0.4878	0.2988
MLP	**0.8605**	0.3643	**0.3772**	0.3977	0.2863
Agent	0.8022	**0.3967**	0.3131	0.6437	**0.3006**
Small Agent	0.7310	0.3555	0.2626	**0.7076**	0.2402

Table 2: Average median uncertainty values across methods.

Method	Median Uncertainty	
	Correct Predictions	Incorrect Predictions
Uniform	0.4081	0.6153
Linear	0.2668	0.4694
MLP	0.2261	0.5717
Agent	**0.0**	**0.5108**
Small Agent	0.0	0.5

aration between correct and incorrect predictions. Additional histograms appear in the supplementary materials.

Table 2 presents the average median uncertainty across all 23 labels, illustrating that a well-calibrated model should exhibit low uncertainty for correct predictions and high uncertainty for incorrect ones. The Agent model yields an average median uncertainty of 0.0 for correct predictions and about 0.5 for incorrect ones, indicating superior calibration compared to the other methods. While this strong separation highlights the model's effectiveness in distinguishing between reliable and unreliable predictions, the consistent 0.0 value for correct predictions also raises the possibility of discretization effects.

3.3 Uncertainty-aware prediction with filtering

Tables 3 and 4 present model performance after filtering out cases with uncertainty $\geq$0.5. Table 3 imposes no cap on excluded cases, while Table 4 limits exclusion to at most 20%. In both scenarios, removing high-uncertainty cases improves accuracy, F1, and Cohen's Kappa. Detailed per-label results can be found in the supplementary materials.

With no exclusion cap (Table 3), the MLP model achieves the highest accuracy (92.42%), whereas the Agent approach yields the best F1 (47.87

Under the 20% cap (Table 4), MLP again leads in accuracy (90.87%), and the Agent method retains the highest F1 (44.94%) and recall (72.95%), and Cohen's Kappa (0.3683). These results highlight the Agent method's strong emphasis on capturing true positives while maintaining reliable calibration, even with minimal case exclusions. The performance improvements achieved by filtering high-uncertainty cases demonstrate enhanced reliability but come at the cost of reduced report coverage, underscoring a fundamental trade-off between accuracy and scalability in automated workflows.

Table 3: Results after applying uncertainty threshold $\geq$ 0.5.

Model	Acc	F1	Prec	Recall	Kappa	Excluded Cases
Baseline	0.824	0.269	0.304	0.309	0.179	0
Uniform	0.918	0.463	0.445	0.532	0.420	200 (43.3%)
Linear	0.897	0.426	0.400	0.508	0.370	96 (20.9%)
MLP	**0.924**	0.403	**0.458**	0.407	0.364	120 (26.0%)
Agent	0.894	**0.478**	0.397	**0.661**	**0.425**	153 (33.1%)
Sm. Agent	0.851	0.421	0.331	0.685	0.353	185 (40.1%)

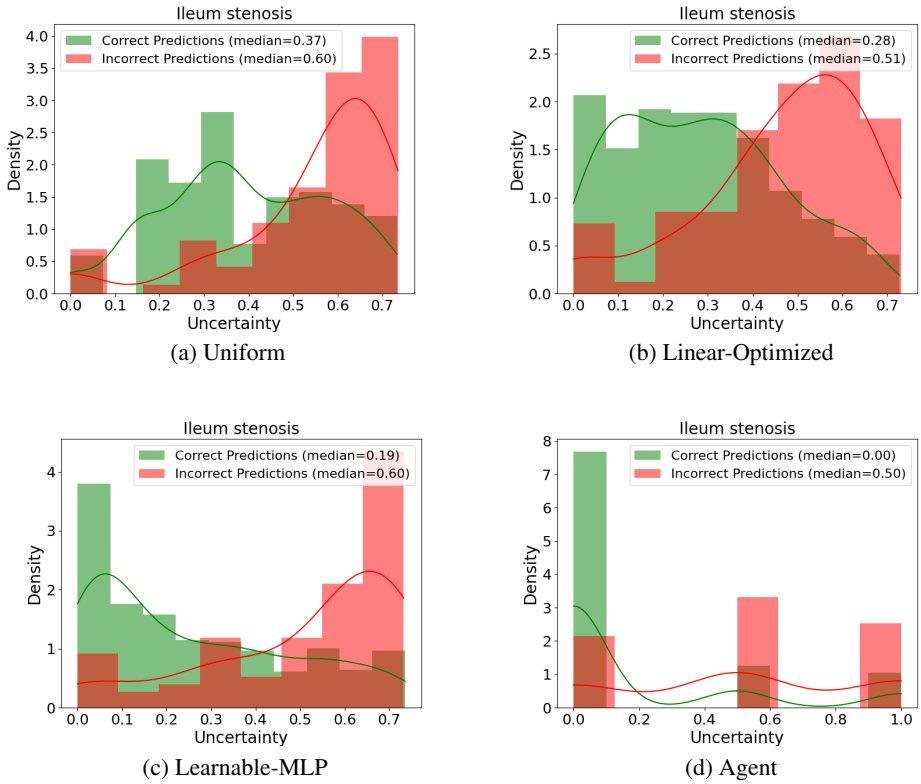

Table 4: Results after threshold $\geq$ 0.5 (max 20% exclusions).

Model	Acc	F1	Prec	Recall	Kappa	Excluded Cases
Baseline	0.824	0.269	0.304	0.309	0.179	0
Uniform	0.878	0.426	0.387	0.530	0.361	92 (19.9%)
Linear	0.890	0.212	0.393	0.507	0.361	80 (17.5%)
MLP	**0.908**	0.393	**0.449**	0.400	0.345	90 (19.5%)
Agent	0.828	**0.449**	0.352	**0.729**	**0.368**	92 (19.9%)
Sm. Agent	0.775	0.388	0.291	0.725	0.288	92 (19.9%)

3.4 Ablation Study: Effect of Agent Model Size

To assess the impact of the agent's language model size on performance, we conducted an ablation experiment replacing the large Llama3.1-70B model with a smaller Llama3.1-8B variant while keeping all other components identical. This setup allowed us to isolate the contribution of model capacity to decision quality and uncertainty calibration.

Across all metrics (Tables 1–4), the *Small Agent* consistently underperformed the full *Agent* model. Before uncertainty filtering (Table 1), the Small Agent achieved the highest recall (0.7076) but showed reduced accuracy and agreement (accuracy 0.7310; Cohen's Kappa 0.2402) relative to the full Agent (accuracy 0.8022; Cohen's Kappa 0.3006). Its higher sensitivity thus came at the cost of lower precision and F1, indicating a tendency toward over-detection. After uncertainty filtering ($u < 0.5$) and under the 20% exclusion cap (Tables 3–4), both models improved, yet the full Agent

(a) Uniform (b) Linear-Optimized

(c) Learnable-MLP (d) Agent

Figure 2: Uncertainty Histograms for Ileum stenosis Computed by: (a) Uniform Weights, (b) Linear-Optimized Weights, (c) Learnable-MLP Weights, and (d) Agent-based decision.

retained superior accuracy, F1, and Cohen's Kappa (e.g., accuracy 0.8285 vs. 0.7751; F1 0.4494 vs. 0.3881; Cohen's Kappa 0.3683 vs. 0.2888). These results suggest larger LLM capacity yields better-calibrated, more balanced decisions, while smaller agents may favor sensitivity.

4 Discussion

In this study, we evaluated prompt-ensemble–based uncertainty awareness for structured data extraction from radiology reports using LLMs. Aggregating predictions from multiple prompts and filtering high-uncertainty cases outperformed single-prompt methods, notably boosting F1 and Cohen's Kappa. Among the tested approaches, the agent-based method provided the best overall balance in F1 and Cohen's Kappa by integrating multiple prompts and accounting for their consistency. Meanwhile, the MLP model attained the highest precision and accuracy, useful for scenarios demanding fewer false positives, but its lower recall indicates some missed positive cases. This trade-off underscores the importance of selecting models based on task needs.

Additionally, the agent approach demonstrated superior calibration, distinguishing correct and incorrect predictions more effectively than other methods. Entropy-based metrics further confirmed the agent's robust handling of complex prompt outputs, enhancing prediction reliability. Excluding high-uncertainty cases improved accuracy, F1, and Cohen's Kappa, showing the value of uncertainty-aware filtering for better alignment between model confidence and prediction correctness. Setting class-specific thresholds at the output layer can improve recall for minority classes while preserving precision for majority classes, thus optimizing performance for the target application.

While filtering high-uncertainty cases demonstrably improves performance metrics, this comes at the cost of reduced automated coverage, as a portion of reports are flagged for exclusion. This presents a critical trade-off for real-world clinical deployment: the system performs better on the cases it does process but offers no direct assistance for the cases it flags as uncertain. Clinicians would still need robust workflows to manually review these excluded reports, potentially impacting workflow efficiency—particularly in the most com-

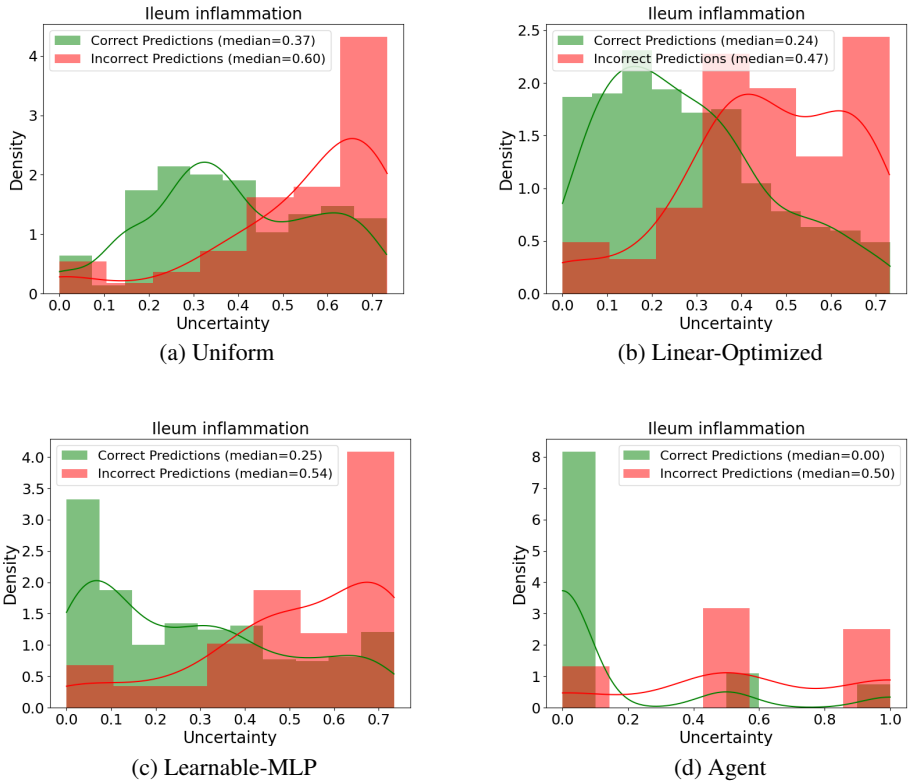

Figure 3: Uncertainty Histograms for Ileum inflammation Computed by: (a) Uniform Weights, (b) Linear-Optimized Weights, (c) Learnable- MLP Weights, and (d) Agent-based decision.

plex cases where automated support may be most needed. Implementing such a system in a clinical setting would necessitate defining clear workflows for handling cases flagged as uncertain. These reports could be automatically routed for mandatory manual review by a radiologist or technician, ensuring that no potentially critical information is missed.

Large language models (LLMs) efficiently automate structured data extraction from radiology reports by converting unstructured text into clinically relevant insights (Busch et al., 2024; Doshi et al., 2024; Reichenpfader et al., 2024). However, ensuring a trustworthy application through robust uncertainty quantification remains an open challenge. While Zeng et al. (Zeng et al., 2024) demonstrated the potential of multiple interacting LLM agents with specialized tasks to improve performance in medical applications, their role in quantifying uncertainty for reliable use remains underexplored. This study is the first to introduce a generalizable agent-based approach that quantifies uncertainty and fosters the trustworthy use of LLMs for structured data extraction from radiology reports.

While domain-specific medical LLMs, such as those fine-tuned on extensive biomedical text, hold significant promise for structured data extraction in healthcare, their applicability can be severely limited in low-resource languages like Hebrew. As noted, Llama 3.1 itself was not trained on Hebrew. However, even dedicated medical LLMs, if primarily trained on English or other well-represented languages, may struggle more profoundly than a multilingual base model when faced with Hebrew medical reports. Their domain-specific fine-tuning, while beneficial for known languages, can potentially make them less adaptable to languages outside their training corpus, exacerbating the performance gap due to the language barrier. This underscores the importance of methods like prompt ensembles and agent-based uncertainty awareness when deploying LLMs for medical text analysis in such linguistically challenging environments.

4.1 Limitations and Future Work

Despite promising results, several limitations merit discussion. First, while the focus was on radiology reports, extending these methods to LLM-based analysis of other medical reports, such as

pathology reports or electronic medical records, requires additional validation. Second, optimizing ensemble techniques for highly imbalanced datasets remains a challenge. Future clinical deployments will require targeted strategy modifications to address extreme class imbalances, such as class-weighted loss optimization for learnable models, threshold tuning specifically calibrated to maximize minority class sensitivity, or cost-sensitive agent prompting protocols. Future work should explore tailored approaches to address these limitations and investigate the application of uncertainty quantification in broader clinical scenarios. Another limitation of our comparison is the use of a significantly larger model (Llama 3 - 70B) for the agent compared to the base LLM (Llama 3.1 - 8B) and the models used in entropy-based methods. While the agent performs a different function (synthesizing outputs rather than initial extraction), its increased capacity could contribute to its superior performance metrics and calibration, representing a potentially unbalanced comparison. This size discrepancy might skew performance relative to simpler entropy-based methods, as the higher parameter count inherently grants stronger linguistic synthesis capabilities independent of the ensembling technique.

5 Conclusion

In conclusion, our findings demonstrate the effectiveness of prompt ensembles-based uncertainty awareness in enhancing LLM performance for structured data extraction in radiology. The agent-based approach emerged as particularly robust, achieving superior results. Incorporating uncertainty quantification not only improves reliability but also facilitates interpretability, paving the way for more impactful and trustworthy AI applications in healthcare.

C Prompts and Agent Examples

Base LLM Extraction Prompts

1. Does the following radiology report indicate that the patient has {*label*}? Here is the report: {}. Answer shortly, format your answer as a JSON file using the following schema: {"Answer": "Yes/No", "Explanation": "str"}. Important: Only return a single piece of valid JSON text.
2. Does the radiology report below suggest that the patient is suffering from {*label*}? Here is the report: {}. Please provide a concise answer, formatted as a JSON object using the following schema: {"Answer": "Yes/No", "Explanation": "str"}.
3. Can the presence of {*label*} be confirmed from the following radiology report? Here is the report: {}. Provide a brief response, formatted as a JSON object according to the following schema: {"Answer": "Yes/No", "Explanation": "str"}.
4. Does the patient appear to have {*label*} based on the analysis of the radiology report provided? Here is the report: {}. Please answer succinctly, formatted as a JSON object in the following schema: {"Answer": "Yes/No", "Explanation": "str"}.
5. Considering the radiology report presented, is there an indication that the patient has {*label*}? Here is the report: {}. Provide a brief answer, formatted as a JSON object according to the schema: {"Answer": "Yes/No", "Explanation": "str"}.
6. Is it possible to conclude from the following radiology report that the patient has {*label*}? Here is the report: {}. Please provide a concise response, formatted as a JSON object using the schema: {"Answer": "Yes/No", "Explanation": "str"}.

Agent Decision Model Example

Input (Multiple Answers from Base LLM):

```
- Answer: "No". Explanation: "The report does not mention Cecum inflammation,
but rather mentions air-filled bubbles in the soft tissue of the right abdomen,
likely originating from the small intestine."
- Answer: "Yes". Explanation: "The report mentions the presence of bubbles or
air pockets in the soft tissue of the right abdomen, which may be indicative
of inflammation in the cecum."
```

Agent Output (Llama 3-70B synthesis):

```
"Decision": "Likely No",
"Explanation":  "The majority of the answers suggest that there is no
inflammation in the Cecum, and the explanations provided are clear and
consistent.  The one answer that suggests yes is not strongly supported and
seems to be an over-interpretation of the report."
```

D Detailed Results Before Filtering

Treating Decoder-Only LLMs as Encoders: A Simple and Effective Fine-tuning Approach for Named Entity Recognition

Ken Yano and Hiroya Takamura
National Institute of Advanced Industrial Science and Technology
Artificial Intelligence Research Center
{yano.ken, takamura.hiroya}@aist.go.jp

Abstract

NER requires token-level classification using both left and right context, which makes encoder-only models like BERT naturally well-suited for the task. Decoder-only LLMs, by contrast, use causal masking during training, so their token representations lack right-side context, limiting their effectiveness on structured prediction tasks like NER despite their strong general capabilities. To address this, the authors propose fine-tuning decoder-only LLMs with causal attention replaced by full attention, combined with label-supervised discriminative training. While similar ideas exist in prior work, those studies were limited in scope. This work evaluates seven LLMs across four model families (Gemma, Qwen2.5, Llama3.1, Llama3.2) and compares full fine-tuning against LoRA. Results show that the proposed approach with an appropriate LoRA configuration outperforms encoder baselines (BERT, RoBERTa, DeBERTa), and achieves strong NER performance without auxiliary data or architectural modifications, though it does not reach SOTA on BC5CDR and CoNLL2003.

1 Introduction

Named Entity Recognition (NER) in the biomedical domain is a foundational task for extracting structured knowledge from clinical and scientific text, enabling downstream applications such as drug-disease relationship extraction, clinical trial mining, and pharmacovigilance. Biomedical NER is traditionally treated as a sequence-labeling task using a tagging scheme such as BIO, enabling detection and classification of entity spans — such as diseases, chemicals, genes, and clinical procedures — via token classification. It is therefore crucial to correctly classify each token using the context before and after it, a particular challenge in biomedical text where entity boundaries are often ambiguous, and terminology is highly specialized.

Encoder-only models such as BioBERT, PubMedBERT, and DeBERTa are trained to predict the masked token given the surrounding context, making their learned token representations well-suited to token classification tasks such as biomedical NER. On the other hand, decoder-only LLMs are trained to generate text in an autoregressive manner using a causal mask. As a result, the learned token representation contains no information about the context to the right of each token, which is a structural disadvantage for span-level extraction tasks.

Nonetheless, decoder-only LLMs trained on massive amounts of text — including biomedical literature, clinical notes, and scientific corpora — can solve various tasks using an instruction prompt, with or without in-context examples, and demonstrate strong capabilities across a wide range of biomedical understanding tasks. However, this generative solution method has not shown sufficient strength for structure prediction tasks such as NER in both general and biomedical domains. In particular, in the biomedical domain, it requires precise extraction of entity spans — including nested and discontinuous mentions extraction common in clinical text — and accurate classification of fine-grained biomedical entity types such as chemical compounds, disease mentions, and genomic variants.

To address these issues, we propose a label-supervised discriminative LLM fine-tuning method that replaces causal attention with a full-attention mask during both training and inference, adapting decoder-only LLMs for NER. Similar methods have been proposed in previous work (Li et al., 2023; Dukić and Šnajder, 2024); however, they examined only a limited number of LLM model families of a few different sizes. Our method also partially overlaps with LLM2Vec (BehnamGhader et al., 2024), where LLMs were effectively transformed into encoders. Our NER method cannot

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 312–325
July 3-4, 2026 ©2026 Association for Computational Linguistics

handle nested and discontinuous entity mentions, which are common in the biomedical domain and require span-based approaches (Tan et al., 2020; Su et al., 2022; Wang et al., 2022), which are beyond the scope of this work.

In this work, we evaluated seven decoder LLMs with varying sizes (from 0.5B to 8B) from four model families — Gemma, Qwen2.5, Llama3.1, and Llama3.2 — on general and biomedical NER benchmarks. For the baseline encoders, we evaluated BERT, RoBERTa, and DeBERTa. We also examined how two different training approaches, full fine-tuning and LoRA, affect the performance of the proposed method in both general and biomedical settings, where labeled data are often scarce and costly to annotate. Our results show that label-supervised discriminative LLM fine-tuning with full self-attention outperforms all baseline encoders when fine-tuned with an appropriate LoRA configuration. Although the results of our proposed method did not reach state-of-the-art on two NER benchmarks, BC5CDR and CoNLL2003, our models still demonstrate strong performance even when fine-tuned solely on each benchmark's training set, without relying on auxiliary corpora, domain-adaptive pretraining, or additional model architecture modifications.

2 Related Work

2.1 Named Entity Recognition

NER is traditionally tackled as a sequence labeling task, and numerous methods have been proposed (Lample et al., 2016; Ma and Hovy, 2016). With the emergence of large-scale transformer-based pretrained models, fine-tuning has become the standard for achieving better performance (Peters et al., 2018; Devlin et al., 2019).

The major approaches using transformer-based models can be categorized as follows: (1) supervised fine-tuning using encoder-based models such as BERT (Devlin et al., 2019) and its variants (Liu et al., 2019), (2) supervised fine-tuning using encoder-decoder models such as T5 (Wang et al., 2023; Paolini et al., 2021), (3) few-shots in-context learning using LLMs (Ding et al., 2021; Monajatipoor et al., 2024; Wang et al., 2025), and (4) supervised fine-tuning using LLMs (Xu et al., 2025; Dukić and Šnajder, 2024; Li et al., 2023).

Another line of effort focuses on the structure prediction task for longer contexts, such as multi-document relation extraction (Tan et al., 2022; Xue et al., 2024; Chen et al., 2020; Amalvy et al., 2023).

2.2 Generative methods by LLMs

Even though decoder-only LLMs have achieved SOTA performances on a variety of NLP tasks, their performance on NER still falls short of the supervised encoder baselines. This is because NER is a sequence-labeling task, whereas decoder-only LLMs are text-generation models.

Although several LLM-based NERs have been proposed, they still perform subpar with supervised encoder models. For example, GPT-NER (Wang et al., 2025) claims to perform on par with the encoder model. However, their method has some limitations, such as the ability to extract only one entity type at a time and the need for many in-context examples to match the performance of supervised encoder models.

There are also issues with converting structured information, such as NER, to a serialized form generated by LLMs. Without guardrails, parsing errors are a significant concern.

To overcome these issues, several approaches exist for generating structured output from LLMs, including prompt engineering, constrained decoding, grammar-based generation, and tool-augmented generation. Even though structured output from LLMs helps mitigate parsing errors, it significantly impacts inference time.

2.3 Discriminative methods by LLMs

This paper is closely related to the work by Li et al. (2023) and Dukić and Šnajder (2024), where the causal attention of LLMs is replaced by full attention to solve structure prediction tasks. Dukić and Šnajder (2024) proposed selectively removing a causal attention mask by identifying some of the decoder layers, instead of all decoder layers, to yield the best performance. However, this search space is enormous if the number of decoder layers n is large.

To reduce the search space to a manageable size, Dukić and Šnajder (2024) proposed dividing the entire set of decoder layers into four layer groups, each with eight consecutive decoder layers, where n is 32. This leaves them $2^4 = 16$ possible search patterns to evaluate.

However, it remains unclear whether this consecutive grouping of an equal number of decoder layers is optimal for achieving the best NER performance. Moreover, their ablation studies did

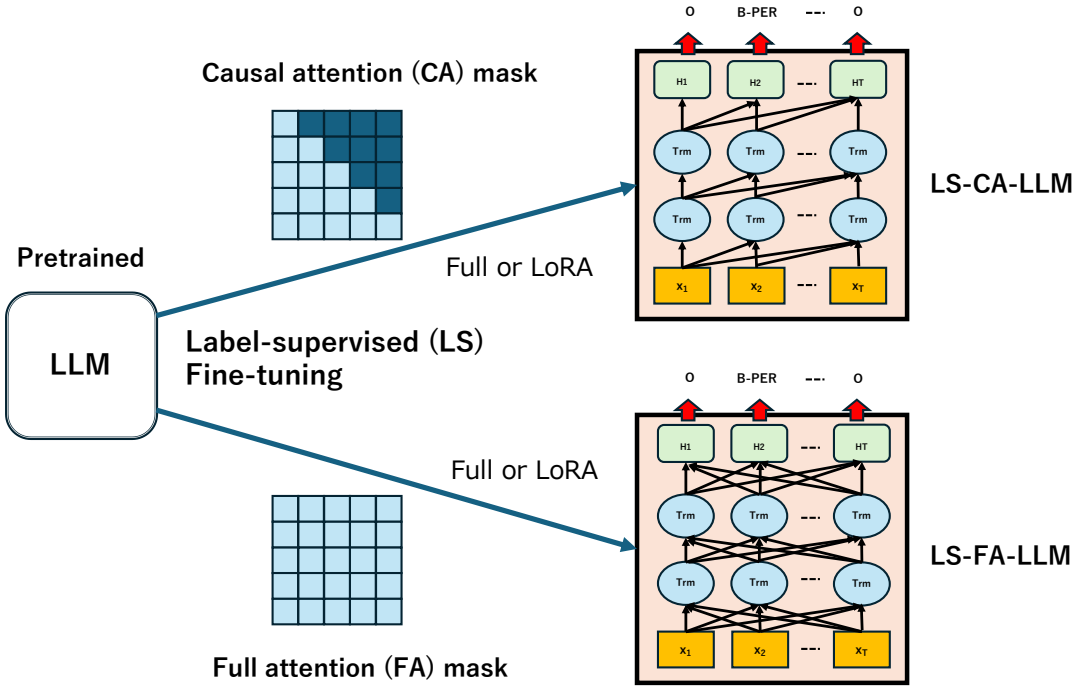

Figure 1: Label supervised (LS) LLM fine-tuning for NER task. The upper right figure shows the default LS fine-tuning with a causal attention mask. The lower-right figure shows the proposed LS fine-tuning, which replaces causal attention with a full attention mask across all decoder blocks. We denote the LS fine-tuned models using causal attention (CA) and full attention (FA) masks as LS-CA-LLM and LS-FA-LLM, respectively.

not identify consistent replacement patterns for decoder layers that yielded significantly better results across different decoder models and NER tasks. Hence, we replaced the causal attention mask with a full attention mask across all decoder layers.

3 Token Classification by Decoder-only LLM

We use LLMs not as generative models but as token classifiers to solve NER tasks, similar to encoder models, in which NER is performed by classifying each token into predefined BIO tags.

Token classification LLM models are defined by replacing the language modeling head with a token classification head initialized with pretrained LLM weights. The token classification head is initialized to random values before fine-tuning.

During fine-tuning, token classification LLMs are trained to classify each token using supervised labels. Here, the self-attention of original LLMs is defined using a causal attention mask, so the learned token representation contains no information about the context to the right of each token. This is a disadvantage, as both past and future token information is essential for classifying each token's label.

So our proposed method replaces the causal attention (CA) mask with a full attention (FA) mask across all decoder transformer blocks, ensuring that learned token representations capture context not only from past but also from future tokens, as shown in Fig. 1. We define label supervised (LS) fine-tuning of LLMs using CA and FA mask by LS-CA-LLM and LS-FA-LLM, respectively, and, for a specific LLM, we append **LS-CA-** and **LS-FA-** as prefixes to the name of LLMs in the following discussion to differentiate them.

Implementation of LS-FA-LLMs

We use HuggingFace Transformers to implement the proposed NER models. For a particular LLM model family, the corresponding token classification model is defined separately in the library. For instance, for Llama, the corresponding token classification model is defined as *LlamaForTokenClassification* in the library.

To replace the causal attention of LLMs, originally implemented for their corresponding token classifier models, such as *LlamaForTokenClassification*, with a full attention mask, we manually modified the source code. Currently, the source modification is ad hoc, meaning we need to manu-

ally change the source code. We leave, making the change systematic for future work.

4 Experimental Setup

4.1 NER datasets

We used two NER datasets for our experiments. One is BC5CDR (Wei et al., 2016) and the other is CoNLL2003 (Tjong Kim Sang and De Meulder, 2003). BC5CDR defines two entity types, chemical and disease, and CoNLL2003 defines four entity types, person, organization, location, and miscellaneous. Details of each dataset are provided in Table 1.

We also constrained our experimental conditions to avoid using any auxiliary datasets that would boost LLM performance. Hence, we train each model using only the corresponding training and validation datasets and evaluate its performance on the corresponding testing dataset.

4.2 Examined baseline encoders and decoder-only LLMs

For the baselines, we used the following encoder models in our experiments: BERT (bert-base-cased) (Devlin et al., 2019), RoBERTa (roberta-base) (Liu et al., 2019), and DeBERTa (deberta-v3-large) (He et al., 2021).

For the decoder models, we selected four LLM model families: Gemma, Qwen2.5, Llama3.2, and Llama3.1. For each model family, we selected one or two models with different model sizes.

Specifically, we evaluated seven LLMs across various model sizes. Gemma-2B and Gemma-7B (Team et al., 2024), Qwen2.5-0.5B and Qwen2.5-7B, Llama3.2-1B and Llama3.2-3B and Llama3.1-8B (Grattafiori et al., 2024).

State-of-the-art models

For BC5CDR, we evaluated BioBERT_v1.1 (Lee et al., 2019), which is specifically fine-tuned for the biomedical domain, on the same experimental setting as other models. In addition, we compare OpenMED's SOTA results (Panahi, 2025) for reference.

For CoNLL2003, we compare the SOTA results of ACE (Automated Concatenation of Embeddings, proposed by Wang et al. (Wang et al., 2021), fine-tuned on CoNLL2003, for reference.

4.3 Training of label-supervised sequence labeling

LS-FA-LLMs, LS-CA-LLMs, and the baseline encoder models were trained for sequence labeling by adding a token classification head on top of the last hidden layer. The token classification head, initialized to random values, was trained alongside the underlying model parameters during fine-tuning.

In our experiments, all models are trained without parameter-efficient fine-tuning (PEFT) technique and with LoRA (Hu et al., 2021). By these experiments, we can analyze the results in four ways: either CA or FA attention mask with either full or LoRA training.

By using LoRA, we can reduce the trainable parameters of LS-CA-LLMs and LS-FA-LLMs to a much smaller size, even compared with the full parameter sizes of encoder models, as shown in Table 4.

Moreover, using LoRA, we were able to fit all LS-CA-LLMs and LS-FA-LLMs during fine-tuning with a consistent device batch size of 8 on a single H200 GPU with 141 GB of memory. To fully train LS-CA-LLMs and LS-FA-LLMs over 7B, we use multiple H200 GPUs to avoid out-of-memory errors. The details of training parameters and LoRA configuration are in Appendix A.

We used the same default LoRA configuration for all training. In the later result section (5.2), we investigate how different LoRA configurations affect the results. We conducted additional experiments with different LoRA configurations for LS-FA-Llama3.2-3B and LS-FA-Llama3.1-8B, which performed better among other models.

4.4 Comparison with generative NER by instruction fine-tuned LLMs

To verify the effectiveness of our proposed method, we also evaluate NER performance using the same LLMs with instruction-fine-tuning (IFT) to solve the same NER tasks in a generative manner.

To fine-tune IFT LLMs, we used the same LoRA configuration and hyperparameters as those used to train LS-FA-LLMs. However, to prevent overfitting to the training dataset, we use early_stopping and stop training when the last 10 consecutive updates do not improve the evaluation loss.

For NER instruction, we adopt a format similar to Alpaca (Taori et al., 2023). The detailed instruction samples are provided in Appendix B. We use **IFT-** as the prefix to denote instruction-fine-tuned

Dataset	Train	Validation	Test	Entity Types
BC5CDR	5,228	5,330	5,865	Chemical, Disease
CoNLL2003	14,041	3,250	3,453	PER,ORG,LOC,MISC

Table 1: The statistics for the number of samples for BC5CDR (Wei et al., 2016) and CoNLL2003 (Tjong Kim Sang and De Meulder, 2003). PER, ORG, LOC, MISC specify person, organization, location, and miscellaneous, respectively.

LLMs such as IFT-Gemma-2B in the results.

5 Results

We first present the NER results by comparing baseline encoders with LS-CA-LLMs and LS-FA-LLMs, all of which are trained with full or default LoRA settings. Then we show performance variability across different LoRA configurations.

In the last section, we show comparative results between generative methods by IFT-LLMs and LS-FA-LLMS with baselines.

5.1 Comparison of baseline encoders and LS-CA-LLMs and LS-FA-LLMs

Table 2 shows precision, recall, and test micro F1 scores of BC5CDR by baseline encoders, LS-CA-LLMs, and LS-FA-LLMs. At the top, we show the SOTA results from OpenMed for reference, along with the results of domain-adapted BioBERT_v1.1. To evaluate sequence labeling results, we used seqeval. The first three columns are results of full training, and the last three columns are results of LoRA training. For each column, the best score is indicated in **bold** font. The scores with a yellow background specify the best score across full and LoRA training. In both full and LoRA training, LS-FA-LLM models significantly outperform the corresponding LS-CA-LLM models by 5-15 points, indicating that the causal attention mask is the main cause of low performance on NER tasks.

When trained with LoRA, LS-CA-LLMs and LS-FA-LLMs consistently outperform fully trained models, indicating that LoRA training is highly effective for fine-tuning LLMs with relatively small training datasets such as BC5CDR.

On the other hand, we cannot confirm a similar performance gain of LoRA over full training for baseline encoders, especially for BERT and RoBERTa. We hypothesize that LoRA training is effective only when the training dataset is not large enough relative to the model's capacity, in which case full training may lead to overfitting.

We confirm that the results of LS-FA-Llama3.2-3B and LS-FA-Llama3.1-8B, trained with LoRA, outperform all baseline encoders and the domain-adapted BioBERT_v1.1, excluding SOTA f1 results by OpenMed (Panahi, 2025).

Similarly, Table 3 shows precision, recall, and test micro F1 scores of CoNLL2003 by baseline encoders, LS-CA-LLMs, and LS-FA-LLMs. At the top, we present the SOTA f1 result by ACE+Fine-tune (Wang et al., 2021) for reference.

We see similar trends to those seen in the previous BC5CDR results in Table 2. Excluding SOTA f1 by ACE+Fine-tune, LS-FA-Llama3.2-3B and LS-FA-Llama3.1-8B, trained with LoRA, outperform all the baseline encoders in all metrics.

5.2 Variability of performance on different LoRA configurations

We evaluate how different LoRA configurations affect performance. We used LS-FA-Llama3.2-3B and LS-FA-Llama3.1-8B, which outperformed the baselines and other LS-FA-LLM results. Table 4 shows the results of five different LoRA configurations for these two models. The row in lightgrey is the result of LoRA configuration used in Tables 2 and 3.

In the table, the columns of "r", "alpha", "dropout", and "modules" specify the LoRA configuration items: attention dimension (rank), LoRA scaling, dropout probability, and target modules, respectively. Column "#trainable params" specified the number of trainable params, and its percentage of the model size. By adopting LoRA, the number of trainable parameters in LS-FA-LLMs is much lower than in encoder models trained without LoRA.

The results of these two LS-FA-LLMs vary across different LoRA configurations. However, we confirm that LoRA configurations with relatively large $rank \geq 32$ and $alpha = 2 \times rank$ targeted for all linear modules achieve higher performance.

Table 2: BC5CDR: Precision, recall and micro F1 scores for the baseline encoders, LS-CA-LLMs and LS-FA-LLMs. At the top, we include SOTA results by OpenMed (Panahi, 2025) for reference and BioBERT_v1.1 (Lee et al., 2019). The first three columns are results of full training, and the last three columns are results of LoRA training. For each column, the best score is indicated in **bold** font. The scores with a yellow background specify the best score across full and LoRA training.

5.3 Comparison with instruction fine-tuned LLMs approach

Table 5 shows the comparison with instruction fine-tuned (IFT) counterparts with label-supervised full-attention LLMs and baseline encoders. We also add zero-shot results by OpenAI GPT-4.1 as a baseline (see in Appendix C for details). The best scores are indicated in bold font.

To train LLMs using IFT, we adopt an Alpaca-based instruction format (Taori et al., 2023) for fine-tuning, as described in the Appendix B. Since the named entities are extracted from the output text, the performance of IFT is evaluated using set-based precision, recall, and F1 scores between the estimated and true sets of entities, ignoring the spans of the extracted entities. We use the exact match when comparing estimated and true results.

To compare with span-based results by label-supervised LLMs and encoders, we convert them to set-based metrics by aggregating extracted entities.

To train IFT models, we used the same LoRA configuration as the label-supervised full-attention counterparts.

First, IFT-LLM results outperformed GPT-4.1 in zero-shot settings, indicating that correctly extracting entities remains challenging for high-performance closed-weight LLMs. Larger IFT-LLM results on BC5CDR show competitive performance relative to baseline encoders; however, they fall short of the baseline encoders on CoNLL2003.

Results on LS-FA-LLMs show superior performance on both BC5CDR and CoNLL2003, outperforming both IFT counterparts and baseline encoders. These results, combined with the results on Tables 2 and 3, underscore the superiority of the proposed LS-FA-LLMs.

6 Analysis

6.1 Training and Inferencing time

Table 6 shows a comparison of training time among all models for one epoch using a single H200 GPU. The column 'rel' indicates the relative time based on BERT's time. In these experiments, baseline encoder models are trained without LoRA, and LS-FA-LLMs are trained with LoRA. We confirm that, even with LoRA, much longer training times are required for LS-FA-LLMs. The training time proportionally increases with the size of the original LLMs. When fine-tuning on 7B LS-FA-LLMs, about $16-18\times$ and $15-16\times$ training times are re-

Training	Full			LoRA

Table 3: CoNLL2003: Precision, recall and micro F1 scores for the baseline encoders, LS-CA-LLMs and LS-FA-LLMs. At the top, we include SOTA results by ACE+Fine-tune (Wang et al., 2021) for reference. The first three columns are results of full training, and the last three columns are results of LoRA training. For each column, the best score is indicated in **bold** font. The scores with a yellow background specify the best score across full and LoRA training.

quired for BC5CDR and CoNLL2003, respectively, compared with BERT.

These results show a negative effect of using larger LLMs for NER, despite achieving higher performance.

However, if multiple GPUs are available, the training time of LS-FA-LLMs can be further reduced using a distributed parallel training method

Table 7 shows the mean and the standard deviation of inference time in milliseconds to process one sample among 10 randomly selected test samples contained in BC5CDR and CoNLL2003 using a single H200 GPU. Larger LS-FA-LLMs such as LS-FA-Gemma-7B and LS-FA-Llama3.1-8B take $\sim$ 10$\times$ inference time compared with BERT, and smaller LS-FA-LLMs proportionally take less inference time as their parameter size gets smaller. LS-FA-Qwen2.5-0.5B shows exceptionally longer inference time compared with models with similar sizes, such as LS-FA-Gemma-2B and LS-FA-Llama3.2-1B. We have yet to analyze this phenomenon and leave it for future work.

We note again that if multiple GPUs are available, the inference time of LS-FA-LLMs can be further reduced using a distributed parallel decoding method.

6.2 Error Analysis

Tables 11 and 12 show the error analysis of DeBERTa, LS-FA-Llama3.1-8B, and LS-CA-Llama3.1-8B for BC5CDR and CoNLL2003, respectively. NER error was classified into three classes: SPAN, TYPE, and DETECTION errors, and each error class was further classified into more detailed error types.

In both analyses, we confirmed that the counts of errors for each error type were lower in LS-FA-Llama3.1-8B than in DeBERTa. This indicates that LS-FA-Llama3.1-8B has acquired more robust named-entity recognition knowledge than DeBERTa. LS-CA-Llama3.1-8B shows poor performance in both analyses, confirming that the causal attention mechanism is the bottleneck for NER.

In the analysis of LS-FA-Llama3.1-8B and DeBERTa, TYPE error counts are much lower in BC5CDR than in CoNLL2003, indicating greater ambiguity among entity types in CoNLL2003.

The above results and analysis confirm that the decoder LLMs' weakness in structured precision tasks, such as NER, can be mitigated by our proposed method.

Model	BC5CDR F1	CoNLL2003 F1	r	alpha	dropout %	modules	#trainable params
LS-FA-Llama3.2-3B	0.883	0.914	8	16	0.05	q,k,v,o	4.60M (0.143%)
	0.889	0.918	16	32	0.05	q,k,v,o	9.19M (0.285%)
	0.899	**0.935**	32	64	0.05	all linear	48.60M (1.490%)
	0.898	0.928	64	128	0.05	all linear	97.30M (2.940%)
	0.900	0.927	128	256	0	all linear	195.00M (5.710%)
LS-FA-Llama3.1-8B	0.888	0.919	8	16	0.05	q,k,v,o	6.84M (0.091%)
	0.893	0.922	16	32	0.05	q,k,v,o	13.70M (0.182%)
	0.904	0.929	32	64	0.05	all linear	83.90M (1.110%)
	0.904	0.929	64	128	0.05	all linear	168.00M (2.190%)
	0.900	**0.932**	128	256	0	all linear	336.00M (4.280%)

Table 4: Test micro F1 scores for LS-FA-Llama3.2-3B and LS-FA-Llama3.1-8B with five different LoRA configurations, including the one used for previous experiments shown in light gray background. Columns "r" and "alpha" specify rank and alpha values of LoRA parameters. The "modules" specifies the targeted modules and "all linear" specifies all linear modules: q_proj,k_proj,v_proj,o_proj,down_proj,gate_proj and up_proj.

7 Conclusion

We address weaknesses in decoder LLMs for structure prediction tasks such as NER by focusing on the attention mechanism and adopting a discriminative approach with supervised labels. Specifically, we demonstrate that this weakness can be mitigated by replacing causal attention with a full-attention mask during both training and inference.

However, our results show that this change to the self-attention mechanism alone does not yield superior NER performance compared with strong baselines such as RoBERTa and DeBERTa. Specifically, we verified that instead of full fine-tuning, using LoRA with a suitable configuration is key to boosting the performance. This is especially true for large LLMs because full fine-tuning on a relatively small training dataset, such as BC5CDR or CoNLL2003, can easily lead to overfitting, hindering performance on the test set.

Our results also suggested that linguistic knowledge acquired during pre-training of LLMs with causal attention is transferable even after the attention mechanism is switched to full-attention during fine-tuning. In our experiments, we used only the training subsets of the NER benchmarks for fine-tuning, so additional training with an auxiliary dataset could increase the performance even more.

Although our proposed best model outperformed all baseline encoders on BC5CDR and CoNLL2003, it requires much longer training and inference times than the baselines. Nonetheless, we verified that our proposed method is highly effective and can serve as an alternative encoder model to BERT-like models in downstream applications.

Since the LoRA configuration significantly affects the performance of the proposed methods, future work should investigate automated methods to obtain an optimal LoRA configuration.

Acknowledgments

This paper is based on results obtained from AIST policy-based budget project "R&D on Generative AI Foundation Models for the Physical Domain".

Limitations

In our experiments, we conducted a single fine-tuning step for each model, using a fixed learning rate and other hyperparameters. With more computing resources, multiple runs with different training parameters might yield more reliable results.

Our experiments were conducted on two NER datasets, one in the biomedical domain and the other in the general domain, so further experiments on datasets in other domains and languages could yield additional insights.

B Instruction format for fine-tuning decoder-only LLMs

Sample instruction for BC5CDR

Instruction:
please extract named entities and their type from the input sentence, all entity types are in options.
Options:
chemical,disease
Sentence:
The hypotensive effect of 100 mg / kg alpha-methyldopa was also partially reversed by naloxone .
Response:
alpha-methyldopa:chemical;naloxone:chemical;hypotensive:disease;

Sample instruction for CoNLL2003

Instruction:
please extract named entities and their type from the input sentence, all entity types are in options.
Options:
organization,miscellaneous,person,location
Sentence:
The European Commission said on Thursday it disagreed with German advice to consumers to shun British lamb until scientists determine whether mad cow disease can be transmitted to sheep .
Response:
European Commission:organization;German:miscellaneous;British:miscellaneous;

C Zero-shot NER using GPT-4.1 by OpenAI

The following is a sample code snippet of zero-shot NER for BC5CDR and CoNLL2003 using OpenAI's structured output.

```python
from openai import OpenAI
from pydantic import BaseModel
from typing import Literal

client = OpenAI()

class Entity_BC5CDR(BaseModel):
    disease: list[str]
    chemical: list[str]

class Entity_CoNLL2003(BaseModel):
    organization: list[str]
    miscellaneous: list[str]
    person: list[str]
    location: list[str]

def extract_entity(content: str, task: Literal["BC5CDR","CoNLL2003"]):

    response = client.responses.parse(
        model="gpt-4.1",
        input=[
                {
                    "role": "system",
                    "content": "You are an excellent linguist. Extract all the mentions that can be considered diseases or chemicals." if task == 'BC5CDR' else "You are an excellent linguist. Extract all the mentions that can be considered organizations, people, locations, or miscellaneous.",
                },
                {
                    "role": "user",
```

```
                    "content": f"{content}",
                },
            ],
        text_format=Entity_BC5CDR if task == 'BC5CDR' else Entity_CoNLL2003,
    )
    entities = response.output_parsed
    return entities

if __name__ == "__main__":
    entities = extract_entity(content, task_name)
```

D Error analysis

NER errors are classified into SPAN, TYPE, and DETECTION error categories, and each error category is further classified into finer error types. Errors are computed by comparing gold and predicted labels, each represented as a list of entity labels of the form (start, end, etype), where 'start' and 'end' are the beginning and end of the entity span, and 'etype' is the entity type.

In SPAN errors, if either 'start' or 'end' position matches, but the span length is not matched, they are classified as too_short or too_long. Whereas in the case of both 'start' and 'end' positions not matching, but the difference of span length is within two words, it is classified as boundary_off. The others are classified as completely_wrong. If span position matches, but 'etype' does not match, they are classified as correct_span_wrong_type.

Abstract

Nutrition misinformation on social media often arises from selective interpretation of scientific evidence rather than outright falsehoods, making it difficult to detect. We introduce a curated, expert-annotated Instagram dataset focused on seed oils and omega-6, two domains characterized by contested dietary claims. We evaluate feature-based, embedding-based, and transformer-based models under in-domain and cross-domain settings. Results show strong in-domain performance across all models, with Sentence-BERT achieving the highest AUPRC (up to 0.96). However, performance drops substantially under cross-domain transfer, indicating limited robustness to topic shift. Analysis suggests that while contextual embeddings capture strong in-domain semantic signals, linguistically and psychologically grounded features are more stable under distribution shift. These findings highlight the value of combining semantic and interpretable linguistic signals for robust misinformation detection.

1 Introduction

Nutrition misinformation has emerged as a significant public health concern, driven in part by the rapid dissemination of unverified or misleading dietary claims on social media (Diekman et al., 2023). Prior research shows that online health information frequently contains inaccurate or contextually distorted statements that can shape public understanding and influence health-related decision-making (Tan et al., 2025). Although recent advances in large language models (LLMs) have improved automated detection of misleading content, reliable identification remains challenging due to the domain-specific and context-dependent nature of discourse (Belkhouribchia and Pen, 2025).

Social media platforms play a central role in shaping public nutrition narratives, but their scale and heterogeneity make systematic monitoring difficult (Garg and Sharma, 2022). Among these platforms, Instagram (https://www.instagram.com) is particularly influential due to its large user base and image-centric design driven by engagement (Dean, 2025). However, most existing misinformation datasets/studies focus on platforms such as Twitter and Facebook, leaving Instagram comparatively underexplored, particularly in nutrition-related contexts (Nguyen et al., 2022). This limits our understanding of how nutrition-related claims are communicated in environments where information is often condensed into short captions, hashtags, and visually supported narratives.

This gap is particularly evident in emerging debates in nutrition, such as on seed oils and omega-6. While dietary guidelines recognize vegetable oils as part of healthy dietary patterns when consumed appropriately (Dietary Guidelines for Americans, 2020), social media narratives frequently reframe them as inflammatory or harmful (Ahmad et al., 2025). Such content often does not rely on entirely fabricated claims, but instead on selective interpretation or reframing of established scientific evidence (Lee and Kurniawan, 2025), making detection more subtle and context-dependent.

From a computational perspective, previous work has shown that linguistic and psycholinguistic features can capture stylistic and rhetorical signals associated with misinformation (Garg and Sharma, 2022). In particular, psycholinguistic cues have been found useful for identifying emotional intensification and rhetorical framing in health-related misinformation (Mahbub et al., 2022). However, generalization across domains remains an open challenge, with performance often degrading when models are applied to unseen topics or distributions (Xarhoulacos et al., 2021).

In this work, we explore a hybrid framework for nutrition misinformation detection in Instagram posts. As outlined in Figure 1, we construct a curated expert-annotated dataset of Instagram captions focusing on seed oils and omega-6. We pro-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 326–341

pose a multi-view representation that integrates linguistic complexity, rhetorical and stylistic features, psycholinguistic signals, and pretrained semantic embeddings. We evaluate both feature-based and transformer-based models under in-domain and cross-domain transfer settings to assess performance under domain shift.

Our experiments show that transformer-based models achieve strong in-domain performance, while feature-based models remain competitive and provide improved interpretability. However, all models exhibit performance degradation under cross-domain evaluation, particularly in ranking-based metrics such as AUPRC. These findings suggest that while both linguistic and neural representations capture useful signals, their ability to generalize across closely related nutrition topics needs further improvement. This highlights the value of combining interpretable linguistic signals with contextual embeddings for misinformation analysis.

2 Related Work

Health misinformation detection has been widely studied using natural language processing techniques, with transformer-based architectures and LLMs achieving strong performance in assessing the credibility of online content (Faruk, 2024; Tan et al., 2025). However, much of this work relies on general-purpose datasets or structured textual sources, which may not fully capture the informal, context-dependent nature of social media discourse, where health misinformation is often embedded in short, unstructured narratives (Belkhouribchia and Pen, 2025; Kauttonen et al., 2020).

A large portion of existing research has focused on platforms such as Twitter, Facebook, and YouTube (Yeung et al., 2022), while Instagram remains relatively underexplored despite its large user base and distinctive visual and caption-driven communication style (Nguyen et al., 2022). This is particularly important in health-related domains, where misinformation is often expressed through short captions, hashtags, and implicit claims embedded in multimodal content. Recent evidence suggests that nutrition misinformation is increasingly prevalent on Instagram, though systematic analysis remains limited due to the lack of curated datasets (Segado-Fernández et al., 2025).

Recurring nutrition misinformation narratives often center on dietary fats, particularly seed oils and omega-6 fatty acids (omega-6). These narratives frequently characterize such fats as harmful or pro-inflammatory, despite established dietary evidence supporting their role in healthy dietary patterns when consumed appropriately (Lee and Kurniawan, 2025; Ahmad et al., 2025). This gap between scientific consensus and public framing highlights the need for computational approaches that capture not only the content of claims but also their rhetorical and stylistic presentation.

Prior work in misinformation detection has demonstrated the usefulness of linguistic and stylistic features, including lexical diversity, readability, and syntactic complexity (Garg and Sharma, 2022). Misinformation is often associated with distinctive rhetorical patterns such as increased certainty, reduced hedging, and emotionally charged language (Mahbub et al., 2022). Hybrid approaches combining such features with dense embeddings, such as WELFake (Verma et al., 2021), have shown improvements in classification performance, though their effectiveness varies across domains and datasets (Khan et al., 2021).

Emotion and affective signals have also been widely studied as predictive indicators of misinformation. Prior studies suggest that misinformation content often exhibits stronger negative emotions such as fear, anger, and disgust compared to factual content (Farhoundinia et al., 2024). High-arousal emotional language has also been linked to reduced critical evaluation and increased susceptibility to misleading claims (Martel et al., 2020; Wurst et al., 2024), motivating their inclusion in computational models, although these signals may vary substantially across domains and contexts.

More recently, cross-domain misinformation detection has gained attention, particularly in health-related settings such as transferring models across disease topics (Goldani et al., 2025). These show that generalization across domains remains challenging, especially when moving between different thematic distributions or communication styles. However, most prior work focuses on disease-related misinformation, while broader lifestyle and nutrition domains remain relatively underexplored.

Despite these advances, existing approaches often treat linguistic features and neural representations separately, with limited systematic evaluation of their combination in domain-shift settings. This is particularly relevant in nutrition misinformation, where both interpretability and robustness are important. Motivated by this gap, we investigate a unified framework that integrates linguistic, rhetori-

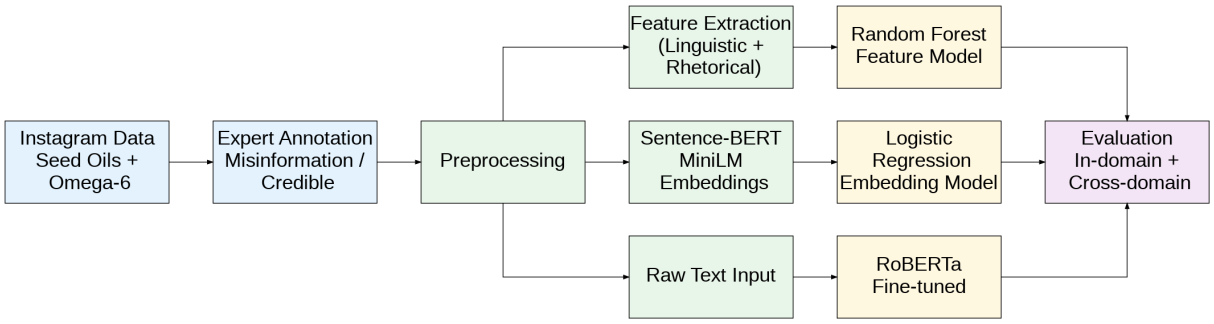

Figure 1: Overview of the proposed framework for nutrition misinformation detection. The pipeline includes data collection from Instagram, expert annotation, preprocessing, feature-based modeling (top branch), embedding-based modeling (middle branch), and transformer-based modeling (bottom branch). We evaluate robustness under domain shift, not just classification accuracy.

cal, and psycholinguistic features with transformer-based embeddings, and evaluate their effectiveness in both in-domain and cross-domain transfer.

3 Methodology

Figure 1 provides an outline of the proposed framework, summarizing the data collection, preprocessing, feature extraction, modeling approaches, and evaluation protocols used in this study.

3.1 Data Collection

A domain expert in nutrition identified relevant Instagram posts using the platform's native search interface. The sampling strategy was centered on two predefined fat-related topics: seed oils and omega-6. These topics were selected for focused analysis due to their frequent mischaracterization on social media as harmful or pro-inflammatory, despite established evidence supporting their role as beneficial unsaturated fats when consumed in appropriate dietary patterns, as reflected in the Dietary Guidelines for Americans 2020–2025 (Dietary Guidelines for Americans, 2020).

The keyword set was developed through expert consultation, iterative examination of nutrition-related content on social media, and preliminary testing of search outputs. Early exploration indicated that broad nutrition terms (e.g., "healthy eating") produced substantial amounts of irrelevant material, whereas targeted fat-specific queries yielded posts with clearer and more substantive health-related claims. The final keywords were chosen because they consistently surfaced high-engagement content and reflected areas where public misconceptions are especially prevalent.

Posts were considered eligible for inclusion if their captions explicitly referenced seed oils (e.g., soybean, sunflower, safflower, canola, or corn oil) or omega-6 in the context of nutrition, health, or disease-related claims. Only English-language posts were retained.

To mitigate the effects of algorithmic personalization, all searches were conducted using newly created Instagram accounts with no prior activity. Each account was used exclusively for one topic (seed oils or omega-6), ensuring that no cross-topic interaction influenced content retrieval. No engagement actions (e.g., likes, follows, or saves) were performed prior to or during data collection.

In addition, all search sessions were performed using a virtual private network (VPN) to minimize geographic and personalization biases. This approach was intended to approximate the content exposure of a new, unconditioned user encountering discussions related to these topics on Instagram.

Data collection took place between May 28, 2025 to June 4, 2025. Eligible posts were restricted to those published between January 1, 2020, and the end of the collection period. To focus on widely disseminated content, only posts from accounts with more than 5,000 followers were included.

All posts were publicly accessible at the time of collection, and no private accounts were accessed. Usernames and other identifying information were removed prior to analysis to preserve anonymity. Captions and associated metadata were extracted using the *Apify Instagram Post Scraper Actors*[1].

This study focuses exclusively on caption text rather than image or video content. This decision was made to enhance reproducibility and reduce ethical concerns, as textual data can be more readily anonymized, whereas visual content may contain identifiable individuals or sensitive information. By

[1] https://apify.com/actors, last accessed 06/04/2025.

isolating caption text, we attempt provide a lower-bound estimate of misinformation detectability, enabling clearer attribution of linguistic and rhetorical effects without visual confounds.

All preprocessing was implemented in Python within a Google Colab environment with fixed random seeds to ensure reproducibility. Preprocessing included removal of non-alphanumeric characters while preserving punctuation, normalization of whitespace, and retention of emojis as tokens. The annotated dataset and code are publicly available on Zenodo under a CC BY 4.0 license (https://doi.org/10.5281/zenodo.20247254).

3.2 Human Annotation

We define health misinformation in line with prior literature as "any health-related factual claim that contradicts established scientific consensus" (Sylvia Chou et al., 2020). In this work, scientific consensus is grounded in the 2020–2025 Dietary Guidelines for Americans (Dietary Guidelines for Americans, 2020). Content that contradicted or distorted these guidelines was annotated as *Misinformation*, whereas content that aligned with or did not conflict with the guidelines was labeled *Credible*. Consistent with prior public health misinformation research, our annotation framework evaluates claims relative to established evidence-based recommendations rather than isolated or emerging studies, and should therefore be interpreted as reflecting alignment with contemporaneous scientific consensus and public health guidance during the data collection period.

Three annotators with formal nutrition training independently labeled each post in two domains: seed oils and omega-6. The annotation team consisted of two graduate students in nutrition supervised by a PhD-trained nutrition faculty at University of North Florida. The annotation was guided by a detailed codebook derived from the Dietary Guidelines for Americans (see the Appendix A). To reduce potential bias, annotators worked independently, were blinded to each other's decisions, and reviewed posts in randomized order. The Inter-rater reliability (IRR) was calculated using Fleiss's κ ($= 0.814$), which accounts for agreement occurring by chance and indicates strong agreement (values above 0.80). Given this high agreement, we used majority voting without additional adjudication to preserve annotation independence. These consensus labels serve as the basis for the subsequent evaluation of model predictions.

Figure 2 presents the distribution of caption lengths by label across both domains. Overall, captions are relatively long, with mean lengths of 156.1 words (SD = 108.5) in the seed oil domain and 236.5 words (SD = 101.2) in the omega-6 domain, indicating that posts often require interpretation of extended context rather than isolated claims. In the seed oil domain, credible posts are longer on average (M = 179.5, SD = 113.9) than misinformation posts (M = 146.8, SD = 105.4), suggesting that misinformation content tends to be more concise in this domain. In contrast, in the omega-6 domain, caption lengths are highly similar across classes, with credible posts (M = 238.9, SD = 110.4) and misinformation posts (M = 235.8, SD = 98.9) showing nearly identical averages. Across both domains, caption lengths vary widely, with an overall mean of 193.6 words (SD = 112.4), reflecting substantial heterogeneity in how claims are presented.

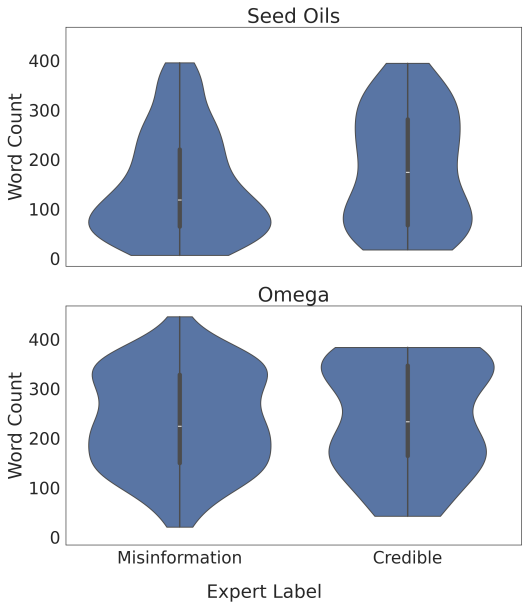

Figure 2: Caption length (word count) by expert label across seed oil and omega-6 domains. Captions in both domains are often long-form, requiring contextual interpretation beyond isolated claims.

The class distribution differs across domains but is consistently skewed toward misinformation. In the omega-6 dataset, 77.0% (114/148) of posts were labeled as *Misinformation*, while 23.0% (34/148) were labeled as *Credible*. In the seed oil dataset, 71.6% (121/169) of posts were labeled as *Misinformation*, compared to 28.4% (48/169) labeled as *Credible*. All captions were manually reviewed in full. Although some posts were brief or minimally informative, they were retained to

preserve the variability characteristic of real-world social media content.

3.3 Feature-Based Model

We develop a topic-agnostic feature-based framework to investigate how misinformation is linguistically and affectively distinguished from credible nutrition discourse. Instead of relying on surface lexical cues or topic-specific words, we focus on capturing how claims are framed across linguistic, rhetorical, and psychological dimensions.

3.3.1 Feature Space Construction

We construct a unified representation consisting of four complementary feature groups. Together, these four types of features form a comprehensive, topic-agnostic representation of linguistic style, persuasion strategy, and affective structure. A complete definition of all features is provided in Appendix B.

(1) Linguistic Complexity Features. We quantify structural and readability properties using `textstat` and `lexicalrichness`, including Flesch Reading Ease, Flesch-Kincaid Grade Level, Gunning Fog Index, lexical diversity, word count, and average word length. These features capture cognitive accessibility and structural complexity independent of topic.

(2) Rhetorical and Persuasive Features. We extract discourse-level signals using rule-based patterns to identify persuasive and stylistic markers. These include certainty and hedging expressions, rhetorical questions, exclamation usage, capitalization intensity, and citation or evidence indicators. These features model how claims are communicated rather than their content. Detailed rule-based patterns used for rhetorical feature extraction are provided in Appendix C.

(3) Affective Features. We use pretrained transformer models to extract sentiment and emotion signals from the transformers library (*cardiffnlp/twitter-roberta-base-sentiment-latest* and *j-hartmann/emotion-english-distilroberta-base*) to gauge the emotional tone of texts. These produce sentiment labels and emotion probability distributions. The full emotion label mapping and output structure of the classifier are provided in (Appendix D).

(4) Psychological Valence and Arousal Features. We operationalize affect using a lexicon-based approach grounded in the Research Domain Criteria (RDoC) framework (Insel et al., 2010), capturing Positive Valence (reward and approach motivation), Negative Valence (threat, loss, frustration), and Arousal/Regulatory systems (activation and intensity). These are combined with VADER (Hutto and Gilbert, 2014) sentiment scores to derive interpretable psychological dimensions reflecting emotional directionality, intensity, and motivational framing. Unlike categorical emotion labels, RDoC dimensions are designed to capture domain-independent affective processes such as threat sensitivity and approach motivation, making them well-suited for cross-topic misinformation analysis. The full lexicons used for RDoC feature extraction are provided in (Appendix E).

3.3.2 Feature-Based Classification Model

Random Forest achieved the best and most stable performance among several traditional machine learning classifiers, and was therefore selected as the final classifier. The model is implemented using `scikit-learn` and trained on the concatenated feature representation consisting of linguistic, rhetorical, and affective features.

Features are standardized prior to training, and model interpretability is examined using SHAP (SHapley Additive exPlanations) values (Lundberg and Lee, 2017). SHAP is used to quantify feature contributions at both global and instance levels, enabling analysis of which linguistic, rhetorical, and affective signals most strongly influence misinformation predictions.

SHAP values are computed using model-specific explainers: *TreeExplainer* for tree-based models, *LinearExplainer* for logistic regression, and *KernelExplainer* when required for non-linear models. We compute SHAP values on the full dataset using the final trained model and report mean absolute SHAP values for the positive class (misinformation) as global feature importance. We further compare SHAP-based rankings with built-in feature importance from tree-based models to assess consistency across interpretation methods.

3.4 Embedding-based model

We compute sentence-level embeddings using the Sentence-BERT model `all-MiniLM-L6-v2` (`https://huggingface.co/sentence-transformers/all-MiniLM-L6-v2`), which produces dense contextual representations of captions. These embeddings are used as features in a logistic regression classifier, allowing us to evaluate whether pretrained semantic representa-

tions improve generalization beyond handcrafted linguistic and psychological features. We select `all-MiniLM-L6-v2` due to its balance between computational efficiency and semantic performance, enabling fast inference while maintaining strong performance in sentence-level similarity tasks. This setup isolates the contribution of pretrained embeddings by using a simple linear classifier without additional modeling complexity.

3.5 Transformer-Based Model

We fine-tune `roberta-base` (Liu et al., 2019) for binary misinformation classification. RoBERTa is selected because it provides strong contextual language understanding and serves as a high-capacity baseline to evaluate whether deep semantic representations alone can capture misinformation patterns without explicit feature engineering. Captions are tokenized with a maximum length of 256 tokens. Approximately 39% of captions exceed the 256-token limit and are truncated during tokenization. Truncation primarily affects longer narrative-style posts, whereas shorter captions remain fully preserved. The model is trained using a learning rate of 2×10^{-5}, batch size of 16, weight decay of 0.01, and early stopping based on validation set performance.

3.6 Evaluation: In-Domain & Cross-Domain

We evaluate models under two settings: **In-Domain Evaluation:** For each dataset (omega-6 and seed oils), we perform stratified 5-fold cross-validation, ensuring balanced class distributions across folds. This procedure is applied consistently across all three modeling approaches. **Cross-Domain Evaluation:** We conduct bidirectional transfer experiments to evaluate cross-domain generalization. Specifically, models are trained on the full source-domain dataset and evaluated on the target-domain dataset without any adaptation. We consider omega-6$\rightarrow$ seed (training on omega-6, testing on seed oils) and seed $\rightarrow$ omega-6 (training on seed oils, testing on omega-6). This setup evaluates robustness under realistic domain shift, where topic-specific cues may not transfer across domains.

All experiments are conducted with a fixed random seed of 42 to ensure reproducibility. In the cross-domain setting, no information from the target domain is used during training or model selection, thereby preventing any form of data leakage.

3.7 Evaluation Metrics

We use evaluation metrics suited for imbalanced classification and misinformation detection, including precision, recall, and F1-score (for the misinformation class), as well as the area under the precision–recall curve (AUPRC). F1-score is the harmonic mean of precision and recall, providing a balanced measure under class imbalance. AUPRC is a threshold-independent metric that summarizes ranking performance and is particularly informative when the positive class is of primary interest. Although the class distribution is moderately imbalanced, we use AUPRC because it evaluates ranking performance independent of decision thresholds and provides a more informative measure of classifier behavior under non-uniform class distributions.

4 Results

4.1 In-Domain Performance

All models perform well on the misinformation class, with consistent trends across both domains (Table 1). To account for class imbalance, we compare against baselines based on majority-class and prevalence, which produce identical performance with AUPRC values of 0.77 (seed oils) and 0.70 (omega-6), reflecting the distributions of the underlying labels. All proposed models consistently outperform these baselines under in-domain settings and achieve higher ranking performance than baseline under most cross-domain transfers, indicating that improvements are not driven solely by class imbalance.

Sentence-BERT (MiniLM) achieves the highest overall performance, reaching 0.96 AUPRC on seed oils and 0.92 on omega-6, outperforming both RoBERTa and the feature-based Random Forest model in metrics. RoBERTa achieves perfect recall (1.00) across both datasets, but with lower precision (0.77 on omega-6, 0.72 on seed oils), resulting in reduced F1. This indicates a consistent tendency to over-predict the positive class.

The Random Forest model remains competitive, reaching F1 scores of 0.87 (omega-6) and 0.86 (seed oils). Despite using only engineered linguistic and rhetorical features, it performs close to neural approaches, indicating that structured features retain strong predictive value.

4.2 Cross-Domain Generalization

Across all models, AUPRC drops under cross-domain transfer (Table 2), indicating reduced rank-

Model	Domain	Prec	Rec	F1	AUPRC
MiniLM	omega-6	0.90	0.89	0.90	0.92
MiniLM	seed oils	0.87	0.89	0.88	0.96
RoBERTa	omega-6	0.77	1.00	0.87	0.86
RoBERTa	seed oils	0.72	1.00	0.83	0.84
Random Forest	omega-6	0.80	0.96	0.87	0.90
Random Forest	seed oils	0.79	0.95	0.86	0.84

Table 1: In-domain performance.

Train → Test	Model	Prec	Rec	F1	AUPRC
omega-6→ seed	MiniLM	0.72	1.00	0.83	0.74
omega-6→ seed	RoBERTa	0.72	1.00	0.83	0.69
omega-6→ seed	RF	0.72	1.00	0.83	0.74
seed → omega-6	MiniLM	0.77	0.95	0.85	0.86
seed → omega-6	RoBERTa	0.77	1.00	0.87	0.82
seed → omega-6	RF	0.77	0.90	0.83	0.80

Table 2: Cross-domain performance.

ing performance when models are applied to unseen topics. For example, MiniLM decreases from 0.92 in-domain on omega-6 to 0.74 when transferred from omega-6 to seed oils, while RoBERTa decreases from 0.86 to 0.69 in the same setting. The degradation is more pronounced for the omega-6→seed transfer direction (Figure 3).

Sentence-BERT (all-MiniLM-L6-v2) achieves the strongest overall in-domain performance and competitive cross-domain AUPRC across both transfer settings, suggesting relatively strong generalization ability compared to the other approaches.

The Random Forest model also demonstrates competitive cross-domain robustness, particularly in the seed→omega-6 setting, where it shows only a modest decrease in AUPRC (0.84 to 0.80). This suggests that topic-agnostic linguistic and rhetorical features may capture more transferable misinformation signals. In particular, rhetorical features (e.g., certainty markers) may generalize more consistently across topics than dense semantic representations.

4.3 Linguistic and Rhetorical Differences

Readability analysis indicates that captions across both classes are moderately complex, with no strong separation in Flesch Reading Ease scores. In the omega-6 domain, credible posts exhibit slightly higher readability (M = 52.95, SD = 11.76) than misinformation (M = 49.26, SD = 15.19). A similar pattern is observed in the seed oil domain (credible: M = 56.57, SD = 15.98; misinformation: M = 51.40, SD = 23.15). However, the substantial overlap and variance suggest that readability is not a primary distinguishing factor.

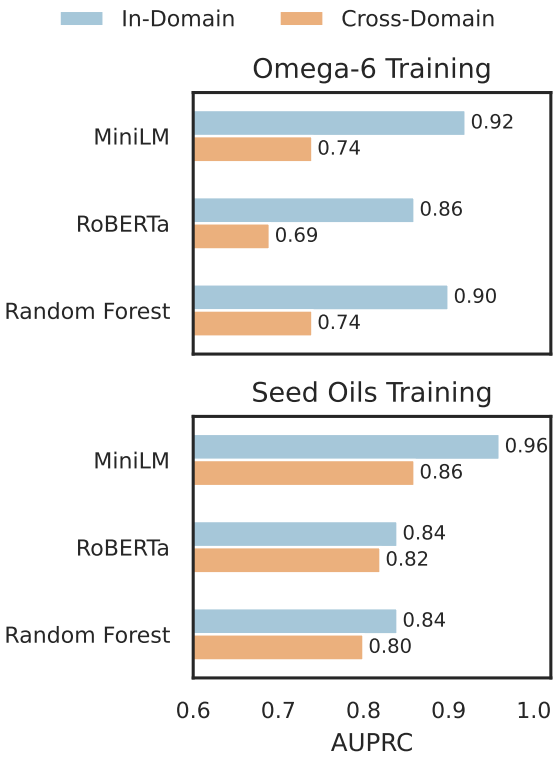

Figure 3: AUPRC comparison across in-domain and cross-domain transfer for omega-6 and seed oil datasets.

Clearer distinctions emerge in rhetorical structure (Figure 4). Across both domains, misinformation consistently exhibits lower levels of hedging, indicating a more assertive and less qualified communication style, while credible posts show more frequent use of hedging and exploratory language.

Misinformation is also characterized by stronger reliance on persuasive and heuristic framing, including more frequent appeal-to-nature arguments and the presence of conspiracy-related cues, which are largely absent from credible posts. In contrast, credible posts show slightly higher levels of exploratory questioning, suggesting a more open-ended or deliberative tone. Misinformation additionally exhibits more emphatic signaling (e.g., exclamation usage and capitalization), particularly in the seed oil domain. Overall, the differences are primarily rhetorical rather than lexical or readability-based, with misinformation distinguished by higher certainty, stronger framing devices, and reduced epistemic caution.

4.4 Affective/Psychological Feature Analysis

Affective analysis reveals a nuanced pattern suggesting affective simplification in misinformation. In both domains, misinformation shows a more con-

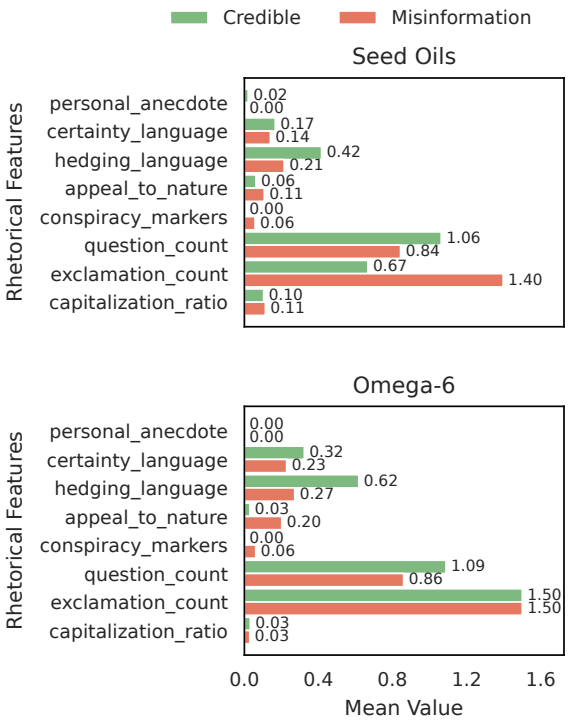

Figure 4: Rhetorical and linguistic feature distributions across credible and misinformation classes.

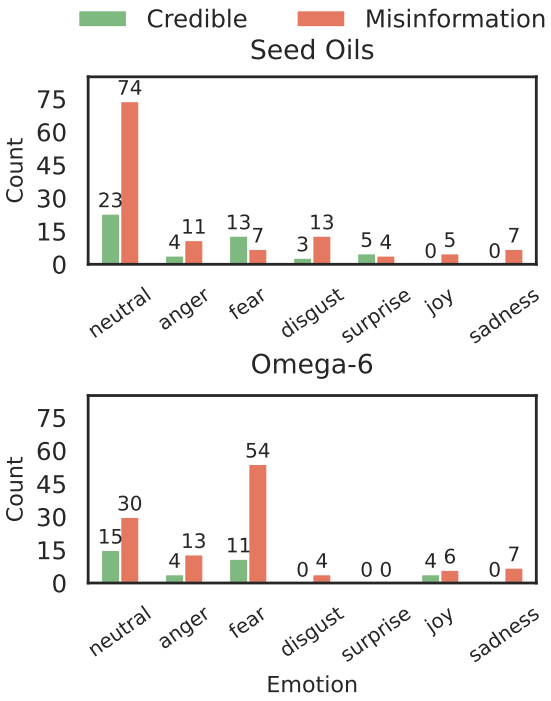

Figure 5: Emotion distribution across credible and misinformation posts in the seed oil and omega-6 domains.

centrated emotional profile, while credible content exhibits a less skewed distribution of affect (Figure 5). In the seed oil domain, misinformation is dominated by neutral affect with secondary anger and fear, whereas credible posts span a broader set of emotions, including fear and disgust. In the omega-6 domain, misinformation is strongly concentrated in fear-related language, while credible content distributes more evenly across negative and mixed emotions. Overall, misinformation is characterized by reduced emotional variability, while credible content shows a more heterogeneous affective distribution.

Across both domains, misinformation captions show lower scores across psychological dimensions, including valence, emotional intensity, and reward/threat systems, indicating reduced emotional richness. These findings suggest that misinformation is characterized not by emotional amplification, but by simplified and less varied affective expression, which may increase perceived clarity and directness.

4.5 Feature Importance and Interpretability

A total of 55 features were extracted per domain. SHAP analysis was conducted over the entire feature space without feature selection to provide an unbiased estimate of the importance of the feature. Figure 6 presents the top 10 features ranked by mean absolute SHAP values.

Across both domains, the most influential features are primarily psychological and affective. Top features include RDoC-based measures of threat and valence, emotion-neutral signals, and sentiment-related features. Rhetorical features, including appeal to nature and question frequency, also contribute to model predictions, highlighting the importance of communicative framing.

The consistency of these features across domains indicates that misinformation is characterized by stable, topic-agnostic signals, including reduced hedging, lower emotional complexity, and increased reliance on persuasive heuristics. These patterns help explain model behavior under domain shift: models likely maintain high recall by capturing generalizable stylistic signals, but may experience reduced AUPRC due to the loss of topic-specific semantic information.

5 Conclusion

In this work, we presented a multi-view framework for detecting nutrition misinformation in Instagram posts, focusing on seed oils and omega-6. We introduced a curated, expert-annotated dataset and eval-

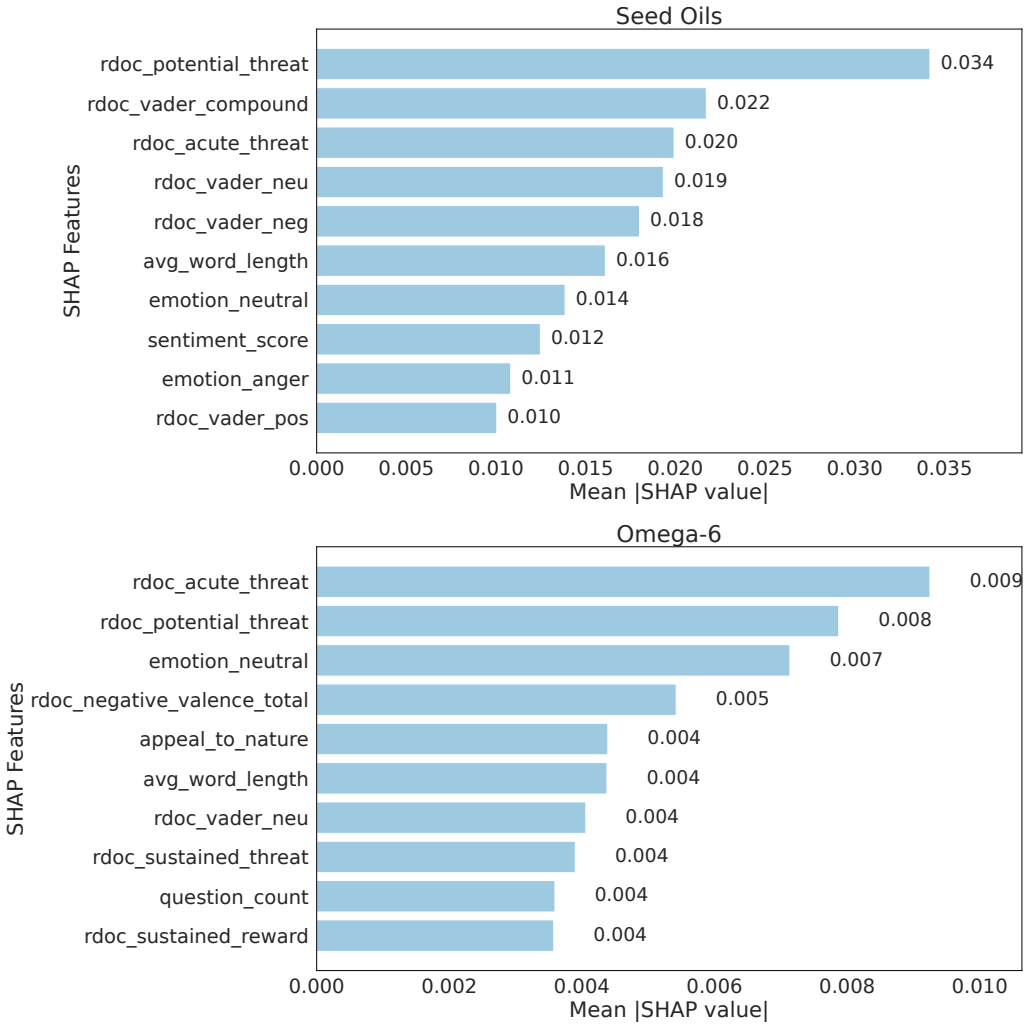

Figure 6: Top 10 features ranked by mean absolute SHAP values for the Random Forest model.

uated both feature-based and transformer-based models under in-domain and cross-domain transfer. Our results show that Sentence-BERT achieves the strongest in-domain performance, while RoBERTa prioritizes recall at the expense of precision. Notably, a feature-based Random Forest model leveraging linguistic, rhetorical, and psycholinguistic features performs competitively, highlighting the value of interpretable representations alongside deep semantic models.

We observe substantial performance degradation under cross-domain evaluation, even between closely related nutrition topics, underscoring limited generalization under domain shift. Beyond predictive performance, our analysis reveals consistent stylistic and affective patterns in misinformation, characterized by rhetorical certainty, reduced hedging, and simplified emotional expression. Feature importance analysis further confirms that psychological and affective signals are among the most informative predictors. Overall, these findings highlight the complementary strengths of interpretable linguistic features and contextual embeddings for robust and explainable nutrition misinformation detection, and motivate future work on multimodal and cross-platform generalization.

Limitations

The dataset used in this study is relatively small and restricted to two closely related nutrition topics, namely seed oils and omega-6. While this focused design allows for controlled analysis of domain shift, it may limit the broader applicability of the findings to other areas of nutrition or health misinformation.

The analysis is also limited to English-language Instagram captions, which excludes multilingual content and may not capture cultural or linguistic variations in how nutrition misinformation is expressed globally. In addition, only textual caption

data is considered, while Instagram is inherently multimodal and includes images, videos, and user engagement signals that may provide important contextual cues for misinformation detection.

Although the annotation process was guided by detailed expert-defined guidelines and inter-annotator agreement was measured, labeling misinformation inevitably involves a degree of subjectivity. Despite efforts to reduce bias through training and independent annotation, some ambiguity may persist, particularly in borderline cases where claims are partially supported or selectively framed. We also acknowledge that nutrition science is an evolving field and that dietary guidance may change over time as new evidence emerges. As with all evidence-based guidelines, the DGA reflects the prevailing scientific consensus at a particular point in time and is therefore subject to revision as the evidence base develops. Accordingly, the annotation framework used in this study should be interpreted as reflecting alignment with contemporaneous public health guidance during the data collection period rather than immutable scientific ground truth.

Finally, while the proposed feature set captures linguistic, rhetorical, and psycholinguistic signals, it is still based on predefined assumptions about informative cues. Transformer-based models are also constrained by the relatively small dataset size and may benefit from larger-scale or domain-adaptive training. Cross-domain evaluation is limited to topic transfer within Instagram, and broader cross-platform studies would be necessary to fully assess real-world generalization.

Ethical Considerations

This study uses only publicly available Instagram content and analyzes caption text without collecting private or sensitive user data. All identifiers were removed to ensure anonymity, and the dataset is fully de-identified. The models developed in this work are intended for research purposes and should be interpreted as probabilistic indicators rather than definitive judgments of truth or falsehood. Our annotation framework operationalizes misinformation relative to contemporaneous evidence-based public health guidance, specifically the 2020–2025 Dietary Guidelines for Americans and the accompanying Scientific Report of the Dietary Guidelines Advisory Committee. These guidelines are developed through systematic evidence review and expert synthesis of the nutrition literature and are intended to reflect prevailing scientific consensus at the time of publication. Consistent with prior public health misinformation research, we evaluate claims relative to established evidence-based recommendations rather than isolated or emerging studies. We acknowledge that nutrition science continues to evolve and that there may be some scientific disagreement; however, individual conflicting findings do not necessarily outweigh the broader consensus reflected in guideline-based recommendations. Care is required when applying misinformation detection systems in real-world settings, as misclassification risks may disproportionately affect nuanced or evolving scientific discussions. This work aims to support, rather than replace, expert evaluation of nutrition-related content.

Acknowledgments

We thank the nutrition experts, Dr. Charlotte Martin, DCN, RDN, and Dr. Alan Flanagan, PhD, for their valuable contributions to screening/extracting/annotating the original Instagram posts. The authors also gratefully acknowledge the School of Computing, College of Computing, Engineering and Construction, and Graduate School at the University of North Florida for their support and funding, which made this research possible.

Appendix

A Annotation Guidelines

A.1 Purpose of These Guidelines

These guidelines ensure that all human coders classify social media nutrition posts consistently using:

- A two-level accuracy scale (0 or 1)

- Rules aligned with the *Dietary Guidelines for Americans, 2020–2025 (DGA)* and the *2020 DGAC Scientific Report*

Coders should reference only the content presented in the post and apply the rules exactly as described.

A.2 What Coders Evaluate

For each post, coders assign:

1. Accuracy classification (1 or 0)
2. An optional brief justification (2–3 sentences)

Coders do **not** evaluate:

- Creator's biography
- Hashtags
- Engagement metrics
- Intent or motivation
- User comments
- Information not shown in the post itself

A.3 Evidence Standard

Coders must evaluate claims solely against:

- *Dietary Guidelines for Americans 2020–2025*
- *DGAC Scientific Report (2020)*

Coders should **not** use:

- Personal knowledge
- Other nutrition guidelines
- Mechanistic physiology not discussed in the DGA/DGAC
- External sources, papers, or reputable organizations
- Internet searches

A.4 The Two-Level Accuracy Classification

1 - Accurate or Mostly Accurate A post is **Accurate** when:

- All nutrition claims fully align with DGA/DGAC
- Any minor inaccuracies do not change the overall message

Examples of Accurate Content

- Saying omega-6 fats are not inflammatory
- Correcting misinformation about seed oils

A post is **Mostly Accurate** when:

- It is evidence-aligned overall
- It contains some non-trivial inaccuracies, but the main message remains correct

Typical patterns

- Slight exaggeration without reversing the evidence

0 - Mostly Inaccurate or Inaccurate A post is **Mostly Inaccurate** when:

- It contains some correct information
- Misleading or incorrect claims dominate

Typical patterns

- Mixing evidence-based advice with unsupported mechanistic claims
- Overstating inflammation, hormone effects, oxidation, or fear-based messages about oils
- Encouraging elimination of seed oils while acknowledging they contain essential fats

A post is **Inaccurate** when:

- The core message contradicts DGA/DGAC
- Accurate statements, if present, are trivial

Examples

- "Butter is heart healthy; seed oils cause disease."
- "Seed oils are toxic poisons that cause inflammation."

A.5 Reasoning Requirements (2–3 Sentences)

Coders may provide a short justification for doubtful annotations. The justification must:

- Evaluate the overall message rather than line-by-line details
- Reference only areas covered by the DGA/DGAC
- Not mention excluded content (e.g., "the DGA doesn't cover . . . ")
- Avoid SEO phrases or quoting the creator directly
- Clearly explain why the classification was chosen

A.6 Special Situations

Mixed-accuracy posts Code based on the **overall message**, not on isolated statements.

Mechanistic claims (inflammation, oxidation, hormones) If the mechanism is not discussed in the DGA:

- Ignore the mechanism itself
- Evaluate whether the dietary conclusion contradicts DGA guidance

Reactive content If a post stitches another creator's video:

- Ignore the introductory clip
- Code only the creator's commentary

B Complete Feature Definitions

This section provides formal definitions of all features used in the feature-based model. Features are grouped into linguistic, rhetorical, affective (emotion and sentiment), psychological (RDoC-based), and interaction features. All continuous features are standardized prior to model training.

B.1 Linguistic Complexity Features

word_count Total number of words in the caption.

avg_word_length Average number of characters per word.

lexical_diversity Ratio of unique words to total words (type-token ratio).

flesch_reading_ease Readability score estimating ease of comprehension (higher values indicate easier text).

flesch_kincaid_grade Estimated U.S. grade level required to understand the text.

gunning_fog Readability index estimating years of formal education required to understand the text.

B.2 Rhetorical and Persuasive Features

certainty_language Count or binary indicator of certainty expressions (e.g., "always", "never", "prove", "guarantee").

hedging_language Count or binary indicator of uncertainty expressions (e.g., "may", "might", "possibly", "perhaps").

question_count Number of question marks in the text.

exclamation_count Number of exclamation marks in the text.

capitalization_ratio Proportion of uppercase characters relative to total characters.

appeal_to_nature Indicator for naturalistic fallacy framing (e.g., "natural is better", "chemical-free implies safe").

conspiracy_markers Indicator/count of conspiracy-related phrases (e.g., "big pharma", "cover-up", "they don't want you to know").

has_personal_anecdote Binary feature indicating presence of first-person experiential claims (e.g., "I tried", "my experience", "I noticed").

B.3 Interaction Features

hedge_x_exclaim Interaction between hedging intensity and exclamation usage.

certainty_x_caps Interaction between certainty language and capitalization ratio.

anecdote_x_exclaim Interaction between personal anecdote presence and exclamation usage.

word_count_x_lexical_div Interaction between text length and lexical diversity.

B.4 Emotion Features (Transformer-Based Model)

Emotion features are probability outputs from a pretrained DistilRoBERTa emotion classifier.

emotion_anger Probability of anger-related emotion.

emotion_fear Probability of fear or threat-related emotion.

emotion_disgust Probability of disgust or aversion.

emotion_joy Probability of positive affect or happiness.

emotion_sadness Probability of sadness or loss-related affect.

emotion_surprise Probability of surprise or unexpectedness.

emotion_neutral Probability of neutral or informational tone.

B.5 Sentiment Features (VADER-Based)

sentiment_score Overall sentiment polarity score ranging from negative to positive.

sentiment_positive Proportion of tokens contributing to positive sentiment.

sentiment_negative Proportion of tokens contributing to negative sentiment.

sentiment_neutral Proportion of tokens contributing to neutral sentiment.

rdoc_vader_pos Positive sentiment score mapped into RDoC positive valence space.

rdoc_vader_neg Negative sentiment score mapped into RDoC negative valence space.

rdoc_vader_neu Neutral sentiment score from VADER.

rdoc_vader_compound Normalized aggregate sentiment score combining all polarity signals.

B.6 RDoC-Based Psychological Features

B.6.1 Valence Features

rdoc_positive_valence_total Aggregate positive appraisal, reward, and pleasure-related language.

rdoc_negative_valence_total Aggregate threat, loss, and negative appraisal language.

rdoc_valence_dimension Net valence score computed as positive minus negative valence.

B.6.2 Arousal Features

rdoc_high_arousal High-energy emotional activation (urgency, excitement, intensity).

rdoc_low_arousal Low-energy emotional states (calmness, fatigue, neutrality).

rdoc_arousal_dimension Overall emotional activation level combining arousal signals.

rdoc_arousal_total Total magnitude of arousal-related activation.

rdoc_arousal_net Net difference between high and low arousal activation.

B.6.3 Threat and Reward System Features

rdoc_acute_threat Immediate or short-term threat-related language (fear, danger, urgency).

rdoc_potential_threat Uncertain or probabilistic threat framing.

rdoc_sustained_threat Chronic or long-term threat framing.

rdoc_loss Language indicating deprivation, harm, or negative outcomes.

rdoc_frustration Expressions of anger, irritation, or blocked goals.

rdoc_reward_expectancy Anticipation of positive outcomes or benefits.

rdoc_sustained_reward Stable or ongoing reward-related language.

rdoc_approach_motivation Goal-directed or desire-driven action language.

rdoc_reward_responsiveness Sensitivity or responsiveness to reward signals.

B.6.4 Composite Psychological Features

rdoc_emotional_intensity Overall magnitude of emotional expression derived from valence and arousal strength.

rdoc_emotional_complexity Entropy-based measure of diversity in emotional signals.

rdoc_threat_reward_ratio Ratio of threat-related to reward-related language intensity.

rdoc_valence_arousal_interaction Interaction between valence and arousal dimensions.

C Rhetorical and Persuasive Pattern Rules

We use rule-based pattern matching to extract rhetorical and persuasive features from text.

Certainty expressions:

- always, never, guarantee, prove, destroy

Hedging expressions:

- may, might, possibly, perhaps

Additional rhetorical markers:

- Question count: number of "?" in text
- Exclamation count: number of "!" in text
- Capitalization ratio: proportion of uppercase characters
- Citation indicators: presence of study, research, http, www, or year (e.g., 2020)

Conspiracy-related markers (used in exploratory analysis):

- terms such as "big pharma", "they don't want", "hidden", "cover-up"

D Emotion Model Output Mapping

Emotion features are extracted using a pretrained DistilRoBERTa emotion classifier. The model outputs probability distributions over the following emotion categories:

- anger
- disgust
- fear
- joy
- sadness
- surprise
- neutral

For each text, we store the probability score for each emotion class. These are used as continuous affective features in downstream classification.

E RDoC Lexicons for Valence and Arousal Features

We use manually constructed lexicons grounded in the Research Domain Criteria (RDoC) framework to operationalize psychological valence and arousal dimensions. These lexicons are used for feature extraction in the main analysis.

Positive Valence (Reward / Approach Motivation)

- reward_words: amazing, awesome, excellent, fantastic, great, wonderful, love, enjoy, happy, joy, excited, thrilled, delighted, perfect, best, incredible, outstanding, brilliant, superb, beautiful, gorgeous, lovely, pleasant, fabulous
- reward_expectancy: hope, expect, anticipate, look forward, optimistic, confident, believe, promise, guarantee, ensure, assure, certain
- approach_motivation: want, need, desire, wish, crave, seek, pursue, strive, goal, achieve, succeed, win, gain, obtain, acquire, try, attempt, effort, motivate, drive, determined

- reward_sustained: satisfaction, fulfillment, gratification, contentment, pleasure, reward, benefit, advantage, profit, success, achievement

Negative Valence (Threat / Loss / Frustration)

- acute_threat: fear, afraid, scared, terrified, frightened, panic, terror, alarmed, worried, anxious, nervous, dread, horror, dangerous, threat, risk, harm, danger, peril, hazard
- potential_threat: uncertain, unsure, doubt, suspicious, wary, cautious, concerned, apprehensive, uneasy, uncomfortable, tense, may, might, possibly, perhaps, suggest, potentially, risk
- sustained_threat: stress, chronic, ongoing, persistent, constant, continual, always, never-ending, relentless, unending, perpetual
- loss: lose, lost, loss, missing, gone, disappear, vanish, deprive, lack, without, absent, void, empty, sad, grief, mourn, regret, sorrow, heartbreak
- frustration: frustrate, annoyed, irritated, angry, mad, furious, rage, upset, disturbed, agitated, provoked, outraged, failed, failure, unsuccessful, denied, rejected, blocked

Arousal / Regulatory Systems

- high_arousal: intense, extreme, powerful, strong, overwhelming, explosive, urgent, critical, emergency, immediate, sudden, shock, surprise, astonish, startle, energy, active, lively, dynamic, vigorous, vibrant
- low_arousal: calm, peaceful, relaxed, tranquil, serene, quiet, slow, gentle, soft, mild, subtle, tired, fatigue, weary, exhausted, drained, lethargic, boring, dull, plain, mundane
- intensity_modifiers: very, extremely, incredibly, absolutely, totally, completely, utterly, highly, deeply, truly, so, quite, really

Ontological Validation of Biomedical Topic Models: SNOMED CT Hierarchy Distance as an Automated Evaluation Metric

Abstract

Standard coherence metrics for biomedical topic models encode no clinical knowledge and cannot detect clinically implausible topic groupings. We propose SNOMED CT Wu–Palmer hierarchy distance as a post hoc, ontology-grounded diagnostic. On vascular surgery (47,318 articles) and craniofacial surgery (27,493 articles) corpora, the metric flags clinically heterogeneous topics that coherence misses—e.g., abdominal aortic aneurysm repair grouped with deep vein thrombosis ($d = 0.600$). Diagnostic signals are nearly identical across eight BERTopic embedding strategies including ontology-enhanced models, but diverge across model families: BERTopic alone produces a positive within- vs. cross-topic Cohen's d, while LDA, NMF, and Top2Vec at matched topic counts score below their own cross-topic baselines (Cohen's $d < 0$; Mann–Whitney $p > 0.99$). The score is therefore sensitive to topic-model output choice, not only to embedding choice within a single pipeline. A pre-clustering screening experiment finds near-zero correlation ($|\rho| < 0.08$) between embedding cosine and SNOMED CT similarity, arguing that ontological validation belongs after clustering rather than as an embedding screen. We additionally describe a two-stage UMLS-CUI stopword filter that preserves high-frequency domain-specific concepts which naive frequency filtering would discard. After one-time concept curation, the diagnostic itself is automated and requires no per-topic expert scoring.

1 Introduction

Topic models have become a standard tool for organizing and exploring biomedical literature at scale (Yeganova et al., 2018). Latent Dirichlet Allocation (Blei et al., 2003) and, more recently, BERTopic (Grootendorst, 2022) are widely applied in bibliometric analyses across clinical specialties, enabling researchers to identify thematic clusters, track temporal trends, and map the intellectual landscape of a field.

Evaluation of topic model quality relies primarily on intrinsic coherence metrics such as u_{mass} and C_v, which measure word co-occurrence statistics within discovered topics (Röder et al., 2015). While these metrics capture statistical regularity, they encode no domain knowledge. As a concrete example, a topic that groups articles on abdominal aortic aneurysm (AAA) repair—an elective *arterial reconstructive procedure*—with articles on deep vein thrombosis (DVT)—a *venous thromboembolic disease*—may achieve acceptable coherence scores because both share vascular vocabulary ("treatment," "graft," "outcome"). Yet the two occupy distinct branches of every clinical taxonomy, and merging them would mislead any researcher relying on the topic structure.

This gap between statistical coherence and clinical coherence has practical consequences. Researchers using topic models for systematic review screening (Thomas et al., 2011), research gap identification, or funding landscape analysis may draw conclusions from topics that conflate clinically distinct entities. A researcher asking "how has vascular surgery research evolved?" using a model that merges AAA repair and DVT into one topic is analyzing an artifact, not a literature structure.

The alternative—human expert evaluation—does not scale. Chang et al. (2009) demonstrated that human topic interpretability judgments are subjective and poorly correlated with statistical metrics. Hoyle et al. (2021) showed that even expert coherence ratings vary substantially, concluding that human evaluations have been largely abandoned by topic model developers. For a vascular surgery corpus producing 37 topics across 40 mapped clinical concepts, exhaustive pairwise clinical review requires evaluating $\binom{40}{2} = 780$ concept pairs—an effort no clinical reviewer can perform systematically, and one where reviewer differences

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 342–352
July 3-4, 2026 ©2026 Association for Computational Linguistics

in training, subspecialty, and clinical culture would introduce arbitrary variation (Lau et al., 2014). An automated, ontology-grounded method is needed.

We address this gap by introducing SNOMED CT hierarchy distance as a post hoc, ontology-grounded diagnostic for biomedical topic models. SNOMED CT (Systematized Nomenclature of Medicine—Clinical Terms) is the most comprehensive clinical terminology, organizing over 350,000 active concepts in a directed acyclic graph via `|is-a|` relationships (Pedersen et al., 2007; Melton et al., 2006). We apply Wu–Palmer normalized distance (Wu and Palmer, 1994) based on the Lowest Common Ancestor (LCA) to score the ontological coherence of topics produced by BERTopic-style pipelines (neural embeddings followed by UMAP+HDBSCAN clustering), and additionally compare against LDA, NMF, and Top2Vec under matched topic counts to test whether the diagnostic generalizes across topic-model families (§4.6). Contextualized topic models remain future work.

Our contributions are:

1. **Ontology-grounded post hoc diagnostic for biomedical topic models.** We define an SNOMED CT Wu–Palmer distance metric over topic-model outputs and show, on vascular (47,318 articles) and craniofacial (27,493 articles) corpora, that it flags clinically heterogeneous topics that coherence scores do not.

2. **Sensitivity across topic-model families.** The score produces near-identical signals across eight BERTopic embedding strategies (mxbai, PubMedBERT, SapBERT, BioLORD, cui2vec, MeSH TF-IDF, CUI co-occurrence, and an ensemble) but diverges across model families: BERTopic produces the only positive within- vs cross-topic Cohen's d on both corpora, while LDA, NMF, and Top2Vec at matched topic counts all score below their own cross-topic baselines (Cohen's $d < 0$, Mann–Whitney $p > 0.99$). This shows the metric is sensitive to topic-model output choice and not only to embedding choice within a single pipeline.

3. **Negative embedding screening result.** Across ten model–corpus combinations the cosine geometry of biomedical embeddings is only weakly correlated with SNOMED CT distance (Spearman $|\rho| < 0.08$), arguing that ontological validation is best applied after clustering rather than as an embedding screen—even for models trained on UMLS relations.

4. **Two-stage CUI stopword filtering.** We identify generic UMLS concepts (e.g., *Patients*, *Clinical Research*) that inflate CUI-based topic overlap scores and cascade-merge BERTopic outputs, and propose a frequency-plus-semantic-type filter that preserves high-frequency domain-specific concepts (e.g., *Cleft Palate* 19.1%, *Complication* 22.5%) which naive frequency filtering would incorrectly drop.

2 Background and Related Work

SNOMED CT and UMLS. SNOMED CT (Donnelly, 2006) is a clinical terminology of ∼350,000 active concepts organized as a polyhierarchical DAG via `|is-a|` relations; each concept has a stable SNOMED Concept Identifier (SCTID). The Unified Medical Language System (UMLS) Metathesaurus (Bodenreider, 2004) aggregates over 200 vocabularies, assigns each concept a Concept Unique Identifier (CUI), and provides semantic types (e.g., T046 Pathologic Function) and crosswalks to MeSH, ICD, and SNOMED CT. In this paper *SCTID* refers to nodes used to compute hierarchy distance, and *CUI* refers to concepts extracted from text via SciSpacy (Neumann et al., 2019).

Topic models for biomedical literature. LDA (Blei et al., 2003) and its biomedical applications (Yeganova et al., 2018; Thomas et al., 2011) preceded the contemporary embedding-plus-clustering family typified by BERTopic (Grootendorst, 2022): encode with a language model, reduce via UMAP (McInnes et al., 2018), cluster with HDBSCAN. Domain-pretrained encoders such as PubMedBERT (Gu et al., 2021), SapBERT (Liu et al., 2021), BioLORD (Remy et al., 2024), and CUI-aware spaces such as cui2vec (Beam et al., 2020) are widely substituted at the embedding stage. Our primary experiments use this family; we additionally compare against LDA, NMF, and Top2Vec (§4.6) to test whether the diagnostic generalizes beyond embedding-based clustering. Contextualized topic models remain future work (§7). Topic quality is typically assessed via word-co-

occurrence coherence (Röder et al., 2015), which Chang et al. (2009) and Hoyle et al. (2021) show agrees poorly with human judgement, motivating automated, knowledge-grounded alternatives (Lau et al., 2014).

Ontology-grounded similarity. A long line of work uses hierarchical taxonomies to score concept similarity—Wu–Palmer (Wu and Palmer, 1994), Resnik, Lin, Jiang–Conrath—surveyed in Harispe et al. (2015) and applied to biomedical ontologies in Pedersen et al. (2007). SNOMED CT distance has been used for patient similarity (Melton et al., 2006). Bhattacharya et al. (2018) applied topic modeling *to* SNOMED codes in EHR data; we work in the opposite direction. The distinction between distributional *relatedness* and taxonomic *similarity* is established in Hill et al. (2015), and Mao and Fung (2020) showed that UMLS relation types are not uniformly captured by biomedical embeddings; our negative screening result (§4.4) extends these findings to SNOMED CT hierarchy distance specifically. To our knowledge, the present work is the first to apply SNOMED CT distance as a post hoc diagnostic on topic-model output of biomedical literature.

3 Methods

3.1 SNOMED CT Hierarchy Distance

We score topic-level ontological coherence using Wu–Palmer normalized distance (Wu and Palmer, 1994) over the SNOMED CT `|is-a|` hierarchy. Among the canonical taxonomy-based measures (Harispe et al., 2015), Wu–Palmer is depth-normalized (yielding $d \in [0, 1]$ for direct comparison across SNOMED branches of differing depth), does not require corpus-derived information content (unlike Resnik, Lin, and Jiang–Conrath, which would introduce a second corpus-dependent quantity into a metric meant to be *purely* ontological), and is the form most commonly applied to SNOMED CT in prior work (Pedersen et al., 2007).

For two concepts c_1 and c_2 with Lowest Common Ancestor (LCA) in the `|is-a|` hierarchy, Wu–Palmer normalized distance is

$$d(c_1, c_2) = 1 - \frac{2\,\mathrm{depth}(\mathrm{LCA})}{\mathrm{depth}(c_1) + \mathrm{depth}(c_2)},$$

where depth is the shortest path from the SNOMED CT root (Pedersen et al., 2007). The distance is 0 for identical concepts and approaches 1 for pairs sharing only a high-level ancestor. For polyhierarchical concepts with multiple `|is-a|` parents we use the shortest path, following standard practice (Harispe et al., 2015). We chose SNOMED CT over MeSH (another common UMLS-linked taxonomy) because SNOMED CT provides finer-grained subspecialty distinctions for surgical concepts and the procedural–disorder branch split that drives several of our representative failure cases; MeSH descriptors are nonetheless used in the embedding-comparison arm (Table 2, MeSH TF-IDF).

3.2 Concept-to-Article Mapping

For each specialty, we curate SNOMED CT concepts representing the major clinical domains: 75 concepts for vascular surgery (spanning aortic, carotid, peripheral arterial, venous, and access procedures and their corresponding disorders) and 48 concepts for craniofacial surgery (spanning congenital anomalies, facial trauma, reconstruction, tumors, and nerve injury). The asymmetry reflects vascular surgery's broader anatomical scope and broader publication remit: beyond procedure and disorder concepts spanning each subspecialty, the vascular set also covers pharmacotherapy, imaging, basic-science, and professional topics that the craniofacial registry, anchored more tightly to anatomy and pathology, largely omits. Each concept is associated with discriminating keywords (e.g., "carotid endarterectomy" → SCTID 174776006). An article maps to a concept by keyword search over both its title and abstract text—abstracts having been shown to carry the highest information density of any article section (Schuemie et al., 2004). Up to 100 articles per concept are retained.

Topic assignments from BERTopic provide the link between articles and topics, enabling determination of which SNOMED CT concepts are represented within each topic.

Coverage. Keyword-based mapping against both title and abstract text achieves 78.8% coverage of vascular articles ($n = 37{,}306$ of 47,318) and 61.0% of craniofacial articles ($n = 16{,}763$ of 27,493). All 37 vascular topics (100%) and 12 of 29 craniofacial topics (41.4%) contain $\geq$2 mapped concepts and are therefore evaluable. The remaining unmapped articles lack concept-specific keywords across both title and abstract text. Prior work found information density highest in abstracts, although full text provides broader coverage (Schuemie et al., 2004). MeSH-to-SNOMED crosswalks (Bodenrei-

der, 2004) could further improve coverage.

3.3 Topic-Level Ontological Validation

For each topic t containing mapped concepts $C_t = \{c_1, c_2, \ldots, c_k\}$ where $k \geq 2$, we compute the mean pairwise ontological distance:

$$\bar{d}(t) = \frac{2}{k(k-1)} \sum_{i<j} d(c_i, c_j) \qquad (1)$$

Using a heuristic default threshold of $\bar{d}(t) > 0.5$, topics are flagged as *clinically heterogeneous*. We additionally identify *illustrative cross-domain pairs*—specific concept pairs within a topic that make the heterogeneity clinically interpretable.

3.4 Embedding Screening (Stage 0)

We test whether embedding geometry mirrors clinical ontology, which would allow embedding selection to serve as an upstream proxy. For each model, we compute centroid embeddings per SNOMED CT concept by averaging embeddings of mapped articles, compute pairwise cosine similarities, and correlate with SNOMED CT Wu–Palmer similarity using Spearman's ρ.

3.5 CUI Stopwords for Topic Reconciliation

When using UMLS Concept Unique Identifiers (CUIs) extracted from title and abstract text via SciSpacy (Neumann et al., 2019) to compare topics—e.g., via Jaccard overlap of per-topic CUI profiles—generic medical concepts that appear across most articles inflate similarity scores and cause spurious cascade merges. We identify these "medical CUI stopwords" empirically via a two-stage procedure. First, for each CUI extracted from the corpus, we compute document frequency (the fraction of articles containing the concept). CUIs exceeding a 15% prevalence threshold are candidates for filtering. Second, we classify each candidate by its UMLS semantic type: CUIs belonging to generic types (T079 Temporal Concept, T078 Idea or Concept, T080 Qualitative Concept, T081 Quantitative Concept, T101 Patient or Disabled Group, T062 Research Activity, etc.) are designated stopwords, while CUIs belonging to clinical types (T046 Pathologic Function, T061 Therapeutic Procedure, T047 Disease or Syndrome, T023 Body Part, etc.) are retained regardless of frequency. This two-stage approach prevents filtering of high-frequency domain-specific concepts that are substantively important within a specialty corpus.

On the vascular corpus (47,318 articles), the frequency threshold identifies 27 CUIs at $\geq$15%, of which 21 are generic (led by *Patients*, C0030705, 77.7%) and 6 are clinical (e.g., *Complication*, 22.5%; *Interventional procedure*, 18.8%). The semantic type filter retains the clinical CUIs and removes only the 21 generic stopwords. Without filtering, CUI-based topic overlap scores are dominated by ubiquitous concepts; in early experiments, Jaccard-based merge rules cascaded 37 topics down to 2. After filtering, no spurious merges occur (Section 4.2).

3.6 Post-Modeling Ontology Reconciliation

As a complementary step, we apply a two-pass pipeline. After BERTopic clustering (Pass 1), a CUI-based reconciliation pass (Pass 2) scores all topic pairs on Jaccard overlap of their CUI profiles (with stopwords removed) and merges pairs exceeding an empirically determined similarity threshold of 0.7 (requiring substantial CUI overlap before merging), with an anti-cascade constraint (each topic merges at most once per pass). This tests whether statistically discovered topics contain redundant clinical content that should be consolidated.

3.7 Corpora

Vascular surgery. 47,318 articles from 8 vascular surgery journals,[1] spanning 1984–2026. Journals were identified via PubMed's NLM Catalog under the "Vascular Surgery" and "Vascular Diseases" Broad Subject Terms, selecting all journals whose primary scope is vascular surgical practice. To test metric robustness across upstream modeling choices, we apply SNOMED CT validation to topic model outputs from eight embedding strategies, selected to span the major design axes available for biomedical text representation: general-purpose transformer (mxbai-embed-large-v1, 335M parameters (Lee et al., 2024)), biomedical transformers (PubMedBERT, 110M (Gu et al., 2021); SapBERT, 110M (Liu et al., 2021)), ontology-grounded models (BioLORD-2023, 110M (Remy et al., 2024); cui2vec, 500-d (Beam et al., 2020); Poincaré embeddings of SNOMED CT `|is-a|` edges, 200-d), a CUI co-occurrence TF-IDF baseline (200-d via SVD), and an ensemble (L2-normalized average of PubMedBERT + BioLORD). All use

[1] JVS, Annals of Vascular Surgery, EJVES, J. Endovascular Therapy, Vascular, JVS-VLD, Seminars in Vascular Surgery, JVS-Vascular Science.

Model	All-pairs	Same-dom.	Weighted	Single.
mxbai	0.711	0.394	0.711	10
PubMedBERT	0.722	0.367	0.742	1
BioLORD	0.715	**0.337**	0.735	2
Ensemble	**0.701**	0.347	**0.711**	**0**

Table 1: SNOMED CT ontological validation applied to four embedding models on JVS ($n = 14{,}290$). The metric yields similar diagnostic signals ($\bar{d} \approx 0.70$–0.74) across models, while still revealing model-specific failure modes (e.g., mxbai produces 10 singleton concepts vs. 0 for ensemble).

BERTopic with UMAP + HDBSCAN clustering (McInnes et al., 2018) (`min_cluster_size` = 300, `min_samples` = 15).

Craniofacial surgery. 27,493 articles from 9 journals,[2] spanning 1994–2025, identified via PubMed NLM Catalog under craniofacial and oral surgery subject headings. BERTopic with mxbai-embed-large-v1 embeddings, producing 29 topics.

3.8 Classical Topic-Model Baselines

To test whether the SNOMED CT diagnostic discriminates across topic-model families (not only embedding choices within BERTopic), we additionally fit three classical models on both corpora with matching topic counts ($k = 37$ vascular, $k = 29$ craniofacial): LDA (Blei et al., 2003) over a bag-of-words representation (min_df = 5, max_df = 0.95), NMF over TF-IDF features (default sklearn settings), and Top2Vec, which jointly learns document and word embeddings followed by HDBSCAN clustering and hierarchical reduction to the target k. The same SNOMED concept mapping and Wu–Palmer scoring pipeline is then applied to each model's topic assignments.

4 Results

4.1 Vascular Surgery Corpus

To assess whether the metric produces stable diagnostic signals across different upstream embedding choices, we apply it to four embedding models on the single-journal JVS corpus (Table 1; 14,290 articles, 75 SNOMED concepts) and then extend to eight embedding strategies on the full multi-journal corpus (47,318 articles, 8 journals).

With under-constrained clustering (`min_cluster_size` = 40), the mxbai model produces a mega-cluster (Topic 0, 36% of corpus) spanning 4+ SNOMED branches with mean intra-topic distance = 0.768 across 78 concept pairs. Six illustrative cross-domain pairs show clinically implausible groupings within this single topic:

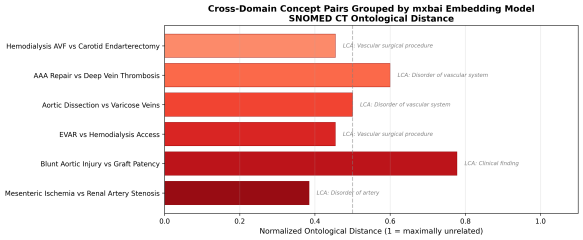

Figure 1: Six representative cross-domain concept pairs grouped within a single topic by the mxbai model. Each bar shows the Wu–Palmer SNOMED CT distance between clinically unrelated concepts that the topic model erroneously merged. Standard coherence metrics do not flag this topic.

- Hemodialysis AVF ↔ Carotid endarterectomy ($d = 0.455$; LCA: Vascular surgical procedure)
- AAA repair ↔ Deep vein thrombosis ($d = 0.600$; LCA: Disorder of vascular system)
- Aortic dissection ↔ Varicose veins ($d = 0.500$; LCA: Disorder of vascular system)
- Blunt aortic injury ↔ Graft patency ($d = 0.778$; LCA: Clinical finding)
- EVAR ↔ Saphenous vein ablation ($d = 0.500$; LCA: Endovascular procedure)
- PAD claudication ↔ IVC filter ($d = 0.714$; LCA: Disorder)

In this setting, the metric flags failures that coherence scores do not: the mega-cluster achieves acceptable coherence despite grouping concepts from 4+ SNOMED branches. Across all four models, the metric flags clinically heterogeneous topics (all-pairs $\bar{d}$ range: 0.701–0.722), suggesting that the diagnostic signal is not confined to a single embedding choice.

Multi-journal robustness (8 embedding strategies). On the full 47,318-article, 8-journal vascular corpus with appropriately constrained clustering (`min_cluster_size` = 300), we test eight embedding strategies (Table 2). Topic counts range

Table 2: Eight embedding strategies on the vascular corpus ($n = 47{,}318$, 8 journals). K = topics, Out.% = outlier rate, Sil. = silhouette. Ontology-enhanced embeddings (Snomed2Vec, cui2vec) do not outperform the baseline ensemble; Snomed2Vec produces negative silhouette, indicating cluster overlap. Bold = recommended model.

CUI (Name)	Doc Freq	%
C0030705 (Patients)	36,752	77.7
C0008972 (Clinical Research)	18,602	39.3
C0439234 (year)	16,739	35.4
C0868928 (Case)	12,990	27.5
C0039798 (therapeutic)	12,360	26.1
C0332281 (Associated with)	12,278	25.9
C0220825 (Evaluation)	11,707	24.7
…	(27 total $\geq 15\%$)	

Table 3: Top generic UMLS CUIs by document frequency in the vascular corpus. These "medical stopwords" must be filtered before CUI-based topic comparison to prevent cascade merges.

from 5 (cui2vec, severe under-clustering) to 49 (CUI co-occurrence). The recommended model (PubMedBERT + BioLORD ensemble, 37 topics, $C_v = 0.792$, 18.3% outliers) eliminates the mega-cluster problem observed with under-constrained parameters, producing topics that domain experts can inspect. Across the six viable arms, mean within-topic distances range from 0.767 to 0.770 (cross-topic baseline: 0.771), with Cohen's d between 0.003 and 0.015. This consistency suggests the findings are not artifacts of a single embedding model. The small positive Cohen's d reflects vascular topics spanning both procedures and disorders within each domain.

Clustering parameters vs. embedding choice. The jump from `min_cluster_size` $= 40$ (43 topics, 30.2% outliers, mega-clusters) to `min_cluster_size` $= 300$ (37 topics, 18.3% outliers, no mega-clusters) suggests that HDBSCAN parameter tuning has a larger effect on clinical face validity than embedding model selection. A topic count in the 30–50 range provided the clearest balance of subspecialty granularity in our data, while under-constrained clustering ($K > 100$) or over-constrained clustering ($K < 20$) produced topics that were implausibly coarse or fragmented.

4.2 CUI Stopwords

Table 3 shows the ten most prevalent CUIs in the vascular corpus. Without filtering, CUI Jaccard overlap between topic pairs is dominated by these generic concepts: in early experiments without a stoplist, Pass 2 reconciliation cascade-merged 37 topics to 2. After filtering the 21 generic CUIs (retaining 6 clinical CUIs via semantic type classification), Pass 2 produces zero merges in our experiments across all eight embedding arms—suggesting that appropriately constrained HDBSCAN already produces non-redundant topics.

Cross-corpus validation. To test whether the same generic-term pattern appears in a second corpus, we performed an analogous analysis on the craniofacial corpus using MeSH descriptor document frequencies (27,305 articles). Of 12 MeSH terms at $\geq$15%, 9 are generic (Humans 93.4%, Male 58.7%, Female 57.5%, Adult 36.7%, Retrospective Studies 25.4%) and 3 are clinical (Mandible 19.3%, Cleft Palate 19.1%, Cleft Lip 16.4%). Frequency-only filtering would incorrectly remove *Cleft Palate*—a defining condition of the specialty appearing in one-fifth of articles—while semantic type classification correctly retains it. The same structural pattern (generic demographics and study-design terms dominating, with domain-specific clinical terms at the boundary) appears in both corpora, supporting the two-stage approach as reusable across these two specialties.

4.3 Craniofacial Surgery Corpus

Table 4 presents per-topic ontological distances for the 12 craniofacial topics containing $\geq$2 mapped SNOMED concepts (48 concepts, 61 intra-topic pairs).

Nine topics ($\bar{d} < 0.5$) are ontologically coherent. T8 (Facial trauma) groups mandible, orbital, zygoma, nasal, and Le Fort fractures—all under "Fracture of bone of face" in SNOMED CT ($\bar{d} = 0.136$). T3 (Cleft lip and palate) groups cleft lip, cleft palate, combined cleft, and Pierre Robin sequence ($\bar{d} = 0.220$).

Three topics ($\bar{d} \geq 0.5$) are flagged as heterogeneous. Representative examples include:

- Rhinoplasty $\leftrightarrow$ Mandible fracture ($d = 1.000$;

Topic	$\bar{d}$	k	Pairs
T2: Orthognathic surgery	0.116	3	3
T8: Facial trauma	0.136	5	10
T1: Bone / distraction	0.200	2	1
T3: Cleft lip and palate	0.220	4	6
T7: Nerve injury	0.278	3	3
T13: Fillers / fat grafting	0.333	2	1
T20: Beauty / aesthetics	0.333	2	1
T6: Tumors and cysts	0.359	3	3
T0: Craniosynostosis	0.434	8	28
T12: Condylar / TMJ	0.511	3	3
T4: Flap reconstruction	0.600	2	1
T16: Hemangioma / vasc. malf.	0.600	2	1

Table 4: Per-topic SNOMED CT distances for craniofacial surgery ($n = 27{,}493$, mxbai embeddings). The midrule separates topics below the heuristic threshold ($\bar{d} < 0.5$) from those at or above it ($\bar{d} \geq 0.5$). k = number of mapped SNOMED concepts.

LCA: SNOMED CT root — elective aesthetic procedure vs. acute trauma)

- Cleft lip ↔ Ameloblastoma ($d = 0.667$; LCA: Disease — congenital anomaly vs. neoplasm)
- Craniosynostosis ↔ Burn injury ($d = 0.556$; LCA: Disease — congenital vs. traumatic)
- Facial nerve palsy ↔ Osteonecrosis of jaw ($d = 0.636$; LCA: Disease — neurological vs. bone pathology)

This thresholding provides a simple operational mechanism for topic-level filtering, enabling identification of topics that may require splitting or further inspection. The overall mean of per-topic mean distances is 0.343 (SD = 0.159), compared to 0.768 for the mxbai vascular mega-cluster. The craniofacial corpus shows better topic-level ontological coherence overall, likely because the 29-topic structure provides finer granularity than the mxbai vascular run's coarser clustering.

Threshold sensitivity. We adopt $\bar{d} > 0.5$ as a heuristic default separating single-domain topics from cross-domain groupings. Discriminative power varies by specialty and granularity—vascular topics inherently bridge procedure and disorder branches—and specialty-specific calibration is recommended.

4.4 Embedding Screening: A Negative Result

Table 5 presents Spearman correlations between embedding cosine similarity and SNOMED CT Wu–Palmer similarity.

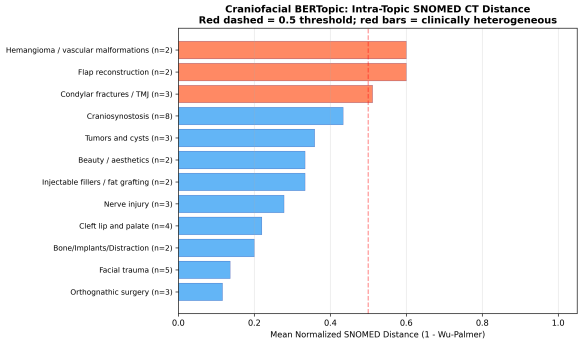

Figure 2: Per-topic SNOMED CT ontological distances for the craniofacial corpus. Topics below the dashed threshold ($\bar{d} = 0.5$) are ontologically coherent; topics above are flagged as clinically heterogeneous.

Model	Corpus	ρ	p	Pairs
mxbai	Vasc. (JVS)	0.037	0.305	780
PubMedBERT	Vasc. (JVS)	0.065	0.071	780

Table 5: Embedding screening: Spearman ρ between cosine similarity and SNOMED CT Wu–Palmer similarity across 10 model–corpus combinations. All show $|\rho| < 0.08$. Vasc. (JVS) = single-journal; Vasc. (8J) = 8-journal corpus.

All ten model–corpus combinations show near-zero correlation ($|\rho| < 0.08$). Most comparisons come from the vascular corpus, but the same near-zero pattern also appears in the craniofacial mxbai run. Within vascular data, the result is consistent across general-purpose (mxbai), biomedical (PubMedBERT, SapBERT), ontology-grounded (BioLORD, CUI co-occurrence, MeSH TF-IDF), and hybrid models, and across both single-journal and multi-journal settings. Notably, BioLORD-2023—which was explicitly trained on UMLS concept relationships including SNOMED CT (Remy et al., 2024)—shows $\rho = 0.013$ ($p = 0.71$).

Embedding models organize biomedical text by literature co-occurrence patterns, not by clinical ontological relationships (Hill et al., 2015). Concepts that are ontologically distant (e.g., AAA and DVT: different vascular systems, different pathophysiology) co-occur in the same journals, the same patient populations, and the same review articles. The embedding space reflects this co-occurrence

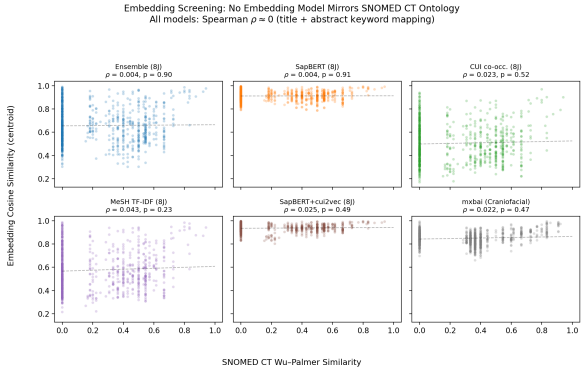

Figure 3: Embedding screening: cosine similarity versus SNOMED CT Wu–Palmer similarity for all concept pairs. All ten model–corpus combinations show Spearman $\rho \approx 0$, suggesting that embedding geometry does not mirror clinical ontological structure.

structure—distributional *relatedness*—not the clinical taxonomy—ontological *similarity* (Hill et al., 2015).

4.5 Informal Clinician Face-Validity Check

We include an informal three-surgeon assessment of one pipeline arm to illustrate—not to validate—the diagnostic's qualitative behaviour. Two vascular surgeons and one acute care surgeon *jointly* discussed the 37 topics from Arm A (ensemble) and proposed merge and split groupings; ratings were not collected independently, no blinding was applied, and no formal scoring rubric was used. We then compared this shared assessment with a domain-level split audit that classifies each topic by its distribution across nine vascular anatomical domains (Aortic, Cerebrovascular, Peripheral, Venous, Access, Visceral, Renal, Trauma, Thoracic Outlet). This comparison only covers Arm A on the vascular corpus, 16 judgements, and one specialty; it should not be read as evidence that the metric tracks clinical judgement in general (§7).

On these 16 judgements, the metric agreed with the surgeons on 4 merge groups comprising 13 topics in 12/13 cases (92%; e.g., Topics 7, 15, 23, 35—aortic aneurysm repair—scored zero heterogeneity with >83% Aortic concentration) and on 2 of 3 split requests (67%); the one miss separated amputation from other peripheral arterial topics, an intra-domain distinction that domain-level analysis cannot capture. Combined directional agreement was 14/16 (88%). We report this number for context only; it cannot establish metric validity. A blinded, independently rated, multi-specialty clinician study with inter-rater agreement is needed and is left to future work.

Corpus	Method	Eval.	$\bar{d}_w$	$\bar{d}_c$	Cohen's d
Cranio.	BERTopic	12/29	0.343	0.768	+0.159
	LDA	28/29	0.715	0.703	−0.043
	NMF	29/29	0.726	0.713	−0.046
	Top2Vec	29/29	0.726	0.712	−0.050
Vasc.	BERTopic	37/37	0.767	0.771	+0.015
	LDA	36/37	0.767	0.747	−0.073
	NMF	37/37	0.770	0.750	−0.071
	Top2Vec	37/37	0.769	0.749	−0.071

Table 6: SNOMED diagnostic applied to classical and neural topic models. $\bar{d}_w$ = mean within-topic distance; $\bar{d}_c$ = cross-topic baseline; Eval. = topics with $\geq$2 mapped concepts. Positive Cohen's d indicates within-topic < cross-topic (clinically coherent grouping). All three alternatives show negative Cohen's d on both corpora (Mann–Whitney $p > 0.99$).

4.6 Classical Baseline Comparison

To test whether the diagnostic generalizes beyond BERTopic-style pipelines, we apply it to three alternative topic models—Latent Dirichlet Allocation (LDA; Blei et al. 2003), Non-negative Matrix Factorization (NMF), and Top2Vec—run on both corpora with matching topic counts ($k = 37$ vascular, $k = 29$ craniofacial). LDA uses bag-of-words input, NMF uses TF-IDF, and Top2Vec jointly learns document and word embeddings with hierarchical topic reduction.

Table 6 shows that all three classical alternatives score below their own cross-topic baselines on both corpora, while BERTopic alone produces positive within- vs. cross-topic separation. On the craniofacial corpus, BERTopic achieves $\bar{d}_w = 0.343$ (well below the cross-topic baseline of 0.768), while LDA, NMF, and Top2Vec produce $\bar{d}_w \approx 0.72$—statistically indistinguishable from their own cross-topic baselines (Mann–Whitney $p > 0.99$; Cohen's $d < 0$). LDA generates 10 mega-clusters containing >40 mapped concepts each (of 48 total), indicating that most concepts co-occur in nearly every topic; NMF and Top2Vec produce 6 and 3 mega-clusters respectively. On the vascular corpus, all four methods show high $\bar{d}_w \approx 0.77$, but only BERTopic produces a (small) positive Cohen's d.

5 Discussion

What the metric does, and what it does not do. The diagnostic flags topics whose mapped SNOMED CT concepts span distant hierarchy branches—a failure mode that coherence metrics, which score word co-occurrence rather than on-

tological position, do not detect. We frame the metric as a post hoc complement to coherence, not a replacement: a topic may be coherent yet ontologically heterogeneous, and vice versa. After one-time concept curation, the scoring step is automated, but curation, threshold selection, and the interpretation of high-distance topics still require domain judgement.

The co-occurrence–ontology gap. The near-zero screening correlation ($|\rho| < 0.08$ across ten model–corpus combinations) extends Mao and Fung (2020) to the specific case of SNOMED CT hierarchy distance: even models trained on UMLS relations (BioLORD-2023, SapBERT) produce embedding spaces that capture distributional relatedness, not taxonomic position. The practical implication is that embedding choice cannot stand in for ontological validation, and that ontological scoring is best applied after clustering.

Clustering constraints matter more than embedding choice. Our eight-arm comparison suggests HDBSCAN parameter selection matters more for clinical face validity than embedding choice within the BERTopic family. Under-constrained clustering (`min_cluster_size` $= 40$) produces mega-clusters spanning 4+ SNOMED branches, whereas over-constrained settings ($K < 20$) collapse subspecialty distinctions. In our data, 30–50 topics gave the best balance, so future studies should report HDBSCAN sensitivity alongside embedding selection.

Sensitivity across topic-model families. The diagnostic is a post hoc score, not a constraint on the underlying models. What the cross-family comparison shows is that the score is sensitive to topic-model output choice, not only to embedding choice within a single pipeline (Table 2 vs. Table 6). We do not claim that BERTopic is universally superior to LDA, NMF, or Top2Vec; we observe only that its outputs have higher SNOMED CT ontological coherence on these two corpora at the tested topic counts. The cross-family direction is consistent across both corpora, but the magnitude of BERTopic's advantage is much larger on craniofacial ($+0.159$) than on vascular ($+0.015$).

Medical CUI stopwords. Generic UMLS concepts dominate CUI-based topic overlap scores in our data; any system using CUI profiles for clustering or merge decisions will encounter the same noise floor. The two-stage filter (frequency $\geq$15% followed by UMLS semantic type) preserves high-frequency domain-specific terms (*Cleft Palate* 19.1%, *Complication* 22.5%) that naive frequency thresholding would discard, while removing demographic, study-design, and temporal qualifiers. The generic/substantive boundary remains context-dependent; semantic types provide a principled default with room for domain-specific override. Pass 2 ontology reconciliation produced zero merges across all eight arms, indicating that constrained HDBSCAN already discovers non-redundant clinical topics in our data.

6 Conclusion

SNOMED CT Wu–Palmer distance flags clinically heterogeneous biomedical topics that word-coherence metrics do not, and it is sensitive to topic-model output choice across families. Across two surgical corpora, eight BERTopic embedding strategies, and the LDA, NMF, and Top2Vec baselines, only BERTopic produces positive within- vs. cross-topic separation (Tables 2, 6). The near-zero embedding-screening correlation argues that ontological validation belongs *after* clustering, not as an embedding screen. We additionally contribute a two-stage CUI stopword filter and find that HDBSCAN constraints may matter more for clinical face validity than embedding choice. Contextualized topic models and a blinded independently rated clinician study remain future work (§7).

7 Limitations

Scope of topic-model family. The primary experiments use BERTopic with UMAP+HDBSCAN. A preliminary comparison with LDA, NMF, and Top2Vec (§4.6) shows the diagnostic generalizes across topic-model families, but contextualized topic models, MeSH-guided variants, and systematic hyperparameter sweeps remain untested. The screening result (§4.4) specifically pertains to embedding-based pipelines.

Concept curation and coverage. Concept curation requires domain knowledge, though the effort is modest (∼50–75 concepts per specialty). Keyword mapping against title and abstract text covers 78.8% of vascular and 61.0% of craniofacial articles; full-text coverage would be broader (Schuemie et al., 2004), and MeSH-to-SNOMED crosswalks via UMLS (Bodenreider, 2004) could improve recall. Topics with fewer than two mapped concepts cannot be evaluated.

Metric calibration. SNOMED CT branch depths vary, and the $\bar{d} > 0.5$ flagging threshold is heuristic and specialty-sensitive; SNOMED CT also does not always capture cross-cutting themes (complications, perioperative care, imaging findings, outcomes) the way clinicians conceptualize them. Elevated distance should prompt inspection rather than be treated as categorical error. The CUI stoplist should be re-derived per specialty.

Method assumptions. Several methodological choices warrant flagging. The article-to-concept mapping caps each concept at 100 articles, which may distort topic statistics for high-frequency concepts; topics with only two mapped concepts are flagged on a single pair, exaggerating noise. The embedding-screening centroid aggregation may wash out fine-grained substructure, and the Spearman correlation assumes a monotonic alignment between embedding cosine and SNOMED CT similarity that need not hold. Wu–Palmer depth normalization assumes comparability across SNOMED branches, which may not hold uniformly between procedural and disorder hierarchies. Both validated corpora are surgical specialties; generalization to non-procedural domains (e.g., psychiatry, primary care, genomics) is untested, and temporal-span differences between corpora (1984–2026 vs. 1994–2025) are not analyzed.

Clinician validation. The three-surgeon assessment (§4.5) was a single joint discussion on one pipeline arm in one specialty, with no independent scoring, blinding, or rubric. It cannot establish metric validity. A blinded, independently rated, multi-specialty study with inter-rater agreement, power calculation, and a formal rubric is needed before the metric should be cited as predictive of clinical judgement.

Systematic Evaluation of the Quality of Synthetic Clinical Notes Rephrased by LLMs at Million-Note Scale

Abstract

Large language models (LLMs) can generate or synthesize clinical text for a wide range of applications, from improving clinical documentation to augmenting clinical text analytics. Yet evaluations typically focus on a narrow aspect – such as similarity or utility comparisons – even though these aspects are complementary and best viewed in parallel. In this study, we aim to conduct a systematic evaluation of LLM-generated clinical text, which includes intrinsic, extrinsic, and factuality evaluations of synthetic clinical notes rephrased from MIMIC databases at million-note scale. Our analysis demonstrates that synthetic notes preserve core clinical information and predictive utility for coarse-grained tasks despite substantial linguistic changes, but lose fine-grained details for task like ICD coding. We show this loss of detail can be substantially mitigated by rephrasing notes by chunks rather than by the whole note, but at the cost of reduced factual precision under incomplete context. Through fact-checking and error analysis, we further find that synthesis errors are dominated by misinterpretation of clinical context, alongside temporal confusion, measurement errors, and fabricated claims. Finally, we show that the synthetic notes – despite their task-agnostic nature – can effectively augment task-specific training for rare ICD codes.

1 Introduction

Large language models (LLMs) have demonstrated impressive capabilities in generating human-like text, including text written by domain experts (Shao et al., 2024). In healthcare, studies have shown that LLMs can generate clinical notes similar to those drafted by clinicians (Van Veen et al., 2024; Small et al., 2025; Kahl et al., 2026), driving interest in LLM-assisted clinical note-taking to reduce the significant burden of documentation (Roberts, 2024; Colicchio et al., 2019). The flexible mechanism of generative LLMs also naturally lends them to synthetic data generation, where LLMs can be prompted to produce task-specific, synthetic clinical texts to help provide larger training samples for improving model performance and fairness in healthcare (Juwara et al., 2024; Ktena et al., 2024), especially since real-world, private patient records are often difficult to access.

Given the growing adoption of LLMs in clinical text generation, it is essential to measure the quality of the generated text. Studies on LLM-generated clinical documentation typically compare the generated notes with human-written reference notes via an array of textual similarity metrics (Croxford et al., 2025; Carandang et al., 2025), which measure the intrinsic quality of the LLM generation. For studies using LLMs for data synthesis, the evaluation is often performed based on a specific downstream task (Loni et al., 2025; Alshaikhdeeb et al., 2025), which focuses on the extrinsic utility of the generated content. While exceptions exist (Wang et al., 2024b), these different evaluation types are rarely presented jointly on a consistent set of synthetic clinical notes. Since existing metrics typically capture only a limited aspect of textual quality, a systematic evaluation combining multiple strategies, spanning multiple metrics and downstream tasks, is vital to understand how LLMs generate clinical text.

In this study, we aim to address this gap through a multi-angle evaluation of LLM-generated clinical notes, including 1) **similarity-based intrinsic evaluation**, 2) **utility-based extrinsic evaluation**, 3) **fairness evaluation in downstream applications**, 4) **fact-checking with LLM-as-judge**, and 5) **human analysis of LLM errors**. We apply these setups to clinical notes rephrased by LLMs, which we treat as synthetic notes.

Rephrasing can be viewed as the most basic form of text generation given that LLMs are provided with complete input contexts, and serves as a lean test case of whether LLMs can interpret clinical in-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 353–371
July 3-4, 2026 ©2026 Association for Computational Linguistics

formation in its original form. Furthermore, LLMs are considered particularly proficient in rephrasing noisy input into high-quality text, a technique now used widely in curating large-scale web corpora (Maini et al., 2025; Li et al., 2024). Intuitively, LLMs should be able to rephrase clinical notes with ease, but our findings reveal that significant information loss can occur, especially when rephrasing whole notes compared to smaller chunks — a finding demonstrated and cross-checked across our evaluation setups.

Additionally, we examine generation scenarios with varied prompts and repeated generation, and discuss their implications. Although the rephrased synthetic notes are task-agnostic, we show they can be valuable resources for data augmentation in a task-specific setting — demonstrated through ICD prediction (Ji et al., 2024; Gan et al., 2025). The benefits are particularly substantial for modeling rare ICD codes. These experiments shed light on the strengths and limitations of LLM-generated clinical notes.

2 Related Work

Evaluation is key to driving the development of models in NLP. In the clinical domain, proper evaluation is critical to ensure an NLP system is fit-for-purpose and can be applied in healthcare, where both accuracy and safety are critical. For LLM-generated text, existing works usually evaluate it by comparing to the human-written counterparts. For example, studies on generating clinical documentation using LLMs (Chung et al., 2025; Soni and Demner-Fushman, 2024) — such as drafting a discharge summary based on patient records (Schwieger et al., 2024) or writing a report from a medical image (Yu et al., 2023; Nicolson et al., 2024) — typically compare the generated notes with ground-truth notes written by human experts. This often involves multiple textual similarity metrics, such as ROUGE (Lin, 2004) and BERTScore (Zhang* et al., 2020). Crafting pairwise similarity metrics is a research field in itself (Croxford et al., 2025).

Another application of LLM-based text generation is clinical text synthesis (Mitra et al., 2025; Liu et al., 2024a; Li et al., 2023), which provides data augmentation for a given task. These studies typically focus on particular note types or labeled datasets, and perform evaluation based on the downstream task of interest (Tang et al., 2023; Soni and Roberts, 2020), with task accuracy serving as the extrinsic measure. Unlike the aforementioned works, leveraging downstream tasks sidesteps the need for expert-written reference notes that are costly to produce at scale.

It is known that many existing metrics for text evaluation are imperfect (Sai et al., 2022) and only capture a specific aspect of textual features. Therefore, it is common to aggregate various metrics when comparing and ranking the performance of different generation models, and such aggregation tends to correlate better with human judgment (Xu et al., 2024; Van Veen et al., 2024). Furthermore, combining and analyzing different evaluation approaches can better illuminate generation quality by allowing results to be compared and cross-checked. In this study, we conduct such a systematic, multi-angle evaluation on a consistent set of synthetic notes generated at large scale — a combination that, to our knowledge, is still lacking in prior work.

Clinical text is noisy and varies in quality, a characteristic that resembles web data. Curating web data is an important research direction given its key role in training language models (Li et al., 2024), and this process can benefit from LLM-based synthesis. LLMs can be instructed to generate content with high "educational value" (Penedo et al., 2024; Gunasekar et al., 2023) or to produce improved versions of existing text snippets (Maini et al., 2024; Kang et al., 2025). The latter is also known as *rephrasing*. It has been found that even small-sized LLMs (<8B) are capable of producing high-quality rephrased corpora for improved and more efficient pretraining, and that larger LLMs do not necessarily improve downstream pretraining quality (Kang et al., 2025; Maini et al., 2024). This method has also been shown effective in the medical domain (Liu and Nguyen, 2024) for domain-specific pretraining compared to text synthesis from patient profiles alone (Kweon et al., 2024). Given its effectiveness, general applicability, and natural pairing with human-written notes for intrinsic evaluation, we adopt this method to generate synthetic clinical notes for our multi-angle evaluation.

3 Synthetic Clinical Notes by Rephrasing the MIMIC Databases

We generate synthetic clinical notes using LLMs by grounding on human-written notes, which are sourced from the MIMIC databases. We describe the synthesis process in the following.

3.1 Data Preparation

The MIMIC databases provide de-identified, real-world clinical data across various modalities. We considered all clinical notes from MIMIC-III (v1.4) (Johnson et al., 2016) and MIMIC-IV (v2.2) (Johnson et al., 2023). MIMIC-IV includes two note types (i.e., discharge summary and radiology report) while MIMIC-III provides a broader range of documentation charted during hospital encounters (e.g., physician and nursing notes). We align the format of the de-identification placeholders to underscores ("___"), consistent with MIMIC-IV. After deduplicating notes with the exact same content, the final pool of MIMIC notes comprises *4.6M clinical notes* with *1.4B words*.

3.2 Rephrasing Setup

Two approaches were considered in rephrasing clinical notes. The first is to rephrase *by the entire note*, preserving the original context. The second splits long notes into chunks and rephrases them *by chunk*. This is motivated by findings that LLMs may struggle to process information as the input context grows longer (Liu et al., 2024b; Hsieh et al., 2024), including during rephrasing (Maini et al., 2024). Each chunk contains approximately 150 words with sentence boundaries maintained, resulting in an average of 2.3 chunks per MIMIC note.

Small-scale generative LLMs are capable of effective rephrasing while maintaining efficiency (Kang et al., 2025; Maini et al., 2024). Following this approach, we use three ~8B models to rephrase MIMIC notes into "high-quality" text: Llama-3.1 (8B) (Dubey et al., 2024), Mistral-v0.3 (7B) (Jiang et al., 2023a), and Qwen-2.5 (7B) (Qwen et al., 2024). These efficient open-source LLMs also represent a realistic deployment choice for privacy- and resource-constrained clinical environments. Prompt templates, decoding parameters, and other inference details are provided in Appendix A. The complete process required about 1.8K GPU hours on NVIDIA H100 with vLLM (Kwon et al., 2023), producing a **9.1B-word** corpus, which we denote as MIMIC-EXT-SYNNOTES (details in Appendix Table 4).

4 Intrinsic Evaluation and Comparison with Human-written Notes

4.1 Experimental Setup

For intrinsic evaluation, we analyzed and compared surface-level and linguistic features between synthetic and human-written notes. We computed sentence and note lengths, part-of-speech (POS) distributions (for nouns, verbs, and numerals), and two standard readability scores: Flesch-Kincaid Grade Level (Solnyshkina et al., 2017) and SMOG Index (Harry and Laughlin, 1969).

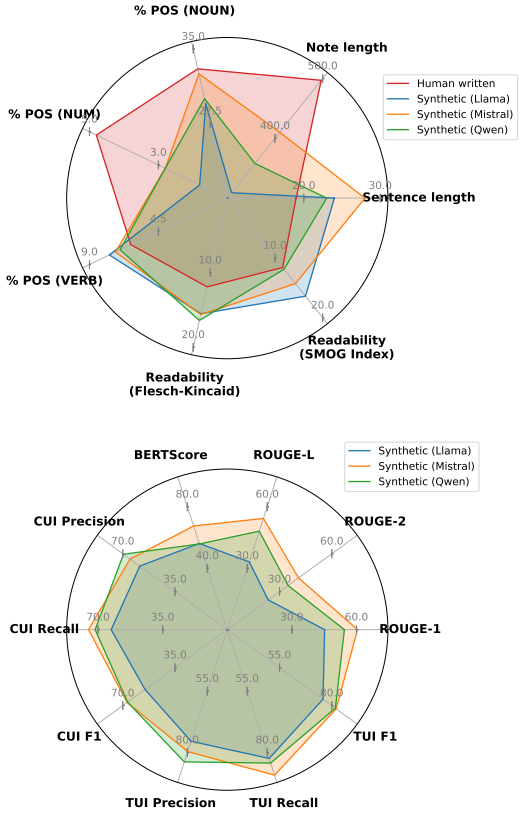

Figure 1: Linguistic features of synthetic notes and their textual similarities to human-written notes.

For pairwise metrics to capture the textual similarity between human-written and synthetic notes, we computed ROUGE (Lin, 2004) and BERTScore (Zhang* et al., 2020). Due to token length limitations in many pre-trained BERTScore base models (typically capped at 512 tokens), we opted for a DeBERTa-based model (He et al., 2023) with flexible input length and adaptation to natural language inference, which offers enhanced capability for semantic similarity comparison.

To quantify the semantic fidelity of LLM-generated notes in terms of medical concepts, we followed previous works (Gao et al., 2022; Xu et al., 2024) to extract UMLS Concept Unique Identifiers (CUIs) using QuickUMLS (Soldaini, 2016), and computed precision, recall, and F1 scores using the original notes as the reference, as proposed in MedCON (Yim et al., 2023). CUIs capture unique medical concepts from UMLS as a bridge

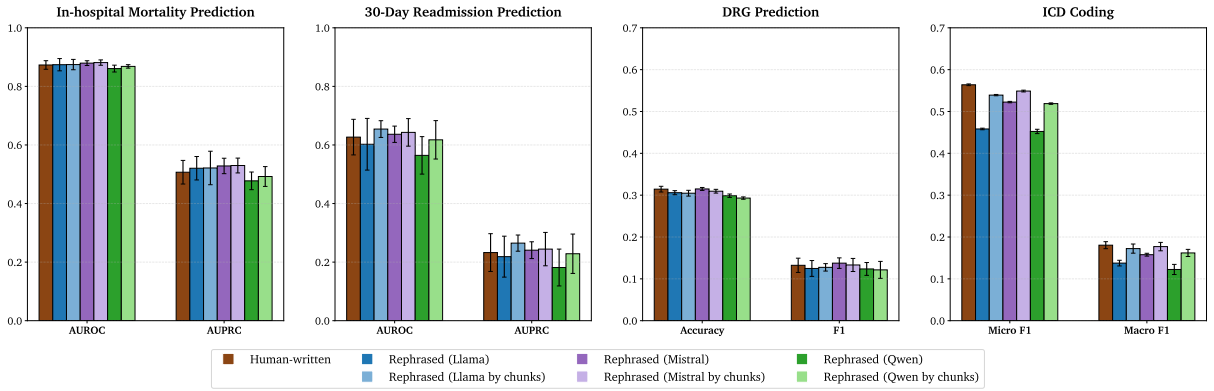

Figure 2: Comparing synthetic notes with human-written notes in downstream modeling. Each metric is calculated as the mean of five runs, and the error bars represent 95% confidence intervals.

for shared medical semantics. Following MedCON, we only considered clinically relevant semantic groups, such as anatomy, chemicals & drugs, and disorders. For a high-level comparison, we also mapped CUIs to their medical semantic types (Type Unique Identifiers, or TUIs) and computed the corresponding scores.

To facilitate efficient evaluation, we sampled 1K discharge summaries and 5K other note types from MIMIC-IV and MIMIC-III, respectively, as we observed that using more notes did not yield significantly different results.

4.2 Results

Figure 1 shows the comparison between human-written and LLM-generated notes. The synthetic notes are noticeably shorter in length but contain longer sentences with higher readability scores. They also show **a significant shift in lexical and semantic distributions**, as reflected by textual similarity scores with different degrees of variation across LLMs.

Analysis of TUI distributions (Table 1) reveals that the synthetic notes tend to omit concepts related to *"Body Space or Junction"* and *"Medical Device"* while introducing more from *"Natural Phenomenon or Process"* and *"Clinical Attribute"*, suggesting that synthetic text is **more descriptive but less dense with anatomical and specialist terminology**. This shows that LLMs may have a tendency to introduce more general terms and phrases in the generated text. The lists of frequent errors in semantic types made by each LLM are presented in Appendix Table 6.

	Semantic Type	%
Added	Natural Phenomenon or Process	16.5%
	Clinical Attribute	13.2%
	Phenomenon or Process	9.8%
	Pharmacologic Substance	9.5%
	Organ or Tissue Function	8.2%
Omitted	Body Space or Junction	12.2%
	Mental Process	11.8%
	Medical Device	11.6%
	Gene or Genome	11.2%
	Cell Component	8.8%

Table 1: Top 5 semantic types added (false positives) or omitted (false negatives) in synthetic notes, aggregated across three LLMs.

5 Extrinsic Evaluation with Healthcare Applications

5.1 Experimental Setup

We compared the utility of synthetic notes with human-written notes by training downstream clinical NLP models as a form of extrinsic evaluation. For a patient in a given task cohort, the input notes for the downstream model are either synthetic or human-written for both training and testing. In other words, we compared *"train synthetic, test synthetic" (TSTS)* and *"train real, test real" (TRTR)* by only varying the source of notes. The downstream performance is considered as a proxy to measure whether synthetic notes provide similar predictive utility to human-written notes. For this purpose, we did not consider *TSTR* (train synthetic, test real) or *TRTS* (train real, test synthetic), which can be confounded by factors such as writing styles and other features in the textual distribution.[1]

[1]Section 7.3 presents results for data augmentation, which aligns with *TSTR*.

We considered four clinical NLP tasks that represent key healthcare applications: risk stratification (in-hospital mortality and 30-day hospital readmission prediction) (Jiang et al., 2023b; Liang et al., 2025) and medical code assignment (DRG and ICD-10 prediction) (Wang et al., 2024a; Douglas et al., 2025). On the input side, they involve multiple note types authored by different caregivers at various stages of the care episode: in-hospital mortality (Jiang et al., 2023b; Si and Roberts, 2019) and DRG prediction (Wang et al., 2024a) tasks occur during the hospital episode and thus utilize all available clinical notes charted by the time of prediction (one day after ICU admission), such as nursing notes and radiology reports. The 30-day hospital readmission prediction (Boag et al., 2021; Huang et al., 2019) and ICD coding (Ji et al., 2024; Liu et al., 2022b) tasks occur after the end of hospital stay, and their input is based on the discharge summary alone.

On the output side, these tasks also involve varying complexities and requirements for clinical details: the first three tasks require the knowledge of overall patient status for a single-label classification, whereas the ICD coding task requires a higher level of attention to clinical details for the challenging multi-label classification with 8K ICD-10 codes (Edin et al., 2023). The four task cohorts are constructed from MIMIC with sample sizes ranging from 18K to 122K patients, and require processing of 546K notes. The statistics of the datasets are presented in Appendix Table 5.

For a given downstream task and a source of clinical notes, a classification model was trained, evaluated on the validation set for early stopping, and then tested on the held-out set to report final results. The only variation for a given task was the source of clinical notes, which are either human-written or synthetic, i.e., rephrased by one of the LLMs. Appendix B presents the details of the task cohorts and the training of downstream models.

5.2 Results

Figure 2 shows that synthetic notes exhibit comparable downstream performance to human-written notes on single-label tasks (i.e., all tasks except ICD coding), with results overlapping the 95% confidence intervals of using original notes. This suggests that **key clinical information is preserved in synthetic notes**, enabling accurate modeling and prediction for three prediction tasks. On the other hand, the ICD coding task (8K classes; multi-label) that requires fine-grained details exhibits much lower performance (with a drop of 4–10% in micro F1 score), suggesting **loss of certain clinical details** during synthesis that are essential for coding. Crucially, rephrasing *by chunks* instead of *by notes* substantially closes this performance gap, indicating **LLMs' difficulty in retaining and integrating information from long contexts** as a primary driver for detail loss.

5.3 Fairness Evaluation on Risk Stratification

Beyond predictive accuracy, we also assess fairness for two risk stratification tasks (in-hospital mortality and 30-day hospital readmission predictions). Following Brown et al. (2025), we split the patients into subgroups based on age (over and under 50), gender (female and male), and ethnicity (non-white and white), and computed the average absolute odds difference (AAOD) (Hardt et al., 2016) and statistical parity difference (SPD) (Besse et al., 2021) across these subgroups.

Figure 3 presents the results of the fairness evaluation, where we observe no significant changes in the fairness of the models trained on synthetic notes compared to those trained on human-written notes. This indicates that the LLMs did not introduce significant biases in their rephrasing that would affect downstream modeling of risk stratification.

6 Fact-checking with Error Analysis

We measure the truthfulness of the synthetic notes by fact-checking their claims against those made in the original notes. We then analyze the common error patterns exhibited by LLMs.

6.1 Experimental Setup

We follow Munnangi et al. (2025) to decompose synthetic notes into atomic facts (Min et al., 2023) and conduct fact-checking via entailment (Wang et al., 2024c). Following Xie et al. (2024), we calculate *precision* (the proportion of synthetic factual claims entailed by the human-written note) and *recall* (the proportion of reference factual claims entailed by those in the synthetic note).

For a pair of synthetic note N_S and human-written note N_H, they are decomposed into atomic factual claims C_S and C_H. Precision is defined as the proportion of facts in C_S that can be entailed by N_H:

$$Precision = \frac{1}{|C_S|} \sum_{c \in C_S} [N_H \vDash c] \quad (1)$$

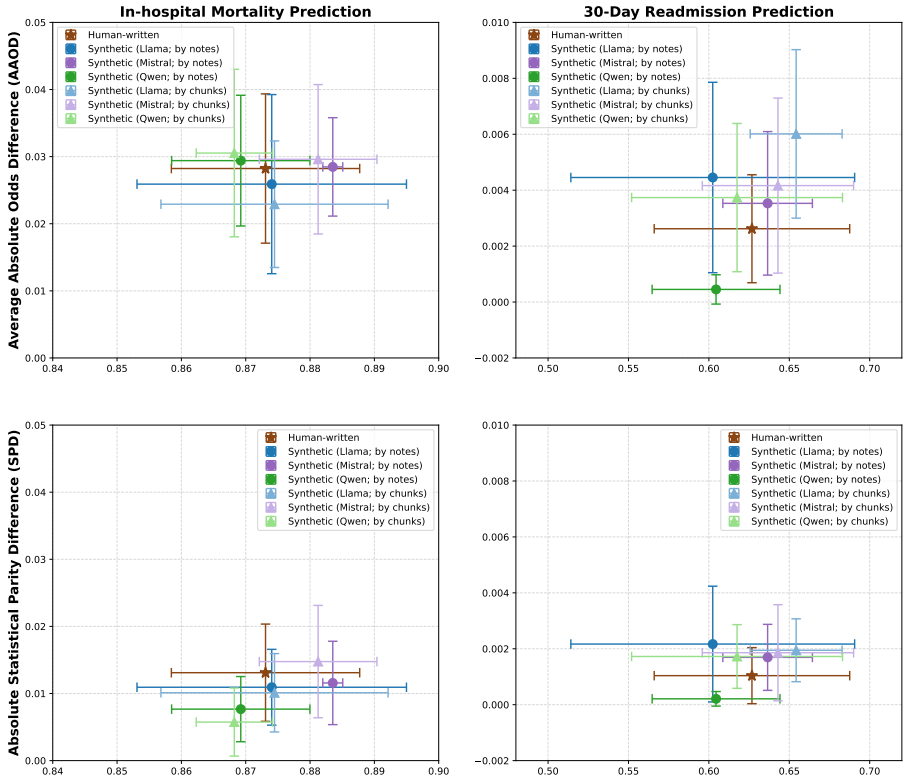

Figure 3: Fairness evaluation of the synthetic notes in downstream modeling in comparison with human-written notes. The x-axis presents model performance (AUROC score) and the y-axis presents model fairness (Average Absolute Odds Difference (AAOD) on the top panel and the absolute Statistical Parity Difference (SPD) on the bottom panel). For fairness metrics, the lower the better. The value of 0 for AAOD and SPD means no model discrimination between the examined subgroups. The results were averaged across age, gender, and ethnicity.

where $N_H \vDash c$ means note N_H entails fact c. Recall is defined as the proportion of facts in C_H that can be entailed by those from the synthetic notes C_S:

$$Recall = \frac{1}{|C_H|} \sum_{c \in C_H} [C_S \vDash c] \qquad (2)$$

Note that this is different from Munnangi et al. (2025), which used sentences from the reference note instead of decomposed facts; we found the latter to be more interpretable. The final precision and recall are macro averages over the sampled datasets, and F1 is the harmonic mean of the final precision and recall scores. We use Gemini-2.5 to decompose facts and assess entailment due to its strong reasoning capabilities. Due to the cost of querying the closed-source model to provide robust assessment, we conducted this part of the experiments on a small set of sampled notes as exploratory analysis, which covered more than 10K facts. More details are described in Appendix C.

6.2 Results

Table 2 shows that synthetic notes generally exhibit **high precision in their factual claims, but considerably lower recall**, indicating missing details. This becomes more pronounced when rephrasing *long notes* (>2K words), with recall as low as 0.3. Meanwhile, rephrasing *by chunk* produces a substantially larger number of facts, improving recall and suggesting a preservation of clinical details, consistent with findings in Section 5.

Beyond aggregated metrics, one author with a background in medical informatics analyzed sample outputs and identified a taxonomy of common error types (see Appendix Table 7): **misinterpretation of clinical context is the dominant failure mode**, followed by measurement errors, temporal/recency confusion, and fabrication of claims when the documentation is subtle. LLMs sometimes make up names and dates even though these are removed from real notes, and they also struggle with shorthand notation, e.g., confusing blood pressure values for respiration rates.

Finally, the results highlight a trade-off inher-

	Fact Prec	Fact Rec	Fact F1	# Avg. Facts
Llama	0.903	0.587	0.712	68
long notes	0.904	0.309	0.460	101
by chunk	0.868 (↓)	0.794 (↑)	0.830 (↑)	297 (↑)
Mistral	0.972	0.812	0.885	105
long notes	0.959	0.719	0.822	186
by chunk	0.938 (↓)	0.779 (↑)	0.851 (↑)	251 (↑)

Table 2: Fact-checking results based on decomposed atomic facts from synthetic notes.

ent to chunk-level rephrasing: while it maintains more claims and improves recall, it also lowers precision and is thus accompanied by higher hallucination rates. In many of these cases, LLMs see incomplete context and may generate plausible but unsupported content whose reference context appears in another chunk.

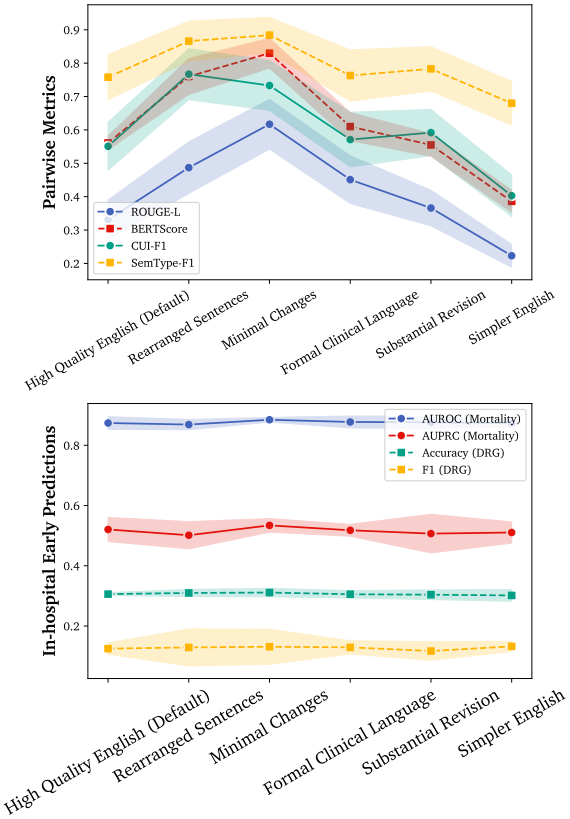

Figure 4: Impact of varied prompt instructions on intrinsic and extrinsic evaluations. Results are averaged over five random seeds.

7 Additional Analyses

We conduct additional analyses to examine the impact of prompting setups on the generated notes, including different instructions and iterative prompting. We also perform a data augmentation experiment on the ICD prediction task.

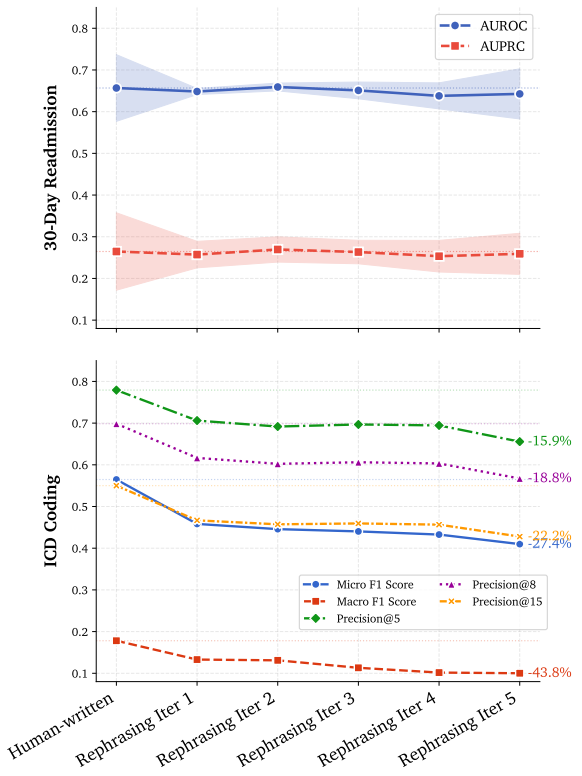

Figure 5: Impact of repeated synthesis on 30-day hospital readmission prediction across 5 iterations. Results are averaged over five random seeds.

7.1 Impact of Varied Prompts

We examine alternative prompts (Appendix E) that vary in structure (e.g., *"rearranging sentences"*) and style (e.g., *"simplified English"*), and observe their impact on synthetic notes, reflected by both intrinsic and extrinsic measurements. As expected, prompt variation significantly affects textual similarity: both syntactic and semantic contents change dramatically from instruction to instruction (Figure 4; top). Interestingly, the default instruction to produce *"high-quality"* language has a similar effect to *"substantial revision"*, showing the complexity of handling clinical documentation from the LLM's perspective.

On the other hand, the change of prompts has minimal impact on downstream modeling (Figure 4; bottom). This indicates that the synthetic notes preserve key clinical information related to patient severity despite differences in linguistic style, consistent with the findings in Section 5.

	All codes		Rare codes	
	micro F1	macro F1	micro F1	macro F1
Human-written notes	0.5644 (0.5622–0.5667)	0.1738 (0.1703–0.1772)	0.0359 (0.0173–0.0596)	0.0134 (0.0070–0.0199)
+*synthetic notes*	**0.5703** (0.5671–0.5736)	**0.2141** (0.2007–0.2278)	**0.1035** (0.0595–0.1485)	**0.0448** (0.0258–0.0656)

Table 3: Augmentation results for ICD coding. Models are evaluated on the human-written notes in the test set by bootstrapping 1000 samples from multiple seeds. The rare codes are 391 ICD codes that appeared only 10 times in the cohort (the benchmark in Edin et al. (2023) excluded codes that appeared fewer than 10 times). The reported scores are mean values and 95% confidence intervals. All augmented results show significant improvements with p-value <0.01 with two-sided t-test.

7.2 Impact of Repeated Synthesis

We explore repeated synthesis, where the LLM iteratively rephrases its own outputs to examine semantic drift. Shumailov et al. (2024) demonstrates cases where recursive generations can lead to model collapse when training happens in a loop. This raises critical concerns over the quality of data for training models over time, as generated content gradually becomes an integral part of the data pool, especially after deploying LLMs in practice.

Figure 5 shows the results on two downstream tasks over five iterations of repeated synthesis, each based on the output from the previous round. The performance on the single-label readmission prediction task remains stable. For ICD coding, although the performance decreases over time and sometimes by a large margin, the decline is progressive rather than sudden, and we have yet to observe a "collapse" in downstream modeling, i.e., scoring zero accuracy. Note that in this setting, the "generator" (i.e., the LLM) was kept unchanged, and only the downstream models (i.e., task-specific "predictor") were trained at each iteration instead of the "generator" (Shumailov et al., 2024). Moreover, the provision of a reference serves as a constraint to keep LLMs from generating completely irrelevant content. Nevertheless, the issue of LLMs missing fine-grained clinical details persists, as demonstrated by the declining ICD performance over repeated rephrasing.

7.3 Rephrased Notes for Augmentation

We examine the value of the synthetic notes in augmenting the training set for downstream modeling. Using LLMs to generate synthetic training data by following annotated examples has been studied for various clinical NLP tasks (Tang et al., 2023; Šuvalov et al., 2025). Unlike these studies, which craft application-specific prompts with demonstrations (i.e., few-shot prompting), our synthesis does not consider any task-related instructions or labels in the prompt. In other words, we apply the **task-agnostic synthetic notes for task-specific data augmentation**.

We focus on the challenging ICD-10 coding task and augment the original training set with synthetic notes generated by Mistral (by chunks), and evaluate on the human-written notes. Note that this *"test real"* setting is different from Section 5, where synthetic notes were examined in a *TSTS* setting.

The results are presented in Table 3, where we see that augmentation with synthetic notes increases all F1 scores (significant improvements with p-value <0.01), especially for rare codes (micro F1: $0.03 \rightarrow 0.10$). This shows the additional potential of LLM-synthesized clinical text for data augmentation despite being task-agnostic.

8 Discussion & Conclusion

Existing studies on synthetic clinical text typically evaluate the generation from one angle and lack direct comparisons between these evaluation strategies on a consistent set of clinical notes. We consider these different angles complementary in essence and useful for providing a unified view of the synthetic text quality; thus, we included textual similarity comparison, downstream utility assessment, and factuality checking in this study. As the results show, the synthetic clinical text generated by LLMs has both potential and weaknesses, and its usage should be assessed according to the application context.

Two findings from our study warrant particular attention for practitioners using LLMs for clinical text generation. **The first is the long-context bottleneck.** The substantial ICD coding gap between note-level and chunk-level rephrasing suggests the use of chunking to improve generation

quality. Meanwhile, the removal of surrounding context by chunking could lead to higher rates of hallucination. This means *a trade-off needs to be made on this decision based on the generative application and tolerance of each error type*, and future work needs to analyze in more depth the decisions related to chunking, such as boundary definition and chunk length.

Second, the error analysis shows that LLM failures are not random but exhibit recurring patterns. This suggests the potential for *future work to develop specialized techniques to address these errors*, such as better prompting for temporal anchoring and explicit handling of abbreviations.

We used rephrasing as the generation method in this study, and we did not explicitly distinguish between "rephrasing" and "synthesizing". Nevertheless, we acknowledge the nuanced difference between them in healthcare, especially the connotation of the term "synthesis" for privacy preservation. Grounding on real notes to create alternative versions of the clinical text — as done in "rephrasing" — forfeits privacy protection. Meanwhile, since the goal of the study is to measure text quality and to shed light on LLMs' capabilities, we maintain this decision to allow evaluation in different setups, i.e., head-to-head comparison with human-written notes and on downstream tasks.

Finally, our experiments show that the rephrased notes can be instrumental in understanding the quality of LLM generation and valuable for data augmentation despite being task-agnostic. To support future research, we compile and share the rephrased notes in this study as MIMIC-EXT-SYNNOTES, a synthetic corpus with 9B tokens based on 4.6M MIMIC notes.[2]

Limitations

Choice of LLMs for generation. We only focused on efficient open-source LLMs in our experiments. While more recent models may handle long contexts better, recent work suggests the gap may be narrower than expected: Kang et al. (2025) showed that using larger and more capable models for rephrasing pretraining data does not necessarily translate into better pretraining performance. Our complementary results with Gemma and Mixtral (Appendix F) did not yield substantially different results, supporting this view. Therefore, we consider the current model selection acceptable for fulfilling the study's objectives. Nevertheless, extending the analysis to models at other scales — both smaller and larger — and considering frontier models in a privacy-preserved setting are important future work.

Methods for text synthesis and evaluation. As mentioned, given the scope of this study, we did not explore alternative approaches for generating synthetic clinical text, particularly reference-free methods. Since MIMIC contains abundant EHR data, future work could incorporate structured measurements in a cross-modal setting to enhance the quality and validity of synthetic text. For evaluation methodologies, we consider the use of models in the current study — such as QuickUMLS for CUI extraction and BERT with sliding window for classification — acceptable as they are consistent for synthetic and human-written notes, but future work needs to further conduct meta-evaluation of the validity and reliability of these methods.

Issues with fact-checking. Although we conducted error analysis using LLM-as-judge for fact-checking, we were unable to directly compare synthetic notes with human-written notes. Such comparison requires extensive time and clinical expertise to review long notes and interpret patient care context, which was infeasible for this study. Instead, we opted to rely on downstream task performance and prior methods from fact-checking (Xie et al., 2024) that demonstrate strong correlation with expert judgment. We also acknowledge the limitations of our current fact-checking setup, which is based on a single family of models and a small number of notes, as we presented it as an exploratory analysis. The choice of model for LLM-as-judge particularly needs further scrutiny, given that models can be sensitive in reported factuality scores (Munnangi et al., 2025). Future work needs to validate the robustness of alternative models — probably the cheaper, open-source options — for this critical task. Nevertheless, we kept the use of models and notes consistent throughout the experiment, so that the analysis of errors and the comparison between note-level and chunk-level rephrasing are still valid.

Ethical Considerations

The generation of synthetic text using LLMs warrants careful ethical considerations. Although our synthesis was based on actual MIMIC notes and

[2]The synthetic note corpus can be found at https://github.com/JHLiu7/MIMIC-Ext-SynNotes.

offered generally high precision of factual claims, we observed that synthetic notes still omit or introduce information, which can be further exacerbated by insufficient context. This highlights the need for cautious use and, in some cases, additional filtering to ensure reliability, depending on the use case. Furthermore, while we assessed potential bias in downstream models for risk prediction, other dimensions of bias might remain and need to be considered in future work.

We assessed the utility of synthetic notes in downstream modeling by comparing *"train real, test real" (TRTR)* and *"train synthetic, test synthetic" (TSTS)*. Real-world signals (e.g., diagnosis codes) were utilized in both settings, so the *TSTS* models are applicable to *"test real"*. Meanwhile, careful consideration and transparency are essential if the synthetic notes were used to develop systems intended for implementation.

We followed the recommended practices for handling MIMIC notes. For rephrasing, we used only local, open-source models, and conducted all experiments in a secure environment to ensure data protection. For fact-checking with Gemini, we adhered to PhysioNet's Responsible Use guidelines[3] by accessing Gemini models via Vertex AI, ensuring compliance with HIPAA regulations.

Acknowledgments

A Details of Rephrasing MIMIC Notes

For clinical text synthesis, each LLM was provided with a system prompt consistent with its chat template and was instructed to synthesize a new version using a paraphrasing prompt found effective in prior studies (Liu and Nguyen, 2024; Maini et al., 2024), denoted as the "high quality" prompt:

Rephrasing prompt

```
[System Prompt] You are a medical artificial
 intelligence assistant. The assistant gives
 truthful, detailed, and professional
answers to the requests.

For the following paragraph give me a
diverse paraphrase of the same in high-
quality English language as in clinical
notes written by medical professionals:
```

We consider two rephrasing setups, one *by note* and the other *by chunk*. For rephrasing *by note*, we stratify the clinical notes by lengths — $(0, 500]$, $(500, 1000]$, $(1000, 2000]$, $(2000, 4000]$, and > 4000 — and set the corresponding maximum number of generated tokens to 1000, 2000, 4000, 8000, and 10,000, respectively. For rephrasing *by chunk*, we set the maximum number of generated tokens to 512 given the short chunk length (~150 words). Temperature was set to 0.75 and top-p 0.9 for all LLMs.

B Implementation Details on Extrinsic Evaluation

We followed previous studies (Liu et al., 2022a) to construct the in-hospital prediction cohorts (mortality and DRG) from MIMIC-III. For ICD coding, we used the benchmark (Edin et al., 2023) that comprehensively examined various types of ICD codes from MIMIC and focused on ICD-10 based on MIMIC-IV. Only ICD codes with a frequency higher than 10 were retained in the benchmark. This threshold was also applied to the DRG cohort with MS-DRG (Medicare Severity-DRG). We constructed a readmission cohort from MIMIC-IV by considering only the first admission of each patient and discarding immediate readmission cases that occurred within 24 hours after discharge. The statistics of the datasets are presented in Table 5.

We chose PLM-ICD (Huang et al., 2022; Edin et al., 2023) as the classification model given its strong performance on ICD coding and adaptability to handle long texts with sliding window. More

	# Total words (billion)	# Avg words per note	# Avg words per chunk
Llama (by notes)	1.21	260	-
Mistral (by notes)	1.34	289	-
Qwen (by notes)	1.13	263	-
Llama (by chunks)	2.24	482	206
Mistral (by chunks)	1.74	376	160
Qwen (by chunks)	1.41	315	146
Total	9.1	332	-

Table 4: Statistics of MIMIC-EXT-SYNNOTES generated by LLMs. When rephrasing based on chunks, each note from MIMIC is segmented into 2.3 chunks on average. The synthetic notes contain 9.1B words in total.

specifically: 1) it leverages a pre-trained encoder (BERT), allowing for domain-specific initialization; 2) it processes text via a sliding-window mechanism, making it efficient for long clinical documents; 3) it has demonstrated strong performance, particularly for ICD coding, compared to other deep learning methods (Edin et al., 2023); and 4) it is adaptable across tasks by modifying only the classification layer.

We initialized the model with a biomedical RoBERTa checkpoint (Lewis et al., 2020). Training was conducted using a batch size of 16 for up to 10 epochs, with early stopping triggered after no improvement for 3 epochs. The learning rate was set to 5e-5, with 2,000 warmup steps followed by linear decay. This training recipe was applied to all versions of input notes, either human-written or LLM-rephrased, to ensure consistent comparisons. The trained model was then evaluated on the test set of the corresponding task. We averaged the results over five runs with different random seeds to report the main results.

C Fact-checking Implementation

Following previous works (Munnangi et al., 2025; Xie et al., 2024), we performed fact-checking of the synthetic notes by decomposing the synthetic notes into atomic facts and measuring entailment. We use Gemini-2.5-Pro, a thinking model, to decompose a note into atomic facts, and Gemini-2.5-Flash to assess entailment. We used the prompts from Munnangi et al. (2025) for fact decomposition and entailment judgment, which are presented in the following.

We sampled 25 notes of varied length (10 radiology reports and 15 discharge summaries) for fact-checking due to the cost related to querying Gemini. We also consider *long notes* over 2K words, constituting five discharge summaries from the 25 notes. We show results (Table 2) on both these 25 notes and the five long notes. For synthetic notes rephrased *by chunk*, we also only present the results on the five long notes. Due to the prolonged content, these five notes take significantly longer to decompose and judge, sometimes requiring 500+ API calls for a single pair. Given the cost consideration, we relied on this small subset for this section. We also only focused on Llama and Mistral for this analysis, which contributed 5.2K and 6.1K facts, respectively.

D Omitted and Added Semantic Types

Table 6 presents the top-10 semantic types of the medical concepts that are either omitted or added by the LLMs after rephrasing. These are based on MedCON (Yim et al., 2023) but mapped CUI to TUI. The added semantic types can be considered as false positives (FPs) and omitted ones as false negatives (FNs) when comparing against the human-written notes.

E Alternative Prompts

We consider the following alternative prompts to explore their impact on generated text.

Rearranged Structure *Rewrite the following paragraph by rearranging sentences and phrases, while retaining the original clinical content and meaning:*

Minimal Changes *Rephrase the following paragraph with minimal changes, keeping the original structure and meaning intact. Make only slight adjustments for clarity and conciseness while preserving the clinical details:*

Formal Clinical Language *Paraphrase the following paragraph using strictly formal clinical documentation language, maintaining the same level of detail and medical accuracy:*

	# Patients	% Train/Val/Test	# Classes	Input notes	Metrics
In-hospital Mortality	33,515 (MIMIC-III)	80%/10%/10%	2 (11.1%)	Nursing notes, physician notes, etc.	AUROC AUPRC
30-Day Readmission	33,518 (MIMIC-IV)	80%/10%/10%	2 (13.0%)	Discharge summary	AUROC AUPRC
DRG Prediction	18,681 (MIMIC-III)	70%/20%/10%	369	Nursing notes, physician notes, etc.	Accuracy F1
ICD Coding	122,278 (MIMIC-IV)	73%/16%/11%	7,942	Discharge summary	Micro F1 Macro F1

Table 5: Description of cohorts and prediction tasks. For diagnosis-related classifications, DRG prediction is based on MS-DRG and ICD coding on ICD-10. All tasks have a single label per patient except for ICD coding, which is multi-label multi-class classification.

Substantial Revision *Produce a substantially revised version of the following paragraph in professional clinical English, changing sentence structure and vocabulary while preserving all critical medical details:*

Simpler English *Paraphrase the following paragraph into simpler clinical English, minimizing jargon and long sentences but keeping the key medical details:*

Entailment judgment prompt

```
You are an expert on natural language
entailment.
Your task is to deduce whether premise
statements entail hypotheses.
Return only '1' if the hypothesis can be
fully entailed by the premise.
Return only '0' if the hypothesis contains
information that cannot be entailed by the
premise.
Generate the answer in JSON format with the
following keys:
'entailment_prediction': 1 or 0, whether the
 claim can be entailed.
Only return the JSON-formatted answer and
nothing else.

Premise: {{premise}}
Hypothesis: {{hypothesis}}

Here is the JSON-formatted answer:
```

Fact decomposition prompt

```
Please breakdown the following text into
independent facts as a string delimited by
"//" to separate the facts

Example 1:
Note: "There is a dense consolidation in the
 left lower lobe."

Atomic facts:
There is a consolidation. // The
consolidation is dense. // The consolidation
 is on the left. // The consolidation is in
a lobe. // The consolidation is in the lower
 portion of the left lobe.

Example 2:

Note: "The patient has been having
intermittent shortness of breath for the
last two years."

Atomic facts:
The patient has been having shortness of
breath. // The shortness of breath is
intermittent. // The shortness of breath has
 been present for the last two years.

Do not include any other text, or say "Here
is the list..."

Note: {{note}}
```

F Alternative Models

Table 8 presents the numerical results presented in Figure 2. We provide additional results on rephrasing with Gemma-2 (9B) and Mixtral-v0.1 (8×7B) by chunks with one seed.

Synthetic text rephrased by Llama	
Added Semantic Types (FP) *Total counts: 9,321*	*Omitted Semantic Types (FN)* *Total counts: 8,979*

Organism Function (8.6%)	Indicator, Reagent, or Diagnostic Aid (8.4%)
Biomedical or Dental Material (8.3%)	Organism Attribute (8.4%)

Table 6: Changes of semantic types in the rephrased notes by the three LLMs. Top 10 semantic types are listed for false positive (FP) and false negative (FN) compared to the original, human-written notes. The ratio is calculated based on total counts of the presented semantic types for each LLM for FP and FN, respectively.

Claim	Error Category	Comment
"The patient presented with fever."	No error	*This is a correct claim.*
"The patient continued to have significant oxygen requirements."	No error	*Correct.*
"An MRI later confirmed the focus was a subacute infarction."	Misinterpretation	*This is likely, but not confirmed.*
"The anemia was treated with iron supplementation."	Fabricated claim	*Patient had iron-binding study. No supplementation intake was documented.*
"The surgery occurred on discharge day."	Misinterpretation	*Wrong interpretation of "Surgery Discharge part".*
"The patient was cleared by occupational therapy (OT) for discharge to rehabilitation."	Misinterpretation	*Cleared by PT.*
"The patient was scheduled for a follow-up appointment with her gastroenterologist."	Misinterpretation	*Appointment scheduled with primary care physician.*
"The patient's name is Mr. John Doe."	Fabricated claim	*Made-up name.*
"The patient is a non-smoker."	Misinterpretation	*Incorrect; tobacco use is mentioned.*
"The patient consumes approximately 1–2 drinks per day."	Measurement/Numeracy	*EtOH: [**4–20**] drinks/day.*
"The adjusted medications include simvastatin."	Fabricated claim	*No adjustment.*
"The patient is asymptomatic with the low blood sugar levels."	Misinterpretation	*"He states that he is asymptomatic," but note shows symptomatic hypoglycemia.*
"In the emergency department, the patient's vital signs were stable."	Misinterpretation	*Incorrect; labs showed elevated WBC.*
"The patient's most recent pulse was 95 bpm."	Temporal/Recency	*Not most recent.*
"The patient's most recent urine output was 2 L."	Temporal/Recency	*Not most recent.*
"The patient is a former smoker."	Temporal/Recency	*Current smoker.*
"All pathology samples of bone and cartilage showed hyaline cartilage with focal acute inflammation."	Misinterpretation	*Incorrect summarization of pathology results: not all samples show hyaline cartilage with focal acute inflammation.*
"In the ER, the patient's respiration rate was 142/min."	Measurement/Numeracy	*142 is blood pressure.*
"In the ER, the patient's blood pressure was 18/97 mmHg."	Measurement/Numeracy	*18 is respiratory rate; 96 (instead of 97) is oxygen saturation.*
"The patient's discharge blood pressure was 168/45 mmHg."	Misinterpretation	*BP in ED, not discharge.*

Table 7: Categorization and analysis of example false positive claims in synthetic texts.

Bridging the Version Gap: Multi-version Training Improves ICD Code Prediction, Especially for Rare Codes

Jinghui Liu **Anthony Nguyen**
Australian e-Health Research Centre, CSIRO
{jinghui.liu,anthony.nguyen}@csiro.au

Abstract

Clinical coding maps clinical documentation to standardized medical codes, an essential yet time-consuming administrative task that could benefit from automation. Current models on ICD coding are typically optimized for codes from a specific ICD version. However, in reality, ICD systems evolve continuously, and different versions are adopted across time periods and regions. Moreover, ICD coding suffers from the long-tail problem, and rare code performance can be a bottleneck for developing implementable models. We examine whether it is viable to train version-independent models by combining data annotated in different ICD versions, which may help address these challenges. We add ICD-9 data to the training of a modified label-wise attention model for ICD-10 prediction, and find that despite the version mismatch, adding ICD-9 yields a 27% increase in micro F1 for 18K rare ICD codes compared to training on ICD-10 alone. On 8K frequent ICD-10 codes, the multi-version training also substantially improves macro metrics, with far fewer model parameters.

1 Introduction

The International Classification of Diseases (ICD) is the global standard for reporting health conditions and diseases. It plays a critical role in healthcare billing, epidemiological research, and health policymaking (Dong et al., 2022; Gan et al., 2025). Assigning ICD codes to clinical documents requires a high level of expertise given that the candidate code set is often large (e.g., ICD-10 includes over 70K diagnosis codes) and the documentation can be lengthy and complex (Motzfeldt et al., 2025; Liu et al., 2023). Consequently, the coding process is time-consuming even for experienced coders, which has motivated extensive research into NLP models that automate or assist the coding process (Stanfill et al., 2010; Ji et al., 2024).

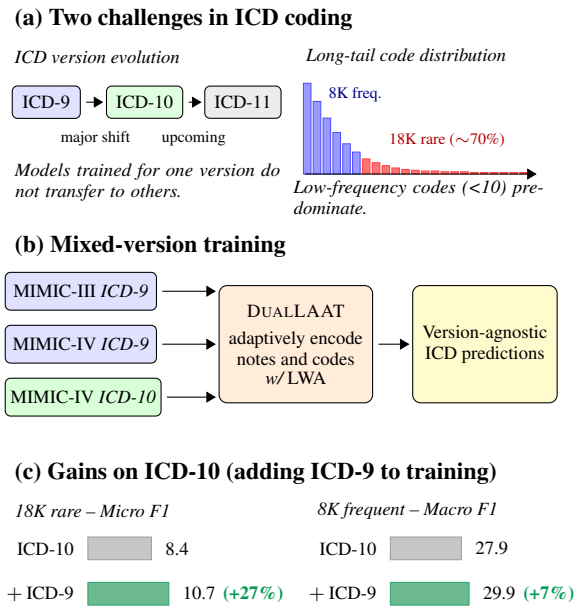

Figure 1: **(a)** ICD coding faces two intertwined challenges: the ICD system evolves continuously and the code distribution is heavily long-tailed. **(b)** We mix three MIMIC-derived datasets spanning ICD-9 and ICD-10 to train a single version-agnostic model, DUALLAAT. **(c)** Adding ICD-9 to ICD-10 training yields a 27% relative gain in micro F1 on rare ICD-10 codes than training on ICD-10 alone.

Current best-performing ICD coding models typically frame the task as a multi-label, multi-class classification problem (Douglas et al., 2025; Edin et al., 2023; Yuan et al., 2022), which requires defining a fixed label space and a substantial amount of data for supervised training. This setup faces two critical challenges in real-world ICD coding. First, **the ICD coding system undergoes continuous updates**, with new codes added and old codes retired. For example, CMS actively updates ICD-10 every year to keep codes aligned with healthcare needs.[1] At certain points, the ICD system undergoes major

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 372–381
July 3-4, 2026 ©2026 Association for Computational Linguistics

transitions, such as the shift from ICD-9 to ICD-10, and the anticipated move to ICD-11 (Harrison et al., 2021). Models with a pre-defined label space have trouble handling these updates, which introduce substantial data shifts (Finlayson et al., 2021).

Second, **ICD code distributions are long-tailed** (Li et al., 2025a; He et al., 2025), which is a critical modeling challenge as the ICD system grows larger and more fine-grained. For example, in MIMIC-IV (Johnson et al., 2023), infrequent ICD-10 codes that appear fewer than 10 times (18K) account for 69.6% of all codes in the database (26K). Collecting sufficient samples for these rare and underrepresented diseases is essential for training. However, achieving this requires consolidating patient records across time periods and regions, which is likely accompanied by mismatched ICD versions. It remains understudied whether such a combination leads to benefits or harm in modeling. For example, given that only 24.3% of ICD-9-CM codes have exact matches in ICD-10-CM (Fung et al., 2021), mixing multiple datasets across versions may plausibly introduce noise that harms rather than helps modeling.

This study explores this question by examining if ICD-9 data is valuable for training an ICD-10 prediction model (Figure 1). Our experiments used two ICD-9 datasets and one ICD-10 dataset based on MIMIC (Edin et al., 2023), and mixed their training sets to train a version-independent model based on label-wise attention (LWA) (Wu et al., 2024; Mullenbach et al., 2018). Adding ICD-9 data to the training set led to **substantially improved performance on rare codes** (micro F1: $8.4 \rightarrow 10.7$) in ICD-10 using **a much smaller model**, as well as **improved per-label performance on frequent codes** (macro F1 of 29.9). Our findings demonstrate the synergistic effect of combining multi-version datasets for ICD coding, showcasing the potential value of leveraging legacy patient records to train more robust ICD prediction systems.

2 Related Work

Research on automated and assisted ICD coding dates back to the 1990s (Larkey and Croft, 1996). Recent advances have largely focused on configuring neural architectures to better model the large code set (Li et al., 2025b; Shi et al., 2017). Ji et al. (2024) surveyed modeling approaches and highlighted that label-wise attention (LWA) (Mullenbach et al., 2018; Wu et al., 2024; Vu et al., 2020) remains a key module to train high-performing models. Edin et al. (2023) conducted a comprehensive benchmark of various LWA-based models across three datasets spanning MIMIC-III and IV and ICD-9 and ICD-10, finding that PLM-ICD with in-domain pretrained checkpoints performed best. Other approaches exploit the relations between codes in the ICD ontology to improve modeling (Luo et al., 2024; Yuan et al., 2022). To the best of our knowledge, all prior models were trained for a specific set of ICD codes as label space, and none were evaluated across different ICD versions.

A growing number of studies have explored prompting LLMs to predict ICD codes (Simmons et al., 2025; Yang et al., 2023). While simple prompting achieves low performance (Soroush Ali et al., 2024), agent-based systems for ICD prediction show promise (Motzfeldt et al., 2025; Zheng et al., 2025). The generative approach is not constrained by a fixed label space and may offer enhanced interpretability. However, most of these studies were conducted on small-scale datasets with a limited label space of about 1K (Cheng et al., 2023), which contrasts with existing benchmarks (8K in Edin et al. (2023)) and public databases (26K in Johnson et al. (2023)). In addition, agent-based approaches often require large token budgets, which can be costly. For this study, we focus on comparing with supervised approaches on datasets with large code sets.

3 Methods and Experiments

3.1 Benchmark Datasets

We adopted the benchmark from Edin et al. (2023), which includes three MIMIC-derived datasets, namely MIMIC-III (ICD-9), MIMIC-IV (ICD-9), and MIMIC-IV (ICD-10). The original benchmark focuses on frequent codes, defined as appearing $\geq$ 10 times in the corresponding database. To also evaluate rare codes, we re-extracted all codes from MIMIC, resulting in substantial expansions of the code space ($6K \rightarrow 11K$ for ICD-9 and $8K \rightarrow 26K$ for ICD-10). Since ICD-9 is no longer in active use, we focused on ICD-10 as the primary evaluation benchmark. Dataset statistics are presented in Appendix Table 5.

3.2 Classification Model

LWA trains code-specific embeddings to attend to relevant text tokens in clinical notes and uses them for classification (Edin et al., 2024). To enable

adaptive modeling across ICD versions, we trained an encoder to generate code embeddings from code descriptions, which are unique textual strings describing each ICD code. We jointly trained two text encoders – one for clinical notes and one for ICD codes – using LWA. Given the dual-encoder feature and the use of LWA from LAAT (Vu et al., 2020), we denote the model as DUALLAAT. The model takes N notes and C codes (as text strings) as input and outputs a probability matrix $\hat{\mathbf{y}} \in \mathbb{R}^{N \times C}$ as prediction. The codes in C are version-agnostic and can be ICD-9 or ICD-10. Detailed notations and training procedures are provided in Appendix B.

3.3 Experiments

To investigate the impact of mixing multiple ICD data sources, we aggregated the three train sets from MIMIC-III (ICD-9), MIMIC-IV (ICD-9), and MIMIC-IV (ICD-10) for training and evaluated on the corresponding test sets. We included all ICD codes (i.e., from full label space) in the aggregated data to train the model. To enable fast experimentation and to highlight the impact of data mixing, we used basic CNN (Mullenbach et al., 2018) and RNN (Vu et al., 2020) as text encoders, denoted as $\text{DUALLAAT}_{\text{cnn}}$ and DUALLAAT, respectively.

We adopted the benchmark metrics (Edin et al., 2023) for evaluation on frequent codes, including both classification and ranking metrics. In particular, macro F1 was calculated as the arithmetic mean of F1 scores per code. Higher macro F1 indicates stronger performance on less frequent codes, reflecting tail-end robustness. We also evaluated on full ICD-10 set and explicitly on rare codes, which in practice can be equally important as frequent codes for reporting disease prevalence and enabling appropriate reimbursement.

3.4 Baselines

We consider two strong supervised models as baselines for frequent and full code sets, respectively:

PLM-ICD. This model adopts in-domain BERT with sliding-window as the text encoder and trains with LWA (Huang et al., 2022). Prior work found replacing BERT with Llama on a dataset with 50 codes did not improve performance (Motzfeldt et al., 2025), highlighting the strong baseline performance of PLM-ICD. We report its results from the previous benchmark study on the frequent 8K codes (Edin et al., 2023).

CoRelation. This model improves code representation learning by modeling the relations between codes through a bipartite graph for enhanced accuracy and efficiency (Luo et al., 2024). It was evaluated on top-50 and full codes in MIMIC. We use this model for reference comparison on full ICD-10 set with 26K codes.

4 Results

4.1 Impact of Data Mixing on Frequent Code Prediction and Benchmark Comparison

Table 1 presents the results on frequent codes. On ICD-10 prediction, mixing additional ICD-9 datasets from MIMIC improves all metrics for both $\text{DUALLAAT}_{\text{cnn}}$ and $\text{DUALLAAT}_{\text{rnn}}$, with about 2 points of improvement on macro F1. This shows that adding ICD-9 to training is beneficial for ICD-10 prediction despite terminological differences. Using a stronger encoder (RNN over CNN) also brings steady improvements, consistent with prior findings (Edin et al., 2023) and suggesting potential gains with stronger encoder models.

Compared with the PLM-ICD baseline, RNN-based DUALLAAT trained on mixed MIMIC datasets achieved similar precision but much higher macro AUC-ROC and macro F1. We also report results for the weaker CAML (Mullenbach et al., 2018) and LAAT (Vu et al., 2020) in Appendix Table 6. These baseline methods with CNN and RNN encoders form a more direct comparison with our model. The additional results also show that DUALLAAT trained using mixed datasets offers lower variance across the metrics.

4.2 Impact on Rare Code Prediction

Mixing additional data sources shows substantial benefits in rare code prediction, as presented in Table 2. Both ICD-10 and 9 benefited from alternative ICD data. For ICD-10, this yielded a 27.4% increase in micro F1, which is a substantial improvement given the number of codes (18K).

Table 4 compares the model performance on the full code set with 26K labels from MIMIC-IV ICD-10. DUALLAAT achieves results comparable to the reported CoRelation numbers on shared metrics, with a notably higher macro F1 (6.3→11.2), suggesting stronger performance across the long tail of rare codes. This shows that enhancing training data can be as important in ICD coding as architectural improvements, which have been the predominant focus in ICD prediction literature (Ji et al., 2024; Dong et al., 2022).

	Classification				Ranking			
	AUC-ROC		F1		Precision@k		R-precision	MAP
	Micro	Macro	Micro	Macro	8	15		
MIMIC-III ICD-9

DUALLAAT (ICD-10 only)	99.3	97.1	57.5	27.9	69.3	54.4	57.2	61.5
DUALLAAT	**99.3** (–)	**97.4** (↑)	58.0 (↑)	**29.9** (↑)	**69.9** (↑)	54.9 (↑)	**58.0** (↑)	**62.3** (↑)

Table 1: Results on frequent ICD codes for MIMIC-III *ICD-9* (3.7K), MIMIC-IV *ICD-9* (6K) and MIMIC-IV *ICD-10* (8K). The means of three random seed runs were reported. For ICD-10 prediction, ↑ indicates improvement of multi-source training (ICD-10 + ICD-9) compared to training on ICD-10 alone.

4.3 Training and Parameter Efficiency

Mixing multiple ICD sources for training also improves efficiency as the model can now be applied to datasets with different ICD versions, in effect reducing the number of model parameters required. In the context of this study, three PLM-ICD models are needed for the three benchmarks on frequent code prediction, whereas one DUALLAAT can handle them all. Training with mixed data also shortens convergence time: our training plateaued at around 10 epochs compared to 20 epochs for PLM-ICD.

Table 3 reports the comparison between PLM-ICD and DUALLAAT. While DUALLAAT with mixed datasets achieves comparable performance, it uses only a fraction of the training time and parameters. This can be an important factor to consider when deploying a model in a low-resource hospital or outpatient setting (Wu et al., 2022).

	F1 Micro	Precision@8	MAP
MIMIC-IV-ICD10			
Single Dataset	8.4	5.8	19.5
+ Mixing Alt ICD	10.7 (27.4% ↑)	6.1 (5.2% ↑)	21.4 (9.7% ↑)
MIMIC-IV-ICD9			
Single Dataset	7.2	5.6	25.4
+ Mixing Alt ICD	10.9 (51.4% ↑)	6.6 (17.9% ↑)	31.2 (22.8% ↑)

Table 2: Results on the rare codes (frequency < 10 in the cohort). DUALLAAT$_{cnn}$ trained on the corresponding train set was used as baseline.

	Training time	# Param
ICD-10 only		
PLM-ICD	34 hrs	137M
DUALLAAT$_{cnn}$	5 hrs	15M
DUALLAAT	18 hrs	37M
ICD-10 + ICD-9 (×3 datasets)		
PLM-ICD (×3 models)	95 hrs	402M
DUALLAAT$_{cnn}$	17 hrs	15M
DUALLAAT	57 hrs	37M

Table 3: Comparison of training time and model size. Mixed training data includes one dataset for ICD-10 and two datasets for ICD-9.

5 Discussion & Conclusion

Training effective ICD coding models is challenging due to the long-tail distribution of codes and the continuous updates to the ICD system. Most existing work focuses on improving modeling methods, yet little attention has been paid to the impact of the training data itself. We show that mixing multiple data sources – even with varied ICD versions – benefits both frequent and rare code predictions. The gains are notable given that less than 25% of ICD-9 have equivalent mappings to ICD-10 (Fung et al., 2021), suggesting the benefits arise from shared clinical semantics rather than direct label overlap, which warrants future investigation.

The viability of mixing ICD versions means **legacy patient records can be utilized in training new models**, an important implication for developing coding systems to handle ongoing modifica-

	AUC-ROC Micro	AUC-ROC Macro	F1 Micro	F1 Macro	Precision@8
PLM-ICD (Luo et al., 2024)	99.0	91.9	57.0	4.9	69.5
CoRelation (Luo et al., 2024)	99.6	97.2	57.8	6.3	70.0
DUALLAAT (ICD-10 only)	99.6	97.0	56.6	10.2	69.3
DUALLAAT	99.7	97.4	57.1	11.2	69.8

Table 4: Results on 26K ICD-10 codes in MIMIC-IV. PLM-ICD and CoRelation results are from the original paper, which uses a different preprocessing pipeline; we include this approximate comparison for reference.

tions of ICD rules. For major rule updates, a model trained on legacy records can avoid cold-start issues and serve as a foundation for fine-tuning.

In conclusion, we demonstrate the advantages of mixing multi-source datasets to train ICD prediction models, resulting in more accurate, robust, and efficient performance. The synergistic effect of combining diverse sources demonstrates the potential for further scaling both training data and model capacity to advance the progress of ICD coding research. Finally, our code and model checkpoints are released to support reproducibility.[2]

Limitations

ICD and Data Coverage. This study only considered the MIMIC databases as the data sources, which originate from a single institution in the United States and use ICD Clinical Modification (CM). Other regional implementations of ICD exist, such as ICD-10-CA for Canada and ICD-10-AM for Australia. Furthermore, many countries adopt ICD systems in non-English languages, including China (CCD/ICD-10-CN) and Germany (ICD-10-GM). We were limited by the scope of data in this initial study and focused on openly available datasets. Given insights from multilingual language modeling, cross-lingual knowledge transfer (Artetxe et al., 2020) may also be feasible for ICD modeling. However, this warrants future research, particularly to address nuanced differences between different ICD versions beyond mere translation and semantic mappings.

Classification Model. For this study, we employed simple classification models in the experiments, but we believe the patterns of data mixing can be extrapolated to other models given the existing findings on modeling architectures (Ji et al., 2024; Edin et al., 2023). Training PLM-based models with multi-source datasets represents a natural follow-up, though we leave this open as newer and more effective modeling methods may emerge in the near future.

Record Overlap. An inherent challenge in mixing data sources is potential overlapping records. MIMIC-III (2001-2012) and MIMIC-IV (2008-2018) overlap temporally, but we could not explicitly identify shared patients because they use different ID conventions and are not linkable. This may have influenced results for ICD-9, although these were not the primary focus of our experiments. Meanwhile, this is less of an issue for ICD-10 since it is distinctly different from ICD-9 and only exists in MIMIC-IV. We found seven patients appearing in both ICD-9 and ICD-10 datasets from Edin et al. (2023) in MIMIC-IV, with only one patient in the ICD-10 test set (19,802 patients). Given the large test size and different data distributions, we deemed it acceptable to retain this patient to enable direct comparison with the baselines.

A Datasets for Evaluation

Table 5 presents the statistics of the three benchmark datasets from Edin et al. (2023). We additionally extracted the infrequent codes that were not included in the prior study to evaluate the models' robustness on tail-end ICD codes.

B Classification Model in Detail

B.1 DUALLAAT with dual encoders

Given a clinical note N with t_{note} word tokens $w_1^N, w_2^N, \ldots, w_{t_{\text{note}}}^N$, we have a clinical code C with t_{code} word tokens $w_1^C, w_2^C, \ldots, w_{t_{\text{code}}}^C$ from the code description. They are transformed into word embeddings by a shared embedding layer into $\mathbf{e}_1^N, \mathbf{e}_2^N, \ldots, \mathbf{e}_{t_{\text{note}}}^N$ and $\mathbf{e}_1^C, \mathbf{e}_2^C, \ldots, \mathbf{e}_{t_{\text{code}}}^C$, respectively.

Clinical note representations at token level $\mathbf{H}_{\text{note}} \in \mathbb{R}^{d_{\text{note}} \times t_{\text{note}}}$ are created by a note encoder as $encoder_{note}$:

$$\mathbf{H}_{\text{note}} = \text{encoder}_{\text{note}}(\mathbf{e}_1^N, \ldots, \mathbf{e}_{t_{\text{note}}}^N) \quad (1)$$

The clinical code representation is encoded by a separate $encoder_{code}$ and pooled into a code-level representation. The representation for one code $\mathbf{h}_{\text{code}} \in \mathbb{R}^{d_{\text{code}}}$ is created as:

$$\mathbf{h}_{\text{code}} = \text{Pooling}(\text{encoder}_{\text{code}}(\mathbf{e}_1^C, \ldots, \mathbf{e}_{t_{\text{code}}}^C)) \quad (2)$$

In practice, we consider L codes by encoding them in a batch to create $\mathbf{H}_{\text{code}} \in \mathbb{R}^{|L| \times d_{\text{code}}}$. Then we have two projection matrices $\mathbf{W}_{\text{note}} \in \mathbb{R}^{d_{\text{shared}} \times d_{\text{note}}}$ and $\mathbf{W}_{\text{code}} \in \mathbb{R}^{d_{\text{code}} \times d_{\text{shared}}}$ for note and code, respectively. The projected code representations $\mathbf{H}_{\text{code}} \cdot \mathbf{W}_{\text{code}} \in \mathbb{R}^{|L| \times d_{\text{shared}}}$ replaces the

code-specific embeddings in typical LWA implementation. With an additional dimension d_{shared} specified, the attention scores and representations based on dual encoders are computed:

$$\mathbf{A}_{\text{dual}} = \text{softmax}\Big(\tanh(\mathbf{H}_{\text{code}} \cdot \mathbf{W}_{\text{code}}) \cdot \tanh(\mathbf{W}_{\text{note}} \cdot \mathbf{H}_{\text{note}}) \Big) \quad (3)$$

$$\mathbf{J}_{\text{dual}} = \mathbf{H}_{\text{note}} \cdot \mathbf{A}_{\text{dual}}^{\top} \quad (4)$$

This formulates the backbone of DUALLAAT, which use separate note encoder and code encoder to create their corresponding representations and compute label-wise attention.

To further enhance the dual label-wise attention, we also consider M attention heads with $\mathbf{W}^1_{\text{note}}, \ldots, \mathbf{W}^M_{\text{note}}$ and $\mathbf{W}^1_{\text{code}}, \ldots, \mathbf{W}^M_{\text{code}}$ as multi-head attention (MHA) (Vaswani et al., 2017). Then we compute $\mathbf{J}^1_{\text{dual}}, \ldots, \mathbf{J}^M_{\text{dual}}$ and obtain the multi-head note representation per code by concatenation:

$$\mathbf{J}^{\text{mha}}_{\text{dual}} = \text{concat}(\mathbf{J}^1_{\text{dual}}, \ldots, \mathbf{J}^M_{\text{dual}}) \quad (5)$$

The final output is computed as:

$$\hat{\mathbf{y}} = \text{sigmoid}(\text{classifier}(\mathbf{J}^{\text{mha}}_{\text{dual}})) \quad (6)$$

The model is trained to minimize binary cross entropy loss. Different from the previous models that consider only note N as input, DUALLAAT now takes both N (notes) and C (codes) as inputs. This enables a flexible choice of L by changing C either during training or at inference. Since the clinical codes C are provided as code descriptions in text, it allows flexibility to feed different versions of ICD codes as long as they are provided in the textual form. During inference, these descriptions can be directly mapped back to the actual codes.

B.2 Training DUALLAAT

To train DUALLAAT in batches, we need to dynamically set the label space L for different codes. For example, given a batch of 32 patients with each patient having 20 codes on average, L would be set dynamically according to appearing clinical codes with $|L| = 640$ (20×32). Meanwhile, in reality the number of clinical codes can vary dramatically from patient to patient, resulting in large variations in code numbers that would destabilize the label space and thus training. In addition, patients in a batch sometimes may contain codes in overlap, in effective reducing the scope of L.

To address this, we specify the label space L to be a fixed number that is larger than the possible codes to appear in a batch. Given the fixed L, we collect the unique codes in the batch as positives L_{pos}, and then randomly sample negative codes L_{neg} from a code pool to form L so that $|L| = |L_{pos}| + |L_{neg}|$. This setup has three advantages. First, it fixes the number of L to stabilize training. Second, it removes duplicated positive codes and allows negative sampling to expand the scope of L, enabling higher sample efficiency. Finally, $|L|$ becomes a hyperparameter to be controlled.

During training, we use a sampler to keep only

one ICD version in each batch, i.e., L is either L^{icd9} or L^{icd10}. These batches of different ICD versions are mixed and shuffled to train the model with standard mini-batch gradient descent.

B.3 Hyperparameter setting

We set the dimensions of the encoders and the projection layers the same $d_{note} = d_{code} = d_{shared}$ without further tuning. We follow the implementation from (Edin et al., 2023) as best practice in setting the hyperparameters, where DUALLAAT has a dimension of 512, one bidirectional layer, and dropout rate of 0.3; and DUALLAAT$_{\text{cnn}}$ has a 256 filters with filter width of 10, and dropout rate of 0.2. All models are trained using a linear scheduler with learning rate of 0.001 and 2000 warmup steps on batches of 32 samples. DUALLAAT is additionally imposed with weight decay of 0.001 to regularize training. The maximum number of tokens in clinical notes is set to 4000, and that for the clinical code descriptions is set to 48.

We pretrain the word embeddings (100 dimensions) based on the three train sets, again following the setup in (Edin et al., 2023). By default, we train the models on full ICD codes, and set the label space size $|L|$ to 8192. We use GRU as the default RNN choice for DUALLAAT$_{\text{rnn}}$, with an alternative DUALLAAT$_{\text{cnn}}$ using CNN.

Abstract

The advent of single-cell RNA sequencing has enabled unprecedented resolution of cell fate decisions and regulatory mechanisms during peri-implantation human embryogenesis, in which accurate cell type annotation is a fundamental prerequisite and the first step for subsequent fate and mechanism inference. Large language models (LLMs) have demonstrated outstanding performance in various fields. However, current studies mostly rely on traditional methods and have not explored the application of LLMs in the field of human embryonic cell annotation. The main reason is the lack of instruction tuning datasets and evaluation benchmarks. In this paper, we proposed EmCellLLM, the first open sourced LLMs that are specialized for human embryonic cell type prediction task based on fine-tuning Qwen3-8B with EmCell4Instruction, the first embryonic cell type prediction instruction dataset. To support LLM instruction tuning, we also build EmCellBench, the first benchmark for evaluating human embryonic cell type prediction ability of LLMs. We compare our models with a variety of LLMs on EmCellBench, where our model outperforms all other open-sourced LLMs as well as DeepSeek.

1 Introduction

Human peri-implantation embryos (approximately days 5–14) represent a critical developmental window in which the embryo transitions from an undifferentiated state to distinct lineages while interacting with the endometrium (Zhai et al., 2022; David et al., 2023). Abnormal development during this period is strongly associated with implantation failure, early pregnancy loss, placental dysfunction, and developmental origins of disease (Norwitz et al., 2001).

Performing single-cell sequencing on the peri-implantation stage and accurately annotating the cells allows the resolution of lineage trajectories, dynamic transitional states, and key regulatory networks at single-cell resolution, thereby reconstructing a comprehensive map of early human development (Ostrer et al., 2006; Latham, 2023; Anger et al., 2025). The challenges of single-cell annotation in peri-implantation human embryos stem from three main factors. (1) Human embryo samples are scarce due to ethical and practical limitations, and each developmental stage contains only a small number of cells, resulting in sparse and noisy datasets. (Petropoulos et al., 2016; Gul and Zhang, 2025). (2) This stage is highly dynamic, with rapid cell fate diversification and continuous, making clear cell-type boundaries and marker-based annotation difficult (Molè et al., 2021). (3) Reference atlases are usually constructed by integrating datasets from multiple sources, but strong batch effects arising from different experimental protocols and sequencing platforms can obscure biological signals and lead to inconsistent or inaccurate annotation (Weatherbee et al., 2023). Accurate annotation is therefore essential for understanding early human development and its applications in reproductive medicine and stem cell modeling.

Traditional embryonic cell annotation relies on known marker genes and manual expert judgment to identify cell types and manually assign cluster labels which is time-consuming, hard to scale, and limited by incomplete marker knowledge and subjective interpretation (Luecken and Theis, 2019; Cheng et al., 2023). Automated cell annotation methods reduce manual curation by leveraging marker-based approaches (e.g., CellMarker 2.0), reference mapping and label transfer methods (e.g., Seurat, SingleR, scmap, TemporalVAE), and supervised or deep learning classifiers (e.g., CellTypist, scTab, scANVI/scVI) (Hu et al., 2023; Stuart et al., 2019; Aran et al., 2019; Kiselev et al., 2018; Liu et al., 2025b; Domínguez Conde et al., 2022; Fischer et al., 2024; Lopez et al., 2018; Xu et al., 2021a). These methods assign cell identities by

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 382–391
July 3-4, 2026 ©2026 Association for Computational Linguistics

mapping query data to reference atlases or learning expression–label relationships. While effective for well-characterized cell types, their performance depends on reference coverage and annotation consistency and is sensitive to batch effects and cross-dataset variation (Cheng et al., 2023; Zhao et al., 2025). In human embryogenesis, where cell states are continuous and reference atlases integrated from multiple sources and incomplete, these methods often fail to resolve rare populations, leading to misannotation or low-confidence predictions.

LLM-based automated cell annotation methods have advanced rapidly in recent years, with the core idea of transforming single-cell transcriptomic data into representations that can be processed by LLMs (Hou and Ji, 2024). For example, the C2S approach converts single-cell gene expression profiles into text sequences by ranking genes in descending order of expression levels, enabling large language models to directly "read" gene expression patterns. While preserving the complexity of single-cell data, this formulation generates biologically meaningful cell representations that can be used for downstream cell type prediction (Levine et al., 2024).

To address the above issues, we construct the first instruction-tuning dataset for embryonic cell type prediction, EmCell4Instruction, to support LLM fine-tuning, which includes a single-cell transcriptome atlas integrating eight human embryo datasets spanning developmental stages from day 3 to day 18.5. Based on this dataset, we propose EmCellLLM, the first open-source LLM for embryonic cell type prediction, which developed by fine-tuning Qwen3-8B on EmCell4Instruction. To systematically evaluate model performance, we further introduce EmCellBench, a benchmark for embryonic cell type annotation. Experimental results on EmCellBench demonstrate that EmCellLLM achieves state-of-the-art performance among open-source LLMs, and we will release both the dataset and the model to the public.

Our main contributions are as follows:

(1) We construct EmCell4Instruction, the first embryonic cell type prediction instruction-tuning dataset.

(2) We develop EmCellLLM, the first open-sourced LLMs that are specialized for the embryonic cell type prediction task.

(3) We build EmCellBench, the first benchmark to evaluate the embryonic cell type prediction ability of LLMs. The results on EmCellBench demonstrate that our model overtakes other open-sourced LLMs.

2 Related work

2.1 Cell Type Annotation

There are few studies semi-automatic or automatic annotate human embryonic cells. Most of them are based on traditional label transfer methods or deep learning methods. Xu et al. (2021b) use Seurat-based integration combined with marker gene curation and reference-guided label transfer for semi-automatic annotation. Zhao et al. (2025) use Seurat-based integration and label transfer to project query datasets onto a reference human embryo atlas for cell type annotation. TemporalVAE annotates cell types by mapping new cells into an atlas-informed latent space and transferring labels from nearest neighbors (Liu et al., 2025b). (Proks et al., 2025) use deep learning models to integrate single-cell RNA-seq data from mouse and human pre-implantation embryos for cross-species cell type annotation and developmental state prediction. However, there is currently no open-sourced LLM specifically designed for the annotation of human embryonic cells.

2.2 Open Sourced Large Language Models

Significant research efforts have focused on developing open-source LLMs as alternatives to closed-source models such as GPT series, with the aim of enabling more accessible research on improving and applying LLMs. Well-known series of open-sourced, general-purpose language models include LLama series (Dubey et al., 2024), DeepSeek series (Liu et al., 2025a), Qwen series (Yang et al., 2025). There are also many open-sourced LLMs for specific domains, including FMDLlama (Liu et al., 2025d) for financial misinformation detection, human cell C2S LLMs (Levine et al., 2024) for somatic cell analysis, ExTES-LLaMA (Zheng et al., 2023) for emotional support chatbots, MeLLaMA for Medical Applications (Xie et al., 2024), and ConspEmoLLM (Liu et al., 2024, 2025c) for conspiracy detection. In this work, we extend the inventory of domain-specific LLMs, by developing the first open-sourced LLM for embryonic cell type annotation.

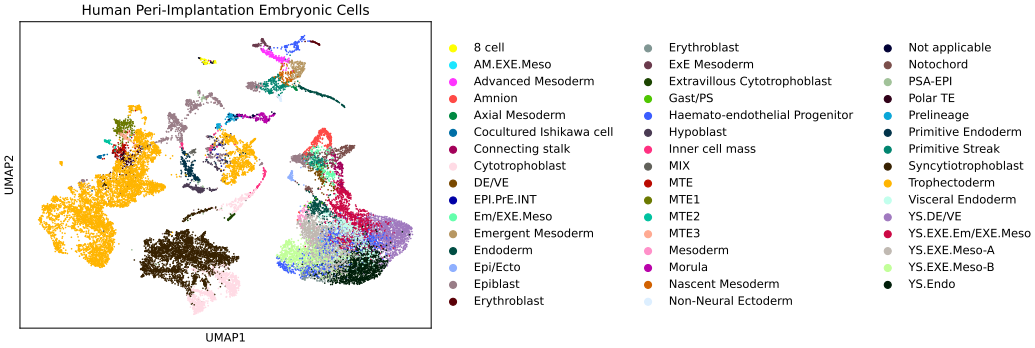

Figure 1: UMAP of Human Peri-Implantation Embryonic Cells

3 Methods

3.1 Task formalization

We approach cell type detection as a generative task, applying a generative model as a foundation. This generative model is an autoregressive language model $P_\phi(y|x)$, parameterized using pre-trained weights ϕ. Each task (t) is represented as a set of context-target pairs: $D_t = (q_i^t, r_i^t)_{i=1,2,...N_t}$, where the context q is a token sequence containing the task description, cell sentence, and query, and r is a further token sequence containing the answer to the query. The model is optimized based on the training dataset, with the aim of maximizing the objective of conditional language modeling to improve prediction and generation performance.

3.2 Construction of instruction tuning dataset

Data	Train	Test
Embryonic cells	19652	4913

Table 1: Dataset statistics. Detailed statistics of each cell type can be found at Table 3.

3.2.1 Raw data

We build our instruction tuning dataset based on a single-cell human embryonic cells transcriptome atlas which integrates 8 human embryo datasets and spanning from embryonic development day 3 to day 18.5 (Liu et al., 2025b). Among them, data from Xiao et al. (2024), Cui et al. (2025) and Tyser et al. (2021) all come from one in vivo human embryo, data from Petropoulos et al. (2016) and Molè et al. (2021) come from 88 and 16 ex vivo embryos, and data from Xiang et al. (2020), Zhou et al. (2019) and Liu et al. (2022) come from 42, 65 and 25 in vitro embryos, individually. Figure 1 presents the UMAP of the datasets.

3.2.2 Construction of the EmCell instruction tuning dataset (EmCell4Instruction) and EmCell benchmark (EmCellBench)

We use the raw dataset without batch correction as the basis for building the instruction dataset. We split the original data into train and test sets. The dataset statistics are presented in Table 1. We construct instruction-tuning data based on the templates in Table 4. One of the 15 instruction templates is randomly selected for each item to enhance diversity. *[num_genes]* represents the top K highly expressed genes used for cell type classification. In this paper, we set K to 200. *[cell_sentence]* is obtained by converting cell expression profiles into natural language sentences in C2S (Levine et al., 2024), which transforms single-cell gene expression data into rank-ordered gene sequences by expression level, enabling LLMs to effectively process transcriptomic information while leveraging standard transformer libraries. LLMs directly output the predicted cell type as their response. Figure 2 presents examples used to fine-tune the LLM.

After constructing the instruction data. We collect the train data as instruction-tuning data (EmCell4Instruction) and test data as the embryonic cells type prediction benchmark (EmCellBench), which are used to fine-tune the LLMs and evaluate the ability of LLMs in the embryonic cells type prediction domain, respectively.

3.3 EmCellLLM

We built EmCellLLM by fine-tuning Qwen3-8b (Yang et al., 2025) using the EmCell4Instruction dataset. The models are trained based on the AdamW optimizer (Loshchilov and Hutter, 2017) for five epochs, using DeepSpeed (Rasley et al., 2020) to reduce memory usage. We set the batch size to 128. The initial learning rate is set to 1e-5 with a warm-up ratio of 0.1. All models are trained

on four NVIDIA L40s GPUs, each with 48GB of memory. We compare with the domain-specific C2S-Pythia-410M (Levine et al., 2024) cell type prediction model, which has been trained on multiple datasets from CellxGene and the Human Cell Atlas for cell type prediction. We further continue training based on EmCell4Instruction as the baseline. Figure 2 provides an overview of instruction tuning of EmCellLLM for the embryonic cell type prediction task.

4 Experiments

4.1 Baseline models

Our extensive evaluation of open-source and proprietary LLMs included the following reasoning-focused models: Qwen3 reasoning variants (8B-R, 14B-R, and 32B-R) (Yang et al., 2025). We also assessed a diverse set of no-reasoning LLMs, DeepSeek-V3.2-Chat (DeepSeek-C) (Liu et al., 2025a), the Qwen3 no-reasoning models (8B, 14B, and 32B), Qwen2.5-72B-Instruct (Qwen72B) (Qwen et al., 2025), Llama-3.1-8B-Instruct, and Llama-3.3-70B-Instruct (Dubey et al., 2024). Additionally, we compare with the domain-specific C2S-Pythia-410M cell type prediction model, which has been trained on multiple datasets from CellxGene and the Human Cell Atlas for cell type prediction. We further continue training based on EmCell4Instruction as the baseline.

4.2 Evaluation methods

We uses metrics such as Accuracy, Precision, Recall, Macro-F1 for embryonic cell type detection task.

4.3 Results

Table 2 presents the results on EmCellBench. From the table, we can see EmCellLLM achieve SOTA results among all other open-sourced LLMs, including DeepSeek. C2S-Pythia-410M follows closely, demonstrating the effectiveness of the instruction-tuning approach. Other open-source general-purpose LLMs perform poorly, likely because they lack domain-specific understanding and require further training to acquire such knowledge. Reasoning models of the same size perform slightly better than their non reasoning counterparts such as the Qwen3 series, indicating that reasoning provides an advantage when handling unseen and complex knowledge tasks. Larger models generally achieve better performance, and among the untrained models, DeepSeek performs the best, suggesting that models with more parameters tend to possess richer knowledge and stronger overall capabilities.

5 Conclusion

In this paper, we propose EmCellLLM, the first LLM for embryonic cell annotation. We also construct an embryonic cell prediction instruction dataset (EmCell4Instruction) and an evaluation benchmark (EmCellBench). We conduct a comprehensive analysis of the performance of EmCellLLM, as well as a variety of LLMs on the EmCellBench benchmark. The results indicate that EmCellBench performs exceptionally well in the embryonic cell annotation task, achieving SOTA compared to the other open-sourced LLMs.

In the future, we aim to augment the EmCell4Instruction and EmCellBench datasets by collecting a more comprehensive single-cell sequencing atlas of human embryonic development, which can help further improve the EmCellLLM and evaluate the embryonic cell annotation ability of LLMs more comprehensively.

Limitations

The potential limitations of our work may be summarized as follows:

Due to restricted computational resources, we only carried out instruction-tuning/evaluation of the task using 8b/14b/32b/70b/72b LLMs. As such, we have not considered the impact of using larger models on the Embryonic cell type prediction task.

Due to the scarcity and limited temporal coverage of in vivo human embryo data, we integrate ex vivo and in vitro datasets to increase diversity and scale, but these remain less ideal than in vivo data due to potential domain shifts and batch effects.

While our dataset covers embryonic stages from day 3 to day 18.5, spanning the peri-implantation period, extending it to include the full developmental trajectory from day 0 to birth would enable the construction of a more comprehensive human embryonic atlas and improve the robustness and generalizability of annotation models.

A Data Details

Table 3 presents the statistics of each cell type. Table 4 shows the instruction templates for EmCell4Instruction and EmCellBench.

B Error Analysis

Figure 3 presents the confusion matrix of EmCell-LLM on EmCellBench. The confusion matrix reveals the misclassification among several cell types. For example, Gast/PS cells are predominantly predicted as Endoderm. This pattern is likely because of the extremely small training sample size (only 4 cells) prevents the model from learning robust class-specific features. Additionally, EPI.PrE.INT cells are dispersed across multiple predicted classes, including Epiblast, Primitive Endoderm, and Trophectoderm. EPI.PrE.INT cells is labeled as a mix cell population in training data which including Epiblast, Primitive Endoderm, and intermediate cells. Therefore, it's it is reasonable to predict Epiblast as Primitive Endoderm. However, as there are only 12 cells used to train model, model did not receive sufficient information for training causing a part of cells were mislabeled as Trophectoderm.

Cell Type	Full Name	Train	Test
8 cell	8-cell stage embryo	50	14

Randomized Controlled Trials as the Gold-Standard for Evaluating LLMs: A Primer for Biomedical NLP Researchers

Vicente Ivan Sanchez Carmona and Shanshan Jiang and Bin Dong
Ricoh Software Research Center (Beijing) Co., Ltd
{Vicente.Carmona, Shanshan.Jiang, Bin.Dong}@cn.ricoh.com

Abstract

Large Language Models (LLMs) are no longer mere laboratory objects of study. LLMs have become everyday tools in society across diverse populations and domains. In clinical contexts, LLMs have already been devised as clinical support applications. However, along with benefits, negative or adverse effects might arise, such as LLMs potentially providing psychologically distressing advice to adolescents when used for mental health support. This raises questions on the benefits of LLMs and calls for real-world evaluations: Are LLMs really helpful and effective for the intended purposes people are using them or will use them for? To answer this type of question we propose to use Randomized Controlled Trials (RCTs). RCTs are considered the most strict experimental design in the fields of Medicine, Psychiatry, Psychology, among others; however, the use of RCTs in the NLP field is almost negligible. In spite of the NLP field being the de facto locus of research on LLMs, other fields, prominently Medicine, are leading the RCT evaluations on LLMs. In this primer paper, we present a concise introduction to the principles of RCTs to guide NLP researchers to design RCT studies for evaluating LLMs.

1 Introduction

In a recent submission to the journal of *Computational Linguistics*, Reiter (2025) argues that the ACL community places a small emphasis on real-world evaluations of NLP applications. While we applaud and echo this argument, we acknowledge that, to the detriment of both the ACL community and the final users, lacking real-world evaluations not only limits our understanding of the efficacy and utility of these applications on those users, it can lead to adverse scenarios, such as users ingesting chemicals with potentially toxic properties as advised by an LLM (Eichenberger et al., 2025).

Critically, evaluation deficits of NLP applications in clinical contexts may potentially open the possibility for negative scenarios such as adolescents being psychologically affected after interactions with LLMs, chatbots, or conversational agents since, according to a survey, it has been estimated that approximately one in eight adolescents and young adults have engaged with online LLMs for mental health advice and to alleviate mental distress (McBain et al., 2025). Although previous works, mainly from clinical fields, have already assessed the impact of generative systems on this outcome, the overall evidence is inconclusive (Feng et al., 2025). In addition, online LLMs are being adopted to other use cases. For example, students of different ages access LLMs for requesting help with homeworks or solving complex problems (Gasaymeh et al., 2025; Wang and Fan, 2025). However, in the NLP field there is scarce scientific evidence on how effective and useful are LLMs to address this type of clinically (and other real-world) relevant cases.

Benchmark evaluations of LLMs such as Big Bench (Srivastava et al., 2023) or MMLU (Hendrycks et al., 2021) may not be representative of real-world, naturalistic scenarios and are not suitable for quantifying the efficacy of LLMs in clinical use cases; these benchmarks assess how well LLMs solve problems, or answer questions, across several domains; but they cannot assess the usefulness of LLMs to allow users to achieve their goals: If an LLM is used as a support counselor by adolescents suffering anxiety, no benchmark evaluation can assess if the LLM was effective in reducing the adolescents' anxiety symptoms.

In this paper, we provide a primer for biomedical NLP researchers on what is considered the *gold-standard* method for evaluating new treatments in clinical disciplines, namely Randomized Controlled Trials (RCTs) (Torgerson and Torgerson, 2008; Kamp et al., 2026; Lilliengren, 2023). RCTs, a type of clinical trial (Hackshaw, 2009), are the gold-standard due to their rigorous experimental

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 392–406
July 3-4, 2026 ©2026 Association for Computational Linguistics

design which allows researchers to control for biases and confounders that threaten to distort the true effect of the target treatment; thus, RCTs can lead to an unbiased and valid conclusion of the efficacy of a treatment (Bishop and Thompson, 2023; Hackshaw, 2009). We firmly believe that adopting RCTs will allow NLP researchers to stringently evaluate LLMs on real-world cases, and also to foster interdisciplinary research with clinical and healthcare communities. We truly hope this primer on RCTs will be widely used as a reference and guide in biomedical NLP in order to keep pushing the scientific progress of the field.

2 Background and Previous Works

2.1 Background

We start our account of RCTs by providing basic terminology. An RCT is an experiment, or study, conducted to provide a valid inference: Is a new treatment useful or effective for some goal when applied to participants? (Jadad and Enkin, 2007) A *treatment* is an intervention, a program, or in general, a mechanism which is hypothesized to provide a benefit to a group of people–the *participants* of the experiment. Similar to experiments in NLP where researchers test if adding a new module to an LLM helps the LLM to improve accuracy scores on a dataset, we seek to evaluate if our proposed treatment–for example an LLM–helps participants to attain a goal, such as distressed adolescents reducing their depression symptoms. In other words, we want to estimate the *effect* of the treatment, i.e. we want to quantify how much our treatment helped participants to attain a goal as measured by an outcome measure, such as a psychological questionnaire. This follows the same spirit as in NLP research where researchers estimate the effect of an improved or new model by comparing its mean accuracy score with that from a baseline model. However, when the evaluation of a treatment includes people, several *biases* and *confounders*–spurious factors–may be present which can distort the treatment effect threatening what is called the *internal validity* of the experiment, i.e. the capacity of a study to provide valid results. To counteract these spurious factors, researchers add another group of participants to the experiment called the *control group*–the equivalent of a baseline model in NLP–which will be compared to the *treatment group* (the group of participants on which we test our treatment), thus rendering valid results of the treatment's efficacy. In the following sections, we will provide the basic scientific principles of RCTs while showing how to avoid biases and confounders to design valid RCTs to evaluate LLMs on real-world scenarios.

2.2 RCTs for Evaluating Treatments in Clinical Disciplines

RCTs are extensively used across clinical disciplines. For example, in Psychiatry, RCTs have been used to evaluate treatments to improve the well-being of autistic children, such as fostering early social engagement (Carruthers et al., 2024), improving their socio-emotional and sleeping patterns (Boone et al., 2022), and developing their interaction and communication skills (Green et al., 2022). In Medicine, researchers have used RCTs to evaluate exercise programs for rehabilitation of people who have suffered a stroke (Moore et al., 2016), to assess interventions for promoting wound healing (Schneider et al., 2025), and to provide reliable evidence of the quality of new methods of cancer surgery (Ceelen and Soreide, 2023) and bone surgery (Jacobsen et al., 2020). Without RCTs assessing these type of critical treatments, end-users could be at risk of facing adverse consequences (Torgerson and Torgerson, 2008).

2.3 RCTs for Evaluating LLMs in Clinical Scenarios

Recently, RCTs have also been used to evaluate the efficacy of LLMs. For example, an LLM-based chatbot demonstrated comparable efficacy to a nurse hotline in reducing anxiety and depression symptoms of participants (Chen et al., 2025). Also, an RCT showed the usefulness of ChatGPT for physicians and medical students to conduct research but not any benefit for clinical decision-making (Weuthen et al., 2025). Furthermore, two RCTs showed that ChatGPT's role as a learning tool enhanced the performance of both dental and medical students for the lectures of clinical operative skills and orthopedics, respectively, compared to control groups (Huang et al., 2025; Gan et al., 2024). Remarkably, all of these evaluations come from medical venues. We strongly advocate for biomedical NLP researchers to be also actively engaged in these evaluations using this paper as a primer guide for learning the scientific principles for designing RCTs for LLMs.

3 Hypothetical Studies: Exemplifying the Evaluation of LLMs

To exemplify some points throughout the paper, we propose two hypothetical studies based on AI-enabled clinical support applications devised by the American Psychological Association (Association, 2025): 1) evaluating the efficacy of a tutor LLM for medical students aimed at improving their training in clinical diagnosis; 2) evaluating the efficacy of a complementary counseling LLM for mental health support aimed at reducing symptoms of distressed adolescents suffering from a psychological condition, such as depression or anxiety.

4 The Perils of Before-and-After Studies

It may seem straightforward to evaluate the efficacy of a new treatment by applying it on a group of participants (a treatment group) and measuring how much they benefited from the treatment based on an outcome measure. This study type is called a *before-and-after* or *pre-test-and-post-test* study (Ho et al., 2018; Sanders, 2019). Let us use our hypothetical example of a tutor LLM: We form one clinical diagnosis class in a school to apply the LLM as a treatment; we hypothesize that the LLM will cause this group to improve their test scores at the end of the study. Then, we assess our hypothesis by first obtaining baseline test scores–the *pre-test* scores–before the LLM is applied; then, we apply the LLM to the group to tutor them on diagnostic problems for a period of time; finally, at the end of the study we re-test the students to obtain their final scores–the *post-test* scores. One way to assess that this group benefited from the tutor LLM is by calculating how much their post-test scores increased with respect to the pre-test scores (Sanders, 2019): If the mean post-test score is higher than the mean pre-test score then we conclude that the LLM had a positive effect by helping the students to achieve such an improvement. However, this conclusion might be plagued with biases and confounders possibly rendering it invalid. These spurious factors could distort the test scores and we cannot disentangle their effects from the LLM's effect in this type of study (Moseley and Pinheiro, 2022). The solution to this problem is using an RCT. Nevertheless, a before-and-after study forms the basis of RCTs and we must learn which biases and confounders we must be cautious of.

4.1 Biases and Confounders

Biases are factors which systematically introduce an error in the form of a deviation to the treatment effect, but cannot be measured in specific units (Ho et al., 2018; Bishop and Thompson, 2023). On the other hand, confounders are measurable variables (unrelated to the treatment) which effect can be conflated with the effect of the treatment (Kingsley and Robertson, 2020) giving us the false impression that the treatment is (or not) useful. In before-and-after studies, confounders can usually be controlled–i.e. their effect can be neutralized; however, effects from biases can only be reduced–only RCTs can neutralize or eliminate them. Below we show the most relevant biases researchers must be aware of before any study is conducted.[1]

Placebo bias Participants volunteering for a new treatment mainly do so due to their willingness to recover from a problematic situation or condition. Evidence in the literature points to this willingness having a psychological effect on the outcomes of the participants regardless of receiving an effective or ineffective treatment; i.e. participants exhibit a placebo effect (Beins and McCarthy, 2018). This effect's magnitude could be so pronounced as to spuriously boost the treatment effect; for example, the adolescents in our hypothetical study may elicit a placebo effect after knowing that they will take part in an experimental group where the supporting counselor is a state-of-the-art LLM; this effect is elicited in response to their high expectation or enthusiasm in the LLM to help them alleviate their depression symptoms, effectively leading to a reduction in these symptoms, as it has been seen before in other cases (Bishop and Thompson, 2023; Torgerson and Torgerson, 2008). We note that the main mechanism of the placebo bias is still not fully understood (Piantadosi, 2017), but in our view, a possible explanation of this bias is that the participants mindset changes in a positive way, due to their high enthusiasm or motivation in receiving a novel treatment, aligning to the direction of the treatment effect; i.e. the participants hold the belief that the treatment will work, and they

[1] Other biases affecting the treatment that can be controlled via RCTs are the *Hawthorne* effect (Torgerson and Torgerson, 2008), the *maturation* bias (Marsden and Torgerson, 2012), the *demand characteristics* bias (Beins and McCarthy, 2018), the *regression to the mean* effect (Smith, 2015), the *history* bias (Marsden and Torgerson, 2012), the *experimenter* bias (Torgerson and Torgerson, 2008), or the *measurement* bias (Creswell and Guetterman, 2018). See Section A.1.

unconsciously exert a positive outcome by taking actions in parallel to the LLM's intervention such as changing daily-life habits or requesting extra-help outside the study, which will have a positive effect on the post-test scores regardless of whether the treatment really worked or not. This bias cannot be controlled in before-and-after studies. The optimal control is via an RCT (Section 6.2).

Test sensitivity or memorization bias Ideally, every participant in a before-and-after study takes two tests, a pre-test and a post-test, to assess their progress; however, this may induce a bias on the participants (Ho et al., 2018). For example, they may become sensitive to the pre-test in the sense of discovering what type of information or problems are used for evaluation; in this way, the participants may actively seek to learn any material aligned to that type of information or problems so as to intentionally improve the post-test evaluation giving the false impression that improvement in performance is due to the LLM when, in fact, it is due to the participants' sensitization and extra-effort (Marsden and Torgerson, 2012). Moreover, if the format or structure of the post-test is highly similar to that from the pre-test, then participants may get a better score just due to being familiarized with the test format or structure (Bishop and Thompson, 2023). This bias not only occurs in educational settings; it can also happen in clinical and psychological studies where participants may receive the same well-being survey or questionnaire as both pre-test and post-test–such as the Patient Health Questionnaire-9 (Yu et al., 2012) developed to assess depressive symptoms–in this case, participants may respond to the post-test questionnaire in a very similar way to how they responded to the pre-test questionnaire due to remembering their previous responses and unconsciously aligning to them (Navarro and Siegel, 2018). The best solution for this bias type is the RCT shown in Section 6.3.

Selection bias Another major threat to the internal validity of before-and-after studies is the problem of a biased sample of participants (Torgerson and Torgerson, 2008). The participants selected to the study may be biased towards a characteristic that could inflate or dilute the effect of the treatment. For example, if the recruitment is open to anyone wishing to take part in it, as is common in several studies, this will lead to one of the most common forms of selection bias: Recruiting people who are particularly enthusiastic to participate in a study mainly because they believe the new treatment can be a great help to their underlying problem or condition. Thus, this enthusiasm is a characteristic that has the potential to spuriously inflate the treatment effect via different mechanisms such as eliciting a placebo bias. In medical or psychological studies, other form of selection bias can take place: Participants willing to take part in a study may exhibit a degraded physical or psychological well-being which, if not profoundly serious, tends to naturally recover after given enough time regardless of receiving or not any treatment (Torgerson and Torgerson, 2008). These are just a few forms of selection bias; depending on the specific research problem many other forms can plunge into the study. RCTs are suited to control this bias.

Confounders effect Characteristics of the participants such as socioeconomic status, age, gender, etc. may have an impact on the post-test scores (Bishop and Thompson, 2023). For example, in our hypothetical study of a tutor LLM, recruiting only students from a high socioeconomic status risks confounding since access to high-cost curricular resources may influence post-test scores, distorting the LLM's effect. Similarly, in our hypothetical study of a counseling LLM, age effects can be confounded with the LLM's effect since younger (or older) participants may tend to recover more easily depending on the target condition. Hence, it is important to consider possible confounders, according to the specific problem, and control them, for example, via variation in the levels of the confounder, such as recruiting participants across varying ages, or via an RCT study.

5 RCTs: The Gold-Standard for Evaluations of LLMs

Since RCTs build on top of before-and-after studies, in this section we elaborate on their basic principles which allow for a strict control of the spurious factors occurring in before-and-after studies (shown in Section 4.1) and on the specific biases RCTs face as well as ways to control them.

5.1 RCTs Can Control Spurious Effects from Before-and-After Studies

The effects of biases and confounders in Section 4.1, which threaten the internal validity[2] of any before-and-after study, can be neutralized by

[2]See Section A.2 for a brief explanation of internal validity.

adding two key elements to this type of study: 1) a control group and 2) the randomized assignment of participants to control and treatment groups, where the treatment group is similar to the group in a before-and-after study; these elements constitute the basic and core structural features of a Randomized Controlled Trial (Creswell and Guetterman, 2018). In the following sections we elaborate on these characteristics.

5.2 Random Assignment of Participants to Groups: Controlling Biases and Confounders

The effects of biases and confounders can be neutralized, or counteracted, via the random allocation of participants to the control and treatment groups (Creswell and Guetterman, 2018). The goal with this action is to have the treatment and control groups nearly identical to each other in all participants characteristics and factors–including confounders and biases–except for the treatment to be evaluated; thus, the only difference between these two groups will be the effect of the treatment allowing us to easily estimate it. Simple randomization is a common method to achieve this as explained below.

Random assignment of participants to treatment and control groups is essential to balance the groups across observable and unobservable characteristics and factors that otherwise can lead to an invalid result. The simplest random method of allocation recommended in the literature is *tossing a coin* (Torgerson and Torgerson, 2008) where for each participant we obtain a computer-generated random binary label ("treatment" or "control"), or alternatively, we generate a random list of numbers, assign participants to numbers, and allocate odd numbers to one group and even numbers to the other. In any scenario, crucially, each participant must have the same chance to be assigned to any group. However, due to chance a confounder may not be fully balanced between control and treatment groups; to purposefully control this confounder we can resort to the method of *matched randomization* (see Section A.3).

5.3 RCTs Can Be Susceptible to Other Biases

RCTs may suffer from particular biases which are important to consider before conducting any study in order to propose any possible solution if required, as we show below (and in Section A.4).

Diffusion of treatment bias This bias, also known as *spillover effect* (Ariel et al., 2021), happens when participants in the treatment group share information of the treatment with participants in the control group in such a way that control participants can follow or adapt this information to their benefit having an effect on the post-test scores and thus threatening the study's validity (Creswell and Guetterman, 2018). A feasible policy to control this bias is to implement a double-blind setup, where neither the participant nor the researcher knows which participant is in which group (Bishop and Thompson, 2023; Friedman et al., 2015), in addition to a non-disclosure agreement where participants are requested to not sharing information from the study other than to relevant parties (such as the participants' parents if the participants are minors).

Resentful demoralization bias When participants assigned to the control group realize that they receive no treatment (or receive a traditional treatment which they believe is not effective), they may develop a feeling of resentment, demotivation, or demoralization which may have one or more consequences (Torgerson and Torgerson, 2008). One possible consequence is that control participants have a lower performance during the study than they usually do in normal days; this will have a negative effect on the post-test scores leading to artificially inflating the treatment effect. Another consequence is that control participants may seek for alternative treatments out of the RCT study; in our hypothetical example, students may seek help from a professor or engage with publicly available LLMs, such as ChatGPT, possibly leading to a spurious boost of their post-test scores. An additional consequence is that participants may quit the experiment due to a high impact of the demoralization or after rationalizing that their participation in the experiment will not lead to any benefit for them. A last possible consequence is that control participants may work harder during the study than they normally do due to their resentment of not being assigned any treatment (Creswell and Guetterman, 2018); this action will lead to inflated post-test scores which will minimize the true treatment effect. The resentful demoralization bias can be ameliorated or resolved either by a) giving a traditional treatment to the control group (such as a human tutor in our example) that can be regarded as an effective treatment (Beins and McCarthy, 2018), b)

reassuring control participants that they will have the same treatment as the treatment group after the experiment is finished (Bishop and Thompson, 2023), or c) replacing the control group with a placebo group (Torgerson and Torgerson, 2008) as we will elaborate on in Section 6.2.

6 Three Recommended RCT Designs to Evaluate LLMs

RCTs' experimental design can be adjusted to specific research questions, problems, and to analyze specific biases and confounders. We selected three main design types that we believe can be useful for biomedical NLP researchers to evaluate the efficacy of LLMs in real-world scenarios, from the basic *treatment vs. control* RCT design to more complex designs that aim to study the effect of relevant biases, namely the placebo bias and the test sensitivity or memorization bias which, we believe, can have a big impact on the outcome measure whenever studying the efficacy of LLMs across several domains, specially in educational and clinical contexts.

6.1 The Basic RCT Design: Treatment vs. Control Groups

A control group is most necessary to counteract the effects of several biases and confounders present in the treatment group via random allocation of the participants to these groups (Section 5.2). This design is the easiest and less costly to implement since only two groups of participants are required, where the suggested number of participants in each group is at least 50 in order to provide a precise estimate of the treatment effect (Navarro and Siegel, 2018). As mentioned before, only the treatment group receives the novel treatment and the control group receives either no-treatment or a traditional treatment (Beins and McCarthy, 2018). However, this design may not render the most precise treatment effect as the control group may not neutralize one possible bias, namely the placebo bias, since it tends to occur on participants who receive a novel treatment as it elicits the participants' high expectations that the treatment will be useful as imagined, overstating the treatment's effect (Piantadosi, 2017). This bias may or may not occur in an RCT; however, there is compelling evidence across fields, particularly Medicine and Psychology (Beins and McCarthy, 2018; Piantadosi, 2017), pointing to its frequent occurrence. To optimally control this bias it is suggested to add a placebo group.

6.2 Controlling the Placebo Bias: The Placebo Group

We introduced the placebo bias in Section 4.1. An optimal way to control this bias is to add a placebo group to the basic RCT design (or alternatively, to replace the control group with a placebo group) (Piantadosi, 2017). This group will receive a placebo[3] instead of a true treatment. The form of the placebo will depend on the form of the treatment under study; crucially, no placebo should provide any real treatment. For example, a placebo counterpart of a clinical diagnostics tutor LLM could be an LLM-based chatbot, in the style of the chatbot Eliza (Weizenbaum, 1966), that provides no support in diagnostics (and crucially, does not generate hallucinations), but responds to queries in a thoughtful-questioning way by asking the students what they think is a possible solution to a clinical problem, or why they think a candidate solution could be a good solution (or not).[4]

By adding the placebo group to our basic RCT design we now have the capability to not only remove the placebo effect from the treatment effect, but also to quantify it (Bishop and Thompson, 2023). More concretely, if we only desire to remove the placebo effect from the treatment effect, then we only need to subtract the mean post-test score of the placebo group from the mean post-test score of the treatment group since these two groups only differ in the treatment provided (novel treatment vs. placebo);[5] however, the placebo effect is mixed with all the other bias effects and we cannot quantify it. If we seek to quantify the placebo effect to develop an understanding of the strength of

[3] In simple and basic terms, a placebo is a mechanism mimicking or emulating a novel treatment, which also elicits high expectations from participants, but has no effect on them.

[4] We remark the potential complexity of proposing and implementing effective placebo counterparts of LLMs due to the inherent necessity of participants to interact with this placebo (e.g. via dialogues): It is difficult to mimic all the form or structure of the treatment without providing any functionality that could become in itself a treatment, while at the same time both not providing any negative effect and not allowing the participants to discover the status of the placebo (specially in long-term studies). For a deeper consideration of this issue and to help identifying an appropriate approach tailored to the needs of a specific study, we suggest previous works in the literature of Education (Hyldgaard, 2020; Adair et al., 1990; Aycock et al., 2018) and Psychology (Blease, 2018; Kirsch et al., 2016; Enck and Zipfel, 2019; Popp and Schneider, 2015; Gaab et al., 2019).

[5] This also removes the effects of all other biases and confounders explained in Section 4.1.

the participants' expectations regarding the efficacy of LLMs in real-world cases, then we simply subtract the mean post-test score of the control group from the mean post-test score of the placebo group–assuming that these two groups only differ in the placebo effect due to the optimal random allocation of participants to the three groups; nonetheless, for a more precise estimation, the recommended method is ANCOVA (Section 7.2).

6.3 The Solomon Design

This RCT design is considered as the ideal design to better quantify and understand the effect of the pre-test on the post-test scores (Solomon, 1949). This, in turn, allows us to tackle the test sensitivity or memorization bias (Section 4.1).

The Solomon design comprises 4 groups; it is a direct extension of the basic RCT study (Section 6.1) to which we add two more groups: Another treatment group receiving the exact same treatment, and another control group receiving either the same traditional treatment or non-treatment. However, these two groups will not receive a pre-test. Let us label our four groups where T_1 and T_2 are the two treatments groups, T_1 receiving a pre-test but not T_2, and C_1 and C_2 are the two control groups where C_1 receives a pre-test but not C_2. In this way, treatment groups only differ in the application of the pre-test, and similarly for control groups.[6] Then, we can estimate the effect of the pre-test on the post-test scores under two scenarios: When the treatment is present and when it is absent. Under the first scenario we compare the mean post-test scores of groups T_1 and T_2; if the mean score of T_1 is significantly larger than that of T_2 then we may ascribe this difference to the pre-test. Similarly, we compare the scores of C_1 and C_2; if there is no difference in this scenario, but there is a difference in the previous scenario, then we can claim that the pre-test affected the post-test not in a direct way but via the treatment (Ariel et al., 2021); for example, students became aware or sensitive of the type of information they must seek from the tutor LLM and thus exploited this sensitization to intentionally perform better on the post-test. Had there been a difference in scores between C_1 and C_2 in a similar magnitude and same direction as that between T_1 and T_2 then we could have claimed that the pre-test affected directly the post-test (possibly via a mechanism from the memorization bias, or due to test practice). This design requires twice as much participants as the basic design (around 200 is recommended (Navarro and Siegel, 2018)); but when the target population is abundant, this is the suggested RCT design to carry out.

[6] We note that assignment of participants to the four groups must be done using a random allocation method where any participant has the same chance to be assigned to any group.

7 Statistical Analysis of RCT Data

To estimate the effect of the treatment we can resort to two simple and popular statistical methods: The difference of means between treatment and control groups or an Analysis of Covariance (ANCOVA). We elaborate on these methods by exemplifying them with the basic RCT design (our account can be easily expanded to more groups).

7.1 The Simplest Method to Estimate the Treatment Effect: Difference of Means

In the basic RCT design, the only difference between treatment and control groups is the treatment effect (Murnane and Willett, 2010);[7] thus, by comparing the mean post-test scores of the two groups we estimate the magnitude of the treatment effect (similarly to how the mean accuracy score of a new NLP model is compared to that from a baseline model). For example, if students in our tutor LLM group obtained a mean post-test score of 8.4 points while the control group mean score was 6.5 points, then the treatment effect was 1.9 points. Alternatively, if we want to estimate the treatment's effect as the mean difference in progress from pre-test to post-test, then we can compare the average change of scores from pre-test to post-test between our two groups (Ariel et al., 2021); i.e., for each group we obtain the change in scores (post-test score − pre-test score) averaged across participants, and compare the two groups' means. (For other details see Section A.5.)

7.2 ANCOVA: Quantifying the Effects of the Treatment and Confounders

ANCOVA is a multivariate linear regression analysis where the dependent variable (post-test scores or change in scores from pre-test to post-test) is determined by a linear combination of independent variables, namely the treatment variable and covariates (i.e. confounders[8]) (Wang et al., 2019); co-

[7] Assuming both an optimal random allocation of participants to both groups and no placebo effect in the treatment group.

[8] Covariates is one name that confounders receive in statistics.

variates such as gender, age, socioeconomic status, etc. may have an effect on the post-test scores, specially when the sample size is small, since due to chance they may not be equally distributed across groups (Torgerson and Torgerson, 2008); moreover, including covariates in an ANCOVA model not only allows us to quantify their effect on the post-test scores, but also allows us to isolate them from the treatment effect (Read et al., 2013); furthermore, we can also estimate the effect of the pre-test on the post-test scores. This specification helps to improve the precision of the treatment effect estimation (Egbewale et al., 2014).

Equation 1 shows ANCOVA's model:

$$y = \mu + \beta_1(x_1) + \beta_2(x_2) + ... + \beta_T(x_T) + \epsilon \quad (1)$$

Variable y represents the dependent variable; term μ is the intercept of the linear model representing the expected score of a control participant when all covariates are set to zero. Coefficients β_i ($i \in \{1, 2, ..., n\}$) are parameters to be estimated and represent the effects of covariates x_i on the dependent variable; if a covariate is continuous, its coefficient represents the mean number of points that will be added to the dependent variable for each unit that the covariate increases; x_T is a binary indicator variable where $x_T = 1$ represents membership to the treatment group and $x_T = 0$ to the control group; thus, β_T is the estimated treatment effect which we interpret as the average number of points that a treatment participant will gain due to receiving the treatment. Interpretation of coefficients of categorical covariates is similar to that of the treatment variable. Finally, ϵ represents the error term.

Let us propose in Equation 2 an ANCOVA model obtained from our hypothetical RCT study testing the efficacy of our diagnostics tutor LLM where the dependent variable represents post-test scores.

$$score = 4 + 0.8(test) + 0.5(SES) + 2(LLM) \quad (2)$$

We include the covariate of socioeconomic status (SES) of students as an indicator variable where $SES = 0$ represents a low-SES student and $SES = 1$ a high-SES student; also, we model the effect of the pre-test score as a continuous variable; the treatment variable is a binary indicator where $LLM = 1$ indicates membership to the treatment group and $LLM = 0$ membership to the control group.

We interpret the model in Equation 2 as follows: The expected post-test score of a control student from low-SES with 0 points on the pre-test is 4 points. The effect of the treatment has a magnitude of 2 points, after adjusting for SES and pre-test; this means that students who have the support of the LLM ($LLM = 1$), compared to those who do not, score on average 2 points more on the post-test. Moreover, the pre-test has an effect on students possibly due to the sensitization or memorization bias depending on the exact form of the pre-test (Section 4.1); we interpret its coefficient as adding, on average, 0.8 points to the post-test score for each point obtained in the pre-test (after adjusting for SES and treatment group). Furthermore, after adjusting for pre-test and treatment group, high-SES students tend to obtain, on average, 0.5 points more on the post-test than low-SES students. (For details of ANCOVA see Section A.6.)

8 Ethical Concerns in RCTs for LLMs

LLMs are a recent technology. The study of their interaction with different user types across clinical domains has just started and significant further research is necessary to thoroughly understand the LLMs' effects; thereby, unexpected results may be obtained in any RCT study. Consequently, we recommend to first carry out RCTs on problems or conditions where the risks of adverse results are low, and avoid critical scenarios such as adolescents with severe depression since any negative side-effect could worsen their initial condition, such as becoming psychologically distressed or even suicidal. Critically, in the event where the LLM treatment were found to be adverse, it would be imperative to both assess the outcomes to decide whether to stop or continue the study and report these negative outcomes (Anderson et al., 2022) to allow the scientific community to ponder the adversities.

Moreover, RCTs are not without any ethical concerns. One common issue is the so-called *compensatory equalization* problem which refers to the unequal situation created under the basic RCT design (Section 6.1) or the placebo RCT design (Section 6.2), where only one group receives a potential benefit (a treatment), while the other group receives no-treatment and thereby no potential so-

lution to their underlying condition or problem (Creswell and Guetterman, 2018). This situation can be solved using either of the first two solutions proposed to control the *resentful demoralization* bias (Section 5.3), namely to give a traditional, helpful treatment to the control group (such as a human teacher or counselor if the novel treatment is an LLM), or to offer the novel treatment to the control (or placebo) group after the experiment has finished.

Another ethical concern in RCTs is the effect of the novel treatment. The usual hypothesis is that the novel treatment will provide a positive and helpful effect on the participants; however, in reality, the treatment effect may be negative or may have adverse secondary effects (Bishop and Thompson, 2023). Hence, it is recommended to continuously observe the participants to spot any sign of negative or adverse reactions in the participants' behaviors, and terminate the study if those reactions are found.

Finally, we strongly emphasize that any RCT study, prior to its deployment, must be reviewed and approved by an ethics committee from a university or an institutional board (Creswell and Guetterman, 2018), and consent must be obtained from all the parties involved in the study including the participants and any parents or legal guardians if required (Moher et al., 2010). Ultimately, participants have the right to drop out of the study at any time, and any action to force the participant to not do so must not be taken. We recommend (Moher et al., 2010) for a next guide on RCTs.

9 Conclusions

Evaluating the efficacy or usefulness of a new medical treatment, educational intervention, or therapy program in Medicine, Psychiatry, among other clinical fields, is done via Randomized Controlled Trials. This strict evaluation has received the nomenclature of evidence-based evaluation in those fields given that RCTs are the experimental method considered pertinent to provide rigorous scientific evidence for the efficacy of a target treatment. As exposed by Reiter (2025), the field of NLP is practically devoid of this type of evaluation for NLP applications. Crucially, we consider RCTs are necessary to assess recent NLP applications such as general-purpose LLMs–and more critically, biomedical or clinical support LLMs–which are no longer laboratory objects but everyday tools, and have shown both positive and negative impacts by helping users with routine tasks or by suggesting the ingestion of chemicals with potentially toxic characteristics, for example. As such, other fields, prominently Medicine, have recently started to evaluate LLMs across tasks and capabilities to provide scientific evidence of their benefit (or not) to specific populations. The NLP field is to take the next step in LLMs evaluations via RCTs as it is the designer and builder of these NLP tools. In this primer paper, we presented the basic principles and statistical methods required for designing Randomized Controlled Trials targeted to assess LLMs' efficacy for real-world cases, helping bio-NLP researchers to take the first step to conduct RCTs.

Limitations

As a primer paper, this work mainly shows content and scope limitations. It lacks advanced methods used in specific problems faced by RCTs such as better random assignment methods of participants to groups or a more comprehensive treatment of the placebo bias, more elaborate or complex RCT designs, recently discovered biases, a wider and more in-depth treatment of ethical concerns in RCTs, or state-of-the-art statistical methods for estimating treatment effects. Nonetheless, we note that advanced methods for each of these issues may be problem- or field-oriented; therefore, by providing a foundational treatment of the design of RCTs, this paper serves as the starting point to discovering advanced methods in specialized literature and to proposing methods tailored for the biomedical NLP field.

Ethical Considerations

We do not claim that this paper is a comprehensive, self-contained, and ultimate guide for designing and conducting RCTs. This is a primer paper that aims to introduce biomedical NLP researchers to the foundational principles of RCTs in order to advance to other specialized guides in other fields, to start the intellectual task of designing and proposing RCTs for evaluating LLMs, and to foster interdisciplinary works with researchers in clinical disciplines. Therefore, we advise the use of this primer paper as an introductory guide–but not the sole resource–for biomedical NLP researchers to start their study in designing RCTs for assessing LLMs while subsequently consulting more advanced texts and research papers.

A Appendix

A.1 Further Biases in Before-and-After Studies

Hawthorne effect Firstly discovered in early work of optimization studies, this bias takes effect on the participants behavior by increasing their effort, workload, or productivity due to their awareness of taking part in a research program and being observed by a researcher (Torgerson and Torgerson, 2008). Thus, part of the results obtained are due to the artificially increased effort of the participants. For example, students in our hypothetical study will work harder than usual when receiving support from the tutor LLM, regardless of their inner motivation, just due to the pressure imposed by the study's monitoring apparatus.

Maturation bias When a treatment is applied over a sustained period of time (usually in the range of months), natural biological or psychological changes can happen to the study participants which may have an effect on the post-test scores (Ho et al., 2018); these changes go under the umbrella terms of *maturation effects* or *temporal effects* (Torgerson and Torgerson, 2008). For example, in our hypothetical study of a counseling LLM, a maturation effect that can bias the effect of the counseling LLM is the natural self-healing of the study participants over time (Bishop and Thompson, 2023); thus, any improvement in their well-being post-test scores could be simply due to this temporal effect rather than due to the support of the LLM.

Demand characteristics bias This type of bias is elicited from the study participants after learning that they will take part in a novel treatment with the goal of improving their skills or solving their underlying problem or condition (Beins and McCarthy, 2018). Participants actively over-engage in the study by increasing their motivation or eagerness which, in turn, may improve their focus and their performance on the study's tasks; for example, students in our hypothetical study may pay more attention to the LLM's outputs than they usually pay to their professors at class, may put more effort and time for out-of-study learning activities, or may ask for extra-help from peers or professors, and so on. This participants' quest to make the treatment effectively work can aid the participants in improving their post-test scores biasing the effect from the LLM alone.

Regression to the mean Some effects occurring in a study may happen only due to chance; these effects are termed *regression to the mean* (Marsden and Torgerson, 2012). For example, in our hypothetical study of the tutor LLM, there is some likelihood that due to chance some of the students will obtain a low pre-test score, and these students will naturally increase their score at post-test time due to their normal intellectual or cognitive capability; consequently, this improvement will be wrongly attributed to the LLM's help; in other words, students who, due to chance, scored particularly high or low at the pre-test will tend to score closer to the group's mean at the post-test (Marsden and Torgerson, 2012; Torgerson and Torgerson, 2008) biasing the effect of the LLM.

History bias There are so-called history events occurring outside the laboratory where the treatment is applied which are not controllable by the researcher. This bias occurs when these events, happening in parallel to the study, affect either the status of the treatment or the participants engagement in the target tasks impacting on the results obtained (Marsden and Torgerson, 2012; Ho et al., 2018). For example, adverse weather leading to temporarily closing the laboratory can directly affect the participants engagement in the study possibly leading to a distortion of the post-test scores and also of the treatment effect.

Experimenter bias In this case, it is the researchers executing the study the ones biasing the participants outcomes (Torgerson and Torgerson, 2008); for example, if researchers firmly believe that the support counseling LLM will be useful for diminishing the symptoms of adolescents suffering anxiety, then these researchers may unconsciously work towards fulfilling their believe by modifying the well-being questionnaires or giving additional support to the participants not planned before the study with the aim of generating outcomes that favor the counseling LLM.

Measurement bias This bias can be present when taking measurements, scoring a test, or when using an incorrect instrument to elaborate the tests (Creswell and Guetterman, 2018), depending on the research problem. For example, if a test (pre-test or post-test) is not correctly designed to measure the intended skill, ability, behavior, or mental/physical state of the participants, then the test will result in an invalid outcome giving a biased result; follow-

ing our hypothetical example of a counseling LLM, if the well-being questionnaire contains ambiguous questions related to the symptoms of the participant, the given answers may not be valid and so may biased the treatment effect.

A.2 Internal Validity of RCTs

The golden goal in any scientific experiment is to obtain valid results (Weisberg, 2010). When we test a new treatment to see its efficacy, we aim to obtain an unbiased relationship between the treatment and the results (post-test scores); i.e. we seek to answer the question: Is the new treatment the real cause of the results obtained? For example, is a counseling LLM really helpful to alleviate the symptoms of a group of adolescents suffering from depression? When answering this question, we expect that the effect obtained on the participants is a true and direct cause from the LLM and not an effect from a bias or a confounder. Hence, to answer this type of question we need an experimental design embodying a necessary characteristic: Internal validity (Beins and McCarthy, 2018), which refers to the capacity of providing valid conclusions, i.e. to neutralize the effects of spurious factors, such as those shown in Section 4.1, that can distort the true treatment effect. Arguably, RCTs' experimental design is one of the study designs with the highest internal validity (West et al., 2008) which is the main reason why RCTs are considered the gold-standard for evaluating new treatments in the fields of Medicine (Torgerson and Torgerson, 2008) and Psychiatry (Spieth et al., 2016), among other fields; and we hope RCTs will become the gold-standard for evaluating LLMs in the NLP field as well.

A.3 Matched Randomization

Using simple randomization we risk that due to chance we may end up with unbalanced groups in one (or more) confounder(s), especially when the sample size is small (30 participants or less (Torgerson and Torgerson, 2008)), which can lead to invalid results. For example, in our tutor LLM study, we hypothesize that socioeconomic status has a significant impact on post-test scores since students in a high socioeconomic status may have access to extra learning resources, such as private lessons or specialized books. Hence, not thoroughly controlling this confounder may give us an inflated (or diluted) treatment effect if students with a high socioeconomic status are mostly allocated to the treatment (or control) group. The method of matched randomization consists of pairing participants with the same level of a confounder and randomly assigning each participant from each pair to treatment and control groups to balance them (Creswell and Guetterman, 2018); this can be extended to more confounders. For example, if we hypothesize that besides socioeconomic status, gender is another confounder, then we create pairs of students across combined levels of these two characteristics: (high, low) $\times$ (female, male); for instance, we match two male, high-socioeconomic-status students, then toss a coin and randomly assign them to treatment and control groups; and similarly for all combinations of levels. Due to its simplicity, matched randomization is a popular method; however, when the number of confounders increases, matching can become restrictive since it may be difficult to find an exact match for a given participant across all levels. In this case, it is recommended to increase the sample size to at least 100 participants and instead implement simple randomization(Torgerson and Torgerson, 2008). Alternatively, we can use a statistical method to control confounders that only requires simple random allocation, as shown in Section 7.2.

A.4 Attrition Bias

There are events that are unforeseeable by the researcher, such as participants dropping out of a study. The primary way how attrition invalidates a study is by inducing selection bias, regardless of participants dropping out from the treatment, control, or both groups, since it breaks the balance of other types of bias and confounders imposed by the random assignment of these participants to the groups (Torgerson and Torgerson, 2008). Attrition occurring in both groups does not guarantee to keep the balance between them since the participants dropping out of one group can have different characteristics from those dropping out of the other group. Moreover, when attrition occurs in one group it is not recommended to remove participants from the other group which have similar observable characteristics since they may not have similar unobservable characteristics. For example, let us suppose that the youngest adolescents in our hypothetical study dropped out of the treatment group because they believed that the counseling LLM was not helpful for reducing their anxiety symptoms; removing the youngest participants from the control group to balance the groups again risks inducing selection bias if dropouts from the treatment group

differ from the youngest control participants in the level of socioeconomic status, or in any other characteristic. To reduce the impact of attrition, it is suggested to implement the policy of Intention-to-Treat (ITT) (Bishop and Thompson, 2023), which advises researchers to keep track of dropouts, with their consent, to obtain their post-test scores since including them in the analysis of results will keep the balance between treatment and control groups imposed by the random allocation. For a deep treatise on ITT we recommend (Torgerson and Torgerson, 2008).

A.5 Details of Estimating the Treatment Effect Via Difference of Means

The estimated treatment effect obtained via the difference of means is free from the effects of bias and confounders; however, it may still have been affected by random variation, i.e. by chance, (Hackshaw, 2009) present in several factors. To account for this randomness we need a statistical test; in this case a common test is the t-test (Murnane and Willett, 2010), which we use to obtain a statistic called the t-statistic (the treatment effect normalized by the variability between the groups), which in turn we use to estimate the p-value which we could interpret as the likelihood that the treatment effect could have been obtained by chance (Hackshaw, 2009). The logic behind the estimation of a p-value is that we compare our t-statistic against a distribution (a t-distribution) of differences between the two group means built under the assumption that, in fact, there is no difference between the two means (i.e. the treatment effect is zero); if our p-value is less than an established threshold then it means that it is unlikely that we would observe such a difference in means under this distribution, so we can claim that this effect seems not to be due to chance (Hossain, 2021). Alternatively, we can estimate a *confidence interval* which is a range of values in which there is certain likelihood that the population treatment effect falls into; if zero is not inside this range, then we can claim that the treatment effect seems to not be due to chance as well (Cumming and Calin-Jageman, 2016). We suggest (Hackshaw, 2009; Hossain, 2021) for an elaboration of this statistical method and (Agresti and Kateri, 2022; Li, 2018) to estimate the t-statistic and its p-value with a statistical software as is commonly done in the literature.

While this is the easiest method to estimate the treatment effect, it has a drawback if our sample size of participants was small: It cannot measure the effects of confounders that may be lurking in the results (due to chance imbalance) which alter the treatment effect. So, unless we have a big sample size of participants and we carefully apply random allocation, and even so, the recommended statistical method for analyzing RCT data is ANCOVA (Van Breukelen, 2006; Vickers, 2005).

A.6 Details of ANCOVA

ANCOVA is one of the predominant statistical methods to analyze RCT data (Tutino et al., 2024) due to 1) its simplicity (Wan, 2021), 2) its flexibility to account for both types of variables (continuous and categorical) which allows us to estimate the treatment effect (a categorical variable) and the covariates' effects (categorical or continuous variables) (Maxwell et al., 2017), and 3) we can also estimate the effect of the pre-test on the post-test scores which results in a more precise estimate of the treatment effect (Egbewale et al., 2014).

The use of ANCOVA assumes some properties such as the linear relationship between dependent and independent variables, the dependent variable being normally distributed, or the variability of the groups being homogeneous; however, ANCOVA has been shown to be robust to departures from such assumptions (Wang et al., 2019).

To evaluate the fit of an ANCOVA model, we can use the mean-squared error: The averaged squared difference between predicted and true post-test scores, or the R^2 metric which estimates how much of the variability in the post-test scores is explained by the treatment and covariates, i.e. it measures the proportional reduction in the difference between predicted and real scores (Agresti and Kateri, 2022). For a deeper treatise on ANCOVA, its evaluation, and its extension to more groups, we suggest (Wang et al., 2019; Maxwell et al., 2017), and (Agresti and Kateri, 2022; Li, 2018) for implementing ANCOVA with a statistical software.

Citation-Aware Continual Pre-Training for Biomedical Language Models

Abstract

The biomedical literature contains rich structured knowledge, including citation links that encode relationships between scientific studies, but such information is typically ignored in standard language model pre-training. We propose a citation-aware continual pre-training method for decoder-only language models that incorporates citation graph information from PubMed into next-token prediction by placing citation-linked abstract pairs within a shared context. We evaluate our method on multiple biomedical QA benchmarks using two model families. Results show that citation-aware continual pre-training achieves higher average accuracy than both the original base models and citation-unaware pre-training across biomedical tasks.

1 Introduction

The biomedical literature constitutes a large and information-rich corpus, with PubMed indexing tens of millions of abstracts (Liang et al., 2021). The citation links among these documents encode a human-curated graph of conceptual relationships. When a researcher cites a prior study, it typically reflects some form of domain relevance, methodological connection, or thematic continuity between the two works. However, this structural information is largely ignored in standard language model pre-training pipelines, which treat each document as an independent sequence drawn uniformly at random.

The encoder-only era demonstrated that citation structure can be a powerful supervision signal. LinkBERT (Yasunaga et al., 2022) placed linked documents into shared BERT (Devlin et al., 2019) contexts and introduced a document relation prediction objective, yielding substantial gains on QA and multi-hop reasoning benchmarks. Its biomedical variant, BioLinkBERT, achieved state-of-the-art results on BLURB (Gu et al., 2021), confirming that awareness of inter-document relationships translates directly into improved clinical language understanding.

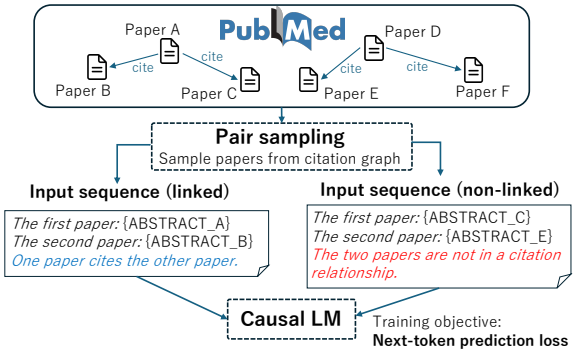

Figure 1: Overview of citation-aware biomedical pre-training. Each training example concatenates two abstracts with a relation text derived from the citation graph, and is trained with next-token prediction.

Decoder-only autoregressive large language models (LLMs), trained with a causal next-token prediction objective, have become the dominant modeling approach, and domain adaptation is typically pursued through continual pre-training on biomedical corpora such as PubMed Central. BioMistral (Labrak et al., 2024), for instance, adapts Mistral-7B with billions of biomedical tokens and reports improvements over general-purpose counterparts on medical QA benchmarks. Despite this progress, continual pre-training for causal LLMs remains document-independent, with each sample consisting of a single abstract or article and lacking structural signals about inter-document relationships. Citation-linked papers typically share concepts, methods, or disease entities, so placing them in a shared context window exposes the model to inter-document concept co-occurrences that no single abstract contains. Prior work has shown that citation structure encodes meaningful semantic relatedness at the document level (Cohan et al., 2020; Ostendorff et al., 2022); our hypothesis is that the same signal,

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 407–412
July 3-4, 2026 ©2026 Association for Computational Linguistics

exposed at pre-training time through next-token prediction, supports integrative biomedical reasoning even when downstream questions are posed in closed-book form over a single passage. This raises a natural, to our knowledge unanswered question: does citation-aware pre-training confer the same benefits in causal LMs as it does for masked LMs?

As illustrated in Figure 1, we propose a method that incorporates information from the PubMed citation graph into next-token prediction pre-training. by constructing training samples that place citation-linked abstract pairs within the same context window together with a natural-language label indicating their relationship. We evaluate our approach on two small language models across multiple biomedical QA benchmarks, with a text-matched baseline that isolates the effect of citation structure from data quantity and lexical content. Our main contributions are as follows:

- We extend citation-aware pre-training from masked LMs to causal LMs by introducing a method that incorporates inter-document relationships while remaining compatible with standard next-token prediction training.
- We show that citation-aware continual pre-training improves accuracy over backbone models and citation-unaware pre-training across biomedical QA benchmarks and model families.

2 Related Work

2.1 Biomedical Pre-trained Language Models

Dedicated pre-training on biomedical corpora has a long history. BioBERT (Lee et al., 2020) first demonstrated that continued pre-training of BERT on PubMed yields substantial gains across named entity recognition, relation extraction, and QA. With the rise of decoder-only architectures, the community has adapted these insights to the autoregressive setting. BioGPT (Luo et al., 2022) is a GPT-2-scale causal LM pre-trained on PubMed abstracts, while PMC-LLaMA (Wu et al., 2024) scales this to 75 billion tokens from PubMed Central and medical textbooks. BioMistral (Labrak et al., 2024) demonstrates that continual pre-training of a strong general-purpose model on PubMed Central is competitive with purpose-built biomedical models at a fraction of the compute cost. More recently, MedGemma (Sellergren et al., 2025) extends the Gemma 3 architecture with medical-domain training on diverse clinical data including radiology images and medical text, while ELAINE-medLLM (Yano et al., 2025) adapts Llama-3-8B for the biomedical domain across English, Japanese, and Chinese through continual pre-training and supervised fine-tuning. Despite the diversity of these approaches, all treat the corpus as a flat collection of documents, ignoring citation relationships. Our work is the first to exploit PubMed's citation graph in causal LM continual pre-training.

2.2 Graph-Aware and Structured Pre-training

Citation links encode semantically meaningful relationships between documents, motivating a line of graph-aware pre-training methods. SPECTER (Cohan et al., 2020) learns document embeddings using citation links as a proxy for semantic similarity in a triplet-loss framework, and SciNCL (Ostendorff et al., 2022) refines this with neighborhood-contrastive learning over citation graphs. LinkBERT (Yasunaga et al., 2022) is most directly related to our work. It augments BERT's masked language modeling objective with a document relation prediction task, classifying whether two text segments are contiguous, randomly paired, or citation-linked. Applied to PubMed, BioLinkBERT achieves state-of-the-art performance on PubMedQA (Jin et al., 2019), BioASQ (Nentidis et al., 2019) and the BLURB (Gu et al., 2021) benchmark. Our work translates the core insight of LinkBERT to the causal LM setting: rather than a classification auxiliary task, we encode document relation information as natural language tokens predicted autoregressively, making our method applicable to any decoder-only architecture without modification.

3 Method

3.1 Overview

We propose a citation-aware continual pre-training approach for decoder-only large language models. Our core idea is to exploit the PubMed citation graph, a large-scale human-curated signal of semantic relatedness between biomedical abstracts, by constructing training samples that place citation-linked document pairs within the same autoregressive context. Unlike LinkBERT (Yasunaga et al., 2022), which requires a separate classification head for document relation prediction, our formulation is architecturally transparent: the citation relation-

ship is expressed as a natural-language sentence appended to each paired-abstract sample and learned via standard next-token prediction.

3.2 Training Sample Construction

Given the PubMed citation graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where each node $v \in \mathcal{V}$ corresponds to an abstract and each directed edge $(u, v) \in \mathcal{E}$ denotes that paper u cites paper v, we construct training samples of the following two forms.

Citation-linked sample:

```
The first paper: {ABSTRACT_A}
The second paper: {ABSTRACT_B}
One paper cites the other paper.
```

Non-linked sample:

```
The first paper: {ABSTRACT_C}
The second paper: {ABSTRACT_D}
The two papers are not in a
citation relationship.
```

For citation-linked pairs, we sample edges $(u, v) \in \mathcal{E}$ and place the abstracts of u and v as ABSTRACT_A and ABSTRACT_B, respectively. The order of the two abstracts within a pair is randomized to prevent the model from exploiting positional cues about citation directionality. For non-linked pairs, we sample two abstracts uniformly at random, verifying that no citation edge exists between them in either direction.

This formulation offers several practical advantages. First, it requires no modification to the model architecture or training objective: existing autoregressive pre-training pipelines can incorporate citation-linked samples without change. Second, the natural-language relation label is semantically informative; the model must associate the content of the two abstracts with the prediction of the concluding token sequence, implicitly encoding inter-document coherence.

3.3 Baseline: Citation-Unaware Pre-training

To isolate the effect of citation structure from the effect of data selection and lexical content, we construct a citation-unaware baseline as follows. Starting from the same set of paired-abstract samples used for our proposed model, we decompose each sample back into its constituent single-document units and shuffle these documents uniformly at random, forming standard single-document training samples. The resulting baseline corpus contains the same abstract texts as the proposed model but without citation-pairing information. The only difference between the two conditions is whether linked pairs are presented in context, enabling a clean ablation of citation structure.

4 Experiments

4.1 Experimental Settings

Backbone Models We apply our continual pre-training procedure to two recent small language models representing different model families.

- **Phi-3.5-mini-instruct** (4B parameters) (Abdin et al., 2024): a decoder-only language model pre-trained on a mixture of web and synthetic data.
- **Llama-3.2-3B-Instruct** (Dubey et al., 2024): an instruction-tuned decoder-only language model from the Llama 3 family.

Training Data Composition We set the total number of tokens after tokenization to approximately 1.8 billion, using the same set of PubMed abstracts for both citation-aware and citation-unaware settings to ensure that any performance differences cannot be attributed to differences in data quantity.

In the citation-aware setting, the total number of training tokens is 1,877,396,650, while in the citation-unaware setting it is 1,807,869,680. Although both settings are constructed from the same set of PubMed abstracts, the citation-aware data contains slightly more tokens because it includes additional textual prefixes such as "One paper cites the other paper." or "The two papers are not in a citation relationship."

While our overall scale is smaller than that of prior biomedical language models such as BioMistral (Labrak et al., 2024), which was trained on 3B tokens, it remains on the same order of magnitude.

Benchmarks We evaluate on five established biomedical QA benchmarks implemented via `lm-evaluation-harness` [1], reporting accuracy on all tasks: **PubMedQA** (Jin et al., 2019), **MedMCQA** (Pal et al., 2022), **MedQA-4opt** (Jin et al., 2020), and medical subsets of **MMLU** (Hendrycks et al., 2021) (*anatomy*, *clinical knowledge*, *college biology*, *college medicine*, *medical genetics*, and

professional medicine). Average accuracy (AVG) across all nine evaluation settings is reported as our primary aggregate metric.

Following prior work (Labrak et al., 2024), we adopt a 3-shot evaluation protocol without task-specific fine-tuning as our default setting. In addition, for the Phi-3.5-4B model, we also report results with supervised fine-tuning on the target tasks to assess the impact of downstream adaptation.

4.2 Results

Tables 1 and 2 present the results of continual pre-training under citation-unaware and citation-aware settings across different model families and evaluation conditions.

Overall, citation-aware pre-training consistently achieves the strongest performance across models and settings. In Table 1, citation-aware models outperform both the original released models (NA) and the citation-unaware baselines (✗) in terms of average accuracy. For instance, on Phi-3.5-4B, citation-aware pre-training improves the average score from 65.0 (NA) and 65.1 (✗) to 65.6, while on Llama-3.2-3B, it increases performance from 68.1 (✗) and 68.9 (NA) to 69.4. These gains are also reflected at the task level, with consistent improvements observed across multiple MMLU subsets and QA benchmarks.

Importantly, citation-unaware continual pre-training does not reliably improve performance over the base models and can even lead to slight degradation in several cases. This suggests that simply continuing pre-training on biomedical text without incorporating structural signals may not be sufficient, and can potentially harm previously acquired capabilities.

Table 2 further examines the effect of supervised fine-tuning (SFT) for Phi-3.5-4B-instruct model. The advantage of citation-aware pre-training not only persists but becomes more pronounced after fine-tuning, achieving the highest average accuracy (70.5) compared to both the base model (69.2) and the citation-unaware variant (68.7). Notably, citation-aware models achieve the best performance in the majority of individual tasks, indicating that the benefits of citation-aware representations transfer effectively to downstream adaptation.

While the magnitude in any single configuration is modest, the gain of citation-aware over citation-unaware pre-training has a consistent positive sign across two backbones, the majority of the nine tasks, and both the zero-shot and SFT regimes. Such cross-setting consistency is more readily explained by a systematic effect of the training signal than by configuration-specific noise.

5 Conclusion

We proposed a citation-aware continual pre-training method for decoder-only language models, incorporating citation graph information from PubMed into standard next-token prediction by placing citation-linked abstract pairs within a shared context. Experiments on biomedical benchmarks show that this approach improves performance over both the backbone models and citation-unaware pre-training across model families.

In future work, we plan to (i) compare citation-aware pre-training against a topically matched non-cited baseline to isolate the contribution of citation structure from topical co-occurrence, (ii) evaluate on multi-hop biomedical benchmarks to test the inter-document mechanism directly, and (iii) extend the approach to full-text articles and finer-grained citation contexts.

Limitations

This work has several limitations. First, our experiments use relatively small models (3B–4B parameters) and a limited pre-training scale (approximately 1.8B tokens), and the gains, while consistent, are modest in absolute terms; scaling to larger models and corpora may yield different outcomes. Second, our citation-unaware baseline draws abstract pairs uniformly at random, so citation-linked pairs differ from it in both citation status and topical similarity. The observed gains may therefore partly reflect co-presentation of topically related documents rather than citation structure per se, and a more controlled comparison would match non-cited pairs on topical similarity (e.g., via MeSH overlap or embedding similarity). Relatedly, all five benchmarks we use are closed-book single-passage QA and do not directly probe inter-document reasoning; multi-hop or cross-document biomedical benchmarks would test the proposed mechanism more directly. Finally, our method operates only on abstract-level data and cannot capture finer-grained relationships expressed at the sentence or passage level, which may limit its ability to fully exploit citation information.

Abstract

While humans can easily produce various types of answers, such as definitions, examples or paraphrases, Large Language Models (LLMs) struggle to provide correct answers to medical questions that require diverse answer formats. In this paper, we introduce TrackList, a fine-grained linguistic and statistical analysis pipeline to investigate the impact of the pretraining data on LLMs answers to diverse linguistic queries. We also propose RefoMed-EN, a medical dataset consisting of 6,170 human-annotated medical terms alongside their corresponding definitions, denominations, exemplifications, explanations, or paraphrases. We investigated whether the high or low frequency of a concept (head or tail knowledge) impacts the language model's performance for answering medical questions. We evaluated the quality of the LLM's output using syntactic and semantic similarity metrics, statistical correlations and embeddings. Results showed that the LLM's answer quality for definition-type questions is the highest, while for the exemplification-type being the lowest. Additionally, we showed that for definition-type medical questions ("What is multiple sclerosis?"), LLMs are prone to paraphrase more for popular medical concepts, and less on more specialized medical knowledge.

1 Introduction

As Large Language Models are becoming widely used in many question-answering tasks and are applied to different fields, such as health and medicine, the need to explain and interpret the generated responses has become crucial. In this paper, we evaluated the most widespread real world use-case of LLMs, which is open question-answering, meaning the model gives a free text answer to a user question (Shailendra et al., 2024). LLMs are most efficient in question-answering tasks that cover popular concepts (head knowledge) (e.g. *cancer*, *asthma*) (Mallen et al., 2023; Li et al., 2024a)

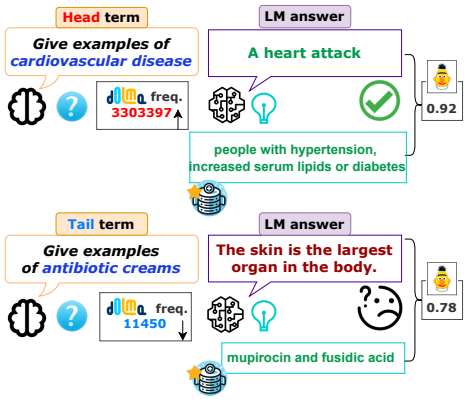

Figure 1: Language Models (LMs) tend to generate more hallucinated *definition-style* outputs even when directly asked to answer an *example-style* query for tail knowledge terms.

and when giving definitions to concepts. However, their performance drops when tested on torso or tail knowledge (*ideatory apraxia* or *erythematous angina*) (Sun et al., 2023; Kandpal et al., 2023) or when tackling complex questions (Daull et al., 2023). Our study analyzed the impact of query linguistic diversity on QA performance in the medical field, focusing on five different types of questions according to pragmatic functions of human communication (definitions, exemplifications, explanations, denominations and paraphrases). We demonstrated that LLMs perform worse when asked to give different types of answers, such as examples, to tail (or rare) medical knowledge (see Figure 1).

As black box and proprietary models such as ChatGPT showed limitations in terms of explainability and reproducibility (Zhao et al., 2024a; Liesenfeld et al., 2023; Ravichandran et al., 2024), more research should be conducted on open-source language models, to foster a deeper understanding of how LLMs process language and knowledge, especially in sensitive fields such as medicine. This study explored non-proprietary and open-source Large Language Models, OLMo (Groen-

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 413–425
July 3-4, 2026 ©2026 Association for Computational Linguistics

eveld et al., 2024) and Pythia (Biderman et al., 2023). We chose these specific language models because they are fully open, thus fostering interpretability and reproducibility. These LLMs were released together with model weights, inference code, training/evaluation code, and pretraining corpus, DOLMA (Soldaini et al., 2024) for OLMo, and The Pile (Gao et al., 2020) for Pythia.

The research questions we investigated are the following: **(RQ1)** *Does the frequency of a medical concept in the pretraining data influence a language model's answer quality?* **(RQ2)** *How does the linguistic diversity and complexity of questions impact the language model ability to give accurate answers?* **(RQ3)** *To what extent are language models paraphrasing the data from their parametric memory for head and tail knowledge?* Based on previously research results on the general domain (Wang et al., 2024), we investigated whether frequent medical terms (head) lead to distributional memorization, and less frequent medical terms (tail) result in lower downstream task performance due to reliance on parametric knowledge.

The contributions of our paper are the following:

1. We proposed a fine-grained analysis and evaluation pipeline, **`TrackList`**, to **`tra`**ce ba**`ck`** query **`li`**nguistic diver**`s`**ity of head and **`t`**ail knowledge in Open Large Language Models. The pipeline is useful for evaluating LLMs' answers on various query types according to word frequency in the pretraining dataset. We will share the `TrackList` code with the NLP community to ensure reproducibility and to foster new research on LLMs' linguistic abilities for open QA tasks[1].

2. We share `RefoMed-EN`, an English dataset of 6,170 human annotated medical terms together with their context, discourse markers, corresponding paraphrases, lexical and pragmatic functions. The dataset is a non-contaminated benchmark extracted from human written texts and it is shared with open license together with the `TrackList` pipeline.

3. We conducted a detailed analysis of the LLMs' performance according to the linguistic complexity of the user question. We showed that LLMs have limited understanding of linguistic differences in queries, as they are more prone to giving definition-style answers to most queries, even when explicitly asked to output an example or a paraphrase for a medical concept.

2 Related Work

Methods such as In-Context Learning (ICL) (Dong et al., 2024), Chain-of-Thought (CoT) prompting (Wu et al., 2023), and Retrieval Augmented Generation systems (RAG) (Lewis et al., 2020) have contributed to further interpret the LLM's generated response, and help mitigate hallucinations (Akbar et al., 2024; Huang et al., 2024; Asai et al., 2023). In the medical domain, LLM's output needs to be correct, therefore methods that combine ICL and RAG showed promising results, such as improving the accuracy of GPT4-Turbo's answers to oncology questions from 62.5 to 83.3% (with ICL) and 79.2% of questions (with RAG) (Iivanainen et al., 2024). Moreover, QA frameworks like Self-BioRAG that answer biomedical questions by reflecting and retrieving relevant documents showed a 7.2% improvement on average over the state-of-the-art open Small Language Models (SLM) of 7b or less (Jeong et al., 2024).

Large medical QA datasets like MedQuAD (Ben Abacha and Demner-Fushman, 2019) and MEDIQA (Abacha et al., 2019) gather different types of medical data, such as treatment, symptoms, definition, susceptibility or prevention. These datasets are built for medical experts, more than for the general public interested in understanding medical concepts (Nguyen et al., 2023). Moreover, these datasets are shared in a XML format, not allowing easy implementation for LLMs prompts. Furthermore, the dataset is divided in more medical than linguistic criteria. Therefore, our dataset, `RefoMed-EN`, is filling a gap in the benchmark leaderbord for query types in the medical field.

While evaluating LLMs answers to open questions is difficult, recent studies showed that human annotation is still needed when the generated answer does not match a gold standard (Kamalloo et al., 2023). In our work, we combine both human evaluation and automatic evaluation through similarity metrics that we further develop in Section 3.2. Determining what is head and tail knowledge is a research question in itself, as recent studies investigated this in detail (Mallen et al., 2023; Li et al., 2024b). We considered that the word frequency in the pretraining data as the popularity metric for our

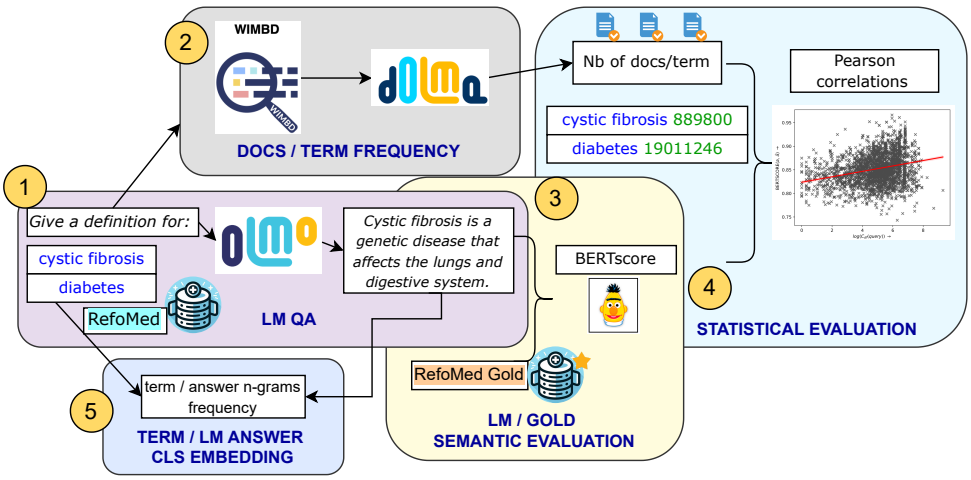

Figure 2: The pipeline of our method represented in five steps. 1) The zero-shot inference QA task using the medical concepts from the RefoMed-EN dataset. The dataset was divided in subdatasets according to the query type (detailed presentation in section 3.4). 2) We obtained the frequency in terms of number of documents for each RefoMed-EN concept. 3) We calculated the BERTScore between the LMs output and the RefoMed-EN gold standard. 4) These two values were used to compute Pearson correlations. 5) We computed a probability metric between the CLS embedding score between the term and the n-grams of the output, and their frequency in the pre-training corpora.

medical dataset.

Recent studies investigated whether LLMs memorize or generalize knowledge by exploring open language models. Wang et al. (2024) introduced the concept of distributional memorization, to measure the correlation between the LLM output probabilities and the frequency of the pretraining data. The authors evaluated the task performance with 3 to 5 n-grams search into The Pile (Gao et al., 2020), the pretraining corpus of the language model Pythia (Biderman et al., 2023). They found that LLMs generalize more in reasoning-intensive tasks, while they memorize more in simpler knowledge-intensive tasks (Wang et al., 2024). We test this hypothesis on the medical domain, to evaluate how knowledge specific concepts impact the LLMs answers' linguistic diversity.

Concurrent work investigated the concept of linguistic diversity in LLMs answers by evaluating their lexical, syntactic and semantic distribution compared to human linguistic richness (Guo et al., 2024). In our study, we investigated the linguistic complexity of LLM queries from a syntactic, semantic and pragmatic perspective, applied to a knowledge intensive task, medical QA. We present our method below.

3 Methodology

We illustrate our method in Figure 2. We conducted our experiments using four fully open language models, OLMo-1b, OLMo-7b, OLMo-7b-instruct, and Pythia-1b. We used the WIMBD tool's API (Elazar et al., 2023) to access the pre-training corpora DOLMA (for OLMo) and the `infini-gram` library (Liu et al., 2024) for The Pile dataset (for Pythia). We counted the number of documents that contain a certain medical concept, thus determining its frequency. We present our detailed rationale in the section below.

3.1 Formulation

We utilized a language model $\mathbb{M}_{\text{LLM}}$ and assumed access to a corpora C with $\mathcal{D}$ documents which was used to train $\mathbb{M}_{\text{LLM}}$. We represented the corpora C by a set of unique words $\{w_1, w_2, w_3, ...w_\infty\}$ present in at least one document $d \in \mathcal{D}$. Each of the document $d \in \mathcal{D}$ can be similarly represented by a subset of C as $\{dw_1, dw_2, dw_3, ...dw_\infty\}$ where dw_i represents word w_i present in document d. We defined a document-frequency count operator over corpora C and denote it by $\mathbf{C}_{df}$. This enabled us to count the number of documents present in corpora C which contained the provided term at least once[2].

We further utilized query-answer (Q, A) pairs where a question denoted by $q \in Q$ can be of different types as mentioned in Table 1 and an reference answer $a \in A$ which is borrowed from the RefoMed-EN dataset. In our experiment setup, we provides as input $q \in Q$ to the language model as

[2]For example, $\mathbf{C}_{df}$("*infection*" | C) outputs 543435456, which implies that there are 543435456 documents in C containing the term *infection* at least once.

follows:

$$\hat{a} = \mathbb{M}_{\text{LLM}}(q) \quad (1)$$

In the above equation, we marked the generated response from the $\mathbb{M}_{\text{LLM}}$ as $\hat{a}$. During evaluation, we considered different evaluation metrics (denoted by Ψ) to calculate the correctness (denoted by E) of the generated response $\hat{a}$ with respect to the gold reference $a \in A$, as follows:

$$E = \Psi(\hat{a}, a) \quad (2)$$

Lower value of E, for example, in case of BERTscore, implies less relevance of generated answer and vice versa.

3.2 Evaluation Metrics

As the goal of our study is to advance the interpretability of open large language models by describing their behavior, we chose simple and easy to interpret metrics that allowed us to analyze the relationship between query term frequency, gold answers, and generated LLM answers.

Tracing back semantic similarity. We calculated the BERTscore (Zhang et al., 2019) between the generated answers and the gold standard from the RefoMed-EN dataset.

Statistical correlation. We computed the Pearson correlation metrics to compare the BERTscore calculated before with the term's frequency in the pretraining corpus.

CLS cosine similarity. We computed the cosine similarity of sentence embeddings to compare the semantic similarity between the medical term and the n-grams of the generated answer.

3.3 Linguistically Annotated Dataset

We constructed RefoMed-EN by automatically translating RefoMed (Buhnila et al., 2024) from its original version in French to English using a licensed DeepL Translator API. RefoMed is a French annotated dataset of 6,170 annotated medical terms with their corresponding reformulations. The dataset is comprised of paraphrases and reformulations semi-automatically extracted from scientific and popularization medical texts and abstracts from the ClassYN (Todirascu et al., 2012) and CLEAR (Grabar and Cardon, 2018) French medical corpora. The dataset required extensive pre-processing as there were formatting and translation inaccuracies from the original annotation. We chose to translate this dataset because there is no freely available benchmark annotated on question types following pragmatic and linguistic theories for the medical field (to the best of our knowledge). More information about the different types of linguistic annotations can be found in Appendix A. The translation of a French dataset assures that there is no benchmark contamination between the pretraining corpora and the test dataset (Sainz et al., 2023; Li et al., 2024c). We share this new non-contaminated benchmark with the NLP community on GitHub. We present below the question types explored in this study.

3.4 Query Linguistic Diversity

Linguistically, the concept of *reformulation* is defined as textual and discursive act performed with a precise objective (Grabar and Eshkol, 2016). *Reformulations* have a well defined pragmatic role by expressing a content in a different semantic or lexical representation, adapted to a specific audience and communicational need, like science popularization or education. The linguistic diversity is correlated to the pragmatic usage of language in humans, such as asking for a definition, an explanation, reformulation or paraphrase of a concept, or to receive examples of a certain concept (Grabar and Eshkol, 2016).

In this work, we analyzed the role of reformulations in the case of medical knowledge popularization for laypeople and patients (Grabar and Eshkol, 2016). We focused on a knowledge intensive question-answering task taking into account the five most common types of questions that require reformulation processes, as shown with examples in Table 1. We present the number of questions by type from the RefoMed-EN dataset in Table 2.

4 Experimental Setup

This section presents the experiments we conducted to evaluate the generated text according to query types and term frequency. Experiments were done on a P100 NVIDIA GPU, for an individual runtime of $\leq$ 15 hours including different steps involved.

4.1 Linguistic Diversity and Frequency for Task Performance

We explored the impact the query linguistic diversity has on the quality of the generated answer. We evaluated the task performance of OLMo and Pythia models in a zero-shot QA setting by conducting several experiments:

Pragmatic function	Definition	Query type	Example
`Definition` (**DEF**)	a difficult or technical concept is defined to ease comprehension	Give a definition for / What is *multiple sclerosis*	Multiple sclerosis (MS) is a *disease of the nervous system of immune origin*
`Exemplification` (**EX**)	the meaning of a concept is illustrated through examples of types and subtypes of entities	Give examples of *heart and vascular diseases*	Heart and vascular diseases include *heart attacks, angina, stroke, sudden cardiovascular death and the need for heart surgery*
`Denomination` (**DEN**)	a concept is reformulated through a semantically similar concept, without simplification	Give another denomination for *motor neuron disease*	Pharmacotherapy for pain management in *amyotrophic lateral sclerosis* (motor neuron disease)
`Paraphrase` (**PARA**)	the concept is reformulated through a easy to understand semantically similar synonym	Give a paraphrase for *hypotension*	Hypotension, i.e. *low blood pressure*, frequently occurs in newborns
`Explanation` (**EXP**)	the concept is explained through its process or a part of it	Give an explanation for *autoimmune diseases*	These are autoimmune diseases that can be explained by the fact that *the organism produces an antibody against the person's skin*

Table 1: Query types, definitions and examples according to pragmatic functions annotated on the RefoMed-EN corpus. These queries were used for prompting in our QA task.

	DEF	EX	DEN	PARA	EXP
`ClassYN EX`	207	305	131	30	32
`CLEAR EX`	919	379	401	73	67
RefM-EN-EX	*1126*	*684*	*532*	*103*	*99*
`ClassYN GP`	862	343	235	285	149
`CLEAR GP`	883	470	175	124	100
RefM-EN-GP	*1745*	*813*	*410*	*409*	*249*
RefM-EN	**2871**	**1497**	**942**	**512**	**348**

Table 2: Distribution of question types across subcorpora in RefoMed-EN (RefM-EN). EX denotes expert-oriented texts; GP targets the general public. Question types are ordered by frequency (left to right).

- We prompted the LLM to give a short answer (**a**) to the given question (**q**) as an expert in the field: `"You are a medical expert. Answer the following question in a short sentence"`. The queries were divided by question type, as shown in Table 2.
- We evaluated the quality of the generated answers for each type of query by computing the BERTscore between the generated answer and the gold standard, the human annotated paraphrases and definitions from RefoMed-EN.
- We calculated the Pearson correlation between the BERTscore and the frequency of the medical concept in the pretraining corpora.

4.2 CLS Embbedings and Co-occurrence Probability

We investigated the link between words embeddings and frequency in the pre-training corpus by conducting the following experiments:

- Firstly, we computed the **cosine similarity score** between the embeddings of the simple or multi-word medical term to be explained or defined, and the embeddings of the answer generated by the language models. We used the sentence-transformer model `paraphrase-MiniLM-L6-v2`. In order to do an exhaustive comparison, we dissolve the reference answer (a) and generated answer ($\hat{a}$) into all possible n-grams. Then, we compute the pairwise cosine similarity between 2, 3, 4 and 5 possible n-gram pairs.
- Secondly, we calculated the **probability score** between two document-frequency counts: 1) the frequency of the query term (q) in the corpora (C), and 2) the frequency of the term together with the generated answer of the language model in the corpus. We used the `WIMBD` tool to found the frequencies in terms of number of documents from DOLMA, and `infini-gram` library for The Pile.

$$P_{cooccurence} = \frac{\mathbf{C}_{df}(q|\hat{a}, C)}{\mathbf{C}_{df}(q|C)} \quad (3)$$

We calculated different n-gram combinations, of 2 to 5 n-gram length. We kept the top-3 semantically meaningful values. We show the statistical correlation between these variables in the Results section.

4.3 Tracing Back Head and Tail Knowledge

We listed the most popular medical concepts (`head`) as those appearing most frequently in the parametric memory, and the least popular medical concepts (`tail`) as having the smallest number of corresponding documents in the parametric memory.

Term	Docfreq	Examples
disease	75724477	A disease is a medical condition that affects the body's structure or function
cancer	50918098	A disease that affects the cells
anxiety	35107524	Anxiety is a feeling of fear and uneasiness
testosterone-inhibiting	115	The answer is testosterone-inhibiting
biological tissue damage	503	Give examples of biological tissue damage
lifelong neurological consequences	29	Explain the neurological consequences of the disease

Table 3: Examples of LLM paraphrasing. Frequent terms are paraphrased, while rare terms yield outputs similar to or derived from pre-training data.

We traced back 100 concepts (1.62%), where 50 were head concepts (0.8%) and 50 percent tail concepts, to the pretraining corpus. We discarded the very long tail concepts from RefoMed-EN that had zero frequency. However, it is important to note that WIMBD's search is exact match based (while ignoring special characters and punctuation), and that some zero frequency terms are very long and technical, such as "disorder of bronchial ventilation" or "SMN1 gene-related proximal spinal muscular atrophy". To compare expert (EX) to general public (GP) datasets, we split this number evenly between RefoMed-EN-EX and RefoMed-EN-GP. We analyzed word level frequencies in 100 documents for each term downloaded with WIMBD.

As the linguistic diversity and the quality of the pretraining data is extremely important in the task performance evaluation, we conducted a close up analysis of corresponding documents in the DOLMA corpus. We analyzed the texts for a selected number of `head` and `tail` concepts.

	DEF	EX	DEN	PARA	EXP
O1b	0.27	0.05	0.15	0.11	0.12
O7b	0.23	0.16	0.15	0.14	0.14

Table 4: Pearson Correlation coefficient (ρ<0.05) between BERTscore(a, $\hat{a}$) and $\texttt{log}(\mathbf{C}_{df}(q))$ for OLMo-1b (O1b) and OLMo-7b (O7b).

5 Results and Analysis

Statistical correlations between medical concepts frequency in the parametric memory. To answer **(RQ1)**, we computed the correlation coefficient between BERTscore and query term frequency C_{df}. We show the Pearson correlations scores coefficient between the BERTscore (a, $\hat{a}$) and log(C_{df} (q)) on the full dataset of 6,170 terms and gold paraphrases, in Table 4. The best scores were obtained with OLMo-1b on the DEF query type (0.27). While the value indicates a weak correlation, it is the highest among all query types, showing some link between the semantic similarity of the generated answer compared to the gold standard answer, and the frequency of the term in DOLMA. Second best scores are on DEN (0.15), while PARA and EXP have lower values (0.11 and 0.12). The lowest correlations score were obtained on the EX query type (0.05). We obtained similar results for the bigger model, OLMo-7b, for DEF (0.23), DEN (0.15), and EXP (0.14). OLMo-7b has better scores for EX (0.16) and PARA (0.14), which shows that the model handles the complex linguistic task better. We conducted a manual analysis of the quality of the generated answers for each query type, described in the next section that tackles **(RQ2)**.

When computed separately by type of corpus, expert medical texts (RefoMed-EN-EX) and general public medical texts (RefoMed-EN-GP), the results are consistent: the scores are the highest for DEF and DEN. However, the scores on RefoMed-EN-EX are better than those on RefoMed-EN-GP for DEF, and even higher than the values on the full dataset (0.31 compared to 0.24 and 0.27). This result might indicate that in the expert texts, the task performance of the model on DEF is slightly more correlated to the term frequency than in the general public (as RefoMed-EN-EX has a higher number of technical terms). On the contrary, for DEN, scores are higher on RefoMed-EN-GP (0.19) than RefoMed-EN-EX (0.11), also surpassing the full dataset score (0.15). We analyzed these results manually in the next section.

QA task performance evaluation on linguistically diverse query types. To investigate **(RQ2)**, we conducted a qualitative analysis of the LLM's linguistic *understanding*. Our hypothesis was that language models show very high performance for the `definition` type query, as this type of query

is very frequent in knowledge intensive QA benchmarks (Rebboud et al., 2024; Zhao et al., 2024b; Fei et al., 2023). The results are consistent with our hypothesis (Table 4). On the flip side, we observed that the LLM does not completely *understand* the concept of `paraphrase` or `explanation`, as it generated definitions as answers instead.

We noticed that OLMo-1b obtained lower task performance with the *denomination* and *exemplification* types of queries, as it tends to either repeat the term (for denomination in particular) or give a definition style answer for both. The difficulties for these two queries come from linguistic and domain specific linguistic traits, such as:

- `Denomination query` - the LLM repeats the term instead of giving another synonym for the medical concept. Furthermore, the presence of highly technical long-tail terms (such as *lymphocytic bacterial meningitis*; freq=2) or opaque abbreviations (e.g. *FixM/F*; freq=11) renders the task even more difficult for the language model.

- `Exemplification query` - the LLM does not output examples (i.e instances, types, subtypes) when the query term is very technical, thus long-tail knowledge: (*Give examples of severe motor disorders* → *The answer is severe motor disorders*). However, the model task performance increases for head knowledge (*1. Give examples of cardiovascular disease* → *a heart attack*; *2. Give examples of psychological factors* → *The answer is: Psychological factors include: fear, anxiety, and depression*).

Tracing back head and tail knowledge in the pretraining corpus. We show the 100 analyzed terms and their document and term frequencies in Table 6 and Table 7 in Appendix B. We looked into a total of 5,074 documents from the DOLMA corpus, where 5,000 contained the `head` words and 74 the `tail` for the tail concepts. For each `head` term out of the 50, we downloaded 100 documents where this term appeared at least once. For `tail` terms, we looked for concepts that appeared in 1 to 3 documents in the DOLMA pretraining corpus.

The `long tail` terms with very low frequency (>4) are very technical long multi-word terms, such as "pseudo-rhizomelic polyarthritis", "lymphocytic bacterial meningitis", "CoA HMG reductase inhibitors". However, there are also very long multi-word terms in RefoMed-EN-GP, like "work-related musculoskeletal disorders of the upper limbs and neck" or "shiftworker sleep disorder" with a term frequency of 2 and 1 in the whole DOLMA corpus.

Criteria	Model	RefM-EN-EX	RefM-EN-GP	RefM-EN
Diversity	OLMo-1b	-0.3904	-0.5710	-0.4403
	Pythia-1b	-0.0206	-0.1202	-0.0317
Scalability	OLMo-7b	-0.3656	-0.3308	-0.3501

Table 5: Pearson correlation between CLS cosine similarity (query term, response-top3-ngrams) and the cooccurence probability of frequency of the term together with its top3 n-grams. (Red color denotes ρ>0.05)

Regarding the `head` terms, the most frequent term from RefoMed-EN is "life", which appears in 497M documents in the pretraining corpus, while the second most frequent is "control" with 230M documents. Other head terms are "conditions" (130M), "function" (114M), "skills" (126M) and typical medical head concepts such as "treatment" (113M), "pain" (80M), "disease" (75M) and "cancer" (50M). While analyzing the term frequency, we noticed that terms such as "control", "function" and "client" appear in code texts, thus irrelevant for your medical knowledge QA task.

CLS n-gram embeddings on head and tail terms. We explored **(RQ3)** in line with Wang et al.'s (2024) hypothesis: LLMs generalize more in reasoning-intensive tasks, and they memorize more in simpler knowledge-intensive task (like in the case of tail knowledge). We conducted the CLS n-gram analysis on the list of 100 head and tail concepts to verify this hypothesis in the medical field. We calculated the CLS embedding BERTscore between the medical term and n-grams of the generated answer of different sizes (2, 3, 4 and 5 n-grams). We kept the top 3 best BERTscore for each term and we compared them with the frequencies of the term together with theses n-grams in the pretraining corpus. We show the distribution of the results in Table 5.

The negative distribution scores (-0.44 on RefoMed-EN for OLMo-1b) indicate that the language model tends to create its own sentences and does not take full information package directly from DOLMA. In terms of scalability, OLMo-7b is inline with OLMo-1b (-0.35 on RefoMed-EN), while another family of models, Pythia-1b, show very low distribution scores. This suggests that the LLM prioritizes semantic paraphrasing (backed by the semantic evidence in relation to the CLS similarity) (see examples in Table 3), and it is less likely to reproduce the same content from the pretraining corpus, as proven by the syntactic evidence related to the n-gram occurrence. OLMo-1b's scores are

better for head terms and for the medical texts destined to general public texts (-0.71). This finding demonstrated that the model used more diverse vocabulary for popular medical knowledge, and less technical medical concepts, particularly in the expert texts (+0.07). For the bigger model, OLMo-7b, we obtained similar values for both types of texts, popular and scientific. This observation supports previous studies on general language (Wang et al., 2024), indicating that the LLM memorizes more on knowledge intensive questions in the medical domain, than for popular medical terms.

6 Discussion

Scaling up small language models does not necessarily improve performance. We replicated our experiments on a bigger model, OLMo-7b. We notice a similar trend for definition-type questions: both OLMo-1b and OLMo-7b exhibit positive Pearson correlation coefficient (p) between BERTscore and query term frequency. Interestingly, we noticed that OLMo-7b shows a weaker trend (p=0.23) compared to OLMo-1b model (p=0.27), this implies that with increase in the size of language models the ability to deal with tail knowledge does not necessarily increase. Regarding overall comparison of CLS n-grams scores on head and tails (see Table 5), we further notice a similar trend between OLMo-1b and OLMo-7b models. However, these findings might change when testing even bigger models.

Human evaluation shows hallucinations are not scale related. We conducted a manual analysis of 400 answers given by the four language models for the 100 head and tail terms dataset (Figure 3). We evaluated task performance and diversity of models by looking directly into the data for hallucinations. Our analysis showed that Pythia-1b is more prone to generating hallucinatory texts (+22%) compared to OLMo-1b, as it was previously shown (Groeneveld et al., 2024). As for bigger models, OLMo-7b is hallucinating more (+19%) than its Instruct version. The best model remains OLMo-1b (33% hallucinated answers), followed by OLMo-7b-Instruct (39%). Pythia-1b demonstrates an opposite trend for definition-type questions (DEF) as compared to OLMo-1b, with a comparatively low Pearson correlation coefficient of -0.103. However, OLMo-7b shows a similar positive trend for paraphrase-type questions (PARA) with a coefficient of 0.14.

We want to stress that results might differ with bigger models. Nevertheless, the main goal of our study was to analyze smaller sized LLMs to support reproducibility and frugality for responsible use of generative AI tools.

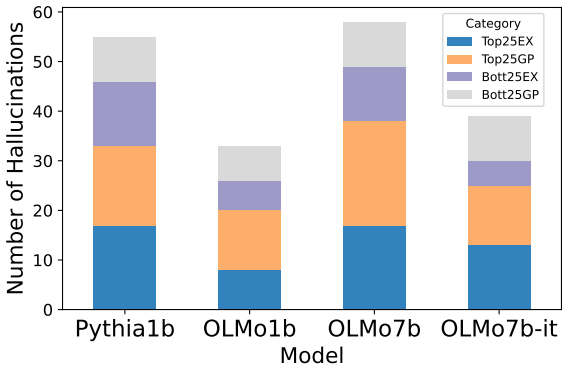

Figure 3: Manual analysis of hallucinations on 100 head and tail terms. Best model is OLMo-1b, with the lowest rate of hallucinations (33%).

More linguistic diversity metrics are needed. BERTscore has limitations in capturing the semantic aspects of query types. For example, for denomination-types queries where the LLM only repeated the medical term in the query, the BERTscore will be very high, but not relevant. In a concurrent study, Guo et al. (2024) compared lexical, syntactic and semantic distribution of LLMs texts to human gold answers. Lee and Lee (2023) proposed a pipeline to identify 220 popular handcrafted linguistic features. However, these features are not thoroughly tested on different writing tasks, and more research needs to be done on their utility for diverse query types.

7 Conclusion

Our study introduced TrackList, a pipeline to analyze, trace back and evaluate a language model's answer to diverse linguistic queries. We showed that frequency of terms in the pretraining corpus impacts performance: LLMs tend to give inaccurate answers for head terms and more accurate answers for tail terms in the medical domain. Furthermore, the LLMs studied were prone to paraphrase more on popular medical terms, and less on very scientific terms. Our linguistic analysis demonstrated that language models tend to give definition-type answers to different queries, even when asked to give examples or paraphrases. This demonstrates that Small Language Models have a limited linguistic *understanding* (or representation) of the best fitted answer for diverse question types.

Our study focused on small size language models to investigate the inner working of LLMs without domain knowledge finetuning, DPO finetuning or RAG systems. Our purpose was to analyze how the pretraining corpus and the word frequency (head and tail) impacts the accuracy of the small LLMs answer to different linguistic types of questions. This research design was motivated by the fact that humans use language models as plug-and-play tools, without any finetuning methods. Future research using these methods might improve vanilla LLM's performance for the QA task. Moreover, LLM-as-a-Judge evaluation could be explored and compared with existing metrics.

Ethical Considerations

The dataset used for this experiments has open license (CC BY-NC 4.0) and can be used for research by the NLP community. The RefoMed-EN dataset contains no personal data or patient data.

Limitations

This work was conducted only on English using only fully open language models, OLMo (Groeneveld et al., 2024) and Pythia (Biderman et al., 2023). Due to computational power limitations, we conducted our analysis on Small Language Models (1b and 7b). Future studies could include more recent models, like OLMo2 (OLMo et al., 2024) and OLMo3 (Olmo et al., 2025), as well as concurrent data tracing tools such as OLMoTrace (Liu et al., 2025). Other open source LLMs give access to their pretraining data, like BLOOM (Workshop et al., 2022) available, but the big size of the dataset makes it difficult to explore.

Moreover, we are aware of this limitation for your semantic similarity evaluation, and we further investigate medical metrics such as MEDCON (Yim et al., 2023), or fact checking metrics and tools like FACTSCORE (Min et al., 2023), FIRE (Xie et al., 2024), or LOKI (Li et al., 2025).

A RefoMed Linguistic Annotation

The RefoMed (Buhnila et al., 2024) has extensive human annotation validated by human inter-annotator agreement. The annotators were French bilingual speakers of different levels of expertise in linguistics and NLP: senior researchers, PhD and master students specialized. The annotation was conducted on the original version in French and then automatically translated in English with DeepL API. The translation was cleaned and verified, however, some translation mistakes might be scattered in the 6,170 lines dataset.

The annotation comprises a linguistic marking of the lexical relations that exists between the reformulation and the medical term. We show a full example of annotation in Table 9. Different relations were tagged, such as *hyperonymy, hyponymy, meronymy and synonymy*. In the case of pragmatic functions that we explored in this study, the annotators marked the reason to the use of the reformulation in the text: to give a *definition, examples, explanations, denominations* (other name for the same concept), and *paraphrases* of the medical term. RefoMed has annotations of discourse markers that help automatically identify reformulations (all pragmatic types presented above) inside the same sentence, such as "is a", "meaning", "also called", "refers to" (Buhnila, 2023).

B Head and Tail Query Terms from RefoMed-EN

We extract the 50 query terms from head and tail of the Dolma corpus. See Table 6 for 25 terms from expert and general public domain and for each term, the table also includes the number of documents (C_{df}) present in the Dolma corpus. Similarly, we extract 50 terms from tail distribution of Dolma corpus (Table 7 and Table 8).

Discharge Instructions are not One Task: Grounding Differences Between Surgical and Non-Surgical Admissions

Abstract

Discharge instructions are patient-facing, safety-critical documents that guide medication use, follow-up care, and recovery after hospitalization. Because they must synthesize information across the clinical record and often include post-discharge guidance not stated verbatim in the EHR, they are a difficult target for clinical text generation. In this work, we study discharge instructions in MIMIC-IV through a grounding-first lens. Using two LLMs, we decompose each discharge instruction into medically relevant statements and verify them against the Electronic Health Record (EHR). We find that discharge instructions for Surgical admissions are much longer, averaging roughly 24–25 statements per admission versus 11–12 in Non-Surgical cases, while supported content remains similar in absolute count. The additional Surgical content is dominated by statements that are not directly stated in the record or require clinically plausible extrapolation. Through this analysis, we advocate for better grounding and completeness evaluations at a fine-grained level, establishing a foundational step toward safer and more reliable discharge-instruction generation.

1 Introduction

Discharge instruction generation has become a central clinical text generation problem because it sits directly at the interface between hospital care and patient self-management. At the center of this progress is the BioNLP 2024 shared task *Discharge Me!*, which established a public benchmark and made discharge documentation a focal task for the community (Xu et al., 2024).

At a high level, discharge instructions should answer three questions for the patient: what happened during this admission, what they should do after leaving the hospital, and what signs should prompt them to seek further medical care. Yet, Discharge instructions can vary a lot depending on the type of admission. Some admissions, especially surgical admissions, contain substantially more content for post-procedural counseling and clinician-authored guidance that may not be directly inferable from the EHR alone. Such cases pose a more challenging grounding problem than shorter, more routine non-surgical admissions. Figure 1 provides an overview of these differences per admission type.

This difference in complexity is easy to overlook in aggregate evaluation. Xu et al. (2024) reports high correctness scores for top-performing systems during clinician review, but it does not provide explicit quantitative detail about the length or procedural complexity of the reviewed discharge instructions. Without that information, it is difficult to know how well current systems handle the most complex and weakly grounded cases. We therefore argue that before asking whether systems can generate discharge instructions well, we should first ask a more foundational question related to grounding and completeness:

> *What content in a discharge instruction can be derived from the EHR?*

In this work, we systematically study the clinician-written discharge instructions themselves to understand which parts of human-written discharge instructions are explicitly grounded in the EHR. Carrying out this study manually is not feasible due to the required number of clinician hours. Hence, we use Large Language Models (LLMs) to analyze the MIMIC-IV dataset, similar to the VeriFact (Chung et al., 2025) framework. For the systematicity, we segment the data into Surgical and Non-Surgical subsets to answer:

1. What are the quantitative differences in the discharge instructions between Surgical and Non-Surgical cases?

2. Which category relies more heavily on ungrounded clinical extrapolation?

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 426–434
July 3-4, 2026 ©2026 Association for Computational Linguistics

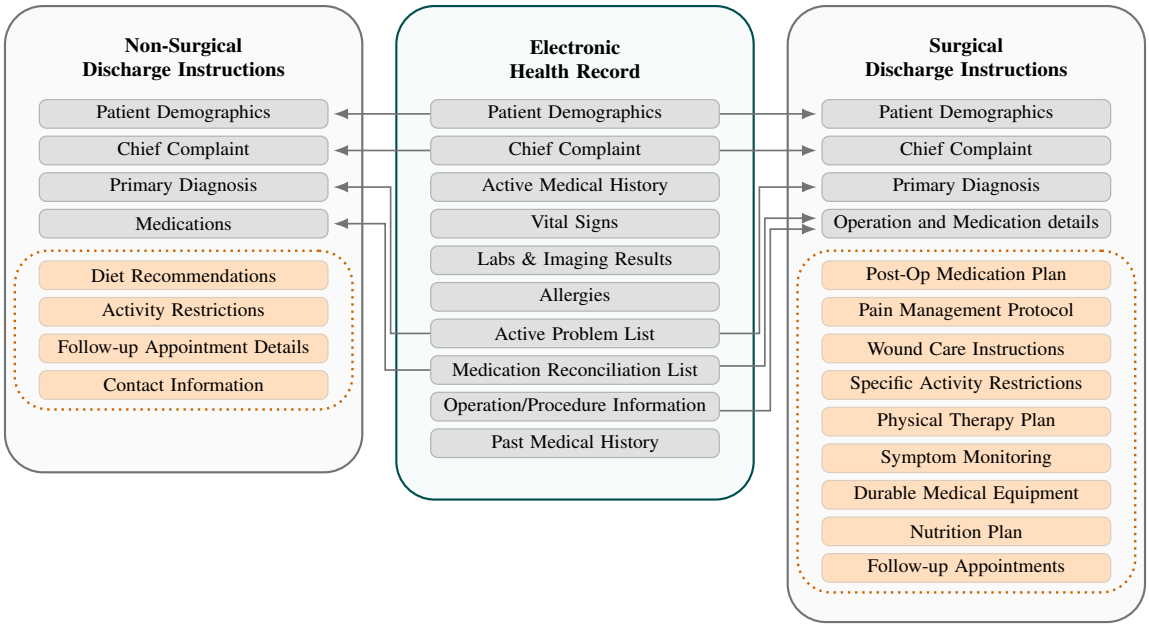

Figure 1: **Surgical and Non-Surgical discharge instructions differ not only in length but in verifiability.** Surgical discharge instructions contain substantially more medically important post-discharge care statements per admission than Non-Surgical instructions. However, the increase is driven primarily by statements that are not directly verifiable from the Electronic Health Records.

Our choice to classify cohorts using the clinical narrative is driven by the structural limitations of structured Electronic Health Record (EHR) fields. While ICD-10 diagnosis codes indicate clinical conditions, they do not reliably confirm whether an operative procedure was performed during a specific hospitalization. Conversely, while procedure codes provide a more direct signal, individual admissions frequently contain multiple overlapping codes. Constructing a rule-based mapping table to resolve these cases would require extensive exception logic and sensitivity analyses to handle procedural ambiguities. Utilizing the text-based clinical narrative allows the pipeline to dynamically determine the primary treatment pathway based on the comprehensive hospital course.

We view this work as a stepping stone toward creating a fine-grained benchmark for evaluating the faithfulness and completeness of generated discharge instructions.

2 Related Work

Early work on discharge-instruction generation used more structured formulations. J Kurisinkel and Chen (2019) cast the task as set-to-ordered-text generation from ICD codes, showing that discharge instructions often require inference rather than direct copying from the input. Re^{3}Writer moves closer to record-grounded generation with a retrieve-reason-refine framework designed to improve faithfulness in patient-instruction generation (Liu et al., 2022). Recent work has focused on benchmarking and improving discharge-section generation at scale. The BioNLP 2024 shared task *Discharge Me!* established a public benchmark for generating *Brief Hospital Course* and *Discharge Instructions*, and representative system papers explored retrieval, section selection, and prompt- or fine-tuning-based methods (Xu et al., 2024; Koontz et al., 2024; Lyu et al., 2024; Damm et al., 2024).

Building upon these evaluations, our work takes a step further by studying the fine-grained clinical differences within the dataset. Specifically, we explore the distinction between Surgical and Non-Surgical admissions to evaluate how grounding complexity varies across different types of patient care.

3 Method

In this section, we provide an overview of each stage of our pipeline for classifying the parts of the discharge instructions.

Dataset. We analyze the *Discharge Me!* Phase II Test split for all our experiments to reduce the risk that the evaluated discharge instructions were seen by the LLMs during instruction tuning or post-training. As the final held-out test split, it provides

a cleaner setting for studying record-grounded verification than training or validation data. This split contains discharge instructions for 10,962 Hospital admissions.

3.1 DI extraction and cleaning

We first transform the discharge notes into a structured sentence-level format using a constrained extraction pipeline. We use GPT-OSS-120B (OpenAI, 2025) to: (i) identify the *Discharge Instructions* section, (ii) copy them verbatim, (iii) remove formatting artifacts and rhetorical questions, (iv) group related clauses into meaningful declarative sentence units, and (v) predict a binary label, SURGICAL or NON-SURGICAL, for the given datapoint. The exact prompts are available in the appendix D.

We observed that GPT-OSS-120B classified most discharge instructions as Non-Surgical. To mitigate this issue, we introduced a secondary deterministic validation step that is applied to the raw clinical narrative. Any admission initially classified as Non-Surgical is re-categorized as Surgical if the discharge instruction documents a major invasive procedure or matches a predefined lexicon of surgical keywords (e.g., *post-op*, *incision*, *sutures*).

3.2 Sentence categorization with LLMs

We then evaluate each discharge-instruction sentence using two LLMs: Llama-3.3-70B-Instruct (Grattafiori et al., 2024) and MediX-R1 (Mullappilly et al., 2026). We choose a Llama-family model because VeriFact uses Llama 3.1 70B for EHR-grounded verification, and we include MediX-R1 as a recent medically specialized LLM with strong reported benchmark performance. Each LLM decomposes a larger declarative sentence unit into smaller medically important statements, retrieves supporting or refuting evidence from the diagnoses and hospital course, and assigns a verification label. The exact prompts are available in the appendix D. We use three main verification labels: *Supported*, *Not Supported*, and *Not Addressed*.

Supported statements are explicitly backed by the clinical context. *Not Supported* statements are addressed by the record but only partially supported, lack sufficient detail, or are inconsistent with it. *Not Addressed* statements are not directly verifiable from the available evidence. We also track two finer subcategories. Within *Not Supported*, we separate *Contradiction* from statements that lack sufficient detail. Within *Not Addressed*, we separate *Clinically Plausible Extrapolation* from statements that are completely not addressed by the record. Since, we are evaluating clinician written summaries, we expect most of the statements to be either *Supported* or *Clinically Plausible Extrapolation*. Other cases may reveal the limitations of LLMs or genuine errors by clinicians while writing Discharge Instructions.

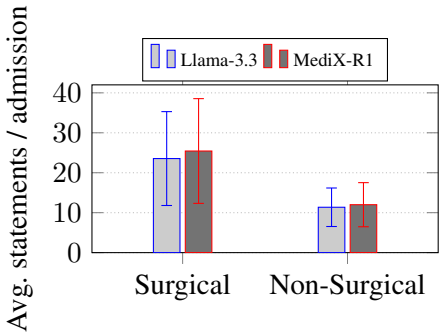

Figure 2: Average number of medically important statements per admission, with standard deviation as error bars. Surgical discharge instructions are approximately twice as long as Non-Surgical ones for both LLMs.

Code. Our code is available on GitHub[1].

4 Results

We start by analyzing the lengths of discharge instructions. We find that the discharge instructions for Surgical admissions are much longer than Non-Surgical admissions. Figure 2 shows that this difference is large and consistent across both LLMs. This suggests that the grounding problem is not uniform across the dataset. Surgical discharge instructions place a substantially larger informational burden on any generation or verification system.

Figure 3 shows that the additional content in Surgical discharge instructions is concentrated in statements that are not directly verifiable from the available EHR evidence (see Table 4 in the Appendix for exact details). For both LLMs, the number of *Supported* statements is similar in Surgical and Non-Surgical admissions, but Surgical admissions contain many more statements in the broad *Not Addressed* category. This means that Surgical discharge instructions are longer not because they contain more directly supported information, but because they include more content that is missing from the diagnoses and Brief Hospital Course or requires inference. Surprisingly, within the *Not*

[1] https://github.com/mayankjobanputra/dischage_differences

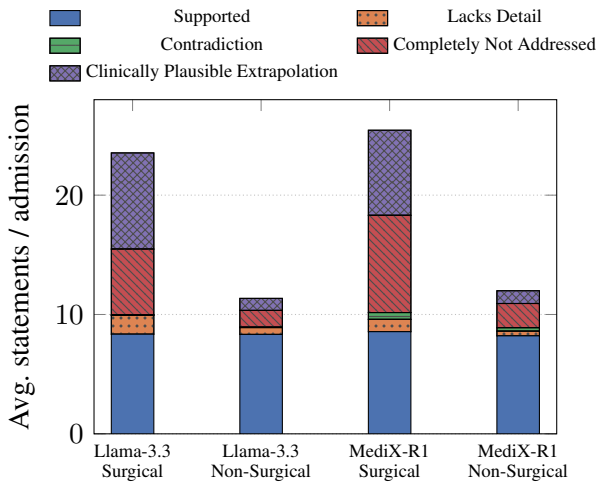

Figure 3: Fine-grained classification results for Surgical and Non-Surgical hospital admissions.

Category	Surgical	Non-Surgical
Broad labels (%)	79.79	85.16
Broad-label κ	0.6366	0.6645
Fine labels (%)	66.02	81.02
Fine-label κ	0.4845	0.5955

Table 1: Agreement stats for Llama-3.3 and MediX-R1. Broad labels refer to *Supported*, *Not Supported*, and *Not Addressed*; fine labels use the full five-label scheme.

Addressed category, the increase in Surgical admissions is distributed across both *Completely Not Addressed* statements and *Clinically Plausible Extrapolation*. We discuss our findings from the manual error analysis on this in Section 5.

Next, we measure the agreement between the two LLMs. Overall, we observe over 82% agreement (κ = 0.66) between Llama-3.3 and MediX-R1 at the broad categories level, but at the fine-grained level, the agreement drops to 72.41% (κ = 0.53). We provide a more detailed analysis in Table 1.

Based on the results from Table 1, we can also see that the agreement is lower in the Surgical admissions than in the Non-Surgical admissions at both the broad level and the fine level. While the agreement levels are encouraging, the overall results need to be verified by clinicians before they can be taken as evidence that the LLM labels are reliable on their own and also to decide which LLM performs better on this classification task.

5 Human Evaluation

To test whether the LLM labels are clinically meaningful, we conducted a targeted human study on 24 admissions comprising 544 medically important statements. The study was stratified across the three subsets introduced above: *Cross-LLM Consensus*, *Cross-LLM Disagreement*, and *Clinically Plausible*. One clinician annotated all 24 admissions. A second clinician independently annotated a subset of 6 admissions, yielding 146 aligned statements for inter-rater agreement analysis.

Comparison	Agreement (%)	κ
Human–human (broad)	96.58	0.8874
Human–human (fine)	91.78	0.7785
Human–Llama-3.3 (broad)	81.2	0.4819
Human–Llama-3.3 (fine)	45.8	0.2333
Human–MediX-R1 (broad)	71.1	0.3591
Human–MediX-R1 (fine)	45.6	0.1918

Table 2: Human-evaluation results. Human–human agreement is computed on the double-annotated subset of 146 aligned statements. Human–Llama-3.3 and Human–MediX-R1 agreements are computed on the 544 aligned statements.

Table 2 shows high human–human agreement at both the broad level ($\kappa = 0.8874$) and the fine level ($\kappa = 0.7785$), indicating that the labeling scheme can be applied consistently by clinicians.

At the broad level, Llama-3.3 agrees with the human annotations more than MediX-R1 (81.2% vs. 71.1%; $\kappa = 0.4819$ vs. 0.3591). At the fine level, however, both LLMs perform similarly poorly (45.8% vs. 45.6%), with low κ values in both cases. This shows that neither LLM is reliable enough to replace clinician judgment, especially for closely related categories such as *Not Addressed* and *Clinically Plausible Extrapolation*.

Error analysis The most frequent error is confusion between *Not Addressed* and *Clinically Plausible Extrapolation*. Routine post-operative advice, such as lifting restrictions, driving restrictions while taking pain medication, light exercise, and incision care, is often labeled *Not Addressed* by the LLMs even when the clinician labels it *Clinically Plausible Extrapolation*.

A second recurring error is over-attribution of support to discharge boilerplate. MediX-R1 more often labels service-level instructions as *Supported*, while the clinician more often labels them *Clinically Plausible Extrapolation* or *Not Addressed*. Examples include refill instructions, brace use, diet advice, and resumption of home medications.

MediX-R1 appears relatively stronger on procedure-specific *Clinically Plausible Extrapolation*, while Llama-3.3 is stronger on explicitly

Supported statements and achieves higher overall agreement with human labels. We provide example statements along with human and LLM labels in Appendix C.

6 Conclusion

In this work, we show that Surgical and Non-Surgical admissions differ substantially in both length and verifiability: Surgical discharge instructions contain many more medically important statements, and the increase is driven mainly by content that is not directly supported by the EHR text. This suggests that future work on discharge-instruction generation should report results separately for Surgical and Non-Surgical cohorts and move toward more fine-grained evaluation of grounding. Our human study shows that LLMs can help surface likely ungrounded content and identify difficult regions of the dataset, but they are not reliable enough for fine-grained labeling without clinician validation. Based on our findings, we suggest that reliable evaluation of generated discharge instructions likely requires resources beyond the EHR alone. A potential future direction can be an agentic setup that can use additional clinical tools, protocols, and knowledge sources in a Biomni-like framework (Huang et al., 2025) adapted to discharge-specific needs.

Limitations

Our study has some limitations. We use only open-weight LLMs in our experiments and do not compare against strong closed-source models, which may differ in both decomposition quality and verification behavior. We also report results from a single run per model, so we do not measure variability across random seeds or decoding configurations. Our analysis is based on a single prompt configuration per stage and does not explore a broader prompt sensitivity study. Different prompt wording, output constraints, or evidence-formatting choices could affect both the extracted statements and the assigned verification labels. More generally, we evaluate only two LLMs, so the observed agreement patterns may not fully characterize the behavior of other model families. We also do not provide any analysis on how exactly this affects recent LLMs's capability of generating factual and clinically complete discharge instructions.

Ethics Statement

This work studies de-identified clinical text and proposes auditing methods for safety-critical patient-facing generation. We emphasize that unsupported or weakly supported discharge instructions can create direct patient harm, and that automated systems should not be deployed without clinician oversight, calibration, and site-specific validation. We also do not use any closed-source LLMs such as GPT-5, Gemini to avoid any kind of sensitive data leakage. All clinicians participating in the study are board-certified physicians and are co-authors of this work.

A Dataset statistics

The summary of corpus and label is provided in Table 3.

B Detailed Distribution Statistics

Table 4 provides the numerical distribution of the broad and fine-grained verification categories for both Llama-3.3 and MediX-R1.

C Qualitative Error Analysis

The examples in Table 5 summarizes the main qualitative error patterns observed in the human evaluation. These errors are grouped by the subset from which they were sampled.

D Prompt Templates

D.1 DI extraction and cleaning: system prompt

```
You are an expert clinical data extraction
↪  assistant. Your primary directive is to
↪  analyze complex hospital admission
↪  records and extract specific,
↪  structured information into a strictly
↪  formatted JSON object.
```

D.2 DI extraction and cleaning: task prompt

```
**TASKS:**

**Task-1: Verbatim Copy of Discharge
↪  Instructions**
- Locate the "Discharge Instructions"
↪  section within the clinical note.
- Extract and copy the entire text of this
↪  section verbatim, exactly as it appears
↪  in the text.

**Task-2: Split and Group into Meaningful
↪  Sentences**
- Take the verbatim discharge instructions
↪  and split them into declarative
↪  sentences.
- Remove all rhetorical or conversational
↪  questions (e.g., "Questions?").
- Remove all splitting markers or visual
↪  separators like "========" or "****".
- **IMPORTANT:** You must group sentences
↪  that talk about the exact same topic or
↪  refer to each other into a single
↪  string item.
  - *Example of Grouping:* If the text says:
  ↪  "We have also prescribed a nebulizer
  ↪  machine that you can use at home. We
  ↪  only recommend using this if you are
  ↪  too short of breath to use your
  ↪  albuterol inhaler effectively."
    *Do NOT split this. Output it as a
    ↪  single array item:* ["We have also
    ↪  prescribed a nebulizer machine that
    ↪  you can use at home. We only
    ↪  recommend using this if you are too
    ↪  short of breath to use your
    ↪  albuterol inhaler effectively."]

**Task-3: Identify the Treatment Service
↪  Type**
```

D.3 Sentence categorization: system prompt

```
You are an expert attending physician and clinical auditor. Your task is to verify the factual accuracy of hospital discharge instructions against the patient's ground-truth clinical record.
```

D.4 Sentence categorization: evaluation prompt

```
**TASKS:**

**Task-1: Atomic Extraction**
- For each sentence in the "TARGET SENTENCES TO EVALUATE" list, break it down into independent, verifiable atomic claims.
- Example: "Take 5mg of Lisinopril daily and follow up in 2 weeks." -> Claim 1: "Take 5mg of Lisinopril daily.", Claim 2: "Follow up in 2 weeks."

**Task-2: Evidence Retrieval and Reasoning**
- Search the provided CLINICAL CONTEXT for evidence that supports or refutes each atomic claim.
- Extract the direct quotes from the context (`evidence_quoted`). Write "None" if the claim is not addressed.
- Explain your clinical logic step-by-step (`thought_process`) *before* assigning a verdict.
- **CRITICAL JSON RULE:** Do NOT use double quotes (") inside your `thought_process`, `atomic_claim`, or `evidence_quoted` fields. If you must quote something from the text, use single quotes ('). Unescaped double quotes will corrupt the JSON object.

**Task-3: Verdict Classification**
- Classify each atomic claim into exactly one of the following categories (`verdict`):
  - `Supported`: The claim is explicitly backed by the context.
  - `Clinically Plausible Extrapolation`: The claim isn't explicitly written, but is standard, safe medical practice based on the diagnoses (e.g., advising a heart failure patient to limit salt).
  - `Contradiction`: The claim directly conflicts with the context (e.g., wrong medication, wrong dosage, wrong follow-up timeline).
  - `Not Addressed`: The claim cannot be verified or safely extrapolated from the context.
  - `Not Supported`: If the claim is addressed and not fully supported by the reference context. This includes cases where the text is only partially supported by the reference context.
```

```
**REQUIRED JSON OUTPUT FORMAT:**
{
  "evaluations": [
    {
      "original_sentence": "<The full target
      ↪  sentence being evaluated>",
      "atomic_evaluations": [
        {
          "atomic_claim": "<The extracted
          ↪  atomic claim>",
          "thought_process": "<Your
          ↪  step-by-step reasoning>",
          "evidence_quoted": "<Direct quote
          ↪  from context or 'None'>",
         "verdict": "<Supported | Clinically
          ↪  Plausible Extrapolation |
          ↪  Contradiction | Not Addressed
          ↪  | Not Supported>"
        }
      ]
    }
  ]
}

**CLINICAL CONTEXT:**
--- Diagnoses ---
{{ diagnoses_text }}

--- Hospital Course ---
{{ hospital_course_text }}

**TARGET SENTENCES TO EVALUATE:**
{{ sentences_json_list }}

Return the result strictly as a structured
↪  JSON object matching the requested
↪  schema.

Abstract

Prion diseases are rare, rapidly progressive, and fatal neurodegenerative disorders that remain difficult to diagnose, particularly in their early stages because of nonspecific clinical presentations. However, to our knowledge, there is no publicly available prion-disease-focused dataset designed to capture a broad range of clinically relevant entities from the biomedical literature. We introduce **PrionNER**, a manually annotated named entity recognition dataset for prion disease clinical information in PubMed abstracts. The current release comprises 317 abstracts, 2,943 sentences, and 6,955 text-bound entity annotations spanning 15 coarse-grained and 31 fine-grained clinically oriented entity types covering diseases, symptoms, diagnostics, findings, anatomy, treatments, and temporal and statistical evidence. Inter-annotator agreement reaches 81.78 exact-match F1, indicating strong annotation consistency. We benchmark supervised BERT baselines, W2NER, and zero-shot extractors on PrionNER. W2NER is the strongest supervised model, and Gemma-4-31B is the strongest zero-shot model, but the benchmark remains challenging, especially for structurally complex mentions and fine-grained clinically adjacent label distinctions. PrionNER provides a clinically grounded benchmark for prion-disease information extraction and supports research on rare-disease biomedical NLP under low-resource, fine-grained, and non-flat extraction conditions. The dataset, annotation guidelines, and evaluation scripts are available at https://github.com/daotuanan/PrionNER/.

1 Introduction

Prion diseases are rapidly progressive, fatal neurodegenerative disorders caused by the misfolding and accumulation of pathological prion protein (Prusiner, 1998). They remain untreatable while carrying a severe risk of iatrogenic transmission (Centers for Disease Control and Prevention, 2026). Early diagnosis is difficult because these diseases are rare and therefore unfamiliar to many general physicians, while their initial symptoms are often vague and overlap with other psychiatric and neurological conditions (Geschwind, 2015). By the time the disease reaches a clearly recognizable stage, it is often already terminal, limiting opportunities for intervention and increasing the risk of inadvertent spread during routine medical procedures (Vallabh et al., 2020). Consequently, recent research efforts have emphasized earlier diagnosis both to reduce transmission risk and to identify patient cohorts for future therapeutic trials (Inada Shimamura and Satoh, 2025). To achieve this, consolidating scattered clinical knowledge into a unified, foundational dataset is essential.

Named entity recognition (NER) has substantially advanced clinical data extraction by structuring key concepts from biomedical text, including diseases, symptoms, diagnostic tests, and biomarkers (Lee et al., 2020; Gu et al., 2021). This progress is supported by widely used biomedical and clinical corpora such as NCBI Disease (Dogan et al., 2014), BC5CDR (Li et al., 2016), CRAFT (Bada et al., 2012), MedMentions (Mohan and Li, 2019), i2b2/VA (Uzuner et al., 2011), and ShARe/CLEF (Pradhan et al., 2013). However, most existing resources target broad biomedical domains, disease mentions, or general classifications rather than the clinically rich diagnostic evidence needed for rare-disease recognition in biomedical literature. Rare-disease-oriented datasets also focus more narrowly on disease, symptom, sign, or phenotype extraction than on the broader diagnostic schema needed for prion disease (Martínez-deMiguel et al., 2022; Groza et al., 2015; Shyr et al.,

*These authors contributed equally to this work.

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 435–463
July 3-4, 2026 ©2026 Association for Computational Linguistics

2024). As a result, there is still no publicly available prion-focused NER benchmark that captures the heterogeneous evidence clinicians rely on when distinguishing prion disease and its subtypes from related conditions. To address this gap, we introduce **PrionNER**, a manually annotated dataset for named entity recognition in prion disease clinical narratives derived from PubMed abstracts.

PrionNER contains 317 abstracts with 15 coarse-grained and 31 fine-grained entity types, and its pre-adjudication double-annotated test split reaches 81.78 entity-level exact agreement F1. We evaluate PrionNER using both supervised biomedical encoders and zero-shot extraction models. Among supervised models, W2NER is strongest in both coarse-grained and fine-grained `flat-ner`, reaching 81.86 F1 and 80.46 F1, respectively. Gemma-4-31B is the strongest zero-shot model in `flat-ner`, reaching 71.41 coarse-grained F1 and 68.41 fine-grained F1. However, `non-flat-ner` remains difficult for all models, with the best F1 scores of W2NER (supervised) reaching 13.48 in coarse evaluation and 13.70 in fine evaluation. These results show that PrionNER is learnable but still challenging: performance consistently drops from coarse-grained to fine-grained prediction, and the remaining difficulty reflects a long-tailed label distribution, clinically adjacent type distinctions, and nested or discontinuous mentions.

This work provides a foundation for prion-disease information extraction and clinically oriented biomedical NLP. More broadly, PrionNER illustrates a general challenge in rare-disease biomedical NLP: clinically useful extraction often depends on modeling heterogeneous evidence types, fine-grained diagnostic distinctions, and non-flat mention structures. In this sense, the dataset is relevant beyond prion disease itself and can serve as a compact case study for building clinically grounded resources in other specialized biomedical subdomains.

2 Related Work

In the biomedical literature, JNLPBA (Collier et al., 2004), NCBI Disease Corpus (Dogan et al., 2014), BC5CDR (Li et al., 2016), CRAFT (Bada et al., 2012), and MedMentions (Mohan and Li, 2019) provide benchmark resources for entity recognition, normalization, and concept annotation in MEDLINE or PubMed texts. In the clinical domain, i2b2/VA (Uzuner et al., 2011), ShARe/CLEF (Pradhan et al., 2013), and MedDec (Elgaar et al., 2024) provide corpora from patient reports, clinical notes, and discharge summaries that focus on clinically meaningful entities or decision spans such as problems, tests, treatments, disorder mentions, and medical decisions.

Resources closest to our setting are mainly rare-disease or phenotype-oriented. The HPO corpora (Groza et al., 2015) target phenotype concept recognition and normalization, while RareDis (Martínez-deMiguel et al., 2022) extends this line with annotations for diseases, rare diseases, symptoms, signs, and anaphoric mentions. However, based on our preliminary inspection of the released RareDis annotations, prion-disease coverage remains limited, and these datasets do not provide the broader clinically oriented schema needed for prion-disease information extraction. More broadly, prior resources reflect different tradeoffs in domain breadth and label granularity: corpora such as NCBI Disease and BC5CDR emphasize wider biomedical coverage with a small number of target categories (Dogan et al., 2014; Li et al., 2016), whereas our goal is richer evidence coverage within a single specialized domain.

For prion disease specifically, PDDB (Gehlenborg et al., 2009) is a structured transcriptomic resource rather than a text annotation benchmark. To our knowledge, no publicly available dataset currently targets prion-disease named entity recognition in the biomedical literature with a broad clinically oriented annotation schema. PrionNER fills this gap by providing a manually annotated dataset for prion disease clinical narratives in PubMed abstracts. We next describe how the corpus was collected, filtered, and annotated.

3 Dataset Construction

3.1 Data Sources

We constructed the corpus from PubMed abstracts retrieved with a keyword-based Boolean query over the title and abstract fields; the full query is provided in Appendix Section A.1. The query combined general and subtype-specific prion disease terms, including *Prion Diseases*, *Creutzfeldt-Jakob Disease*, *CJD*, *sporadic CJD*, *familial/genetic CJD*, *variant CJD*, *iatrogenic CJD*, *Kuru*, *Gerstmann-Straussler-Scheinker*, and *Fatal Familial Insomnia* (*FFI*), with clinically oriented terms such as *diagnosis*, *clinical*, *symptoms*, *case*, *progression*, and *treatment*. To bias retrieval toward human clinical

Dataset	Domain	Task	Text Source	Entity Coverage	Size
JNLPBA (Collier et al., 2004)	Biomedical	NER	MEDLINE abstracts	Protein, DNA, RNA, cell line, cell type	2,404 abstracts
I2B2/VA 2010 (Uzuner et al., 2011)	Clinical	NER + RE	Patient reports	Problems, tests, treatments, assertions	871 reports
CRAFT (Bada et al., 2012)	Biomedical	Concept Ann.	Full-text articles	Ontology-linked biomedical concepts	97 articles
SHARE/CLEF (Pradhan et al., 2013)	Clinical	NER + Norm.	Clinical reports	Disorder mentions	300 reports

BC5CDR (Li et al., 2016)	Biomedical	NER + RE	PubMed abstracts	Chemicals, diseases, chemical-disease links	1,500 abstracts
MEDMENTIONS (Mohan and Li, 2019)	Biomedical	Concept Ann.	PubMed abstracts	UMLS-linked biomedical concepts	4,392 abstracts
RAREDIS (Martínez-deMiguel et al., 2022)	Rare disease	NER + RE	Rare-disease texts	Disease, rare disease, symptom, sign, anaphor	1,041 texts
PrionNER (ours)	Prion disease	NER	PubMed abstracts	15 coarse / 31 fine clinically relevant types	317 abstracts

Table 1: Comparison of PrionNER with representative prior datasets and related resources.

narratives, we excluded terms commonly associated with animal or basic-science studies, including *mice*, *mouse*, *rat*, *animal*, *cell*, *protein*, and *in vitro*. The PubMed query returned 3,414 abstracts, and 3,138 remained after basic preprocessing, including removal of records with empty abstracts.

A pilot manual screening of approximately 500 abstracts by two annotators showed that the retrieved set still contained many off-target papers unrelated to clinical prion disease narratives. Common exclusion cases included basic science, animal or other non-human research, non-clinical analyses such as economic or purely epidemiological studies, and papers in which prion disease was not the main focus. Based on this pilot review, we defined an operational criterion for *related* abstracts and used GPT-5.4 (OpenAI, 2026), prompted as described in Appendix Section A, to screen the 3,138 preprocessed abstracts and reduce manual review workload. Under this criterion, abstracts were retained if they primarily concerned human prion disease in a clinical context, including diagnosis, symptoms, disease progression, or treatment. Across the full 3,138-abstract pool, GPT-5.4 predicted 1,304 abstracts as related and 1,834 as unrelated. We then manually reviewed abstracts from the screened pool together with the pilot-screened set to confirm relevance and remove duplicates. In total, we manually reviewed 1,383 abstracts, including 868 abstracts rated as related by GPT-5.4. Within this set, 772 abstracts were labeled related and 611 were labeled not related by human review. The GPT-5.4 model achieved 90.60 accuracy and 97.80 recall for the related class; it missed only 17 relevant abstracts but incorrectly marked 113 irrelevant abstracts as related, indicating a high-recall but over-inclusive screening strategy. This bias was appropriate for corpus construction because missing clinically relevant rare-disease abstracts would have been more costly than forwarding some extra candidates to manual review. Although we initially intended to annotate all 772 eligible abstracts, practical time constraints limited the current release to 317 annotated abstracts. We therefore treat the present release as a high-quality first benchmark for this specialized domain rather than an exhaustive survey of all eligible prion-disease abstracts. Appendix Section A also provides the relevance-filter audit.

3.2 Entity Schema

We designed the schema to capture clinically meaningful evidence needed for prion-disease diagnostic reasoning and future knowledge graph construction. It was developed through pilot annotation and iteratively revised after joint review of 20 shared annotated abstracts by two medical doctors with experience in neurological diseases together with one coordinator, so that the labels remained clinically meaningful while also remaining coherent from an NLP annotation perspective. Because the dataset is intended to support future clinical decision-support work for prion disease diagnosis, the schema reflects the evidence integration a clinician uses when evaluating a suspected case. Compared with earlier biomedical and rare-disease corpora, which often focus on narrower mention types such as diseases, chemicals, phenotypes, symptoms, signs, or anaphora, our schema is broader because prion diagnosis depends on combining multiple kinds of

diagnostic evidence (Dogan et al., 2014; Li et al., 2016; Groza et al., 2015; Martínez-deMiguel et al., 2022). To reflect this workflow, we organize the schema into three groups: *Case Input*, *Case Diagnosis*, and *Clinical Course and Context*. *Case Input* captures the information available at a patient's presentation, including `Age`, `Symptom`, `Test_name`, `Sequences`, `Anatomic_location`, and `Findings`. *Case Diagnosis* captures the interpretation of those inputs, including disease names, subtype labels (`Generic_Prion`, `Sporadic_Prion`, `Familial_Prion`, `Acquired_Prion`), and alternative conditions considered during evaluation (`Differential_Diagnosis`). *Clinical Course and Context* captures clinically relevant supporting information, including `Treatment`, `Complication`, `Time`, and `Stats`. This broad-entity, focused-domain design differs from prior related datasets such as RareDis, which do not combine the same breadth of clinically oriented entities within a single prion-focused annotation schema (Martínez-deMiguel et al., 2022). We include these categories selectively because of their direct clinical relevance and their potential to support diagnosis in realistic settings. The schema comprises **15** coarse-grained types and **31** fine-grained entity types, and annotation was performed at the mention level using minimal span selection. Table 2 provides a short schema summary for the main text, and Appendix Table 8 provides full definitions with representative examples.

3.3 Annotation Workflow and Quality Control

Pilot annotation. Annotation began with a pilot phase of 20 PubMed abstracts. During this stage, two annotators independently labeled entity mentions in order to identify ambiguities in span boundaries, type assignment, and difficult clinical expressions. Disagreements were reviewed jointly, and these pilot annotations were used to establish the initial annotation guidelines before large-scale annotation. To preserve anonymity, we refer to the two annotators as *Annotator 1* and *Annotator 2*.

Training annotation and guideline refinement. Using the pilot guidelines, the remaining training abstracts were annotated individually, with 151 abstracts annotated by *Annotator 1* and 96 abstracts annotated by *Annotator 2*. During this stage, the guidelines were iteratively refined to address recurring ambiguities and improve consistency across the corpus.

Double annotation, agreement measurement, and final test-set selection. After the training-stage guideline refinement, an additional 70 abstracts were independently annotated by both annotators. Inter-annotator agreement was computed on these independent annotations before any disagreement resolution. Only after agreement measurement did the annotators jointly adjudicate disagreements in this 70-abstract subset to produce a single finalized annotation layer containing 787 sentences and 1,806 text-bound entity annotations. We designated this double-annotated and adjudicated subset as the test split because it is the highest-confidence evaluation subset in the corpus: both annotators labeled these abstracts independently, agreement was measured on the pre-adjudication annotations, and disagreements were then resolved to create the final released test annotations. The clarified adjudication decisions were then propagated back to the training annotations to ensure consistency with the final guideline version, and the final dataset was validated for annotation integrity, including span correctness, label consistency, and the absence of duplicate or conflicting entity annotations.

4 Dataset Statistics

4.1 Corpus Overview

Overall, PrionNER contains 317 abstracts, 2,943 sentences, and 6,955 text-bound entity annotations across the training and test splits. The dataset covers 15 coarse-grained and 31 fine-grained entity types spanning diagnostically relevant clinical evidence in prion disease literature. The training split contains 247 abstracts, and the finalized test split contains 70 abstracts. As described in Section 3.3, the released test split reflects a single merged annotation layer derived from the adjudicated 70-abstract double-annotated subset. To support reproducibility, Appendix Section A, Appendix Section B, and Appendix Sections A.4–A.5 document the PubMed search query, the abstract-screening prompt, the annotation guidelines, and the model settings used in this work. The dataset annotations, annotation guidelines, and evaluation scripts are publicly available at `https://github.com/daotuanan/PrionNER/`.

Coarse-grained Type	Fine-grained Types	Definition Summary
Case Input (Willis, 2006)		
Age	Age	Age or age-at-onset expressions.
Symptom	Symptom	Symptoms, signs, and other explicit clinical manifestations.
Test_name	Imaging_test, Electrophysio_test, Blood_biomarker_test, Genetic_test, Molecular_assay, Autopsy	Diagnostic procedures, assays, and examination types.
Sequences	Imaging_sequence	Imaging acquisition or sequence terms.
Anatomic_location	Anatomic_location	Anatomical sites linked to findings or symptoms.
Findings	Imaging_finding, Autopsy_finding	Radiologic and pathological findings.
Case Diagnosis (Washington State Department of Health, 2022)		
Generic_Prion	Generic_Prion	Prion disease mentions without explicit subtype specification.
Sporadic_Prion	sCJD, sFI, VPSPr	Sporadic prion disease subtypes.
Familial_Prion	fCJD, GSS, FFI	Familial or inherited prion disease subtypes.
Acquired_Prion	vCJD, iCJD, Kuru	Acquired prion disease subtypes.
Differential_Diagnosis	Differential_Diagnosis	Non-prion diseases considered in differential diagnosis.
Clinical Course and Context (Thabane et al., 2013; Willis, 2006; Murad et al., 2023)		
Treatment	Treatment	Therapies, medications, and care strategies.
Complication	Complication	Secondary conditions or end-stage outcomes.
Time	Duration, Time_point	Temporal spans and specific time anchors.
Stats	Sensitivity, Specificity, Prevalence, Incidence	Diagnostic and epidemiological quantitative measures.

Table 2: Short summary of the PrionNER entity schema. Full type definitions and representative examples are provided in Appendix Table 8.

Split	Abstracts	Sentences	Entities
Train	247	2,156	5,149
Test	70	787	1,806
Total	317	2,943	6,955

Table 3: Corpus-level statistics of PrionNER.

Entity Type	Train n	Train %	Test n	Test %
Most Frequent				
Symptom	791	16.99	248	15.03

Incidence	6	0.13	4	0.24
Sensitivity	0	0.00	4	0.24
Specificity	0	0.00	4	0.24

Table 4: Selected most frequent and least frequent observed schema-defined fine-grained entity types in the train and test splits. The full split-wise fine-grained distribution is provided in Appendix Table 18.

4.2 Inter-Annotator Agreement

Inter-annotator agreement. We report agreement on the pre-adjudication independent annotations of the 70-abstract double-annotated subset described in Section 3.3. Agreement is assessed using three complementary symmetric measures: entity-level exact agreement F1, Jaccard similarity, and Cohen's kappa. Entity-level exact agreement F1 summarizes span-level agreement under the standard NER criterion that an entity counts as correct only when both annotators select the same text span and assign the same entity type (Tjong Kim Sang and De Meulder, 2003). Jaccard similarity measures the overlap between the two annotators' entity sets as the size of the intersection relative to the union (Jaccard, 1901). Cohen's kappa is computed on token-level BIO labels to quantify agreement while correcting for agreement expected by chance (Cohen, 1960). On the 70 compared documents, entity-level exact agreement is 81.78 F1. Jaccard similarity over the annotated entity sets is 69.17, and token-level BIO Cohen's kappa is 81.05. Together, these metrics provide complementary views of annotation consistency at both the span and token levels, and Appendix Table 17 provides the full per-label agreement breakdown.

4.3 Label Distribution and Structural Complexity

Tables 3 and 4 show that PrionNER covers a broad range of diagnostically relevant evidence while remaining strongly long-tailed. The most frequent fine-grained labels are *Symptom*, *Generic_Prion*, and *Anatomic_location*, whereas several clinically meaningful types remain rare. The adjudicated test set also retains structurally complex mentions, including 34 discontinuous entities, 80 nested pairs, and 2 overlapping pairs. Figure 1 gives representative examples of these discontinuous, nested, and overlapping annotations from the test set. Full split-wise label counts and structural statistics are provided in Appendix Section C. With the corpus characteristics established, we next describe the experimental setup used to benchmark the dataset.

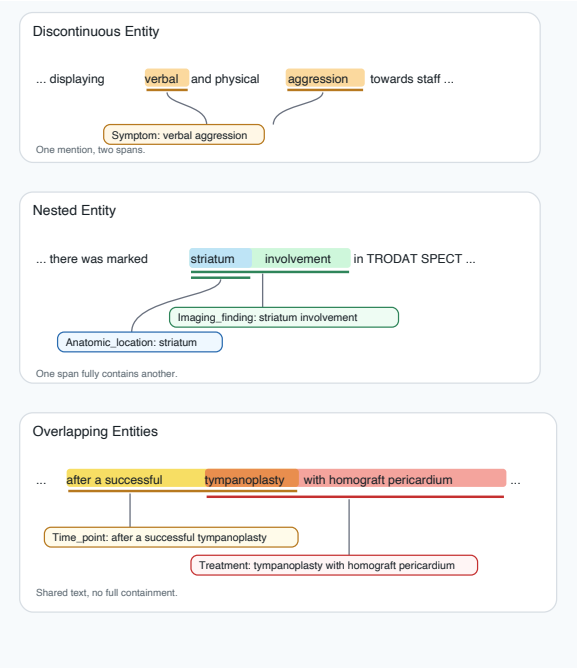

Figure 1: Representative discontinuous, nested, and overlapping entity annotations from the test set.

5 Experiments

5.1 Experimental Settings

We formulate PrionNER as a sequence-labeling task over schema-defined entity mentions. For supervised models, this sequence-labeling setup is implemented with standard BIO tagging, where each entity type is paired with `B-` and `I-` prefixes together with the outside label `O` (e.g., `B-Symptom`, `I-Symptom`, `O`). Models are trained on the training split and evaluated on the test set, with corpus statistics summarized in Table 3. Because the corpus is relatively small and highly long-tailed, we do not introduce a separate development split, as doing so would further reduce training coverage for already sparse labels. Instead, we use fixed model configurations applied uniformly within each model family, and no hyperparameters are selected based on test-set performance. We evaluate the corpus under two structural settings. In the `flat-ner` setting, both training and evaluation are restricted to the flat-compatible portion of the corpus, so only contiguous, non-overlapping gold entities are included. In the `non-flat-ner` setting, evaluation is restricted to the structurally complex portion of the corpus, so the gold annotations include only nested, discontinuous, and overlapping entities. We evaluate the dataset under two label-granularity settings. In the *fine-grained* setting, models are trained and evaluated using the 31 schema-defined entity types. In the *coarse-grained* setting, models are trained and evaluated separately using the 15 coarse-grained categories. This coarse setting is implemented as a separate task rather than by collapsing fine-grained predictions at evaluation time. We report entity-level precision, recall, and F1-score using exact span-and-label matching. Our primary metric is micro-averaged F1 on the test set, and we report it for both coarse-grained and fine-grained settings. The search query and screening prompt are documented in Appendix Section A, and model configurations are documented in Appendix Sections A.4 and A.5, so that the dataset construction and evaluation pipeline can be reproduced more directly.

5.2 Models

5.2.1 Supervised Models

We evaluate supervised baselines fine-tuned on the PrionNER training data. These include BioBERT (Lee et al., 2020), ClinicalBERT (Alsentzer et al., 2019), and PubMedBERT (Gu et al., 2021), which are widely used pretrained encoders for biomedical and clinical text mining, together with W2NER (Li et al., 2022) as an additional structured supervised baseline. We include W2NER because it is a supervised model that can also handle the `non-flat-ner` setting, allowing a supervised comparison beyond standard BIO-style flat tagging. For W2NER, we use PubMedBERT embeddings as the underlying biomedical text representation. The encoder baselines are implemented as BIO-based token classification systems and trained under the same data and model-selection protocol. The BERT baselines operate only in the standard `flat-ner` setting, whereas W2NER is additionally evaluated in the `non-flat-ner` setting. Detailed checkpoints and training hyperparameters are described in Appendix Section A.4.

5.2.2 Zero-shot Models

We additionally evaluate extraction performance using model families that do not require task-specific supervised fine-tuning on PrionNER. These models include OpenAI GPT-5.4 (OpenAI, 2026), Gemma 4 models (Team et al., 2024), the GLiNER2 variants GLiNER2-short and GLiNER2-def (Zaratiana et al., 2025), and GLiNER-BioMed (Yazdani et al., 2025). Because these systems typically return entity strings rather than reliable character offsets, their outputs require a determinis-

GLiNER2-short	2.07	2.22	2.14	2.90	2.96	2.93

Table 6: `non-flat-ner` results on PrionNER under coarse-grained and fine-grained label spaces. This setting includes only nested, discontinuous, and overlapping entities. Best scores are bolded separately within the supervised/structured and zero-shot sections.

tic span-alignment step before exact-match evaluation. For GLiNER2, we consider two input modes: GLiNER2-short, which provides only entity type names, and GLiNER2-def, which provides entity type names together with their definitions. GLiNER-BioMed is evaluated only in the *short* setting. In our current GLiNER-based pipeline, non-flat behavior can be represented for nested and overlapping entities through multiple contiguous spans, but the model does not support explicit discontinuous multi-span entity objects. We also explored additional small local biomedical LLMs, including `Llama3-OpenBioLLM-8B` and `BioMistral-7B`, but found them unreliable for strict exact-span extraction in this pipeline. This setting allows us to assess how well general or biomedical zero-shot extractors transfer to rare-disease clinical literature without supervised adaptation. Detailed model checkpoints, prompting, and inference settings are described in Appendix Section A.5.

5.3 Main Results

Tables 5 and 6 report the main results under coarse-grained and fine-grained label spaces in the `flat-ner` and `non-flat-ner` settings. All models are evaluated in `flat-ner`, whereas `non-flat-ner` is reported only for W2NER and the zero-shot models because the BERT baselines operate only in the standard flat setting. This design keeps discontinuous and other structurally complex gold annotations in the benchmark rather than discarding them.

In the `flat-ner` setting, W2NER is the strongest supervised model in both label spaces, reaching 81.86 F1 in the coarse-grained setting and 80.46 F1 in the fine-grained setting. Among the zero-shot systems, Gemma-4-31B performs best, with 71.41 coarse-grained F1 and 68.41 fine-grained F1.

A notable pattern in `flat-ner` is the relatively high precision of the strongest zero-shot models under the span-recovery pipeline described in Appendix Section A.5. Gemma-4-31B reaches 78.33 precision in the coarse-grained setting and 80.14 precision in the fine-grained setting, suggesting that the schema is semantically coherent enough for strong zero-shot label assignment from definitions and task instructions alone, even though recall remains well below the supervised baselines. Appendix Sections A.5 and D.3 further suggest that the strongest zero-shot model is limited more by omission than by label precision: Gemma-4-31B remains close to PubMedBERT in entity-only precision while trailing much more clearly in recall.

In the `non-flat-ner` setting, performance drops sharply for all models, but W2NER remains clearly stronger than the zero-shot systems, reaching 13.48 coarse-grained F1 with 12.40 precision and 14.81 recall, and 13.70 fine-grained F1 with 12.74 precision and 14.81 recall. Among the zero-shot systems, the best coarse-grained `non-flat-ner` score is 7.75 for Gemma-4-26B, while the best fine-grained score is 6.55 for Gemma-4-31B. GPT-5.4 is second among these models in the fine-grained `non-flat-ner` setting with 5.84 F1 and remains competitive in the coarse-grained setting, but it does not lead there. Within the GLiNER family, coarse-grained `non-flat-ner` performance improves slightly relative to fine-grained evaluation, but the GLiNER variants remain clearly behind the

top LLMs, and GLiNER-BioMed fails to recover any non-flat entities in this setting.

Overall, fine-grained prediction is generally harder than coarse-grained prediction, confirming that finer label distinctions remain substantially harder, especially once structurally complex mentions are retained in evaluation. Appendix Figure 2 further visualizes the fine-grained precision–recall trade-offs across the evaluated models.

5.4 Per-Type Analysis

Appendix Figure 3 summarizes the per-type fine-grained F1 patterns for the main supervised and zero-shot models, and Appendix Table 16 gives the full scores. Performance is uneven across the schema. Supervised models dominate many frequent labels such as *Anatomic_location*, *Generic_Prion*, *Imaging_test*, *Symptom*, and *sCJD*, which helps explain their strong aggregate performance. Zero-shot models remain competitive on several semantically clearer or clinically distinctive labels, with GPT-5.4 or Gemma 4 achieving the best score for types such as *FFI*, *Electrophysio_test*, *fCJD*, *Genetic_test*, *Molecular_assay*, and *Differential_Diagnosis*. GLiNER2-def is a notable exception within the GLiNER family, reaching 1.00 F1 on *Sensitivity*, but sparse or boundary-sensitive labels such as *Time_point*, *iCJD*, *Imaging_finding*, and especially *Prevalence* remain difficult for nearly all systems. These extreme per-type values should be interpreted cautiously for very rare labels, where isolated perfect or zero scores may reflect only a handful of test mentions rather than stable schema-wide behavior.

6 Discussions

The main results and per-type patterns motivate a broader discussion of why the benchmark remains difficult and how well it aligns with prion-disease clinical evidence.

6.1 Remaining Challenges

First, the entity distribution is long-tailed. As shown in Table 4, a small number of frequent labels account for a large share of mentions: *Symptom*, *Generic_Prion*, and *Anatomic_location* account for 791, 741, and 646 mentions in the training split and 248, 233, and 223 in the test split, respectively. At the same time, many clinically meaningful categories remain sparse, including *Prevalence* (4 in the training split, 1 in the test split) and *Sensitivity* and *Specificity* (0 in the training split and 4 each in the test split). This skew is not merely a corpus artifact but reflects the structure of real diagnostic reporting, where a few common evidence types dominate while rarer findings and subtypes remain clinically important. Difficulty also reflects lexical diversity rather than frequency alone: even common labels such as *Symptom*, *Anatomic_location*, and *Duration* cover hundreds of distinct normalized surface forms in the training split. There is also substantial train–test surface-form mismatch, so models must generalize beyond memorized mention dictionaries even for relatively common categories.

Second, the schema requires distinctions among diagnostically adjacent categories, including prion subtypes, test names, findings, temporal expressions, and differential diagnoses, so errors are not only boundary errors but often clinically meaningful type confusions. In practice, subtype mentions such as *fCJD*, *iCJD*, and "corneal transplant-related CJD" are sometimes predicted as *Generic_Prion*. Others arise when late-stage downstream consequences such as *dysphagia* or *death* appear lexically symptom-like even though they are better labeled as *Complication* in context. The imaging cluster is also challenging, with *Imaging_test*, *Imaging_sequence*, and *Imaging_finding* often requiring fine-grained distinction among modality names, acquisition terms, and radiologic abnormalities. Appendix Section D.3 provides a more detailed entity-only confusion analysis with illustrative examples.

Third, the corpus contains discontinuous, nested, and overlapping mentions that are difficult for standard extraction pipelines. This difficulty is partly a consequence of dataset design itself: PrionNER preserves clinically adjacent labels and non-flat mention structures because simplifying them away would reduce the realism of the target task. At the structural level, the training split contains 97 discontinuous entities, 235 nested pairs, and 5 overlapping pairs, while the test split contains 34 discontinuous entities, 80 nested pairs, and 2 overlapping pairs. In practice, this means that most structural difficulty comes from nesting rather than true overlap. Appendix Tables 10–13 provide the full structural breakdown, and Figure 1 illustrates representative examples from the test set.

6.2 Clinical Alignment

PrionNER captures key prion-disease characteristics, including symptoms, tests, and disease pro-

gression described in the academic literature and clinical guideline documents, rather than arbitrary lexical patterns (Washington State Department of Health, 2022; Centers for Disease Control and Prevention, 2026). CJD-related terminology is strongly represented in the labeled terms, with *CJD* appearing 576 times, which is consistent with the prominence of Creutzfeldt-Jakob disease in scientific reports. The `Symptom` entity (1,279 mentions) aligns closely with current medical guidance and captures hallmark clinical features such as *dementia* (79), *myoclonus* (79), and *ataxia* (47). The dataset also preserves rarer but clinically important prion-disease subtypes and variants such as FFI (85), GSS (63), and the Heidenhain variant (4). Finally, the `Duration` entity (290 mentions) captures meaningful disease-course information, with frequent expressions such as *within a year* (7) and *12 months* (7), reflecting the typical one-year survival duration described in the clinical literature. Taken together, these patterns show that PrionNER aligns well with expert knowledge and published guidelines. This makes the dataset useful not only for benchmarking NER systems but also for downstream knowledge extraction and future diagnostic-support settings.

7 Conclusions

In this paper, we introduce PrionNER, a manually annotated named entity recognition dataset for prion disease biomedical literature derived from 317 PubMed abstracts. We present a clinically grounded schema that captures fine-grained diagnostic evidence and non-flat entity structure, together with a benchmark spanning supervised and zero-shot extraction settings. PrionNER provides a reliable annotation resource, with 81.78 entity-level exact agreement F1 on the pre-adjudication double-annotated test split. Our experiments show that W2NER provides the strongest supervised results, PubMedBERT is the strongest BERT baseline, and Gemma-4-31B is the strongest zero-shot model, while the remaining performance gaps confirm that PrionNER is a useful but challenging benchmark for prion-disease information extraction. More broadly, the benchmark surfaces challenges that are likely to recur in other rare-disease settings, including sparse but clinically important labels, fine-grained diagnostic distinctions, and nested or discontinuous spans. We hope PrionNER will support future research on rare-disease information extraction, structured knowledge construction, and clinically oriented biomedical NLP, including relation extraction, document-level evidence consolidation, and normalization or retrieval settings that connect extracted mentions to structured rare-disease knowledge resources.

Limitations

PrionNER has several limitations. First, it is built from 317 PubMed abstracts, which limits corpus size and coverage. Second, its focus on prion diseases may reduce generalizability to other disorders. Third, the data come from biomedical abstracts rather than clinical notes, so the language is more summarized and structured than real-world records. Future work should expand the corpus, improve coverage of sparse labels, and incorporate additional clinical text sources.

Ethics Statement

This study uses publicly available PubMed abstracts and does not involve human subjects or protected health information. No identifiable personal data were collected or processed, so institutional review board approval was not required.

A.2 Prompt Used for Abstract Relevance Screening

Before applying model-based screening to the full retrieval set, two annotators manually screened approximately 500 abstracts and observed that a large fraction of the keyword-matched results were not actually suitable for corpus construction. The most common false matches were papers centered on basic science, animal or other non-human studies, non-clinical analyses such as economic or purely epidemiological reports, or papers in which prion disease was only a secondary topic. We used this pilot review to formulate an operational definition of *related* abstracts for automated screening.

The GPT-5.4 screening prompt asks the model to determine whether an abstract is relevant to *human prion diseases in a clinical context*, based only on the abstract text. Relevant abstracts are defined as those primarily focused on diagnosis, symptoms, disease progression, or treatment in human prion disease. The prompt explicitly instructed the model to reject abstracts centered on basic science, animal or non-human studies, protein mechanisms without clinical human focus, unrelated primary diseases, or non-clinical reports such as economic, policy, surveillance, or purely epidemiological analyses.

The model is required to return a strict JSON object with three fields: ‘is_relevant‘, ‘reason‘, and ‘evidence_spans‘. If relevance checking is enabled, we verify that the response is a JSON object with `is_relevant` as a Boolean value, `reason` as a non-empty string, and `evidence_spans` as a list. We then retain only evidence spans that can be matched to the source abstract after light text normalization. A simplified version of the prompt structure is shown below.

```
System: You are a biomedical abstract screening
    assistant.
Decide whether the abstract is relevant to human
     prion
diseases in a clinical context.
Return one strict JSON object only.

User:
- Use the provided relevance definition.
- Judge based only on the abstract text.
- Exclude basic science, animal, non-human,
    unrelated-topic, and non-clinical abstracts.
- Return JSON only in the form:

{
  "is_relevant": true,
  "reason": "<short reason>",
  "evidence_spans": [
    "<short exact span from abstract>"
  ]
}
```

A.3 Audit of the Relevance Filter

After the initial retrieval and preprocessing stage produced 3,138 abstracts, GPT-5.4 screened the full set with the relevance definition above and labeled 1,304 abstracts as related and 1,834 as unrelated. We then manually reviewed abstracts from the screened pool together with the earlier pilot screening results to confirm relevance and remove duplicates. In total, this yielded 1,383 manually reviewed abstracts for auditing the screening process, including 868 abstracts rated as related by GPT-5.4.

Within this manually reviewed set, 772 abstracts were judged truly related and 611 were judged truly unrelated. GPT-5.4 predicted 868 abstracts as related and 515 as unrelated. Among the 868 abstracts rated as related by GPT-5.4, 755 were truly related and 113 were actually unrelated, corresponding to a precision of 86.98 for the related class. The resulting confusion pattern was strongly asymmetric: only 17 truly related abstracts were missed, whereas 113 unrelated abstracts were incorrectly marked as related. This shows that GPT-5.4 was aggressive in calling abstracts relevant.

On this 1,383-abstract audit set, GPT-5.4 achieved 90.60 accuracy and 89.65 balanced accuracy. For the related class, precision was 86.98, recall was 97.80, and F1 was 92.07. For the unrelated class, precision was 96.70, recall was 81.51, and F1 was 88.45. These headline metrics indicate that about 90.60% of all abstracts were classified correctly. Balanced accuracy of 89.65% is a useful summary here because it averages recall on the related and unrelated classes, which is important given the model's asymmetric behavior. For the related class, GPT-5.4 was correct 86.98% of the time when it predicted *related*, and it recovered 97.80% of all truly related abstracts, indicating that it was very effective at not missing relevant papers. For the unrelated class, GPT-5.4 was correct 96.70% of the time when it predicted *not related*, but its recall for that class was lower at 81.51%, meaning that it did not label unrelated abstracts as *not related* often enough. In practical terms, GPT-5.4 functioned as a strong high-recall relevance screener: it is well suited to settings where the priority is to avoid missing relevant abstracts, but it is weaker at filtering out irrelevant abstracts cleanly. In plain terms, the model tends to over-include, which may be acceptable for screening but increases downstream manual review effort and can introduce more false positives for later NER annotation.

A.4 Supervised Model Details

The supervised BERT model aliases and checkpoints are as follows: `biobert` = `dmis-lab/biobert-base-cased-v1.2`, `clinicalbert` = `emilyalsentzer/Bio_ClinicalBERT`, and `pubmedbert` = `microsoft/BiomedNLP-PubMedBERT-base-uncased-abstract-fulltext`. To avoid further reducing training coverage for rare labels, we do not create a separate development split; instead, we fix the training hyperparameters in advance and apply the same settings across the BERT baselines. No hyperparameter choices are made based on test-set results. All BERT models use the same hyperparameters: `max_length` = 512, `num_train_epochs` = 5.0, `learning_rate` = 5e-05, `weight_decay` = 0.01, `train_batch_size` = 8, `eval_batch_size` = 16, and `seed` = 42. BERT flat-ner results for this 5-epoch setup are as follows. In coarse-grained evaluation, BioBERT reaches 80.96 precision, 81.47 recall, and 81.22 F1; ClinicalBERT reaches 79.45 precision, 79.10 recall, and 79.28 F1; and PubMedBERT reaches 81.88 precision, 81.37 recall, and 81.62 F1. In fine-grained evaluation, BioBERT reaches 78.61 precision, 78.61 recall, and 78.61 F1; ClinicalBERT reaches 78.29 precision, 78.73 recall, and 78.51 F1; and PubMedBERT reaches 78.93 precision, 80.06 recall, and 79.49 F1. For W2NER (Li et al., 2022), we use PubMedBERT embeddings as the encoder input representation and train for 10 epochs. We include it specifically because it remains supervised while also supporting the `non-flat-ner` setting, unlike the BIO-based BERT baselines. We additionally report aggregate W2NER runs in both `flat-ner` and `non-flat-ner` settings. In coarse-grained `flat-ner`, W2NER reaches 84.23 precision, 79.63 recall, and 81.86 F1; in fine-grained `flat-ner`, it reaches 83.07 precision, 78.01 recall, and 80.46 F1. For `non-flat-ner`, W2NER reaches 12.40 precision, 14.81 recall, and 13.48 F1 in the coarse-grained setting, and 12.74 precision, 14.81 recall, and 13.70 F1 in the fine-grained setting.

A.5 Zero-shot Prompting and Inference Details

For zero-shot evaluation, we apply the GLiNER2 variants GLiNER2-short and GLiNER2-def (Zaratiana et al., 2025) together with GLiNER-BioMed (Yazdani et al., 2025), without supervised fine-tuning on PrionNER. For both GLiNER2-short and GLiNER2-def, we use the checkpoint `fastino/gliner2-large-v1`; for GLiNER-BioMed, we use `Ihor/gliner-biomed-base-v1.0`. GLiNER2-short supplies only the entity type names, whereas GLiNER2-def supplies both the entity type names and short type definitions. GLiNER-BioMed is evaluated only with entity type names. In our current GLiNER-based pipeline, non-flat behavior can be represented for nested and overlapping entities through multiple contiguous spans, but the model does not support explicit discontinuous multi-span entity objects. We also tested smaller local biomedical LLMs, including `aaditya/Llama3-OpenBioLLM-8B` and `BioMistral/BioMistral-7B`, but excluded them from the main comparison because in our pipeline they frequently produced chat-style outputs, malformed or truncated JSON, corrupted labels, and non-literal spans, making them unreliable for strict exact-span NER extraction. The models are run at the abstract level.

For the LLM-based setting, we evaluate OpenAI GPT-5.4 (OpenAI, 2026), `google/gemma-4-31B-it`, and `google/gemma-4-26B-A4B-it` from the Gemma 4 family (Team et al., 2024) using a fixed prompt template that introduces the task, specifies the target entity schema, and requests structured outputs. Each input instance is processed at the abstract level, and the model outputs are required to follow a constrained format such as JSON with entity text.

After inference, we apply a verification and normalization pipeline before evaluation. For NER outputs, we first verify the output shape: the model response must be a JSON object containing an `entities` list, and for OpenAI/Gemma outputs the returned `text` field must match the input abstract after collapsing whitespace. We then validate entity labels against the schema, rejecting invalid `coarse_type`/`fine_type` combinations. In limited cases, we repair partially correct predictions: in the coarse-only schema setting, `fine_type` is normalized to the same value as `coarse_type`, and if a predicted `fine_type` is valid but the `coarse_type` is missing or incorrect, we infer the corresponding coarse label from the schema. Next, we verify that each predicted mention can be aligned back to the source text and attach start/end offsets with deduplication. This alignment step is necessary for the zero-shot systems because LLM- and GLiNER-style outputs typically return entity strings but not reliable character offsets, whereas exact-match NER evaluation requires position-specific spans. When the same predicted surface form occurs multiple times in the same abstract, we map that mention to all exact string-matching occurrences in order to recover candidate offsets deterministically. This expansion step should therefore be understood as an offset-recovery procedure for span-text outputs rather than an additional modeling component, although it introduces an evaluation asymmetry relative to supervised token-level baselines that predict positions directly. For OpenAI/Gemma outputs, mentions that cannot be aligned are skipped and logged with warnings.

The GPT-5.4 prompt template used in our experiments is shown below.

```
System:
You are an information extraction model for
    biomedical case reports and reviews about
    prion disease.
Your job is to label entity spans using only the
    provided schema and output one valid JSON
    object.

User: Read the schema carefully and follow it
    exactly.

Schema JSON: {entity_schema}

Rules:
1. Extract only explicit spans from the text.
2. Use exact labels from the schema.
3. Use exact text spans from the input.
4. Do not output start or end offsets.
5. Do not output comments, markdown, or extra
    keys.
6. If uncertain, omit the span instead of
    guessing.

Input text: {text}

Output exactly one JSON object with this
    structure:
{
  "text": "<original input text>",
  "entities": [
    {
      "mention": "<exact span>",
      "coarse_type": "<schema coarse type>",
      "fine_type": "<schema fine type>",
      "normalized": "<normalized form or same as
      mention>"
    }
  ]
}
```

B Annotation Guidelines and Schema

B.1 Guideline Principles

Global rules: annotate only explicit mentions; prefer the most specific label available; keep spans minimal but complete; annotate both long form and abbreviation when both are explicit; treat molecular subtype strings such as *MM1*, *MV2*, and *VV2* as `sCJD` mentions, with finer subtype interpretation handled in normalization; treat exposure or treatment phrases such as *corneal transplantation*, *cadaveric-derived hormone treatment* (e.g., growth hormone), and *cadaveric dura mater graft* as `Treatment` mentions rather than disease mentions; include generic heads such as *disease*, *syndrome*, and *symptom* when they are part of the explicit annotated mention; and for statistical expressions annotate only the value span (e.g., *100%*, *0.06%*) rather than surrounding cue phrases.

Do not assign labels by keyword alone. A span is a disease mention only if it names a disease entity in context, and a span is a symptom mention only if it expresses a clinical manifestation in context. For example, *disease duration* is not a disease label, and *symptom onset* is not a `Symptom` label.

B.2 Train Annotation Consistency and Guideline Drift

The training annotations were produced over multiple rounds by the two annotators and then consolidated through adjudication into a single final corpus version. Because the train split was not preserved as two separately frozen annotator-specific versions, we do not report a formal per-annotator label-distribution comparison here. Instead, Table 7 summarizes the main recurrent sources of early annotation-style drift that were resolved during guideline refinement and then applied consistently in the final schema. Most of these changes affected boundary selection or distinctions between nearby label types rather than the overall entity inventory.

No.	First Guideline / Early Practice	Final Guideline
1	*brain* was not labeled as `Anatomic_location`.	*brain* is labeled as `Anatomic_location`.
2	*died* and *death* were not labeled as `Complication`.	*died* and *death* are labeled as `Complication`.
3	*FLAIR*, *T1-weighted*, *T2-weighted*, *ADC*, and *DWI* were labeled as `Imaging_test`.	These sequence terms are labeled as `Imaging_sequence` rather than `Imaging_test`.
4	Time expressions such as *in year 2013*, *in 2013*, and *12 months after onset of symptoms* were not consistently separated into anchor vs. duration components.	`Time_point` captures anchor expressions such as *2013* and *onset of symptoms*, while `Duration` captures spans such as *12 months*.
5	`Autopsy` was restricted to explicit procedure mentions such as *autopsy* and *autopsy examination*.	`Autopsy` was expanded to include additional procedure-reporting forms such as *pathologically*, *autopsy*, and *neuropathological examination*.
6	Statistical entities were often annotated as full cue phrases, e.g., *sensitivity of 61%* or *prevalence of 1/1 million people per year*.	Only the value span is annotated: e.g., *61%* as `Sensitivity` and *1/1 million people per year* as `Prevalence`.
7	*Heidenhain variant* was not labeled as `sCJD`.	*Heidenhain variant* is labeled as `sCJD`.

Table 7: Examples of guideline drift observed during training annotation and the final adjudicated guideline used in PrionNER.

B.3 Full Entity Schema

Table 8: Full coarse-grained and fine-grained entity schema of PrionNER, including definitions and representative examples.

Coarse-grained Type	Fine-grained Type	Definitions
Case Input (Geschwind, 2015)		
Age	Age	The age of a patient at disease onset. Examples: age 62; 45-year-old; at 58 years
Symptom	Symptom	Any subjective experience reported by the patient or objective observation made by a clinician. *Examples:* memory loss; fatigue; hyperreflexia; Babinski sign; rigidity; startle response
Test_name	Imaging_test	MRI; CT scan; PET scan
	Electrophysio_test	nerve conduction study, Polysomnography
	Blood_biomarker_test	CSF 14-3-3 assay; tau assay; complete blood count
	Genetic_test	PRNP genetic testing; mutation analysis; gene panel testing
	Molecular_assay	RT-QuIC; PCR; Western blot
	Autopsy	brain autopsy; neuropathological examination; postmortem analysis
Sequences	Imaging_sequence	DWI; FLAIR; diffusion-weighted imaging; ADC maps
Anatomic_location	Anatomic_location	A specific anatomical structure where a clinical finding or pathological change is observed. *Examples:* cortex; basal ganglia; thalamus; caudate nucleus; cerebral cortex
Findings	Imaging_finding	pulvinar sign; restricted diffusion; cortical ribboning
	Autopsy_finding	spongiform change; neuronal loss; astrogliosis
Case Diagnosis (Centers for Disease Control and Prevention, 2026)		

Continued on next page

Table 8: Full coarse-grained and fine-grained entity schema of PrionNER, including definitions and representative examples (continued).

Coarse-grained Type	Fine-grained Type	Definitions
Generic_Prion	Generic_Prion	Prion disease mentions without specific subtype classification. *Examples:* prion disease; CJD, bovine spongiform encephalopathy, BSE, mad cow disease, Transmissible Spongiform Encephalopathy, TSE
Sporadic_Prion	sCJD	Sporadic Creutzfeldt-Jakob Disease
	sFI	Sporadic Fatal Insomnia
	VPSPr	Variably Protease-Sensitive Prionopathy
Familial_Prion	fCJD	Familial Creutzfeldt-Jakob Disease
	GSS	Gerstmann-Sträussler-Scheinker Syndrome
	FFI	Fatal Familial Insomnia
Acquired_Prion	vCJD	Variant Creutzfeldt-Jakob Disease
	iCJD	Iatrogenic Creutzfeldt-Jakob Disease
	Kuru	Kuru
Differential_Diagnosis	Differential_Diagnosis	Non-prion diseases used for differential diagnosis (no fine-grained subtypes in this schema). *Examples:* Alzheimer's disease; autoimmune encephalitis; viral encephalitis; Parkinson's disease
Clinical Course and Context		
Treatment	Treatment	A therapeutic intervention, medication used to manage a disease or its symptoms. Examples: supportive care; quinacrine; doxycycline; symptomatic treatment (Benavente and Morales, 2024)
Complication	Complication	A secondary medical condition that arises as a consequence of disease progression. Examples: pneumonia; aspiration pneumonia; respiratory failure (Willis, 2006)
Time	Duration	A span or length of time over which a clinical event, symptom, or disease progression occurs. *Examples:* within 3 months; over 2 years; rapidly progressive over weeks
	Time_point	A specific point in time associated with clinical symptoms or a specific event. *Examples:* at onset; at age 62; in 2021
Stats	Sensitivity	The true positive rate for a diagnostic test (Saltelli et al., 2019). *Examples:* sensitivity of 85%
	Specificity	The true negative rate for a diagnostic test (Saltelli et al., 2019). *Examples:* specificity of 92%
	Prevalence	Disease frequency within a population (Tenny and Hoffman, 2017). *Examples:* 1 per million; prevalence of 0.5%
	Incidence	The rate at which new cases of a disease occur in a population during a specified time period. *Examples:* annual incidence of 2 per million

B.4 Compact Annotation Guideline

Table 9: Compact PrionNER annotation guideline.

Label	Use For	Annotate	Do Not Annotate
`Generic_Prion`	Prion disease mentions without explicit subtype classification	*prion disease*, *prion diseases*, *Creutzfeldt-Jakob disease*, *CJD*, *bovine spongiform encephalopathy*, *BSE*, *mad cow disease*	Specific subtype mentions such as *sporadic CJD* or *variant CJD*; protein mentions such as *prion protein*, *PrP*, or PrP^{Sc}; pathological finding uses such as *spongiform encephalopathy* when used as an autopsy finding
`sCJD`	Sporadic Creutzfeldt-Jakob disease	*sporadic Creutzfeldt-Jakob disease*, *sporadic CJD*, *sCJD*, *MM1*, *MV1*, *VV2* when clearly used as sCJD subtypes	Generic *CJD* without a sporadic cue
`sFI`	Sporadic fatal insomnia	*sporadic fatal insomnia*, *sFI*	*fatal familial insomnia*, *FFI*, *FFI-1*, *FFI-2*

Label	Use For	Annotate	Do Not Annotate
VPSPr	Variably protease-sensitive prionopathy	*variably protease-sensitive prionopathy*, *VPSPr*	*PrP*, *PrP^{Sc}*, *PrP-res*, or other protein-level mentions
fCJD	Familial or hereditary CJD	*familial CJD*, *familial Creutzfeldt-Jakob disease*, *hereditary CJD*, *genetic CJD*, *fCJD*	Mutation or genotype mentions alone
GSS	Gerstmann-Sträussler-Scheinker syndrome	*Gerstmann-Sträussler-Scheinker syndrome*, *GSS*, *GSS102*, *GSS105*	Mutation names alone; pathological descriptors such as *kuru plaques*
FFI	Fatal familial insomnia	*fatal familial insomnia*, *FFI*, *FFI-1*, *FFI-2*	Isolated *insomnia*; use Symptom instead
vCJD	Variant CJD	*variant Creutzfeldt-Jakob disease*, *variant CJD*, *vCJD*, *new variant CJD*, *nvCJD*	Generic uses of *variant* without clear disease reference
iCJD	Iatrogenic CJD	*iatrogenic Creutzfeldt-Jakob disease*, *iatrogenic CJD*, *growth hormone-associated CJD*, *dural graft associated CJD*, *iCJD*, *dCJD*	*iatrogenic* alone when the CJD referent is unclear
Kuru	Kuru disease mention	*Kuru*, *kuru*	*kuru plaques*; use Autopsy_finding instead
Differential_ Diagnosis	Non-prion diseases considered as alternatives or comparators	*Alzheimer disease*, *autoimmune encephalitis*, *Huntington disease*	Prion diseases; symptom phrases unless they are clearly used as alternative diagnoses
Symptom	Symptoms, signs, and clinical manifestations	*dementia*, *myoclonus*, *cerebellar ataxia*, *psychotic symptoms*, *hyperreflexia*	Disease names; imaging findings; autopsy findings
Imaging_ test	Imaging modalities or procedures	*MRI*, *CT*, *PET*, *SPECT*	Sequences such as *FLAIR*, *DWI*; findings such as *pulvinar sign*
Electrophysio_ test	Electrophysiology procedures	*EEG*, *electroencephalogram*, *polysomnography*	Electrophysiologic findings or waveform targets
Blood_ biomarker_ test	Biomarker assays and specimen-as-test shorthand	*CSF*, *tau assay*, *blood tests*	Molecular methods such as *PCR*, *RT-QuIC*, or *Western blot*
Genetic_ test	Genetic testing procedures	*genetic testing*, *Prion gene analysis*, *genetic analysis*	Gene names and mutation names alone
Molecular_ assay	Molecular or biochemical assays	*RT-QuIC*, *PCR*, *Western blot*, *molecular analysis*	Biopsy or autopsy procedures; gene targets without a testing method
Autopsy	Postmortem or tissue examination procedures	*brain autopsy*, *postmortem examination*, *brain biopsy*	Pathological findings themselves; anatomy alone
Imaging_ sequence	Acquisition or sequence terms	*DWI*, *FLAIR*, *T2 weighted*, *ADC maps*	Imaging modality names; imaging abnormalities
Imaging_ finding	Radiologic abnormalities or named signs	*pulvinar sign*, *restricted diffusion*, *cortical ribboning*	Test modality alone; anatomy alone unless separately annotated
Autopsy_ finding	Pathological or postmortem findings	*spongiform change*, *neuronal loss*, *gliosis*, *florid plaques*, *kuru plaques*, *spongiform encephalopathy* when used as a pathological finding	Procedure terms; disease names
Anatomic_ location	Body locations linked to findings or symptoms	*thalamus*, *basal ganglia*, *caudate nucleus*, *cortex*, *deep white matter*	Non-anatomical descriptors; whole finding phrase when only one part is anatomy
Age	Age or age-at-onset expression	*58-year-old*, *age 62*, *young adults*	Durations; calendar dates

Label	Use For	Annotate	Do Not Annotate
`Treatment`	Therapies, medications, or care strategies	*palliative care*, *quinacrine*, *doxycycline*, *antipsychotics*; annotate the full treatment mention when expressed as a therapy or care strategy	Diagnostic tests; non-intervention goals unless expressed as actual therapy
`Complication`	Secondary adverse conditions or end-stage outcomes	*pneumonia*, *respiratory failure*, *SIADH*, *death*, *died*	The primary prion disease itself
`Duration`	Time span or length	*within 3 months*, *over 2 years*, *13 months*	Calendar dates; age expressions
`Time_point`	Specific time anchor	*at onset*, *on admission*, *1996*, *January 2012*	Durations; exclude discourse connectives such as *in*, *after* when they are not themselves the time anchor
`Sensitivity`	Diagnostic sensitivity expression	*100%*, *91%* when they are explicitly the sensitivity value, e.g., annotate only *100%* in *sensitivity of 100%*	The cue word alone, e.g., *sensitivity*, when no value is included; unrelated percentages
`Specificity`	Diagnostic specificity expression	*92%*, *95%* when they are explicitly the specificity value	The cue word alone, e.g., *specificity*, when no value is included; unrelated percentages
`Prevalence`	Disease frequency expression	*1–2 people per million annually*, *0.5%* when it is explicitly the prevalence value	The cue word alone, e.g., *prevalence*, when no value is included; sample size counts
`Incidence`	New-case rate expression	*0.06%*, *2 per million annually*, *0.37 cases/million*, *1 in 1 000 000* when they are explicitly the incidence value	The cue word alone, e.g., *incidence*, when no value is included; sample size counts; surrounding time or cue phrases such as *in 2023*, *million per year*, or *annual incidence of*

C Extended Dataset Statistics

C.1 Structural Annotation Statistics

The train and test splits both contain non-trivial structural complexity at the span level (Table 10). Discontinuous entities remain relatively uncommon in absolute terms, but they appear in both splits and are distributed across clinically salient labels rather than being confined to a single category. In both train and test, *Symptom* is the most common discontinuous label, followed by *Anatomic_location*; train also shows notable discontinuous cases for *Imaging_finding*, while test includes comparatively more *Blood_biomarker_test* discontinuities (Table 11).

Nested structures are much more frequent than overlapping ones, and they are concentrated in recurring clinically meaningful label pairs (Tables 12 and 13). In the training split, the most common nested envelope patterns are *Symptom* within *Symptom*, *Duration* with *Time_point*, and *Anatomic_location* paired with *Symptom*; in the test split, the dominant patterns shift toward *Anatomic_location* with *Symptom* or *Imaging_finding*, with an additional cluster of *Treatment–iCJD* nesting. By contrast, overlapping envelope pairs are rare in both splits, suggesting that the benchmark's structural difficulty is driven primarily by discontinuity and especially nesting rather than widespread partial-overlap phenomena.

Split	Docs	Entities	Disc.	Nested Env.	Overlap Env.
Train	247	5,149	97	235	5
Test	70	1,806	34	80	2

Table 10: Span-structure summary for the train and test splits. Discontinuous entities are text-bound entities with more than one atomic span. Nested and overlapping pair counts are reported at the entity-envelope level.

Table 15: Train/test comparison of unique normalized surface forms and non-meta mention counts for the most frequent entity types.

C.2 Split-Level Entity Summary

C.3 Entity Surface-Form Dictionary Summary

Unique surface forms are counted per entity type after lowercasing, trimming edge whitespace, collapsing internal whitespace, and joining discontinuous spans with spaces.

D Extended Results

D.1 Overall Performance

Figure 2 complements the main fine-grained results by showing the precision–recall trade-offs across the evaluated models. The supervised BERT baselines cluster in the strongest region overall, while the zero-shot models show a wider spread and sharper trade-offs; among them, Gemma-4-31B occupies the strongest overall position in the fine-grained setting.

D.2 Per-Type Fine-grained Results

Figure 3 and Table 16 show that fine-grained performance is highly uneven across the schema. The heatmap makes clear that there is no single difficulty level for PrionNER: some labels are solved reliably by most strong systems, while others re-

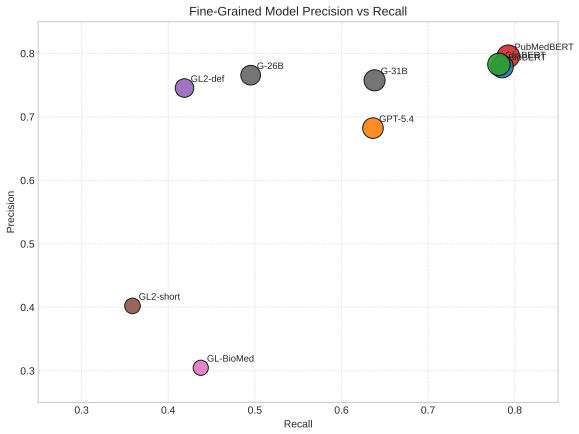

Figure 2: Precision–recall trade-offs for fine-grained entity extraction across the evaluated models.

main unstable even for the best models. This heterogeneity tracks both frequency and semantic specificity. Common and lexically anchored categories such as *Generic_Prion*, *sCJD*, *Imaging_test*, *Symptom*, *Age*, and *Anatomic_location* are comparatively robust, whereas sparse or context-dependent labels such as *Prevalence*, *Specificity*, *Sensitivity*, *Time_point*, *Molecular_assay*, and subtype distinctions such as *iCJD* and *fCJD* remain much harder.

The supervised encoders occupy the strongest region overall and are more consistent across label families. PubMedBERT in particular is among the top performers on many of the clinically common labels, reaching 91.77 on *Generic_Prion*, 90.79 on *Imaging_test*, 89.74 on *sCJD*, 88.89 on *Age*, 84.95 on *Symptom*, and 81.48 on *Blood_biomarker_test*. BioBERT and ClinicalBERT show a similar profile and outperform PubMedBERT on a few categories, such as *Anatomic_location*, *vCJD*, *Complication*, *Autopsy*, *Autopsy_finding*, *Incidence*, and *iCJD*. Taken together, the supervised models suggest that once training data are available, the main gains come from broad coverage across the entire schema rather than isolated wins on a handful of labels.

The zero-shot models show a much sharper specialization pattern. Gemma-4-31B is the strongest zero-shot model overall, but its strengths are concentrated in a narrower subset of distinctive labels, including *FFI* (100.00), *fCJD* (77.78), *Genetic_test* (71.43), *Molecular_assay* (65.79), *Duration* (65.98), and *Differential_Diagnosis* (61.29). GPT-5.4 is competitive on several labels and is best on *Electrophysio_test* (89.19) and *Time_point* (40.78), while GLiNER2 occasionally produces isolated best scores on very sparse categories such as *Sensitivity*, *Specificity*, and *Duration*. However, these zero-shot wins are scattered and do not translate into the same schema-wide stability seen in the supervised baselines.

Two further patterns are worth noting. First, the imaging and diagnostic-context families remain difficult even when overall F1 is moderate: *Imaging_finding*, *Imaging_sequence*, *Blood_biomarker_test*, *Autopsy_finding*, and *Time_point* all show larger cross-model variation than canonical disease-name labels. Second, the most extreme values should be interpreted with caution for very rare labels. For example, *Prevalence* remains at 0.00 for all models, and isolated perfect or near-perfect results on labels such as *Sensitivity* or *FFI* reflect very small test counts rather than uniformly solved clinical reasoning. Overall, the per-type view reinforces the main conclusion of the paper: PrionNER rewards models that combine strong lexical grounding on common biomedical entities with fine-grained contextual discrimination on rarer, semantically adjacent categories.

D.3 Entity-only Confusion Analysis

Figures 4a and 4b provide a complementary entity-only view of fine-grained errors for the two strongest models. Under this evaluation, PubMedBERT is clearly stronger overall, reaching 0.794 flat entity-level F1 compared with 0.684 for Gemma-4-31B. The main difference is recall: PubMedBERT reaches 0.793 recall versus 0.597 for Gemma-4-31B, while their precision remains very similar at 0.796 and 0.801, respectively. This pattern shows that Gemma-4-31B is comparatively conservative, preserving Gemma-level precision but missing many more entities.

In these row-normalized, entity-label-only matrices, PubMedBERT has the cleaner diagonal overall. More labels retain darker diagonal mass with less off-diagonal spill, indicating more consistent label assignment across the schema. Gemma-4-31B looks reasonable on a few canonical labels, but its diagonal is visibly weaker for many harder clinical categories, including *Autopsy*, *Autopsy_finding*, *Blood_biomarker_test*, *Time_point*, and *Treatment*.

Several confusion patterns are shared by both models. *Prevalence* and *Incidence* remain difficult to separate, the imaging cluster shows substantial overlap among *Imaging_finding*, *Imaging_sequence*, and *Imaging_test*, and the prion sub-

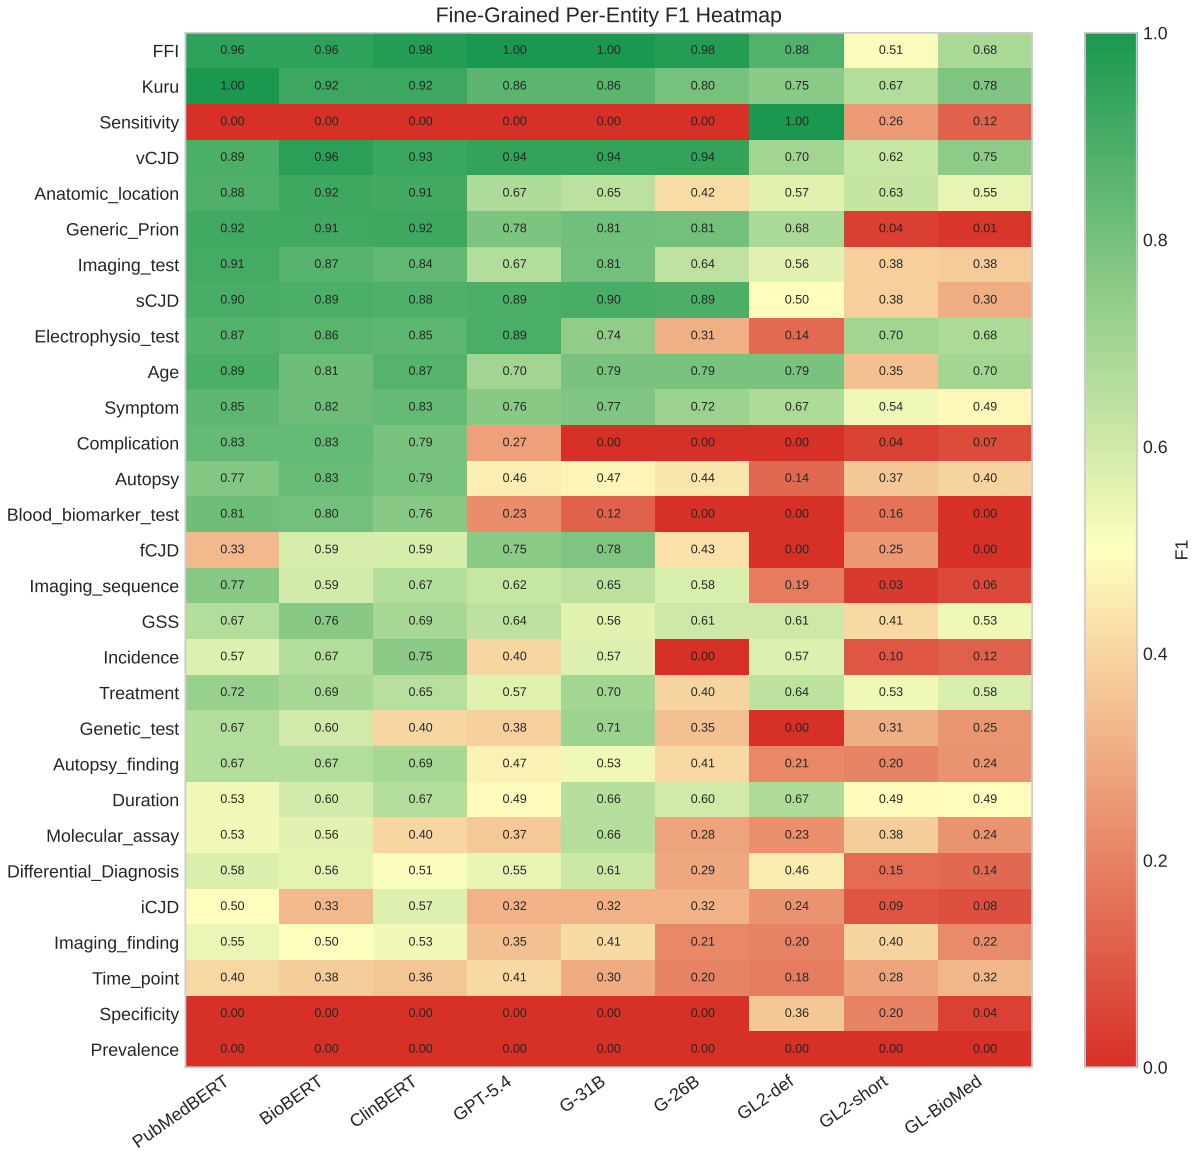

Figure 3: Per-type fine-grained F1 heatmap for the main supervised and zero-shot models on the test set.

type region also remains imperfectly separated, especially among *fCJD*, *iCJD*, *GSS*, *sFI*, and nearby subtype labels. These are largely fine-grained semantic confusions between clinically adjacent categories rather than arbitrary label noise. One recurring shared error is the prediction of *Generic_Prion* for *fCJD* and *iCJD*. For *fCJD*, a plausible explanation is that abstracts often realize the subtype as phrases such as "familial CJD" or "familial form of CJD," where the diagnostically important modifier appears before the base disease name. In these cases, the model appears to anchor on "CJD" while failing to consistently preserve the prefix that signals the familial subtype. The same pattern likely explains part of the *iCJD* → *Generic_Prion* confusion: the model often captures "CJD" but misses the preceding cue that indicates an iatrogenic or transmitted form. This error is amplified by longer compositional mentions such as "corneal transplant-related CJD," where the treatment-related phrase can be separated from the disease name; in such cases, the model may label "corneal transplant" as *Treatment* and the remaining "CJD" span as *Generic_Prion* rather than assigning the full mention to *iCJD*. Another plausible shared confusion is between *Complication* and *Symptom*. Some complication mentions are lexically symptom-like in isolation, but are labeled as *Complication* because they denote downstream consequences of disease progression rather than primary manifestations. For example, *dysphagia* can be a symptom in many settings, but in prion

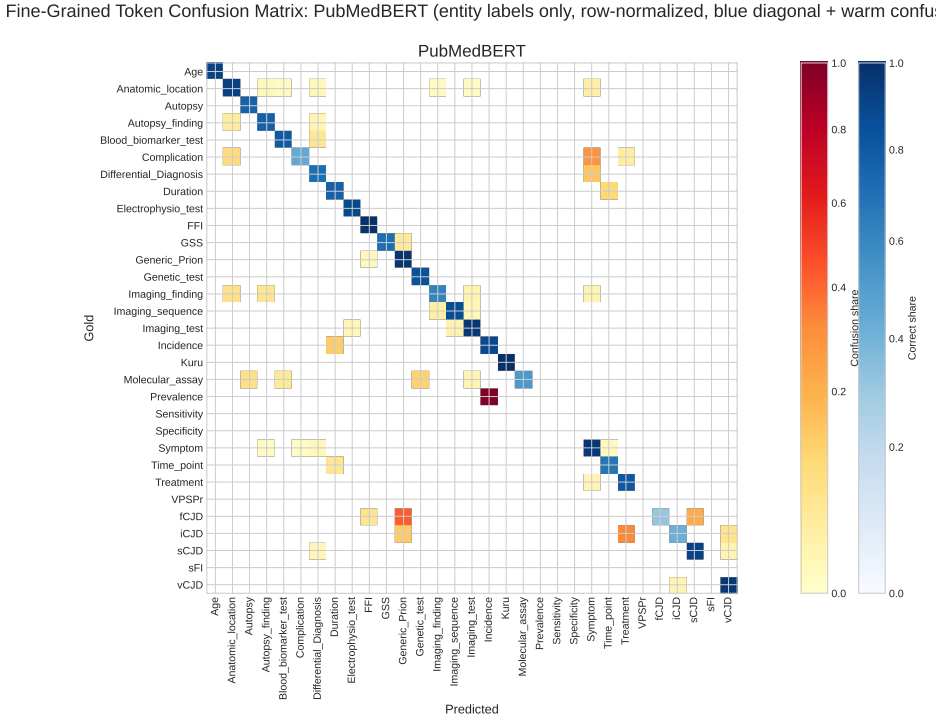
Table 16: Per-type fine-grained F1 scores for selected supervised and zero-shot models on the test set, sorted by the best score achieved for each entity type. Header abbreviations: ClinBERT = ClinicalBERT; GL2-def = GLiNER2-def; GL2-short = GLiNER2-short; GL-BioMed = GLiNER-BioMed; G-26B and G-31B = Gemma 4 26B and 31B.

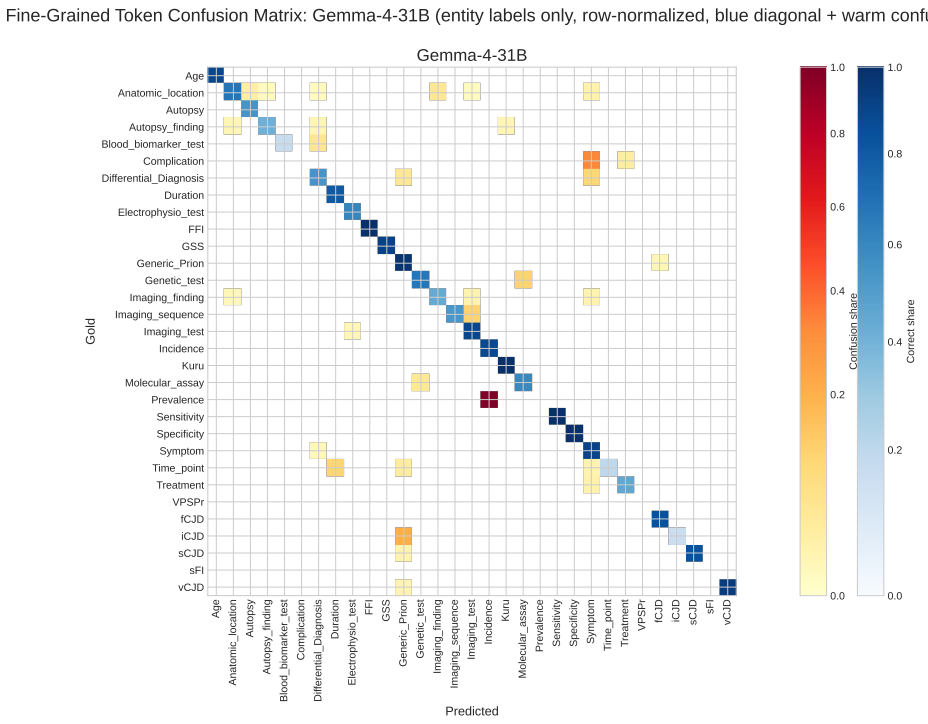
disease abstracts it may appear as a late-stage secondary consequence of earlier neurological decline, which makes the boundary between the two labels difficult to recover from local context alone. Similarly, mentions such as "died" or "death" may be pulled toward *Symptom* or other outcome-like categories even though they are not direct symptomatic expressions of prion disease itself. Instead, they typically reflect the final downstream result of severe functional deterioration and accumulated health complications over the course of the disease.

For PubMedBERT, the strongest diagonal cells are concentrated on common, high-volume labels such as *Symptom*, *Anatomic_location*, *Imaging_test*, *Generic_Prion*, and *sCJD*. Its remaining errors mostly look like local mix-ups within semantically related label families rather than broad collapse across the label space. Gemma-4-31B, by contrast, is weaker on context-heavy diagnostic labels and on imaging-related distinctions; its diagonal is often present but noticeably lighter, suggesting less stable fine-grained label assignment even when an entity span is recovered.



This entity-only view should also be read together with the full confusion analysis that includes *O*. Because these matrices exclude non-entity predictions, they likely understate Gemma-4-31B's main weakness, namely omission of the entity altogether. In other words, PubMedBERT appears stronger and more balanced, with errors concentrated within semantically adjacent labels, whereas Gemma-4-31B shows reasonable zero-shot behavior but is less reliable on subtle distinctions and is likely more omission-heavy in the full setting.

At the label level, PubMedBERT remains strong on common clinical categories, including *Generic_Prion* (0.918), *Imaging_test* (0.908), *sCJD* (0.897), *vCJD* (0.887), *Anatomic_location* (0.883), and *Symptom* (0.850). Gemma-4-31B is still strong on a narrower set of distinctive labels,



including *Generic_Prion* (0.917), *FFI* (0.977), *Kuru* (0.923), *Age* (0.792), *Imaging_test* (0.781), and *Symptom* (0.773), but its performance drops sharply on rarer or more context-dependent categories. Its weakest flat F1 values include *Complication* (0.000), *Prevalence* (0.000), *Sensitivity* (0.000), *Specificity* (0.000), *Blood_biomarker_test* (0.172), *iCJD* (0.286), *Time_point* (0.317), and *Imaging_finding* (0.321). PubMedBERT also shows weak spots, but they are milder and are concentrated in rare epidemiology labels and subtype distinctions: *Prevalence* (0.000), *Sensitivity* (0.000), *Specificity* (0.000), *fCJD* (0.333), *Time_point* (0.404), *iCJD* (0.500), and *Molecular_assay* (0.528). Overall, these figures reinforce the main result: PubMedBERT is the better model for PrionNER because it maintains Gemma-4-31B-level precision while recovering many more entities, whereas Gemma-4-31B remains the strongest zero-shot model but is still limited primarily by recall.

D.4 Per-label Annotation Agreement

Table 17 provides the full per-label agreement breakdown for the test split. Agreement is highest for common and semantically distinctive disease labels such as *vCJD*, *GSS*, *FFI*, and *sCJD*, while lower agreement is concentrated in sparse or boundary-sensitive categories such as *Complication*, *Prevalence*, *Incidence*, and *Imaging_finding*.

Abstract

Individuals with particular mental health disorders may find it difficult to learn about their own condition. Therefore, efforts have been made to create materials that explain complex medical information in simpler words, which are also beneficial for caregivers and others. However, text simplification is commonly done in English and only sporadically in other languages. In this study, we explore potential ways for language-agnostic medical text simplification for the mental health domain. Our approach is to simplify the ICD-11 articles on primary psychotic disorders in English, German and French, using small LMs and various metrics for evaluating different aspects of the texts: lexical complexity and readability. Our results show that acceptable texts were produced only in English, and that a joint analysis of Measure of Textual Lexical Diversity (MTLD) and Flesch Reading Ease (FRE) provides the most insight, capturing both the best outcomes and signaling different types of issue. The study is preliminary and requires further investigation.

1 Introduction

As with any professional or technical domain, medical texts tend to be difficult to understand for non-specialists. Clinical NLP explores methods for different transformations of medical texts (Hasan and Farri, 2019), including *paraphrase generation* and *text simplification*, where the latter is a more complex task even in English (Basu et al., 2023).

Simplification of medical texts in languages other than English remains understudied. Some research on French and Romanian focuses primarily on paraphrase generation and shows good results when using language- and domain-specific models (Buhnila and Todirascu, 2024; Buhnila et al., 2024; Buhnila, 2025), whereas research on text simplification in Polish and some Indian languages, Arabic and Swahili reports that general purpose LLMs, such as GPT-4, provide better results than smaller fine-tuned models (Grzybowski et al., 2025; Gangavarapu, 2024).

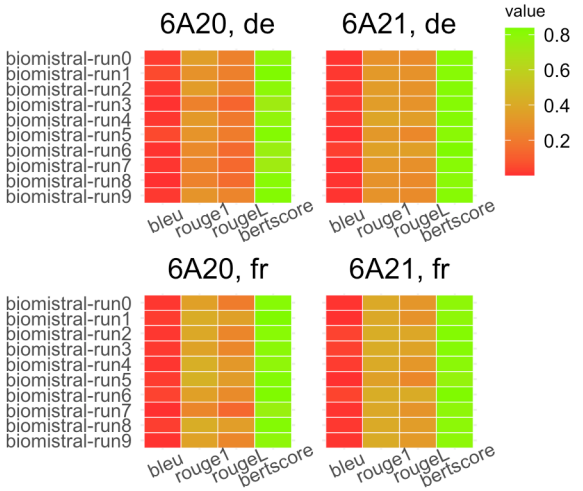

Figure 1: Typically used similarity metrics BLEU, ROUGE and BERTScore do not reflect fine-grained differences in simplified texts when comparing different languages, model runs and ICD-11 articles, although the resulting texts vary greatly in terms of fluency and simplicity (our results).

In contrast to text simplification in primary medicine, the mental health domain requires further attention to potential cognitive impairments in some mental health disorders, neutral and non-stigmatizing tone, simplifying both words and sentences without making text unnatural. These nuances can be challenging to account for in multilingual settings, even when translating medical texts manually (Natoli, 2026).

Given the ambitious nature of the outlined task, we conduct a preliminary study to investigate evaluation methods capable of detecting various issues in a multilingual setting. In this study, we explore small models, intentionally including some negative results (poor-quality texts), to focus on identifying key metrics that highlight text properties of the best and worst simplified texts across 3 languages.

Small models are chosen for greater reproducibility in a metric exploration study.

2 Related Work

The need for reading materials in simplified language has long been recognized, especially in healthcare contexts. Different lay persons are considered beneficiaries of so-called Easy Language, and various practices for it have been established across countries for manual adaptation of texts (Nomura et al., 2010; Lindholm and Vanhatalo, 2021).

Despite these efforts, automatic methods for clinical text simplification remain heavily focused on English, with only limited work on other European languages (Buhnila and Todirascu, 2024; Buhnila et al., 2024; Buhnila, 2025; Grzybowski et al., 2025; Scholz and Wenzel, 2025) and even less beyond Europe (Gangavarapu, 2024).

Automatic simplification of medical texts raises ethical considerations, such as the risk of meaning distortion. (Gooding, 2022) This is even more important when targeting texts in the psychiatric domain (Aich et al., 2025) and audiences with mental health disorders (Gralton et al., 2010), given the long history of stigmatization (Rössler, 2016). Evaluation of the resulting texts typically relies on metrics coming from machine translation (MT) that measure similarity between the original and the simplified texts on the level of word tokens (Papineni et al., 2002; Lin, 2004) and on semantic level (Zhang et al., 2019), which provide only limited insight on the quality of the simplified texts (Figure 1). The Flesch Reading Ease metric (Flesch, 1948) is widely used to assess readability, while the other readability metrics and other properties of text, such as lexical complexity, are typically overlooked.

Our preliminary study addresses these gaps by analyzing 3 lexical complexity and 9 readability metrics to identify more informative and potentially language-agnostic evaluation methods.

3 Data & Methods

We extract five articles from ICD-11 (Harrison et al., 2021) using ICD API[1], containing definitions of primary psychotic disorders: 6A20–6A24 including all the sub-definitions (6A20.0, 6A20.1, etc.). The concatenated definitions serve as input to the following small language models, fine-tuned for text simplification and/or for multilingual use:

- **LingConv** (Elgaar and Amiri, 2025): a text conversion tool[2] based on a T5-Base (Raffel et al., 2020) model intended for general paraphrase generation in English;
- **PRISM** (Thompson and Post, 2020): a transformer-based MT model adapted for general paraphrase generation, trained on 39 languages;
- **Ascle** (Yang et al., 2024): a toolkit for medical text generation, incl. a text simplification function. The toolkit includes 3 models (BigBird-Pegasus Large (Zhang et al., 2020); BART Large (Lewis et al., 2020) and BioBART v2 Base (Yuan et al., 2022)), each in 2 versions fine-tuned on different medical data, primarily in English.
- **BioMistral 7B** (Labrak et al., 2024): a Mistral 7B Instruct model (Jiang et al., 2023) fine-tuned for biomedical domain in 9 languages. We use the BioMistral SLERP model[3] with 4-bit GPTQ quantization (Frantar et al., 2022).

All models except BioMistral were given the ICD-11 articles as input, while for BioMistral we provided a simple prompt: "Rewrite this medical definition for a layman person. Keep it as close to the original meaning as possible, just use simpler words and syntactic constructions."; we manually translated it into German and French.

We test all the models on English texts first and calculate the following evaluation metrics:

- **Similarity**: BLEU, ROUGE 1 and ROUGE L, BERTScore. These are standard metrics in MT for assessing the preservation of the n-gram combinations and the underlying meaning;
- **Lexical complexity**: TTR (type-token ratio), MATTR (moving-average type-token ratio) (Covington and McFall, 2010), MTLD (measure of textual lexical diversity) (McCarthy and Jarvis, 2010). All of these measures are based on the ratio of unique words (types) and all word instances (tokens) in a given text;
- **Readability**: Flesch Reading Ease (FRE), Flesch-Kincaid grade level (FKGL), Automated Readability Index (ARI) (Kincaid et al.,

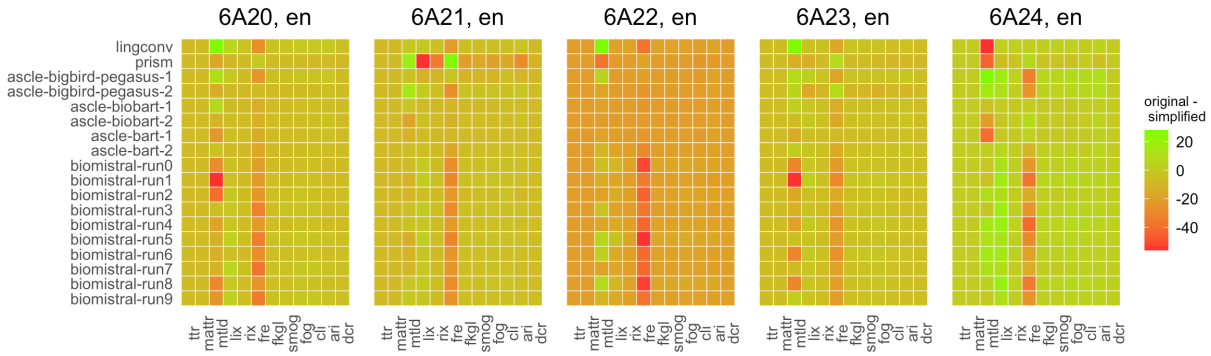

Figure 2: Difference in complexity and readability metrics across 9 models and 5 ICD-11 articles in English.

1975), SMOG index (SMOG) (Mc Laughlin, 1969), Gunning Fog index (Fog) (Gunning, 1952), Coleman–Liau Index (CLI) (Coleman and Liau, 1975), Dale-Chall Readability (DCR) (Chall and Dale, 1995), Läsbarhetsindex (LIX) (Björnsson, 1968) and Readability Index (RIX) (Anderson, 1983). These metrics capture length of words, sentences; some of them also check a set of familiar words (e.g. Dale-Chall).

Given the results on English, we manually evaluate the simplified texts from each model and identify the most aligned metrics. The reduced set of metrics is further used to evaluate the results on German and French, taking into account that some of the readability metrics cannot be easily transferred to languages other than English.[4] In addition, three human annotators evaluated BioMistral results in English.

We use textstat (Bansal and Aggarwal, 2026) and LexicalRichness (Shen, 2022) Python libraries to calculate all the readability and lexical complexity metrics. In particular, we observe the *differences* in these metrics between the original and simplified texts, so that rather than relying on absolute metric values, we assess the *reduction in complexity*, which allows us to do better comparisons cross-linguistically. Our code is open sourced and available at: `https://github.com/uit-hdl/multilingual-text-simplification-icd-11`

4 Results & Discussion

Figure 2 shows the differences in complexity and readability metrics measured on English texts. The general paraphrasing models LingConv and PRISM produce the worst texts, but in different ways: LingConv tends to produce just one short and simple sentence (e.g. "Schizophrenia is known as a disease."), while PRISM tends to keep sentences very close to the original definitions ("Schizophrenia can be characterized by disorders").

Rank	#1	#2	#3
Best (1)	4, 0	**8**, 7	0
Good (2)	**9**, **8**	**9**, 6	1, 2
Medium (3)	7, 6	2, 3	3, 7, 8, 9
Poor (4)	**5**, **1**	4, **5**	4, 6
Worst (5)	3, 2	**1**, 0	**5**

Table 1: Human experts' rankings of the texts in English, BioMistral model's runs 0–9, grouped into categories from 1 to 5. We mark runs with $\geq$2 annotator agreement and no opposing third (Cohen's $\kappa \approx 0$).

Thus, the first two rows stand for extreme cases, where LingConv is too simple and PRISM is too complex. Ascle models produced texts of mediocre quality, somewhat close to PRISM but not as complex (e.g. "Schizophrenia is a mental illness that is characterized by changes").[5] BioMistral model produced the most natural simplified texts when given 6A20 article as input compared to the other models (e.g. "Schizophrenia is a mental illness that affects how you think, feel, and behave").

Observing the differences in metrics, we notice that MTLD (3rd column in Figure 2) and FRE (6th column) are the most prominent features[6]. The best simplified texts of the 6A20 article in English produced by BioMistral are characterized by increase in MTLD (in red) with a *simultaneous* increase in FRE (in red). The only results with substantial increase of these two metrics were produced by BioMistral when processing 6A20 and 6A23

[4]The library textstat provides adaptations of FRE and Fog to several languages: https://pypi.org/project/textstat/.

[5]See original texts in Appendix, Table 2.

[6]Note that some of the metrics cannot show big difference in values by nature, e.g. based on grade level; we observed each of these metrics separately and did not find any consistent patterns with respect to the quality of the models' output.

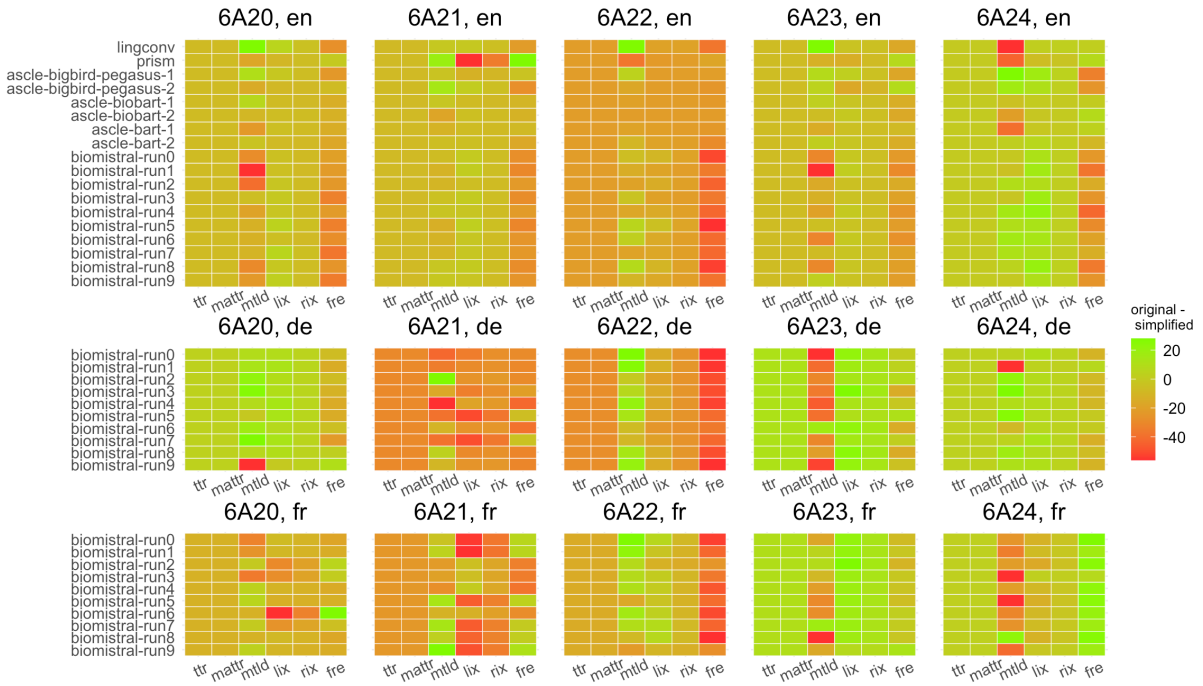

Figure 3: Difference in complexity and readability metrics between the original and simplified texts: across 5 ICD-11 articles (6A20–6A24), 3 languages (English, German, French) and 9 models.

articles.

The other models mostly produce texts which either show a decrease in MTLD (in green) and increase in FRE (in red) or vice versa, or no change compared to the original texts.

We did an additional check by three human experts to evaluate the texts produced by BioMistral in English for 6A20 definition to see if the fluctuations in MTLD and FRE align with human judgements (Table 1). While the human experts reported that generally the texts look similar to each other, they could identify some best and worst results within the BioMistral runs: at least two of the experts mark runs 8, 9 as the best and 1, 5 as the worst. Best results have a moderate increase in MTLD (in the range of 27–37), unlike the worst texts, where the increase in MTLD is very high (82 in run 1) or very low (8 in the run 5) (see examples in Appendix, Table 3).

Figure 3 shows the differences in complexity metrics across English, German and French. We only present results of the BioMistral model, as the other multilingual model PRISM did not produce any paraphrases neither in German nor in French; in fact, some English outputs contained mixed expressions with French or Spanish (e.g. "caractérisated"). BioMistral in German and French struggles more than in English: texts mostly remain complex, contain grammatical mistakes and are not smooth. This is reflected by increase in MTLD (in red) and decrease in FRE (in green) and vice versa (see examples in Appendix, Table 4, 5).

Some poor-quality results might be due to the inherent properties of the input text, e.g. 6A22 is a short article, thus, not much transformation is happening in all three languages: FRE increases as expected, but MTLD consistently decreases. This is also noticeable in differences of the number of word tokens and types (see Appendix, Figure 4).

5 Conclusion

In this study, we explored 3 lexical complexity and 9 readability metrics to evaluate multilingual text simplification in the mental health domain. We find that a combination of differences in MTLD and FRE helps evaluating simplified texts: increase of FRE means that words become shorter, and increase in MTLD makes the lexical diversity higher, while decrease in MTLD results in repetitive words. Increase in MTLD and decrease in FRE signify the opposite: words become longer and there is high lexical diversity, making texts too dense. In addition, small LMs worked well only on English, while German and French resulted in poor-quality texts. We suggest exploring these metrics for medical text simplification further with LLMs and using them as a pre-check for human evaluation.

Limitations

This is a preliminary study, and we acknowledge that stronger claims could be made if we had extended our analysis to more models, languages and text samples. We report mostly negative results in terms of the quality of the simplified texts; however, we intentionally limit this study to small models to allow for better control and exploration of the evaluation metrics. We recognize that higher-quality texts and more effective use of the metrics would likely be achieved when using large language models.

Original text (en)	Original text (de)	Original text (fr)
Schizophrenia is characterised by disturbances in multiple mental modalities, including thinking (e.g., delusions, disorganisation in the form of thought), perception (e.g., hallucinations), self-experience (e.g., the experience that one's feelings, impulses, thoughts, or behaviour are under the control of an external force), cognition (e.g., impaired attention, verbal memory, and social cognition), volition (e.g., loss of motivation), affect (e.g., blunted emotional expression), and behaviour (e.g., behaviour that appears bizarre or purposeless, unpredictable or inappropriate emotional responses that interfere with the organisation of behaviour). Psychomotor disturbances, including catatonia, may be present. Persistent delusions, persistent hallucinations, thought disorder, and experiences of influence, passivity, or control are considered core symptoms. Symptoms must have persisted for at least one month in order for a diagnosis of schizophrenia to be assigned. The symptoms are not a manifestation of another health condition (e.g., a brain tumour) and are not due to the effect of a substance or medication on the central nervous system (e.g., corticosteroids), including withdrawal (e.g., alcohol withdrawal). Schizophrenia, first episode should be used to identify individuals experiencing symptoms that meet the diagnostic requirements for Schizophrenia (including duration) but who have never before experienced an episode during which diagnostic requirements for Schizophrenia were met. Schizophrenia, multiple episodes should be used to identify individuals experiencing symptoms that meet the diagnostic requirements for Schizophrenia and who have also previously experienced episodes during which diagnostic requirements were met, with substantial remission of symptoms between episodes.	Schizophrenie ist durch Störungen in mehreren mentalen Modalitäten gekennzeichnet, einschließlich des Denkens (z. B. Wahnsymptome, Desorganisation in der Form des Denkens), der Wahrnehmung (z. B. Halluzinationen), des Selbsterlebens (z. B. das Erleben, dass die eigenen Gefühle, Impulse, Gedanken oder das Verhalten unter der Kontrolle einer externen Kraft stehen), der Kognition (z. B., Beeinträchtigung der Aufmerksamkeit, des verbalen Gedächtnisses und der sozialen Kognition), des Willens (z. B. Motivationsverlust), des Affekts (z. B. reduzierter Gefühlsausdruck) und des Verhaltens (z. B. Verhalten, das bizarr oder zwecklos erscheint, unvorhersehbare oder unangemessene emotionale Reaktionen, die die Organisation des Verhaltens stören). Psychomotorische Störungen, einschließlich Katatonie, können vorhanden sein. Anhaltende Wahnvorstellungen, anhaltende Halluzinationen, Denkstörungen und Beeinflussungserleben gelten als Kernsymptome. Die Symptome müssen mindestens einen Monat lang bestanden haben, damit die Diagnose Schizophrenie gestellt werden kann. Die Symptome sind nicht Ausdruck eines anderen Gesundheitszustands (z. B. eines Hirntumors) und sind nicht auf die Wirkung einer Substanz oder eines Medikaments auf das zentrale Nervensystem (z. B. Kortikosteroide) zurückzuführen, auch nicht auf einen Entzug (z. B. Alkoholentzug). Schizophrenie, erste Episode sollte verwendet werden, um Personen zu identifizieren, deren Symptome die diagnostischen Anforderungen für Schizophrenie (einschließlich Dauer) erfüllen, die aber noch nie eine Episode erlebt haben, in der die diagnostischen Anforderungen für Schizophrenie erfüllt wurden. Schizophrenie, mehrfache Episoden sollte verwendet werden, um Personen zu identifizieren, die Symptome aufweisen, die die diagnostischen Anforderungen für Schizophrenie erfüllen, und die auch schon früher Episoden erlebt haben, in denen die diagnostischen Anforderungen erfüllt waren, wobei die Symptome zwischen den Episoden deutlich zurückgegangen sind.	La schizophrénie se caractérise par des perturbations de multiples modalités mentales, notamment la réflexion (p. ex. idées délirantes, désorganisation dans la forme de la pensée), la perception (p. ex. hallucinations), l'expérience de soi (p. ex. l'impression que ses propres sentiments, impulsions, pensées ou comportements sont sous le contrôle d'une force externe), la cognition (p. ex. trouble de l'attention, de la mémoire verbale et de la cognition sociale), la volition (p. ex. perte de motivation), l'affect (p. ex. expression émotionnelle émoussée) et le comportement (p. ex. comportement qui semble bizarre ou inutile, réactions émotionnelles imprévisibles ou inappropriées qui perturbent l'organisation du comportement). Des troubles psychomoteurs, y compris une catatonie, peuvent être présents. Les idées délirantes persistantes, hallucinations persistantes, troubles de la pensée et expériences d'influence, de passivité ou de contrôle sont considérés comme des symptômes fondamentaux. Les symptômes doivent avoir persisté pendant au moins un mois pour qu'un diagnostic de schizophrénie soit posé. Les symptômes ne sont pas une manifestation d'une autre affection médicale (p. ex. une tumeur cérébrale) et ne sont pas dus à l'effet d'une substance ou d'un médicament sur le système nerveux central (p. ex. corticostéroïdes), y compris à un sevrage (p. ex. sevrage alcoolique). La schizophrénie, premier épisode doit être utilisée pour identifier les individus qui présentent des symptômes satisfaisant les critères de diagnostic de la schizophrénie (y compris la durée) mais qui n'ont jamais présenté d'épisode précédent durant lequel les critères de diagnostic de la schizophrénie étaient satisfaits. Schizophrénie, épisodes multiples doit être utilisé pour identifier les personnes présentant des symptômes qui répondent aux critères diagnostiques de la schizophrénie et qui ont également déjà connu des épisodes au cours desquels les critères diagnostiques ont été remplis, avec une rémission substantielle des symptômes entre les épisodes.

Original text (en)	Original text (de)	Original text (fr)
Some attenuated symptoms may remain during periods of remission, and remissions may have occurred in response to medication or other treatment. Symptoms fulfilling all definitional requirements of Schizophrenia have been present for almost all of the illness course over a period of at least one year, with periods of subthreshold symptoms being very brief relative to the overall course.	Einige abgeschwächte Symptome können während der Remissionsphasen bestehen bleiben, und Remissionen können als Reaktion auf Medikamente oder andere Behandlungen eingetreten sein. Die Symptome, die alle definitorischen Anforderungen der Schizophrenie erfüllen, waren fast während des gesamten Krankheitsverlaufs über einen Zeitraum von mindestens einem Jahr vorhanden, wobei die Perioden mit unterschwelligen Symptomen im Vergleich zum Gesamtverlauf sehr kurz waren.	Certains symptômes atténués peuvent persister pendant les périodes de rémission, et des rémissions peuvent se produire en réponse à des médicaments ou à un autre traitement. Des symptômes satisfaisant tous les critères de définition de la schizophrénie ont été présents pendant la quasi-totalité de l'évolution de la maladie sur une période d'au moins un an, avec des périodes de symptômes en-dessous du seuil très brèves par rapport à l'évolution globale.

Schizophrenia is a mental illness that affects many different parts of the mind. It can cause problems with thinking, feeling, and behaving. People with schizophrenia might have strange thoughts or beliefs (delusions), see or hear things that aren't really there (hallucinations), feel like their thoughts or actions are being controlled by someone else, or have trouble remembering things or paying attention. They might also feel less motivated, have trouble controlling their emotions, or behave in ways that seem strange or out of place. Sometimes, people with schizophrenia might become stuck in one position for a long time (catatonia). To be diagnosed with schizophrenia, a person must have had symptoms for at least a month that are not caused by another medical condition or by drugs or alcohol. Schizophrenia is usually divided into three categories: first episode, multiple episodes with remission, and persistent. First episode schizophrenia.	Schizophrenia is a mental illness that affects the way you think, feel, act, and sense things. It can cause problems with your thoughts, like having false beliefs or trouble organizing your thoughts. It can also affect your senses, like hearing or seeing things that aren't really there. You may feel like your emotions are out of control or that you're not in control of your own actions. You might have trouble remembering things or paying attention. You may lose motivation or interest in things. People with schizophrenia may behave in strange or unusual ways, like being overly emotional or having trouble controlling their body movements. They may also have trouble understanding social situations or other people's feelings. Psychomotor disturbances, like being stuck in one position for a long time, may be present. To be diagnosed with schizophrenia, you must have symptoms that have lasted for at least a month and that are not caused by another medical condition or

Abstract

The rapid expansion of biomedical literature presents a major challenge for researchers seeking to organize knowledge, identify emerging scientific trends, and explore large PubMed result sets. Existing literature exploration systems primarily rely on predefined ontologies, user-selected features, or clustering approaches that may produce unstable topic structures across runs. We present BioTopicXplor, a tool for interactive exploration of user-defined PubMed article collections through reproducible topic discovery and hierarchical organization.

BioTopicXplor is powered by ConvexTopics, an optimization-based topic modeling framework that formulates topic discovery as a convex optimization problem with mixture model parameters drawn directly from the data. Unlike traditional clustering approaches that depend on random initialization and may converge to local optima, ConvexTopics guarantees convergence to a global optimum, eliminates the need to predefine the number of topics, and produces stable, fine-grained, and interpretable topic structures across repeated runs on the same corpus.

To support intuitive exploration, BioTopicXplor integrates large language models to generate concise literature-grounded summaries and organize fine-grained subtopics into higher-level thematic groups. The system combines reproducible topic modeling with an interactive human-centric interface that enables users to navigate biomedical literature collections from broad conceptual themes to specific subtopics and associated PubMed articles. BioTopicXplor is freely available at: https://www.ncbi.nlm.nih.gov/CBBresearch/Wilbur/IRET/topics/dev/create.html.

1 Introduction

The exponential growth of biomedical publications presents a critical challenge for researchers seeking to organize, interpret, and discover knowledge or emerging scientific trends. PubMed (https://pubmed.ncbi.nlm.nih.gov/) remains the main gateway to biomedical literature and provides access to relevant documents given a query. However, it does not offer support for understanding the conceptual structure of a collection.

Several companion tools enable alternative options for exploring biomedical literature. Anne O'Tate (Engwall, 2017) enables users to analyze PubMed search results by ranking and grouping articles based on important words in titles and abstracts. It also allows clustering by MeSH term–based topics, author names, affiliations, journal names, and publication year. BioTextQuest v2.0 (Theodosiou et al., 2024), extends this paradigm by offering interactive clustering based on user-selected biomedical terms. Ontology-based interfaces such as GoPubMed (Doms and Schroeder, 2005) organize PubMed records within structured vocabularies, including Gene Ontology and medical Subject Headings (MeSH), facilitating exploration but remaining constrained to predefined ontological categories rather than enabling unsupervised topic discovery. While these tools facilitate exploration, they rely on predefined features and user-selected terms, or curated ontologies to organize the literature. As a result, they may be limited in their ability to capture the data-driven structure of a document collection or to reveal fine-grained, emergent topics in an unsupervised way.

To address these limitations, we present BioTopicXplor, a tool for interactive exploration of user-defined PubMed article collections. Given a PubMed query, BioTopicXplor performs on-demand clustering/topic discovery and organizes the resulting topics into an intuitive representation that supports exploration of literature collections both through navigating the topics and querying within the topics.

BioTopicXplor is powered by ConvexTopics

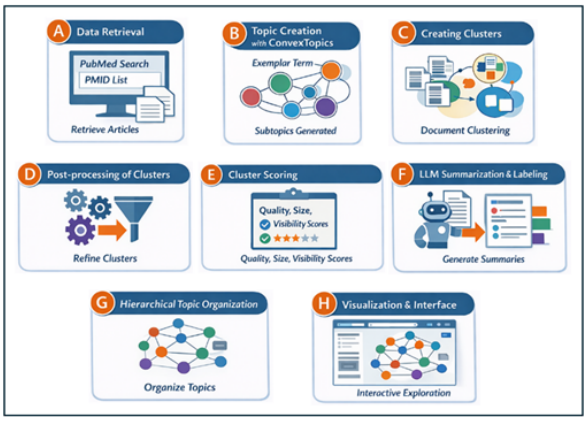

Figure 1: BioTopicXplor architecture.

(Yeganova et al., 2026), an optimization-based topic modeling framework that is formulated as a convex optimization problem with exemplars drawn directly from the data (Lashkari and Golland, 2007). We chose this approach to avoid limitations of traditional clustering methods such as K-means (Ja, 1979) or expectation–maximization for mixture models (Blei et al., 2003). These suffer from sensitivity to initialization and convergence to local optima, limiting reproducibility and scalability on large corpora. As a result, these methods generally produce different document or term groupings across runs.

ConvexTopics guarantees convergence to a global optimum, which means it yields the same set of topics across repeated runs on the same document collection. Additionally, it eliminates dependence on random initialization, and the need to predefine the number of topics. The algorithm produces a large number of fine-grained topics, referred to as subtopics.

To support interpretation and exploration of these subtopics, BioTopicXplor integrates large language models for two key tasks: (1) to generate concise summaries for each subtopic, and (2) to construct a second layer that organizes subtopics into higher-level groups, referred to as major topics. This hierarchical structure enables users to navigate from broad thematic areas to more specific ones. In addition, the tool provides a search functionality that allows users to query and explore subtopics interactively. We demonstrate the utility of the system through application to anti-aging literature, illustrating its ability to reveal meaningful thematic structure leading to knowledge discovery.

2 System Overview

Given a user-specified PubMed query, BioTopicXplor retrieves the corresponding articles, applies the ConvexTopics framework to generate a set of subtopics, and subsequently organizes them into higher-level, more general topics. The overall pipeline (illustrated in Figure 1) integrates data retrieval, text processing, optimization-based topic modeling, document clustering, and visualization components, as well as large language models to generate summaries for each subtopic, allowing users to seamlessly move from raw literature collections to structured, interpretable topics.

As LLMs become increasingly integrated into biomedical text mining, their ability to generate user-friendly summaries is highly valuable. However, they remain prone to hallucination. ConvexTopics provides a stable backbone that constrains the use of LLMs, ensuring that summaries are grounded in algorithmically derived topics. We believe this controlled integration provides the benefit of human-readable summaries while minimizing hallucinations by keeping the summaries tightly anchored to the topic terms and relevant documents computed by ConvexTopics.

Data Retrieval. BioTopicXplor begins by retrieving a set of PubMed articles based on a user-specified query. By default, the retrievals are limited to the last five years. The system collects titles and abstracts for downstream processing.

Creating Subtopics with ConvexTopics The subtopics are computed using the ConvexTopics algorithm (Yeganova et al., 2026), which reformulates clustering as a convex optimization problem by restricting potential cluster centers to exemplars drawn directly from the data. This transforms what is ordinarily a combinatorial search into a tractable convex objective that is guaranteed to converge to a globally optimal solution (Lashkari and Golland, 2007). Applied to biomedical text, the algorithm operates over a vocabulary of statistically enriched single terms and noun phrases, as many biomedical concepts are expressed as multi-word expressions (Yeganova et al., 2009, 2011). Term similarity is measured via the Dice coefficient (Manning, 2008). The number of resulting subtopics is determined automatically during computation, yielding fine-grained, reproducible topic structures without manual tuning. Each subtopic is defined by an exemplar and a set of representative terms that are used to rank documents by relevance.

Creating Document Clusters. For each subtopic created above, we use its topic terms to compute the list of the most relevant PubMed articles. These documents are selected based on their relevance to the topic terms and provide a cluster of documents associated with each topic. Clicking on a PubMed ID or article title leads to the article view in PubMed, where one can read, download, or follow links to full-text, if available.

Post-processing of Clusters. Following initial clustering, a post-processing step is applied. Redundant clusters and clusters with substantial overlap (greater than 50% shared documents) are removed to ensure a diverse and non-redundant set of subtopics.

Cluster Scoring. Each topic/cluster is assigned three scores based on the following criteria: (i) an intrinsic cluster quality score, (ii) the size of the cluster measured by the number of associated documents, and (iii) a visibility score that reflects the prominence of the ten top scoring topic terms in the ten top scoring documents. Each of these scores can be used to rank subtopics for presentation.

Summarization and Labeling. BioTopicXplor employs large language models to generate concise, literature-grounded summaries and descriptive titles for each subtopic. The summaries are generated based on the top ten documents associated with each cluster using GPT-5.1. Each generated summary sentence is linked to PMID(s) that were used for extracting the underlying evidence. The title is generated to best describe the summary.

Hierarchical Topic Organization. To organize the large number of subtopics for presentation, they are grouped into higher-level topics (major topics). This step leverages large language models to group semantically related subtopics and construct a hierarchical representation.

Visualization and Interface. The resulting higher-level topics are presented through an interactive interface that allows users to explore clusters, view summaries, and access associated PubMed articles. The visualization is designed to provide an overview of the conceptual structure of literature.

Implementation Details. The user-facing web interface was developed in-house using standard HTML, CSS, and JavaScript. The front end is compatible with modern desktop browsers and iPads. Although not specifically optimized for phone screens, the server is functional on mobile devices. User requests are submitted to the server, which was also developed in-house using C++ and Python. Both the front end and backend components run on a Linux-based system. The system runs on a shared machine equipped with a 12-core Xeon(R) Gold CPU operating at up to 2.30 GHz and 196 GB of RAM. Most of the processing time is spent generating cluster titles and summaries using an OpenAI GPT model, currently GPT-5.1.

3 Usage

Users initiate an analysis by submitting a PubMed query, after which the system automatically retrieves the corresponding articles and executes the full processing pipeline. The results are provided through a uniquely generated web link. Multiple analyses can be conducted concurrently, and previously generated instances remain available for subsequent exploration.

View Major Topics. On the main page, users are presented with Major Topics derived for the dataset. These serve as starting points for exploration. Selecting a Major Topic leads to corresponding Subtopics, which can be ranked according to multiple scoring criteria.

Explore Subtopics. Each subtopic is associated with a dedicated page that includes a concise summary and title generated from the ten most relevant documents, a ranked list of associated PubMed articles with links for direct access, and a set of topic terms defining the topic.

Explore the data through Search. In addition to hierarchical navigation, the system supports keyword-based search across topics. Search can be performed globally across the entire collection or restricted to a specific major topic, enabling targeted exploration of relevant subtopics.

Use Case: Exploring Anti-Aging literature in PubMed. The growing interest in longevity and anti-aging has led to a proliferation of resources promoting various interventions, not all of which are supported by rigorous scientific evidence. This underscores the need for systematic analysis of biomedical literature to distinguish evidence-based claims. Using anti-aging research as a representative use case, (Yeganova et al., 2026) demonstrates how BioTopicXplor, applied to 12,000 PubMed articles, captures the research landscape through nuanced subtopics with summaries, and hierarchical organization.

Figure 2 illustrates the framework. The left panel shows the main page, where users are presented with a list of major topics. The right panel shows

a detailed topic page. Demonstrated in Figure 2 is a topic page produced by choosing the "Gut Microbiota and aging" major topic and selecting the "Beneficial Bacteria and Natural Compounds Combat Aging" subtopic.

Using this analysis, (Yeganova et al., 2026) observed that although NAD supplements are widely available, their safety remains insufficiently supported by evidence. Key uncertainties include pharmacokinetics and pharmacodynamics, particularly bioavailability, metabolism, and tissue specificity (Poljšak et al., 2022). Moreover, the lack of long-term safety studies and limited clinical trials leaves optimal dosing unclear, with some studies suggesting a potential risk of kidney inflammation in older populations (Song et al., 2023; Nadeeshani et al., 2022).

4 Evaluation

Many factors can be considered for evaluating BioTopicXplor as an end-to-end system, examining not only the quality of the topics produced by ConvexTopics but also the interpretability and utility of the resulting framework.

The quality of Subtopics. The ConvexTopics algorithm has been evaluated on both general-purpose NLP benchmarks and biomedical text corpora in (Yeganova et al., 2026). The annotated baselines include 20-Newsgroups (`http://people.csail.mit.edu/jrennie/20Newsgroups`) and Reuters-21578 (Lewis et al., 2004), while the biomedical datasets consist of PubMed articles on Anti-Aging, Diabetes Mellitus, and Age-Related Macular Degeneration. ConvexTopics was compared with state-of-the-art clustering and topic modeling approaches, including K-means (Ja, 1979; Lloyd, 1982), LDA (Blei et al., 2003) and BERTopic (Grootendorst, 2022) and was shown to perform favorably.

The quality of Major Topics. To facilitate navigation, BioTopicXplor organizes subtopics into major topics using large language models. We evaluated this hierarchical structure through manual inspection. The major topics were observed to correspond to meaningful thematic groupings, providing a coherent high-level view of the literature while preserving access to detailed subtopics. While some variations in major topics may occur accross the runs, the resulting groupings remain meaningful.

Timing. Depending on the size of the dataset, processing may take up to several hours. For example, analysis of 1,099 documents retrieved using the query “familial Mediterranean fever” (limited to 5 most recent years) completed in 65 minutes, while the same query without time restriction produced 5,731 documents and required 87 minutes. The relatively small increase in processing time between 1,099 and 5,731 documents is explained by the fact that overall runtime is dominated not by ConvexTopics clustering itself, but by downstream LLM-based summarization and hierarchical organization steps. These stages depend primarily on the number of generated subtopics and summaries. We are currently working on enabling users to access preliminary results generated by ConvexTopics, allowing them to access the subtopics before the full set of summaries and hierarchical organization is completed.

5 Discussion and Conclusions

BioTopicXplor provides a scalable, reproducible framework for organizing and exploring biomedical literature. It enables exploration not possible with PubMed alone, and is particularly valuable for researchers entering a new area or seeking deeper understanding of a topic. It may also benefit a broader audience by providing a human-interpretable overview of terminology-heavy PubMed literature. We demonstrate its effectiveness through application to the rapidly growing field of anti-aging. Across domains, BioTopicXplor reveals meaningful substructures and maintains consistent topic organization.

Several limitations should be noted. ConvexTopics tends to produce a large number of subtopics, requiring additional post-processing and hierarchical organization to improve interpretability. Additionally, as a web-based system, BioTopicXplor is subject to computational and latency constraints when processing very large document collections in real time. A substantial portion of the processing time is spent generating topic summaries and titles using large language models. These titles are important for comprehension, and play a role in organizing subtopics into higher-level topics. We find that the improved interpretability and resulting organizational structure provided to the user justify the increased processing time.

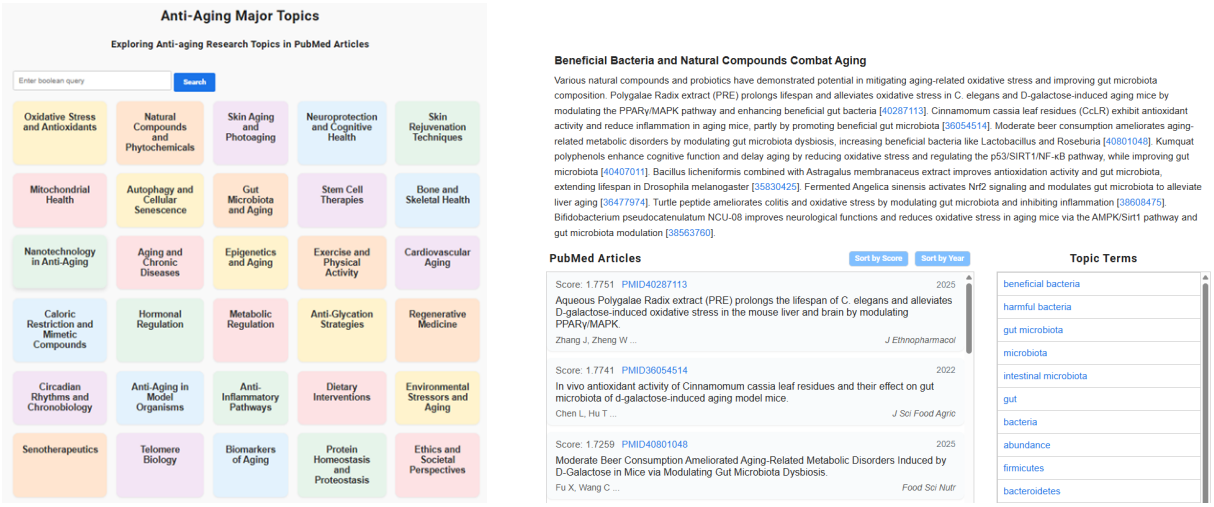

Figure 2: The visualization of the BioTopicXplor applied to the Anti-Aging literature in PubMed. Left panel shows the high-level topics displayed on the main page. Clicking one of these major topics leads to a list of subtopics relevant to the major topic. Clicking on a subtopic leads to a topic page containing topic terms, related pmids, topic summary and title, presented on the right panel. The graphics are adapted from the earlier ConvexTopics paper.

Reading Between the Lines: Toward Translating Verbose Patient-authored Messages into Clinician-Formulated Questions

Sarvesh Soni, Madeline Bittner, Dina Demner-Fushman
Division of Intramural Research
National Library of Medicine, National Institutes of Health, Bethesda, MD, USA
{sarvesh.soni, madeline.bittner}@nih.gov, ddemner@mail.nih.gov

Abstract

Patient portal messages often embed clinical questions inside long, emotionally nuanced narratives, requiring clinicians to infer the underlying information need. We study the task of rewriting verbose patient-authored narratives into concise, clinician-interpreted questions framed as if querying an electronic health record (EHR) system. We evaluate a lightweight LLM-based rewrite pipeline that constrains outputs to 10–15 words and uses rule-based validation with regeneration. We test the approach on 140 distinct patient questions drawn from the ArchEHR-QA dataset and shared task. Each system output is double-annotated by two annotators for quality (Good/Ok/Bad) and error types (Generic, Malformed, Tangential, Hallucination). Results show that while models follow output constraints, they often produce overly generic or tangential questions, and occasional hallucinations introduce unsupported clinical details. Across both clinician-question and patient-narrative comparison settings, automatic metrics show substantial overlap across human quality labels; in pairwise meta-evaluation, BERTScore is the strongest proxy for human preferences. We release our code and annotations to support future work[1].

1 Introduction

Patients frequently contact healthcare teams via patient portals with questions about tests, diagnoses, and care plans (Tai-Seale et al., 2017). In practice, these questions are often embedded in lengthy narratives with extraneous detail, uncertainty, and emotion (Table 1), forcing clinicians to "read between the lines" to determine what the patient is actually asking (Dymek et al., 2021; Yan et al., 2021). Translating patient-authored narratives into concise clinician-interpreted questions is key for downstream systems: it clarifies the clinical information needs, enables targeted retrieval of supporting electronic health record (EHR) evidence, and reduces the risk that automated assistance addresses the wrong intent. We view this reformulation as an auxiliary representation that complements, rather than replaces, the original patient message.

Patient Question: Hi I ... started shaking ... woken up ... confused ... been told that there is a shadow on my brain ...
Clinician-interpreted Question: What caused the patient's confusion and short-term memory loss?
Output #1 (**Quality:** *Ok*; **Error:** *Generic*): What are possible causes of a brain shadow after seizure activity?
Output #2 (**Quality:** *Bad*; **Error:** *Hallucination*): What is the likely cause of the new cerebral lesion on imaging?

Table 1: Abbreviated example of question reformulation and human evaluation; full version in Appendix Table 5.

Prior work on medical question summarization targets generic consumer health queries answerable from general medical knowledge (Yadav et al., 2022). In contrast, answers to patients' EHR-related questions depend on hospitalization records. Therefore, reformulation must (i) remain faithful to patient intent, (ii) support patient-record retrieval, and (iii) avoid medical details not supported by the message. Moreover, existing methods rarely model patient-to-clinician perspective shift. Prior natural language processing work on portal messages has emphasized triage or generic response generation (Anderson et al., 2025; Biro et al., 2025); however, reformulating EHR-grounded patient narratives into clinician-style questions is underexplored. We make three contributions:

1. We present a simple large language model (LLM)-based system with constrained output, rule-based validation, and regeneration for patient-to-clinician question reformulation.

2. We conduct double-annotated human evaluation of LLM outputs, rating quality (*good*,

[1] https://github.com/soni-sarvesh/patient-question-reformulation

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 481–489
July 3-4, 2026 ©2026 Association for Computational Linguistics

ok, or *bad*) and categorizing errors (*generic*, *malformed*, *tangential*, *hallucination*).

3. We analyze automatic metrics in two comparison settings (against the reference clinician question and the patient-authored narrative) and meta-evaluate which metrics best track human preferences for model comparison.

2 Related Work

Medical question summarization. Generating clinician-interpreted questions from patient narratives is question summarization, which is widely studied for consumer health questions answerable from general medical knowledge rather than patient-specific records (Ben Abacha et al., 2021).

EHR question answering (QA) and information retrieval (IR). Most clinical QA and IR work focuses on clinician-authored questions over EHR content (Bardhan et al., 2024; Sivarajkumar et al., 2024). Differently, ArchEHR-QA (Soni and Demner-Fushman, 2026a) is a publicly available resource that pairs patient-authored narratives with clinician-interpreted questions and annotated EHR evidence for patient-specific QA. We build on this line of work by isolating the upstream *reformulation* step, focusing on translating patient language into a clinician-formulated query suitable for downstream retrieval and grounding.

Patient portal messaging. Prior work on patient portal messages has emphasized message classification and triage to reduce clinician burden and improve routing (Tafti et al., 2019; Ren et al., 2023; Anderson et al., 2025). More recently, large language models (LLMs) have been integrated for drafting responses to patient messages, raising both efficiency opportunities and safety concerns (Chen et al., 2024; Garcia et al., 2024; Biro et al., 2025). Clinician question reformulation is complementary: by surfacing the inferred clinical information need, it can support safer downstream retrieval of patient-specific evidence and grounded response drafting.

3 Methods

3.1 Data

We use patient-authored questions and corresponding clinician-interpreted questions from ArchEHR-QA (Soni and Demner-Fushman, 2026a), which links questions from public health forums about recent hospitalizations to de-identified clinical notes from MIMIC (Johnson et al., 2016, 2023). To preserve clinical fidelity, the clinical notes are unedited; the patient questions are minimally edited to match surface details in the associated note (e.g., pronoun changes such as "he" to "she"). In total, we evaluate on 140 distinct patient questions. This set combines the 108 unique questions in the original ArchEHR-QA release (134 question–note instances before deduplication) with 32 additional questions from the ArchEHR-QA 2026 Shared Task data (Soni and Demner-Fushman, 2026b).

3.2 Model

We use a simple LLM-based generation approach with rule-based validation. Given a patient-authored narrative, an instruction-tuned LLM is prompted to produce a concise clinician-interpreted question that captures inferred clinical intent and is suitable for downstream EHR-oriented use. The prompt constrains the output to a single 10–15-word clinician question to promote uniformity (Table 4). Validation uses deterministic string processing to extract the clinician question from the prompted markdown format and verify that exactly one non-empty question is present. If extraction fails (i.e., the generated output does not conform to the prompted format), the same prompt is reused for up to five attempts; the first generation that passes the format check is retained. In our runs, every retained output passed validation within five attempts. This rule-based check only enforces output format, not the 10–15-word length; the length constraint is specified in the prompt and influences generation, but is not strictly enforced post-hoc. Beyond this, we do not use retrieval, external medical knowledge, or hand-crafted rewriting rules. We evaluate two open-weight LLMs with different parameter scales: Llama 3.1 8B and 3.3 70B (Grattafiori et al., 2024); decoding and inference settings are reported in Appendix A.1.

3.3 Evaluation

Manual evaluation. Three annotators with clinical/biomedical expertise (an MD, a clinical informaticist, and a biomedical researcher) evaluated model outputs for *Quality* (*Good*: faithful and specific; *Ok*: usable but imperfect; *Bad*: unusable) and assigned *Error* labels as needed. We used four non-mutually-exclusive error categories: *Generic* (too general), *Malformed* (ill-formed), *Tangential* (not focused on the core patient intent), and *Hallucination* (unsupported details). Annotators could view

3-class *Good / Ok / Bad*		Binary {*Good, Ok*} / *Bad*	
P_o	κ	P_o	κ
36.8%	0.162	71.1%	0.234

Table 2: Inter-rater agreement on *Quality* annotations for 3-class (*Good*/*Ok*/*Bad*) and a binary recoding (*Acceptable*/*Bad*). Exact match P_o and Cohen's κ are reported.

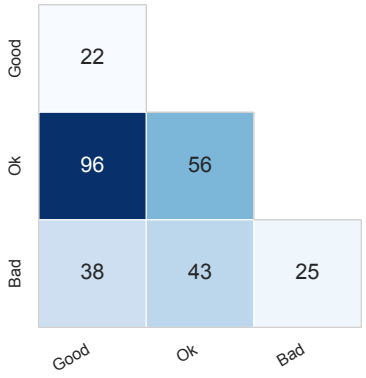

Figure 1: Pairwise agreement/disagreement matrix for *Quality* ratings between annotators ($N = 280$). Diagonal cells show agreement counts; off-diagonal cells show disagreement counts for each label pair.

the reference clinician question, but overlap with the reference was not a rating criterion, since multiple reformulations could be valid; annotators were blinded to model identity. All 280 outputs (140 cases×2 models) were double-annotated. For the first 50 cases (100 outputs), annotators discussed disagreements to calibrate guideline interpretation, but did not revise labels for subjective disagreements; the remaining cases were annotated independently, and we retain both labels without adjudicating subjective disagreements.

Automated evaluation. We compute ROUGE-L (Lin, 2004), BERTScore (Zhang et al., 2019), Medcon (Yim et al., 2023), and AlignScore (Zha et al., 2023) between each generated question and two comparison texts: the reference clinician question and the patient-authored narrative. These metrics capture lexical overlap (ROUGE), embedding similarity (BERTScore), clinical concept overlap (Medcon), and factual consistency (AlignScore).

4 Results and Discussion

The average lengths of the patient narratives and reference clinician-interpreted questions are 100.4 and 11.9 words, respectively. The Llama 8B and

Set-level (multi-label) agreement	
Metric	**Score**
Mean Jaccard similarity	0.283
Exact match rate (%)	19.3

Per-error-type agreement		
Label	P_o(%)	κ
Generic	45.7	−0.086
Malformed	93.2	0.629
Tangential	60.7	0.070
Hallucination	84.6	0.230

Table 3: Inter-rater agreement for *Error* annotations. Set-level agreement for multi-label error sets uses mean Jaccard similarity and exact match; per-error-type agreement reports percent agreement P_o and Cohen's κ.

70B models generated questions averaging 15.5 and 11.5 words, respectively. Since the 10–15-word constraint is conveyed via the prompt but not enforced by validation, these averages reflect how closely each model follows the prompted length instruction. The 70B model adheres tightly to the prompted range: 95% of its outputs fall within 10–15 words (with the remaining 5% slightly under 10). The 8B model follows the lower bound reliably (100% of outputs are at least 10 words) but frequently exceeds the upper bound, with only 48.6% of outputs in the 10–15 range.

Inter-rater Agreement. On *Quality*, annotators agreed on 36.8% of instances, increasing up to 71.1% with binary recoding (Table 2). This is consistent with a subjective boundary between *Good* and *Ok* and with the difficulty of judging adequacy; Figure 1 shows the distribution of disagreements, and Cohen's κ indicates slight agreement.

For *Error* labels, set-level agreement is moderate with the mean Jaccard similarity of 0.283, while the exact match is 19.3% (Table 3). Per-label agreement varies widely: *Malformed* errors are easiest to identify with a percent agreement (P_o) of 93.2%, whereas *Generic* is hardest ($P_o = 45.7\%$), likely because judgments about whether a reformulation is overly broad or insufficiently specific are more subjective than judgments about surface forms.

Inter-rater variability is also common in clinical interpretation itself, where specialists may legitimately disagree (Novack et al., 2006). Related open-ended biomedical annotation tasks, including Medical Subject Headings (MeSH) indexing and evaluation of generated clinical notes, also report modest inter-rater agreement (Fernandez-Llimos, 2025; Moramarco et al., 2022). We therefore pre-

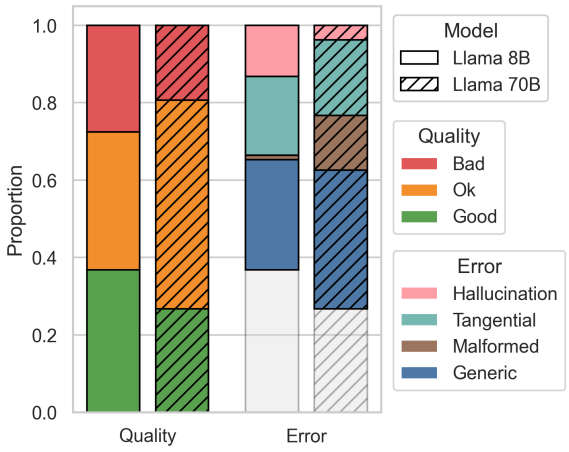

Figure 2: Human judgments of *Quality* and *Error* for questions generated by Llama 8B and 70B models.

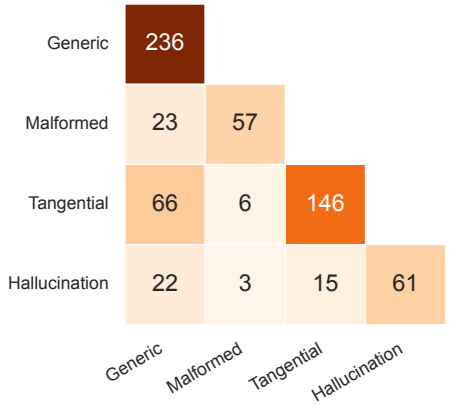

Figure 3: *Error*-label co-occurrence matrix computed over all annotator-output instances (no adjudication). Diagonal: count of each error label; off-diagonal: within-instance co-selections of error pairs.

serve these annotations as complementary annotator judgments rather than as a single gold label.

Human ratings. Figure 2 summarizes *Quality* and *Error* judgments for both models. Overall, the 70B model produces fewer *Bad* outputs, but many generations remain *Ok*, reflecting that partially correct intent capture may still be too generic or miss patient-specific nuance. Both models exhibit substantial *Generic* and *Tangential* errors; the 8B model shows a higher fraction of *Hallucination*-labeled errors, while the 70B model shows relatively more *Malformed*-labeled errors.

Error co-occurrence. Figure 3 characterizes error frequency and co-occurrence across annotated *Error* label instances (error categories are non-mutually exclusive). *Generic* is the dominant failure mode (236 instances), followed by *Tangential* (146), with *Hallucination* (61) and *Malformed* (57) occurring less frequently. *Generic* frequently co-occurs with *Tangential* (66 instances), suggesting that a model latches onto a peripheral detail and produces a broad question about it rather than the most clinically relevant information need.

Hallucinations are less common but clinically important. As shown in Table 1, hallucinations can introduce unsupported details (e.g., assuming a "lesion" when the patient only mentions a "shadow"), which would misdirect downstream EHR retrieval and response drafting. Hallucination co-occurs more often with *Generic* (22) or *Tangential* (15) than with *Malformed* (3), suggesting that hallucinations are often fluent and well-formed, making them harder to detect using format checks alone.

Automatic metrics and human quality judgments. ROUGE, BERTScore, Medcon, and AlignScore stratified by human *Quality* labels are shown in Appendix Figures 4 and 5. When computed against the reference clinician question, automatic metrics align only weakly with human *Quality* ratings. BERTScore shows the clearest upward shift for both 8B and 70B models (higher median for *Good* than *Bad*/*Ok*). ROUGE and AlignScore show heavy overlap across *Bad*/*Ok*/*Good*, and the median scores for *Good* are not consistently higher than those for *Ok* or *Bad*. Medcon is largely zero-dominated with high variance and overlap across quality levels, consistent with sparse concept overlap when only a single reference clinician question is available and when acceptable reformulations may use different clinically meaningful terms. Thus, automated metrics may flag very low-scoring outliers but do not reliably distinguish reformulations with different *Quality* labels and may miss clinically consequential errors (e.g., fluent hallucinations), reinforcing the need for expert evaluation and richer multi-reference benchmarks. Using the patient-authored narrative instead yields the same broad conclusion: metric score distributions still overlap substantially across quality labels. However, the clinician-question setting appears somewhat more informative overall, most clearly for BERTScore, while differences for the other metrics are smaller or less consistent.

Automatic metrics and human pairwise preferences. We meta-evaluate automatic metrics against human pairwise preferences, following

prior work (Freitag et al., 2024), on the subset of cases where the two systems received different human quality ratings (Appendix Table 6). When computed against the reference clinician question, BERTScore achieves the highest overall pairwise accuracy (PA; 61.0%) and is the best metric in each quality-pair bucket, whereas ROUGE-L and AlignScore remain below 50% PA overall. When computed against the patient narrative, BERTScore still ranks first (52.0%), but the gap to ROUGE-L and AlignScore narrows (both 48.0%). Medcon remains weaker, though its PA increases from 26.8% with clinician questions to 40.7% with patient narratives. Overall, BERTScore is the strongest proxy for human preferences in our setting.

5 Conclusion

In a simple LLM-based constrained generation approach to translating verbose patient-authored narratives into concise clinician-interpreted questions, with outputs assessed through double-annotated human evaluation, we found that fluent rewrites are often *generic* or *tangential*, and occasional *hallucinations* introduce unsupported clinical details. Automatic metrics do not cleanly separate more useful reformulations from less useful ones; in pairwise meta-evaluation, BERTScore provides the most informative signal for relative model comparison among the metrics we tested.

Limitations

First, clinician interpretation of a patient narrative is inherently subjective, and we do not adjudicate disagreements; instead, we retain multi-annotator labels. While this better reflects variation in clinician reasoning, it complicates learning and evaluation with a single "gold" label. Second, each instance currently provides only one reference clinician-interpreted question, even though multiple rewrites may be equally acceptable. This is mitigated by the judgments on the generated questions that could now be used as paraphrases in future evaluations. Third, we evaluate two open-weight models from a single family (Meta Llama 3.1 8B and 3.3 70B). This is a deliberate scope choice: the paper's contribution is a characterization of reformulation error modes and a meta-evaluation of automatic metrics, rather than a leaderboard-style model comparison. The specific error rates and metric rankings may not transfer to other open-weight, proprietary, or clinically adapted LLMs. Fourth, the 10–15-word output constraint was chosen to promote uniformity and to discourage models from echoing patient narrative verbatim, but it can force compression of multi-part patient concerns into a single question. The reference clinician questions in ArchEHR-QA average 11.9 words, and themselves often collapse compound concerns; we did not separately quantify how often important nuance is lost by the constraint. Relaxing or removing the length cap, or allowing multiple sub-questions, is worth exploring in future work. Fifth, the evaluation set contains 140 patient cases, so small between-model differences should not be over-interpreted. Sixth, we report one final valid generation per model–instance pair under a fixed prompting and decoding setup. The pipeline is intentionally simple and is not tuned to maximize task performance through extensive prompt engineering, retrieval augmentation, or model adaptation. Stronger systems or averaged multi-sample evaluations could change the absolute performance levels and possibly the relative behavior of the automatic metrics. Finally, our evaluation isolates the reformulation step and does not measure downstream effects such as evidence retrieval or answer grounding; assessing these is a natural next step.

Ethical considerations

This work uses a publicly available, de-identified dataset and releases additional annotations for research. Nevertheless, the task involves clinical language and could be misused if deployed without oversight. In particular, hallucinated clinician questions could misdirect evidence retrieval or clinical reasoning. We position our work as a benchmark and analysis of failure modes, and any real-world deployment should include clinician-in-the-loop review, monitoring for hallucinations, and safeguards against inappropriate clinical decision-making.

A Implementation Details

This section reports decoding settings and the complete generation prompt.

You are provided with a patient question under `[PATIENT NARRATIVE]`.

`[PATIENT NARRATIVE]:`

`{...}`

Your task is to generate a clear and concise clinician question that a clinician would interpret from the patient narrative. Assume that the clinician is asking this question to a smart electronic health record system to help themselves in formulating a response to the patient. Restrict the length of the clinician question between 10 to 15 words.

Format instructions: Output your response in a markdown format, containing only the clinician question. For example:

```clinician-question
This is a clinician-version of the patient question.
```

Table 4: Complete prompt used to automatically generate the clinician-interpreted questions.

A.1 Hyperparameters

We use fixed decoding parameters for all runs (HuggingFace Transformers text-generation pipeline): do_sample=True, temperature=0.9, top-p=0.6, top-k=50, repetition_penalty=1.05, and max_new_tokens=512; we do not perform hyperparameter search. For each model and patient narrative, we generate a single final clinician question (with up to five retries only when the output fails format/length validation); we do not sample multiple valid generations or average across random seeds.

A.2 Prompt

Table 4 gives the complete prompt used to generate clinician-interpreted questions.

B Supplementary Example

Table 5 provides the full version of the abbreviated example in Table 1.

C Supplementary Analyses

This section provides supplementary figures, tables, and analyses that complement the results in the main text.

C.1 Quality-rating disagreements

Figure 1 shows that disagreements were mostly between adjacent labels (*Good* vs. *Ok*: 96; *Bad* vs. *Ok*: 43) rather than the extremes (*Good* vs. *Bad*: 38), supporting the use of multi-annotator labels rather than a single adjudicated "gold" label.

Patient Question: Hi I was in hospital in a critical care unit after having a fit and started shaking on one side of my body. I spaced out. I have woken up but I am confused, I don't remember what happened. I have been told that there is a shadow on my brain what could this be
Clinician-interpreted Question: What caused the patient's confusion and short-term memory loss?
System Response #1: What are possible causes of a brain shadow after seizure activity? **Quality:** *Ok* | **Error:** *Generic* **Reason:** Generated question is general.
System Response #2: What is the likely cause of the new cerebral lesion on imaging? **Quality:** *Bad* | **Error:** *Hallucination* **Reason:** Patient question does not mention a lesion.

Table 5: Complete example of patient-to-clinician question reformulation and human evaluation of model outputs.

C.2 Automatic metric distributions

Figures 4 and 5 show distributions of ROUGE-L, BERTScore, Medcon, and AlignScore stratified by human *Quality* labels, computed against the reference clinician-authored question and the patient-authored narrative, respectively.

C.3 Pairwise metric meta-evaluation

Table 6 reports pairwise accuracy results for automatic metrics against human preferences under both comparison settings.

Additional observations. Table 6 also shows a few additional trends. In the clinician question setting, Medcon yields ties for more than half of the comparisons (72/123), although its accuracy rises to 64.7% when ties are excluded. These ties likely reflect Medcon's frequent zero scores, since the compared texts are short and often share few or no clinical entities. In the patient narrative setting, Medcon still produces many ties (27/123), although fewer than in the clinician question setting. We also observe greater asymmetry by the human-preferred system in the patient narrative setting, suggesting that some metrics are more sensitive to cases where the 70B output is preferred than to cases favoring the 8B output.

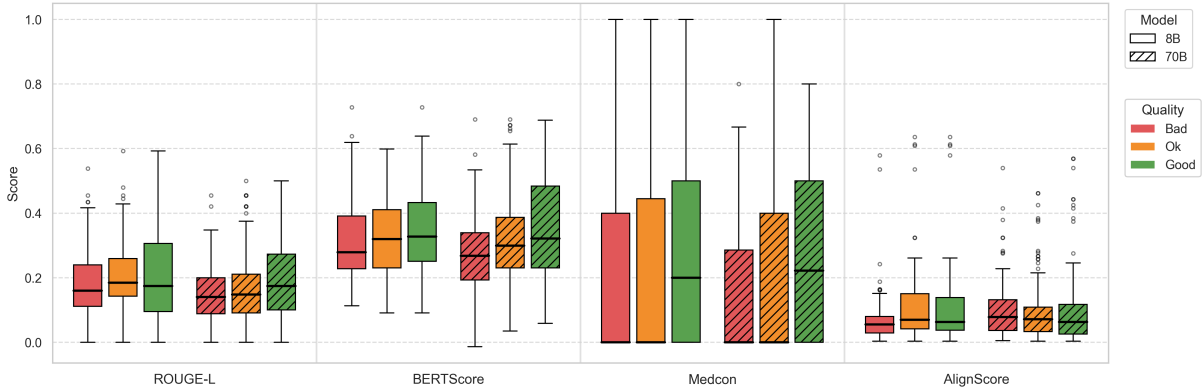

Figure 4: Distributions of automated metric scores computed between each system-generated question and the reference clinician-authored question, stratified by human *Quality* label, for outputs from Llama 8B and 70B.

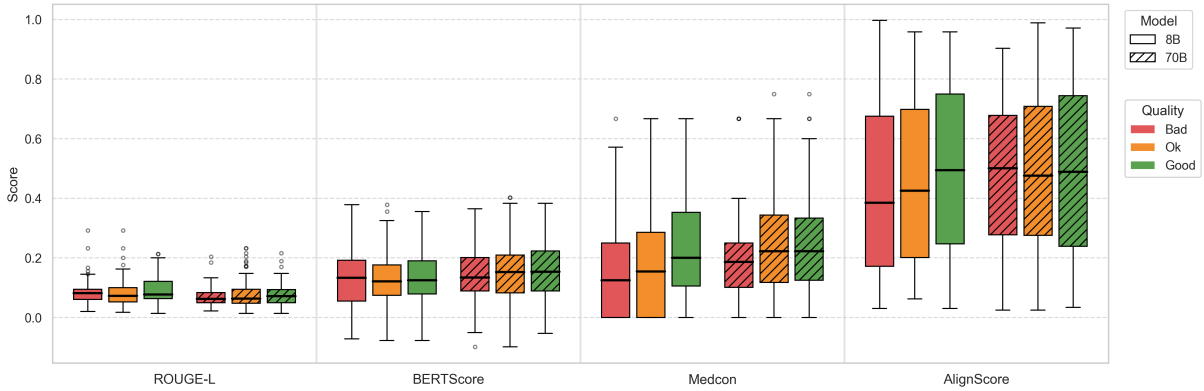

Figure 5: Distributions of automated metric scores computed between each system-generated question and the original patient-authored narrative, stratified by human *Quality* label, for outputs from Llama 8B and 70B.

Metric	Overall			PA by human winner		PA by quality pair		
	PA *N=123*	*Ties* *N=123*	*PA w/o ties* *N=123 − ties*	*8B* *N=66*	*70B* *N=57*	*good/bad* *N=28*	*good/ok* *N=58*	*ok/bad* *N=37*
Using Clinician Question								
ROUGE-L	49.6	2	50.4	51.5	47.4	60.7	44.8	48.6
BERTScore	**61.0**	0	61.0	**63.6**	**57.9**	**71.4**	**56.9**	**59.5**
Medcon	26.8	72	**64.7**	25.8	28.1	21.4	34.5	18.9
AlignScore	48.0	0	48.0	48.5	47.4	60.7	43.1	45.9
Using Patient Narrative								
ROUGE-L	48.0	4	49.6	**43.9**	52.6	**53.6**	43.1	51.4
BERTScore	**52.0**	0	52.0	39.4	**66.7**	**53.6**	**44.8**	**62.2**
Medcon	40.7	27	**52.1**	30.3	52.6	42.9	37.9	43.2
AlignScore	48.0	0	48.0	36.4	61.4	39.3	**44.8**	59.5

Table 6: Meta-evaluation of automatic metrics against human pairwise preferences on a subset of cases where the two models received different human quality ratings. PA denotes pairwise accuracy. All entries except *Ties* are percentages (%); denominators are shown below the column headers. PA treats metric ties as disagreements, whereas PA w/o ties is computed on the non-tied subset only. Columns 8B and 70B report PA conditioned on which system the human preferred, and columns good/bad, good/ok, and ok/bad report PA within each human quality-pair bucket. Bold indicates the highest overall PA within each setting.

Investigating Stigmatizing Language in Clinical Documentation with Open-Source Large Language Models

Abstract

Clinical documentation is essential for patient care, billing, and medical research, but it is subject to entrenched bias. While manual chart reviews can identify such bias, they are labor-intensive and expert-dependent. We introduce and evaluate StigMAD, a Multi-Agent Debate framework leveraging open-source Large Language Models (LLMs) to detect stigmatizing language in clinical documentation. We investigate reasoning (multi-agent debate), self-reflection, and self-consistency within this framework. Experiments on clinical notes and patient summaries demonstrate that our framework provides significant advantages over rule-based and supervised baselines. A domain-specific LLM (MedGemma) achieved its highest performance using the StigMAD reasoning framework, while a general-purpose LLM (Llama) showed superior results with the self-consistency framework. These findings suggest that open-source LLMs, steered by structured prompting and reflective reasoning, can effectively support the auditing of stigmatizing language, marking a critical step toward more equitable clinical NLP systems.

1 Introduction

A wide variety of clinical documentation, including history and physical examination notes, daily progress notes, special consults, surgery or procedure reports, discharge summaries, and nurses' notes, can contribute to narrating patient care. Holistically, these narratives provide continuity of care across diverse medical teams and support activities such as billing and medical research (Rizvi et al., 2016). They may be supplemented by other free-text healthcare documentation such as interview transcripts, patient-provider communication logs, case reports, and survey responses, especially in research or mental health settings (Park et al., 2019). However, all of this documentation may vary in tone, structure, and completeness, and bias

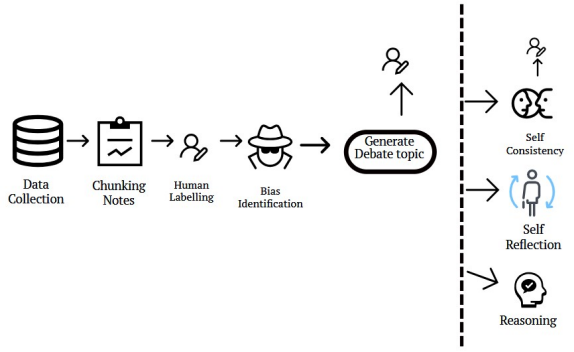

Figure 1: Methodological framework for bias detection.

can easily enter the process. For example, Black patients are more than twice as likely as white patients to have negative descriptors applied in their notes, which can influence diagnosis, treatment, and referral decisions (Sun et al., 2022). Stigmatizing language and assumptions in documentation can affect downstream AI and human decisions (Liu et al., 2023) and can produce disparities in clinical, policy, and organizational outcomes (Rozier et al., 2022). Bias can also lead to inappropriate provider decision support, lower reimbursements, and disparities in treatment recommendations, affecting clinical decision-making and contributing to health disparities in patient care (Obermeyer et al., 2019).

Bias in clinical documentation has traditionally been uncovered through manual chart review, qualitative coding, and formal interviews. All of these processes are time-consuming and expert-reliant, making them difficult to scale. To address this, researchers have started to harness artificial intelligence to uncover patterns of bias in clinical documentation (Zhang et al., 2020), for example by detecting stigmatizing language, classifying note sentiment (Valentine et al., 2024), or predicting bias-prone words. However, automatically detecting implicit forms of bias in continually evolving healthcare settings is challenging. Approaches

Proceedings of the 25th Workshop on Biomedical Language Processing (BioNLP 2026), pages 490–501
July 3-4, 2026 ©2026 Association for Computational Linguistics

often rely on fixed labeled data and miss subtle, context-dependent bias (Himmelstein et al., 2022). Frameworks relying on lexicon-based detection of these phenomena may have limited performance without further expansion and more sophisticated classification methods (Walker et al., 2025).

In this work, we introduce the STIGMAD framework, which harnesses self-consistency, self-reflection, and multi-agent debate to identify stigmatizing language using open-source LLMs, hypothesizing that the framework will enable models to reason through ambiguity and more critically analyze output. We illustrate its potential to uncover hidden stigmatizing language patterns and offer an adaptive strategy for identifying and analyzing bias in clinical documentation. Our hope is that the framework can be replicated for use with other forms of bias in the future, and we lay the groundwork for doing so in this work. Our core contributions involve (1) evaluating how effectively and confidently open-source LLMs can detect stigmatizing language in clinical documentation using the STIGMAD framework; (2) deriving how stigmatizing language observed in clinical documentation propagates into clinical summary notes; and (3) ablating individual components of the STIGMAD framework, including self-consistency, self-reasoning, and self-reflection.

2 Literature Review

2.1 Bias in Clinical Documentation

Previously, Chen et al. (2024a) systematically reviewed AI-based bias mitigation and detection strategies for electronic health records (EHRs), identifying implicit bias, selection bias, algorithmic bias, and temporal bias. FitzGerald and Hurst (2017) discussed the presence and impact of implicit biases in healthcare professionals, performing a meta-analysis of findings from 42 studies and establishing that healthcare professionals have extensive implicit biases across numerous areas, including race, ethnicity, and gender. Burton et al. (2022)'s study of 401 patient safety reports found unequal reporting by physicians' gender and race/ethnicity. They also regularly found subthemes such as "inappropriate communication," "verbal abuse," "ignoring or omission of procedure," and "physical intimidation."

Wong and Jackson (2023) discussed positive bias, negative bias, stigmatizing language, implicit bias, explicit bias, gender bias, and racial bias, and highlighted common healthcare domains in which bias may arise. Similarly, Vela et al. highlighted stigma, racial bias, explicit bias, implicit bias, and gender discrimination in their study. We focus on stigmatizing language specifically as our test case, using the subset of MIMIC-IV clinical notes annotated for "Stigmatizing Language" in Harrigian et al. (2023)'s study. Harrigian et al. (2023) identified and classified three types of stigmatizing language in medical records: *credibility and obstinacy*, *compliance*, and *descriptors*.

2.2 LLM-Mediated Bias Analyses

Several studies have examined the potential of LLMs to aid in bias detection (Qiao et al., 2024; Hayes, 2025; Eschrich and Sterman, 2024), by performing zero-shot detection and categorization of bias in emergency department and discharge notes (Apakama et al., 2024). Xavier et al. (2026) evaluated the performance accuracy of LLMs in detecting stigmatizing language across diffent temperature settings and model size. We build on these studies to explore the potential of open-source general-domain (i.e., `Llama3.3-70b-instruct` (Dubey et al., 2024)) and domain-specific (i.e., `medgemma-27b-text-it` (Sellergren et al., 2025)) LLMs to detect stigmatizing language in clinical documentation. In more general domains, counterfactual techniques (e.g., Counter-GAP (Xie et al., 2023)) have emerged as strong performers in this area by enabling precise measurement of model biases through minimally altered, attribute-specific text pairs. Approaches like FACTUAL (Li et al., 2025) further leverage counterfactual augmentation to detect and effectively mitigate bias in LLMs, particularly for stance detection tasks.

With respect to approaches leveraged in our STIGMAD framework, Madaan et al. (2023) introduced *self-refine*, which refines initial LLM output through iterative feedback and refinement. Similarly, Chen et al. (2024b) introduced *self-debugging*, where the model identifies its mistakes in the output it generates. Although several studies have revealed that self-reflection may deteriorate performance (Chen et al., 2024b; Huang et al., 2024; Valmeekam et al., 2023), Xu et al. (2024) found that LLM size can reduce bias in the self-refinement pipeline. We use models with larger parameter sizes to implement *self-reflection* in our study. Finally, *self-consistency* (prompting the LLM with the same prompt multiple times while using a higher temperature value) has produced

promising results in many domains (Ahmed and Devanbu, 2023; Wang et al., 2023).

2.3 Agentic AI for Stigmatizing Language Detection

Acharya et al. (2025) comprehensively studied the use of agentic AI across many fields, including healthcare, motivating our exploration of an agentic AI framework for stigmatizing language detection. While Du et al. (2023) explored LLMs' reasoning ability through a multi-agent debate (MAD) framework, recent studies suggest that although MAD improves reasoning, it can inadvertently reinforce societal biases. For example, Borah and Mihalcea (2024) show that implicit gender biases persist and often escalate during multi-agent LLM interactions. Oh et al. (2026) correspondingly identified bias reinforcement as a key limitation of MAD. These limitations may be attributed to a lack of context and shared reasoning patterns (Borah and Mihalcea, 2024; Oh et al., 2026). Our setup in STIGMAD addresses these limitations fundamentally. By providing each agent with a clearly defined debate paragraph, a quote highlighting the bias, and explicit information about the stigmatizing language bias and its definition, we reduce ambiguity and encourage deliberate, reflective reasoning. We hypothesize that this makes bias reinforcement less likely in our setting, since agents are tasked with detecting and debating bias explicitly.

3 Dataset

3.1 Data Sources

We downloaded the PMC-Patients summary dataset (Zhao et al., 2023) from HuggingFace and also obtained access to the MIMIC-IV Dataset (Johnson et al., 2024, 2023) of real-world clinical documents.[1] Accessing MIMIC-IV notes required credentialed access via PhysioNet (Goldberger et al., 2000) and acceptance of a Data Use Agreement. All uses are within the scope of non-commercial research, in accordance with their respective licenses and access agreements. PMC-Patients summary notes correspond to the 167,000 patient summaries from PMC-Patients including patient visit, medical history, symptoms, treatments, discharge summary, and intervention based on case reports in PubMed Central (PMC). The stigmatization subset of MIMIC-IV is a collection of 4,710 de-identified free-text clinical notes for 4,259 patients and contains 5,043 annotations.

Notes in the MIMIC-IV stigmatization subset had 1802.71±479.59 tokens on average, and summaries in PMC-Patients had 288.58±113.28 tokens. Given the length disparity, we selected seven MIMIC-IV notes and 50 PMC-Patients summaries for further annotation of stigmatizing bias. These document quantities provided us with equal numbers (n=71 each) of context length-limited chunks. The design of our reasoning framework motivated our focus on chunk-level analysis rather than full-file analysis, and the inclusion of both MIMIC-IV and PMC-Patients allowed us to validate the generalizability of our framework.

3.2 Stigmatizing Language

Stigmatizing language has been defined in numerous ways in prior work (Harrigian et al., 2023; Himmelstein et al., 2022; Barcelona et al., 2024). While some studies treat the terms "stigma," "stigmatizing language," and "bias" interchangeably (Barcelona et al., 2024), others emphasize that stigmatizing language can serve as a mechanism for transmitting bias (Himmelstein et al., 2022). Harrigian et al. (2023) positioned the detection of stigmatizing language as a bias-related task in relation to other bias detection tasks in NLP, and we adopted their definition in our work:

> ***Stigmatizing Language:*** *Any language that portrays the patient in a negative or judgmental way—by expressing doubt about their credibility, implying they are difficult, noncompliant, or deceptive, or by using language that casts their behavior, attitude, or emotional state in a negative light. This includes both overt and subtle wording that reflects blame, shame, or disrespect.*[2]

In Prompt A.1, we also included definitions of other bias types from existing literature alongside stigmatizing language to reinforce that in real-world scenarios, multiple biases may coexist.

[1] This study was reviewed by the Institutional Review Board (IRB) at our institution and determined not to involve human subjects as defined by the Department of Health & Human Services (DHHS) and/or U.S. Food and Drug Administration (FDA) regulations.

[2] The final single definition is curated using class-based definitions from three stigma types for Stigmatizing Language.

3.3 Annotation

For MIMIC-IV, we implemented the existing stigmatizing language annotations developed by Harrigian et al. (2023). For PMC-patients summary dataset, we developed annotation guidelines collaboratively with a licensed physical therapist who had extensive experience writing and analyzing clinical notes. Additional guidance was provided by experts specializing in (1) fair and responsible AI, and (2) the intersection of computer science and healthcare. The physical therapist and three computer science graduate students carried out the annotations, following the guidelines provided in §3.2 and Prompt A.1. The graduate students followed the established rules to extend coverage and ensure consistency across the dataset, while the physical therapist oversaw the work to maintain clinical accuracy. All annotators underwent a training session using real clinical notes (not included in the final dataset) to practice annotations together and ensure consistency. They separately annotated every chunk (n=71) and held follow-up meetings to discuss discrepancies and align their understanding. The experts were also involved in these meetings to ensure that clinical and methodological perspectives were incorporated.

We calculated inter-annotator agreement for PMC-Patients using Cohen's cappa (Cohen, 1960) and obtained k=0.70 which is a substantial agreement (Landis and Koch, 1977). A clinician adjudicated the final label for cases of disagreement. Stigmatizing language was found in n=28 chunks and n=19 chunks from the MIMIC-IV and PMC-Patients datasets, respectively.

4 Methodology

4.1 Baseline Framework

Given an input clinical document, our base framework *bias-identifier* (see Prompt A.1) identifies instances of stigmatizing language and uses these as debate topics. We leverage two open-source LLMs, `Llama-3.3-70B-Instruct` and `medgemma-27b-text-it`, to generate the debate topic using a multi-step process. We first ask the LLM to identify stigmatizing language, based on a relevant quote from the input. We set the LLM temperature to 0.1 to encourage more deterministic detection, maintaining logical consistency.

Since medical notes vary in size depending on note-taking context, we chunk the note into 300-token windows, with a sliding window chunk overlap of 10 tokens to preserve coherence across segments.[3] Each chunked paragraph is fed to the LLM to extract the bias (stigmatizing language) itself and quotes. We conducted this process in a zero-shot manner, experimenting with multiple prompting strategies and styles to identify those that performed best.

4.2 Self-Reflection Framework

Our self-reflection framework revisits previously identified quotes and stigmatizing language from clinical documents, along with the definition of stigmatizing language. Its role is to re-evaluate whether the quote within the context of the note truly reflects the specified stigmatizing language. The model provides a boolean output regarding its decision, without providing any explanation. Since justification and reasoning are already addressed elsewhere within the StigMAD framework, the binary reflection provides complementary validation of the correctness of the extracted quote and the predicted stigmatizing language. We used few-shot prompting to implement this framework. The prompt contains few-shot examples of other bias type from existing literature to reinforce real-word scenarios (see Prompt A.2). This framework is conceptually similar to stigma detection guided prompt by (Chen et al., 2025). However, Chen et al. (2025) rely on fixed set of predefined stigmatizing keywords whereas self-reflection uses contextually extracted quotes identified dynamically by bias identifier.

4.3 Self-Consistency Framework

Our self-consistency framework is analogous to *bias-identifier*, but we run this model eight times while increasing the temperature to 0.5 to promote response diversity. The added variability makes it easier to identify consistent outputs through voting across runs. We consider only those outputs for stigmatizing language that occur at least three times out of eight runs for a given input chunk. We keep this threshold low since the *bias-identifier* also extracts quotes, and the exact quote boundary may vary across different runs. The prompt used to implement the self-consistency framework is the same as that of *bias-identifier*.

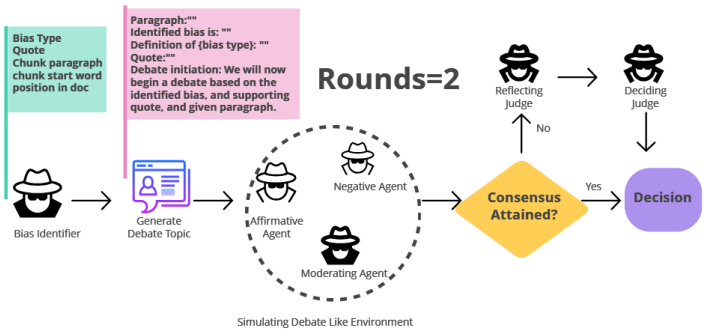

Figure 2: Proposed STIGMAD framework.

4.4 Reasoning Framework

The quotes for the stigmatizing language generated by the *bias-identifier* are converted into a debate topic as shown in Figure 2. The debate topic includes the input clinical document chunk, identified stigmatizing language, definition of stigmatizing language, quote that supports the identified bias, and debate initiation process. Overall, STIGMAD comprises four types of agents:

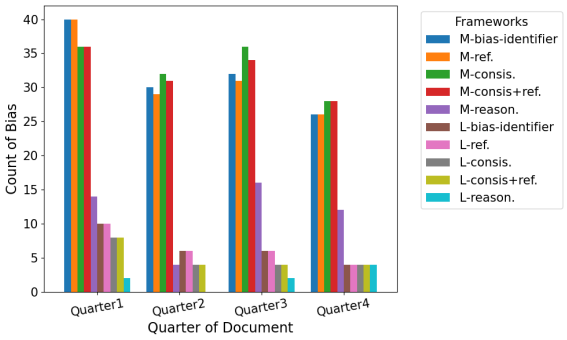
Affirmative Agent. Can support or deny the debate topic. It justifies its reflection on that topic, arguing affirmatively in brief structured statements (see Prompt A.4).

Negative Agent. Challenges or critiques the affirmative agent's perspective, providing arguments or support for its position (i.e., whether the stigmatizing language exists) (see Prompt A.5).

Moderator Agent. Oversees debate rounds and analyzes responses from affirmative and negative agents, determines whether consensus on bias classification has been reached, and summarizes reasons supporting its final decision. It ensures consistency across debates, reassesses contentious cases, and validates that the consensus aligns with bias definitions. The agent moderates the debate process for two rounds. If consensus is reached at the final round, its decision is the final decision (see Prompt A.3).

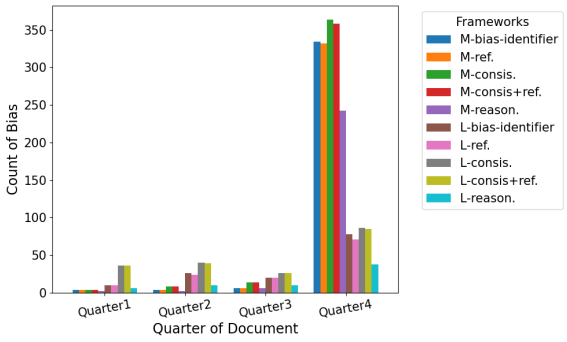
Judge Agent. Triggered when no consensus is reached after two moderation rounds. The judge agent takes two roles. The *reflecting judge* (see Prompt A.6) compiles upto five final arguments from affirmative and negative agents's results of the final debate rounds conclude, by listing bias classifications and reasoning without initial evaluation. The *deciding judge* (see Prompt A.7) makes the ultimate decision regarding bias presence based on its initial reflection. This agent is fed with debate topic information, and uses compiled pointers as context to produce a single JSON decision in the form `{"Presence":"True/False", "Reason":""}` which constrains output to one binary label and one justification.

4.5 External Baselines



For the stigma-annotated MIMIC-IV dataset, we also compared to the rule-based baseline established by Himmelstein et al. (2022) and the supervised stigmatizing language detection model created by Harrigian et al. (2023) as an external point of comparison on the same data [4].

5 Evaluation



We evaluated our frameworks across PMC-Patients and MIMIC-IV. Experiments were run using four NVIDIA A100 80GB PCIe GPUs and runtime for the full suite of experiments was approximately four days. Models were loaded in native precision float (bfloat16) across four A100 GPUs. Decoding used the temperature 0.1 for bias-identifier and self-reflection frameworks, and temperature 0.5 for self-consistency and reasoning. For bias-identifier and self-consistency framework, max_length was set to 4096. Similarly, max_new_tokens was set to 1 and 250 for self-reflection and reasoning framework respectively. In the following subsections, we discuss stigmatizing language across datasets and documents (§5.1), the framework-level evaluation (§5.2), and comparison to external baselines (§5.3). For brevity, we

[3]We observed hallucination and context drift when longer passages were provided. The reasoning framework also benefited from shorter, focused spans to directly interrogate.

[4]Code is available at https://github.com/RajashreeDahal4/Stigmatizating_Language_identification.

a. PMC-Patients Summary Dataset.

b. MIMIC-IV Dataset.

refer to `Llama-3.3-70B-Instruct` as *Llama* and `medgemma-27b-text-it` as *MedGemma* throughout §5.1–§5.3.

5.1 Stigmatizing Language across Datasets and Documents

We found that *bias-identifier* extracted 13 (Llama) and 64 (MedGemma) debate topics from PMC-Patients. It extracted 68 (Llama) and 178 (MedGemma) debate topics from MIMIC-IV. When dividing each note into equal-length quartiles, stigmatizing language was observed across all quartiles for PMC-Patients (Figure 3), with a slight elevation in the first quartile, whereas it was heavily concentrated in the final quartile for MIMIC-IV. MedGemma extracted more stigmatizing language across all quartiles for PMC-Patients, and in the last quartile for MIMIC-IV notes. The more frequent presence of stigmatizing language near the end of MIMIC-IV notes suggests that it may feature more prominently in evaluative language, which is usually found towards the end of healthcare provider notes. Except for reasoning, stigmatizing language concentrations were consistent regardless of which framework (see §4) was implemented using a particular LLM.

5.2 Framework Performance

We compared stigmatizing language identified by all proposed frameworks (*bias-identifier*, *self-consistency*, *self-reflection*, and *reasoning*) across both datasets using both models. We observed that the *self-reflection* and *reasoning* frameworks penalized documents or remained consistent with lower stigmatizing language counts in most cases (see Figure 3). *Self-consistency-reflection* did not show a similar trend. This may due to the voting strategy involved in making the final prediction. The main effect of self-reflection and reasoning was to prune spurious predictions when applied on top of *bias-identifier*, reducing ambiguity in detected stigmatizing language locations. Similarly, the number of debate topics identified by *bias-identifier* and *self-consistency* were comparable, perhaps due to the LLM's confidence at generating similar debate topics across different runs. Adding self-reflection to *bias-identifier* reduced this disparity by a small margin, highlighting stigmatizing language more across both datasets.

MedGemma and Llama exhibited different trends across frameworks (see Table 1). MedGemma's reasoning framework outperformed the baseline across both datasets, whereas Llama demonstrated its lowest performance with the reasoning framework. This was interesting given that MedGemma is less than 2.5 times the size of Llama, and suggests that MedGemma's pretraining data (including a diverse set of medical text) may enable it to leverage the reasoning framework to a much fuller extent in the structured clinical setting than a larger model pretrained on general-purpose data. Also, Llama's reasoning drop might be from sparse initial extractions (13 debate topics vs MedGemma's 64, where overpruning by debate agents devastates recall). The self-consistency framework in turn demonstrated superior performance for Llama. Finally, we observed that while reasoning and consistency-based prompts sometimes increased performance, the gains were not consistent across datasets (see, e.g., Llama on PMC-Patients).

From a qualitative perspective, some examples of false positive quotes included "he did not comply with during his admission," "homeless male with long history of etoh and heroin abuse," and

Table 1: Performance across models*.

Model	MIMIC(m)			PMC(p)		
	Framework	F_1	A	Framework	F_1	A
MedGemma	m-bias-identifier	0.36	0.34	p-bias-identifier	0.54	0.66
MedGemma	m-refl.	0.36	0.35	p-refl.	0.55	0.68
MedGemma	m-reason.	0.39	0.42	p-reason.	0.59	0.80
MedGemma	m-consis.	0.37	0.28	p-consis.	0.49	0.62
MedGemma	m-consis+refl.	0.37	0.28	p-consis+refl.	0.51	0.65
Llama	m-bias-identifier	0.34	0.73	p-bias-identifier	0.43	0.82
Llama	m-refl.	0.34	0.73	p-refl.	0.43	0.82
Llama	m-reason.	0.34	0.73	p-reason.	0.20	0.77
Llama	m-consis.	0.51	0.73	p-consis.	0.43	0.82
Llama	m-consis+refl.	0.51	0.73	p-consis+refl.	0.43	0.82

* F_1= F_1 score and A = accuracy. A total of 71 chunks were human-labeled, each treated as either stigmatizing or not.

"pt's paranoia seemed to be based in reality as the other resident in past had 'picked on' a gay resident." Some of these flagged examples are qualitatively ambiguous and may require closer examination in future work.

5.3 Comparison to External Baselines

We aligned Harrigian et al. (2023)'s fine-grained work on the MIMIC-IV stigmatizing language subset by mapping their "Exclude," "Neutral," and "Positive" model predictions to *non-stigmatizing* and the rest ("Disbelief," "Difficult," "Negative") to *stigmatizing*. We also fine-tuned the `emilyalsentzer/Bio_ClinicalBERT`[5] (Alsentzer et al., 2019) model on the binarized MIMIC-IV stigmatizing language data (*baseline-stigma*) using a 0.7/0.2/0.1 train-test-validation split. The 7 MIMIC-IV evaluation notes were part of test split. All reasoning frameworks outperformed these external alternatives (Figure 4) by a wide margin across models and datasets, with the exception of MedGemma with MIMIC-IV (`M-m`). This exception might be due to the poor *bias-identifier* score upon which the reasoning framework is dependent. The *bias-identifier* framework outperforms the alternatives in general though, justifying the additional computational cost of LLM-based approaches for improved performance at identifying stigmatizing language. While *baseline-stigma* slightly outperformed *L-bias-identifier*, we observed that *L-consistency* and *L-consistency + reflection* outperformed by a wider margin (13.5% improvement in precision). The *baseline-stigma* method achieved a perfect recall (1.0) for stigmatizing language but low precision (0.37).

[5]We implemented Bio_ClinicalBERT because the original work by Harrigian et al. (2023) implemented this model in their work.

6 Discussion and Conclusion

Through the study of self-reflection, self-consistency, and self-reasoning frameworks, our work sheds light on the use of LLMs to detect stigmatizing language across two popular clinical datasets. We found that *bias-identifier* tended to over-predict stigmatizing language with low precision. Self-reflection improved (or remained constant) over this outcome, and self-consistency introduced stability across multiple runs. MedGemma generally had higher performance using the STIGMAD framework across both datasets, although Llama achieved stronger performance using the self-consistency framework specifically. Our analysis shows that self-reflection and self-consistency can provide comparable results to more complex self-reasoning frameworks. Self-reasoning outperforms alternative frameworks when used with MedGemma, although not when used with the general-domain Llama. This might be because Llama, as a general-purpose model lacks clinical domain grounding to correctly adjudicate borderline cases during debate.

We focused our investigation on building comprehensive understanding of the capacity of STIGMAD to recognize stigmatizing language in clinical settings. The self-consistency framework itself validates performance stability, through its inherent aggregation of multiple sampled outputs (repeated runs) of *bias-identifier*. While STIGMAD incurs higher computational cost compared to simpler approaches (e.g., *baseline-stigma*), our study reveals what appears to be a clear performance tradeoff. For those wishing to study stigmatizing language in their own clinical environments as a downstream

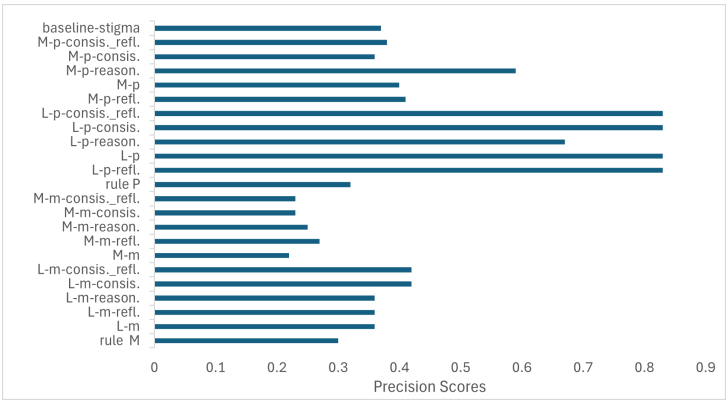

Figure 4: We compare precision scores of the rule-based method (*rule*) proposed by Himmelstein et al. (2022) and the baseline stigma detection method (*baseline-stigma*) from Harrigian et al. (2023) on the MIMIC-IV dataset, alongside our proposed frameworks evaluated on both MIMIC-IV and PMC using two LLMs. Here, `reason.` denotes reasoning, `refl.` denotes self-reflection, `consis.` denotes consistency, `p` refers to PMC, `m` refers to MIMIC-IV, `L` denotes Llama, and `M` denotes MedGemma.

application, we recommend weighing the relative performance advantages of STIGMAD against the available computational infrastructure and/or associated costs to build such an infrastructure.

Applying reasoning frameworks to stigmatizing language detection in clinical documents is an emerging topic; thus, a large part of the innovation for the work reported here lies in the task formulation and the discovery of domain-specific debate protocols. The resulting performance advantages compared to internal and external baselines highlights the strength of the implementation. Overall, our results confirm that open-source LLMs, steered by structured prompting and agent roles through STIGMAD, are well-positioned as a tool to detect stigmatizing language in clinical text. Our hope is that this work acts as a stepping stone to the development of responsible clinical NLP systems for stigmatizing language detection, as well as for other forms of bias detection and auditing.

Limitations

We aim to scale this research to larger, more heterogeneous clinical datasets to evaluate performance across more diverse clinical settings. We will also experiment with smaller, resource-light models for self-consistency and self-reflection to allow for faster and more scalable clinical deployment.

Our research was carried out on 57 patient files from MIMIC-IV (n=7) and PMC-Patients (n=50), which may not be representative of the overall datasets. We also acknowledge that annotating stigmatizing language requires interpreting tone and writer intent from text alone, which naturally opens the door to ambiguity. To mitigate the potential for this, annotators were trained to closely follow stigmatizing language definitions grounded in contemporary literature. Moreover, our annotation process was guided by experts in both the clinical and computational domains.

While individual outputs from LLMs are inherently non-deterministic, our framework improves internal consistency by structuring the generative process, supporting reproducible evaluation pipelines. Temperature values were set according to the conventions of their respective frameworks with low temperature for deterministic single-pass extraction and moderate temperature for diversity-dependent voting. Here, a formal sensitivity analysis across temperature remains an important direction for future work. The future work should also include sensitivity analysis over the self-consistency voting threshold and number of rounds for debate, which were set based on computational constraint and task-specific reasoning rather than formal hyperparameter search.

Finally, analyzing the influence of de-identification on stigmatizing language annotation and automated identification is beyond the scope of our research; however, it presents an intriguing avenue for future work. Likewise, broadening the analysis to include HIPAA-compliant closed-source models (e.g., ChatGPT for Healthcare) was infeasible for the current study due to cost and access constraints, but would present a valuable next step for external validation.

Ethical Considerations

This study was reviewed by the Institutional Review Board at the University of Illinois Chicago and determined not to be human subjects research according to Department of Health & Human Services (DHHS) or US Food and Drug Administration (FDA) regulations. While no direct patient interaction was involved, this research touches on ethically sensitive areas, including bias in healthcare. Our research includes a publicly available, de-identified clinical dataset (MIMIC-IV notes) and the PMC-Patients Summary dataset. While our goal is to identify bias in clinical notes, our findings are intended for academic analysis and model improvement, not direct clinical use. We have used open-source LLMs in our local machine to maintain privacy. However, we acknowledge the limitations of such models in reliably detecting nuanced or systemic bias, and emphasize that automated outputs should not replace human judgment in clinical settings.
