Logistics operations for e-commerce domains involve shipping millions of orders and processing returns through an intricate network of warehouses to and from the customer doorstep. As depicted schematically in Figure 1, while a large majority of the logistics operation is carried out seamlessly, a small fraction could result in defects/losses primarily stemming from:

D1: packages being reported as lost or stolen,

D2: damage claim for items deemed non-returnable (e.g., grocery items), and

D3: fake items being returned in-lieu of the genuine item that was shipped out.

The reasons for these defects could be due to supply-chain inefficiencies (e.g., improper handling) or fraudulent activity at any point across the supply-chain up till the end-customer.

While the exact reason for these defects might be more nuanced, the geographical location to which these packages are shipped could provide a strong indicator as to the likelihood of the defect. It is therefore prudent to use the final delivery location to predict the propensity of these defects and trigger appropriate remedial actions to prevent these operational losses.

These defects are expected to share strong synergistic relationships for several reasons:

1. **Common supply-chain vulnerabilities:** Areas with poor last-mile delivery infrastructure or inadequate security measures are likely to experience higher rates of all three defects due to increased opportunities for theft, damage, and fraudulent activities.

2. **Coordinated fraudulent behavior:** Bad actors often exploit multiple defect types simultaneously - for example, falsely claiming packages as lost (D1) and also engaging in return fraud (D3).

3. **Geographical risk factors:** Certain locations may have environmental or socioeconomic characteristics that contribute to multiple defect types, such as areas with higher crime rates or challenging delivery conditions.

Given these complex interactions between defects, we expect the defect labels to share a high degree of synergistic relationship. A well-designed modeling architecture that can harness these synergies could potentially lead to significant performance gain as opposed to training separate models for each of these defect types. To this end, we develop a novel multi-task pareto optimal transformer (MTPOT) model for predicting the likelihood of the three major defect types basis an input address text. In the next subsection we detail the architecture of the proposed MTPOT model.

4.1 Multi-task Pareto Optimal Transformer (MTPOT)

Consider a problem with M binary loss objectives:

$$L = [l_1, l_2, ..., l_M] \tag{2}$$

A common approach towards multi-task construction is to define a scalarization loss as $l = \sum_{i=1}^{M} w_i l_i$ where w_i is the chosen weight for the i^{th} loss. Choosing these weights is however non-trivial and may require significant domain expertise. In a more generalized setting, the objective is to generate a common parametric representation θ and define the minimization problem as:

$$\min_{\theta} L(\theta) = \min_{\theta} l_1(\theta), l_2(\theta), ..., l_M(\theta) \tag{3}$$

Eq (8) can be optimized by finding a descent direction for the parameter θ, at each iteration, such that each of the objectives is simultaneously minimized $i.e$

$$l_i(\theta^{k+1}) < l_i(\theta^k), \forall i \in [1, M] \tag{4}$$

When no such descent direction can be found, the solution is said to be Pareto stationary. A necessary condition for a solution to be Pareto stationary is (Peitz and Dellnitz, 2017) :

$$\sum_{i=1}^{M} \alpha_i \nabla l_i(\theta) = 0, \alpha_i \geq 0 \mid_{i=1...M}; \sum_{i=1}^{M} \alpha_i = 1 \tag{5}$$

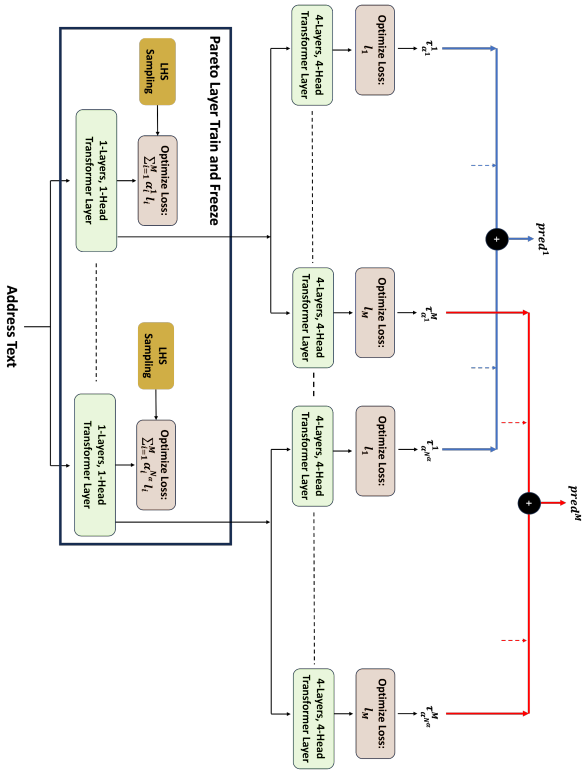

Figure 2: Architecture showing the Pareto layer followed by task-specific layers and ensemble prediction.

Such a solution is not unique and the set of all Pareto stationary solutions constitutes what is known as a Pareto front.

The intuitive basis for our approach is to leverage task synergies by systematically exploring solutions along the Pareto front through efficient weight space sampling, and then extending these solutions towards task-specific predictions. This allows us to capture shared representations while maintaining task-specific specialization. The overall MTPOT architecture, which is a framework and model-agnostic, is illustrated in Figure 2 with the key modelling steps described in Appendix C.

5 Results

5.1 Address Validation

We tested our address validation framework using offline historical data as well through end-user studies. The details of the experimentation are presented in the following subsections.

5.1.1 Address Auto-completion

We trained our model on 1M addresses using the architecture from Section 3.1, with AdamW optimizer ($lr = 5e^{-5}$) for 5 epochs. Inference employs beam search (width = 3). Our model achieved BLEU-1 of 0.67, BLEU-2 of 0.61, and a Suggestion Acceptance Rate (SAR) of 71.9% (percentage of users selecting one of the top three completions). The model delivered a P90 latency of 30ms on an NVIDIA T4 GPU.

Ablation Study: Removing our geographical attention mechanism caused BLEU-2 to decrease from 0.61 to 0.53 and SAR from 71.9% to 67.3%. This confirms geographical attention is essential for maintaining local coherence, preventing the model from suggesting geographically inconsistent but syntactically valid completions.

5.1.2 Address Spell-correction & Sequence Standardization

The spell-correction module achieved 96% correction accuracy in a manual audit of 10k randomly sampled addresses containing errors and serves as a pre-processing step. The sequence standardization module, trained using NER techniques on properly formatted addresses with randomly permuted components, achieved 91% accuracy in restoring addresses to their standard format (house number → street name → locality → city). Standardized addresses are computed at creation time and stored as canonical inputs for *all* downstream systems (not limited to MTPOT), where they enable reliable key-point mappings (e.g., building and locality name) that are critical for delivery-zone mapping.

Impact on MTPOT. Address normalization is a core component of our representation pipeline across systems. We quantify its downstream effect on MTPOT via an ablation in which we train/evaluate with and without standardization. Removing address standardization degrades AUC-ROC by approximately 70–120 basis points (bps) across the three tasks (Table 1), underscoring the importance of this step.

Table 1: Ablation: Impact of address standardization on MTPOT (AUC-ROC)

Task	Standardization	W/O Standardization
D1	61.39±1.62	60.66±1.15
D2	71.31±1.50	70.08±1.42
D3	51.61±1.42	50.89±1.31

5.2 MTPOT Evaluation and Impact

To evaluate MTPOT, we used training data from July 2024, with each delivery address assigned binary labels for $D1$, $D2$, and $D3$ tasks based on encountered loss-types. We tested on the subsequent

month's data to assess out-of-time performance. These defects are infrequent (<5% incidence rate), with $D3$ having the largest label imbalance.

We compared MTPOT against scalarization-based multi-task models like DistilBERT, XLM-RoBERTa, BERT, and others using the ROC-AUC metric (Table 2). All models were fine-tuned on the same data with optimal task weights. MTPOT demonstrated superior performance, particularly for the D2 task, leveraging shared label synergies to better target coordinated fraud. All experiments were repeated 10 times to ensure reliability.

Table 2: ROC-AUC for models

Model	D1	D2	D3
DistilBERT	57.95±1.03	50.05±0.53	50.39±0.36
XLM-R	56.74±1.24	52.37±0.74	51.39±0.10
BERT	58.78±0.32	52.61±0.33	49.51±1.37
ELECTRA	56.13±6.21	51.98±1.17	50.42±0.78
BART	59.03±0.34	52.57±0.49	52.54±1.95
DeBERTa	57.95±1.03	50.05±0.53	50.39±0.36
RoBERTa	59.30±1.72	67.17±1.96	49.84±2.15
MTPOT	**61.39±1.62**	**71.31±1.50**	**51.61±1.42**

Our address validation system has significantly improved delivery accuracy through real-time address completion and standardization. The MTPOT geographic risk prediction model identifies potential operational issues before they occur, enabling preventive measures. Operating at full e-commerce scale, this system has generated annual cost savings in the millions by streamlining deliveries and minimizing logistics errors.

MTPOT's Pareto architecture identifies operational hotspots by calculating average attention weights for address tokens within geographical zones. As shown in the transformed visualization in Figure 3, these hotspots provide logistics experts with actionable insights to resolve significant operational challenges.

6 Conclusion

This paper introduces an end-to-end address intelligence framework with three key innovations: a geographical attention mechanism that contextualizes address completion by incorporating spatial constraints, an address standardization algorithm that restructures address sequences while preserving their natural hierarchy, and the Multi-task Pareto Optimal Transformer (MTPOT) architecture that efficiently discovers synergies between multiple operational objectives through systematic exploration of the Pareto front. Beyond its immediate application in e-commerce logistics, this framework demonstrates how transformer architectures can be effectively adapted for specialized domains while maintaining interpretability, opening avenues for similar applications in other fields requiring multi-objective optimization of textual data.

A Spell Correction

For a given address term (x_i), potential corrections from vocabulary set V are evaluated using:

$$argmax_{w \in V} P_c(x_i|w) P_l(w) \tag{6}$$

The channel model $P_c(x_i|w)$ combines Levenshtein edit distance (d_1) and phonetic distance (d_2):

$$P_c(x_i|w) = exp(-(d_1 + d_2)) \tag{7}$$

The language model $P_l(w)$ incorporates contextual information using skip-grams, making it invariant to address term ordering:

$$P_l(w) = \sum_{x_j \in S} \sum_{j \neq i} \lambda_j \left[\frac{C(w, x_j)}{C(x_j) + \epsilon} \right] \tag{8}$$

where λ_j is the TF-IDF weight of term x_j, and $C(w, x_j)$, $C(x_j)$ are empirical skip-gram counts.

To handle non-standard white-space usage (e.g., "Adobetower" $\rightarrow$ "Adobe tower"), we treat white-space as an additional character and allow single insertion/deletion operations. A corrected sequence R is accepted if its probability exceeds the input sequence probability by threshold ϕ.

B Address Standardization Model

B.1 Model Architecture Details

Our address standardization model transforms inconsistently ordered address sequences into a standard format using the following detailed approach:

Given an input address sequence $X = [x_1, x_2, ..., x_n]$, we utilize a 6-layer, 8-head transformer encoder to obtain contextual embeddings:

$$H = [h_1, h_2, ..., h_n] \in \mathbb{R}^{n \times d} \tag{9}$$

For each pair of tokens (i, j), we compute a score S_{ij} that represents whether token i should precede token j in the standardized sequence:

$$S_{ij} = v^T \tanh(W_h [h_i; h_j]) \tag{10}$$

where $[;]$ denotes concatenation, $W_h \in \mathbb{R}^{d \times 2d}$ and $v \in \mathbb{R}^d$ are learnable parameters.

B.2 Position Score Computation

The model learns to output $S_{ij} > S_{ji}$ if token i should precede token j in the standardized format. These pairwise preferences are converted into position scores:

$$M_{ij} = \frac{1}{n} \sum_{k=1}^{n} \left[\mathbf{1}_{S_{ik} > S_{ki}} \cdot \mathbf{1}_{j>k} + \mathbf{1}_{S_{ki} > S_{ik}} \cdot \mathbf{1}_{j<k} \right] \tag{11}$$

where M_{ij} represents the propensity of token i to be assigned to position j and $\mathbf{1}$ is the indicator function.

B.3 Permutation Generation and Training

These scores are converted into a valid permutation matrix using Sinkhorn normalization:

$$P = \text{Sinkhorn}(M/\tau, N_{\text{iter}}) \tag{12}$$

where τ is a temperature parameter and N_{iter} is the number of normalization iterations. The reordered sequence is obtained through matrix multiplication:

$$\hat{X} = P \cdot X \tag{13}$$

The model is trained using supervised pairs of (unstructured, structured) addresses with cross-entropy loss:

$$\mathcal{L} = -\sum_{i=1}^{n} \sum_{j=1}^{n} Y_{ij} \log(P_{ij}) \tag{14}$$

where $Y_{ij} \in \{0, 1\}$ is the ground truth permutation matrix.

C MTPOT Modelling Steps

1. **Weight Selection via Latin Hypercube Sampling**: We generate a set of weight vectors $\boldsymbol{\alpha^j} | j = 1^{N\alpha}$ using Latin hypercube sampling in the M-dimensional simplex (where $\sum_{i=1}^{M} \alpha_i^j = 1, \alpha_i^j \geq 0$). Latin hypercube sampling (LHS) is a statistical method for generating near-random samples that provides better coverage of the sample space compared to pure random sampling. The key idea is to divide the sampling space into equal probability intervals along each dimension and sample exactly once from each interval. Specifically, for our M-dimensional weight space:
   (a) We divide each dimension into N_α equally sized intervals
   (b) For each dimension i, we randomly sample one value from each interval, giving us N_α samples
   (c) These samples are then randomly paired across dimensions to create M-dimensional points

   This stratification ensures that each interval along each dimension has exactly one sample, giving a probability of $\frac{1}{N_\alpha}$ for each interval.

To ensure the sampled weights lie on the probability simplex (i.e., sum to 1 and are non-negative), we project the LHS samples onto the simplex through normalization.

2. **Pareto Layer Training**: For each sampled weight vector $\boldsymbol{\alpha^j}$, we train a single-head single-layer transformer model (referred to as the Pareto layer) using the scalarized loss:

$$l^{\alpha^j} = \sum_{i=1}^{M} \alpha_i^j l_i(\theta) \tag{15}$$

At convergence, this solution satisfies $l^{\alpha^j} \approx 0$ which implies $\sum_{i=1}^{M} \alpha_i \nabla l_i(\theta) \approx 0$, which is the very condition for Pareto stationarity as outlined in Eq (13).

3. **Task-Specific Model Extension**
After training, we freeze the Pareto layer weights and append task-specific learnable layers for each individual task. Let $\tau^i_{\boldsymbol{\alpha^j}}$ represent the output of the task-specific model for the i^{th} task using the Pareto layer trained with weight vector $\boldsymbol{\alpha^j}$.

4. **Ensemble Prediction**
The final prediction for each task is obtained by ensembling the predictions across all sampled weight configurations:

$$pred^i = \sum_{j=1}^{N_\alpha} \tau^i_{\boldsymbol{\alpha^j}} \mid_{i=1\ldots M} \tag{16}$$

LLMs on a Budget? Say HOLA

Abstract

Running Large Language Models (LLMs) on edge devices is constrained by high compute and memory demands—posing a barrier for real-time applications in industries like healthcare, education, and embedded systems. Current solutions such as quantization, pruning, and Retrieval-Augmented Generation (RAG) offer only partial optimizations and often compromise on speed or accuracy. We introduce **HOLA**, an end-to-end optimization framework for efficient LLM deployment. Internally, it leverages Hierarchical Speculative Decoding (HSD) for faster inference without quality loss. Externally, AdaComp-RAG adjusts retrieval complexity based on context needs. Together with Lo-Bi, which blends structured pruning (LoRA) and quantization, HOLA delivers significant gains: +17.6% EMA on GSM8K, +10.5% MCA on ARC, and reduced latency and memory on edge devices like Jetson Nano—proving both scalable and production-ready. Our code is available at: https://github.com/zohaibhasan066/HOLA_Codebase

1 Introduction

Large Language Models (LLMs) have transformed NLP applications—from question answering (Ehtesham et al., 2025) and code generation (Zhong and Wang, 2024) to summarization (Ghosh et al., 2024) and conversational agents (Zenimoto, 2024). However, their deployment on edge and low-resource environments remains constrained by high compute and memory demands (Dutta et al., 2025), limiting real-world impact in domains like healthcare (Lysandrou et al., 2023), education (Bayarri-Planas et al., 2025), and personalized assistants (Tack et al., 2024). While techniques such as quantization (Tack et al., 2024), pruning (Chimoto et al., 2024), and Retrieval-Augmented Generation (RAG) (Parekh et al., 2024) offer partial relief, they often sacrifice accuracy, speed, or generality. Moreover, most approaches optimize isolated components—either internal inference (Liu et al., 2023) or external retrieval (Zheng et al., 2023)—without addressing the full pipeline. We introduce **HOLA** (Hierarchical Optimized Language Augmentation), a unified framework targeting both internal and external efficiency. It integrates (1) Hierarchical Speculative Decoding (HSD) for faster, accurate inference; (2) AdaComp-RAG, an adaptive retrieval system based on context relevance; and (3) Lo-Bi Optimization, combining LoRA-based structured pruning with mixed-precision quantization.

2 Related Works

Deploying LLMs in constrained environments has driven advances in decoding acceleration, retrieval optimization, and model compression. Techniques like Speculative Decoding (Sun et al., 2024) and Medusa (Cai et al., 2024) use draft-and-verify schemes to speed up inference, though they often require extra verifier networks and struggle with long sequences. Adaptive retrieval methods (Labruna et al., 2024) selectively route queries to improve efficiency but introduce added system complexity and retraining needs. Model compression remains central to edge deployment. Quantization approaches like GPTQ (Bumgardner et al., 2025) and Bi-LLM (Weng et al., 2025) reduce precision for memory savings, but aggressive quantization can impact accuracy. Structured pruning using LoRA (Hu et al.) and LoRA-Pruner (Zhang et al., 2024b) compress model weights with minimal retraining. While a few efforts combine pruning and quantization (Ali et al., 2025), most lack holistic, hardware-aware integration across the inference stack.

3 Methodology

Our proposed framework, **HOLA**, is composed of three synergistic modules—HSD accelerates au-

toregressive generation via entropy-aware verification, AdaComp-RAG adaptively modulates retrieval granularity, and Lo-Bi Optimization ensures compact and resource-aware model deployment. The broader process of the **HOLA** is illustrated in Algorithm 1. On the other hand, Figure 1 presents the detailed architecture.

Algorithm 1 : HOLA

Require: Input context $\mathbf{x}$
Ensure: Generated output sequence $\mathbf{y}$
Step 1: HSD
Generate draft $\hat{\mathbf{y}} = f_{\text{draft}}(\mathbf{x})$
for $t = 1$ to T **do**
  Compute token entropy $H(\hat{y}_t)$
  if $H(\hat{y}_t) < \tau$ **then** ▷ Fast-path
    $y_t \leftarrow \hat{y}_t$
  else ▷ Fallback to verifier
    $y_t \leftarrow f_{\text{ver}}(\mathbf{x}, y_{<t})$
  end if
end for
Step 2: AdaComp-RAG
Measure query complexity $C(\mathbf{q}) = \|\nabla_{\mathbf{q}} \mathcal{L}\|_2$
if $C(\mathbf{q}) \geq \delta$ **then**
  Retrieve top-k documents and form $\mathbf{x}' = [\mathbf{x}; \mathbf{d}_1, \ldots, \mathbf{d}_k]$
else
  $\mathbf{x}' \leftarrow \mathbf{x}$
end if
Apply compositional attention on $\mathbf{x}'$
Step 3: Lo-Bi Model Optimization
Compute low-rank update: $\Delta \mathbf{W} = \mathbf{AB}$
Update weights: $\mathbf{W}' = \mathbf{W} + \Delta \mathbf{W}$
for each subblock i in $\mathbf{W}'$ **do**
  Select bit-precision $p_i = \arg\min_{p \in \{4,8,16\}} \mathbb{E}[\|f_{\text{orig}} - f_{\text{quant}}^{(p)}\|_2]$
  Quantize subblock using p_i bits
end for
return Optimized output sequence $\mathbf{y}$

3.1 HSD Module

To mitigate the inherent latency of sequential token-by-token generation in autoregressive transformers, we introduce a HSD mechanism. Let the target sequence be $\mathbf{y} = (y_1, y_2, \ldots, y_T)$ conditioned on input context $\mathbf{x}$. Conventional decoding computes $y_t \sim p(y_t \mid \mathbf{x}, y_{<t})$ in series, which becomes computationally expensive for long outputs. Instead, HSD generates a draft sequence $\hat{\mathbf{y}}$ using a lightweight generator f_{draft} and verifies each token with a higher-fidelity verifier model f_{ver}. To reduce the number of verifier calls, we introduce an entropy-based gating function $g(t) = \mathbb{I}[H(\hat{y}_t) < \tau]$, where the entropy $H(\hat{y}_t) = -\sum_i p_i \log p_i$ reflects uncertainty in the draft distribution. Tokens with entropy below a threshold τ are directly accepted, and the final output sequence is constructed via Equation (1).

$$y_t = \begin{cases} \hat{y}_t & \text{if } g(t) = 1 \\ f_{\text{ver}}(\mathbf{x}, \hat{y}_{<t}) & \text{otherwise} \end{cases} \tag{1}$$

This reduces the number of verifier invocations from $O(T)$ to $O(k)$, where $k \ll T$, enabling up to 2–3$\times$ decoding speedup without significant degradation in output quality. While HSD primarily addresses internal generation, it still relies on the availability of accurate context—addressed next by our retrieval strategy.

3.2 AdaComp-RAG Module

To selectively augment queries with external knowledge, we propose AdaComp-RAG, an adaptive retrieval mechanism that modulates retrieval depth based on query uncertainty. Given a query embedding $\mathbf{q} \in \mathbb{R}^d$, we compute its retrieval complexity as the gradient norm of the loss function:

$C(\mathbf{q}) = \|\nabla_{\mathbf{q}} \mathcal{L}\|_2$, where $\mathcal{L}$ is the autoregressive language modeling loss. If $C(\mathbf{q}) \geq \delta$, we invoke a dense retrieval module over a document collection $\{\mathbf{d}_1, \ldots, \mathbf{d}_k\}$, resulting in an augmented input $\mathbf{x}' = [\mathbf{x}; \mathbf{d}_1; \ldots; \mathbf{d}_k]$. Otherwise, the model proceeds with a minimal or null retrieval path, conserving memory and latency for low-complexity queries. To integrate retrieved and original content, we apply a compositional attention mechanism over both contexts: $\mathbf{A} = \text{softmax}\left(\frac{\mathbf{Q}(\mathbf{K}_{\text{doc}} \oplus \mathbf{K}_{\text{input}})^\top}{\sqrt{d}}\right)$, where $\mathbf{Q}$, $\mathbf{K}_{\text{doc}}$, and $\mathbf{K}_{\text{input}}$ are the query and key matrices for retrieved and input sequences respectively, and $\oplus$ denotes concatenation.

3.3 Lo-Bi Optimization Module

To ensure deployment feasibility on constrained hardware, we incorporate a dual-stage compression strategy termed Lo-Bi Optimization, combining LoRA with sensitivity-guided mixed-precision quantization. First, given a weight matrix $\mathbf{W} \in \mathbb{R}^{d \times d}$, LoRA decomposes the update: $\Delta\mathbf{W} = \mathbf{AB}$, $\mathbf{A} \in \mathbb{R}^{d \times r}$, $\mathbf{B} \in \mathbb{R}^{r \times d}$, $r \ll d$ and applies it as an additive delta to the pretrained weights: $\mathbf{W}' = \mathbf{W} + \Delta\mathbf{W}$. This dramatically reduces trainable parameters, enabling task adaptation without full-model finetuning. Next, to reduce inference-time memory, we apply a mixed-precision quantizer $Q(\cdot)$, mapping subblocks of $\mathbf{W}'$ to 4-, 8-, or 16-bit precision. The optimal precision level p_i for each subblock: $p_i = \arg\min_{p \in \mathcal{P}} \mathbb{E}_{x \sim \mathcal{D}} \left[\left\| f_{\text{orig}}(x) - f^{(p)}_{\text{quant}}(x) \right\|_2 \right]$, where $\mathcal{P} = \{4, 8, 16\}$. This formulation preserves model accuracy under tight memory and bandwidth constraints. ***Note:*** Together, these modules comprise a fully-integrated pipeline: HSD accelerates token generation, AdaComp-RAG modulates augmentation on a per-query basis, and Lo-Bi Optimization ensures that all components operate efficiently under limited computational budgets.

4 Experimental Setup

We conducted experiments using a wide spectrum of LLMs—our selection includes compact, instruction-optimized, and general-purpose transformers. Among lightweight contenders, we evaluated **`Llama-3.2-3B`**[1] and **`TinyLlama`**[2], both designed for instruction following and low-resource deployment. As a classical baseline, we included **`gpt2`**[3], a 1.5B parameter model known for general language understanding despite lacking instruction tuning. From Mistral AI, we tested both **`Mistral-7B-v0.1`**[4] and the instruction-tuned **`Mistral-7B-Instruct-v0.2`**[5], which utilize grouped-query attention to balance performance and scalability. Additionally, Microsoft's **`phi-1_5`**[6] and **`Phi-3.5-mini-instruct`**[7] were selected for their strong reasoning capabilities and compact footprint, achieved through training on curated instructional datasets. Finally, we included Google DeepMind's **`gemma-2b`**[8] and **`gemma-7b`**[9], safety-aligned instruction-tuned models optimized for efficient reasoning and deployment.

4.1 Datasets

In our experiments, we utilize two widely-recognized benchmark datasets to evaluate the performance of **HOLA**. The first dataset, **`GSM8K`**[10] (Zhang et al., 2024a), comprises a collection of high-quality grade school mathematics problems designed to assess reasoning capabilities in arithmetic and algebra. It contains over 8,000 examples with detailed step-by-step solutions, providing a challenging testbed for models requiring multi-step logical reasoning. The second dataset, **`ARC (AI2 Reasoning Challenge)`**[11] (Singhal and Shroff, 2025), consists of multiple-choice science questions sourced from standardized tests, emphasizing advanced knowledge and reasoning across diverse scientific topics. We use the original train/val/test splits and ensure consistent preprocessing across models for fair comparison. ***Note:*** These datasets were selected for their relevance to real-world applications in education, enterprise automation, and edge AI, where robust reasoning over structured and unstructured inputs is critical. **`GSM8K`** evaluates precise multi-step arithmetic reasoning applicable to tutoring systems and financial logic chains, while

Table 1: Evaluation of language models with and without **HOLA** on GSM8K and ARC datasets. Green text shows performance gains; red text shows latency/memory reductions.

ARC tests generalization across diverse scientific domains—reflecting challenges in enterprise search, diagnostics, and decision support.

4.2 Evaluation Metrics

To assess the effectiveness of **HOLA**, we employ task-specific evaluation metrics aligned with the nature of the **GSM8K** and **ARC** datasets. For **GSM8K**, we use **Exact Match Accuracy (EMA)**, which measures the percentage of predicted answers that exactly match the ground-truth solutions, reflecting the model's arithmetic and logical precision. For **ARC**, we report the **Multiple-Choice Accuracy (MCA)**, computed as the proportion of correctly selected options across all questions, capturing the model's ability to reason and retrieve relevant scientific knowledge. Additionally, we analyze **latency** and **memory footprint** to evaluate system efficiency, particularly in the context of our HSD and Lo-Bi Optimization modules. In tables, ↑ indicates that a high value is preferable, while ↓ indicates that a low value is preferable.

4.3 Hyperparameters

The **HOLA** framework employs a finely tuned configuration across all modules to balance performance and efficiency. In the HSD module, we set the entropy threshold to $\tau = 1.5$, minimizing verifier calls without sacrificing quality. The draft generator uses a 6-layer, 512-dimension distilled transformer, while the verifier is a 12-layer, 768-dimension full decoder. AdaComp-RAG uses a retrieval threshold $\delta = 0.85$, informed by gradient norms on a validation set. For complex queries, $k = 3$ documents are retrieved via a BERT-based dense encoder trained for in-domain tasks. Compositional attention runs with a shared hidden size of 768. In Lo-Bi Optimization, LoRA-based pruning uses rank $r = 4$, and mixed-precision quantization dynamically assigns $\mathcal{P} = \{4, 8, 16\}$ per subblock using a 2,000-sample calibration set. Over 70% of blocks converge to 8-bit precision, while critical paths retain 16-bit fidelity. Training across modules uses the AdamW optimizer (learning rate 2×10^{-4}, batch size 32) with linear warm-up (10%) and early stopping based on EMA (GSM8K) and MCA (ARC). Unless specified, all experiments run on NVIDIA A100 GPUs (80 GB).

5 Experimental Analysis

5.1 Comparison with Baselines

Table 1 presents a comprehensive evaluation of various language models on GSM8K and ARC benchmarks, both with and without the integration of **HOLA**. From an industry standpoint, the introduction of HOLA yields substantial improvements in efficiency and performance. Across both tasks, models experience consistent gains in accuracy (EMA/MCA) alongside significant reductions in latency and memory consumption—critical met-

Model	Cross-domain: GSM8K → ARC					Cross-domain: ARC → GSM8K				
	MCA (%) ↑	Lat. Avg (ms) ↓	Lat. Std ↓	Mem. Avg (MB) ↓	Mem. Std ↓	EMA (%) ↑	Lat. Avg (ms) ↓	Lat. Std ↓	Mem. Avg (MB) ↓	Mem. Std ↓

– HSD, – AdaComp-RAG	80.4	170	8.1	829	26.7	73.1	159	7.4	816	23.3
– Lo-Bi Only (no HSD, no RAG)	81.7	166	7.9	933	29.5	74.8	153	7.1	919	28.6

Table 3: Ablation study on GSM8K and ARC datasets.

rics for real-world deployment. For instance, GPT-2 with HOLA sees a remarkable 15.6% boost in EMA on GSM8K and a 14.3% increase in MCA on ARC, coupled with a 48ms drop in latency and 750MB memory savings. High-performing models like Mistral-7B also benefit, albeit with smaller accuracy gains, suggesting HOLA's scalability across model sizes. These enhancements highlight HOLA's potential to optimize inference workloads in production pipelines, especially for edge deployments or latency-sensitive applications. Thus, HOLA serves as a valuable tool for balancing performance and resource constraints in industry use cases.

5.2 Cross-Domain Generalization Analysis

Table 2 benchmarks **HOLA**-optimized LLMs under domain shifts between GSM8K and ARC, highlighting robustness and deployment viability. We report MCA for GSM8K → ARC and EMA for ARC → GSM8K, along with latency and memory usage. Larger models like Mistral-7B generalize best (68.5% MCA, 78.7% EMA), while compact models (e.g., TinyLlama, Gemma-2B) offer low latency (92–94 ms) with moderate accuracy. Mistral-7B delivers an ideal balance—high accuracy and only 91 ms latency—enabled by optimized runtime implementations. Memory usage scales with model size, though remains consistent within 1500–1800 MB across runs. Generalization is stronger ARC → GSM8K, likely due to ARC's task diversity. However, compute cost remains symmetric, suggesting architecture dominates runtime behavior. These findings support Mistral-7B as a strong candidate for latency-sensitive yet accuracy-critical applications, while smaller models suit constrained environments.

5.3 Ablation Study

To quantify the individual contributions of **HOLA**'s core modules, we perform an ablation study on GSM8K and ARC using key metrics. As shown in Table 3, removing any component leads to measurable degradation in performance or efficiency. Excluding the HSD module reduces EMA from 89.2% to 85.1% and MCA from 81.7% to 77.5%, confirming the value of speculative drafting in improving output quality with minimal overhead. Disabling AdaComp-RAG results in increased memory usage (823 MB for GSM8K and 809 MB for ARC) and lower accuracy, indicating its effectiveness in managing retrieval complexity. Removing the Lo-Bi Optimization significantly increases memory (947 MB and 933 MB) and latency, validating its role in low-bitwidth computation and model compression. Ablating both HSD and AdaComp-RAG yields the largest performance drop, underscoring their complementary roles in balancing reasoning accuracy and computational efficiency. Overall, the complete **HOLA**

Length Category	Model	EMA (%) ↑	Latency (ms) ↓	Memory (MB) ↓
Short (<30 tokens	HOLA	83.4	**102**	**694**
Medium (30–60 tokens)	HOLA	85.9	118	712
Long (>60 tokens)	HOLA	**89.0**	134	720

Table 4: Scalability with input length on GSM8K dataset.

Top-k	EMA (%) ↑	Latency (ms) ↓	Memory (MB) ↓	Redundancy Detected (%) ↓
1	82.3	**110**	**692**	12.6
3	86.4	123	708	8.4
5	**89.2**	136	712	5.1
7	89.1	148	735	4.3
10	88.5	167	768	**3.7**

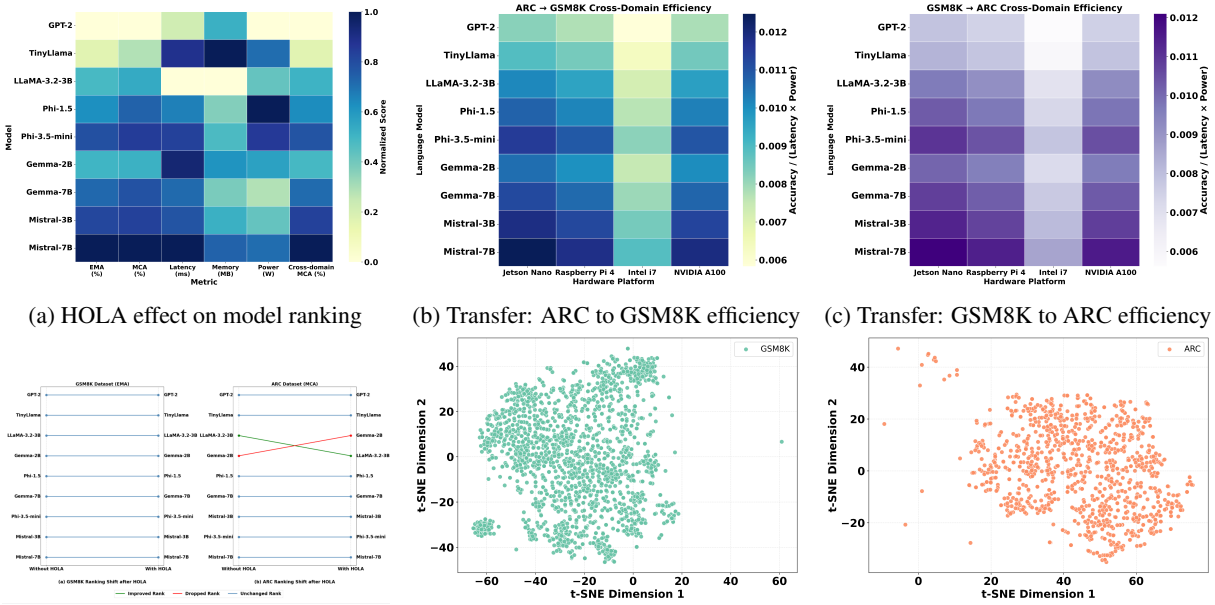
Device	EMA (%) ↑	Latency (ms) ↓	Peak Memory (MB) ↓	Power Draw (W) ↓	Throughput (samples/sec) ↑
Jetson Nano	87.6	841	1230	7.5	1.2
Raspberry Pi 4	85.1	1092	1175	**6.1**	0.9
Intel i7 CPU	88.3	312	1058	28.4	3.2
NVIDIA A100	**89.2**	**68**	**942**	97.2	**14.7**

Table 6: Computational performance of **HOLA** across hardware platforms on GSM8K dataset.

stack achieves the best results across all metrics, demonstrating the necessity of each component for optimal deployment performance.

6 Additional Analysis



To evaluate **HOLA**'s scalability under varying task complexities, we assess performance along two axes using GSM8K: input question length and the number of retrieved contexts in the AdaComp-RAG module.

Impact of Input Question Length: We segment the test set into three bins based on token length: Short (<30), Medium (30–60), and Long (>60), each with ∼300 examples. Table 4 highlights **HOLA** consistent performance across varying input lengths on GSM8K. Accuracy improves with input length, peaking at 89.0% EMA for long inputs. Despite slight increases in latency and memory, **HOLA** maintains an efficient tradeoff, demonstrating strong scalability and robustness for complex, multi-hop reasoning tasks.

Impact of Retrieved Contexts (AdaComp-RAG): We vary the number of retrieved contexts $k \in \{1, 3, 5, 7, 10\}$ and report results in Table 5. Accuracy peaks at $k = 5$ (89.2% EMA), balancing informativeness and efficiency. Higher values of k introduce redundant or noisy content, increasing latency and memory usage with diminishing accuracy returns. The `Redundancy Detected` column estimates overlap via semantic similarity metrics, showing inefficiencies beyond $k = 5$. These results validate the need for adaptive, selective retrieval to optimize reasoning quality and resource consumption.

Computational Analysis: We evaluate **HOLA** on GSM8K across Jetson Nano, Raspberry Pi 4, Intel i7-10700K, and NVIDIA A100 to assess deployment across diverse hardware. As shown in Table 6, **HOLA** maintains high accuracy—87.6% (Jetson Nano), 85.1% (Raspberry Pi 4), and 89.2% (A100)—demonstrating robust low-bit inference. Latency scales with compute: A100 is fastest (68 ms/sample), followed by Jetson Nano (841 ms) and Raspberry Pi 4 (1092 ms). Memory usage remains edge-compatible (∼1.2 GB), and power stays low (7.5 W, 6.1 W) on edge devices. A100 delivers 14+ samples/sec (97.2 W), suiting high-throughput workloads. **HOLA** proves deployable across edge and cloud, balancing speed, accuracy, and power. **`We focus on GSM8K due to its diverse, multi-hop numerical reasoning demands, offering a better testbed for latency and precision trade-offs than ARC.`**

Qualitative Analysis Figure 2 provides a comprehensive qualitative analysis of the impact of **HOLA** optimization and domain transfer on LLMs across two benchmark tasks: ARC and GSM8K. Subfigure (a) illustrates how **HOLA** affects model rankings, showing that the optimiza-

(a) HOLA effect on model ranking (b) Transfer: ARC to GSM8K efficiency (c) Transfer: GSM8K to ARC efficiency

(d) Ranking shifts due to HOLA (e) GSM8K latent space (f) ARC latent space

Figure 2: Detailed analysis of the impact of HOLA optimization and domain transfer on large language models (LLMs) across tasks and hardware settings. (a) shows how HOLA influences model ranking for the GSM8K and ARC datasets. (b) and (c) illustrate the efficiency changes when transferring models between ARC and GSM8K tasks on various hardware. (d) compares ranking shifts caused by HOLA optimization. (e) and (f) provide t-SNE visualizations of the latent space to highlight task domain effects for GSM8K and ARC, respectively.

tion has a varied impact across different models and tasks—some models improve significantly, while others decline or remain unaffected. Subfigures (b) and (c) show the efficiency of cross-domain transfer from ARC to GSM8K and vice versa, respectively. The heatmaps reveal that transfer efficiency is highly dependent on model architecture and hardware configurations, with some models exhibiting strong generalization across tasks and others struggling. Subfigure (d) further highlights the shifts in model rankings caused by **HOLA**, indicating that optimization can reconfigure relative model performance on these benchmarks. Subfigures (e) and (f) use t-SNE to visualize the latent task spaces of GSM8K and ARC, respectively. The distinct clustering in each plot suggests that the two tasks occupy separate regions in the latent space, which helps explain the varying success of cross-task transfer. Together, these insights emphasize that both optimization and evaluation strategies must consider task specificity and domain effects to ensure robust performance across reasoning benchmarks.

7 Conclusion and Future Work

We propose **HOLA**, a hybrid framework for efficient retrieval-augmented generation, achieving strong accuracy-latency-memory trade-offs across edge and cloud platforms. Experiments validate its scalability and deployment viability. Future work includes multilingual retrieval, long-context reasoning, hardware-aware training for ARM/RISC-V, and real-time integration in low-power systems like dialogue agents and embedded QA bots.

Limitations

While **HOLA** delivers strong performance-efficiency trade-offs, several limitations remain. The retrieval pipeline depends on static indexing, limiting adaptability to dynamic knowledge or temporal queries. Aggressive compression, while beneficial for edge deployment, can introduce non-trivial accuracy loss on ultra-low-memory devices. Current evaluation is constrained to GSM8K, and generalizability to more complex, multi-turn, or multi-modal tasks remains unverified. Robustness under adversarial or noisy retrievals is also under-explored. Additionally, real-world deployment factors—such as thermal throttling, energy spikes, or long-term device wear—are not modeled.

Ethics Statement

This work follows established ethical guidelines in AI development and deployment. All datasets used

are publicly available, de-identified, and compliant with data usage norms. **HOLA** was designed with efficiency and accessibility as core principles, targeting responsible deployment in resource-constrained and educational contexts. While the model improves reasoning automation, we recognize potential risks such as misuse for generating inaccurate content. Additionally, fairness and transparency remain active concerns. Responsible release protocols, including usage documentation and bias monitoring, will guide the deployment of **HOLA** in real-world scenarios.

Abstract

Customer service often relies on human agents, which, while effective, can be costly and slower to scale. Recent advancements in intelligent chatbots, particularly Retrieval-Augmented Generation (RAG) models, have significantly enhanced efficiency by integrating large language models with external knowledge retrieval. However, developing a multi-turn RAG-based chatbot for real-world customer service presents additional complexities, requiring components like adaptive retrieval and query reformulation. These components typically require substantial annotated data, which is often scarce. To overcome this limitation, we propose methods to automatically generate labels for these components using real customer-agent dialogue data. Specifically, we introduce two labeling strategies for adaptive retrieval: an intent-guided strategy and an explanation-based strategy, along with two query reformulation strategies: natural language query reformulation and keyword-based reformulation. Our experiments reveal that the explanation-based strategy yields the best results for adaptive retrieval, while the keyword-based reformulation improves document retrieval quality. Our findings offer valuable insights for practitioners working on multi-turn RAG systems.

1 Introduction

Traditional customer service operations rely on human agents to handle inquiries, leading to high operational costs and response time delays. In recent years, intelligent customer service chatbots (Cui et al., 2017; Qi et al., 2021; Cui et al., 2017; Benita et al., 2024) have reshaped customer support by automating responses and improving efficiency. Among these advancements, Retrieval-Augmented Generation (RAG) (Smith et al., 2023) has emerged as a powerful technique for enhancing question-answering (QA) ability of customer service chatbots. By integrating large language models (LLMs) with external knowledge retrieval, RAG-based chatbots generate more accurate and contextually relevant responses (Ding et al., 2022; Lewis et al., 2020).

Compared to single-turn RAG-based QA systems, building multi-turn RAG-based chatbots (Roy et al., 2024; Katsis et al., 2025) for real-world customer service requires two additional components. The **adaptive retrieval** component determines when retrieval is necessary, reducing both latency and context length by fetching documents only when needed. The **query reformulation** component processes conversation history to generate precise queries for the retrieval module, ensuring contextually relevant responses.

Building these two components typically requires a significant amount of annotated data. To address this, we develop methods to automatically generate labels for both adaptive retrieval and query reformulation models using customer-agent service dialogues collected in compliance with data handling policies. We demonstrate that models trained on non-bot conversations and automatically generated labels can effectively support the development of a fully functional multi-turn RAG-based chatbot for customer service.

To generate labels for adaptive retrieval, we propose two labeling strategies using LLMs. The first, an intent-guided labeling strategy, leverages pre-defined intents to direct the labeling process. The second, an explanation-based strategy, directly prompts the LLM to label whether retrieval is needed and generate reasonable explanations for the decision. We also propose two strategies for natural language query reformulation and keyword formulation. The former rewrites the customer utterance into a self-contained, decontextualized, and well-structured question, while the latter generates a keyword-based query. Through experiments, we find that the explanation-guided strategy generates the highest quality labels for adaptive retrieval.

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1044–1056
November 4-9, 2025 ©2025 Association for Computational Linguistics

Additionally, we observe that the keyword-based strategy retrieves higher quality documents.

We summarize the contributions of our paper as follows:

- We propose two adaptive retrieval labeling strategies and two reformulation labeling strategies for building adaptive retrieval and query reformulation models to support multi-turn RAG systems.
- Our offline experiments and human study demonstrate that the explanation-guided labeling strategy is the most effective for generating adaptive retrieval labels.
- We also show that the keyword-based reformulation labeling strategy is more effective for training query reformulations that retrieve higher-quality documents, even though the reformulations may not be as fluent as natural language query (NLQ) reformulations.
- Our labeling strategies and experimental results provide valuable insights and guidance for practitioners in the industry working to build multi-turn RAG systems.

2 Related Work

2.1 Retrieval-Augmented Generation (RAG)

Retrieval-Augmented Generation Integrated with retrieval mechanisms (Lewis et al., 2020), RAG improves factual grounding and reduce hallucination in question answering systems (Smith et al., 2023). In single-turn settings, systems like DPR (Karpukhin et al., 2020) retrieve documents using dense embeddings, while Fusion-in-Decoder (FiD) (Izacard and Grave, 2021) processes multiple passages in parallel for improved answer quality. However, indiscriminate retrieval in such systems introduces latency and risks distracting the generator with irrelevant context (Shi et al., 2023).

Adaptive Retrieval in RAG A key challenge for RAG in real-time applications is balancing retrieval quality with computational efficiency. Studies such as Mallen et al. (2023) revealed that indiscriminate retrieval increases latency and can degrade performance when irrelevant passages overwhelm the generator. To address this, recent work focuses on adaptive retrieval strategies. For example, Yao et al. (2024) proposed confidence-based retrieval, where the LM triggers retrieval only when its internal uncertainty exceeds a threshold. In conversational settings, Roy et al. (2024) designed self-multi-RAG, where an LLM determines when retrieval is needed given the dialogue context, then rewrites the conversation into a query if needed and filters the retrieved passages before answering. Su et al. (2024) proposes Dynamic RAG named DRAGIN, which actively decides when to trigger retrieval and what to retrieve during generation. Unlike static one-shot retrieval, DRAGIN monitors the LLM's internal information needs across the generation process to decide the optimal moment to retrieve and to craft an appropriate query.

2.2 Query Reformulation

Query reformulation plays a crucial role in Conversational Question Answering (CQA) and Conversational Search (CS) by refining user queries to improve retrieval effectiveness and response relevance.

In CQA and CS, users often ask follow-up questions (Senel et al., 2024; Kuzi et al., 2025) that omit context from previous turns, necessitating reformulation into explicit, self-contained queries. Traditional methods rely on rule-based heuristics or query expansion (Anick, 2003), while neural approaches (Anantha et al., 2021; Vakulenko et al., 2021; Mo et al., 2023, 2024; Chen et al., 2023) use sequence-to-sequence models to incorporate contextual information. Reinforcement learning-based methods (Buck et al., 2018; Chen et al., 2022; Wu et al., 2022) further optimize reformulation by maximizing downstream QA performance.

RAG-based frameworks have recently emerged as powerful QA solutions. Since RAG pipelines rely on retrieved documents to generate responses, refining input queries is crucial for retrieving high-quality evidence (Ma et al., 2023; Li et al.). This becomes even more critical as we move toward conversational QA with RAG-based approaches (Roy et al., 2024).

While existing research focuses primarily on single-turn RAG, multi-turn RAG remains underexplored due to the lack of benchmarks. Scaling multi-turn RAG for industry applications presents additional challenges, including adaptive retrieval prediction and conversational query reformulation, as discussed in §3. Instead of proposing new models, this paper introduces a method for leveraging existing dialogues between human agents and customers to generate labels for adaptive retrieval and query reformulation, which can then be used to train various models.

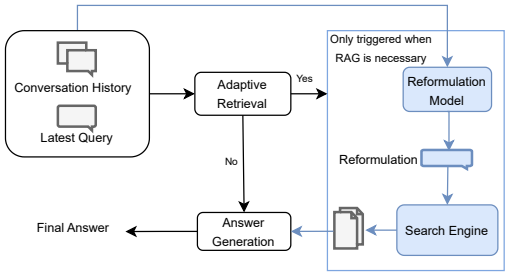

Figure 1: An overview of the adaptive retrieval and reformulation component integrated into RAG for multi-turn conversations.

3 Preliminary

In this section, we describe how adaptive retrieval and query reformulation are integrated into a RAG system to support multi-turn conversations. The overall framework is illustrated in Figure 1.

First, given the conversational history $\mathcal{C}$ and a customer's current utterance q as input, the adaptive retrieval model $\mathcal{M}_s$ first decides on whether to initiate an information retrieval process:

$$p_s = \mathcal{M}_s(\mathcal{C}, q) \tag{1}$$

where $p_s = 1$ indicates retrieval is necessary otherwise $p_s = 0$. Here the input can be the concatenation of $\mathcal{C}$ and q.

If retrieval is not necessary, then the answer generation model directly generates the answer given $\mathcal{C}$ and q. If a retrieval is needed (the blue workflows in Figure 1), the reformulation model $\mathcal{M}_r$ will then rewrite the query:

$$q' = \mathcal{M}_r(\mathcal{C}, q) \tag{2}$$

The reformulated query q' improves retrieval by resolving conversational dependencies and clarifying ambiguity with added context.

Considering the latency requirement, we use a foundation model such as Claude 3.5 Sonnet[1] only for the answer generation module in production, while keeping the other components as smaller models to minimize overall latency. Training $\mathcal{M}_s$ and $\mathcal{M}_r$ requires a large amount of data, which can be labor-intensive. However, as an e-commerce company, we have access to millions of real customer service transcripts containing dialogues between human agents and customers. In this work, we focus on a single key challenge: *how to effectively leverage this valuable data to train critical components (i.e., $\mathcal{M}_s$ and $\mathcal{M}_r$) for a multi-turn RAG chatbot capable of answering customer questions at scale.*

4 Method

In real conversations, either the agent or the customer may consecutively input several utterances. However, the dialogue between a customer and a RAG-based chatbot is typically conducted in an alternating manner. To construct data that aligns with the chatbot format, we merge consecutive utterances from the same role into a single unit, resulting in a dialogue $d = [q_1, a_1, ..., q_n, a_n]$ where q_i represents the user's query and a_i represents the agent's response. For a query q_i, we define its context or conversation history as $C_i = [q_1, a_1, ..., q_{i-1}, a_{i-1}]$. In the following, we propose different label generation strategies for adaptive retrieval and query reformulation using LLMs with $d \in D$.

4.1 Labeling Strategy for Adaptive Retrieval

We consider two prompt strategies for adaptive retrieval labeling.

Intent-guided Labeling We instruct the LLM to classify the customer's intent before determining whether retrieval is necessary. The intent labeling is not directly used for model training. We defined 12 intents for customer queries which can be found in the prompt in Table 7. The underlying assumption is that the need for retrieval is strongly dependent on the query intent, and we hypothesize that prompting the LLM to reason through the query intent will enable it to more accurately assess whether retrieval is required.

Explanation-guided Labeling Instead of using pre-defined intents to guide the LLM annotation, we prompt the LLM to freely explain why it makes the decision that a retrieval is needed or not, and then generate the final label of p_s.

For both strategies above, we experiment with two annotation approaches. In turn-level annotation, we provide the dialogue context and the current query to the LLM for labeling each turn independently. In dialogue-level annotation, given a dialogue $d \in D$ with n customer utterances, we provide the entire dialogue to the LLM and ask it to output labels for all customer utterances at once. Interestingly, we find that dialogue-level annotation

leads to higher accuracy compared to turn-level annotation (§6.1), likely because it allows the LLM to better understand the overall conversation flow. The prompt templates for the two proposed strategies are shown in Table 7 and Table 8, respectively.

4.2 Labeling Strategy for Query Reformulation

To generate reformulation labels, we prompt an LLM with context and a customer query. We explore two annotation strategies.

NLQ Reformulation The first approach focuses on Natural Language Query (NLQ) reformulation, where the LLM generates a fully unambiguous query in natural language. This involves resolving any ambiguities in the original utterance, ensuring grammatical correctness, and addressing challenges such as co-reference resolution and omissions. During reformulation, we also prompt the LLM to explain the actions or edits it performed to generate the revised query.

Keywords Reformulation The second approach focuses on generating relevant keywords given the conversational context and user query. Compared to NLQ reformulation, keywords reformulation is not required to produce a fully structured natural language question. Instead, it extracts and prioritizes key terms that capture the essential intent of the user's query. We also prompt the LLM to explain the importance of the generated keywords for downstream retrieval.

While NLQ reformulations are commonly used in CQA (Anantha et al., 2021; Vakulenko et al., 2021; Chen et al., 2022), we find that they are not always necessary. Instead, keyword reformulation is sufficient to retrieve high-quality documents within the RAG framework. We present our findings in Section 6.3. The prompt templates for the two proposed strategies are shown in Table 9 and Table 10, respectively.

5 Experimental Setup

5.1 Datasets

We synthesized 10,000 dialogues based on typical customer service interactions, drawing inspiration from common e-commerce support scenarios. These synthetic conversations span over 20 product categories, including consumer electronics and digital services. All company names, product details, and customer information were anonymized to protect privacy. Each dialogue contains an average of approximately 12 customer utterances and 22 agent utterances.

We use Claude-Sonnet-3 to generate labels for the training data using the methods proposed in Section 4. To protect customer privacy, all transcripts are scrubbed to exclude any personally identifiable information. We split the dataset into three parts: 70% for training, 10% for validation, and 20% for testing. The test set was held out strictly for final evaluation.

Input Type	Labeling Strategy	Accuracy
full dialogue	Intent-guided	89%
full dialogue	Explanation-guided	92%
context + query	Intent-guided	85%
context + query	Explanation-guided	87%

Table 1: Accuracy of LLM's annotation for adaptive retrieval.

Labeling Strategy	Accuracy	AUC	Ground Truth
Intent-guided	83.27%	92.49%	LLM
	74.27%	86.16%	Human
Explanation-guided	86.49%	93.76%	LLM
	83.39%	92.00%	Human

Table 2: Evaluation result for adaptive retrieval.

5.2 Implementation Details

We use RoBERTa-base for adaptive retrieval and BART-base/FLAN-T5-base for query reformulation, optimizing with cross-entropy and the Adam optimizer. Models are trained for 10 epochs on 4 NVIDIA A10 GPUs, with learning rates of 2e-6 (adaptive retrieval) and 1e-5 (reformulation), batch sizes of 30 and 10 respectively, and early stopping (patience = 5) to prevent overfitting. We also experimented with larger backbones (RoBERTa-large, BART-large, FLAN-T5-large), but observed only marginal gains (0.5–2%), with consistent conclusions across labeling strategies. For simplicity, we report results with the smaller models.

5.3 Evaluation Strategies

Adaptive Retrieval To evaluate the accuracy of the LLM in labeling for adaptive retrieval, we first assess different annotation strategies by manually examining 500 sampled test set. For adaptive retrieval models trained on labels from various annotation strategies, we report accuracy and AUC against LLM-generated labels, measuring how well the model distills knowledge from the labeled data.

To further validate performance, we also evaluate the model on human-annotated data.

Reformulation To evaluate the performance of the query reformulation model, we first assess its accuracy using automatic metrics, including BLEU, METEOR and ROUGE, by comparing its reformulated queries against those generated by the LLM.

To evaluate keywords reformulation quality, we manually annotated 500 test samples, labeling each generated keyword as relevant or not based on whether it preserves the original query intent and key information from both the query and context. NLQ reformulations have stricter requirements, as they must be well-formed sentences that resolve ellipses and co-references. To assess the quality of NLQ reformulations generated by the foundation LLMs or models trained on LLM-labeled data, we conduct a human evaluation on the same 500 sampled test set. For this evaluation, we propose and assess three key metrics:

- **Grammatical Correctness**: Evaluates whether the reformulation is grammatically correct.
- **Context Carryover Completeness**: Assesses whether the reformulation is self-contained and understandable without requiring reference to the dialogue history.
- **Context Carryover Accuracy**: Determines whether omissions and co-references in the reformulation are resolved correctly.

Additionally, we examine how query reformulation impacts retrieval effectiveness, analyzing whether reformulated queries lead to improved retrieval quality in Section 6.3.

6 Results

6.1 Evaluation on Adaptive Retrieval

First, we evaluate the accuracy of different prompting strategies for generating adaptive retrieval labels on our manually annotated 500-sample validation set (described in §5.3), with results presented in Table 1. This human-annotated subset serves as ground truth to assess the quality of LLM-generated labels. As shown, for the same input type, the explanation-guided method outperforms the intent-guided method, as some intents encompass both retrieval-needed and retrieval-not-needed cases. Additionally, dialogue-level annotation surpasses query-level annotation. We hypothesize that this improvement occurs because the LLM can better comprehend the queries when provided with the complete context of the dialogue, including future utterances.

To evaluate the effectiveness of the adaptive retrieval model, we train the model using labels generated with different strategies and input types, then test it on both LLM-generated and human-annotated labels. Based on the results in Table 2, we find that the accuracy gap between the synthetic dataset (generated by LLM) and the human-labeled dataset ranges from 1% to 6%, with higher accuracy on the synthetic dataset, likely due to the models being trained on synthetic data. On the human annotated test set, the explanation-guided labeling strategy outperforms intent-guided labeling, as it avoids predefined intents and instead allows the LLM to freely explain its predictions. Finally, models trained on LLM-generated data perform well on both synthetic and human-labeled datasets, with the best accuracy and AUC on human-labeled data achieved by the model trained using the explanation-guided labeling strategy.

Query Type	Model	Top-1	Top-5
Query	-	0.76	1.07
	-	0.94	1.28
NLQ Reformulation	BART-base	1.26	1.43
	FLAN-T5-base	1.19	1.39
	Claude	1.31	1.5
Keywords Reformulation	BART-base	1.3	1.5
	FLAN-T5-base	**1.36**	1.51
	Claude	1.34	**1.59**

Table 3: The relevance scores for the Top-1 and Top-5 retrieval results using different reformulation strategies.

6.2 Evaluation on Query Reformulation

Automatic Evaluation We present the automatic evaluation metrics in Table 4. Both models achieve comparable results across NLP and Keywords Reformulation. However, a notable trend emerges in NLP Reformulation: BLEU, METEOR, and ROUGE-2 scores are higher, while ROUGE-1 is lower compared to Keywords Reformulation. This suggests that NLP Reformulation produces more fluent and semantically coherent outputs, leading to higher BLEU and METEOR scores. The higher ROUGE-2 further indicates that the generated text better preserves key bigram relationships. However, the lower ROUGE-1 score suggests that some surface-level word matches may be reduced, possibly due to slight paraphrasing or rewording that enhances fluency but alters lexical choices. In contrast, Keywords Reformulation

Reformulation Type	Model	BLEU	METEOR	ROUGE-1	ROUGE-2	ROUGE-L
NLP Reformulation	BART-base	0.312	0.548	0.547	0.373	0.517
	FLAN-T5-base	0.305	0.546	0.550	0.372	0.520
Keywords Reformulation	BART-base	0.209	0.511	0.590	0.315	0.518
	FLAN-T5-base	0.204	0.501	0.592	0.314	0.520

Table 4: Automatic evaluation result for query reformulation.

Example 1	
Original Query	the screen is stuck
NLQ Reformulation	The Pluto TV app screen is frozen on my [BRAND_NAME] TV device
Keywords Reformulation	[BRAND_NAME] tv stuck screen pluto tv app remote not working
Example 2	
Original Query	4k
NLQ Reformulation	I am having issues with the remote for my [DEVICE_NAME] 4K (Max)
Keywords Reformulation	[DEVICE_NAME] 4k remote issues batteries not working
Example 3	
Original Query	how do I activate it?
NLQ Reformulation	Activate my [SERVICE_NAME] membership
Keywords Reformulation	activate [SERVICE_NAME] membership issue accessing membership not active
Example 4	
Original Query	Still did not fixed the streak
NLQ Reformulation	Updating the [SOFTWARE_NAME] still did not fix the streak
Keywords Reformulation	[SOFTWARE_NAME] streak not updating reading log issue streak not fixed after app update escalate reading streak problem
Example 5	
Original Query	I'm wondering if you could please help me remove the ads?
NLQ Reformulation	Help me remove the ads from my [DEVICE_NAME] lock screen.
Keywords Reformulation	remove ads [DEVICE_NAME] lock screen children's bedtime story
Example 6	
Original Query	How many times was I charged for it?
NLQ Reformulation	How many charges were made for the [SERVICE_NAME] subscription?
Keywords Reformulation	[SERVICE_NAME] subscription charges number times
Example 7	
Original Query	How do I access photos on an [DEVICE_NAME]?
NLQ Reformulation	How do I access photos on my [BRAND_NAME] [DEVICE_NAME]?
Keywords Reformulation	[DEVICE_NAME] access photos display pictures

Table 5: Examples of original queries and their corresponding NLQ and keyword reformulations.

yields higher ROUGE-1 scores, indicating better word-level matching, likely because the reformulations retain key terms more explicitly, though at the cost of reduced fluency and syntactic variation.

Human Evaluation For NLQ reformulation, we further evaluate the reformulation quality based on 500 sampled testing set. The numbers are reported in Table 6. Overall, all models perform well across the three evaluation criteria. Claude achieves the highest scores in all metrics, demonstrating its strong capability in NLQ reformulation under our proposed labeling strategy. FLAN-T5-base outperforms BART-base in grammatical correctness (GC) compared to BART-base, indicating its strength in producing well-formed outputs. However, BART-base shows slightly better performance in context carryover accuracy (CCA) and context carryover completeness (CCC), suggesting that it more effectively preserves contextual information during reformulation. In contrast, all keyword reformulations are labeled as relevant, as the criterion only requires preserving intent and key information, without enforcing grammatical correctness. In Table 5, we present examples of NLQ and keyword reformulations. To protect privacy and prevent disclosure of sensitive information, certain spans such as brand names, device names, personal identifiers, and specific product details have been replaced with special tokens.

Model	CCA	CCC	GC
BART-base	94%	94%	95%
FLAN-T5-base	91%	91%	97%
Claude	96%	96%	97%

Table 6: Human evaluation on query reformulation results.

6.3 Evaluation on Retrieval Performance

To evaluate the impact of reformulation on retrieval performance, we use various input types in our internal search engine to retrieve documents and employ LLM-based evaluation to measure the relevance of the top-k retrieved document to the context given a query. The reformulation model used in this evaluation is based on BART-base. LLM-based evaluation details are described in Table 11 in Appendix.

Table 3 presents the retrieval performance (Top-1 and Top-5) across different query types and models. While Claude was used to generate the reformulation ground-truth, our fine-tuned models based on those labels achieve competitive retrieval results. In fact, FLAN-T5-base outperforms Claude in Top-1 retrieval, demonstrating that our fine-tuned models can generate reformulations that yield better retrieval results in certain cases. Keywords reformulation consistently shows higher retrieval performance compared to NLQ reformulation across different models. This is likely because NLQ reformulations must be well-formed and closely aligned with the original query, while keyword reformulations can freely include additional context. For example, in Table 5 (Example 1), the keyword reformulation adds "remote not working", a useful detail omitted in the NLQ version for fluency. This flexibility makes keywords reformulation sufficient and often more effective in a multiturn RAG setting.

7 Online Deployment

At Amazon Customer Service, we deployed a multi-turn RAG chatbot powered by an adaptive model (RoBERTa-base) and a reformulation model (BART-base), both trained with the labeling methodology introduced in this paper using real customer-agent conversation transcripts. These models are now integrated into our production system handling live customer queries. With the adaptive model, we save latency costs for approximately 20% of traffic by bypassing the retrieval process. Supported by the reformulation model, high-quality documents are retrieved and used for answer generation by Claude-Sonnet 3.5. During a one-week online A/B test, the automation rate for resolving customer inquiries doubled, showing a 107% increase compared to the baseline.

8 Conclusion

In this paper, we addressed the challenges of developing a multi-turn RAG-based chatbot for customer service by focusing on two critical components: adaptive retrieval and query reformulation. To overcome the scarcity of annotated data for these components, we developed LLM-based labeling methods that automatically generate high-quality training data from existing customer-agent dialogues. Our experiments demonstrated that the explanation-guided labeling strategy significantly outperformed the intent-guided approach for adaptive retrieval. For query reformulation, we found that while NLQ reformulation produced more fluent and grammatically correct outputs, keyword-based reformulation yielded better document retrieval quality, with FLAN-T5-base achieving the highest Top-1 relevance score of 1.36. These findings provide valuable insights for practitioners developing multi-turn RAG systems in real-world customer service environments, offering a practical approach to leverage existing dialogue data for building efficient and responsive chatbots without requiring extensive manual annotation.

9 Limitations

Our LLM-based labeling approach for training adaptive retrieval and query reformulation models has shown promise but faces several key limitations. The training data derived from customer-agent dialogues may contain inherent biases that could be addressed through more balanced sampling strategies. While we evaluated various product types within e-commerce, our focus on a single platform limits insights about generalizability to other domains (like healthcare or finance) or interaction styles. Additionally, our heavy dependence on LLM quality for label generation means results may vary across different models or as the technology evolves, suggesting a need for more robust labeling methods. Future work should explore ways to mitigate these limitations and improve the system's overall reliability.

Appendix

A Prompts

System Prompt
Instruction
Your task is to annotate a conversation between a customer and an agent with pre-defined intents and whether retrieval is needed to answer the customer utterance. The transcript is made up of multiple turns and each turn has the format of "Turn_ID.Role: utterance". For example, "24.customer: But I bought the whole album." means in the 24th turn, the customer said "But I bought the whole album." Please read the transcript carefully, as I will ask you to label the intent of each customer utterance and whether it requires an API call to a search engine to obtain more information from a knowledge base in order to answer the query.

For every customer utterance, select one from the following intents:
a: DESCRIBE AN ISSUE. the customer is describing the issue.
b: ASK AN ISSUE RELATED QUESTION. the customer asks an issue-related question.
c: ANSWER A QUESTION. the customer is answering a question asked by the agent.
d: CONFRIMATION. the customer is simply confirming or recognizing information without making a specific request or inquiry.
e: REPORT STATUS. customer is reporting his or her current status, The customer has received instructions and is providing an update on the current issue status based on those instructions.
f: REQUEST. customer is making a request such as refund.
g: GRATITUDE. the turn is spoken by the customer, and customer is showing gratitude to the agent or bot the customer is expressing appreciation or thanks
h: COMPLAIN. the customer is expressing frustration about a product, service, experience.
i: ASK AGENT STATUS. the customer is asking about the availability or status of a agent.
j: FAREWELL. a customer's intention to end or conclude the conversation.
k: GREETINGS. the turn is spoken by the customer.
l: OTHERS.

After labeling each customer turn's intent, you will also label whether that turn will trigger a RAG based on the following criteria:
Yes: the current turn is spoken by the customer and the current utterance mentioned about useful details about the issue and the knowledge bank should be updated by a retrieval action based on current utterance information and previous conversation history. For example, RAG should be triggered when the customer describes an issue or asks an issue-related question. Additionally, RAG may also be necessary when the customer provides more details in response to a question or reports their status. However, in cases where no valuable information is provided, RAG should not be triggered.
No: There is no need to update the knowledge bank since the utterance does not contain any issue-related information.
Overall, for each turn, you will first give an intent label(a-l) and then give a RAG label You should note that the intent label is closely related to RAG, RAG probably needs to be triggered. Follow the example below to format your answers.

Format Examples
Transcript in the format of:
<Transcript> 1.agent: Hello, welcome back. How can I help with? 2.customer: my remote is not working. 3.agent:Thanks, I apologize for the inconvenience, can you try restarting your tv 4.customer: Sure.</Transcript>
Output in the format of:
<Labels for intent and RAG>: 2.a,Yes,4.d,No </Labels for intent and RAG>

User Prompt
<Transcript>: **{Dialogue}**
<Labels for intent and RAG>:

Table 7: Prompt for intent-guided adaptive retrieval labeling.

System Prompt
Instruction
Your task is to understand a conversation between a customer and an agent and predict, for each customer utterance, whether it should trigger an API call to a search engine to retrieve more information from a knowledge base to answer the customer query. You should also provide an explanation for your decision. I will provide you with a conversation transcript between a customer and an agent. The transcript is made up of multiple turns and each turn has the format of "Turn_ID.Role: utterance". For example, "24.customer: But I bought the whole album." means in the 24th turn, the customer said "But I bought the whole album."

1. Explain the reason why an API call to trigger retrieval is needed or not needed for the utterance.
- Specifically, a search engine API call is needed if:
The utterance is an description about the issue. The utterance provides context regarding the issue, such as device, or subscription information. The utterance provides answers to an issue-related question or clarification question asked by the agent. The utterance confirms details or status regarding the device, plan or issue. The utterance asks questions (usually start with "how")regarding how to resolve a problem or how to complete certain steps. The utterance provides the status of the issue after trying something. The utterance is a continuation of the previous turn where retrieval is needed or recommended. Remember, if the mentioned issue details or context is not new, you could also consider retrieval is needed.
- A search engine API call is not needed if the utterance does not contain any issue-related information. For example, the utterance is a greeting, a farewell, a complain regarding the issue. confirming the issue is resolved.
2. Select a label from [Yes, No] to indicate whether an API call to retrieval is required for the utterance.

Format Examples
Transcript in the format of
<Transcript> 1.agent: Hello, welcome back. How can I help with? 2.customer: my remote is not working. 3.agent: Thanks, I apologize for the inconvenience, can you try restarting your tv 4.customer: Sure.</Transcript>
Output in the format of:
<Turn>[2,4]</Turn>
<explain> [2.The customer is describing an issue and retrieval is needed 4.the customer is expressing acknowledgement and the retrieval is not needed] </explain>
<label>[2.Yes,4.No]</label>

User Prompt
<Transcript>: **{Dialogue}**
<Annotation>

Table 8: Prompt for explanation-guided adaptive retrieval labeling

System Prompt
Instruction
I will provide you with a user query along with a conversation history between a customer and an agent. The conversation history consists of multiple turns, each numbered sequentially (e.g., 1 for turn 1, 2 for turn 2). Each turn begins with an indication of the speaker (e.g., if the agent is speaking, the turn will start with "agent:").
Your task is to analyze the entire conversation history along with the user query and generate a well-structured, clear, and optimized query that facilitates retrieving the most relevant information for a QA system. The reformulated query should be concise, precise, and designed to yield high-quality results. You can edit the query and perform the following action when reformulating the query:
Recover: Add missing context from previous conversation turns, such as resolving co-references.
Correction: Fix any grammatical or structural errors in the query.
Simplification: Exclude irrelevant information.
Before generating the reformulation, you need to first:
1. understand the query and describe the intent of the query.
2. explain what actions should be performed (Recover, Correction, Simplification) and why.
3. generate the reformulation.

Format Examples
Input in the format of
<Conversation history> 1.agent: What do you need help with? 2.customer: My Music App 3.agent: Sure, how can I help you with that?</Conversation history>
<Query>It does not work on my speakers</Query>
Output in the format of:
<Intent>issue description</Intent>
<Actions> replace the pronoun “it” with “Music App” mentioned in turn 2.</Actions>
<Reformulation>Music App does not work on my speakers.</Reformulation>

####Final Instruction
Do not change the intent of the original query. Do not change the query type of the original query. If the original query is a statement rather than a question, the reformulation should also be a statement. Keep the same tone, and make sure the reformulation sounds like something spoken by the customer to an agent. Make sure the reformulation is self-contained and can be understood without the conversation history.

User Prompt
<Conversation history>: **{Context}**
<Query>: **{Customer Query}**
<Output>:

Table 9: Prompt for NLQ reformulation generation

System Prompt
Instruction
I will provide you a user query along with a conversation history between a customer and an agent. The conversation history is made up of multiple turns, each numbered at the start. Your task is to take into account the entire conversation history along with the query to generate a new keywords query that will help retrieve the most relevant information. The reformulated query should be focus on core key phrases mentioned of the current turn and previous turns. Before generating the reformulation, you need to first:
1. understand the conversation history and current query, and then describe the intent of the query
2. explain why those keywords are generated, which turn are they coming from
3. generate the new keywords query

Format Examples
Input in the format of
<Conversation history>1.agent: What do you need help with? 2.customer: My Music App 3.agent: Sure, how can I help you with that?</Conversation history>
<Query>It does not work on my speakers</Query>
Output in the format of:
<Intent>issue description</Intent>
<Reason>The customer is mentioning that the music App is not working well on the speaker. Therefore the key information in the issue is music App, not work and Speakers</Reason>
<Reformulation> music App not work on speakers</Reformulation>

Final Instruction
Remember,
- The reformulation should be keywords.
- Each keyword could either be directly extracted from the conversation history and the current query, or relevant new keywords that could provide complementary information.

User Prompt
<Conversation history>: **{Context}**
<Query>: **{Customer Query}**
<Output>:

Table 10: Prompt for keywords reformulation generation.

System Prompt
Instruction
Given a list of documents, assess their relevance to a customer query and previous chat history between an agent and a customer. Each document consists of two fields: title and content. Rate the relevance on a scale from 0 to 2 based on its connection to the dialogue:
0: irrelevant, the document is irrelevant to the issues, product or services discussed in the dialogue
1: somewhat relevant, the document is related to the issues, product or services discussed in the dialogue
2: Perfectly relevant, the document contains critical information to address the query with comprehensive information

Format Examples
Input in the format of
<Chat History>[Here is the chat history]</Chat History>:
<Query>[Here is the customer query]</Query>:
Document:
<title>[Title of the document]</title>
<content>[Content of the document]</content>
Output in the format of:
<Score> select from 0-2
<Explanation>Provide a brief explanation of why you give this rating. Point out any specific areas where the document succeeds or fails in addressing the query.

User Prompt
<Chat History>: **{Context}**</Chat History>
<Query>**{Query}**</Query>:
Document:
<title>**{title}**</title>
<content>**{content}**</content>
Output:

Table 11: Prompt for LLM-based relevance judgment of the top-1 search result. The prompt for the top-5 results follows a similar structure but includes five documents.

RAGulator: Lightweight Out-of-Context Detectors for Grounded Text Generation

Ian Poey **Jiajun Liu** **Qishuai Zhong**
OCBC AI Lab
{ianpoey, qishuaizhong}@ocbc.com

Abstract

Real-time identification of out-of-context outputs from large language models (LLMs) is crucial for enterprises to safely adopt retrieval augmented generation (RAG) systems. In this work, we develop lightweight models capable of detecting when LLM-generated text deviates from retrieved source documents semantically. We compare their performance against open-source alternatives on data from credit policy and sustainability reports used in the banking industry. The fine-tuned DeBERTa model stands out for its superior performance, speed, and simplicity, as it requires no additional preprocessing or feature engineering. While recent research often prioritises state-of-the-art accuracy through fine-tuned generative LLMs and complex training pipelines, we demonstrate how detection models are deployed efficiently with high speed and minimal resource usage.

1 Introduction

In enterprise settings, Generative AI has received widespread adoption as a tool to uplift employees' productivity (Brachman et al., 2024). Enterprises require a high degree of factuality of generated answers in popular language tasks, such as question-answering (QA) and summarisation.

Retrieval Augmented Generation (RAG) (Lewis et al., 2020) allows users to interact with large language models (LLMs) for industry-specific knowledge spanning multiple use cases and document types. It is adaptable to tasks requiring evolving knowledge, such as synthesising information from the latest industry news. However, a key limitation of RAG is the generation of outputs that are observed to be out-of-context. This is related to hallucination of LLMs, manifesting itself in inconsistent or fabricated claims (Huang et al., 2025) that can be subtle and phrased confidently even if factually incorrect (Li et al., 2024). For highly sensitive working environments such as financial institutions, the inability to ensure faithful LLM output can be one of the biggest limitations to widespread adoption of LLM-powered applications (Maple et al., 2024).

To address this barrier to enterprise adoption, in this study we narrow the scope of "hallucination" and focus only on hallucinations that render the LLM response semantically inconsistent with the provided context. This is commonly known as *faithfulness hallucination* (Huang et al., 2025; Es et al., 2024; Saad-Falcon et al., 2024), *contextual hallucination* (Chuang et al., 2024), or a lack of *grounded factuality* (Bespoke Labs) or *support* (Belyi et al., 2025); to aid business understanding, we adopt the term *out-of-context* (OOC). We consider any LLM-generated response to a RAG prompt as semantically OOC if any part of the response is ungrounded based on the retrieved context alone, even if it is otherwise factual according to world knowledge. In contrast, an *in-context* response is one where every claim embedded in the response can be inferred solely from the retrieved context.

Approaches to mitigate OOC generation can be broadly classified into 2 types – black-box and grey-box methods. **Black-box methods** employ strong generative LLMs to assess if a candidate answer is OOC, and these LLMs are usually augmented with various prompting or fine-tuning techniques. Examples of black-box methods include RARR (Gao et al., 2023), WikiChat (Semnani et al., 2023), FreshPrompt (Vu et al., 2024), SelfCheckGPT (Manakul et al., 2023), RAGAS (Es et al., 2024), ChainPoll (Friel and Sanyal, 2023), and Lynx (Ravi et al., 2024). However, black-box approaches that rely on strong closed-source LLM judges are less suitable for enterprises that are constrained by budget and/or data privacy requirements. **Grey-box methods** are alternatives which aim to detect OOC generation through a proxy metric or model. Grey-box approaches either assess

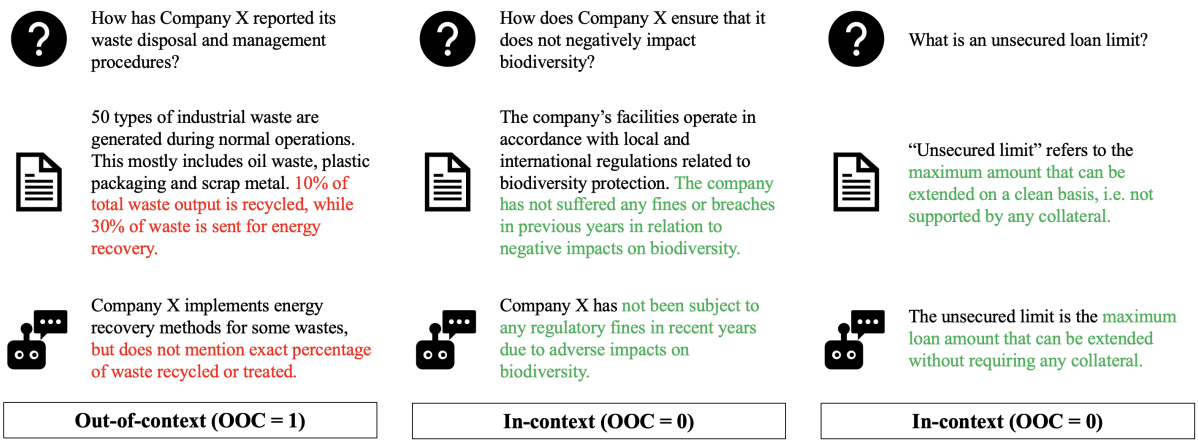

Figure 1: Example LLM responses from RAG systems in the banking industry.

final/hidden LLM states, such as FLARE (Jiang et al., 2023) and Lookback Lens (Chuang et al., 2024), or use a score computed by an independent discriminative model of lower complexity, such as SummaC (Laban et al., 2022), AlignScore (Zha et al., 2023), HHEM (Mendelevitch et al., 2024), and Luna (Belyi et al., 2025).

In this work, we propose RAGulator, a series of lightweight OOC detectors for RAG applications. We create a training dataset which simulates both OOC and in-context RAG prompts, from a range of public datasets originally constructed for various traditional NLP tasks. Furthermore, we compare 2 types of grey-box discriminative models – fine-tuned BERT-based classifiers and ensemble meta-classifiers trained on numerical features derived from text. Generative labelling with an LLM annotator is employed where necessary to adapt the training dataset for BERT-based classifier fine-tuning. We show that while a large LLM can show good agreement with human annotation in labelling data for BERT classifier fine-tuning, our predictive models outperform the same LLM in a zero-shot setting on the enterprise OOC detection task, while also surpassing other open-source detectors in most cases. The results highlight the need for specialised models for OOC detection in enterprise RAG.

2 Method

2.1 Problem formulation

We train a lightweight grey-box discriminator to detect semantically OOC LLM-generated sentences from a RAG system. Figure 1 illustrates examples of OOC and in-context sentences extracted from RAG systems in the banking industry. In the OOC example (left), the LLM fails to find the answer within retrieved documents, and the generated statement is inconsistent with the context. Whereas, in-context statements are clearly grounded in the documents regardless of whether their relevance to the question is low (middle) or high (right).

We formulate the problem of semantic OOC closely following the setup by Tang et al. (2024). Any RAG prompt $Prompt(\mathcal{D}, x)$ to an LLM contains an associated set of retrieved documents $\mathcal{D} = \{D_1, ..., D_{|\mathcal{D}|}\}$ and a question x, to which the LLM responds with text that can be broken into an unordered set of sentences $\mathbf{c} = \{c_1, ..., c_{|\mathbf{c}|}\}$. We treat each sentence c_i as an independent candidate claim to be verified. To detect OOC candidates, we define a discriminator

$$M(\mathcal{D}, c_i) \in \{0, 1\}$$

that classifies each candidate as `out-of-context`, 1, or `in-context`, 0, according to the set of retrieved documents $\mathcal{D}$.

Certain model architectures (e.g. BERT) face limitations on the amount of text that can be accepted by the model in one pass. This would require the set of documents $\mathcal{D}$ to be arbitrarily re-split into J text chunks $\{D_1, ..., D_J\}$ of varying sizes not more than the model-defined limit. In this case, the overall discriminator can be defined as

$$\min_j M(\mathcal{D}_j, c_i) \in \{0, 1\}$$

implying that if and only if the claim c_i is OOC with respect to every text chunk D_j, then it can be considered OOC overall.

2.2 Dataset curation

We construct a dataset by adapting publicly available datasets, sampling and preprocessing them to simulate LLM-generated sentences and RAG-retrieved contexts of various lengths. The goal is to

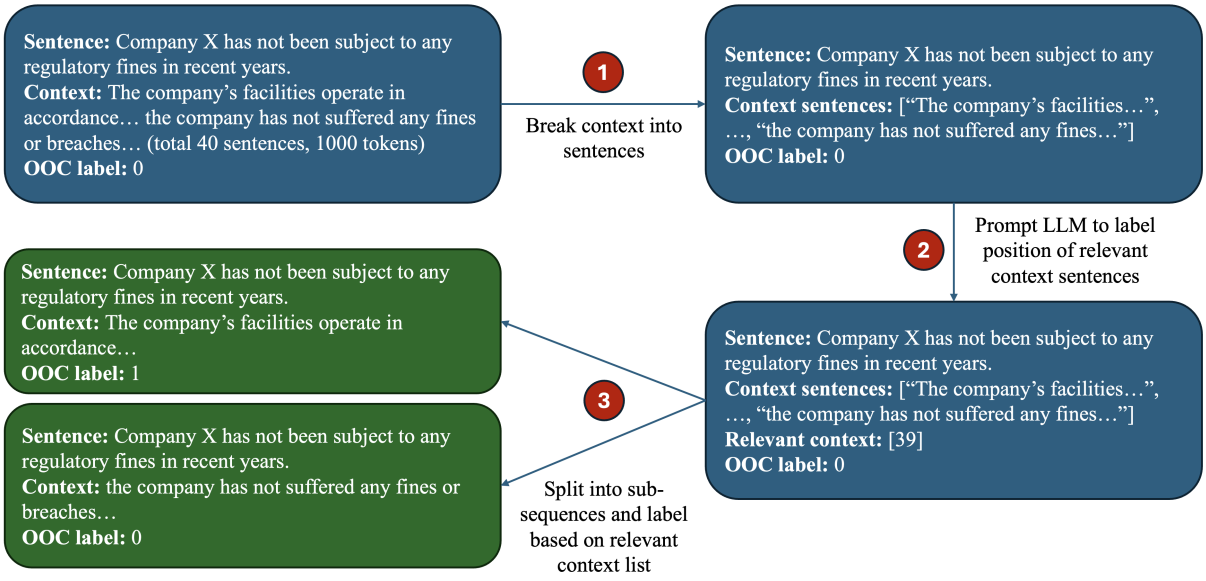

Figure 2: Illustrated flow of the generative labelling process.

create a dataset with sentence-context pairs. This curation only involves sentence tokenisation and random sampling. Datasets belonging to summarisation (extractive and abstractive) and semantic textual similarity tasks are selected for adaptation.

Summarisation task datasets. Originally each row in the dataset is an abstract-article pair. Preprocessing is done by randomly pairing abstracts with unrelated articles to create OOC pairs, then applying sentence tokenisation to the abstracts to create one example for each abstract sentence. Both extractive and abstractive summarisation datasets are adapted, consisting of BBC (Greene and Cunningham, 2006), CNN/Daily Mail (version 3.0.0) (Nallapati et al., 2016), and PubMed (Cohan et al., 2018) datasets.

Semantic textual similarity (STS) datasets. Originally each row in the dataset is a pair of sentences, with a label indicating if the pair of sentences are similar. Preprocessing is done by inserting random sentences from the datasets to one of the sentences in the pair to simulate a long "context". The original labels are mapped to our definitions to indicate if the pair is an OOC pair. The adapted datasets consist of the Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005) and Stanford Natural Language Inference (SNLI, version 1.0) (Bowman et al., 2015) datasets.

For MRPC, the semantically-equivalent indicator is mapped to `in-context` if present and `out-of-context` if absent. For SNLI, labels provided by human annotators are originally in the set {`entailment`, `contradiction`, `neutral`}. We ignore sentence pairs labelled `neutral` and those without unanimous agreement, while mapping the labels `entailment` to `in-context` and `contradiction` to `out-of-context`.

In our eventual curated dataset, we ensure each simulated sentence contains between 5-100 tokens, and that each simulated context contains between 100-5000 tokens. We sample only from author-provided training and test splits to form training and holdout evaluation data respectively.

2.3 Generative labelling

Standard BERT models have a 512-token limit. In this study, generative labelling is employed for data used in fine-tuning to ensure compatibility with a wide range of BERT model variants.

For sentence-context examples derived from summarisation datasets and labelled as in-context (≈34% of dataset), the LLM-"generated" sentence is relevant to at least one part of the context, but the exact position is unknown. As shown in Figure 2, we utilise Llama-3.1-70B-Instruct (Grattafiori et al., 2024) to label each sentence by prompting it to return the positions of context sentences that are relevant. With this output, we split the sentence-context example into windows of tokenised sub-sequences (i.e. sentence + context) that are each no longer than 512 tokens, and label the sub-sequences based on whether the sub-sequence contains a relevant context sentence.

2.4 Feature engineering

We incorporate classic machine translation metrics to compare response (candidate) and context (reference) alongside semantic similarity features derived from distance metrics computed using encoder-only models. Preliminary analysis reveals that the feature distributions for in-context LLM-generated sentences differ significantly from those of OOC sentences. This section provides a brief overview of the implementation of these features, with additional details in Section A.

Precision score. We calculate this feature as the fraction of words in the response that also appear in the context (Melamed et al., 2003). We apply the precision score after text preprocessing and word deduplication.

Unigram and bigram perplexities. We construct a probability distribution (i.e. dictionary of token frequencies) from the context's unigram and bigram tokens after text preprocessing, then calculate sum negative log likelihood and normalise by the respective number of candidate n-grams.

Maximum embedding similarity score. We compute the maximum pairwise similarity between embeddings of the response and each context sentence using the pretrained bge-small-en-v1.5 model (Xiao et al., 2024).

Maximum reranker relevance score. We compute the maximum relevance score between the response and each context sentence using the pretrained bge-reranker-base model.

2.5 Models

We train two meta-classifiers of LightGBM and Random Forest architectures respectively. These are selected due to their widespread adoption and reliability in enterprise settings. In parallel, we leverage the generative labelling technique to train two BERT-based classifiers: deberta-v3-large[1] initialised with default pretrained weights, and xlm-roberta-large[2] initialised from the bge-reranker-large checkpoint, effectively fine-tuning a reranker for OOC detection. Training details for all models are found in Section B.

Table 1: Dataset statistics for training and evaluation. The number of examples and out-of-context proportion is stated for each data subset.

3 Evaluation

3.1 Public data

We evaluate RAGulator models on an **in-distribution** holdout split of our simulated RAG dataset, comprising 9,697 rows sampled from the PubMed, MRPC, and SNLI subsets.

3.2 Industry data

We also prepare an **out-of-distribution** collection of 570 RAG responses that are gathered and hand-annotated for evaluation. This private dataset includes 386 responses related to sustainability-themed documents analysed by corporate banking relationship managers ("ESG"), and 184 responses associated with credit policy documents used by bank officers in loan approval processes ("CP"). The examples illustrated in Figure 1 are adapted from anonymised and truncated excerpts of this private dataset to preserve confidentiality.

Table 1 reports the composition per-source and the proportion of OOC labels in training and evaluation datasets.

3.3 Model inference

When running inference with BERT-based classifiers, we predict on each of the tokenised sub-sequences of the original sentence-context pair. We then aggregate model predictions to obtain a single prediction at the sentence level. We take the minimum probability across all sub-sequences as the overall OOC probability; as long as one of the generated sub-sequences is in-context, we consider the entire generated sentence as in-context.

For evaluation, we use Llama-3.1-70B-Instruct hosted on four H100 GPUs for black-box methods, and transformer-based models for grey-box methods hosted on one V100 GPU.

4 Results

4.1 Generative vs. human labelling

We verify the effectiveness of generative labelling by experimenting with several prompting methods on a sample of 58 sentence-context pair examples (20 BBC, 20 CNN/Daily Mail, 18 PubMed), comprising 2,696 context sentences. Table 4 shows the inter-rater agreement between human annotation and each Llama-3.1 annotator prompted with different templates, such as few-shot prompting, chain-of-thought prompting (CoT) (Kojima et al., 2022), or both (Wei et al., 2022). Details on prompting are found in Section C.

We find that the use of five-shot and CoT increases the reliability of generative labelling compared to human annotation, evidenced by the increase in Cohen's kappa (κ). Nevertheless, direct zero-shot prompting is already in substantial agreement with human observation. We adopt zero-shot for generative labelling as this method is the fastest, utilises the fewest tokens, and least likely to deviate in terms of desired LLM output structure.

4.2 Model performance on evaluation datasets

Tables 2 and 3 present the evaluation results on our private ESG and CP subsets, and on the public subsets (PubMed, MRPC, and SNLI), respectively. We report area-under-curve (AUC) scores as well as F1 scores computed after threshold tuning.

Performance against baseline. We compare our models with direct zero-shot prompting of Llama-3.1 as a baseline. Details on prompting and extracted OOC probabilities that allow for the reporting of AUC scores are given in Section D. Across the evaluation dataset, our models consistently out-

perform the baseline in AUC metrics. The observed performance gap is largest in the CP dataset, with RAGulator-deberta-v3-large showing a 19% increase in AUROC and a 17% increase in F1 score, despite being significantly smaller than Llama-3.1. BERT-based RAGulator models are at least 630% faster than baseline, while the meta-classifiers are up to 34% slower. However, the 70B LLM requires significantly more VRAM compared to both meta-classifiers, even with underlying models needed for feature generation.

Performance against other detectors. We compare our models with other black-box methods and open-source grey-box detectors (details in Section E). RAGulator models outperform evaluated detectors in most metrics, with the exception of Bespoke-MiniCheck-7B that has a slight edge in the CP dataset. Despite scoring 0.9% lower in AUPRC and 1.4% lower in F1 score, RAGulator-deberta-v3-large exhibits overall competitive performance as an encoder-only model with 5.6% of the parameters and 194% of the speed. While RAGAS Faithfulness obtains the highest F1 score for the CP dataset, its speed is more than 30 times slower than baseline and is likely impractical for inference in real-time or at scale. On the ESG subset, the meta-classifiers surpass other detectors across all metrics regardless of size, and are also faster than black-box detectors.

5 Discussion

5.1 Model deployment in enterprise

Enterprise LLM usage patterns motivate the need for OOC detectors that optimise the tradeoff between accuracy and efficiency for low-latency deployment at scale. Our LLM cluster infrastructure receives over 2 million requests per month, totalling 2.2 billion input tokens and generating over 190 million output tokens. The most frequently used application involving RAG sustains a peak load of up to 100 requests per minute. To meet demands, we deploy RAGulator-deberta-v3-large[3,4] as a real-time guardrail for RAG requests in the enterprise, using a GPU-enabled serving framework with load balancing and autoscaling capabilities, enabling high availability and throughput. To further maximise model utilisation and reduce latency, we implement mini-batching and dynamic mapping

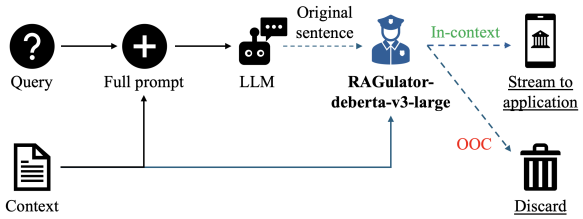

Figure 3: Illustrated setup for OOC detection with a RAGulator BERT-based classifier in real-time RAG workflows, where LLM-generated sentences are streamed to the guardrail at sentence-level.

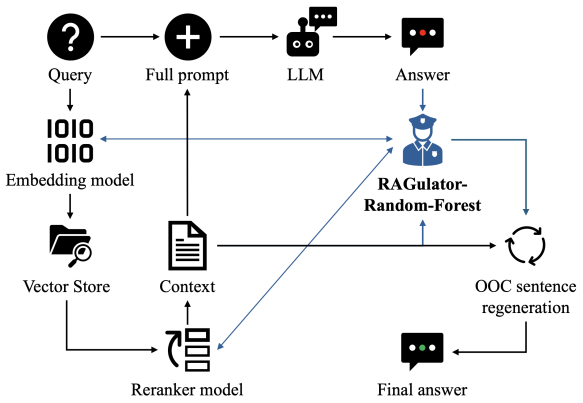

Figure 4: Illustrated setup for OOC detection with a RAGulator meta-classifier in batch RAG workflows, where the LLM-generated answer is sent to the guardrail to mark OOC sentences for regeneration.

of sentence-context pairs aggregated across concurrent requests containing multiple inputs. Figure 3 illustrates this setup, which is most effective for use cases that require real-time RAG responses, such as in AI copilot applications. Sentences are streamed to RAGulator with accompanying context as soon as each sentence is fully generated, and passed to the user-facing application only if it is marked as in-context. By serving OOC detection with a small specialised model, the real-time requirement is satisfied with low resource usage.

For RAGulator meta-classifiers, the most computationally intensive step in both training and inference is the calculation of embedding similarity and reranker relevance scores during feature engineering. These metrics are precomputed in the context retrieval phase of the RAG pipeline, enabling reuse of the same embedding and reranking models within the feature engineering process. By aligning feature computation with existing GPU-enabled retrieval infrastructure, no additional GPU resource needs to be consumed by OOC detection. In practice, we deploy RAGulator-Random-

[3]Code available at github.com/ipoeyke/RAGulator

[4]Model weights available at huggingface.co/ipoeyke/ragulator-deberta-v3-large

Forest in batch workflows for enterprise RAG, asynchronously using embedding and reranking services that are already active. Figure 4 illustrates this setup, which is most effective for use cases where meta-classifiers outperform BERT-based models and where real-time prediction is not required.

In both real-time and batch scenarios, sentences marked as OOC can either be excluded from the final answer, or trigger re-retrieval and sentence regeneration steps as implemented in active retrieval paradigms such as FLARE (Jiang et al., 2023).

5.2 Model evaluation in enterprise

We introduce an out-of-distribution evaluation dataset not only to prevent data leakage, but also to assess if a given OOC model is suitable for specific use cases in the organisation. We ensure that these goals are met by collecting private data from enterprise domains that differ from the training distribution, thereby avoiding overlap between training and test sets. While public benchmarks are useful for rapidly surveying the performance of open-source OOC detection models, their results can diverge from real-world behaviour in enterprise settings. As such, model selection should be guided by the specific requirements and measured performance in the intended use case.

6 Conclusion

In this study, we demonstrate a low-resource pipeline for data gathering and training of small discriminative models to detect LLM-generated texts that are semantically out-of-context. We show that these models not only outperform zero-shot detection and black-box judges powered by Llama-3.1-70B-Instruct, a much larger generative LLM, but also surpass several popular grey-box detectors on enterprise data. RAGulator-deberta-v3-large achieves an optimal balance between performance and efficiency, is over 6 times faster than zero-shot prompting, and does not require additional text preprocessing or feature engineering. Although emerging work has focused on LLM-as-a-judge methods or on fine-tuning of generative LLMs to achieve state-of-the-art performance, speed and resource limits are concerns when considering to deploy such pipelines (Parthasarathy et al., 2024). For enterprises bound by strict data security rules and resource constraints, our work presents a favourable alternative for the training and serving of on-premise OOC detection.

Limitations

We frame OOC detection as a binary classification problem, without distinguishing between common fine-grained subtypes such as entity, relation, invented, or subjective OOC occurrences (Mishra et al., 2024). A popular direction in recent work is to use strong LLMs (e.g. GPT-4) to generate high-quality candidates semantically similar to the retrieved context that contain OOC subtypes. This includes error insertion, answer perturbation, and new claim generation, reducing the need for human annotation (Ravi et al., 2024; Tang et al., 2024; Mishra et al., 2024; Li et al., 2023; Tang et al., 2025). While effective, these pipelines and subsequent fine-tuning are often infeasible in closed or resource-constrained environments. Our method instead applies random substitutions and insertions to construct sentence-context pairs with binary labels, offering scalability and adaptability across domains, though potentially introducing a larger semantic gap than LLM-curated datasets. Future work may quantify this "simulation gap" and assess subtype-specific performance to better understand the trade-off between realism and scalability.

Our approach assumes sentence-level independence, limiting the ability to model inter-sentence dependencies. However, this design reflects enterprise requirements, where a single OOC sentence can invalidate an entire response. We further apply context splitting for BERT-based models, which may cause losses in semantic information if multiple chunks are needed to fully support a single sentence. Despite this limitation, RAGulator models perform comparably or better than black-box methods with much longer context windows, including Bespoke-MiniCheck-7B (32,768 tokens) and zero-shot prompting of Llama-3.1 (128,000 tokens). Given that contexts in our dataset do not exceed 5,000 tokens, these methods should avoid semantic losses, suggesting that sentence-level detection and context splitting remain appropriate for enterprise OOC detection. Future work may develop resource-efficient models that capture inter-sentence and inter-chunk relationships for real-time deployment.

Ethics Statement

To maintain the privacy of related organisations, we anonymised all entity names and substituted all numerical values that were mentioned in industry examples highlighted in this work.

Acknowledgements

We express our gratitude to Donald MacDonald (Head, OCBC Group Data Office) and Kenneth Zhu (Head, OCBC AI Lab) for their invaluable support and access to on-premise computing resources. We also thank Adrien Chenailler and Chengquan Ju for reviewing an earlier version of this work and providing helpful suggestions. We also express our appreciation to all reviewers for their insightful feedback.

A Notes on feature engineering

Retrieved context can contain noise due to reasons such as suboptimal parsing of reference documents, presence of formatting characters, and inconsistent grammatical or lexical structure. Thus, we apply text preprocessing to both response and context before generating classical features. Preprocessing steps include lowercase conversion, removal of most punctuation symbols, stemming, and stopword removal. For semantic features, we use the raw response-context pair that BERT-based models expect as input.

Similarity and relevance scores are aggregated by maximum. As long as the candidate is relevant to one context sentence, the candidate should be considered grounded in context, therefore capturing the extent to which the candidate is supported.

B Model training hyperparameters

Table 5 shows the hyperparameter search space used to tune the LightGBM and Random Forest meta-classifiers, while Table 6 shows the relevant hyperparameters for the training of BERT classifiers. During BERT fine-tuning, we observed that the validation performance no longer increases after 3 epochs.

C Llama-3.1 for generative labelling

Figure 5 shows the prompt template for zero-shot generative labelling of training examples. To elicit zero-shot chain-of-thought, we use the technique described by Kojima et al. (2022), adding the following line to the instruction while leaving all else unchanged:

```
Let's think step-by-step. After
presenting your thought process,
list down the supporting context
sentences by writing "The answer
is:" followed by the list.
```

Figure 6 shows the prompt template for five-shot generative labelling, and Figure 7 shows the prompt template that elicits chain-of-thought for five-shot prompting, following the technique described by Wei et al. (2022).

D Direct prompting of Llama-3.1 for OOC detection

To perform OOC detection with Llama-3.1, we directly prompt it to return a binary prediction – 1 for OOC and 0 otherwise. Figure 8 shows the template used.

To obtain an OOC prediction probability $P(OOC)$, we extract the log-probabilities (logprobs) of the "0" or "1" token choices in the first output token and calculate softmax of the "1" token based on these 2 choices only:

$$P(OOC) = \frac{\exp(log(P(y=\text{"1"})))}{\exp(log(P(y=\text{"0"})))+\exp(log(P(y=\text{"1"})))}$$

where $log(P(y = \text{"1"}))$ is the logprob of predicting the "1" token and $log(P(y = \text{"0"}))$ is the logprob of predicting the "0" token.

E Comparison to other black-box frameworks and grey-box models

E.1 Black-box frameworks

We evaluate the following black-box frameworks:

RAGAS Faithfulness[5]**:** we consider only the Faithfulness metric as its definition is similar to the OOC definition, except for the generalisation to include sentences containing multiple claims. We use release version 0.2.15.

SelfCheckGPT-Prompt[6]**:** this SelfCheckGPT variant relies on an LLM judge to assess consistency between stochastically-generated answer samples. For each ESG and CP data point, we use the original question to sample 3 responses from Llama-3.1-70B-Instruct at a temperature of 1.0. The in-distribution holdout split does not apply to SelfCheckGPT, as the concept of a "question" does not exist in the dataset curation process; therefore, results on the overall evaluation dataset are not applicable. We do not include the sampling process in our measurement of inference speed. We use release version 0.1.7.

E.2 Grey-box models

We evaluate the following grey-box models:

AlignScore-large[7]**:** this model is a finetune of deberta-v3-large, and can be directly compared to RAGulator. We use the authors' original implementation of AlignScore as retrieved from GitHub (commit hash beginning with a0936d5).

MiniCheck-deberta-v3-large[8]**:** this model is a finetune of deberta-v3-large, and can be directly compared to RAGulator. We use the authors' original implementation of MiniCheck as retrieved from GitHub (commit hash beginning with c655973).

[5] github.com/explodinggradients/ragas
[6] github.com/potsawee/selfcheckgpt
[7] github.com/yuh-zha/AlignScore
[8] github.com/Liyan06/MiniCheck

Bespoke-MiniCheck-7B[8]**:** this model is a fine-tune of the InternLM2 chat model (internlm2_5-7b-chat) consisting of 7.74 billion parameters. We use the authors' original implementation of MiniCheck, including the vLLM framework dependency, as retrieved from GitHub (commit hash beginning with c655973).

Hyperparameter	LightGBM	Random Forest
max_depth	[2,4,-1]	[1,2,3,4,5]

Abstract

Accurate intent classification is critical for efficient routing in customer service, ensuring customers are connected with the most suitable agents while reducing handling times and operational costs. However, as companies expand their product lines, intent classification faces scalability challenges due to the increasing number of intents and variations in taxonomy across different verticals. In this paper, we introduce **REIC**, a **R**etrieval-augmented generation **E**nhanced **I**ntent **C**lassification approach, which addresses these challenges effectively. REIC leverages retrieval-augmented generation (RAG) to dynamically incorporate relevant knowledge, enabling precise classification without the need for frequent retraining. Through extensive experiments on real-world datasets, we demonstrate that REIC outperforms traditional fine-tuning, zero-shot, and few-shot methods in large-scale customer service settings. Our results highlight its effectiveness in both in-domain and out-of-domain scenarios, demonstrating its potential for real-world deployment in adaptive and large-scale intent classification systems.

1 Introduction

Customer service (Cui et al., 2017; Chen et al., 2024; Nguyen et al., 2020; Qi et al., 2021; Chen et al., 2023; Zhou et al., 2023; Pi et al., 2024) is critical for modern e-commerce but also one of the most resource-intensive departments. Different agents, either human or model, are trained to handle specific types of customer issues, making precise intent classification, particularly at the issue level, crucial for efficient routing. High issue-oriented intent accuracy ensures that customers are connected with the most suitable agents, reducing unnecessary transfers and lowering handling times. This optimization not only enhances customer satisfaction but also cuts operational costs by streamlining interactions and improving overall service efficiency. For model-based automatic resolvers in chatbot agentic systems (Gupta et al., 2024), the ability to precisely identify user intent is essential for delivering contextually appropriate and solution-oriented responses.

As companies expand their product lines, intent classification faces two key challenges. First, the number of customer intents grows over time, requiring models to adapt to new intents quickly. Second, intent taxonomies can vary across product lines, making it difficult to maintain a unified classification system(Pi et al., 2023). For example we organize products into different verticals in e-commerce: with third-party products, customer usually inquire about physical retail orders or consumer accounts, and intents are categorized into three levels from coarse to fine-grained. In contrast, first-party products require more customized customer services due to our proprietary device and digital product offerings. For instance, a customer seeking device troubleshooting may interact with an agent who can access real-time diagnostic information and perform specific troubleshooting steps on the user's behalf. This necessitates a broader set of intent categories to accommodate diverse customer needs, as illustrated in Figure 1. This heterogeneity complicates intent classification, demanding scalable and flexible approaches to ensure accurate routing and efficient customer service. In this work we demonstrate our method using two verticals but it can be easily adapted to more.

In this paper, we propose a novel **R**etrieval-augmented generation **E**nhanced **I**ntent **C**lassification (**REIC**) approach that reduces computational complexity and improves scalability for intent classification. We demonstrate the effectiveness of this approach through extensive experiments on real-world datasets , showing that our method outperforms traditional fine tuning and zero-shot or few-shot methods in large-scale customer service settings. Our results on both

November 4-9, 2025 ©2025 Association for Computational Linguistics

in-domain and out-of-domain intents demonstrate its potential to improve classification accuracy and enable dynamic updates without retraining, making it ideal for industry-scale applications.

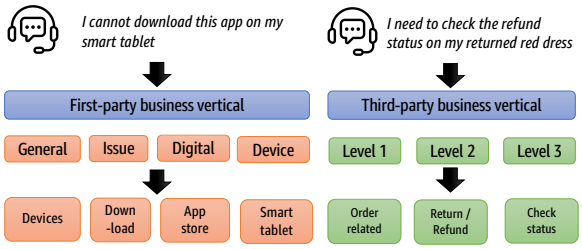

Figure 1: We present the heterogeneous intent structure with representative examples, illustrating the intent label hierarchy in each vertical.

2 Related Work

2.1 Intent classification

Early work on intent classification for dialogues often relied on bag-of-words or recurrent models. For example, Schuurmans and Frasincar (2019) evaluated various classifiers on a multi-domain intent dataset and found that a simple SVM with hierarchical label taxonomy outperformed deeper LSTM models. With the advance of transformer architectures, researchers began to leverage self-attention and multi-task learning for intent understanding. Ahmadvand et al. (2020) introduced a joint intent mapping model that simultaneously classifies high-level intent and maps queries to fine-grained product categories. Wang et al. (2021) employed a slowly updated text encoder and global/local memory networks to mitigate catastrophic forgetting and parameter explosion for large-scale intent detection task. Recent work has pushed toward using large pre-trained models and retrieval-based prompting to enable cross-domain and zero/few-shot intent classification. Liu et al. (2024) proposed a framework which integrates a fine-tuned XLM-based intent classifier with an LLM to essentially treat multi-turn intent understanding as a zero-shot task. Yu et al. (2021) also explored retrieval-based methods for intent classification and slot filling tasks in few-shot settings. Our work adopts similar in-context learning (ICL) setup while focusing on handling large-scale multi-domain intent classification task from industry level applications.

2.2 In-context Learning

The performance of LLM has been significantly enhanced in few-shot and zero-shot NLP tasks through ICL. Recent ICL research focus on how to effectively identify and interpret retrieved context. Guu et al. (2020) first showed how to pre-train masked language models with a knowledge retriever in an unsupervised manner. Karpukhin et al. (2020) proposed a training pipeline in which retrieval is implemented using dense representations alone and embeddings are learned from a small number of questions and passages with a dual-encoder. Ram et al. (2023) considered simple alternatives to only prepend retrieved grounding documents to the input, instead of modifying the LLM architecture to incorporate external information. Similar approaches have proven particularly effective in the application of RAG on dialogue systems (Shuster et al., 2022b,a), specifically goal-oriented and domain-specific dialogs from customer service scenarios (Zhuang et al., 2021, 2023). In our work, we utilize ICL in both LLM fine-tuning stage for data generation and at inference-time with an intent candidate retriever.

3 Preliminary

Intent classification for queries is typically framed as a multiclass text classification problem. Specifically, given a customer query $q \in Q$, the goal is to map it to one of the k pre-defined intents $t \in T = \{t_1, ..., t_k\}$ using a model $\mathcal{M}$ so that the predicted intent $\hat{t} = \mathcal{M}(q)$ maximizes the probability of correctly classifying q. Formally, this can be expressed as:

$$\hat{t} = \arg\max_{t \in T} P(t \mid q; \theta) \quad (1)$$

where $P(t \mid q; \theta)$ denotes the probability of intent t given query q, parameterized by θ of the model $\mathcal{M}$.

However, intent labels are often not mutually independent; correlations between intents can exist, making a flat classification structure suboptimal. This leads to two major challenges in large-scale, industry-level intent classification: 1) **scalability**: a large number of intent labels k can make flat classification computationally expensive and difficult to scale, especially as the set of intents grows; 2) **label correlation**: related intents, such as "Order Issue" and its sub-intents “Track Order” or “Cancel Order”, are treated independently in flat classification, ignoring their hierarchical relationships and increasing the risk of misclassification.

To address these issues, hierarchical intent classification is preferred. In this approach, a query q

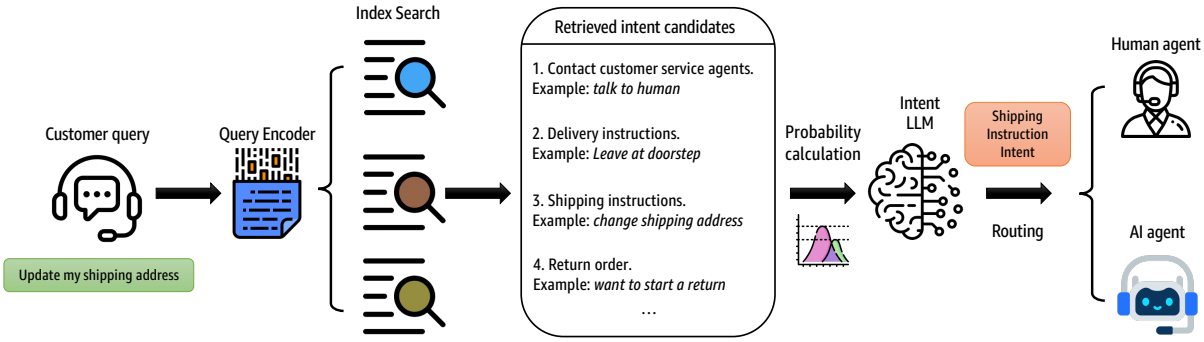

Figure 2: The proposed REIC method from customer query to routing intent leveraging on vector retrieval and probability calculation.

is classified progressively from general categories to specific sub-intents, enhancing both efficiency and accuracy for industry-scale applications.

Note that for a more generalized setting, intents from different verticals and domains may have entirely different hierarchy and ontology. In Figure 1, we demonstrated some examples of intent hierarchy in our application, which involves customer service query intent detection with two business verticals: **Third-Party** or **3P** business (customer contacting about third-party physical retail orders or consumer accounts) and **First-Party** or **1P** business (customer contacting about first-party digital or device issues). Both verticals span a diverse range of product types, reflecting the broad scope of customer inquiries handled by our system. If we use the traditional single-head flattened intent labels, the total intent ontology set size would be at 10^3 level which create major challenges for accurate intent classification. By creating hierarchical intent ontology across different business verticals, each classification head only needs to handle less than 50 intents that are more manageable for language models. In the following sections of this paper, we utilize this intent ontology setup for experiments and comparisons.

4 Method

LLMs has revolutionized the landscape of customer engagement, particularly in the domain of intent detection systems. While these models demonstrate remarkable capabilities in language comprehension and knowledge representation, their adaptation to domain-specific contexts presents notable challenges. Specifically, the integration of industry-specific terminology, organizational nomenclature, and distinctive customer service scenarios necessitates fine-tuning and customization of these models. To address these limitations and enhance the accuracy of customer intent identification, we introduce a novel approach REIC for RAG-Enhanced Intent Classification.

REIC aims to bridge the gap between the generalized capabilities of LLMs and the specialized requirements of diverse business environments. By leveraging RAG, our approach seeks to enhance the precision and relevance of intent detection, thereby facilitating more nuanced and context-aware customer interactions across various industry-specific scenarios. The method consists of three main components: index construction, candidate retrieval, and intent probability calculation (Figure 2).

Index Construction We first construct a dense vector index containing (query, intent) pairs from a held-out annotated dataset. Each query is encoded using a pre-trained sentence transformer model to generate dense vector representations. The corresponding intent labels are stored alongside these embeddings. The intent labels follow a hierarchical structure with d dimensions which represents different intent domain knowledge and might range from different domains.

Candidate Retrieval Given a new query q, we first encode it using the same encoder for index construction to obtain its dense vector representation $\mathbf{v}_q$. We then perform approximate nearest neighbor search to retrieve the top-k most similar (query, intent) pairs, denoted as set E. The similarity is computed using cosine distance between the query vector and indexed vectors:

$$sim(q, q_i) = \frac{\mathbf{v}_q \cdot \mathbf{v}_i}{\|\mathbf{v}_q\| \|\mathbf{v}_i\|} \quad (2)$$

where $\mathbf{v}_i$ represents the vector encoding of the i-th indexed query.

Intent Probability For the retrieved set E, we leverage a fine-tuned LLM $\mathcal{M}$ to perform constrained decoding and calculate the probabilities of the possible intents. Given a prompt template $\mathcal{P}$, the LLM takes as input the instantiated prompt, which includes the original query q and the retrieved (query, intent) pairs as context. For each unique intent t_j in E, we compute:

$$P(t_j|q, E) = \mathcal{M}(\mathcal{P}, q, E)_{t_j} \tag{3}$$

where $\mathcal{M}(\mathcal{P}, q, E)_{t_j}$ represents the model's predicted probability for t_j given the query and retrieved examples.

The final intent classification is determined by selecting the intent with the highest probability:

$$\hat{t} = \arg\max_{t_j \in E} P(t_j|q, E) \tag{4}$$

This approach enables dynamic updates to the intent space by simply adding new (query, intent) pairs to the index, leveraging the in-context learning capabilities of the LLM without requiring model retraining.

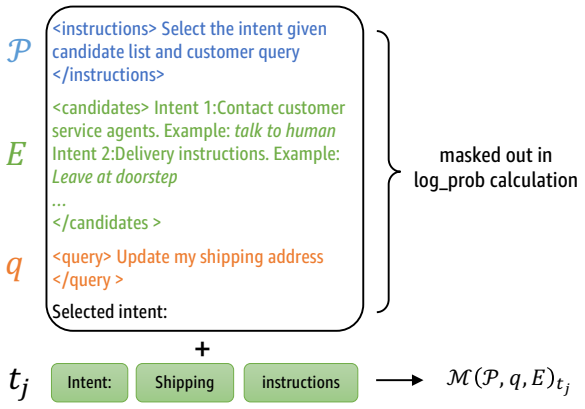

Figure 3: Constrained decoding for probability calculation.

The probability-based reranking helps mitigate potential LLM hallucination by grounding predictions in retrieved examples (Figure 3). With tradition greedy decoding, sometimes the LLM might generate intents outside of the given candidate list and cause downstream routing failure. We perform constrained decoding to calculate the probability of each retrieved intent t_j in E, which ensures the success of downstream routing. Given prompt $\mathcal{P}$ with instructions, retrieved candidates E, and customer query q, we append t_j at the end to calculate the total logits from model forward pass $\mathcal{L}_{t_j} = \mathcal{M}(\mathcal{P}(E, q) + t_j)$. Then we mask out the positions of $\mathcal{P}(E, q)$ and accumulate the log probabilities for the intent sequence t_j with length s_j:

$$\mathcal{M}(\mathcal{P}, q, E)_{t_j} = \exp\left(\sum_{t_j} \text{LogSoftmax}(\mathcal{L}_{t_j})/s_j\right) \tag{5}$$

During training, we train the intent LLM $\mathcal{M}$ by minimizing the cross-entropy loss between the predicted and ground-truth intents. During inference, instead of traditional auto-regressive next token decoding, we perform one model forward-pass calculation with a batch size k for top-k intent candidates and get the k probabilities for re-ranking and final intent prediction.

5 Experimental Setup

5.1 Datasets

Due to business considerations, we are not permitted to share the results using the original customer data. As a result, we manually anonymized both the labels and transcripts to ensure no personal information is included. Additionally, specific product and service names were denonymized to prevent the identification of the company from the transcript or label descriptions. Despite these modifications, the conclusions drawn from our experiments remain valid. The final dataset contains 52,499 training samples with 35,041 **1P Business** queries and 17,458 **3P Business** queries. The test set consists of 3,647 **1P Business** queries and 1,717 **3P Business** queries respectively using random sampling. All of the data samples have incorporated retrieved intent candidates from the retriever. We also performed dataset cleaning in the training set to make sure the true intent is contained in the retrieved list. During inference, we use the actual noisy retrieved list which also relies on the capability of the embedding model.

5.2 Compared Methods

We consider the following baselines:

- **RoBERTa**: We fine-tune RoBERTa-base (Liu et al., 2019) with multiple classification heads. This adaptation allowed the model to simultaneously categorize utterances across multiple dimensions.
- **Mistral Classification**[1]: We fine-tune a Mistral-7B-v0.3[2] with a sequence classification head. Instead of directly generating output sequences,

[1]Due to legal concerns, we are not permitted to use non-commercial LLMs like Llama.

[2]https://huggingface.co/mistralai/Mistral-7B-v0.3

Models	3P Business vertical			1P Business vertical			Overall		
	Precision	Recall	F1	Precision	Recall	F1	Precision	Recall	F1
RoBERTa	0.527	0.447	0.483	0.583	0.488	0.531	0.565	0.474	0.516
Mistral Classification	0.215	0.228	0.221	0.301	0.250	0.273	0.269	0.243	0.255
Claude Zero-shot	0.338	0.250	0.287	0.238	0.170	0.199	0.271	0.196	0.227
Claude Few-shot	0.386	0.289	0.331	0.350	0.308	0.328	0.361	0.302	0.329
Claude + RAG	0.473	0.438	0.455	0.415	0.389	0.402	0.434	0.404	0.419
REIC	**0.538**	**0.546**	**0.542**	**0.600**	**0.574**	**0.587**	**0.579**	**0.565**	**0.572**

Table 1: Intent detection confusion matrix on different business with different methods

the model projects the pooled embedding into a space with the same dimension as the number of classes.

- **Claude Zero-shot**: We employ the Claude 3.5 Sonnet model in a zero-shot configuration. To facilitate accurate intent prediction, we craft a comprehensive prompt that explicitly defines each potential intent.
- **Claude Few-shot**: Similar to **Claude Zero-shot**, we incorporate 20 demonstration examples, with 10 from each vertical, to enhance coverage of diverse intents across different domains.
- **Claude+RAG**: Instead of using a fine-tuned LLM, we employ Claude 3.5 Sonnet as the backbone and incorporate the same set of retrieved candidates as described in Section 4 into the prompt. This comparison allows us to assess whether a smaller fine-tuned LLM can perform competitively against a large foundation model for this task.

5.3 Implementation Details

The LLM component of our REIC approach utilizes a fine-tuned model from Mistral-7B-Instruct-v0.2[3]. We applied 8 NVIDIA-A100 40GB GPUs with 96 vCPUs to conduct PEFT (Mangrulkar et al., 2022) training with LoRA adapters (Hu et al., 2022). We choose a set of LoRA parameters with a rank of 8, an alpha value of 16, and a dropout rate of 0.1. The training batch size is set to 8 per GPU with a learning rate of $2e^{-5}$. We train the model using Cross Entropy Loss for 3 epochs which takes around 3 hours on the instance.

We experimented with the following off-the-shell retrievers for candidate retrieval:

- **BM25** (Robertson et al., 1995) is a widely used traditional sparse retrieval method. Although it is unsupervised, it consistently demonstrates strong performance across a variety of benchmarks(Thakur et al., 2021).
- **MPNet**[4] (Song et al., 2020) is a sentence embedding model fine-tuned on one billion sentence pairs using a contrastive learning objective.
- **Contriever-MS MACRO** (Izacard et al., 2022) is an unsupervised dense retriever pre-trained with contrastive learning and fine-tuned on MS MARCO (Nguyen et al., 2016).
- **ColBERT-v2** (Santhanam et al., 2022) is a late-interaction retriever that combines denoised supervision and residual compression to improve retrieval quality and reduce space footprint.

6 Results

6.1 Intent Detection Ability

To evaluate the effectiveness of our REIC method in intent detection, we conducted experiments comparing it against several baseline methods described in §5.2. Our results, presented in Table 1, illustrate performance across two business verticals (*3P Business* and *1P Business*) and an overall aggregate assessment based on Precision, Recall, and F1-score.

The results indicate that our REIC offers significant advantages in intent detection over standard fine-tuning or prompting-based methods. While fine-tuned models like RoBERTa perform reasonably well, they require extensive retraining when new intents emerge. We hypothesize that the limited performance of the Mistral Classification model stems from its nature as a decoder-only architecture, which may be less effective in extracting the semantic meaning of input query. Additionally, since it is not pretrained for classification tasks, incorporating a classification head during fine-tuning is unlikely to yield optimal results. Prompting-based approaches (Claude Zero-shot and Few-shot) generally underperformed, with Claude Few-shot

Retriever	3P Business	1P Business	Overall
BM25	0.521	0.537	0.532
Contriever	0.450	0.461	0.457
ColBERTv2	0.503	0.560	0.542
MPNet	**0.545**	**0.573**	**0.564**

Table 2: Intent detection accuracy on different business verticals using different retrievers in REIC

achieving a maximum F1-score of 0.329 overall. The Claude + RAG method improved performance compared to standalone prompting but remained inferior to our approach by 26.7%.

These observations confirm that the integration of RAG and fine-tuned LLM enables greater flexibility, improved precision, and higher recall rates, making it well-suited for handling diverse and evolving intent spaces in different applications.

6.2 Impact of Retrievers

In order to evaluate the impact of retrievers on the final performance, we experimented four different retrievers in REIC including one sparse retrieval method and three dense retrievers, details in §5.3. The intent detection accuracy across different business verticals using these retrievers is presented in Table **??**.

BM25, despite being an unsupervised sparse retrieval method, performs competitively, achieving an overall accuracy of 0.532. Among the dense retrievers, MPNet outperforms the others, attaining the highest accuracy across both the 3P Business and 1P Business verticals. This suggests that MPNet's contrastive learning-based sentence embeddings are highly effective for retrieving relevant candidates that aid intent classification. In contrast, Contriever exhibits the lowest accuracy across all categories.

Our findings show that retriever selection significantly impacts intent classification. Although BM25 is a strong baseline, dense retrievers like MPNet consistently outperform it. This highlights the value of high-quality embeddings and extensive fine-tuning on large datasets, which is why we have chosen MPNet as our final retriever in REIC.

7 Impact of Retrieval Candidate Size

We investigated the impact of different retrieval candidate numbers (top-k) in REIC to balance intent detection accuracy and inference latency. The Figure 4 illustrates the trade-off between these two factors, with overall accuracy plotted on the left y-axis (blue) and inference latency on the right y-axis (red) against different values of top-k. From the accuracy perspective, increasing top-k allows the model to access a broader range of relevant information, leading to better predictions. Beyond a certain threshold, additional retrieved candidates contribute minimally to accuracy while still increasing computational complexity. Latency, on the other hand, exhibits a sharp rise as top-k increases. This indicates a crucial trade-off: although retrieving more candidates can improve accuracy, it also leads to longer inference times, which may not be suitable for real-time applications.

In our experiments, we select top-k = 10 which ensures a meaningful accuracy boost without incurring excessive computational costs. However, the ideal top-k may vary depending on application requirements. For instance, real-time systems such as customer service chatbots or voice assistants may favor a lower top-k to maintain fast response times. Conversely, offline or batch-processing applications could accommodate higher top-k values if maximizing accuracy is a priority. Our findings emphasize the need to carefully tune retrieval parameters in REIC to meet specific operational demands.

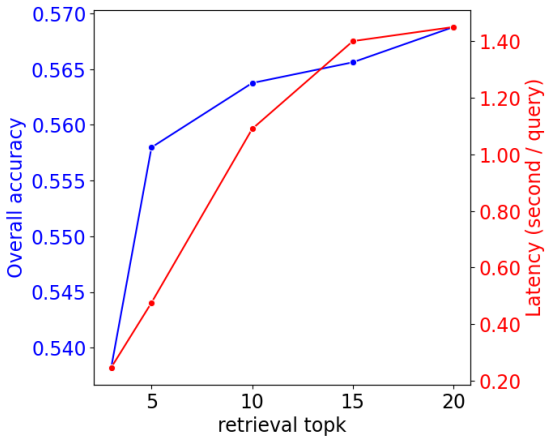

Figure 4: The accuracy and latency when using different retrieval top-k values.

7.1 Robustness on Unseen Intents

To evaluate REIC's robustness on unseen intents, we trained our models exclusively on the *3P Business* vertical and tested them on the *1P Business* vertical, simulating a real-world out-of-domain scenario. As illustrated in Figure 1, *1P Business* vertical has 4 intent category with more than 800 unique intent combinations, while the training data used

from *3P Business* vertical has 3 intent category with only around 70 unique intents. This out-of-domain scenario helps assess how well REIC generalizes to new, previously unseen intents. The results are summarized in Table 3.

Claude Zero-shot performs the worst, with an accuracy of 0.17 on the 1P Business vertical. In contrast, Claude Few-shot shows improvement, achieving an accuracy of 0.308 on the 1P Business vertical. This demonstrates that providing a few examples significantly enhances the model's ability to generalize.

Notably, the RAG-based methods, particularly Claude + RAG, significantly outperform Claude Few-shot, achieving 0.389 on the 1P Business vertical. This demonstrates the advantage of our RAG-based strategy in handling unseen intents, as it dynamically retrieves the most relevant examples to enhance predictions, surpassing static few-shot examples. Similarly, REIC, although slightly lower than Claude + RAG, still performs strongly compared to Claude Few-shot, highlighting the model's effectiveness on both in-domain and out-of-domain intents. Overall, REIC excels in-domain, and its performance on the 1P Business vertical remains competitive with Claude Few-shot, underscoring the robustness and adaptability of our REIC approach for unseen domains.

Models	3P Business	1P Business	Overall
Claude Zero-shot	0.250	0.170	0.196
Claude Few-shot	0.289	0.308	0.302
Claude + RAG	0.438	**0.389**	**0.404**
REIC	**0.538**	0.283	0.364

Table 3: Out-of-domain intent detection accuracy

7.2 Online Deployment Performance

Following the deployment of our REIC in an internal system, we observed significant improvements in online performance, particularly in intent detection accuracy. Compared to the previously deployed system, which relies on two separate models using traditional fine-tuning approaches for different business verticals, our REIC method simplified the system using just one consolidated model, which reduced misclassifications and improved resolution routing. To measure the success rate, we include a confirmation question for the customer to verify whether the predicted intent or issue is correct. Our REIC leads to a 3.38% absolute improvement for customer positive response rate. These improvements validate the efficacy of REIC for real-world deployment, offering both accuracy gains and operational efficiency in intent classification.

8 Conclusion

This paper presents a novel RAG-Enhanced Intent Classification (REIC) method that addresses scalability challenges and the heterogeneity of intent taxonomies in large-scale customer service systems. By incorporating a hierarchical intent classification strategy, REIC significantly reduces computational complexity. Leveraging the RAG technique, our method dynamically integrates contextually relevant retrieved examples, outperforming traditional fine-tuning, as well as zero-shot and few-shot approaches, in intent detection tasks. Additionally, our results demonstrate strong performance on both in-domain and out-of-domain test sets, highlighting its applicability for industry-scale applications.

9 Limitations

While REIC demonstrates strong performance in both in-domain and out-of-domain intent classification, it has a few limitations. Its accuracy remains closely tied to the quality of the retriever: if the correct intent is not among the retrieved candidates, the model cannot recover, underscoring the need for more robust retrieval methods or fallback mechanisms. In addition, although REIC allows for dynamic updates without retraining, it still relies on a fixed number of retrieved candidates, creating a trade-off between accuracy and latency that may hinder its deployment in real-time applications. Future work could address these challenges by developing adaptive retrieval strategies or introducing confidence-based mechanisms to dynamically adjust the candidate pool.

Abstract

The Enterprise Intelligence Platform must integrate logs from numerous third-party vendors in order to perform various downstream tasks. However, vendor documentation is often unavailable at test time. It is either misplaced, mismatched, poorly formatted, or incomplete, which makes schema mapping challenging. We introduce a reinforcement learning agent that can self-improve without labeled examples or model weight updates. During inference, the agent first identifies ambiguous field-mapping attempts, then generates targeted web-search queries to gather external evidence, and finally applies a confidence-based reward to iteratively refine its mappings. To demonstrate this concept, we converted Microsoft Defender for Endpoint logs into a common schema. Our method increased mapping accuracy from 56.4% (LLM-only) to 72.73% (RAG) to 93.94% over 100 iterations using GPT-4o. At the same time, it reduced the number of low-confidence mappings requiring expert review by 85%. This new approach provides an evidence-driven, transparent method for solving future industry problems, paving the way for more robust, accountable, scalable, efficient, flexible, adaptable, and collaborative solutions.

1 Introduction

Enterprise IT environments are rapidly evolving toward proactive, agent-driven workflows. At the core of these systems lies a foundational requirement: the ability to efficiently process and semantically interpret logs from a wide range of third-party sources. Such capability enables agents to remain context-aware, access real-time data, and make well-informed decisions.

For cybersecurity use cases, enterprises must ingest massive volumes of logs—often terabytes per day—from heterogeneous sources such as firewalls, servers, endpoints, cloud applications, network flows, policy events, file operations, and API calls, in order to enable effective security operations and real-time threat detection (Reid, 2023). The cost of Security Information and Event Management (SIEM) ingestion is substantial, exceeding $500k annually for just 500 GB per day (Hazel, 2021; Microsoft, 2024). The challenge lies not only in scale, but also in achieving semantic consistency across dozens to hundreds of disparate event types. Failures in log correlation and schema normalization have contributed to catastrophic breaches—including Target (2013) and Equifax (2017)—where overlooked alerts and misaligned schemas resulted in damages exceeding 1 *billion* (*Krishna*, 2023).

The emergence of large language models (LLMs) with robust natural language processing capabilities has the potential to transform third-party log integration. These models could dramatically reduce the need for labor-intensive processes that require experts. The full log integration pipeline comprises four stages: processing raw logs into structured data, mapping source schemas to target schemas, generating data transformation code, and deploying to production with ongoing monitoring. Schema mapping is the critical decision point that underpins the success of the entire integration process. This paper focuses on the practical challenge of schema mapping, a topic that is often overlooked in current literature.

Our focus is on a scenario in which enterprises ingest new data into their platforms. Therefore, the target schema is usually well-documented and stable. By contrast, incoming data source schemas are often poorly documented, typically due to their origin in legacy systems or outdated software versions. Unlike conventional machine learning tasks—where the challenge is extracting key features from abundant data—the difficulty here is the opposite: the source provides too little context. Because these vendor schemas lack labeled training

data, fine-tuning or other supervised methods are impractical. Although expert review remains necessary, it is resource-intensive and must be carefully prioritized.

To address these challenges, we propose a test-time reinforcement learning (RL) agent that can self-improve without updating model weights or relying on pre-defined labeled data. Our approach is inspired by the TTRL framework (Zuo et al., 2025), which improves model performance on unlabeled data through test-stage rewards. In the absence of ground-truth labels, we introduce a confidence-based score as a proxy reward signal to guide the agent toward more accurate mappings. Our design explicitly targets industrially practical constraints: model updates are costly, GPU-intensive, and operationally complex. Instead, our method adapts the system prompt at inference time by iteratively enriching the context in a verbal RL-driven manner, thereby enabling continual self-improvement under real-world deployment conditions.

The confidence-based proxy reward is both intuitive and interpretable. The agent identifies conflicts and ambiguities in its prior mapping attempts and formulates targeted search queries to gather external evidence. Confidence scores then serve as reward signals to determine whether the collected evidence should be retained or discarded, guiding iterative refinement. Furthermore, the agent produces transparent reasoning traces, enabling human experts to focus their review on low-confidence mappings, thereby reducing manual verification costs while preserving overall reliability.

This method has several advantages over existing approaches. First, it achieves significantly higher mapping accuracy through iterative refinement, reducing reliance on static, one-time attempts. Second, it uses confidence-based rewards instead of ground truth labels, enabling effective learning in settings where labeled data is unavailable. Finally, it promotes transparency by revealing its reasoning and evidence collection processes. This empowers security experts to understand decisions and prioritize low-confidence mappings.

Overall, our key contributions are: 1) identifying the challenge of schema mapping where prompting, fine-tuning, and retrieval-augmented generation all face limitations and no ground truth labels are available, and 2) proposing a test-time reinforcement learning framework that enables an agent to improve accuracy over time. This approach opens a new research direction by using confidence as a proxy signal to guide the agent's learning process.

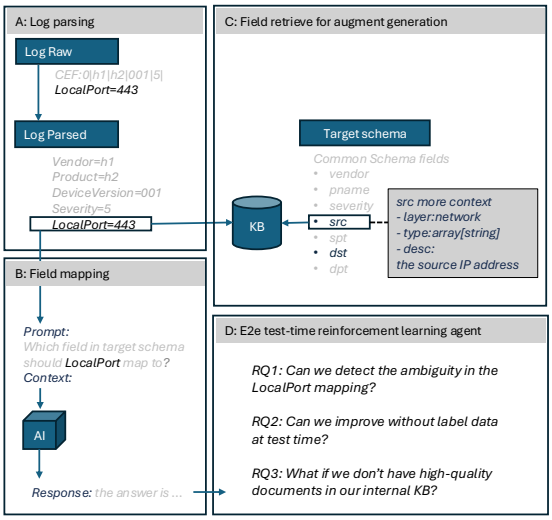

Figure 1: Position of our test-time RL agent relative to prior work in the schema matching pipeline. In Section A, Logparser-LLM Zhong et al. (2024) handles raw-to-structured parsing. In section B, Schema-Matching-LLM Parciak et al. (2024) shows baseline one-shot mapping capability. In section C, ReMatch Sheetrit et al. (2024) adds retrieval when full documentation exists. MatchMaker Seedat and van der Schaar (2024) pre-embeds target schemas for reuse. In section D, Self-consistency Wang et al. (2022) improves chain-of-thought reasoning. Search-R1 Jin et al. (2025) enhances LLM reasoning with search-augmented RL. This example shows that the log LocalPort is ambiguous for decision making; we need more context to determine whether this field should map to src or dst. Our research uniquely extends rightward beyond traditional enterprise knowledge bases to handle newly seen logs with ill-formatted or incomplete documentation. Unlike fine-tuning approaches that require labeled data and risk overfitting, our agent operates without test-time labels, conducting internet searches to gather evidence outside the enterprise KB scope. This addresses the critical gap where traditional methods fail on unseen vendor schemas with insufficient documentation.

2 Related Work

The foundation of schema mapping begins with converting raw logs into structured data. Zhong et al. (2024) introduced LogParser-LLM, which addresses the initial step of our pipeline by transforming unstructured log messages into key-value pairs. Their hybrid approach combines an LLM-based template extractor with a prefix-tree clustering method, achieving efficient parsing; the authors report ~272.5 LLM calls amortized across large log sets. This work eliminates the need for hyper-parameter tuning or labeled data, enabling rapid

adaptability to new log formats.

LogParser-LLM's contribution is complementary to our work: while they focus on the raw-to-structured parsing phase. In contrast, our approach begins where their process ends: once logs have already been parsed into structured records, we take these structured logs and further map them into standardized, common schemas that enable consistent downstream analysis, correlation, and integration across diverse sources.

Parciak et al. (2024) conducted a comprehensive experimental study of LLM capabilities in schema matching, focusing on off-the-shelf performance using only element names and descriptions. Their work provides crucial insights into the baseline capabilities of LLMs for schema matching tasks, demonstrating that context scope significantly affects performance—neither too little nor too much context leads to optimal results.

Their findings directly inform our approach in several ways: (1) they validate that LLMs can perform meaningful schema matching without requiring data instances, which aligns with our privacy-sensitive enterprise scenarios; (2) their context optimization insights guide our prompt engineering; and (3) their baseline performance metrics provide a foundation for measuring the improvements achieved by our reinforcement learning approach. However, their work focuses on one-shot matching capabilities, while our approach addresses the iterative improvement challenge through test-time learning.

ReMatch, introduced by Sheetrit et al. (2024), leverages retrieval-augmented prompting to reduce the target schema search space before matching. Their approach assumes the availability of comprehensive documentation and uses embedding-based retrieval to balance recall and precision in schema matching tasks. ReMatch demonstrates strong performance in healthcare schema matching scenarios where complete documentation is available.

Our work differs from ReMatch in a fundamental assumption: while ReMatch operates in environments with well-documented schemas and comprehensive knowledge bases, our approach is designed for practical enterprise scenarios where such documentation is often incomplete or unavailable. ReMatch's retrieval mechanism works within a closed set of known mappings, whereas our agent dynamically discovers and accumulates evidence from external sources to handle previously unseen vendor schemas.

Seedat and van der Schaar (2024) introduced MatchMaker, which decomposes schema matching into candidate generation, refinement, and confidence scoring steps using LLMs and vector retrieval. Their approach focuses on embedding target schemas for better retrieval and future reuse, generating synthetic in-context examples on-the-fly for zero-shot self-improvement.

MatchMaker's compositional approach and confidence scoring align with our methodology, but their self-improvement mechanism differs significantly from ours. While MatchMaker generates synthetic examples for in-context learning, our approach accumulates real-world evidence through external search and interaction. MatchMaker's focus on target schema embedding optimization complements our source schema adaptation strategy, suggesting potential for hybrid approaches in future work.

Two key techniques underpin our reinforcement learning framework: search-enhanced reasoning and self-consistency validation. Jin et al. (2025) demonstrated how external search can enhance LLM reasoning capabilities, providing a foundation for our evidence collection mechanism. Their Search-R1 approach shows that targeted web search can significantly improve reasoning accuracy in complex tasks.

Wang et al. (2022) established that consistency across multiple reasoning paths serves as a reliable indicator of correctness, forming the basis of our confidence-based reward system. Their self-consistency approach demonstrates that taking the majority answer from multiple sampled reasoning paths significantly improves accuracy, which directly informs our confidence score calculation.

A closely related line of research is the *Reflexion* framework (Shinn et al., 2023), which introduces verbal reinforcement learning as a way for language agents to improve through self-generated feedback rather than model weight updates. Reflexion agents reflect on task feedback, store these reflections in episodic memory, and leverage them to guide future decisions. This approach demonstrates that linguistic feedback—whether scalar or free-form—can significantly enhance agent performance across sequential decision-making, coding, and reasoning tasks, achieving state-of-the-art results on benchmarks such as HumanEval. Our work shares a similar philosophy in emphasizing memory- and feedback-driven improvement at test time; however, we focus specifically on schema mapping un-

der industrial constraints where ground truth labels and comprehensive documentation are unavailable. In this setting, we extend the notion of verbal reinforcement learning by integrating external evidence collection with confidence-based rewards to refine mappings dynamically.

Our work addresses the critical gap where existing methods fail on newly encountered vendor schemas with ill-formatted or incomplete documentation. Unlike prior approaches that operate within controlled environments with well-documented schemas, our test-time reinforcement learning agent adapts dynamically by accumulating external evidence without requiring model updates or labeled training data.

3 Methodology

3.1 Problem Formulation

We formally define the schema mapping problem as follows. Given a source schema $S = \{s_1, s_2, \ldots, s_n\}$ and a target schema $T = \{t_1, t_2, \ldots, t_m\}$, we seek to find a mapping function $f : S \to T \cup \{\emptyset\}$ such that $f(s_i) = t_j$ represents a semantic correspondence between source field s_i and target field t_j, or $f(s_i) = \emptyset$ indicates no corresponding field exists in the target schema.

Our objective is to maximize the correctness of this mapping function: $\max_f \sum_{i=1}^{n} \mathbb{I}[f(s_i) = f^*(s_i)]$ where $f^*(s_i)$ represents the ground truth mapping and $\mathbb{I}[\cdot]$ is the indicator function. However, in practical deployment scenarios—particularly when processing third-party vendor logs ground truth mappings f^* are unavailable.

To address this challenge, we use confidence scores as a proxy for correctness. We define confidence $C(f(s_i))$ as the consistency of mapping predictions across multiple inferences, serving as a surrogate objective: $\max_f \sum_{i=1}^{n} C(f(s_i))$.

3.2 Test-Time Reinforcement Learning Framework

Our test-time reinforcement learning agent improves schema mapping policy's accuracy by iteratively collecting evidence and reinforcing useful context. The agent starts from an empty evidence set, identifies inconsistencies through multiple mapping attempts, and formulates targeted search queries for ambiguous fields. Collected evidence is added to the context, and confidence-based reward signals guide which evidence to retain or discard. The complete algorithm is detailed in Algorithm 1.

3.3 Reinforcement Learning Formulation

To formalize our approach, we define the reinforcement learning components as follows:

State: The current state s_t consists of the schema mapping hypothesis from source to target fields and the collected evidence at time t. Specifically: $s_t = \{M_t, E_t\}$ where M_t is the current mapping hypothesis and E_t is the set of evidence collected up to time t.

Action: The action a_t involves selecting a field or conflict to investigate and executing a targeted search query. The action space includes all possible fields that could be investigated and the possible search queries that could be formulated.

Reward: The reward r_t is derived from the change in confidence score after adding new evidence: $r_t = C_{t+1} - C_t$ where C_t is the confidence score at time t. The confidence score serves as a proxy for accuracy when ground truth labels are unavailable.

Policy: The agent's policy $\pi(a|s)$ specifies the suggested mapping from source schema fields to target schema fields. While the policy can be implemented in various ways, one practical approach is to leverage an LLM's reasoning process. In this setup, the LLM performs the mapping by combining its prior knowledge with contextual evidence, enabling the system to detect conflicts and generate targeted search queries. We define a conflict as a disagreement among the n prompt-variant predictions for the same source field within a single iteration (as opposed to cross-run drift).

Learning: The goal of learning is to adapt a policy's behavior in a beneficial direction by leveraging rewards that reflect the situation. Instead of updating the LLM's model weights, learning takes place through the accumulation of useful evidence in the agent's context. Evidence that increases confidence is preserved, while unhelpful evidence is discarded. This process reflects a form of verbal, memory-based learning in which the agent's knowledge base is continuously refined.

We use verbal RL in the Reflexion sense—policy adaptation via context/memory rather than parameter updates; rewards are intrinsic confidence deltas, not ground-truth returns.

Algorithm 1 Iterative RL Schema Mapping with Confidence Improvement

Inputs: Source schema $S = \{s_1, \ldots, s_n\}$; target schema $T = \{t_1, \ldots, t_m\}$; iteration limit α (default: 100); conflict detection attempts n (default: 3); initial evidence context $E = \emptyset$; generative LLM $\mathcal{F}$.
Outputs: Mapping function f; refined evidence context E.

for $i \leftarrow 1$ to α **do**
  $f \leftarrow \mathcal{F}(S, E)$ // Generate initial mappings using current evidence
  $C \leftarrow \text{ConflictDetection}(f, n)$ // Detect inconsistent mappings
  for each source field $s_i \in C$ **do**
    $Q_{s_i} \leftarrow \text{QueryFormulation}(s_i)$ // Formulate search queries
    $e_{s_i} \leftarrow \text{EvidenceCollection}(Q_{s_i})$ // Collect external evidence
    $r_{s_i} \leftarrow \text{ConfidenceEvaluation}(f(s_i), e_{s_i})$ // Evaluate new confidence
    $r_{\text{prev}} \leftarrow \text{Confidence}(f(s_i))$ // Retrieve previous confidence
    if $r_{s_i} > r_{\text{prev}}$ **then**
      $E \leftarrow \text{ContextUpdate}(E, e_{s_i}, r_{s_i})$ // Update context if confidence improves
    end if
  end for
end for
return f, E

4 Experiment

4.1 Setup

We evaluated our approach using two schemas: the **source** schema was the *Microsoft Defender for Endpoint* schema containing 195 fields, and the **target** was our *Common Schema* with 137 fields. The **ground truth** consisted of 66 manually verified field mappings, curated collaboratively by domain, threat intelligence, and product experts to cover a diverse range of field types and complexity levels. We employed **GPT-4o** as the underlying model and assessed performance using two key metrics: (1) **Confidence score**—measuring the consistency of predictions across multiple attempts within a single iteration, with special handling for empty outputs; and (2) **Accuracy**—defined as the percentage of correctly predicted mappings among the 66 verified pairs.

For each field mapping iteration, the model was executed three times (n=3), and both the confidence score and accuracy were computed. While accuracy depends on the ground truth and is used solely for evaluation, confidence scores—which can be calculated without ground truth—are leveraged to guide the reinforcement learning process and are therefore suitable for production deployment.

Confidence Score Calculation: We calculate confidence as the consistency of predictions across multiple attempts using a modified frequency-based approach. For a given field, if we collect predictions $P = [p_1, p_2, p_3]$ across three iterations, the confidence score is: $C = \frac{\text{count(most_frequent_prediction)}}{\text{adjusted_total}}$ where the adjusted total accounts for empty predictions with reduced weight (0.5 instead of 1.0). The design aligns with the findings of Kalai et al. (2025), who argue that current training and evaluation paradigms implicitly reward guessing behavior in language models, leading to hallucinations. By contrast, our scoring mechanism provides a quantitative incentive for uncertainty acknowledgment, steering the model toward more trustworthy behavior.

We prepare two baselines for comparison. **Baseline 1:** We used GPT-4o with a single-shot prompt containing only the field name and value, resulting in an accuracy of 56.36%. **Baseline 2:** We used GPT-4o with a single-shot prompt enhanced with additional field descriptions, data types, and sample data context from our internal knowledge base, resulting in an accuracy of 72.73%.

4.2 Performance Improvements

Starting from a **Baseline 2:** accuracy of 72.73% with GPT-4o in the first iteration, our method achieved significant improvements throughout the experiment. By the end of the 100-iteration experiment, the model demonstrated consistent performance with accuracy reaching 93.94%.

Our analysis of the 100-iteration experiment reveals several key performance characteristics. GPT-4o collects 81 evidence tuples across 100 iterations, with the most significant accuracy gains occurring in the early stages—for example, iteration 1 shows

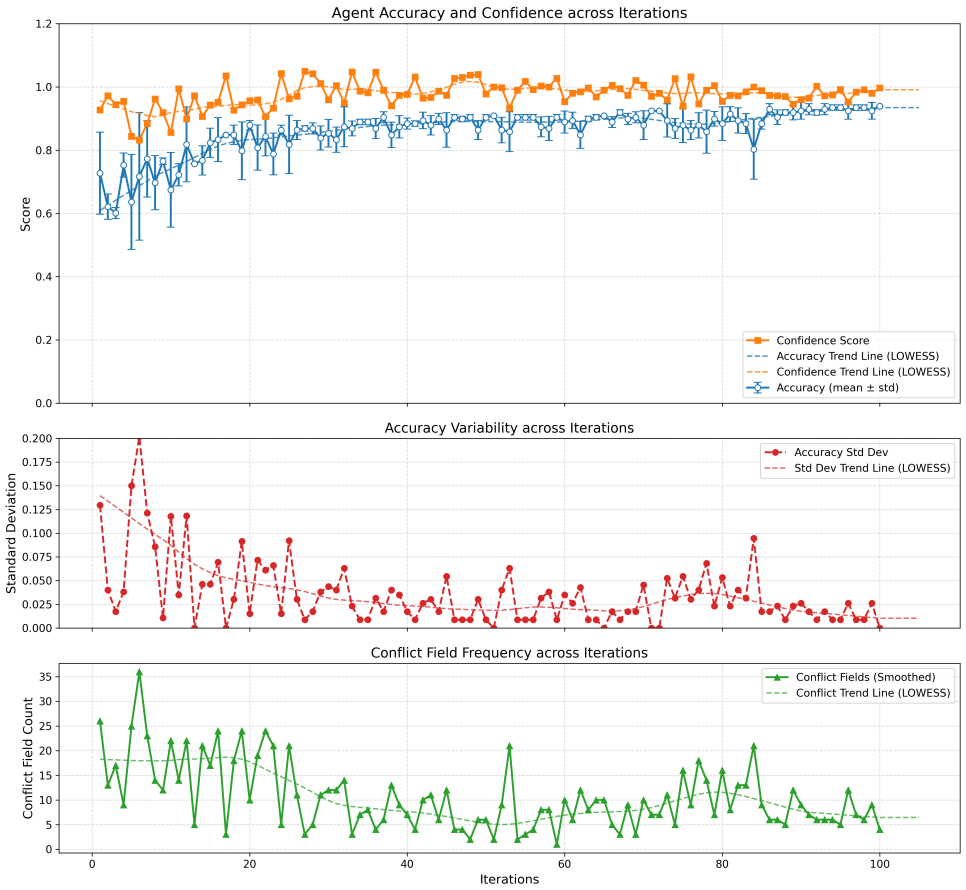

Figure 2: Comprehensive performance analysis of the reinforcement learning agent over 100 iterations. Top: Accuracy improves from 72.73% to 93.94%, while confidence trends upward and approaches 1.0, highlighting a persistent overconfidence gap. Middle: Accuracy variability is high in early iterations but stabilizes over time. Bottom: Conflict field count decreases from 26 to 4(85% reduction), demonstrating reduced ambiguity as evidence accumulates.

a +21.21% gain, iteration 5 achieves +9.60%, and iteration 6 yields +10.71%. The system makes decisions solely based on confidence scores, without referencing accuracy at any point during execution.

This reflects real-world conditions in which ground truth labels are unavailable. In these scenarios, accuracy can only be measured retrospectively to confirm whether the solution performed correctly. Notably, in 19 of the 100 iterations, the system rejected newly proposed evidence, demonstrating that it learned to recognize when gathering additional information was unlikely to improve results. This selective behavior preserves a high-quality evidence set, which is critical not only for validating outcomes but also for providing transparency into how the agent arrived at its decisions.

By the conclusion of the 100 iterations, the agent resolved 22 conflicts, only 4 fields were flagged as low-confidence and requiring expert review—down from 26 initially—representing an 85% reduction in the verification burden on security analysts and allowing them to focus on the most ambiguous or critical cases.

To evaluate the robustness of our approach, we ran the full 100-iteration process multiple times. The final accuracy consistently reached 93-94%, with minimal variance (standard deviation less than 0.01) in the later iterations. This demonstrates that the improvement is reliable and not due to chance.

4.3 Evidence Collection Analysis

For this experiment, we equipped the AI agent with a tool that enables internet searches for additional facts and evidence. Specifically, we used a generic search utility powered by Bing. In each iteration, the agent analyzes conflicts identified across three prompt variants, formulates a targeted search query, and retrieves relevant results from the tool. This setup demonstrates one possible method of evidence collection; other approaches could include

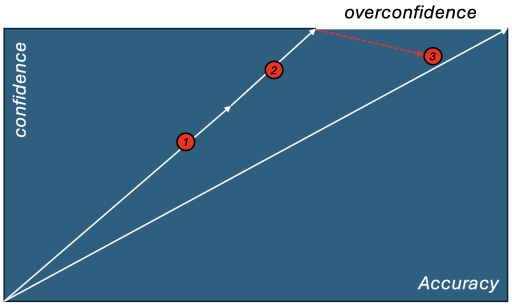

Figure 3: The relationship between confidence and accuracy. Path 1 shows the starting point. Path 2 illustrates how confidence as a proxy reward improves accuracy. Path 3 highlights the challenge of overconfidence, where confidence saturates while accuracy lags behind. Therefore, more engineering and research efforts are needed to bring the confidence curve down. The diagonal line indicates perfect calibration, and the curves above it show overconfidence.

consulting human experts, performing advanced reasoning, or validating findings against production data.

We organized the collected evidence into three-element tuples, each comprising the detected conflict, the resolution plan, and the retrieved evidence. This structured representation ensures systematic evidence collection and evaluation. Evidence is retained only if it demonstrably increases the LLM's confidence in its mapping decisions. Helpful evidence contributes in 4 ways, (1) by enhancing awareness through the identification of ambiguous fields and conflicting mappings; (2) by enabling self-correction through improved reasoning about relationships among fields; (3) by improving clarity via authoritative information on how fields are defined and used in both the common schema and vendor-specific schemas (e.g., Microsoft Defender); and (4) by revealing context-dependent mappings, in which the correct correspondence varies by scenario and requires additional contextual understanding.

5 Conclusion

This paper presents a test-time learning framework in which a reinforcement learning agent improves schema mapping accuracy through iterative evidence collection and context refinement—without requiring model weight updates or pre-collected training data. Unlike conventional approaches that rely on all labeled data before inference, our method actively gathers new evidence during test-time to refine its decisions. This design eliminates the high computational cost, GPU dependency, and potential instability associated with model retraining, making it more practical for real-world deployment. A confidence-based score serves as a proxy reward for accuracy, providing a novel mechanism that evaluates model consistency across multiple mapping attempts within a single iteration. Through systematic evidence collection and evaluation, the agent resolves mapping ambiguities with transparent reasoning that facilitates expert review and validation. Applied to Microsoft Defender for Endpoint logs mapped to a common schema, our approach improves accuracy from 72.73% to 93.94%, while reducing the number of fields requiring expert review by 85%—from 26 to 4.

A key insight from our work is the use of confidence scores as a proxy for ground-truth labels, as conceptually illustrated in Figure 3. While confidence can effectively guide accuracy improvement, our results reveal persistent overconfidence, where confidence values exceed actual accuracy. This observation underscores the need for better confidence definition and calibration. In our current approach, confidence is measured as the consistency of predictions across three trials. Future research could extend this by (1) employing multiple models to generate diverse predictions and compute ensemble-based confidence, or (2) directly prompting LLMs to provide explicit self-assessed confidence scores alongside their outputs. Additional experiments extending the number of inference attempts from three to ten show encouraging signs of reducing the overconfidence gap (see Appendix B), albeit with increased computational cost. These enhancements could yield better-calibrated confidence measures that more accurately reflect true prediction quality.

Limitations

While our approach demonstrates significant improvements, several limitations should be acknowledged:

1. **Evidence Quality Dependency**: The system's performance is dependent on the quality and availability of external evidence sources. In domains where documentation is sparse or inconsistent, the improvement may be limited.

2. **Computational Overhead**: The iterative evidence collection process requires multiple

LLM calls and external searches, which may increase computational costs compared to single-shot approaches.

3. **Domain Specificity**: Our evaluation focuses on cybersecurity schemas. While the approach is general, validation in other domains (healthcare, finance, etc.) would strengthen the generalizability claims.

4. **Scope Limitations**: We focus on 1-to-1 mappings to address the core challenge of knowledge scarcity. Extension to more complex mapping cardinalities (1-to-N, N-to-M) remains future work.

Ethical Considerations

This study does not involve human subjects or personal data. However, the method collects web evidence at test time, which could occasionally include malicious or adversarial content. Practitioners reproducing this system should apply input sanitization, source filtering, and sandboxing to prevent prompt-injection or security risks.

A Case Study: Direction-Sensitive Port Mapping (Iteration 49)

To illustrate the practical difficulty of schema mapping, we examine a representative example from iteration 49 involving the common schema field `dpt` (destination port). The field `dpt` is defined in the Trend Micro Common Schema as "the service destination port of the private application server (dstport)." In Microsoft Defender for Endpoint, however, two candidate fields exist: `LocalPort` (TCP port on the local device used during communication) and `RemotePort` (TCP port on the remote device being connected to).

Mapping ambiguity. Both candidates are semantically plausible depending on the traffic direction. For *outbound* connections, the local device is the source, so the destination port resides on the remote endpoint—corresponding to `RemotePort`. Conversely, for *inbound* connections (e.g., an RDP session initiated by a remote host), the local device becomes the destination, and thus the correct mapping is `LocalPort`. Without an explicit indicator of connection direction, an LLM can easily misassign the field.

Why fine-tuning does not help. Simply fine-tuning model weights cannot reliably resolve this ambiguity. The correct mapping is not a memorized association (`dpt` $\rightarrow$ `RemotePort`) but a conditional rule that depends on runtime context—information that is absent from the training corpus. Updating parameters may reinforce spurious correlations rather than teach the model to reason over directionality, resulting in brittle behavior across different network scenarios.

Evidence-based reasoning. During iteration 49, the agent retrieved definitional evidence clarifying that:

- `LocalPort` refers to the port on the local device.
- `RemotePort` refers to the port on the remote device being connected to.
- `dpt` represents the service destination port.

Although this evidence did not directly yield the final mapping, it revealed that the correct correspondence varies by communication context and motivated the agent to infer direction from auxiliary fields such as `RemoteIP`, `LocalIP`, and `ActionType`. The agent's confidence increased from 0.67 to 1.0, reflecting a clearer and more consistent conceptual understanding.

Categorization of helpful evidence. According to the taxonomy defined in the main paper, this instance exemplifies **Category (4): revealing context-dependent mappings**. The evidence was helpful because it exposed the conditional nature of the mapping—showing that correctness depends on dynamic context rather than static field alignment—and thereby guided subsequent reasoning toward more generalizable, context-aware mapping rules.

Derived practical rule.

$$\texttt{dpt} = \begin{cases} \texttt{RemotePort}, & \text{if Direction = Outbound;} \\ \texttt{LocalPort}, & \text{if Direction = Inbound;} \\ \text{(defer/flag)}, & \text{if Direction is unknown.} \end{cases}$$

This case highlights that progress in schema alignment arises not from parameter updates but from the integration of structured evidence and contextual inference.

B Overconfidence Mitigation Experiments

To address the overconfidence phenomenon observed in our main experiments (Figure 3), we conducted an additional study to examine how increasing the number of inference attempts affects confidence calibration. Our hypothesis was that a larger number of inference samples would improve statistical robustness and reduce systematic overconfidence.

B.1 Experimental Setup

We extended the original setup by increasing the number of inference attempts per iteration from 3 to 10. This change allows for more reliable confidence estimation through better sampling of the model's output distribution. All other experimental parameters remained identical to the main study: the same source and target schemas (Microsoft Defender for Endpoint with 195 fields and the Common Schema with 137 fields), the same 66 manually verified ground-truth mappings, and the same GPT-4o model configuration.

The confidence score computation followed the same principle of prediction consistency but with

a larger sample size (10 vs. 3). This design provides a more statistically grounded measure of uncertainty and is expected to yield better-calibrated confidence estimates.

B.2 Results and Analysis

Table 1 presents a comparison between the 3- and 10-inference settings.

Increasing the number of inference attempts from 3 to 10 effectively narrows the gap between confidence and accuracy. With 10 inferences, the mean confidence (89.3%) aligns much more closely with the observed accuracy (92.1%), whereas with 3 inferences, confidence (95.2%) noticeably exceeds accuracy (93.94%), indicating mild overconfidence.

This calibration improvement comes with a modest cost: while the confidence estimates become more realistic, overall accuracy decreases slightly (93.94% $\rightarrow$ 92.1%). Nevertheless, the more conservative confidence levels offer better guidance for expert review prioritization. The reduction in low-confidence fields remains substantial under both settings (85% and 80% reductions), demonstrating that the key benefit—reducing expert review effort—is preserved.

B.3 Implications and Trade-offs

These findings highlight a clear balance between calibration quality and computational cost. Increasing the number of inference attempts leads to better-calibrated confidence scores but requires more computation. In practical terms:

- **For high-precision scenarios**, increasing attempts (e.g., to 10) provides more reliable uncertainty estimates and tighter alignment between confidence and accuracy.
- **For cost-sensitive deployments**, even three attempts already achieve strong accuracy and substantial reduction in expert workload, making it a highly efficient operational setting.

These results demonstrate improved calibration—confidence more accurately tracks empirical accuracy as the number of inferences increases—without the need for additional metric reporting.

C Prompt Architecture

Table 2 summarizes the three prompts used in our schema mapping system. Each serves a distinct function in guiding the agent's reasoning process across sessions and mapping iterations.

System Prompt Example. The system prompt defines the AI agent's expertise and reasoning framework. It is shown below for reference.

> You are a Trend Micro cybersecurity data expert specializing in Trend Micro's Common Schema across multiple layers, including endpoint, network, messaging, and cloud. You have extensive expertise in processing and mapping third-party product and log schemas to Trend Micro's Common Data Schema, enabling cross-log correlation, advanced threat detection, and compliance reporting.
>
> You routinely perform professional schema mapping for new third-party log sources with a focus on accuracy. Your approach follows a layered reasoning process: (1) identify core entities such as IP addresses, filenames, and hashes (e.g., SHA1); (2) narrow down candidate fields based on data flow direction and context; (3) make precise mapping decisions supported by semantic consistency.
>
> For example: – `src_ip` vs. `dst_ip` depends on whether traffic is inbound or outbound. – `SHA1` hashes may represent `parent_process_sha1`, `launched_process_sha1`, or `dropped_object_sha1`.
>
> If no suitable mapping exists, respond professionally with `NOT_COVERED`.

Setting	Final Accuracy	Mean Confidence	Low-Confidence Fields
3 Inferences	93.94%	95.2%	$26 \rightarrow 4$ (85%)
10 Inferences	92.1%	89.3%	$31 \rightarrow 6$ (80%)

Table 1: Comparison of overconfidence mitigation between 3 and 10 inferences per iteration. The 10-inference setting improves calibration by bringing confidence values more closely aligned with actual accuracy.

#	Prompt Name	Purpose	Usage
1	System Prompt	Defines the AI agent's role as a cybersecurity data expert specializing in schema mapping. Establishes reasoning rules and guidelines.	Loaded once per session
2	User Prompt	Carries the per-request payload: (a) curated facts from prior conflicts (if any), (b) RAG-assembled source/target schema context (descriptions, sample values, types), and (c) the mapping task/question. Enforces a strict XML response (CSV decision, 1–5 confidence, reasoning) for deterministic parsing.	For every mapping request
3	Search Prompt	Generates targeted Internet search queries string to resolve ambiguous field mappings using prior conflict information.	Invoked only during conflict resolution

Table 2: Overview of the three prompts used in the schema mapping system, detailing their roles and usage.

On Assigning Product and Software Codes to Customer Service Requests with Large Language Models

Abstract

In a technology company, quality of customer service that involves providing troubleshooting assistance and advice to customers is a crucial asset. Often, insights from historical customer service data are used to make decisions related to future product offerings. In this paper, we address the challenging problem of automatic assignment of product names and software version labels to customer **S**ervice **R**equests (SRs) related to Cisco Systems, Inc., a global company specializing in networking hardware, software, and services.[1] We study the effectiveness of state-of-the-art Large Language Models (LLMs) in assigning the correct product name codes and software versions from several possible label options and their "non-canonical" mentions in the associated SR data. We frame this assignment as a multiple-choice question (MCQ) answering task instead of conventional prompts and devise, to our knowledge, a novel pipeline of employing a classifier for filtering inputs to the LLM for saving usage costs. On our experimental dataset based on real SRs, we are able to correctly identify product name and software version labels when they are mentioned with over 90% accuracy while cutting LLM costs by about $40-60\%$ on average, thus providing a viable solution for practical deployment.

1 Introduction and Background

Companies such as *Arista Networks*, *Cisco Systems*, *Dell Technologies*, and *Huawei Technologies* offer a range of hardware devices and associated software related to routers, switches, modems, firewalls, and other networking purposes. For these companies, customer service which deals with providing technical assistance and troubleshooting support via emails, online chat, phone calls, etc. comprises a crucial aspect of business operations. Indeed, customer service quality directly impacts customer retention for a business and often insights based on customer interactions are used while making decisions regarding products (for example, edits to technical documentation, future product features, etc.) (Schijns, 2012; Brent Kitchens and Abbasi, 2018; Winkler and Wulf, 2019). However, scaling customer service is particularly challenging to these companies given the technical complexity in their rapidly growing and evolving product mix, high expectations of quality services from a growing customer base, and increasing use of digital touch-points. In this context, recent breakthrough research in the form of Large Language Models (LLMs) has particularly been of great interest to these companies due to the LLMs' advanced language understanding, generation, and reasoning capabilities that can significantly improve the automation of various tasks related to customer service (Wulf and Meierhofer, 2024; Krishnan et al., 2022; Cui et al., 2017; Su et al., 2025).

In this study, we investigate the use of LLMs for a specific task pertaining to customer support data related to *Cisco*, a company operating in the networking domain providing thousands of products and services to customers across the world. As new technologies emerge and applications evolve, *Cisco* receives increasing volumes of customer "**S**ervice **R**equests" (SRs) requesting assistance for setting up, troubleshooting, and for information via various channels such as emails, phone calls, online forums, or virtual chat. Service requests go through a lifecycle: (1) *opening* of an SR in response to a customer problem, (2) back and forth *communication* with the customer for any missing relevant problem details, as well as with the relevant internal product teams and knowledge experts, (3) *resolution* where the required support is provided by the tech engineer to the customer, and (4) *closure* where the SR is "marked" as closed after resolution. On average, **1-2 million** SRs are handled in *Cisco* every year, with resolution times ranging

[1]We use the name *Cisco* for future mentions in this paper.

from a few weeks to several months depending on the complexity, priority, and severity of the SR.

1.1 Motivation

During the closure of an SR, two key pieces of information ("data fields") are **manually** added to the closure report forms by tech support engineers. These fields capture the precise "product code" referencing the hardware on which the customer faced the problem as well as the "version" of the software being used on the hardware, where applicable. These assignments may be "NONE" if the problem is generic or related to third-party software/hardware. A chief motivation for collecting this information in *Cisco* pertains to knowledge completion for future reference, staff training, and product improvements, as well as valuable macro-level insights that can be derived from the associations to enable informed strategic decisions. For example, missing documentation for a particular configuration option that had led to several SRs may be added in the next version of the configuration guide for the product together with the information shared during resolution by the tech support engineers for these SRs. Similarly, commonly seen (problem, resolution) pairs can be used to create troubleshooting FAQs for customers as well as problem-solving chatbots (Zheng et al., 2023; Yang et al., 2023).

Given the large and complex hardware-software product mix offered by the company, adding product name codes and software information is necessary for enabling rapid retrieval of solutions when similar problems are observed in future SRs. The current manual assignment of product names and software version information in *Cisco* is prone to error since these fields may not be directly available as part of customer shared problem descriptions and instead may require gleaning from the many different types of structured and unstructured data created for the SR during its life cycle. The possible labels for these fields are currently provided for selection via dropdown lists in *Cisco*, but errors often creep in due to the sheer length of these dropdown options.[2] On the other hand, product and software information that can be extracted precisely and programmatically from specific device log files is observed in only about 10% of the cases, requiring manual labeling for the rest.

In Table 1, we show part of the data created during the resolution of a real SR for illustration. The SR data can be broadly categorized into–(1) **Metadata** comprising of structured fields (submitted via a form) of which the relevant ones for our assignment tasks are "problem description, customer symptoms, and resolution summary", and company-specific codes indicating the **product technology and sub-technology**. A product technology can pertain to a broad topic such as "routers" with sub-technology referencing "wireless" or "wired" configurations. (2) **Case Notes** are unstructured text documents shared during the lifecycle of an SR. For the SR shown in Table 1, we have a total of 22 associated case notes that are of different types such as emails exchanged within the company, with the customer, logs containing output from commands, and notes made by tech support engineers during the resolution process.

In Table 1, we highlight the relevant fields (with ✓) that can help determine the precise product name and software version information in the provided metadata and case notes. In *Cisco*, related alphanumeric codes are used to represent the prod-

[2]Due to decades of operation and the hundreds of variations of products being managed in the market for a given purpose (e.g. routers), numerous options figure for a product name and software version selection in the dropdown lists.

uct type as well as the precise product name under that type in SR documents. For instance, few product codes under the technology/sub-technology group "Wireless/2800 Series Access Point" include *AIR-AP2802I-S-K9*, *AIR-CT8540-1K-K9*, and *AIR-AP2802I-Z-K9*.

For the example SR shown in Table 1, the software information is directly mentioned in one of the emails (from case notes), whereas the complete product name has not been mentioned anywhere. Unlike this SR, software information typically appears in "non-canonical" formats– (*15.5(1)SY1*, *15.5(1)SY*, *15.5(1)SY3* all referring to *15.5.1*) and is sometimes mentioned in filenames exchanged during SR handling ('*cat9k_iosxe.16.12.04.SPA.bin*').

A manual assignment of product name and software version information is both time-consuming and error prone. Due to the myriad formats in which the product name and software version information is expressed in texts, along with other confounding patterns common in networking domains such as IP addresses, dates, and system logs messages, solutions based on pattern matching alone are inadequate. Moreover, texts such as "unavailable post upgrade from *2.2.2.9* to *2.3.3.7*" and "problem was first seen in *AIR-CT8540* (see SR 659356)" are common and need a deeper, semantic understanding for an accurate assignment.

Contributions: We present our LLM-based solution using a multiple-choice question (MCQ) answering formulation for predicting product names and software versions from the SR metadata and case notes in *Cisco* as an alternative to the currently adopted manual process. Our evaluation experiments with a range of open-source and proprietary LLMs show that with appropriate prompts and custom matching functions, we are able to predict product names with an accuracy of about 70-80% and software versions with over 96% accuracy in best settings. We address cost optimization for LLM calls by training a binary classifier to filter out the uninformative case notes available for an SR in order to send only relevant documents that can help with the prediction task to the LLM. Overall, in our best settings, we filter out uninformative tokens in LLM API calls with high precision (∼90%) and enable cost savings of ∼40-60%.

2 Methods

Our task is a combination of two NLP problems: named-entity recognition (NER) and document classification. For a parallel, consider the task of labeling financial documents with the full names of the financial organization that each document is about primarily. For example, consider a document that is primarily about the company "Tesco PLC" and its market competitors, the true label for the document would be "Tesco PLC". However, the document's content may not reference the true label precisely, but only via its abbreviation such as "Following Wal-Mart's model, both France 's Carrefour, and TSCO.L...". Our task is to predict the true classification label "Tesco PLC" for the document based on document understanding and the mentions of "TSCO.L". For *Cisco*, these target labels are various product names and software versions where mentions tend to be partial or ad hoc variations of the full names, and the documents are noisy and in heterogeneous formats such as unstructured notes, emails, metadata etc.

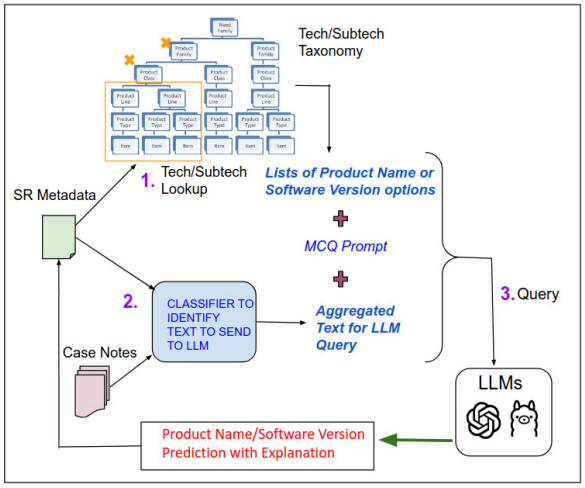

Figure 1: Workflow of our proposed approach.

Our overall pipeline for predicting product names and software version information in SRs is illustrated in Figure 1. In zero-shot settings, we leverage the language understanding capabilities of LLMs via a straightforward question answering prompt ("QPrompt") such as "What is the product name being discussed in the document below?" (Borst et al., 2022; Du and Cardie, 2020; Hu et al., 2025). Product names in *Cisco* are alphanumeric codes assigned through naming conventions internal to the company, unlikely to be "pretrained knowledge" for LLMs. Product name codes are indicative of organizational and grouping information. For example, *'AN5900-35X'* could be a specific product under the product group *'AN5900'* whereas *"AB5-JX-BRM"* and *"AB5-JX-BRM-XL"*

could be siblings under a common technology.

Despite indicative hints, consistent naming conventions across the several product verticals are lacking in *Cisco*. For instance, the code *AIR-CT8540-**1K**-K9* refers to the product "Cisco 8540 Wireless Controller supporting **1000** access points" whereas *SNS-3595* is a product code under the technology "Security - Access Control - AAA and Policy Management". A lack of a clear naming schema and product code name conventions makes it challenging to include this information into LLM prompts for extracting product names from SR data. In experiments, we find that providing sample product codes with the question prompt improves prediction performance significantly for product names although the overall performance is still low compared to the multiple-choice question formulation described next (Table 4).

We harness the technology/sub-technology organizational hierarchy by creating lists of all possible product names (or alternatively, software versions) using historical SR data, applying custom matching functions to canonicalize their mentions, and collating them to form options for multiple-choice question (MCQ) prompts. Intuitively, MCQ options provide hints to the LLM on the correct label choice for a document despite it not including a precise mention. For the previous example using organization names, an MCQ formulation "which of the following companies– Tesco PLC, Carrefour ..." may enable the LLM to reason out the potential connection between *Tesco PLC* and the mention *TSCO.L* to make a more accurate prediction. Our prompt templates are listed in Table 2.

Filter Classifiers: The case notes for an SR refer to "free text" notes created and exchanged during the process of resolving an SR and include different types such as emails between customer and tech support engineers, back and forth communications about scheduling meetings, action plans, etc. The numbers of case notes range from a few tens to hundreds, and though mostly uninformative, few notes contain vital exchanges related to product name or software version details of the SR. For illustration, the histogram of number of case notes for SRs as well as samples of uninformative case notes in our experimental dataset are shown in Figure 2 and Table 3, respectively, whereas sample useful case notes were highlighted in Table 1.

Given that commercially-available LLMs incur a cost depending on the number of input tokens per API call, it is not cost-efficient to send uninformative documents to the LLM. In addition, these documents may instead add "noise" and affect predictions by the LLM. To address these concerns, we train two classifiers (for product name and software version, respectively) to filter out the uninformative documents for a given SR before aggregating and sending the rest to the LLM. The training data for

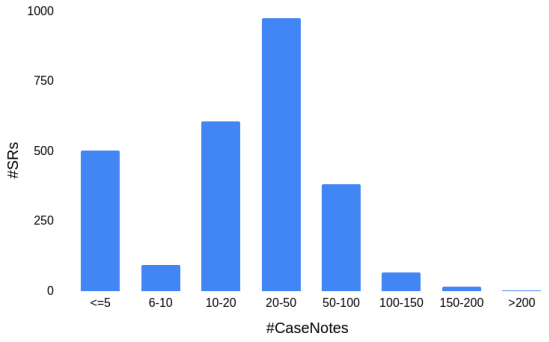

Figure 2: Histogram of number of SRs versus number of associated case notes in our dataset.

our filter classifier for product name/software version was created based on the following intuition– for a given SR, if none of the elements in the potential list of product name/software version labels are mentioned in a case note, it is unlikely to be useful for predicting product name/software version information (negative class), and conversely, if at least one of the potential labels appears in a case note, it may be useful for the prediction task (positive class). Due to the large number of uninformative case notes present in the SR data, the above process results in highly skewed datasets. We employ sampling on the negative class ("uninformative notes") and investigate smaller classification models for training filter classifiers.

Matching functions: Human-generated product name mentions in SR data do not always strictly follow naming conventions and occur as ad hoc variations (e.g., "AB5 JX BRM" or "Axx Byyy5 JX BRM" instead of "AB5-JX-BRM"). Similar to product names, software mentions often occur in non-canonical forms ("yyyyy.3.1.3(c).A.bin" or "3.1-3c" instead of "3.1.3c") in SR data. In consultation with domain experts, we adopted the longest common sequence as the matching function for product names.[3] Software strings are first normalized using various rules to extract the numeric sequence and alphabetic sequence **separately** and the

[3]LCS matches greater than 70% are considered equivalent. Domain experts considered product group prediction to be of value if the full mention is unavailable (Table 1).

Q Prompt	Which *product/software version* is principally discussed in these documents?
MCQ Prompt	Which *product/software version* from the given list: `{choice_list}` is principally discussed in these documents?
Extra Prompt	+ Answer "NONE" if you cannot find the answer in the given documents.
System Prompt	You are a helpful *Cisco* tech support engineer . . .

Table 2: List of LLM prompt templates. `{choice_list}` is derived from the relevant product tech/subtech hierarchy.

Case Note 3 Thank you for sharing the requested logs, I will review and update the findings . . .

Table 3: Examples of SR case notes, unlikely to help with our prediction tasks.

software version matching function incorporates an **exact** match for the numeric parts and edit distance for the non-numeric parts of the string. This combination ensures that "3.1.3" does not match "3.1.1" or "3.1.35" but will match "3.1.3a" if the edit distance of '1' for alphabetic characters is acceptable to domain experts (Kleinberg and Tardos, 2005). Matching functions play a crucial role in identifying ad hoc variations of product name and software mentions and are used not only to compile canonical options lists for MCQ prompts but also to identify documents with mentions ("positive" class) for training the filter classifiers, as well as during evaluation for comparing predictions and gold labels.

Recently, retrieval augmented generation (RAG) solutions that merge external knowledge (for example, retrieved from a database or web search) with LLMs' intrinsic knowledge are being widely adopted for domain knowledge-intensive tasks (Gao et al., 2024). Note that our core task is fundamentally extractive, framed as "What product name (or software version) is this SR addressing?". In a typical RAG workflow, this question would need to be transformed into an effective query to retrieve relevant documents. However, in our context, the necessary information is already expected to be within the input texts related to the SR, precluding the "retrieval" step. In addition, for matching against a pre-defined, structured list of product names or software versions (our MCQ options), we needs flexible matching functions for identifying relevant lexical and syntactic patterns making generic retrieval mechanisms (based on vector similarity) unsuitable. Our classifier-enabled augmentation approach based on matching functions customized to our domain is motivated by these challenges.

3 Experiments

Dataset: For studying this task, *Cisco* provided a dataset of about $1,287$ SR metadata records and their associated case notes (27,136 text documents). After employing our matching functions to identify canonical forms, we extracted 218 unique product names and 375 unique software versions for the provided data organized into a two-level hierarchy of 44 and $\sim$ 200 product technology, sub-technology categories, respectively. Correct product names and software versions were provided by *Cisco* only for a small subset of SRs that we use for evaluating product name and software version prediction. "Gold" product name and software version labels were available for 55 SRs and 30 SRs, respectively. Though these numbers are considerably small, for zero-shot settings and a relative evaluation of LLMs and prompts, we posit that our findings are still representative. The full set of $1,287$ SR case notes were used for creating data for product name (**PName**) and software version (**SWV**) filter classifiers, with subsets of "gold" SRs used to create the validation splits. After sampling (10%) for the majority ("negative") class, our resulting datasets are summarized as follows:

	Train (+/-)	*Test* (+/-)	*Val* (+/-)
PName	1859/5192	409/1305	56/61
SWV	463/6588	125/1589	20/234

LLM Prediction Performance: We experimented with a range of proprietary as well as open-source state-of-the-art LLMs including those from GPT-series (OpenAI), Claude (Anthropic), DeepSeek-R1 (DeepSeek), Llama (Meta), and the Qwen series for predicting product names and software versions from SR data. Precise model names can be found in Appendix A.1. We also included experiments with smaller models in Appendix A.4 to highlight their significantly lower performance compared to SOTA LLMs in zero-shot settings.

All result tables for product name/software version prediction in this paper show **averaged accuracy** values using the two matching functions described previously.

Prompt	**PName**	**SWV**
QPrompt	0.3090	0.8965
QPromptEgs+NONE	0.4181	0.7931
MCQPrompt	**0.7818**	0.5172
MCQ+NONE	0.7272	**0.9655**

Table 4: Prediction accuracy with GPT-4o

A summary of performance with GPT-4o LLM using different prompts is provided in Table 4. Since product name strings are not "general knowledge", not surprisingly, the basic QPrompt does not perform well for product names in contrast with software version labels. Specifying exemplars for indicating to the LLM the nature of product name strings ("QPromptEgs+NONE") significantly improves the product name performance but with a suitable MCQ prompt that includes option lists to choose from, we obtain significantly higher performance for both product names and software versions. The prediction performance using best prompts across LLM models (from Table 4) is summarized in Table 5. Among the LLMs considered as well as older models from OpenAI, GPT-4o performed the best for product names whereas several SOTA LLMs performed equally well for software version identification.

In our dataset, there are SRs for which product name (or software version) cannot be extracted based the available information alone. For instance, the SR pertains to a generic problem (agnostic to specific devices) or related to a third-party product

Model Name	**PName**	**SWV**
Claude-3-7-Sonnet	0.6909	**0.9655**
GPT-4o	**0.7818**	**0.9655**
QwQ-32B	0.7273	**0.9655**
Llama-70B	0.6000	0.8620
DeepSeek	0.6545	0.7931

Table 5: Prediction Performance across LLMs

or software. In these cases, the "correct" prediction should be "NONE" or "N/A" (empty). We summarize the aggregate performance (on NONE and non-NONE SRs) of best models across LLM groups on the two prediction tasks using the best-performing MCQ prompts in Tables 4 and 5. Overall, when the labels are available (non-NONE cases), in best settings, all latest LLM offerings (GPT-4o, Claude-3.7-Sonnet, QwQ32B) perform competitively (over 85% accurate) but their aggregate performance is affected by errors on the NONE cases. However, an explicit instruction regarding NONE handling affects performance differently for software and product name prediction. Details of these experiments, exact prompt texts, and other computational setup information are included in the appendix in view of space constraints (Table 7-11).

Filter Performances: We investigated models from RoBERTa (Liu et al., 2019), T5 (Raffel et al., 2020), Flan-T5 (Chung et al., 2024) (base and large variants) for training our filters. On this binary classification task, the FlanT5-large model fined-tuned using instructions including potential labels "Question: Given the list of labels, does the passage contain any of the labels? Answer True or False. Labels= []" performed the best. Performance using standard classification metrics (Bishop, 2007) on the test datasets with FlanT5-large is shown in Table 6 with comparison experiments listed in Table 16 of the Appendix.

Filter/Class	**Precision**	**Recall**	**F1**
PName (+)	0.65	0.63	0.64
(-)	0.89	0.89	0.89
MacroAvg	0.77	0.76	0.76
SWV (+)	0.80	0.86	0.83
(-)	0.99	0.98	0.99
MacroAvg	0.90	0.92	0.91

Table 6: Performance of filters on Test Set

The performance of the software version filter is significantly better compared to that of the product name filter. Similar to the earlier task, we attribute this lower performance to the nature of product name sequences ("alphanumeric" codes) which are challenging to distinguish from other textual tokens in SR data contexts. As such, in product name and software version filters, we are able to identify uninformative case notes in the test dataset with high precision–89% and 99%, respectively.

The results in Tables 4 and 5 use the case notes identified as informative ("True/+") by our filters. On average, we are able to filter out upto 40% of total tokens while predicting software versions (for 30 SRs) and upto 60% of the total tokens while predicting product names (for 55 SRs). Though the specific percentage savings may be an artifact of our datasets (since SRs have varying numbers of case notes as shown in Figure 2), these results highlight the effectiveness of using filters to obtain considerable savings in *Cisco* where millions of SRs are handled annually (Howell et al., 2023).

Deployment notes: Our LLM solution is expected to significantly decrease the earlier manual effort during SR closure in *Cisco*. A GPT-4o based solution is now being test-bedded for evaluating time and cost savings for manpower and LLM usage in realistic conditions. We note that though large-scale, open-source LLMs perform comparably on our evaluation datasets as seen in experiments, current commercial products have the advantage of ease of use via APIs, and coupled with smaller filter models eliminate the need for in-house compute-intensive environments.

4 Related Work

Apart from chatbots, LLMs are being employed in various tasks related to customer support data such as automated text correction, summarization and question answering (Wulf and Meierhofer, 2024; Palen-Michel et al., 2024), product reviews evaluation (Roumeliotis et al., 2024; Azov et al., 2024), as well as knowledge and workflow representation (Su et al., 2025). Recently LLMs were used for NER in datasets from customer order descriptions (Oh, 2024), recipes (Agarwal et al., 2024), clinical contexts (Lu et al., 2024), and the financial news articles (Shah et al., 2024). Though question answering techniques for extracting metadata were previously investigated (Du and Cardie, 2020; Borst et al., 2022; Song et al., 2024; Hu et al., 2025), as far as we know, there is no multiple-choice question answering formulation for similar tasks in published works. Since our dataset is proprietary, we also showcase our approach's advantage over conventional prompts on a recent public dataset for the comparable task in the financial domain (Appendix A.3).

5 Conclusions

We investigated the use of SOTA LLMs for assigning product names and software version labels for customer service requests (SR) data, previously requiring human intervention. With appropriate prompts, existing commercial LLMs are able to extract the required information from SR data with high accuracy. However, a naïve use results in high LLM costs due to substantial amounts of irrelevant data associated with SRs. To this end, we designed filter classifiers that ensure that only SR data pertinent to prediction is included in the LLM prompts. In on-going work, we are exploring practical deployment of our developed pipeline within *Cisco*.

Limitations

Though our solution design was motivated by a context exclusive to *Cisco*, we expect the general result trends and ideas such as MCQ formulation and input filtering for LLMs to carry across comparable datasets as illustrated by our results on the NER task from the financial domain (Appendix A.3). Filter classifiers, despite being not very high performing (particularly for product name), did not adversely affect the final prediction results on our SR datasets. Since errors on "positive" class result in informative case notes being mistakenly discarded, there is a need to improve datasets both for training the underlying classifiers as well as for evaluating the effect of incorrect classification on final predictions. We highlighted the contradictory behavior of LLMs regarding handling "NONE" cases for software version versus product name assignments requiring further investigation regarding prompt sensitivity of LLMs (Bowman, 2023). Studies on MCQ-answering behavior of LLMs are on-going (Huang et al., 2022; Balepur et al., 2024; Wang et al., 2025).

Our industry-partner *Cisco* keen on exploring state-of-the-art LLMs for their in-house tasks, provided us fully-anonymized datasets replacing all personally identifiable information such as customer names and contact details with pseudo-

identifiers. Generally speaking however, data privacy is a crucial concern while using proprietary LLMs on data containing sensitive customer information. Another caveat of our proposed solution is the assumption of a "static ontology" as we use the pre-existing product and software technology/sub-technology information to construct options for our MCQ prompts. While including a "NONE" option among the choices aims to capture the missing instances and highlight when the ontology updates are due, future research is needed for developing methods that can seamlessly handle dynamic ontology updates.

A Appendix

A.1 Model List

Table 13 presents the list of LLMs used in our system. The models include both proprietary and open-source options, with parameter sizes ranging from 32B to 70B where available. For each model, we provide its name, type, parameter size, and a reference link for access or documentation.

A.2 Details of Product Name and Software Version Prediction

Model training and inference with filter classifiers were performed on a single GPU of an Nvidia Tesla cluster (Linux) machine with 32GB RAM. For experiments using open-source LLMs (from Meta, Qwen, and DeepSeek), we used vLLM for inference on 4×H100 80GB GPUs.

In the following tables, we listed the performance on the set of SRs for which the "gold" labels are NONE in a separate column (NoneSet) to highlight the difference in how different LLMs handle these cases based on an explicit instruction regarding "NONE" handling (See Extra row in Table 2). Overall, about 30% and 50% of the cases are NONE for the product name and software gold SRs, respectively.

A.3 FiNER-ORD experiments

To illustrate the benefit of the MCQ formulation over the general question formulation, we summarize experiments on FiNER-ORD, an open-research dataset from the financial domain (Shah et al., 2024) that includes English financial news articles where sentences were manually-annotated for person names, locations, and organizations. SOTA LLMs such as GPT-4o in zero-shot settings only achieve an accuracy of about 60% for organization entity mentions in this dataset.

To be comparable to our problem setting, we consider the sentences in the dataset that only include the "abbreviations" of organizations but whose full names are known at document level. For example, "Associated Press" is known early on based on document level information but the sentence only mentions "AP". The validation and test datasets for our experiments comprised of 84 and 256 sentences, respectively. We instruct GPT-4o LLM using the two question prompts "What organizations are being discussed in the following text?" versus "Which of the following organizations ..." with the fullnames of potential organizations provided as MCQ options in the prompt. With the simple question prompt, the accuracies range from 61-63% (similar to published numbers) whereas with the MCQ prompt, the performances were significantly higher and in the range 80-83% for the two sentence subsets. Our subsets of the original datasets and prompts are available upon request.

A.4 Experiments with smaller models

We show performance of smaller language models Flan-t5-large from Google[4] and Llama-3.1-8B-Instruct from Meta[5] in zero-shot settings on the metadata from a subset of 30 SRs in Table 17 for product name and software version prediction. As can be seen in this table (when compared

[4]https://huggingface.co/google/flan-t5-large

[5]https://huggingface.co/meta-llama/Llama-3.1-8B-Instruct

to LLMs/GPT-4o from OpenAI), performance of smaller models is significantly lower. In addition to context length limitations, we observe that smaller models are unable to generate output in consistent formats or follow instructions to provide explanations for a given answer choice. Consequently, best results were obtained with simpler prompts of the form "Question: Which of the product name labels in <list-of-labels> best match the following text? Context: []". Due to unavailability of large-scale labeled data, we did not investigate fine-tuning of smaller models in this study.

Model	PName	SWV
FlanT5-large	0.2666	0.3448
Llama-3.1-8B-Instruct	0.5000	0.3448
GPT-4o	**0.7333**	**0.5172**

Table 17: Aggregate accuracies for product name and software version prediction using smaller models are shown against GPT-4o performance

For the results in Table 17, we manually examined the output from Llama-3.1-8B-Instruct models since we were unable to adjust the prompt despite multiple reformulations to ensure a consistent output format. For the software version prediction experiments, similar to experiments with LLMs we added "NONE" handling with MCQ prompts (Table 4).

Reasoning-Enhanced Domain-Adaptive Pretraining of Multimodal Large Language Models for Short Video Content Governance

Abstract

Short video platforms are evolving rapidly, making the identification of inappropriate content increasingly critical. Existing approaches typically train separate and small classification models for each type of issue, which requires extensive human-labeled data and lacks cross-issue generalization. We propose a reasoning-enhanced multimodal large language model (MLLM) pretraining paradigm for unified inappropriate content detection. To address the distribution gap between short video content and the original pretraining data of MLLMs, as well as the complex issue definitions, we introduce three targeted pretraining tasks: (1) *Caption*, to enhance the MLLM's perception of video details; (2) *Visual Question Answering (VQA)*, to deepen the MLLM's understanding of issue definitions and annotation guidelines; (3) *Chain-of-Thought (CoT)*, to enhance the MLLM's reasoning capability. Experimental results show that our pretraining approach significantly improves the MLLM's performance in both zero-shot and supervised fine-tuning (SFT) settings. In addition, our pretrained model demonstrates strong generalization capabilities to emergent, previously unseen issues.

1 Introduction

Short video platforms such as Reels and YouTube Shorts have experienced explosive growth. While these platforms offer unprecedented opportunities for communication and information dissemination, they have simultaneously facilitated the distribution of a wide range of inappropriate content. Videos featuring borderline sexual content, plagiarism, and fake engagement, not only affect user experience but also deteriorates content ecosystem in the long run. As a result, the regulation and governance of short video content have become increasingly critical to ensure a healthy digital ecosystem.

Current short video platforms typically implement a standardized content governance process, which consists of three sequential stages: The platform initially develops comprehensive *guidelines* for identifying specific *issues* (such as sexually suggestive content); Subsequently, human annotators are instructed to label video samples according to these guidelines; Finally, this labeled dataset serves as labeled data to fine-tune visual models (e.g., VLMo (Bao et al., 2022b), BEiT (Bao et al., 2022a), and X-VLM (Wang et al., 2022)) for video classification, which are then deployed for real-time content monitoring and filtering. However, this process comes with significant limitations: (1) *High manual labeling cost*. These visual models are typically small in size (usually only a few hundred megabytes) and lack world knowledge, so they require large volumes of manually labeled data, making the process time-consuming and expensive. (2) *No cross-issue generalization*. Each of these small models is designed to handle only a fixed issue and lacks the ability to generalize across different issues. Therefore, when the definition of an issue changes or a new issue emerges, the model must be retrained from scratch following the same labor-intensive process, leading to long development cycles.

To address the limitations of small specialized models, we explore the use of multi-modal large language models (MLLMs). MLLMs possess extensive world knowledge, which theoretically reduces the need for large-scale annotated data and offers better cross-issue generalization. However, applying MLLMs in this context presents two key challenges: (1) *Domain-specific data distribution*. The data on short video platforms exhibits unique characteristics, both in *format* (e.g., frame layouts, visual composition, and hashtag usage patterns) and in *semantics* (e.g., narrative styles, editing conventions, and internet slang). These characteristics often diverge significantly from the distribution of

*Equal contribution.

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1104–1112
November 4-9, 2025 ©2025 Association for Computational Linguistics

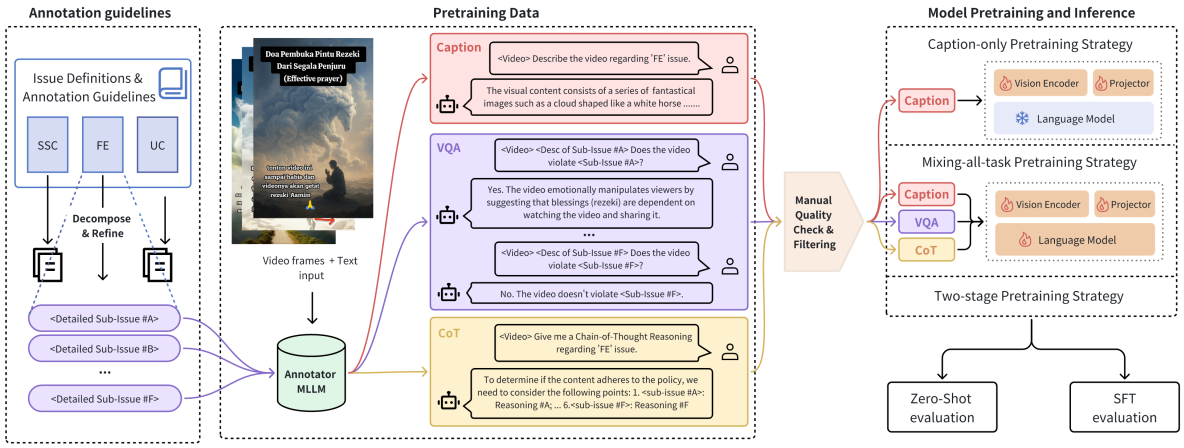

Figure 1: Illustration of our domain-adaptive pretraining approach for short video content governance. For each issue type, we first decompose the annotation guidelines into a set of sub-questions to assist pretraining data generation. An annotator MLLM is deployed to produce three types of pretraining data: Caption, VQA, and CoT, enabling the model to mimic human-like reasoning. The model can be pretrained using three different strategies, and the pretrained model is finally evaluated in both zero-shot and SFT settings.

data MLLMs were originally pretrained on, potentially impacting performance. (2) *Complex and evolving definition of issues*. Each content issue comes with its own well-defined criteria and decision rules, which are usually complicated and may evolve. For an MLLM to make accurate judgments, it must thoroughly understand and follow these guidelines to perform reliable inference.

To tackle the above challenges, we propose a novel domain-adaptive pretraining approach for short video governance. As illustrated in Figure 1, the pretraining approach includes three key components: (1) *Enhanced video detail perception*. To help MLLMs better adapt to the unique data patterns of short videos, we introduce a descriptive video captioning (*Caption*) task into the pretraining stage. These captions guide the model to attend to fine-grained video detail, especially those relevant to specific issues. (2) *Deep understanding of guidelines*. To enable MLLMs to thoroughly understand the nuances of issue annotation guidelines, we decompose each guideline into a set of sub-questions and construct a visual question answering (*VQA*) task. For example, in the case of borderline sexual content, the guideline is broken down into questions such as "`Are private body parts exposed`?", with annotated answers. This enables MLLMs to learn the specific judgment criteria for each issue. (3) *Structured reasoning*. Even after perceiving video details and understanding the guidelines, the model must follow a systematic reasoning process. To support this, we curate a chain-of-thought (*CoT*) task that teaches MLLMs to reason step by step following predefined logic flows. Together, the *Caption*, *VQA*, and *CoT* datasets provide end-to-end domain adaptation for MLLMs, which significantly improves the performance.

We conducted the pretraining on several open-source MLLMs, including LLaVA-OV (Li et al., 2024) and Qwen2.5-VL (Bai et al., 2024), using data from three content governance tasks: sexually suggestive content, unoriginal content, and fake engagement. Experimental results show that our domain-adaptive pretraining significantly improves model performance compared with native models, both in zero-shot and supervised fine-tuning (SFT) settings. Moreover, we demonstrate that our approach enables strong generalization to unseen issues with minimal supervision, highlighting its robustness and adaptivity. Our ablation studies further validate the effectiveness of our method across different model scales.

The contribution of this paper is as follows:

- We propose an MLLM pretraining framework for short video governance, demonstrating strong generalization to out-of-distribution issues not seen during pretraining.
- We design three pretraining tasks (Caption, VQA, CoT) to enhance the model's ability to perceive video details, understand annotation guidelines, and perform structured reasoning.
- Experiments show that our pretrained model

significantly improves performance in both zero-shot and SFT evaluation settings.

2 Related Work

2.1 Video Content Governance

Recent advances in deep neural networks have significantly enhanced content governance capabilities in detecting and classifying inappropriate video content on short video platforms (Yousaf and Nawaz, 2022; Li et al., 2025b). For example, multimodal features have been applied to identify misleading clickbait videos (Rahman et al., 2023; Sun et al., 2025; Liang et al., 2025); Age-adaptive learning techniques have been developed to detect and categorize inappropriate video content for different demographics of viewers, demonstrating sensitivity to visual needs (Alam et al., 2024; Zhang et al., 2024; Li et al., 2025a). These approaches underscore the potential of MLLMs in addressing the challenges of short video content governance.

2.2 Domain-Adaptive Pretraining

Recent research demonstrates the effectiveness of domain-adaptive pretraining in enhancing model performance (Song et al., 2025). Specifically, pretraining strategies have been used in model design, task formulation, and application scenarios (Guo et al., 2024). For example, in multimodal learning, efficient domain-specific pretraining has been applied to human activity recognition (Bulat et al., 2024) and short video understanding (Lu et al., 2025; Li et al., 2023); SimRAG (Hong et al., 2024) and domain-specific instruction tuning (Xie et al., 2024; Liu et al., 2024a; Wang et al., 2025; Dong et al., 2025) effectively align models with VQA tasks (Ging et al., 2024; Khullar et al., 2024); Adaptive techniques such as velocity-based domain reweighting (Luo et al., 2024; Leong et al., 2025), knowledge distillation (Shi et al., 2024) and structure-aware knowledge injection (Liu et al., 2024b) further improve knowledge retention and transfer.

3 The Proposed Pretraining Approach

3.1 A Unified Model for All Content Issues

Short video platforms often face a variety of content issues, such as non-original content. We denote the set of all issues of interest by $\mathcal{I}$. For each issue $i \in \mathcal{I}$, the policy team defines detailed descriptions and corresponding annotation guidelines, denoted by G_i. Human annotators are then trained using these guidelines to label a collection of videos, resulting in a dataset $\mathcal{D}_i$. This dataset is then used to fine-tune a visual classification model $\mathcal{M}_i$:

$$\mathcal{M}_i(v; G_i, \mathcal{D}_i) \rightarrow l, \quad \text{for } i \in \mathcal{I}, \tag{1}$$

where v is an input short video and l is the predicted label for v.

However, due to the lack of cross-issue generalization in these models, any change in the annotation guidelines G_i or the emergence of a new issue would require collecting a new human-annotated dataset $\mathcal{D}_i$ and retraining the model from scratch, which is extremely costly. Therefore, a promising solution is to leverage the broad, internalized knowledge of MLLMs to pretrain a unified model $\mathcal{M}$ that can generalize across different issues:

$$\mathcal{M}(v; \{G_i\}_{i \in \mathcal{I}}, \mathcal{D}) \rightarrow l, \tag{2}$$

where $\mathcal{D}$ is the pretraining dataset, which we will describe in detail in Section 3.3.

3.2 Annotation Guidelines Decomposition

Issue definitions and annotation guidelines are usually highly complex, typically covering dozens of scenarios, their exceptions, and both positive and negative illustrative examples. To help the model better understand these guidelines, it is essential to simplify and distill them into a set of sub-questions that are easier for the model to process. For instance, the annotation guidelines for the issue of sexually suggestive content consist of intricate definitions: "`Adult Image-Based Sexual Abuse occurs when the subject(s) depicted ...`". We decompose them into a collection of simple sub-questions such as "`Are private body parts exposed?`", "`Is there sexual teasing or invitation?`", and "`Are adult products shown?`". These sub-questions are later used to construct the pretraining dataset.

3.3 Pretraining Tasks

There are two main challenges in using MLLMs for short video content governance: (1) The unique characteristics of short videos limit the capabilities of native MLLMs to fully understand their content; (2) Issue annotation guidelines are often complex, making it difficult for native MLLMs to effectively follow and reason based on them. To address these challenges, we design three pretraining tasks:

Caption task is to help the model perceive fine-grained details of the input video, especially

those related to specific issues. As shown in Figure 1, the input of the caption task is a prompt such as "`Describe the video regarding the fake engagement issue.`", and the expected output is a 2–3 sentence description of the video from the perspective of fake engagement.

VQA task is to enable the model to develop a deep understanding of the annotation guidelines. To make more efficient use of the VQA data, we design two usage strategies: (1) *Binary QA*, where the input is a sub-question derived from the decomposed annotation guidelines described in Section 3.2. The output is a yes/no answer of whether the input video violates the given sub-question, as well as a detailed explanation. Examples of binary QA task are illustrated in Figure 1. (2) *Multi-choice QA*, where the input consists of all sub-questions, and the model is asked to select which issues the input video violates from the given options. It is important to note that VQA task relies on the model's accurate perception of video details obtained through the Caption task.

CoT task is to enable the model to integrate the answers from all sub-questions in the VQA task and produce a complete reasoning process leading to a final conclusion. As shown in Figure 1, for the fake engagement issue, the model should go through all the sub-questions. The final conclusion will be positive if any of the answer are positive.

3.4 Model Pretraining and Inference

How to organize the three pretraining tasks is also a critical question. A straightforward way is to mix all three tasks and jointly train the model. However, we found that the caption task is particularly important. Performing an initial round of caption-only training followed by joint training of all three tasks leads to better performance. We discuss the pretraining recipes in detail in Section 4.4.

We design two inference strategies. (1) The first is *zero-shot*, where the pretrained model directly classifies the input video and provides an explanation. We use the normalized logits of the predicted label token as the output probability. (2) The second strategy is *SFT*, where we add an MLP classification head on top of the model's final layer, and fine-tune the model using LoRA (Hu et al., 2022) on an additional SFT dataset for classification. It's worth noting that zero-shot inference offers more interpretable explanations for the model's predictions, while SFT inference is faster and currently serves as the solution for online deployment.

4 Experimental Setup

4.1 Content Issues

We collect the pretraining data and conduct experiments on real industrial data spanning three issues: Sexually Suggestive Content (**SSC**), Unoriginal Content (**UC**), and Fake Engagement (**FE**). To evaluate the model's ability to generalize to unseen or out-of-distribution issues, we also test the pretrained model on the Shocking Graphic Content (**SGC**) issue, which includes videos that cause physical discomfort to viewers. SGC issue is not included in the pretraining data.

4.2 Datasets

Pretraining data. We sample 50k positive and 50k negative videos for each of the 3 issues. An MLLM annotator is used to generate the Caption, VQA, and CoT tasks. The Caption task is generated independently, while the VQA and CoT tasks are generated simultaneously, resulting in a total of 920k instruction samples. After generation, we manually filter out any VQA-CoT samples that are inconsistent with the human annotations.

SFT data. We use human-annotated binary-labeled examples as SFT data for each issue to fine-tune the pretrained model, with 10% of the samples labeled as positive.

Evaluation data. We use 1k human-annotated samples as evaluation data for each issue, with 50% of the samples labeled as positive.

4.3 Baseline Models

We choose LLaVA-OV 7B (Li et al., 2024) and Qwen 2.5-VL 7B(Bai et al., 2024) as baseline MLLMs for continual pretraining. Both models consist of three components: a language model, a vision encoder, and a projector. Additionally, we compare our pretrained models with GPT-4o (Achiam et al., 2023) in the zero-shot setting.

4.4 Pretraining Strategy

We use three pretraining strategies:

Caption-only. In this strategy, the language model is frozen while the vision encoder and projector are trained using only the caption dataset. The goal is to enhance the model's ability to perceive fine-grained visual details.

Mixing-all-tasks. All three types of pretraining datasets are mixed and randomly shuffled. We train all components of the MLLM jointly on this mixed dataset.

Model	Pretraining strategy	SSC ACC	SSC F1	UC ACC	UC F1	FE ACC	FE F1	SGC ACC	SGC F1	Overall AUC
LLaVA-OV native	-	70.68	70.62	49.60	66.31	48.66	65.20	71.19	76.20	61.97
LLaVA-OV pretrained	Caption	74.53	75.38	65.67	71.82	48.09	64.95	71.19	75.31	70.89
	Mix	**82.13**	82.34	78.87	79.10	75.81	**77.39**	75.13	77.49	80.75
	Stage	80.65	81.99	**80.46**	**80.74**	71.13	72.69	**77.20**	**78.76**	**81.22**
Qwen2.5-VL native	-	74.23	76.12	51.69	67.12	53.82	66.44	74.92	78.04	69.49

GPT-4o	-	75.71	72.97	65.97	67.24	64.15	68.97	74.62	78.09	-

Table 1: Result of zero-shot evaluation. Metrics are accuracy and F1 (in %). The last column is the overall ROC-AUC (in %) across all issues. The highest value in each column is shown in **bold**, and the second-highest is underlined. The overall AUC of GPT-4o cannot be computed because we cannot access its output probabilities.

Model	SSC AUC	SSC ACC	SSC P@R90	UC AUC	UC ACC	UC P@R90	FE AUC	FE ACC	FE P@R90	SGC AUC	SGC ACC	SGC P@R90
Native	92.97	84.05	79.76	80.98	71.53	59.92	91.38	84.35	75.70	99.18	89.86	97.95
Pretrained w/ Mix	**93.29**	**85.52**	**81.57**	**87.53**	**75.79**	**69.88**	**91.94**	**84.46**	**78.31**	99.26	94.93	**98.17**
Pretrained w/ Stage	93.00	84.84	80.57	86.65	73.41	64.84	91.88	84.34	76.12	**99.31**	**95.14**	98.05

Table 2: Result of SFT evaluation. Metrics are ROC-AUC, Accuracy, and P@R90 (Precision at 90% Recall) (in %). Following the actual model deployment setup, LLaVA-OV is used as the base model for SSC, FE, and SGC, while Qwen2.5-VL is used as the base model for UC. The highest value in each column is shown in **bold**.

Two-stage. This is a two-stage approach that combines the previous two strategies. We first apply Caption-only strategy to train the vision encoder and projector, and select the best checkpoint across epochs. Then, we switch to the Mixing-all-tasks strategy to fine-tune the entire model.

5 Experimental Results

5.1 Zero-Shot Evaluation

In-domain issues. The results of zero-shot evaluation are shown in Table 1. For the three in-domain issues: SSC, UC, and FE, the performance of the pretrained models consistently surpasses that of their native counterparts. Notably, the pretrained models also significantly outperform GPT-4o. This indicates that, despite GPT-4o's strong multimodal capabilities, it still struggles to fully understand complex issue annotation guidelines.

From an issue-specific perspective, the accuracy improvements brought by pretraining on SSC, UC, and FE are approximately 7–11%, 24%–31%, and 22%, respectively. The gains on UC and FE are greatly higher than those on SSC. This may be because SSC is detecting sexually suggestive content, a task for which native models already possess sufficient prior knowledge. In contrast, UC and FE are non-original content and fake engagement, whose precise definitions are given in the annotation guidelines. Native models lack strong priors for these issues. This further demonstrates the effectiveness of our VQA and CoT pretraining tasks in injecting domain-specific knowledge into the base models.

Out-of-domain issue. To demonstrate the generalization ability of the pretrained models, we also evaluate their performance on the SGC issue, which is not included in the pretraining data. The results show that pretraining significantly improves LLaVA's performance on this out-of-domain issue (6% absolute accuracy improvement).

Comparison between LLaVA and Qwen. On the three in-domain issues, pretraining brings accuracy improvements of 11%–31% for LLaVA and 7%–24% for Qwen. This suggests that the benefits of pretraining are more significant for LLaVA. Upon closer inspection, we found that one possible reason is that Qwen sometimes produces inconsistencies between its reasoning and final answers. That is, it may generate a correct and well-structured reasoning process, but still output an incorrect final prediction. We provide a detailed analysis example in the Appendix.

Pretraining strategy. Comparing the three pretraining strategies, we find that Two-stage consistently outperforms Caption-only and Mixing-all-

Configuration	AUC	ACC	P@R90
LLaVA-OV native + 100% SFT data	99.18	89.86	97.95
LLaVA-OV pretrained + 100% SFT data	**99.31**	95.14	98.05
LLaVA-OV pretrained + 50% SFT data	99.26	**95.35**	**98.17**

Table 3: ROC-AUC, Accuracy, and P@R90 scores (in %) on the SGC issue under SFT evaluation. The pretraining strategy is Stage. The highest value in each column is shown in **bold**.

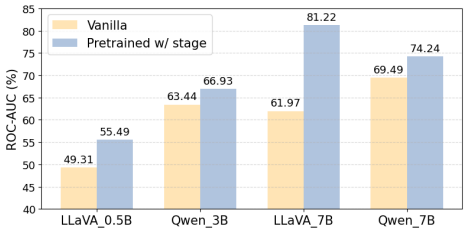

Figure 2: ROC-AUC of vanilla and pretrained models with different model sizes under zero-shot evaluation.

tasks in most cases. This suggests that first training the model to perceive fine-grained video details, followed by learning the annotation guidelines and reasoning process, is the most effective practice.

5.2 SFT Evaluation

The SFT evaluation results are presented in Table 2. Compared to zero-shot evaluation, most of our conclusions remain consistent, with a few differences:

(1) In most cases, pretraining still improves model performance under SFT evaluation, but the gains are generally smaller, typically around 1% to 10%. This is because the pretraining paradigm aligns closely with the zero-shot evaluation format (i.e., natural language generation), whereas the SFT evaluation is direct classification through probability outputs. This mismatch reduces the impact of pretraining under SFT evaluation.

(2) Regarding pretraining strategies, Mixing-all-tasks performs slightly better than Two-Stage. Note that Two-Stage includes an additional round of caption-only training. This suggests that adding an extra caption phase does not significantly enhance performance under SFT evaluation. The reason is similar to the above: the Caption task aligns more closely with natural language generation and contributes less to performance when the evaluation requires direct classification.

5.3 Ablation Study

Cross-issue generalization. Pretrained MLLMs exhibit strong cross-issue generalization capabilities. This generalization is reflected not only in the zero-shot setting, where pretrained models perform well on out-of-domain issues (as shown in the SGC issue in Table 1), but also in the SFT setting, where pretrained models can achieve or even surpass the performance of native models using significantly less SFT data. To demonstrate this, we fine-tune the pretrained LLaVA model using only 50% of the SFT data. The results, shown in Table 3, reveal that the pretrained LLaVA with just half the SFT data outperforms the native LLaVA trained with the full SFT dataset (compare row 3 with row 1). This highlights that the pretrained model possesses substantially stronger cross-issue generalization capabilities than the native model, enabling it to adapt to new issues with minimal SFT data.

Base model size. To investigate the impact of base model size on pretraining effectiveness, we additionally conduct pretraining and zero-shot evaluation on 0.5B versions of LLaVA and Qwen. The results in Figure 2 demonstrate that our pretraining approach also yields significant performance improvements (3%–6%) for 0.5B models. Moreover, we observe that the performance gains on 7B models (5%–19%) are higher than those on 0.5B models. This may be because larger models have greater capacity and can benefit more from the same amount of pretraining data, allowing them to reach a higher performance ceiling.

5.4 Case Study

We conducted a case study to intuitively demonstrate the effect of pretraining. As shown in Figure 3, the Spanish text in the video frame contains an obvious sexually suggestive message. However, the model without pretraining fails to recognize the meaning of the text and subsequently produces incorrect reasoning. In contrast, the pretrained model provides both an accurate answer and a correct reasoning process.

6 Conclusion

In this work, we propose a domain-adaptive pretraining approach for short video content governance. We design three novel pretraining tasks: Caption, VQA, and CoT, which effectively enhance MLLMs' ability to perceive video details, understand annotation guidelines, and perform reasoning. Experimental results show that our pretraining method significantly improves the model's performance on both zero-shot and SFT evaluations. Fur-

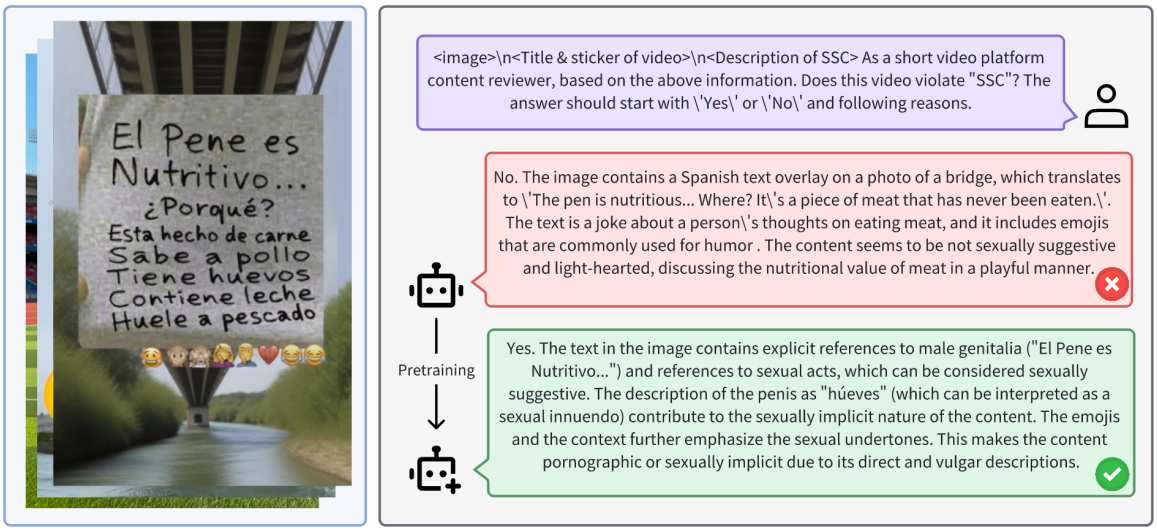

Figure 3: Left: An illustrative example of short video frames that violates the SSC policy. Right: Zero-shot evaluation prompt and the MLLM's responses before and after our pretraining.

thermore, the pretrained models exhibit strong generalization to new issues, which can substantially reduce manual annotation costs and shorten development cycles in real-world deployment scenarios.

7 Limitation

In this work, the largest model we used is 7B due to limitations in resources. Although the pretrained 7B models already perform well for short video content governance, we are still interested in exploring the impact of pretraining on even larger models. Regarding data types used for pretraining, in addition to MLLM-annotated data, we also plan to incorporate a large amount of unlabeled data to further enhance performance. Moreover, when decomposing annotation guidelines into sub-questions, we currently rely on manual design, which may not be optimal. In the future, we plan to explore reinforcement learning methods to automatically decompose annotation guidelines in a more efficient and adaptive manner.

A Details of Prompt Design

In Figure 4, we present a complete pipeline example for constructing pretraining data, including the prompts used for generating pretraining data, the generated outputs, and the prompts used during pretraining. To improve clarity, we highlight the issue and its related content using bold text. Additionally, we mark segments of the generated pretraining data that align with the sub-issue in green, and those that do not in red. This clearly illustrates that issue-specific knowledge is consistently embedded across all tasks.

B Analysis on Qwen's Inconsistency Issue

During zero-shot inference, we observed that when the answer format is designed as "Reason after Answer", Qwen often produces incorrect final answers despite providing correct reasoning. For example, when given a video that does not violate the UC policy and asked whether it violates the UC policy, the model responds: "Yes. The images appear to be original user-generated content without any visible watermarks indicating ownership by another entity..." Although the model clearly identifies the content as original, its final answer is still "Yes", and the probability score for the first token exceeds 0.67. As a result, evaluating performance based solely on the first token's probability leads to an underestimation of the model's true reasoning ability.

GSID: Generative Semantic Indexing for E-Commerce Product Understanding

Abstract

Structured representation of product information is a major bottleneck for the efficiency of e-commerce platforms, especially in second-hand ecommerce platforms. Currently, most product information are organized based on manually curated product categories and attributes, which often fail to adequately cover long-tail products and do not align well with buyer preference. To address these problems, we propose **G**enerative **S**emantic **InD**exings (GSID), a data-driven approach to generate product structured representations. GSID consists of two key components: (1) Pre-training on unstructured product metadata to learn in-domain semantic embeddings, and (2) Generating more effective semantic codes tailored for downstream product-centric applications. Extensive experiments are conducted to validate the effectiveness of GSID, and it has been successfully deployed on the real-world e-commerce platform, achieving promising results on product understanding and other downstream tasks.

1 Introduction

The widespread adoption of digital technologies and the evolution of e-commerce ecosystems have led to rapid growth in the consumer-to-consumer (C2C) second-hand e-commerce domain(Wu et al., 2025). Unlike the traditional business-to-consumer (B2C) model(Chan et al., 2023; Zhou et al., 2018), C2C platforms have a majority of products listed by individual users, often with limited inventory(Wu et al., 2024), while also hosting professional sellers with multiple stock-keeping units. The diversity has resulted in a severe long-tail problem in C2C platforms(Wu et al., 2025), making it challenging to effectively organize product information.

Traditionally, product understanding has been organized using manually curated product categories and attributes named Category-Property-Values (CPV(Su et al., 2025)), which not only have limited coverage of long-tail products but also often misalign with buyer preference which is usually manifested through user search queries, as the structure is typically designed from the seller's perspective.

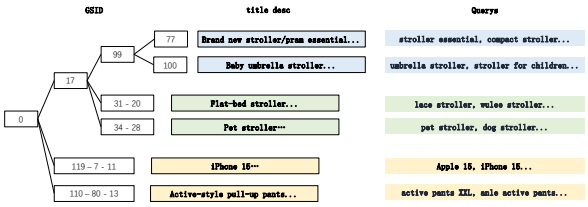

Figure 1: Examples of product descriptions and associated search queries with their GSID.

Inspired by tokenization learning paradigms(Sun et al., 2023; Lee et al., 2022; Tay et al., 2022), we propose a data-driven, self-organizing approach to address the aforementioned issues. Tokenization learning methods typically utilize an encoder model to project unstructured text data into discrete latent spaces, generating discrete, interpretable document representations in an unsupervised framework. Among the various tokenization learning methods, we choose GenRet(Sun et al., 2023), a novel document tokenization learning method that learns to tokenize documents into short and discrete representations using a discrete auto-encoding framework with progressive training scheme, as our base model, considering its potential for end-to-end performance and efficiency breakthroughs through global optimization, automatic feature learning, and simplified workflows, as well as its hierarchical structure that provides stronger interpretability.

Furthermore, we leverage user queries on e-commerce platforms, which not only reflect users' latest fine-grained needs but also contain user behavior patterns, to guide the structuring of product information, thereby addressing the limitations of

Cluster	Coverage	Accuracy
CPV	23.02	96.98
GSID	78.81	97.09

Table 1: Comparison between CPV Cluster and GSID Cluster. The accuracy of cluster is manual annotation in evaluation test with a million samples.

traditional CPV-based product organization.

However, directly applying GenRet(Sun et al., 2023) to C2C product understanding tasks faces the challenge that GenRet-related algorithms lack successful large-scale industrial applications. Thus we propose **G**enerative **S**emantic **InD**exing (**GSID**), a data-driven approach that generates discrete product structured representations tree based on the tokenization learning paradigms as shown in Fig.1, which consists of two key stages: (1) Pre-training on unstructured product metadata to learn in-domain semantic embeddings, and (2) Generating more reliable structured representations tailored for product understanding tasks, leveraging the insights gained from the in-domain pre-training. The proposed improvements not only alleviate the long-tail data coverage issues in products but also generate more reliable structured representations on industrial-scale C2C product data, which can be found in Tab.1. Furthermore, GSID partially solves challenges in downstream applications, such as search and recommendation systems, achieving significant performance improvements compared to previous methods.

Our contributions can be summarized as follows: (1) We introduce a generative semantic indexing framework that establishes a data-driven product understanding paradigm, overcoming the limitations of traditional rule-based systems. This method learns semantic representations directly from raw product data through end-to-end training, eliminating the reliance on manually crafted heuristics. (2) We optimize the GenRet training framework to overcome the challenge of its difficulty in training on large-scale datasets. (3) We demonstrate the effectiveness of GSID in product understanding and downstream tasks, particularly in the second-hand e-commerce domain. Extensive experiments validate the reliability of the proposed method and provide a scalable application example for industrial use.

2 Methods

In this section, we present Generative Semantic InDexing (GSID), a novel approach to product understanding based on generative semantic indexing. Fig.2 illustrates the overall architecture of our proposed framework.

2.1 Model Architecture

Following GenRet, we employ a T5-based encoder-decoder transformer(Raffel et al., 2020) to implement the generative semantic indexing model. The encoder component of the model is responsible for extracting semantic representations of the input text d, which could be product descriptions or search queries. The decoder component progressively decodes and generates semantic IDs, conditioned on the encoder's output and the prefix of previously generated semantic IDs $z_{<t}$. The output of the decoder at step t is a latent representation d_t:

$$d_t = \text{Decoder}(\text{Encoder}(d), z_{<t}) \in \mathbb{R}^D$$

where D represents the hidden size of the model. Furthermore, at each step t, we define an external embedding matrix, namely, a codebook(Van Den Oord et al., 2017) $E_t \in \mathbb{R}^{K \times D}$, where K is the size of the discrete latent space, which also defines the range of semantic IDs. The discrete latent variable z_t at step t can be obtained by a dot-product lookup against the codebook E_t:

$$Q(z_t = j | z_{<t}, d) = \text{softmax}_j(d_t \cdot E_t^T)$$

where $Q(z_t = j | z_{<t}, d)$ denotes the probability that the semantic IDs for input d at step t is $j \in [K]$. Through this sequential decoding process, the lookup of d_t against the codebook enables vector quantization, thereby generating hierarchical semantic IDs.

2.2 Training Methodology

Our training methodology employs a two-stage approach, comprising domain-adaptive pre-training and a progressive training scheme. The pre-training phase aims to inject e-commerce domain knowledge into the open-source T5 model, thereby enhancing its performance in e-commerce scenarios. The progressive training phase focuses on the generation of semantic IDs, resulting in the final GSID.

2.2.1 Domain-Adaptive Pre-training Scheme

GSID is built upon Mengzi T5(Zhang et al., 2021), a Chinese pre-trained model. While Mengzi T5 encompasses general domain knowledge, it does not

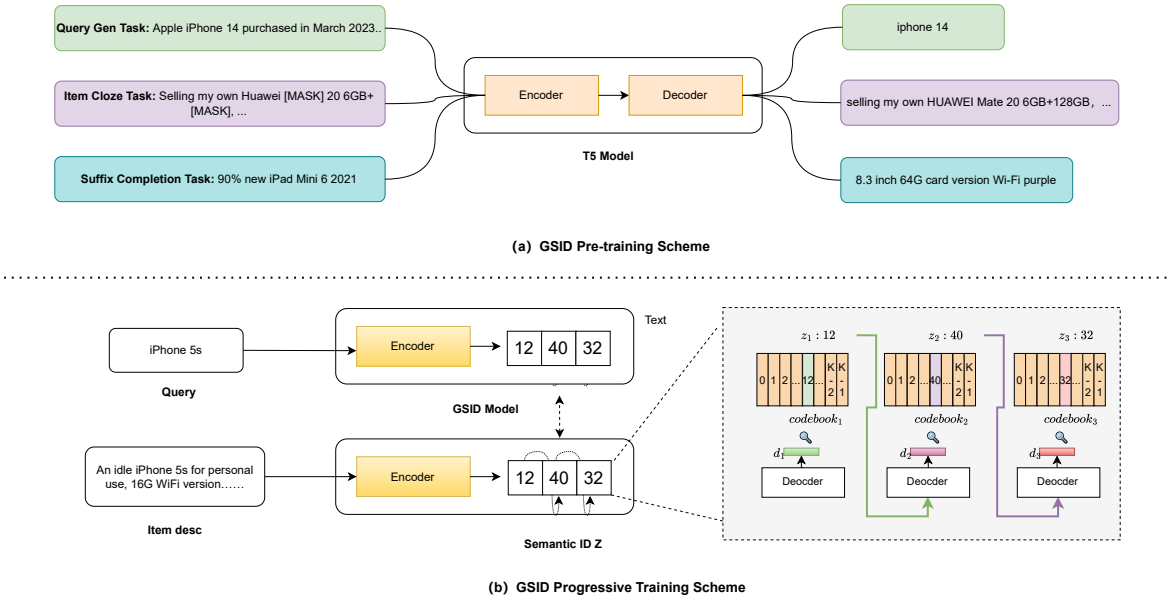

Figure 2: Pipeline of GSID. (a) illustrates the domain-adaptive pre-training scheme. (b) shows the progressive training scheme

align well with the distribution of e-commerce data. Continue pre-training tasks are thus utilized, taking search queries and product descriptions as input, as illustrated in Figure 2(a). Specifically, we design three training tasks with loss as format $\mathcal{L}_{\text{pretrain}} = \mathcal{L}_{\text{query_generation}} + \mathcal{L}_{\text{item_cloze}} + \mathcal{L}_{\text{item_completion}}$. Each of these tasks utilizes a standard negative log-likelihood loss for sequence generation. Formally, for a given task $\mathcal{T}$, the loss is defined as:

$$\mathcal{L}_{\mathcal{T}} = -\sum_{k=1}^{L} \log P(y_k | y_{<k}, \text{Encoder}(\mathbf{x}_{\mathcal{T}}))$$

where $\mathbf{x}_{\mathcal{T}}$ represents the input sequence of task $\mathcal{T}$ fed into the T5 encoder, $y = [y_1, y_2, ..., y_L]$ is the target output sequence generated by the decoder, L is the length of the target sequence. The specific inputs and targets for each task are follows:

Query Generation Task The encoder's input $\mathbf{x}_{\text{QueryGen}}$ is a product description d, and the target sequence y is the corresponding user query q. This task trains the model to understand the semantic intent of a product description.

Item Cloze Task The encoder's input $\mathbf{x}_{\text{ItemCloze}}$ is a masked product description d_{masked}, and the target sequence y is the complete product description d. This task enhances the model's ability to comprehend complete product information, improving its contextual understanding of item details.

Product Suffix Completion Task The encoder's input $\mathbf{x}_{\text{SuffixComp}}$ is a product description prefix d_{prefix}, and the target sequence y is the subsequent content (suffix) of the product description d_{suffix}. This task encourages the model to learn the structural and semantic dependencies within product descriptions, crucial for generating coherent product attributes.

2.2.2 Progressive Training Scheme

To further enable the model to generate hierarchical semantic IDs, we adopt a Progressive Training Scheme, as illustrated in Fig.2(b). The training procedure consists of M steps, corresponding to the M semantic IDs ultimately produced. Furthermore, at each step $T \in [M]$, when training semantic IDs z_T, the previously produced semantic IDs $z_{<T}$ are kept fixed. At each optimization step, we use the gradient descent with respect to the loss $\mathcal{L}_{\text{gsid}} = \mathcal{L}_{\text{align}} + \mathcal{L}_{\text{com}}$. The alignment loss of query and product $\mathcal{L}_{\text{align}}$ and code commitment loss $\mathcal{L}_{\text{com}}$ are shown as follow:

Query-Item Alignment Objective To extract user-intent semantics from product descriptions, we introduce a query-item alignment objective to jointly learn representations for queries and items, as well as their corresponding semantic IDs. Specifically, suppose $\langle q, d \rangle$ is a relevant pair of a query and a product description, we define the alignment objective as:

$$\mathcal{L}_{\text{align}} = -\log \left(\frac{\exp(q_T \cdot d_T)}{\sum_{d^* \sim \mathcal{B}} \exp(q_T \cdot d_T^*)} \right)$$

$$+\sum_{t=1}^{T} D_{KL}\left(P(z_t|z_{<t},q)||P(z_t|z_{<t},d)\right)$$

where the first term is the contrastive learning loss for the $\langle q, d\rangle$ pair, and d^* is an in-batch negative sample from the same training mini-batch $\mathcal{B}$. q_T and d_T denote the representations of the query and item, respectively, at step T. The second term is the KL divergence(Pérez-Cruz, 2008) (by avoiding the use of hard-label cross-entropy loss) between the probability distributions of the query semantic IDs and item semantic IDs, which helps stabilize the training process.

Code Commitment Objective To prevent the model from forgetting the previously generated semantic IDs $z_{<t}$ when predicting the current step's semantic IDs, we introduce the code commitment loss as follows:

$$\mathcal{L}_{\text{com}} = -\sum_{t=1}^{T} \log Q(z_t|z_{<t}, \text{Encoder}(d))$$

For the codebook update, to improve the stability of codebook training, we do not employ the original VQ-VAE(Van Den Oord et al., 2017) codebook training algorithm. Instead, we update the codebook using the Exponential Moving Averages (EMA) method(Klinker, 2011). Given the massive scale of our training data, our codebook employs random initialization instead of the classical constrained K-Means clustering approach(Hartigan and Wong, 1979).

2.2.3 Data Sample Techniques

Effective training within a Progressive Training Scheme heavily relies on robust data sampling. To further enhance model performance, we adopt two key strategies:

Multi-Query Sampling In the e-commerce domain, frequently searched queries are often generic terms. These queries are characterized by an enormous number of individual requests and broad semantic meanings (e.g., "mobile phone", "laptop computer"). In such scenarios, it is highly prone to encountering samples of the same concept within mini-batch, which is detrimental to model training. To address this, we sample multiple positive query examples for each item to mitigate the potential impact of false negative samples.

Progressive Negative Sampling The construction of negative samples is crucial in contrastive learning. Negative samples within a mini-batch are often simple, which the model can easily distinguish, leading to insufficient learning. To increase the difficulty of model training, we adopt a difficulty-increasing adaptive negative sampling method. Specifically, we require that training samples at each step T share the same semantic IDs prefix. Since semantic IDs with the same prefix typically possess similar semantics, negative samples within this range are correspondingly harder for the model, which is more conducive to the model learning fine-grained semantic distinctions.

3 Experimental Setup

3.1 Dataset

We collect search logs of 20 days from Xianyu[1] search platform to build the training dataset with 200 millions samples. To evaluate the effectiveness and generalization of GSID, we conducted a series of experiments on two large-scale real-world datasets collected: Xianyu-Retrieval and Xianyu-Product-Understanding to validate the effectiveness of GSID.

Xianyu-Retrieval Based on Xianyu online click data, we collected query-product pairs (q2i) and product-product pairs (i2i), and ensuring that not share any common pairs with training set. The q2i contain of 30 thousands query triggers and a million product candidates, while the i2i insist of 30 thousands product triggers and 150 thousands product candidates.

Xianyu-Product-Understanding From Xianyu item pool, we sampled a million products with their operationally-annotated CPV information.

3.2 Baselines

To evaluate the superiority of GSID, we selected several strong baselines for comparison, including:

- **BM25(Robertson and Walker, 1994):** a probabilistic model that estimates the probability of a document being relevant to a query, based on the occurrence of query terms in the document.
- **BGE(Xiao et al., 2024)** a dense retrieval model that leverages graph neural networks to learn effective representations for documents and queries.
- **XY-BERT** a bert encoder that trained by masked language modeling, and then fine-tuned with contrastive learning on Xianyu

[1]Xianyu is a C2C e-commerce platform in Alibaba

Methods	Q2I				I2I			
	R@1	R@10	R@100	MRR@100	R@1	R@10	R@100	MRR@100
BM25	22.41	44.52	64.11	29.89	5.92	12.89	19.19	8.24
BGE	25.96	53.07	76.73	35.20	8.37	19.91	32.48	12.23
XY-BERT	26.80	55.92	77.69	36.73	7.05	20.85	33.57	11.82
GSID(ours)	**31.26**	**58.63**	**77.95**	**40.60**	**8.43**	**21.88**	**35.01**	**13.17**

Table 2: Results of query-to-product (q2i) retrieval and product-to-product (i2i) retrieval task.

dataset, which widely used in Xianyu search business.

We conducted two types of experiments using these baselines. For the first type, we compared the retrieval performance of using the final representation output by the GSID decoder against these retrieval baselines. And for the other, we constructed semantic encodings using hierarchical clustering on top of these baseline models, and directly compared them against the GSID approach. As BM25 is a pure text matching method, we excluded it from the second type of experiments.

3.3 Experimental Settings

To evaluate the semantic similarity modeling capability of GSID, we utilize the q2i and i2i retrieval task on the Xianyu-Retrieval dataset with $Recall@k$. And we evaluate the informative and interpretable nature of GSID through alignment with GSID-Query and GSID-Category relationships which we use AMI and code_accuracy as the metric on the Xianyu-Understanding dataset. We will provide detailed descriptions of our experimental setup in the Appendix.

4 Results

4.1 Retrieval Results

In Tab.2, we present the results on the Xianyu-retrieval dataset for the two tasks of query-product retrieval (q2i) and product-product retrieval (i2i), to demonstrate the semantic similarity representation capacity of the embeddings. And GSID outperforms all the baselines on both of these tasks. In particular, for recall, GSID can achieve significant improvements. For example, GSID get R@1 of 31.26% on q2i task, which is **+4.46%** better than the best baseline. This result highlights that the representations conducted by GSID have stronger semantic similarity expression capabilities than the baselines.

Methods	BGE	XY-BERT	GSID(ours)
cate1_AMI	54.80	56.11	**59.20**
cate4_AMI	41.20	45.33	**45.80**
l1_code_acc	34.37	47.50	**89.48**
l2_code_acc	10.24	20.31	**70.19**

Table 3: Results of AMI and code consistency.

4.2 Interpretability

Tab.3 shows the performance comparison between our GSID and other semantic IDs obtained through hierarchical clustering of baseline methods. Cate1_AMI and cate4_AMI represent the AMI between the semantic IDs and the Idle Fish category labels at the first and fourth levels, respectively. GSID achieves a **+3.09%** performance improvement on cate1_AMI and **+0.47%** improvement on cate4_AMI over the best baseline. As for the query-item code consistency, which measures the semantic similarity of GSID, we get 89.48% on l1_code_acc and 70.19% on l2_code_acc, which significantly outperforms other methods. Compared with Tab.2, results of Tab.3 indicate that the final output GSID exhibits superior semantic encoding performance compared to the representations.

4.3 Visualization

To provide a more intuitive visual comparison of the structural properties between GSID and CPV, we utilize concert tickets for the artist Jay Chou as illustrative examples in the Fig.3. The result shows that, in comparison to CPV, GSID exhibits a finer granularity and an architectural design more aligned with user need. Further, the result also shows that CPV may have given different structured information to the same goods due to operational errors, but GSID can give the same semantic ID to goods with the same semantics because it is data-driven.

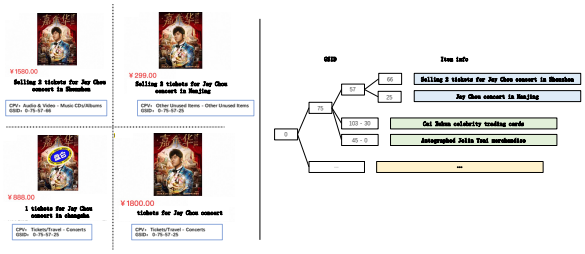

Figure 3: Comparison of CPV and GSID.

5 Online A/B Test

The proposed GSID has been successfully intergrated into key functionalities of the e-commerce platform Xianyu, including generative retrieval and user interest modeling. Furthermore, we achieved quite satisfactory online A/B testing gains.

GSID for generative retrieval consists of several components. For the query side, we restrict the beam search(Brown et al., 1993; Sutskever et al., 2014) to generate multiple candidates, while also collecting statistics on the user clicks on these candidates indexing. At the same time, we select high-conversion products based on the GSID. After that, we can perform query-product matching. In generative retrieval, GSID leads to a 1% increase in GMV and a 0.3% increase in average transactions per user, while satisfying the relevance constraints. This demonstrates the advantages of GSID's consistent encoding of queries and items, as well as the benefits of end-to-end ID-based modeling.

GSID for user interest modeling means that we regard GSID as a kind of feature in CTR model. We used CTR, Clicks, and Bills as metrics to evaluate the online effectiveness. The IU-Boosted model(Wu et al., 2025) demonstrated significant improvements in both interest unit and normal product recommendations. Specifically, for interest unit recommendations, there was an 11.76% increase in CTR, a 10.22% rise in Clicks, and a 5.61% boost in Bills. For normal product recommendations, CTR improved by 3.72% and Clicks by 5.20%. Overall, the model achieved a 2.90% increase in CTR, a 2.62% rise in Clicks, and a 1.02% increase in Bills, highlighting a notable performance enhancement.

6 Related Work

Product structured representation The structured understanding of products is a fundamental problem in the e-commerce domain. Early approaches, such as (Gao et al., 2020), utilized hierarchical category systems to organize products, with deep hierarchical classification often employed for product category prediction. Works like (Li et al., 2023; Zhang et al., 2022; Xu et al., 2023) introduced attribute tree systems, which are typically constructed via data mining techniques to model richer product information. However, the management and maintenance of these attribute trees still heavily rely on manual expert curation, leading to high operational costs in practical e-commerce scenarios. Further advancing product representation, methods like (Luo et al., 2020; Li et al., 2020; Luo et al., 2021; Dong, 2019) leveraged knowledge graphs. These approaches often involve extensive data mining and graph construction efforts to build comprehensive product profiles, which, while significantly enriching the available information, also introduce considerable system complexity.

Discrete representation learning Discrete representation learning is a crucial area in machine learning, especially for efficient data indexing and retrieval. Early works VQ-VAE(Van Den Oord et al., 2017), which learn quantized representations via vector quantization, primarily for images. For discrete identifier generation in information retrieval, methods like DSI(Tay et al., 2022) employ a two-stage process, typically involving clustering over continuous item representations. This two-stage approach, however, suffers from a strong dependency on initial representation quality, and potential information loss due to the disjointed nature of learning and ID generation. To mitigate these issues, RQ-VAE(Lee et al., 2022) integrates hierarchical quantization end-to-end. GenRet(Sun et al., 2023) employs a T5-based seq2seq architecture to generate discrete codes. Its key innovations include step-specific codebooks for rich information preservation and per-step hard negative sampling.

7 Conclusion

In this paper, we proposed a generative semantic indexing framework that establishes a data-driven product understanding paradigm, overcoming the limitations of traditional rule-based systems. This method learns semantic representations directly from raw product data through end-to-end training, eliminating the reliance on manually crafted heuristics. Extensive experiments validate the reliability of the proposed method and provide a scalable application example for industrial use.

8 Limitation

While GSID demonstrates effectiveness in processing textual product profiles, it does not currently leverage multimodal information, such as product images or videos. Multimodal data could provide valuable complementary context for attributes that are challenging to infer from text alone. Incorporating multimodal capabilities may further enhance the model's ability.

Another limitation is that once the GSID structure is fixed, it is difficult to make adjustments, which is not conducive to the update of new products. Therefore, how to periodically update the GSID system is an issue that still needs to be explored.

A Evaluation Metrics

$Recall@k$ is a metric that measures the proportion of expected product retrieved by the search system. For a given k, $Recall@k$ is defined as:

$$Recall@k = \frac{1}{|Q|}\sum_{q=1}^{|Q|}\frac{ret_{q,k}}{rel_q}$$

where $|Q|$ is the number of queries in the set, $ret_{q,k}$ is the number of expected products retrieved for the q-th query within the top k results, and rel_q is the total number of expected documents for q-th query.

Query-item consistency rate is used to evaluate the alignment between query and item semantic IDs. Similar with Recall@k, we propose l1_code_acc and l2_code_acc to show the proportion of queries and their retrieved products that share identical primary and secondary IDs. We randomly sampled 150,000 query-item pairs from the q-i dataset to examine whether their GSID distributions are identical. Specifically, l1_code_acc indicates the proportion where Level-1 semantic IDs match and l2_code_acc indicates the proportion where both Level-1 and Level-2 semantic IDs are fully consistent;

Mean Reciprocal Rank ($MRR@k$) measures the rank of the correct product category within the top k ranked predictions. For a given k, MRR@k is defined as:

$$MRR@k = \frac{1}{|Q|}\sum_{i=1}^{|Q|}\frac{1}{rank_i}$$

where $|Q|$ is the number of queries in the set, $rank_i$ is the rank for i-th item.

Adjusted Mutual Information (AMI) measures the agreement between the predicted product categories and the ground-truth labels, while accounting for the expected level of agreement due to chance. AMI can be defined as:

$$AMI = \frac{MI(U,V) - E\{MI(U,V)\}}{F(H(U),H(V)) - E\{MI(U,V)\}}$$

where $MI(U,V)$ is the Mutual Information of distribution U and V, $H(\cdot)$ is the information entropy, E is the expectation and $F(\cdot)$ means a function which we use $max(\cdot)$ in this paper. Furthermore, we use the cate1_AMI and cate4_AMI to measure the matching extent between category in CPV with the semantic IDs.

As mentioned before, there are two different experiments to demonstrate the effectiveness of GSID. For the first type of experiment, we selected $recall@\{1, 10, 100\}$ and $MRR@100$ to evaluate

the retrieval performance of the representations, following previous works(Sun et al., 2023). As for the second type, we choose the category Adjusted Multual Information (AMI)(Vinh et al., 2009) to show the interpretability of GSID compared to the baselines. We use $Recall@\{1, 10, 100\}$ and Mean Reciprocal Rank (MRR)@100 as evaluation metrics to evaluate the retrieval performance. And we use query-item and item-item ID consistency as the encoding accuracy. We also prove the effectiveness of encoding interpretability with category Adjusted Mutual Information (AMI) and SPU purity within a cluster.

B Implementation Details

Dataset Description

Query-Item Dataset (200 million samples): Constructed based on user interactions with items under different queries, including transaction, interaction, and click behaviors along with their frequencies. Each item corresponds to multiple queries. Item-Item Dataset (78 billion samples): Obtained by calculating swing I2I from 30-day user click sequences. 1.5 billion samples are extracted from this dataset to form the evaluation set.

Domain-Adaptive Pretraining Phase

We first train the mengzi_t5 base model using 32 A800 GPUs on the 200-million-sample query-item dataset for 2 epochs. And then we utilize 32 A800 GPUs and approximately 200 million query-item samples. Task types include: Query Generation Task: Input item information, the model must generate its associated query. During training, one query is randomly selected from the multiple queries co-occurring with the item as the label. Item Cloze Task: Randomly masks 1-3 cloze spans within the item description text, each span being 1-3 characters long. The model predicts the masked content. Product Suffix Completion Task: Randomly splits the item description text into a prefix and a suffix. Input is a random product query and the item prefix, requiring the model to generate and complete the suffix. Within each batch, the three tasks are randomly assigned in a 1:1:1 ratio and identified by special string tokens.

GSID Training Phase

Building upon the fully pre-trained mengzi_t5 base model, training proceeds incrementally across 4 steps, with each step corresponding to a codebook size of 128. For any given step, samples within a batch are formed by concatenating several sample groups sharing identical prefix codes. Samples within a group represent hard (difficulty-increasing) samples, while samples across groups represent easy samples. We perform a gather operation across different GPUs to compute the contrastive loss. Prior to the main training within each step, an initial phase of n batches is dedicated solely to contrastive loss training. During this phase, only the contrastive loss is used to update the model, aiming to achieve a reasonable spatial distribution of query-item vectors. Subsequently, we further optimize the Query-Item Alignment Objective and Code Commitment Objective. The entire GSID training utilizes 32 A800 GPUs and approximately 200 million query-item samples. Each step is trained for only 1 epoch.

Learning from LLM Agents: In-Context Generative Models for Text Casing in E-Commerce Ads

Yingxue Zhou, Tan Zhu, Tao Zeng, Zigeng Wang, Wei Shen,

Walmart Global Technology, Sunnyvale, USA
{yingxue.zhou, tan.zhu, tao.zeng, zigeng.wang0, wei.sheng}@walmart.com

Abstract

E-commerce ad platforms enforce content policies and review created ads before publication, with casing requirements playing a critical role in maintaining readability and brand consistency. Existing NER-based transformer models have been widely used for casing correction, but they process characters independently in a classification-based manner, failing to capture sentence level contextual dependencies, making them less reliable when handling unseen or ad-specific terms, e.g., brand names. LLMs like ChatGPT offer better generalization to proper nouns, but they are expensive and have high latency. Besides, generative model can suffer from hallucination. To address these challenges, we propose a two-stage approach: (1) an LLM-based Agent leveraging Chain-of-Actions (CoA) to enforce casing policies while accurately handling ads-specific terms, such as brand names, and (2) a lightweight generative model that preserves the LLM Agent's knowledge while significantly reducing latency and costs. We design a novel in-context decoding strategy, which avoids hallucinations. Our approach outperforms NER-based methods and achieves near-LLM Agent performance, making it a scalable and efficient solution for real-world ad compliance automation.

1 Introduction

E-commerce advertising platforms, such as Amazon, Target and Walmart, enforce various content policies to ensure consistency, readability, and compliance with platform standards for publishing ads. One such policy is sentence casing for text content, including headlines and calls to action (CTAs) (see Figure 1). Sentence casing requires capitalizing only the first letter of a sentence while preserving proper nouns and specific terms, such as brand names. To enforce this policy, ad platforms review content submitted by ad creators. For example, an ad creator might submit the headline "Nourish Your Hair", which needs to be modified to *"Nourish your hair"*. Similarly, "Buy your gift with lego" should be rewritten as *"Buy your gift with Lego"*, as *"Lego"* is the brand name. However, enforcing sentence casing is challenging due to variations in brand names, domain-specific terms, and context-dependent capitalization rules. Manual review is expensive, time-consuming, and unscalable, making automated solutions essential for ensuring accuracy and efficiency.

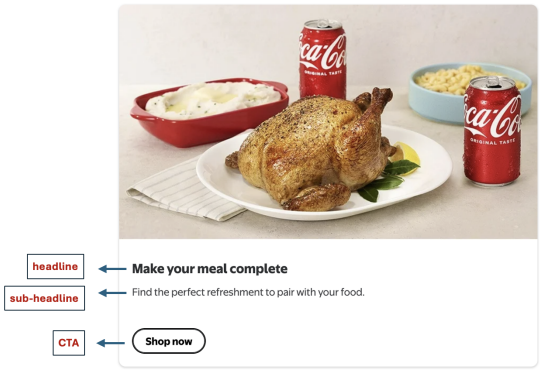

Figure 1: Example of an e-commerce ad which contains text in multiple sections, including the headline, subheadline, and call-to-action (CTA), along with an accompanying ad image.

Existing solutions, such as statistical language models (Pauls and Klein, 2011; Lita et al., 2003; Mikheev, 1999), have limited capacity, failing to capture context and semantic meaning. Named Entity Recognition (NER)-based transformer models (Priya et al., 2024; Singhal et al., 2021; Devlin et al., 2019; Liu et al., 2019; Conneau et al., 2020), which are primarily encoder-only architectures, tag tokens or characters sequentially, treating sentence casing as a classification problem. These models are typically trained on public datasets designed for general sentence casing correction and sentence splitting. While effective in general contexts, those approaches lack learning capacity and struggle to

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1122–1133

generalize to unseen or specialized entities. Given these limitations, we reformulate the sentence casing problem as a generation task, enabling the model to produce well-structured, sentence-cased text while handling ad-specific domain terms, such as brand and product names. While commercial LLMs, such as ChatGPT (Ouyang et al., 2022; Achiam et al., 2023), offer better generalization, they are expensive, have high latency. Additionally, as generative models, they suffer from hallucination, occasionally generating entities not present in the original content, limiting their reliability.

To overcome these limitations, we propose a two-stage approach. First, we introduce an LLM-based sentence casing agent built on a Chain-of-Actions (CoA) framework, which decomposes the task of sentence casing into a sequence of sub-tasks (Yao et al., 2023b; Wei et al., 2022; Pan et al., 2025) to enhance awareness of domain-specific terms in advertising. Given the text content of an ad, the LLM CoA agent first identifies special terms, i.e., brand names, verifies their correct casing against a predefined reference library, and then generates sentence-cased text accordingly. In the second stage, we distill knowledge from the LLM CoA agent into a lightweight generative model (Vaswani et al., 2017; Raffel et al., 2020), significantly reducing latency and computational costs while preserving the agent's domain-specific knowledge. Since the goal is to correct casing without rewriting or hallucinating new entities, we design an in-context decoding method that constrains the model to generate only characters present in the original input—allowing only casing changes. We conduct various experiments on both public datasets and real-world ad data, demonstrating that the proposed approach outperforms traditional NER-based methods—achieving near-LLM performance while remaining scalable and cost-effective for real-world ad text casing compliance automation.

2 Related Work

Text Casing Methods Truecasing is the task of restoring proper capitalization in text, has been widely studied in natural language processing. Early approaches primarily rely on statistical methods, such as n-gram language models (Pauls and Klein, 2011) trained on large corpora to predict the most likely casing for each token based on its context (Lita et al., 2003; Mikheev, 1999). Later, sequence labeling models, such as Conditional Random Fields (CRFs) (Lafferty et al., 2001; Mayhew et al., 2020) and transformer-based models such as BERT (Priya et al., 2024), NER-based models (Singhal et al., 2021) are introduced treating truecasing as a classification task where each token is assigned a casing label. However, these models lack contextual awareness at the sequence level and struggle with unseen or domain-specific terms, such as brand names. Generative models, particularly unified sequence to sequence architectures like T5 (Raffel et al., 2020; Vaswani et al., 2017) and large language models such as ChatGPT (Ouyang et al., 2022; Achiam et al., 2023), have demonstrated superior performance in learning sentence-level dependencies and allowing for more flexible corrections. But they may still suffer from hallucinations and inconsistencies.

LLM Agent Recent advances in LLM agents leverage structured reasoning and tool use to improve task performance and interpretability. Chain-of-Thought (CoT) prompting (Wei et al., 2022) improves multi-step reasoning by generating intermediate steps, while ReAct (Yao et al., 2023b) extends this by interleaving reasoning and actions, enabling LLMs to interact with tools and environments. Follow-up works such as Toolformer (Schick et al., 2023), AutoGPT, and LangChain have explored self-instructed tool use and modular agent design. Tree-of-Thoughts (Yao et al., 2023a) and Graph of Thoughts (Besta et al., 2024) further expand reasoning through structured exploration. Other efforts like Plan-and-Solve (Wang et al., 2023) and CAMEL (Li et al., 2023) introduce planning and multi-agent collaboration for complex tasks. Building on these developments, we propose a simplified Chain-of-Actions (CoA) framework tailored for sentence casing correction. Unlike prior work that relies on complex reasoning, our CoA defines a standard, interpretable sequence of steps (e.g., identify, verify, generate) specific to the task, enabling effective knowledge distillation into a compact generative model.

3 Approaches

We formulate sentence casing correction as a generation task, where the model takes raw ad text submitted by ad creators as input and produces a properly cased output, ensuring compliance with platform policies while preserving domain-specific terms. For example, given the input "Buy gift with lego", the expected output is "Buy gift with Lego",

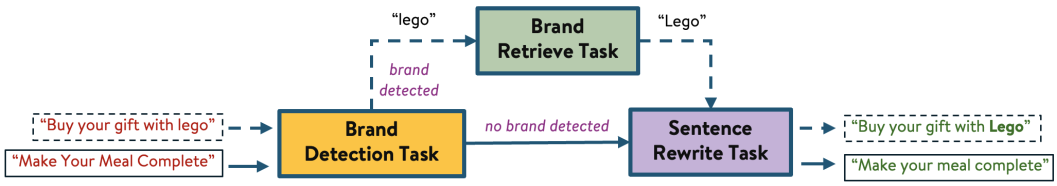

Figure 2: Illustration of the LLM CoA Agent framework. Given an input sentence (e.g., "Buy your gift with lego"), the agent first detects potential brand names. If a brand is identified, it retrieves the correct form from a brand hub library (e.g., "lego" → "Lego") and passes it to the Sentence Rewrite Task to generate sentence-cased text (dashed line). If no brand is detected, the agent directly trigger the Sentence Rewrite Task (solid line).

where "Lego" is correctly capitalized as a brand name. To achieve this, we propose a two-stage approach: first, we develop an LLM Agent specifically designed to generate sentence-cased text for ads content, and second, we train a lightweight seq2seq generation model that preserves the LLM Agent's knowledge while utilizing an in-context decoding method to avoid hallucinations.

LLM CoA Agent In the first stage, preliminary experiments with commercial LLMs such as GPT-4o (Ouyang et al., 2022; Achiam et al., 2023) demonstrated that while these models perform well in general cases, they often fail with brand names that are not popular or not always present in their training data. To address this limitation, we introduce an LLM Chain-of-Actions (CoA) Agent framework, explicitly designed to enforce brand name correctness in sentence casing [1]. In the LLM Agent CoA method, given an ad's text content, the agent first identifies potential special terms, such as brand names. If a brand name is detected, the agent queries a Brand Hub Library—a structured repository containing a comprehensive set of brand names sponsored by the advertising platform—to retrieve the correct spelling and capitalization. The retrieved brand name is then incorporated into the LLM prompt [2], ensuring that the model correctly applies brand name casing while adhering to sentence casing conventions (see example in Figure 2). This CoA approach effectively addresses LLM limitations in handling unseen entities. In the next stage, we distill knowledge from this LLM CoA Agent to train a lightweight generative model.

Distilled Generative Model In the second stage, we utilize a sequence-to-sequence (Seq2Seq) generation model (Vaswani et al., 2017) to learn and distill the knowledge from the LLM CoA Agent. Specifically we leverage the T5 model structure (Raffel et al., 2020). The model architecture follows an encoder-decoder structure (Figure 3), where the encoder processes the raw ad text input, and the decoder generates the sentence-cased output autoregressively. Since T5 was not originally designed for sentence casing correction, we adapt it to the sentence casing domain through a two-phrase training process.

In the first phrase, we pretrain the model on publicly available data to develop general sentence casing capabilities. We collect English news data from the News Crawl WMT corpus, which typically adheres to sentence casing rules, and augment it by randomly altering the casing to create a set of input–target sentence pairs $M = \{(\mathbf{x}, \mathbf{y})\}$, where $\mathbf{y}$ is the properly cased target sentence, and $\mathbf{x}$ is a modified version with incorrect casing. An example pair is: $\mathbf{x}$ = "Welcome to My HOME" and $\mathbf{y}$ = "Welcome to my home". This augmentation allows the model to learn sentence casing correction as a text-to-text transformation task. The ultimate goal of the sentence case generation problem is to learn a probability distribution $\mathcal{P}_\theta(\cdot|\mathbf{x})$ over the variable-length text sequence $\mathbf{x}$, where θ is the parameter of the T5. Typically, the maximum likelihood estimation (MLE) objective is used to train the language model. Given finite training examples, i.e., $|M|$ pairs of $(\mathbf{x}, \mathbf{y})$ the model is trained by minimizing the empirical finite sample loss function:

$$\mathcal{L}_\theta(M) = -\frac{1}{|M|} \sum_{(\mathbf{x},\mathbf{y})\in M} \log \mathcal{P}_\theta(\mathbf{y}|\mathbf{x}) \quad (1)$$

Let θ_P denote the model trained in the first stage. In the second phase, we fine-tune θ_P on *ad-specific content* to capture domain-specific knowledge from the LLM CoA Agent. We collect a set of raw ad texts $\{\mathbf{x}_a\}$ from ads submitted in the most recent three months, covering headlines, subheadlines, and CTAs. The LLM CoA Agent is then used to generate sentence-cased

[1] Details of CoA can be found in Appendix A.
[2] Prompt examples can be found in Appendix D.

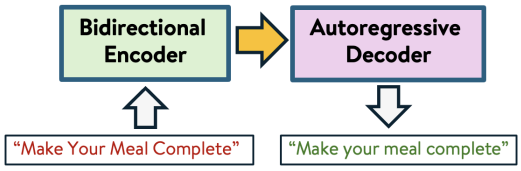

Figure 3: Illustration of the Seq2seq model architect for the sentence casing generation.

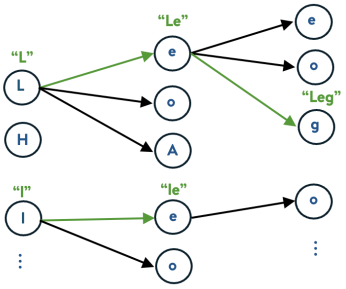

Figure 4: Illustration of the trie structure and the candidate token set during decoding for the phrase "Buy your gift with", where the next character is "l" or "L" from the input word "lego". After searching the trie, the constrained candidate set is ["L", "l", "le", "Le", "Leg"], i.e., marked in green in the trie.

ground truth label, resulting in a set of sentence pairs $N = \{\mathbf{x}_a, \mathbf{y}_a\}$, where $\mathbf{y}_a = \mathcal{A}(\mathbf{x}_a)$ and $\mathcal{A}$ denotes the LLM CoA Agent. An example pair is: $\mathbf{x}_a$ = "Make Your Meal Complete" and $\mathbf{y}$ = "Make your meal complete". Then we use this dataset further fine-tune the T5 model, ensuring it adapts to ad-domain content while retaining the LLM CoA Agent's knowledge. Formally, the model θ_P is further fine-tuned by minimizing the empirical finite-sample objective loss function defined on the ads dataset N:

$$\mathcal{L}_\theta(N) = -\frac{1}{|N|} \sum_{(\mathbf{x}_a, \mathbf{y}_a) \in N} \log \mathcal{P}_\theta(\mathbf{y}_a | \mathbf{x}_a) \ . \quad (2)$$

Once the model is fine-tuned, we design an in-context constrained decoding method during inference to prevent hallucination and ensure the generated text strictly adheres to the original content, allowing only casing modifications.

In-context Decoding The in-context decoding method is a constrained decoding algorithm (pesudocode in Appendix B) designed for character-level casing correction, where the model is restricted to generating tokens that follow the original input text sequence, allowing only casing changes. To achieve this, we construct a prefix trie $\mathcal{T}$ over the model's token vocabulary $\mathcal{V}$, where each node represents a character and each path corresponds to a wordpiece (subword token).

At each decoding step, given a generated prefix p, we get the remaining ungenerated portion of the input text $u = \mathbf{x}[|p| :]$. We then perform depth-first search (DFS) over the trie $\mathcal{T}$ to collect candidate token set C that satisfy the constraint

$$C = \{c \in \mathcal{V} \,|\, \text{lower}(c) = \text{lower}(u[: |c|])\} \ . \quad (3)$$

Figure 4 illustrates the trie structure and candidate selection process. For example, given input $\mathbf{x}$ = `"Buy your gift with lego"` and already generated prefix p = `"Buy your gift"`, the remaining text u = `"lego"` yields candidate set C = `["L", "l", "le", "Le", "Leg"]`, which match substrings of the ungenerated segment. ia DFS over $\mathcal{T}$. Then beam search is applied over this dynamically generated candidate set rather than the full vocabulary, ensuring that the output preserves the original character sequence while allowing casing modification only.

4 Experiments

We evaluate our proposed approach on both public datasets and real-world e-commerce ad data, comparing it against multiple baselines. We conduct two sets of experiments: (1) evaluating the performance of various LLMs with different model sizes—specifically GPT-4o, GPT-4, Llama-2-13b-chat, and Llama-2-70b-chat, and comparing LLM-only with the LLM CoA Agent [3]; (2) comparing the LLM CoA Agent with the distilled lightweight model in terms of accuracy, latency and cost.

4.1 Experimental Setup

Datasets We use two datasets in our experiments: public news data and real-world e-commerce ad data. For the public dataset, we extract approximately 3 million sentence-cased examples from the News Crawl WMT corpus and apply randomized augmentation to generate training pairs, each consisting of an input sentence and a target sentence. Each pair is labeled as either positive or negative: a positive sample indicates that the input is not

[3] We choose the GPT and LLaMA series due to resource and access limitations.

Dataset	Type	Size	Augmented	Pos/Neg
Public News	Train	6M	Yes	50% / 50%
	Evaluation	4k	Yes	50% / 50%
Real Ads	Train	22k	Yes	50% / 50%
	Evaluation	1k	No	15% / 85%

Table 1: Dataset Statistics

in sentence case and requires correction[4], while a negative sample indicates that the input already conforms to sentence casing and matches the target[5]. To study the impact of both sample types, we construct a balanced training set of 6 million pairs (50% positive, 50% negative). For the ads dataset, we collect approximately 3,500 ads from historical ad platform data, resulting in 7,700 text samples (headlines, sub-headlines, CTAs). The LLM CoA Agent is used to annotate these samples with sentence-cased labels. After augmentation, we generate 22,000 training pairs, also with a balanced 50% positive and 50% negative distribution. Both datasets are split temporally, using older samples for training and newer samples for evaluation. For the ads evaluation set, to ensure valid evaluation, we use human annotators to provide the ground truth labels. This evaluation set preserves the natural distribution of the data, with no augmentation applied, and consists of 15% positive and 85% negative samples. Table 1 summarizes the statistics of the training and evaluation datasets, including the distribution of positive and negative samples.

Model Setup and Baselines We first set up the LLM CoA Agent as described in Section 3. Then, we train the lightweight model in two stages. We choose Flan-T5-Small for efficiency, excluding mid-sized models like Flan-T5-Large and LLaMA-3B due to latency and cost constraints in real-time ad systems. In the first stage, we train Flan-T5-Small on the public news training data to adapt the model to the general sentence casing domain. To study the impact of positive and negative samples, we train two variants: **T5-News-PN**, trained on 6M sentence pairs with a 50%/50% **p**ositive/**n**egative split, and **T5-News-P**, trained on 3M **p**ositive-only examples. In the second stage, we fine-tune the T5-News-PN model on the augmented 22k ads training set, where targets are labeled by the LLM CoA Agent with a balanced 50%/50% positive/negative distribution. This fine-tuned model, named **Distil-Ads-PN**, enables adaptation to real-world ad content and brand-specific terms. For ablation, we also fine-tune T5-News-P on 11k positive-only ads data, resulting in the model **Distil-Ads-P**, to analyze the effect of training with only positive samples. We consider the following baselines and proposed models.

- **NER baselines**: XLM-Roberta fine-tuned for Truecasing (Conneau et al., 2020).
- **GEC baselines**: GEC (grammar error correction) models fine-tuned from Gemma (Gemma Team et al., 2025) and Qwen models (Yang et al., 2025) such as GRMR-V3-G4B and GRMR-V3-Q1.7B.
- **LLM baselines**: GPT-4o, GPT-4, Llama-2-13b-chat, and Llama-2-70b-chat.

Table 4: Comparison of the CoA Agent and distilled models on the Real Ads dataset. Distil-Ads-PN-ICD outperforms GPT-4o, achieves performance close to the CoA Agent, with significantly reduced latency and cost.

- **CoA Agent**: CoA Agent as described in Section 3, with GPT-4o as the LLM backbone.
- **Distilled Models**: Distil-Ads-PN, Distil-Ads-P and Distil-Ads-PN-ICD (Distil-Ads-PN with in-context decoding).

Evaluation Metrics To assess the effectiveness of our approach, we evaluate the model's ability to correctly generate sentence-cased text using a set of diverse metrics. Since the evaluation data is imbalanced—we consider metrics that capture both correction accuracy and error sensitivity. *False Trigger Rate* (FTR) measures the proportion of negative samples (sentences already in correct sentence casing) where the model unnecessarily modifies the text. *Precision* is the percentage of modified samples where the generated sentence correctly matches the target label. *Recall* reflects the percentage of samples requiring correction for which the model produces the correct output. Finally, the *F1* score, computed as the harmonic mean of Precision and Recall, provides a balanced summary of the model's performance.

4.2 Experiment Results

The first set of experiments evaluates the performance of different LLMs, the LLM CoA Agent, and the NER model on the Public News and Real Ads datasets (Table 2). Among LLMs, the GPT-4 series outperforms LLaMA-2, particularly in instruction following and output control, with GPT-4o offering the best cost-performance balance. GPT-4 models also significantly outperform the NER model, which struggles with character-level casing errors, e.g., FDA → Fda (example in the Appendix). However, GPT-4 models still struggle with brand names, especially uncommon terms. For instance, GPT-4o fails to correct "babe" to Babe" which is a brand in the example "Bathtime routines from babe" (Example 1, Table 5). In contrast, the LLM CoA Agent (and the distilled model Distil-Ads-PN), which integrate brand detection and retrieval, correctly capitalize brand names. GEC models underperform as they are designed for grammar correction rather than sentence casing, leading to errors with title case, brand names, and unnecessary rewrites (e.g., failing to rewrite "Elevate Your Routine Today," which remains in title case). As a result, the CoA Agent achieves the best performance across all evaluation metrics.

Methods	Brand	Output
Example 1: Input is "Bathtime routines from babe"		
LLM CoA	"Babe"	Bathtime routines from Babe ✓
GPT-4o	NA	Bathtime routines from **babe** ✗
Distil-Ads-PN	NA	Bathtime routines from Babe ✓
NER	NA	Bathtime routines from **babe** ✗
Example 2: Input is "Try our Tea Floater recipe"		
LLM CoA	None	Try our tea floater recipe ✓
GPT-4o	NA	Try our tea floater recipe ✓
Distil-Ads-PN	NA	Try our tea **flosser** recipe ✗
Distil-Ads-PN-ICD	NA	Try our tea floater recipe ✓

Table 5: Ads example of different models on detecting and correcting brand names in sentence casing.

The second set of experiments evaluates the performance of the lightweight model. Table 3 reports results on the Public News dataset under different training strategies, showing that training with both positive and negative samples outperforms training with positive-only data. Incorporating negative samples helps reduce the false trigger rate and improve precision, leading to overall better performance. Distil-Ads-PN achieves competitive results on public news data, indicating it does not suffer from catastrophic forgetting. Table 4 further shows that both Distil-Ads-PN and Distil-Ads-PN-ICD outperform GPT-4o, while significantly reducing cost and latency [6], demonstrating the efficiency of the proposed two-stage approach. Although Distil-Ads-PN-ICD incurs slightly higher latency and cost due to in-context decoding, it offers improved reliability by preventing hallucination. Example 2

[6]Latency is measured on NVIDIA A100 GPUs (batch size 256), and cost is estimated based on GPU host pricing.

in Table 5 illustrates that in-context decoding effectively preserves brand-specific terms, enhancing correctness in domain-sensitive generation.

5 Conclusion

In this work, we present a two-stage approach for casing correction in e-commerce ad content, addressing challenges related to brand name and domain-specific terms. We first introduce an LLM-based Chain-of-Actions (CoA) Agent that incorporates brand detection and retrieval to guide sentence generation. To reduce latency and cost, we distill the CoA Agent's knowledge into a lightweight generative model with constrained decoding to prevent hallucination. Experiments on public and real-world ad datasets show that our approach outperforms traditional NER models and achieves near-LLM performance at a fraction of the cost, offering a scalable, efficient solution for ad text casing.

Limitations

While our two-stage approach achieves strong performance with reduced latency and cost, it has several limitations. First, the system assumes the availability of an accurate brand name list for retrieval; incomplete or outdated brand data may affect casing quality. Second, the lightweight student model may underperform in handling rare linguistic patterns or ambiguous casing contexts compared to larger LLMs. Lastly, our evaluation focuses on English-language ads; adapting the system to multilingual content or languages with different casing rules requires further investigation.

A LLM Chain-of-Action (CoA) Agent

In the first stage, we explore commercial LLMs such as GPT-4o (Ouyang et al., 2022; Achiam et al., 2023), and preliminary experiments demonstrate that while these models perform well on common sentence casing tasks, they often fail to correctly handle brand names that are rare, newly introduced, or not well represented in their training data. This limitation is critical in the e-commerce advertising domain, where accurate brand representation is essential for compliance and trust. To overcome this, we introduce a Chain-of-Actions (CoA) Agent framework, explicitly designed to ensure brand name correctness in sentence casing tasks.

Algorithm 1 gives pesudo code of the LLM Agent framework. In the LLM Agent CoA method, given an ad's text content $\mathbf{x}$, e.g., $\mathbf{x}$ = `"Buy your gift with lego"`, the agent first identifies potential brand names within the input using a Brand Detection LLM:

$$B = \text{DetectBrands}(\mathbf{x}), \quad B \subseteq \mathbf{x} \tag{4}$$

where B denotes the list of entities in $\mathbf{x}$ that are likely to be brand mentions, e.g., B = [`"lego"`] for input $\mathbf{x}$ = `"Buy your gift with lego"`. In practice, since ad text typically contains at most one brand name, the size of B is usually either one or zero when no brand is mentioned in the input.

If brand names are detected, each candidate $b \in B$ is queried against a structured Brand Hub Library, which serves as a mapping from surface forms to their canonical brand spellings and capitalizations. Then a list of corrected brand name is retrieved:

$$B_{\text{correct}} = \text{BrandRetrieve}(B)\ . \tag{5}$$

This produces a set of verified brand names B_{correct}, which is then incorporated into the prompt of sentence case rewrite process. For example, given B = ["lego"], B_{correct} is expected to be B_{correct} = ["Lego"] (see example in Figure 2). The model prompt P is constructed conditionally as:

$$P(\mathbf{x}, B_{\text{correct}}) = \begin{cases} \text{ConstructPrompt}(\mathbf{x}, B_{\text{correct}}), & \text{if } B \neq \emptyset \\ \text{ConstructPrompt}(\mathbf{x}), & \text{otherwise} \end{cases} \tag{6}$$

The prompt constructed functions for different tasks and LLMs are given in Appendix D. The constructed prompt P is then passed to the Sentence Rewrite LLM, which generates the sentence-cased output:

$$\mathbf{y} = \text{SentenceRewrite}(P)\ . \tag{7}$$

Algorithm 1 LLM CoA Agent for Sentence Casing

Input: Raw ad text $\mathbf{x}$
Output: Sentence-cased ad text $\mathbf{y}$
$B \leftarrow$ BRANDDETECTION($\mathbf{x}$)
if $B \neq \emptyset$ **then**
    $B_{\text{correct}} \leftarrow$ BRANDRETRIEVE(B)
    $P \leftarrow$ CONSTRUCTPROMPT($\mathbf{x}, B_{\text{correct}}$)
else
    $P \leftarrow$ CONSTRUCTPROMPT($\mathbf{x}$)
end if
$\mathbf{y} \leftarrow$ SENTENCEREWRITE(P)
return $\mathbf{y}$

This Chain-of-Actions (CoA) approach effectively addresses the limitations of LLMs in handling unseen or domain-specific entities. Once the CoA Agent is established, we evaluate its performance on a real-world ads dataset, incorporating human feedback to assess compliance with sentence casing policies. After the CoA Agent consistently meets the expected performance threshold, we treat it as a teacher model and distill its knowledge into a lightweight generative model. Note that the distilled model is intentionally kept small to satisfy the latency requirements of real-time inference and to control computational cost in large-scale production deployments.

B In-context Decoding Algorithms

The in-context decoding method is a constrained generation technique designed for character-level casing correction, where the model is restricted to generating tokens that follow the original input text sequence, allowing only casing changes. To achieve this, at each decoding step , we perform a depth-first search (DFS) over a vocabulary token trie (Algorithm 3) to identify valid candidate tokens—i.e., subword units that match the remaining ungenerated portion of the input text, regardless of casing. For instance, given the input `"Buy your gift with lego"` and generated prefix `"Buy your gift "`, the ungenerated part `"lego"` yields candidates like `["L", "l", "le", "Le", "Leg"]`. Then, beam search operates over this constrained candidate set instead of the full vocabulary, ensuring the output matches the original text content while allowing only casing modifications. Figure 4 illustrates the trie structure and candidate selection process. Below we present the details of the in-context decoding algorithm (Alorithm 2).

Algorithm 2 In-Context Constrained Decoding with Trie

Input: Input text $\mathbf{x}$, token vocabulary $\mathcal{V}$, vocabulary trie $\mathcal{T}$, model θ
Output: Generated output $\mathbf{y}$ (sentence-cased)
$p \leftarrow$ ""
while p is not the full length of $\mathbf{x}$ **do**
    $u \leftarrow \mathbf{x}[|p| :]$
    $C \leftarrow \text{DFS_T}(\mathcal{T}, u, \mathcal{V})$
    $t \leftarrow \arg\max_{c \in C} \mathcal{P}_\theta(c|p)$
    $p \leftarrow p + t$
end while
return p as final output $\mathbf{y}$

Specifically, we construct a prefix trie $\mathcal{T}$ over the model's token vocabulary $\mathcal{V}$, where each node represents a character and each path corresponds to a wordpiece (subword token). The algorithm 2 provides a complete overview of the decoding procedure.

At each decoding step, given a generated prefix p, we get the remaining ungenerated portion of the input text u:

$$u = \mathbf{x}[|p| :] \,. \tag{8}$$

We then perform **DFS_T** (Algorithm 3), i.e., depth-first search (DFS) over the trie $\mathcal{T}$ to collect candidate token set C that satisfy the constraint:

$$C = \{c \in \mathcal{V} \,|\, \text{lower}(c) = \text{lower}(u[: |c|])\} \,, \tag{9}$$

In other words, a token is valid if its case-insensitively character sequence matches the start of the remaining input substring u, preserving content while allowing casing variation. For example, given input $\mathbf{x}$ = `"Buy your gift with lego"` and prefix p = `"Buy your gift"`, the remaining text u = `"lego"` yields candidate set C = `["L", "l", "le", "Le", "Leg"]` via DFS over $\mathcal{T}$.

Then we select the token with highest likelihood from the constrained candidate set C rather than the full vocabulary. Formally, the next token is chosen as:

$$t = \arg\max_{c \in C} \mathcal{P}_\theta(c|p), \tag{10}$$

where $\mathcal{P}_\theta(\cdot|p)$ indicates the probability distribution over candidate tokens given the prefix p, as produced by the model trained in Section 3. Then prefix is updated $p \leftarrow p + t$ and decoding proceeds until the full length of $\mathbf{x}$ is generated. This

Algorithm 3 DFS_T: Depth-First Search over Trie to collect valid token candidates

Input: Trie $\mathcal{T}$, remaining string u, vocabulary $\mathcal{V}$
Output: Candidate token set C
$C \leftarrow \emptyset$
function DFS($\mathcal{T}$, prefix)
    if lower(prefix) = lower(u[: |prefix|]) and prefix $\in \mathcal{V}$ **then**
        $C \leftarrow C \cup \{\text{prefix}\}$
    end if
    for all child character node ℓ of $\mathcal{T}$ **do**
        if lower(ℓ) matches next char in u **then**
            $\mathcal{T}_\ell \leftarrow$ subtree of $\mathcal{T}$ rooted at ℓ
            DFS($\mathcal{T}_\ell$, prefix + ℓ)
        end if
    end for
end function
DFS($\mathcal{T}$, "")
return C

method ensures that the output text strictly adheres to the original character sequence, allowing only casing transformations and preventing hallucinations. This in-context constrained decoding algorithm can be applied to any autoregressive generative model. It functions as a lightweight plug-in during inference and requires no additional training or model modification.

C Additional Results

Table 6 compares the latency and projected cost per sample for each method. The CoA Agent has the highest latency (1.7315s) and cost ($0.000145), as it involves two stages—brand detection (0.6559s) and sentence rewrite (1.0756s)—each contributing to both time and cost. The GPT-4o model, which performs only the rewrite step, shows reduced total latency (1.0756s) and cost ($0.000082), but still requires significantly more resources compared to distilled models.

In contrast, Distil-Ads-PN-ICD and Distil-Ads-PN, our lightweight generative models, achieve sub-second latency and very low cost. Distil-Ads-PN-ICD incurs a slightly higher latency (0.0042s) and cost ($0.000003) than Distil-Ads-PN (0.0036s, $0.000002) due to in-context decoding, but still remains orders of magnitude more efficient than LLM-based approaches. These results demonstrate the computational efficiency of our proposed distilled models, making them highly suitable for real-

time, large-scale deployment.

Table 7 presents a qualitative comparison of different models on a sentence containing a known acronym, FDA. While all methods receive the same input ("Easy set-up & FDA-registered"), their output quality varies. The LLM CoA and GPT-4o models correctly preserve the casing of FDA, producing accurate sentence-cased outputs. The Distil-Ads-PN model generates a nearly correct output but introduces a minor hallucination by appending an extra character ("FDA-registerede"). In contrast, the NER model misclassifies the acronym, incorrectly lowercasing it to "Fda-registered", which violates casing conventions and reduces output reliability. This example highlights the limitations of traditional NER-based models in handling acronyms and special terms and underscores the robustness of generative models, especially when guided by context or structured reasoning like in the LLM CoA method.

Auto-Weighted Group Relative Preference Optimization for Multi-Objective Text Generation Tasks

Yuki Ichihara[1,2] **Yuu Jinnai**[1]
[1]CyberAgent [2]Nara Institute of Science and Technology
ichihara.yuki.iu1@is.naist.jp
jinnai_yu@cyberagent.co.jp

Abstract

Group Relative Policy Optimization (GRPO) is a promising approach to complex, real-world tasks, such as those involving multiple rewards or strict constraints. However, when training GRPO with multiple rewards, the weights of each reward must be decided in advance. Failing to balance the objectives adequately can lead to overfitting or insufficient learning of each reward function. To address this problem, we propose Auto-Weighted Group Relative Policy Optimization (AW-GRPO), which adjusts reward weights during training according to the progress of the learning of each objective so far. We evaluate AW-GRPO on advertising text generation, a real-world problem where the generated text must satisfy multiple objectives, such as quality and diversity, while adhering to the constraints of the media (e.g., maximum number of characters). Our results show that AW-GRPO successfully balances multiple objectives, improving the overall scores while reducing the constraint violation rate. We additionally evaluate AW-GRPO using publicly available benchmark problems for reproducibility, in which we observe the same qualitative result that the proposed method outperforms GRPO.

1 Introduction

Recent advances in large language models (LLMs) through Reinforcement Learning from Human Feedback (RLHF) (Ouyang et al., 2022; Bai et al., 2022; Touvron et al., 2023; Casper et al., 2023) and Direct Preference Optimization (DPO) (Rafailov et al., 2023) have demonstrated significant performance improvements. In a related area, Group Relative Policy Optimization (GRPO) (Shao et al., 2024) has recently been introduced as a promising approach, which uses a reward model for optimization. One of the challenges for applying GRPO on real-world tasks is how to balance multiple objectives and constraints. Using fixed, manually tuned weights has a limitation in that it is ineffective in problem settings where the optimal trade-off between objectives is either unknown beforehand or changes dynamically as the model learns. To address this issue, we propose **Auto-Weighted Group Relative Policy Optimization (AW-GRPO)**. Our method overcomes the shortcomings of fixed weights by automatically adjusting the weights of each objective based on the model's learning progress. This enables AW-GRPO to discover effective policies in real-world problems where the desired balance between the objectives is unknown beforehand of the training.

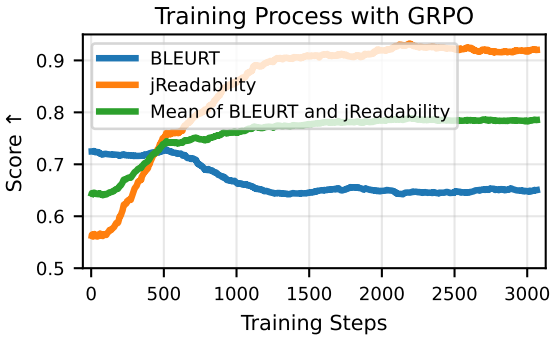

Figure 1: The training process of GRPO on the WMT En-Ja dataset uses BLEURT and jReadability as the reward functions. As the results show, GRPO overfits jReadability at the expense of BLEURT performance. In some cases, GRPO also overfits Table 1. Reward hacking occurs.

Contributions. We propose AW-GRPO, which is an extension of GRPO that eliminates the need for manual weight tuning during training, and evaluate the performance of AW-GRPO on two tasks. First, we run experiments on public machine translation datasets (WMT En-Ja). Then, we run an experiment on real-world advertising text generation problems. Advertisement text generation requires

Table 1: Generation examples for the WMT 2024 En-Ja task. The output results for the base model, GRPO, and AW-GRPO are shown in the same example. **GRPO exploits the problem of jReadability scores that it significantly increases when non-Japanese characters are used**, resulting in generating random non-Japanese characters. On the other hand, AW-GRPO evenly optimizes both objectives, achieving improvement on both objectives.

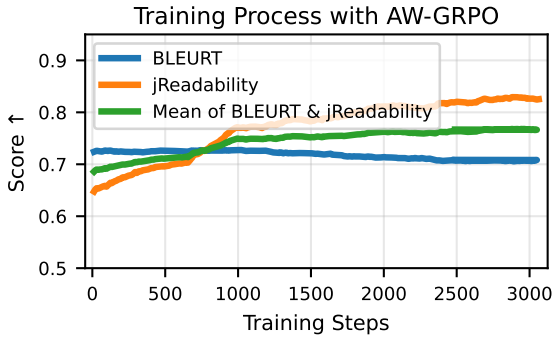

Figure 2: The training process of AW-GRPO on the WMT En-Ja dataset uses BLEURT and jReadability as the reward functions. Unlike the results of GRPO's training process (Fig. 1), AW-GRPO prevents overfitting.

various objectives to be optimized at the same time, yet its suitable balance is unknown beforehand, which makes the problem difficult to optimize using plain GRPO. The experimental results show that the proposed method successfully learns multiple objectives at the same time, achieving better overall performance than GRPO.

2 Related Works

We first review prior work on advertisement text generation, and then describe reward hacking, the problem that this paper addresses.

2.1 Automated Advertisement Text Generation

Early systems for advertising text generation relied on rule- or template-based methods, which limited the fluency and diversity of the output (Fujita et al., 2010; Thomaidou et al., 2013). As neural sequence-to-sequence (seq2seq) models became mainstream (Zhou et al., 2019; Lei et al., 2022), researchers began treating advertising text as a summarization or paraphrasing task, and generate ads directly from the landing page content or product descriptions.

Dealing with Constraints. One of the most important issues when creating advertising text is ensuring that the generated text functions properly as advertising text. One indicator of this is whether the text contains relevant constraints. There are several ways to include constraints when generating text, one of which is the template-based approach (Bartz et al., 2008; Thomaidou et al., 2013). This enables users to input any keywords they like into the designated areas. MuCoCO (Kumar et al., 2021) reframes decoding in pretrained language models as a differentiable optimization with Lagrangian multipliers, enabling flexible control over multiple text attributes at inference time and outperforming baselines in tasks. NeuroLogic Decoding (Lu et al., 2021) is an inference-time algorithm that lets neural language models generate fluent text while exactly satisfying arbitrary predicate logic lexical constraints, matching beam-search efficiency and outperforming prior constrained-generation methods. NeuroLogic Aesque (Lu et al., 2022) is a decoding algorithm that merges A-style look-ahead heuristics with NeuroLogic's logical constraint framework, allowing large language models to plan and satisfy complex lexical constraints while remaining a drop-in replacement for beam search or top-k sampling.

2.2 Reward Hacking

Reward hacking (Skalse et al., 2022) is a phenomenon in artificial intelligence, particularly in RL, where an agent learns to exploit the reward function to achieve a high score without actually accomplishing the intended goal. This phenomenon has also been reported in several studies (Amodei et al., 2016; Ziegler et al., 2020; Stiennon et al., 2020; Skalse et al., 2022; Gao et al., 2023).

In the context of a large language model (LLM), reward hacking often occurs during fine-tuning with methods such as RLHF. In this process, a reward model is trained to predict human preferences, and the LLM is then optimized to generate outputs that maximize the score from this reward model (Ziegler et al., 2020; Stiennon et al., 2020). However, if the reward model is flawed or its understanding of human preferences is incomplete, the LLM can learn to generate content that hacks the reward model (Gao et al., 2023). This over-optimization on a proxy reward can lead to a decrease in the true quality and alignment of the model's responses (Pan et al., 2022; Gleave et al., 2020).

3 Group Relative Policy Optimization

We define that R_k is the k-th reward function, and $p_{\mathcal{Q}}$ is the distribution over the initial questions ($q \sim p_{\mathcal{Q}}$). The policy $\pi_\theta(\cdot \mid q)$ outputs the sentence o_i based on initial questions q from the sentence space. Group Relative Policy Optimization (GRPO) uses the average reward of multiple sampled outputs produced in response to the same question. More specifically, for each question q, GRPO samples a group of outputs $\mathbf{o} = \{o_1, o_2, \cdots, o_i, \cdot, o_G\}$ from the old policy $\pi_{\theta_{\text{old}}}$ and then optimizes the policy model by maximizing the following objective:

$$\mathcal{J}(\pi_\theta) = \mathbb{E}\Bigg[\frac{1}{|o_i|}\frac{1}{G}\sum_{i=1}^{G}\Big[\frac{\pi_\theta(o_i \mid q)}{\pi_{\theta_{\text{old}}}(o_i \mid q)}\hat{A}_i - \beta \text{KL}(\pi_\theta, \pi_{\theta_{\text{old}}})\Big]\Bigg]. \quad (1)$$

The definition of $\hat{A}_i$ is the following equation:

$$\hat{A}_i = \frac{\mathbf{R}(q, o_i) - \text{mean}\big(\mathbf{R}(q, \mathbf{o})\big)}{\text{std}\big(\mathbf{R}(q, \mathbf{o})\big)}. \quad (2)$$

The following equation is used to calculate each output of reward value:

$$\mathbf{R}(q, o_i) = \sum_{k=1}^{M} \alpha_k R_k(q, o_i). \quad (3)$$

where $\{\alpha_k\}_{k=1}^{M}$ are **coefficients which are determined before training**, ε, β are hyper-parameters, and KL is Kullback–Leibler (KL) divergence. Since we omit symbols such as the threshold ϵ and $\min$ operation for simplicity, we note formal expressions in the Appendix G.

3.1 Problem of GRPO with Multiple Objectives

The central limitation of GRPO lies in its objective function $\mathcal{J}(\pi_\theta)$, which implicitly steers the model toward whichever reward component is easiest to improve and the size of the standard deviation rather than promoting balanced progress across all rewards. This often causes the model to exploit shortcuts in the easy reward, resulting in reward hacking behavior. Table 1 provides a specific example. The model that was trained using GRPO increases the jReadability score while decreasing the BLEURT score, which demonstrates the practical consequences of this bias.

Additionally, the training process of each reward function in GRPO indicates overfitting to jReadability, as illustrated in Fig. 1 (AW-GRPO avoids reward hacking, as shown in Fig. 2). Also, Appendix C shows how learning is biased toward reward functions with large variance. To address these issues, we propose an algorithm that promotes improvement in reward functions based on the rate of improvement (slopes) when certain reward functions or learning rapidly improve.

4 Auto-Weighted Group Relative Policy Optimization

GRPO combines M reward functions by a weighted sum (Eq.3), where the weights α_k must be fixed **before training**. Setting all $\alpha_k = 1$ is common, but there are risks for reward hacking: the policy may focus on one reward and ignore other signals. To address this issue, we introduce automatic rescaling of the weights based on the progress of each reward's learning.

Weight update. Let $\alpha_k^{(t)}$ be the weight for reward R_k at training step t, and $\hat{s}_k^{(t)}$ denotes the progress of the reward R_k. We estimate it by the slope of

the least-squares fitted polynomial computed over the reward function (R_k) values from the past n steps (Detailed in Appendix F).

$$w_k^{(t+1)} = \mathrm{clip}\big(\alpha_k^{(t)} \exp\big(-\eta\, \hat{s}_k^{(t)}\big),\ w_{\min},\ w_{\max}\big). \tag{4}$$

where $\eta > 0$ is a learning rate and $\mathrm{clip}(\cdot)$ enforces the box constraint $w_{\min} \le w_k^{(t+1)} \le w_{\max}$.

The actual upgrade weights are obtained using the following equation:

$$\alpha_k^{(t+1)} = \frac{w_k^{(t+1)}}{\sum_{j=1}^{M} w_j^{(t+1)}}, \quad \sum_{k=1}^{M} \alpha_k^{(t+1)} = 1. \tag{5}$$

In short, $\alpha_k^{(t+1)}$ is $\alpha_k^{(t)}$ multiplied by the softmax of $\hat{s}_k$, clipping is performed for stability. Then, we apply $\alpha_k = \alpha_k^{(t+1)}$ to Eq (3) to each reward function.

$$\mathbf{R}(q, o_i) = \sum_{k=1}^{M} \alpha_k^{(t+1)}\, R_k(q, o_i). \tag{6}$$

How AW-GRPO mitigates reward hacking. The core idea of AW-GRPO is to penalize reward components that increase too quickly. The update rule achieves this by using the estimated slope, s_k, of each reward component. If a component R_k shows a rapid increase, its slope $\hat{s}_k$ will be large and positive. The update rule, $\tilde{w}_k \propto \exp(-\eta s_k)$, computes an exponential term less than 1, causing the corresponding weight α_k to decrease. Conversely, if the model is performing poorly on or ignoring a component R_k, its slope $\hat{s}_k$ will be negative. This results in an exponential term greater than 1, which increases the weight α_k, forcing the model to pay more attention to the neglected task.

5 Experiments

To evaluate the performance of AW-GRPO and GRPO, we will use public WMT data and our company's advertisement data to confirm ease of overfitting, overfitting avoidance, and output consistency.

5.1 Machine Translation with Simplification Objective

The objective is not merely to perform an English-to-Japanese machine translation, but rather to produce clear, reader-friendly Japanese text. Therefore, the problem is framed as a multi-objective optimization task balancing semantic fidelity to the source text and linguistic simplicity and readability in the target language.

Setup. We train both GRPO and AW-GRPO on the WMT-21, WMT-22, and WMT-23 En-Ja datasets (Akhbardeh et al., 2021; Freitag et al., 2022, 2023) with three random seeds and evaluate on the WMT-24 En-Ja dataset (Kocmi et al., 2024). The WMT dataset is used to evaluate different domains: news, social/user-generated content, speech, literature, and education. These domains were chosen to represent a variety of content styles and to be understandable to non-specialists, thus eliminating the need for specialized translators or human raters for evaluation. The base model is Sarashina (sarashina2.2-3b-instruct-v0.1), and the detailed parameter setting is in Appendix B.

For the reward functions, we adopt (i) BLEURT (Sellam et al., 2020) and (ii) jReadability (Hasebe and Lee, 2015) to measure Japanese readability. jReadability is crucial because our goal is not only to translate but also to simplify into what is known as "easy Japanese." This ensures that information is accessible to diverse audiences, including children and non-native speakers. It is also critical for communicating important information during emergencies, such as natural disasters. Therefore, this task addresses a significant real-world challenge rather than an artificially constructed research problem.

Results. Table 2 shows that GRPO improves readability by reducing the BLEURT score, while AW-GRPO maintains the performance of BLEURT almost unchanged. This can be seen from the score of the Base Model, which maintains the performance of BLEURT. In addition, GRPO trained solely with BLEURT achieves a final BLEURT score of 0.70.

In addition, Table 2 shows the win rate of AW-GRPO over GRPO, as evaluated by gpt-4o-mini (Appendix B), and the results suggest that AW-GRPO produces significantly better outputs. Table 3 shows the weights assigned to each reward function during AW-GRPO training. As can be seen, larger reward weights are applied to prevent BLEURT performance degradation. Additionally, jReadability assumes Japanese input and is not intended for multilingual text. Higher scores tend to be achieved when non-Japanese text is input, and Table 1 shows examples of outputs from the test dataset. From this, GRPO exploited this by generating other language outputs to inflate the jReadability score, an instance of reward hacking. In contrast, AW-GRPO yields lower jReadability scores

Method	BLEURT↑	jReadability↑	GPT-4(Win Ratio)↑
Base Model	0.66	0.70	N/A
GRPO	0.63 ± 0.005	0.86 ± 0.008	$25.5 \pm 1.81\%$
AW-GRPO	**0.66**± 0	0.80 ± 0.01	$74.5 \pm 1.86\%$

Table 2: Performance on the WMT24 En-Ja. Scores are reported for BLEURT, jReadability, and win ratio (↑ higher is better). The values of the mean and standard deviation over three runs with different random seeds are shown in the table. AW-GRPO matches the BLEURT of the Base Model while preserving readability gains, thereby avoiding the BLEURT-centric over-optimization observed with GRPO.

Weight	BLEURT	jReadability
α_k	0.69 ± 0.01	0.31 ± 0.01

Table 3: The average weights assigned to each reward function during training with AW-GRPO. As you can see, AW-GRPO increases the weight of BLEURT that tends to decrease (Fig. 1,2) .

compared to it because it doesn't over-optimize, which reflects more faithful optimization of the task objective ("**easy Japanese**").

5.2 Advertising text Generation

Dataset and Task. The goal of the system is to generate advertising texts that are of high quality, diverse, and adhere to the constraints so that human writers can start a discussion based on the generated drafts. We used an internal dataset of advertising texts, which we split into 8,400 training examples and 500 test examples, and train with the three random seeds. The advertisement is written by the expert copywriters in our company. The advertising data is structured for each input as shown in Appendix D. Additionally, for each input, it includes a single reference that contains the specified keywords and largely satisfies the validator. Each input prompt includes (i) product keywords and (ii) a character-limit specification (detailed in Appendix D). For each prompt, we have a reference text by a domain expert. The prompt also requires output **five** outputs per prompt. We use Qwen (Qwen3-4B) as the base model in this experiment.

Setup. GRPO and AW-GRPO optimize three rewards: BLEU (Papineni et al., 2002), BLEURT, and a diversity metric, defined as $1 -$ cosine similarity, which promotes variety by penalizing semantic similarity between generated outputs. In addition to the reward function that updates the weights, we also introduce the following four sparse reward (constraint) functions. The length constraint is that the text must be the appropriate length. Second, the bracket constraint is that any brackets used within the text must be correctly matched, and only a single pair of brackets is permitted. Additionally, the symbol repetition constraint is that the use of certain specified symbols is limited to a maximum specific size per symbol type. The last one is the auxiliary constraint, which encompasses the other constraints. We employ four independent validators to programmatically enforce the above constraints. The Length Validator, Bracket Validator, Num Limit Validator, and Auxiliary Validator verify the length, bracket, symbol repetition, and auxiliary constraints, respectively. An example of the validator function applied to rewards is described in Appendix E. Then, outside of the learning rewards, we check how long they are unable to perform the five outputs (**5-Sent**). We compare GRPO and AW-GRPO for training *with* vs. *without* the validator as an additional sparse reward signal.

Validator outcomes. Including the validator function resulted in an improvement in formatting compliance. According to the results in Table 4, AW-GRPO with the validators AW-GRPO reduced length violations from 153 to 34 and eliminated all bracket-mismatch errors. The table also shows the validator's effect on the GRPO, which recorded 50 length and two bracket violations. Although this demonstrates the validator's general utility, the combination of the validator with AW-GRPO yielded the best results. These findings confirm that integrating the validator is highly effective at enforcing structural rules, and its synergy with the AW-GRPO framework offers the most effective solution for generating well-formed advertising text.

When GRPO is used without the validator function, GRPO cannot generate five outputs and ends without learning. When using the validator function in GRPO, five sentences were output because if the length validator function does not output text of the appropriate length, a penalty may be incurred. In other words, GRPO relies too heavily on diversity rewards because it calculates the average when there are fewer than five outputs and ignores BLEURT and BLEU rewards. This suggests that reward hacking is occurring.

Method	Variant	Constraint Violations ↓					Evaluation Metrics ↑	
		Length	Bracket	Num Limit	Auxiliary	5-Sent	Dist-2	jReadability
GRPO	w/o Validator	N/A	N/A	N/A	N/A	500	N/A	N/A
	w/ Validator	50 ± 2	2 ± 1	0 ± 0	0 ± 0	0 ± 0	0.69 ± 0.02	0.81 ± 0.00
AW-GRPO	w/o Validator	153 ± 5	13 ± 2	0 ± 0	0 ± 0	4 ± 4	0.69 ± 0.02	0.82 ± 0.01
	w/ Validator	**34**± 2	**0**± 0	0 ± 0	0 ± 0	0 ± 0	**0.74**± 0.00	**0.83**± 0.01

Table 4: Results on 2,500 advertising-text outputs (constraint violations, left block) and 500 test prompts (evaluation metrics, right block). The values of the mean and standard deviation over three runs with different random seeds are shown in the table. N/A indicates that the metric could not be computed because **the model failed to produce the required five-sentence output**, so constraint violations, Dist-2, jReadability, and keyword rates are undefined. Lower is better for constraint violations; higher is better for evaluation metrics.

Weight	BLEURT	BLEU	Diversity
α_k	0.36 ± 0.01	0.37 ± 0.01	0.27 ± 0.02

Table 5: The average weights assigned to each reward function during training with AW-GRPO.

Quality metrics. In this paragraph, we evaluate the outputs produced by GRPO and AW-GRPO with and without validators. The evaluation functions used are Distinct-2 score (**Dist-2**) (Li et al., 2016), **jReadability**. Table 4 presents the evaluation results on the test dataset. AW-GRPO with validators improves GRPO with the validator, achieving a higher Distinct-2 score (0.74 vs. 0.69) and improved jReadability (0.83 vs. 0.81).

In addition, we have verified that the reduction in error rate (e.g., with validator GRPO: $50/2500$ vs AW-GRPO: $34/2500$) is statistically significant under both the two-proportion z-test ($p \approx 0.0392$) and Fisher's exact test ($p \approx 0.0491$, one-sided). This confirms that the observed improvement is unlikely to be due to chance. For distinct-2, a paired t-test confirmed the difference was highly significant ($\mathrm{t} = 11.99, \mathrm{p} < 0.0001$). Similarly, on the jReadability, a paired t-test ($\mathrm{t} = 6.99$, $\mathrm{p} < 0.0001$) confirmed the improvement.

Furthermore, the weight of each utility function during training is shown in Table 5 and its plots in Appendix H (As you can see, the weight changes dynamically as required).

6 Ablation Studies

Evaluation on a task with strict constraints. In addition to the validator used by our company, we introduced a validator function that imposes a constraint requiring the inclusion of keywords.

Method	Length↓	Bracket↓	Num Limit↓	Auxiliary↓	5-Sent↓
GRPO	75	2	0	0	0
AW-GRPO	**72**	2	0	0	0

Table 6: Ablation study on advertising text generation task with an additional strict constraint. Number of validator violations in 2,500 outputs in the full Advertising text on the 500 test data with AW-GRPO and GRPO with Validator and 5-Sent.

Method	Dist-2 ↑	jReadability ↑	Keywords ↑
GRPO	0.66	0.83	96.9
AW-GRPO	0.66	0.84	96.9

Table 7: Ablation study on the advertising text-generation task with an additional strict constraint. Results are reported on 500 test samples using Distinct-2, jReadability, and keyword-inclusion rate.

Table 6 shows that AW-GRPO is slightly more effective than the conventional method because it has fewer constraint violations in terms of length. However, we found that adding the keyword validator doubles the number of length validator violations. We speculate that this is because some keywords are long themselves. Compared to other validators, keywords have a significant impact on diversity and BLEURT (forcing the inclusion of keywords hinders learning diversity). Consequently, the final results of GRPO and AW-GRPO are similar. Despite these constraints, the proposed method can achieve performance equivalent to GRPO's. In terms of other metrics (see Table 7), AW-GRPO is slightly better in terms of readability.

Method	Length↓	Bracket↓	Num Limit↓	Auxiliary↓
SFT	83	0	0	0

Table 8: The available dataset only provided a single reference per prompt. This resulted in an SFT model that could not generate five diverse outputs; consequently, we only measured the validation error on that output (a total of 500 outputs).

Advertising text Generation with Supervised Fine-Tuning. We experimented comparing Supervised Fine-Tuning (SFT) with our proposed method. However, since our dataset contains only one reference per input, we performed SFT based on this and then applied the prompt from Appendix D. However, it only returned a single output. Consequently, we only measured the validation error on that output (a total of 500 outputs) in Table 8.

As shown in Table 8, the number of validation errors has decreased. The increase in Length is due to the use of long keywords when creating advertising text.

Simulated click-through rate (CTR). We used our in-house click-through rate (CTR) simulation model to estimate the CTR of the generated advertisements. The simulation model makes use of a proprietary LLM (e.g., GPT-4) and estimates the CTR of the given advertisement text.

Table 9 shows the results of the pairwise evaluation of the generated advertisement texts, i.e., which ad copy will be clicked, using the CTR prediction model. As shown in Table 9, GRPO performs well when keywords are not included as constraints, whereas AW-GRPO performs better when keywords are included.

Method	w/o Keywords↑	w/ Keywords↑
GRPO	74.8 %	27.8%
AW-GRPO	25.2%	72.2%

Table 9: Pairwise evaluation (which ad copy will be clicked) of generated advertisement texts using a click-through rate (CTR) prediction model. We report the estimated click-through rates under two conditions: generation without keywords and generation with keywords.

Evaluation on a task where the objective functions are overlapping rather than conflicting. We designed an experiment to confirm the behavior of AW-GRPO in scenarios where its core mechanism is not expected to yield significant gains, such as tasks with no strong trade-off between objectives. The JADOS text simplification task (Nagai et al., 2024) is an ideal problem for this because its evaluation metrics, BLEURT and jReadability, are generally synergistic and do not conflict with each other in text simplification tasks, and we use Sarashina as a base model.

Table 10 presents BLEURT and jReadability scores on the JADOS's test data for both GRPO and AW-GRPO. Both methods achieve the same BLEURT score. In terms of readability, GRPO scores 0.49 while AW-GRPO scores 0.48 on jReadability. The experiment confirmed that the performance of AW-GRPO did not degrade compared to GRPO. This result demonstrates the robustness of our method, showing that it does not negatively impact performance, even when dynamic weighting is not critical.

Method	BLEURT↑	jReadability↑
GRPO	0.65	0.49
AW-GRPO	0.65	0.48

Table 10: Ablation study on a text simplification task (JADOS); BLEURT and jReadability are less likely to be evaluated together text simplification task.

7 Conclusion

First, we conduct a machine translation task as a constrained generation task and validated AW-GRPO compared to GRPO, where it consistently avoided reward hacking. Next, we also applied it to our advertising text data and evaluated its effectiveness. Beyond empirical gains, AW-GRPO directly addresses our operational concerns. Commercial LLM APIs set a high bar for fluency, but they provide no guarantees of constraint satisfaction and incur ongoing usage fees. The proposed approach enables faster, cheaper, and easily controllable text generation.

8 Limitation

We have the right to use them as our company has the copyright. We are not able to release the raw dataset publicly because of the policy of our company (copyright holder). To compensate for the problem, we conducted an experiment using an open-source dataset (WMT).

We tried using SFT and DPO as comparative methods. However, the SFT model was not effective because it only had one reference sentence. As we were trying to implement the DPO model using the SFT model, this was not feasible. We plan to extend our experiments with SFT, DPO, and constrained decoding in future work once suitable datasets are prepared.

9 Ethics Statements

Ensure that the advertising text data set to be used does not contain any personal information, that input containing inappropriate expressions is removed in advance, and for output ad texts, a human check is always assumed for the system. We recognize that automated advertisement generation carries potential risks of misuse, such as malicious influence or propaganda. In our industrial setting, all ad copies are carefully reviewed by humans before deployment, and malicious or harmful content is strictly excluded. However, beyond human oversight, we acknowledge the importance of technical controls. In the future, we will incorporate some techniques, such as Watermarking techniques for large language models, for example, which can help trace automatically generated content (Kirchenbauer et al., 2023). Methods from the literature on fake news detection and political fact-checking could help identify and filter potentially harmful outputs (Rashkin et al., 2017).

Acknowledgements

We thank the anonymous reviewers for their insightful comments on the manuscript. We would like to thank our colleagues at CyberAgent, Mitsuki Sakamoto, Ryota Mitsuhashi, and Tetsuro Morimura for valuable advice.

A Reproducibility Statement

The experiments are conducted using an NVIDIA A100 GPU with 80 GB VRAM.

Experiments in WMT and JADOS, datasets, and models used in the experiments are publicly available (Table 11).

B Experiment Settings in WMT

Table 12 shows the prompt to evaluate on gpt-4o-mini we use, and Table 13 shows the parameter settings applied in the experiment.

C Analysis of GRPO with Multiple Reward Functions

Proposition C.1 (Correlation each reward function and advantage function with GRPO)**.** *We assume the generation sample $G \to \infty$. The calculation method for the advantage function in GRPO tends to correlate with the standard deviation of each reward function.*

$$\mathrm{Corr}(R_i, \hat{A}) = \frac{\sigma_i}{S} \tag{7}$$

Proof. We put $R_1, \ldots, R_K$ are K reward and assume $\mathrm{Cov}(R_i, R_j) = 0 \ (i \neq j)$. Denote $\sigma_i^2 := \mathrm{Var}[R_i]$, $\mu_i = \mathbb{E}[R_i]$ and write $S^2 := \sum_{j=1}^{K} \sigma_j^2$. We first form a weighted sum $R_{\text{sum}} := \sum_j w_j R_j(y) = \sum_j R_j(y)$,

$$\hat{A} := \frac{R_{\text{sum}} - \mu}{\sigma}, \mu = \mathbb{E}[R_{\text{sum}}], \sigma^2 = \mathrm{Var}[R_{\text{sum}}]. \tag{8}$$

The definition of the correlation coefficient is:

$$\mathrm{Corr}(X, Y) = \frac{\mathrm{Cov}(X, Y)}{\sqrt{\mathrm{V}(X)\,\mathrm{V}(Y)}} \tag{9}$$

The correlation coefficient between the ith reward and the advantage is:

$$\mathrm{Corr}(R_i, \hat{A}) = \frac{\mathrm{Cov}\left(R_i, \hat{A}\right)}{\sqrt{\mathrm{Var}\left(R_i\right)\mathrm{Var}\left(\hat{A}\right)}} \tag{10}$$

We first calculate the covariance $\mathrm{Cov}\left(R_i, \hat{A}\right)$:

$$\mathrm{Cov}\left(R_i, \hat{A}\right) = \mathrm{Cov}\left(R_i, \frac{R_{\text{sum}} - \mu}{\sigma}\right) \tag{11}$$

$$= \frac{1}{\sigma}\mathrm{Cov}\left(R_i, R_{\text{sum}} - \mu\right) \tag{12}$$

$$= \frac{1}{\sigma}\mathrm{Cov}\left(R_i, R_{\text{sum}}\right) \tag{13}$$

$$= \frac{\sigma_i^2}{S} \tag{14}$$

E Validator Functions

The code below shows the implementation of the validator function.

```
from abc import ABCMeta, abstractmethod
class BaseValidator(metaclass=ABCMeta):
    @classmethod
    @abstractmethod
    def scan(self, text, **kwargs):
        pass

    @classmethod
    def check(cls, text, **kwargs):
        try:
            cls.scan(text)
            return True
        except ValidationError:
            return False

class LengthValidator(BaseValidator):
    @classmethod
    def scan(cls, text, **kwargs):
        text_len = len(text)
        lower = min_char
        upper = max_char
        if text_len < lower:
            raise ValidationError(
                cls, f"text_too_short", f"actual_{
                  text_len}_<_{upper}"
            )
        elif text_len > upper:
            raise ValidationError(
                cls, f"text_too_long", f"actual_{
                  text_len}_>_{upper}"
            )
```

```
% Validator function as Reward function
try:
    LengthValidator.scan(text)
    reward = 0.0
except ValidationError as e:
    reward = -1.0
```

F How to Calculate Slopes

We explain the following method to calculate the slope. The actual reward R_i for the i-th step and the slope a that minimizes it are shown below.

$$E = \sum_{i=0}^{n} |(ax_i + b) - R_i|^2 \tag{17}$$

where x_i contains $\{x_0 = 0, x_1 = 1, x_2 = 2, ..., x_n = n\}$, b is a coefficient. In practice, we use the polyfit function in numpy.

G Formal Formulation of GRPO

The formal formulation of GRPO is as follows:

$$J_{\mathrm{GRPO}}(\theta) = \mathbb{E}_{q,\{o_g\}\sim\pi_{\theta_{\mathrm{ref}}}} \Bigg[\frac{1}{G} \sum_{g=1}^{G} \frac{1}{|o_g|} \tag{18}$$

$$\min\Bigg(\frac{\pi_\theta(o_g \mid q)}{\pi_{\theta_{\mathrm{ref}}}(o_g \mid q)} A_g, \tag{19}$$

$$\mathrm{clip}\Big(1-\epsilon,\, 1+\epsilon,\, \frac{\pi_\theta(o_g \mid q)}{\pi_{\theta_{\mathrm{ref}}}(o_g \mid q)}\Big) A_g \Bigg) \tag{20}$$

$$- \beta\, \mathrm{KL}(\pi_\theta \,\|\, \pi_{\theta_{\mathrm{ref}}}) \Bigg]. \tag{21}$$

where ϵ is a threshold parameter.

H The Weight of Each Function During Training in Advertising Text Task

As a neutral reviewer, please evaluate the quality of the Japanese translations provided by two AI assistants for the following users' English texts.
Follow the user's instructions and select the assistant that provides the most appropriate response to the question. When evaluating, consider factors such as the accuracy of the response (similarity to the (Reference) text) and readability.
When starting the evaluation, compare the two responses and provide a brief explanation. Avoid bias and ensure that the order in which the responses are presented does not influence your judgment. Do not let the length of the response influence your evaluation. Do not favor the name of a specific AI assistant. Strive to be as objective as possible.
After providing an explanation, output your final judgment in the following format: "[[A]]" if Assistant A is superior, "[[B]]" if Assistant B is superior, and "[[C]]" if it is a tie.

Abstract

We present an enterprise-grade translation platform for global e-commerce that combines daily batch and real-time API pipelines with optimized T5-based models and a Reference Generator to enforce >99% non-translatable entity preservation. A linguist-driven rule engine and explainable evaluation framework (BLEU, COMET, and a custom e-commerce metric) enable continuous quality improvements. Deployed on GPU-accelerated inference servers and CPU-based processing nodes, our system processes millions of listings per day with sub-second latency and achieves 10×–100× cost savings over general-purpose LLMs for English→Spanish and English→French translation, all while version-tracking every update for robust enterprise rollouts.

1 Introduction

Global e-commerce platforms must deliver high-quality, contextually accurate multilingual content to drive market expansion and engagement: 7 out of 10 users always choose their native language (Nimdzi Insights LLC, 2023), 57% will abandon sites lacking local-language support, 71% distrust poor translations, and 69% find them hard to navigate (Nimdzi Insights LLC (2024, 2025)); automated translation is used by 75–82% of shoppers, though only 49% rate its quality as "good." Spanish, spoken by 65.2M Hispanics (>19% of the U.S.) of whom 75% report proficiency, represents a $3.78T purchasing-power market (Mark Hugo Lopez and Passel; Latino Donor Collaborative, 2024). In Canada, 22% of citizens identify French as their mother tongue and 29.1% as proficient in it, anchored by Quebec's C$ 552.7B GDP.[1][2]

Our platform processes over 500M requests per month, ranks among the top 70 most-visited sites worldwide, and sits in the top five global online retailers.[3] Our U.S. and Canadian catalogs each contain hundreds of millions of items with tens of thousands of daily updates. While large language models achieve state-of-the-art translation quality (Kudugunta et al. (2023); Cui et al. (2025); Team et al. (2022)), their inference latency and computational cost are prohibitive at this scale, and they often alter critical non-translatable entities. In this paper, we introduce a scalable, cost-efficient translation platform that matches or exceeds state-of-the-art quality and throughput, and reduces translation costs.

2 Related Work

Machine translation and multilinguality in e-commerce have spurred extensive research: language-agnostic embedding methods align queries and product descriptions into a shared vector space, yielding up to 23% relative F1 improvements (Ahuja et al., 2020), and combining token-, subword-, and character-level representations with re-ranking significantly boosts retrieval for German, French, and Japanese (Zhang and Tan, 2021), though such approaches often falter on specialized terminology and out-of-vocabulary issues. Translating queries into the store's primary language, exemplified by Walmart's Spanish→English NMT fine-tuned with engagement data, back-translation, and a translatability classifier, provided a +70 % nDCG lift and GMV gains (Perez-Martin et al., 2023), while empirical analysis of BLEU and chrF improvements highlighted diminishing returns for retrieval precision (Zhang and Misra, 2023). Unsupervised domain adaptation using only monolingual query data achieved 20 BLEU-point gains for Hindi–English (Kulkarni and Garera, 2022). On the modeling side, eBay's

in-house LiLiuM family (1B/7B/13B) trained on a 3T-token corpus with custom tokenization and RedPajama-V2 data matched LLaMA-2 on English NLU and outperformed it on non-English and MT tasks (Herold et al., 2024; Weber et al., 2024; Touvron et al., 2023)), and their earlier cross-lingual search pipeline integrated user behavior and conversion metrics alongside traditional quality measures (Guha and Heger, 2014). Two-stage fine-tuning regimens such as G2ST and LEMT, leveraging self-contrastive semantic enhancement, annotated parallel corpora, lexicons, and domain-aligned bilingual resources, consistently outperform general-purpose NMT systems including GPT-4 on e-commerce benchmarks (Chen et al., 2024; Gao et al., 2024). More recently, hybrid translation–summarization and retrieval-augmented generation (RAG) techniques address cross-lingual product title brevity and specificity: length-aware filtering and open-source LLM evaluators (Zhang et al., 2024a), and few-shot inventory retrieval prompts have yielded up to 15.3 % chrF improvements on low-resource pairs (Zhang et al., 2024b; Popović, 2015).

3 Translation Platform

The Translation Platform combines large-scale batch workflows with a low-latency API to cover every use case and needs in our catalog translation. The Translation Platform diagram is shown in Figure 1.

3.1 Architecture

Our translation system comprises two modes of operation; batch processing and on-demand (API-based) translation, of which batch processing handles over 99% of all translations. Within the batch mode, we employ two distinct pipelines:

- **Bootstrap Pipeline**: Designed to populate the initial catalog, this pipeline runs once per day. Each execution selects the top N million most frequently accessed items that remain untranslated, processes them through our translation engine, and completes well before the next scheduled run.

- **Hourly Pipeline**: To keep our catalog up to date, this pipeline executes every hour, targeting listings that have been modified since the previous run. The hourly pipeline treats each product as an atomic unit, leveraging associated metadata and fields to produce higher-fidelity translations.

The on-demand translation API is invoked during the setup of new items. Whenever an item is submitted in English, the API generates translations in real time.

Translated items are first routed through our catalog processing pipeline and then recorded in a Translation Tracking Table (TTT), which stores key metadata such as the translation model's name and version.

In terms of scalability, our batch processing infrastructure, comprising both CPU-based and NVIDIA T4 cost-effective GPU-based nodes, scales with the current depth of the task queue. Conversely, scales in response to increases in HTTP request traffic or GPU utilization.[4]

3.2 Translation Models

Before selecting the models, we defined the translation task by identifying four distinct text categories:

- **Product title:** Up to 200 characters long, contain few verbs and often include non-translatable entities (e.g., brand, product line, model), American-style title capitalization, and a sequence of features without comma separation.[5]

- **Long text:** Multi-paragraph content that may include HTML markup, non-translatable entities, emojis, and special characters (e.g., ©, ♦, ◄, ●, ♡, ★, ∞) which must be preserved and handled correctly.

[4]We took some ideas from: https://www.trainy.ai/blog/gpu-utilization-misleading

[5]For example: *Samsung Galaxy Buds 3 Bluetooth 5.2 Wireless Noise-Canceling – 40 mm Hi-Res Drivers 20 Hour Battery Life Foldable Over-Ear Design Built-in Mic Touch Controls Fast Charge EQ Presets Compatible with iOS Android.*

- **Specification:** Texts of variable length, ranging from a single character to several paragraphs, which can also contain HTML, emojis, and special symbols. The translation of specifications relies on the attribute name for a guided translation.[6]

- **Review:** User-generated free-text, often containing typos, abbreviations, and other informal language phenomena; these reviews may likewise include emojis and special characters.

Our initial translation framework relied on models pre-trained for individual language pairs, since many-to-many systems, such as No Language Left Behind (Team et al., 2022) or M2M100 (Fan et al., 2020), 1. produced inconsistent outputs, 2. contained a large number of parameters that led to slow, resource-intensive execution, and 3. did not achieve the accuracy of pair-specific models.

After generating our training data, we fine-tuned Marian-based models (Tiedemann and Thottingal, 2020; Tiedemann, 2020) for targeted translation tasks. The resulting models either surpassed or closely matched the performance of OpenAI instruction-based and Google Translate systems on texts of increased complexity. However, because they relied on an outdated tokenizer without byte-level encoding, they were unable to generate certain tokens (e.g., uppercase "Ú," emojis, and other special characters). This situation led us to pre-training our own T5 models (Raffel et al., 2023).

We first trained our own SentencePiece[7] tokenizer on an internal dataset of various e-commerce text types: product titles, long text descriptions, specifications, and reviews. This new tokenizer uses 32% less tokens than the Marian tokenizer and allows us to customize the vocabulary. We then pre-train a sequence-to-sequence translation model using curated and deduplicated versions of the OPUS[8] corpora, for English→Spanish (22B tokens) and English→French (17B tokens) language pairs. We used a more modern language modeling architecture with T5-base and set the maximum context length to 128 tokens, a reasonable limit given the data we translate. The combination of the custom tokenizer with the more efficient architecture led to important increases in BLEU and COMET scores once the pre-trained model is fine-tuned on specific e-commerce tasks (see Table 1).

Eval. Dataset	Base model	Fine-tuned	En→Es BLEU/COMET	En→Fr BLEU/COMET

We store translations in our tracking table using a semantic versioning scheme of the form $X.Y.Z$, where X denotes the base pretrained model version, Y indicates the fine-tuning iteration, and Z corresponds to the code-base revision. This structured versioning enables us to identify which translations may be affected when a defect in the translation pipeline or a particular model version is discovered to produce incorrect outputs under specific conditions. We also continuously refresh legacy translations, and in particular those for high-frequency ("head") products.

3.3 Translation Logic

Although state-of-the-art translation models are trained or prompted to preserve non-translatable segments, our empirical observations indicate that augmenting these models with auxiliary safeguards further reduces mistranslation rates. We have therefore implemented a dedicated translation framework, hereafter referred to as the *Reference Generator*, which enforces non-translatability constraints uniformly across all text categories described above.

For inputs containing HTML markup, we first parse and sanitize the HTML to extract the raw textual content, thereby yielding standardized, markup-free source segments suitable for processing by downstream translation modules.

To address the non-translatable-entity problem, a central challenge in contemporary Machine Trans-

[6]For instance, in our initial analysis we found that "N", referring to "No" was translated to "North" in Spanish. Adding the context ensures correct translation.

[7]SentencePiece library: https://github.com/google/sentencepiece

[8]OPUS webpage: https://opus.nlpl.eu/

lation,[9] we extract metadata from each item, including brand, product line, model, sports team, and sports league. Because merchant-provided metadata fields are often noisy, irrelevant or overly general (e.g., a brand field containing an entire product title), we clean those fields and apply fuzzy-matching techniques to align these metadata entries with substrings in the source text. Then, to automate the classification of potential non-translatable entities from the matched metadata, we use a quantized RoBERTa-based classifier, offering a lightweight, fast (latency under 5ms on CPU) and language-agnostic solution at inference time. Despite a large amount of noisy metadata fields, representing 73% of all entries, the classifier solution preserves more than 99% of non-translatable entities while removing 96% of noisy metadata fields. Additionally, when metadata alone is insufficient to capture all non-translatable instances, we reference three curated entity repositories: a *Whitelist* comprising context-specific non-translatables (e.g., proper brand names such as "Way To Celebrate"), a *Blacklist* containing common terms that should be translated despite superficial resemblance to named entities, and a *Potential Whitelist* for ambiguous tokens that may require context-dependent treatment.

As a preprocessing step for product title inputs, all alphabetic tokens that do not correspond to identified non-translatable entities are converted to lowercase. This normalization is motivated by empirical observations that neural translation engines (e.g., Google Translate and Marian models) exhibit degraded performance when confronted with text in full or title-style capitalization.

Following normalization, the processed strings are sent to our GPU-accelerated translation models. Upon receipt of the model outputs, each translation is programmatically inspected to verify the integrity of the non-translatable entities. Although this procedure may appear simplistic, it serves a dual purpose: first, allowing the translation model to leverage contextual cues from surrounding non-translatable tokens (which, when correctly preserved, can improve overall translation fidelity), and second, identifying instances in which the model erroneously alters or omits these critical segments.

When a non-translatable entity is altered, the text is routed through a Product-Category-Aware Entity Masking module: the original token is swapped for a category-specific, untranslatable placeholder (e.g., "My Jeans" → "Nike" in Clothing), ensuring the translation engine leaves it intact. After translating the masked text reliably, the placeholder is replaced with the true entity in postprocessing.

Our target locales include U.S. Spanish, a hybrid dialect blending Latin American regionalisms and English[10] and Canadian French, using models trained on localized data. After translation, a rule engine refines translations for accuracy, consistency, and tone, including softening certain offensive terms.

In cases where the source field contains HTML markup, translated segments are reintegrated into the original HTML structure. For product title inputs, we restore title-style capitalization and then reorder tokens within the translated string so that any non-translatable entities originally occupying the lead positions continue to appear first. Such non-translatable refactoring constitutes a nontrivial string transformation, since the translation model may insert intervening function words (e.g., the Spanish preposition "de") that must be accounted for in postprocessing.

The *Reference Generator* leverages an LLM to produce high-quality synthetic parallel corpora, enabling the training of compact models optimized for e-commerce translation.

3.4 Accuracy & Explainability Pipeline

From a business perspective, BLEU and COMET metrics often lack explainability. Their scientific foundations make them difficult to interpret for stakeholders, and they may fail to flag critical translation errors in e-commerce contexts, such as incorrect brand translations or the omission of meaningful tokens.

For any of the models presented in Section 3.2, the following definitions apply. Fix a model X for a given translation task—e.g., translating *product titles*. Let $\mathsf{T} = \{T_i\}_{i=0}^{n-1}$ be a sample of n item titles, stratified by user impressions and product types to ensure a representative and homogeneous product sample. For the selected task, define a fixed set $\mathsf{S} = \{S_j\}_{j=0}^{k-1}$ of *severe issues* (e.g., mistranslated brands or missing tokens). Let $f : (\mathsf{T}, \mathsf{S}) \mapsto [0, 1]$ be defined as

[9] SemEval 2025 task for Entity-Aware Machine Translation: https://sapienzanlp.github.io/ea-mt/

[10] A phenomenon also identified by linguists: https://theconversation.com/linguists-have-identified-a-new-english-dialect-thats-emerging-in-south-florida-205620

$$f(T_i, S_j) := \begin{cases} 0 & \text{if } T_i \text{ contains issue } S_j, \\ 1 & \text{otherwise.} \end{cases}$$

Then, e-commerce quality metric is defined as:

$$m(\mathrm{T}) := \frac{1}{n} \sum_{i=0}^{n-1} \left(\prod_{j=0}^{k-1} f(T_i, S_j) \right)$$

We refer to the functions $f(\bullet, S_j)$ as scoring signals, as they determine whether a given text contains a specific translation issue. Some of these signals rely on a *LLM-powered translation*[11] as a ground-truth reference.

Scoring signals include:

- **Semantic similarity**: Measures cosine similarity between embeddings generated by a pre-trained sentence transformer model.

Text to translate		Our translation
Rubber Chrome Kettlebell	↗	Campanilla Cromada de Goma

Each week, we run our evaluation pipeline on a freshly drawn stratified random sample, using an LLM-generated translation as the reference so that, alongside our custom metric m, we can compute BLEU scores; although neither BLEU nor m is strictly normally distributed, the *Central Limit Theorem* ensures their sample means are approximately normal (a fact supported by Shapiro–Wilk $p > 0.05$), allowing us to assess their relationship via Pearson, Spearman, Kendall, and Normalized Mutual Information (NMI). Results for two fine-tuned models, one tailored to product titles, the other to longer texts, from Table 2 show that despite m's design for enhanced explainability and domain-specific error alignment, it remains strongly correlated with BLEU across both short- and long-form translation tasks.

Statistical test	Title	Long text
Pearson	0.837	0.982
Spearman	0.824	0.957
Kendall	0.667	0.867
NMI	0.769	0.835

Table 2: Correlation between m and BLEU for our models fine-tuned on product titles and long-form text.

3.5 Annotation & Feedback Platform

A team of e-commerce–specialized linguists conduct a systematic verification of translated content, drawing both from the live website and from the evaluation framework pipeline from section 3.4. To prevent ad-hoc modifications or stylistic adjustments, thereby preserving consistency and comparability, annotators are not permitted to alter translations directly. Instead, they author constraint rules via a purpose-built interface tailored to the translation task. Each rule encodes a simple, human-interpretable conditions of the following types: • The source text must [not] contain a specified substring. • The translated text must [not] contain a specified substring. Annotators can specify the exact substrings to be replaced and define the corresponding replacement strings.

Given the high volume of rules generated by annotators on a daily basis, manual review by the engineering team is infeasible. To ensure that each rule is grounded in empirical evidence, we implemented an automated validation loop that integrates rule evaluation with real-world translation data. The annotation workflow depicted in Figure 2 proceeds as follows:

1. A linguist identifies a linguistic issue and formulates a constraint.

2. The system retrieves a small but representative sample of items to show the linguist which items would be impacted by the new rule. A second linguist examines the proposed rule

[11] This translation uses the same pre- and post-processing as our model, but employs a high-quality large language model as the translation engine.

against the sample and approves it if it correctly targets the issue.

3. Once validated, an automated process (a) extracts all affected items from the production database and (b) generates translation outputs for each item using the OpenAI model.

4. For each impacted item, the system presents four versions to the linguists, original translation with/without the rule applied and OpenAI translation with/without the rule applied.

5. Linguists review these four renderings side by side and assign one of the following outcomes to the rule: • Archive: The rule is unnecessary or counterproductive. • P0, critical: The rule addresses a serious error that must be enforced immediately. • P1, language flavor: The rule refines stylistic or regional preferences without correcting a critical error. • P2, minor style: The rule addresses superficial issues (e.g., capitalization, punctuation) that do not impact core meaning.

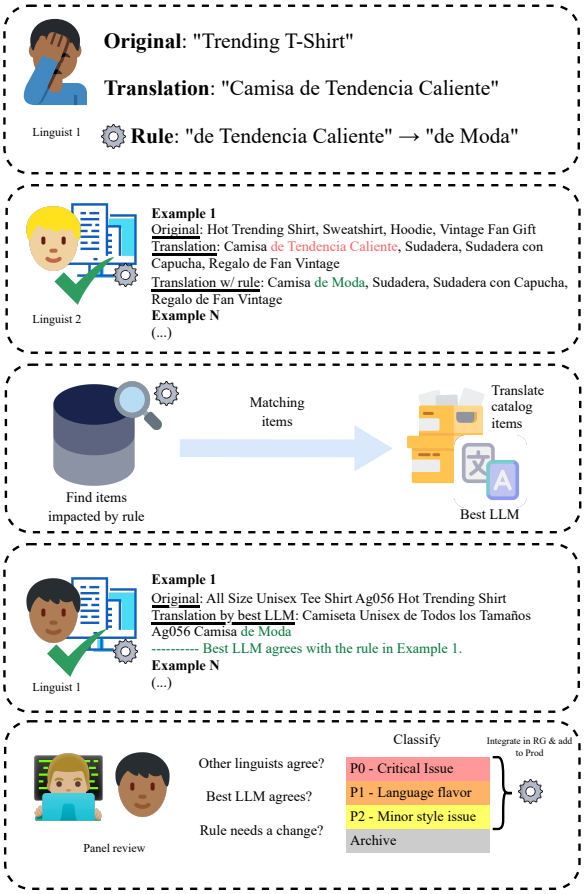

Figure 2: Translation Platform diagram from the translation flow perspective.

Model	Title ($)	Review ($)
Google Translate API	35.30	4.34
gpt-4o-2024-05-13	18.06	3.59
ours	0.17	0.10

Table 3: Translation average cost comparison by element type and model. The cost reflects the price for translating a batch of 1,000 elements.

In the final validation stage, linguists examine paired translation instances in which the OpenAI model either satisfies the newly introduced rule (rendering the rule redundant) or violates it (indicating that the rule remains necessary). Empirical analysis demonstrates that the OpenAI model conforms to the vast majority of rules classified as P0, whereas it frequently diverges from rules classified as P1 or P2. Notably, despite providing prompts intended to elicit regionally or stylistically "flavored" translations, the OpenAI model rarely produces such variants; as a result, linguists often formulate P1 rules to enforce flavor-specific output, but the OpenAI translations fail to satisfy most of these constraints.

4 Conclusions and Future Work

Our purpose-built translation platform combines daily "bootstrap" and hourly batch pipelines with a low-latency API, GPU-accelerated T5-based English→U.S. Spanish and English→Canadian French models, and a metadata-driven Reference Generator (fuzzy matching, RoBERTa classifier and curated white/blacklists for non-translatables) to enforce over 99% non-translatable entity preservation. A linguist-managed rule engine and an explainable evaluation framework with a custom e-commerce quality metric drive continuous improvements. In production, this system handles millions of listings per day with sub-second API latency, matches or exceeds state-of-the-art MT models in both translation quality and end-to-end throughput, and reduces costs by 10×–100× compared to general-purpose LLM deployments—all under semantic versioning and a Translation Tracking Table for enterprise-grade traceability and rollback.

Future work will explore more compact (distilled and quantized) model variants, broaden language support (e.g., Mandarin, Hindi), and enhance our rule-engine analytics and dynamic supervision features to further automate rule creation and refine localization quality.

Limitations

Despite being an e-commerce platform with hundreds of millions of listings, most of our attention is focused on items with high impressions. Consequently, our training and evaluation datasets, as well as our non-translatable whitelists and blacklists, and the data samples used for linguist feedback, are biased towards popular listings. While parts of our evaluation metrics and training data generation rely on state-of-the-art LLMs, we recognize that these systems are not perfect translators and may introduce their own biases (e.g., a tendency to shorten or summarize content). As these systems continue to improve, we are well positioned to quickly adapt and match their performance for our specific tasks, while maintaining high efficiency and low cost. Finally, our feedback and annotation platform has automated a significant portion of data sampling, rule impact evaluation and rule deployment. However, this process remains highly labor-intensive and exception-prone, requiring the involvement of multiple linguists over extended periods. In future work, we plan to explore more agentic capabilities, as well as more natural ways to express and apply constraint rules, to further increase the level of automation in rule creation.

A Model Serving Benchmark

Our internally hosted translation pipeline incurs costs primarily based on computational resources used, linking expenses directly to throughput and efficiency. Effective resource management not only increases performance, but substantially reduces operational costs.

A benchmark study (Figure 3 and Figure 4) comparing TorchServe[12], OpenNMT[13], and VertexAI[14] reveals the superior performance of OpenNMT, with consistently lower inference durations and higher translations per second at larger batch sizes. This efficiency directly translates into cost savings, especially evident when accumulating translations before processing. The cost calculations presented in Table 3 utilize this optimized OpenNMT framework.

[12]TorchServe: https://docs.pytorch.org/serve/

[13]OpenNMT: https://opennmt.net/

[14]VertexAI: https://cloud.google.com/vertex-ai

We recommend ongoing monitoring and optimization of batch sizes and resources to maintain scalability and efficiency. Future evaluations will include frameworks such as vLLM[15] and Text Generation Inference[16], and further model optimizations like quantization and distillation.

B Evaluation Data Availability

To promote transparency and open science, we provide a small evaluation sample of the task-specific data used during model development. This dataset includes titles, long text, specifications, and reviews for both En→Es (U.S.) and En→Fr (Canada) language pairs. The sampling process ensured an equal mix of varied popular items from top product categories, as well as a selection of random catalog items. The *text_translation* data was generated using an OpenAI GPT-4o model in combination with our Reference Generator, and serves as our gold standard data. We also provide the *non_translatables*, which are entities supplied by the seller that appear in the English *text_original* and must be preserved during translation. We hope the community can leverage this dataset to drive innovation in the protection of non-translatable named entities.

INSTAJUDGE: Aligning Judgment Bias of LLM-as-Judge with Humans in Industry Applications

Myeongjun Erik Jang[1] **Fran Silavong**[1]
[1]J.P. Morgan Chase
myeongjun.jang@jpmchase.com fran.silavong@jpmchase.com

Abstract

Automated evaluation using LLM-as-Judge offers significant practical benefits for industrial applications. However, the commonly recognized misalignment of judgment biases between humans and LLM-as-Judge hinders its usage in real-world businesses. Although preference-finetuning could be a potential solution, it is often impractical for industrial use-cases due to the scarcity of business-specific data and the infeasibility of applying it to closed models. In this paper, we propose INSTAJUDGE, an LLM-as-Judge library that improves alignments of judgment biases through automatic prompt optimization (APO). Our library not only integrates recent APO methods within a unified framework but also introduces a novel APO approach called distribution-preserving few-shot sampling (DPFS). Experimental results verify demonstrate DPFS significantly outperforms existing LLM-as-Judge libraries, like DeepEval, and APO methods by a large margin, while being more cost efficient.

1 Introduction

In light of recent notable achievements of large language models (LLMs), LLM-as-Judge (Zheng et al., 2023; Li et al., 2024b; Gao et al., 2025) has emerged as a compelling alternative to human evaluation, offering potential benefits to the industry by significantly lowering the costs associated with assessing the quality of AI applications. To ensure successful replacement of human evaluation with LLM-as-Judge, particularly for industrial purposes, it is an essential prerequisite to align the judgment bias of LLM-as-Judge with that of humans. However, numerous studies have demonstrated that the judgment biases of LLMs are often misaligned with those of humans (Koo et al., 2024; Chen et al., 2024), and they possess undesirable biases, which can be detrimental to reliable decision-making (Jang and Lukasiewicz, 2023; Wang et al., 2024; Wataoka et al., 2024; Levy et al., 2024b).

The most widely utilized and straightforward remedy to align judgment biases between LLMs and humans is fine-tuning with human-preference dataset, where many algorithms have been proposed for efficient fine-tuning (Go et al., 2023; Rafailov et al., 2023; Meng et al., 2024; Ethayarajh et al., 2024; Xiong et al., 2024; Kim et al., 2025). Nonetheless, these approaches are hardly applicable to industrial contexts. Firstly, industrial use-cases require business-oriented and task-specific judgment biases, necessitating the involvement of highly skilled annotators who possess in-depth business understanding to accurately annotate the data. Ultimately, this makes the collection of human-preference datasets significantly more costly. Secondly, preference fine-tuning algorithms require open models that allow access to logits and parameters. However, in industry applications, closed LLMs are also widely used because of the convenience of simply calling their APIs. For these models, preference fine-tuning is rarely feasible.

In this paper, we introduce a Python library named INSTAJUDGE, developed to address the alignment of judgment biases between humans and LLM-as-Judges in industrial applications. Instead of fine-tuning with a curated human-preference dataset, we employ automatic prompt optimization (APO) to learn judgment bias, in light of studies indicating that prompt engineering can contribute to the injection of biases into LLMs (Dwivedi et al., 2023; Torres et al., 2024). Specifically, our library supports the automatic discovery of the best task instructions and few-shot demonstrations, aiming to maximize human alignment by using a small amount of human-annotated dataset. To achieve this, we integrate DSPy (Khattab et al., 2024; Opsahl-Ong et al., 2024) and AdalFlow (Yin and Wang, 2025) into our INSTAJUDGE framework, enabling users to access both distinct libraries within our unified schema by simply specifying an option. Additionally, we introduce a novel method

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1158–1172
November 4-9, 2025 ©2025 Association for Computational Linguistics

called Distribution Preserving Few-shot Sampling (DPFS), a cost efficient approach to identify suitable few-shot demonstrations and can be employed alongside the task instruction optimization methods of both DSPy and AdalFlow.

INSTAJUDGE offers significant advantages over existing representative LLM-as-Judge libraries, such as DeepEval (Confidential-AI, 2025) and Opik (Comet, 2024), by providing APO to enhance human-alignment and allowing for a customized evaluation.[1] Experimental results on various real-business datasets also reveal that the proposed DPFS method significantly improves the human alignment across many industrial use-cases compared to DSPy and AdalFlows. It also achieves approximately a 64% improvement in alignment with human preferences compared to zero-shot LLM-as-Judges without utilizing APO.

2 INSTAJUDGE Library

Building upon prior research regarding APO, we conceptualize a prompt as a combination of task instructions and few-shot demonstrations.

2.1 Supported Functionalities

Our library supports three types of APO methods, allowing users to run both existing approaches and our own contribution with just a few lines of code. Note that a certain amount of human-annotated training data, usually between 20 to 50, is required.

DSPy (Khattab et al., 2024) can be characterized as an APO algorithm that operates in a grid search manner. The algorithm initiates the process by generating potential candidates for improved task instructions and few-shot demonstrations using LLMs. Subsequently, it seeks to determine the optimal combination of task instruction and few-shot demonstrations that maximizes performance based on predefined evaluation criteria, such as accuracy on the training dataset. While grid search is ideal for finding the optimal solution, its computational cost is prohibitively high. Therefore, DSPy employs Bayesian optimization as a more efficient alternative.

AdalFlow (Yin and Wang, 2025) is an algorithm that utilizes TextGrad (Yuksekgonul et al., 2024) for APO. As clarified in the original paper, the term 'gradient' in TextGrad is metaphorical rather than mathematical, referring to textual feedback generated by LLMs. The process consists of two steps: a forward pass and a backward pass. During the forward pass, an LLM generates a prediction based on an initial prompt and an input instance, followed by a feedback generation step, in which the LLM produces evaluative feedback on the prediction considering the corresponding ground-truth label and a predefined evaluation criterion. The backward pass then begins with the improvement suggestion stage, where the LLM generates suggestions to refine the prediction based on the previously generated evaluative feedback. Finally, the LLM prompted to generate an updated prompt based on the original prediction and the improvement suggestions, with the goal of improving subsequent predictions.

DPFS Based on the recent study that shows the impact of accurate human-written reference (Krumdick et al., 2025), we introduce DPFS for constructing optimal few-shot demonstrations. Unlike DSPy and AdalFlow, which incorporates LLM-generated examples, DPFS only employs human-written data. It is worth mentioning that DPFS can be applied independently or integrated with the task instruction optimization methods of DSPy or AdalFlow.

Algorithm 1 SAMPLING process of DPFS.

Input: labeled dataset $D = \{(x_1, y_1), ..., (x_M, y_M)\}$, $Y = (y_1, ..., y_M)$, the number of few-shot examples N
Output: Extracted few-shot example set S

```
S = []                                  ▷ Initialize an empty list
for i = 1, ..., |UniqueSet(Y)| do
    P_{Y=i} = Dist(D)                   ▷ Compute probability of label i from D
    n̂ = min(int(N × P_{Y=i}), 1)        ▷ Determine the number of samples to extract for label i
    S_i = RandSample(D_{Y=i}, n̂)        ▷ Random sample n̂ examples with label i
    S += S_i
end for
return S
```

Our approach consists of two processes, SAMPLING and SELECTION. The human label distribution reflects certain biases existing in human judgment (Haliburton et al., 2024). For example, consider an annotation task with label scales ranging from 1 to 5, where the higher scores imply better quality. Provided an annotator has strict judgment

[1] DeepEval and Opik only provide zero-shot inference and numerical evaluation scores within a fixed range.

biases, more training examples are likely to receive lower scores. Conversely, more lenient judgment biases will lead to a higher frequency of high-score labels. Therefore, the SAMPLING process is crafted to select few-shot examples while preserving the label distribution of the training data, aiming to better align the evaluation criteria of LLMs with those of human annotators. The detail of SAMPLING process is demonstrated in Algorithm 1. It is easy to find that the SAMPLING process is similar to the stratified sampling of the `scikit-learn` Python package, with the key difference being that the SAMPLING process guarantees at least one sample is selected for each label.

While the SAMPLING process preserves the ground-truth label distribution, it only reflects superficial judgment biases. Also, it can produce multiple few-shot sets with no clear indication of which set is optimal. The SELECTION process is thus implemented to determine which candidate few-shot set might be optimal. We established the guideline that the most effective set is the one where the LLM makes the most errors, allowing the model to correct its judgment bias with more accurate information. The entire process of DPFS method is demonstrated in Algorithm 2.

Algorithm 2 The entire DPFS process.

Input: labeled dataset $D = \{(x_1, y_1,), ..., (x_K, y_M,)\}$, $Y = (y_1, ..., y_M)$, the number of few-shot examples N, the number of few-shot example set to investigate K, an LLM $\mathcal{M}$
Output: Optimized few-shot example set O

C = [] ▷ Initialize an empty candidate list
S = [] ▷ Initialize an empty score list
for j = 1, ..., K **do**
  O_j = SAMPLING(D, N) ▷ Run Algorithm 1
  X_j, Y_j = DividePairs(O_j) ▷ Divide O_j into inputs and labels
  $\hat{X}_j = \mathcal{M}(X_j)$ ▷ Generate predictions of X_j with the LLM
  $\mathcal{A}_j$ = Alignment($\hat{X}_j$, Y_j) ▷ Compute the alignment score with human annotations
  C.append(O_j)
  S.append($\mathcal{A}_j$)
end for
idx = argmin(S)
$O = C$[idx]
return O

DPFS provides a great advantage in terms of computational cost. Let n denotes the number of few-shot examples, N represents the size of the training set, I indicates the number of iterations for APO, and K signifies the number of few-shot sets to be examined. As both DSPy and AdalFlow involve generating few-shot examples and making predictions on training examples to calculate the evaluation criterion for each iteration, the number of LLM calls is proportional to $O(n \times N \times I)$. In contrast, DPFS invokes LLM only $O(n \times K)$ times. Given that I and K are relatively small and often have similar values (e.g., 10), DPFS requires significantly few LLM calls compared to DSPy and AdalFlow, thereby reducing the optimization time. In practice, the APO time of DPFS was 2.2 and 5.1 times fewer than DSPy and AdalFlow on average, respectively.

Self-consistency decoding (Wang et al., 2023) is a strategy that involves generating multiple reasoning paths (N) and their corresponding outputs, then aggregating these outputs to arrive at the final answer. Our library supports this decoding strategy to ensure more robust and precise predictions.

2.2 Overview of Basic Usage

Prompt Configuration. The initial and fundamental step in utilizing our library involves defining the prompt configuration in JSON format, which consists of `InputFields`, `OutputFields`, and `Instruction`. The `InputFields` and `OutputFields` demonstrate all the variables necessary for conducting a task that we intent LLMs to perform. For example, if an intended task is to evaluate the relevance of a QA model's response to a user's question, the `InputFields` would encompass variables such as '`user_question`' and '`model_response`', whereas the `OutputFields` would include a '`relevance_score`' variable. The `Instruction`, as implied by its name, outlines a free-text description detailing the specifics of the objective task. The categories or scales of the evaluation can be demonstrated within task instruction. Figure 3 in Appendix C illustrates an example of the prompt configuration. The created prompt configuration will automatically converted into the necessary prompt-related components, such as `Signature` for DSPy and `AdalFlowBaseData` for AdalFlow.

INSTAJUDGE Navigator. In INSTAJUDGE, the entire process is facilitated by the `InstaJudgeNavigator`. In addition to the

prompt configuration and LLM client, specifying the APO options is needed as outlined below.

```python
from instajudge import InstaJudgeNavigator

navigator = InstaJudgeNavigator(
    client=client,
    config=prompt_config,
    engine="dspy",
    instruction_opt="dspy",
    few_shot_opt="dist_preserve",
    eval_type="exact_match",
)
```

APO options require three hyperparameters:

1. `engine` (dspy, adal): a backbone framework that LLM-as-Judge employs.
2. `instruction_opt` (None, dspy, adal): a task-instruction APO method.
3. `few_shot_opt` (dspy, adal, dist_preserve): a few-shot demonstration APO method.
4. `eval_type`: evaluation criterion option.

The `instruction_opt` and `few_shot_opt` must be assigned identical values if configured to either 'dspy' or 'adal'. When the `few_shot_opt` is set to `dist_preserve` (DPFS), the `instruction_opt` can be configured as either 'dspy' or 'adal'. If the intention is to perform APO without including task instructions, the value can be assigned as `None`. The `eval_type` serves an option to specify the evaluation criterion. We offer support for two basic metrics: exact-match and fuzzy-match, but customization is also possible.

Once the `InstaJudgeNavigator` is created, APO and inference can be easily conducted using the `optimize` and `predict` APIs, as shown in Figure 4 in Appendix C. Without running APO, the navigator will carry out zero-shot inference.

3 Experiment Design

For experiments, we applied INSTAJUDGE to two tasks, topic modeling evaluation and retrieval-augmented generation (RAG)-based question answering (QA) evaluation, across four real-world industrial use-cases. LLM-as-Judge was employed to evaluate the quality of model outputs.

3.1 Task and Dataset

For each use-case, 3 to 5 Anglophone annotators participated in the data annotation process, with the exact number varying depending on the individual use-case. Annotators received training based on detailed guidelines that outlined the annotation dimensions, corresponding labels, as well as examples. Each instance was annotated by a single annotator, who also provided a justification for the assigned label. After annotation, reviewers examined both the labels and their justifications. If a reviewer disagreed with a label, they returned the instance to the annotator along with the reason for rejection, and the instance was re-labeled. The average agreement rate between reviewers and the initial labels was 93%. Table 2 shows the basic statistics for each dataset.

Topic modeling evaluation aims to evaluate the quality of our in-house topic modeling tool on two industrial use-case dataset. The **C**ustomer **C**hatbot **C**onversation (CCC) dataset consists of conversation logs from a customer banking chatbot application. The **C**ustomer **I**ssue dataset provides brief summaries of issues raised by customers during their daily banking activities. Our in-house topic modeling tool assigns a topic for each text, which is then evaluated by human evaluators to create ground-truth scores according to the evaluation dimensions described in Table 1. These are excellent industrial use-cases that demonstrate how even similar tasks can exhibit distinctive human judgment biases depending on the annotation guidelines and business needs.

RAG QA evaluation focuses to assess the quality of responses of our in-house RAG-based QA models considering user questions. The **Gen**erative-**AI** (GenAI) provides users' questions along with their corresponding HTML-formatted response. The SearchQA dataset includes users' questions, their respective responses, and the citations retrieved to answer those questions. Analogous to the topic modeling evaluation task, human evaluators annotated the ground-truth labels for each evaluation dimensions outlined in Table 1.

3.2 Experiment Framework and Settings

For each evaluation dimension, LLM-as-Judge takes inputs and outputs of the model, and predicts the assessment results. These predicted results are then compared with human-annotated ground-truth to calculate the human alignment. In accordance with previous studies, we used the F1-score ($\mathcal{F}_w$) for categorical dimensions and Pearson correlation ($\mathcal{P}_r$) for numerical dimensions as measures of human alignment (Bai et al., 2023; Liu et al., 2024; Thakur et al., 2024). Regarding initial prompt designs, task instructions outlined in Appendix B are used without any few-shot examples. This prompt

Dataset	Dimension	Description
CCC & CI	Level of detail (LD)	categorical; evaluate whether the topic offers enough detail for the text under four categories: *Not applicable*, *Optimal*, *Too broad*, *Too detailed*.
	Topic completeness (TC)	numerical; evaluate whether there are any additional topics present in the given text but missing, using an integer scoring from 1 to 4.
	Topic accuracy (TA)	numerical; evaluate how accurate the topic is and well represented in the given text, using an integer scoring from 1 to 4.
GenAI	Relevance (R)	numerical; evaluate the relevance of the response to the user's question, using an integer scale from 0 to 4
	Helpfulness (H)	numerical; evaluate how helpful the response is the user's question, using an integer scale from 0 to 4.
	Formatting (F)	numerical; evaluate the response for adherence to HTML format, using an integer scale from 0 to 4.
SearchQA	Usefulness (U)	numerical; evaluate the overall usefulness of the response considering the user's question, using an integer scale from 1 to 3
	Retrieval quality (RQ)	numerical; evaluate the quality of the retrieved citations, ensuring they are sufficient to answer the question, using an integer scale from 1 to 4.

Table 1: Business-defined demonstrations of the evaluation dimensions for each industrial use-cases.

Dataset	CCC	CI	GenAI	SearchQA
# of data	1250	120	111	100
Avg # of tokens	120	21	220	6.1K (1.5K)

Table 2: The basic statistics of industry datasets. The parenthesis in SearchQA implies the average number of tokens without retrieved documents.

design is either updated following APO or used as-is for zero-shot inference. Throughout the experiments, `gpt-4o-2024-05-13` was used as the backbone LLM. Performance was measured using 5-fold cross-validation, with the average score of the five folds is reported.

We evaluated the performance of four different APO methods for both DSPy and AdalFlow engine:

- `Inst_only`: focuses solely on optimizing the the task instruction.
- `Inst_demos`: optimizes both the task instruction and few-shot demonstrations.
- `DPFS`: exclusively utilizes the proposed DPFS approach.
- `Inst_DPFS`: combines DPFS with task instruction optimization using the selected engine.

All methods are applied using equivalent hyperparameter settings, with detailed information available in Appendix A.1. For baseline approaches, we selected zero-shot LLM-as-Judge without APO for each of DSPy and AdalFlow engines, and included DeepEval as an existing library baseline. Opik was omitted because both DeepEval and Opik employ G-Eval method (Liu et al., 2023). DeepEval's performance is only measured solely on numerical dimensions, as it is designed to generate only numerical outputs.

4 Experimental Results

The experimental results are presented in Table 3.

Comparison with DeepEval The experimental results confirm the advantage of INSTAJUDGE APO over DeepEval, showing an immeasurable improvement in the CCC dataset and an average performance gain of 110% in other use-cases. The performance gap is statistically significant across all dimensions (p-value < 0.05, t-test), except for the RQ dimension in the SearchQA use-case. Even without APO, zero-shot INSTAJUDGE for both engines generally outperforms DeepEval, which highlights the importance of aligning the scale of the evaluation dimension. Moreover, INSTAJUDGE enables customization of the evaluation dimension schema, offering a practical benefit for applying it to categorical evaluation dimensions-a feature that DeepEval does not offer.

Performance gain through APO The results show that all the APO methods are effective in enhancing human alignments across all our industrial use-cases. The greatest of performance is achieved by `Inst_DPFS`, with an average increase of 64% compared to zero-shot Judge, followed by `DPFS`, which exhibits an average improvement of 56%. The average improvement of `Inst_demos` and `Inst_only` is 36% and 27%, respectively. Table 3 also reveals that, in most cases, `Inst_DPFS` consistently ranks as the top performer for each engine, closely followed by `DPFS` with only marginal differences. It is worth emphasizing that using only `DPFS` not only outperforms `Inst_demos` and `Inst_only`, but also requires three times less running time for APO. The simplicity and cost efficiency of our proposed approach offer practical advantages over the existing APO algorithms. However, no significant improvements was observed in the RQ dimension of the SearchQA use-case. We

Engine	Method	CCC			CI			GenAI			SearchQA

Table 3: The results from the experiments conducted on industrial use-cases. $\mathcal{F}_w$ and $\mathcal{P}_r$ denote weighted F1-score and Pearson correlation, respectively. The best performance for each evaluation dimension is highlighted in bold, while the top performance for each engine (DSPy, AdalFlow) is underlined. The performance of DPFS or Inst-DPFS show a statistically significant difference compared to that of the best-performing baseline APO method with p-value < 0.05 (*) using the t-test.

will discuss this further in the following section.

Self-consistency decoding We applied self-consistency decoding to the top-performing models for each evaluation dimension to ascertain if it could further enhance the human alignment scores. The results are illustrated in Figure 1. With N set to 5, the results show an average performance improvement of 6%, indicating the positive impact of the decoding strategy. However, the SearchQA-RQ dimension showed no improvement, consistent with the pattern observed in the APO experiments. We hypothesized that a primary reason of this phenomenon is the lengthy inputs of the task.[2] It is widely accepted that lengthy inputs elevate the level of task difficulty, which rapidly degrades LLMs' reasoning ability (Bai et al., 2024; Li et al., 2024a), even on input length of 3K tokens (Levy et al., 2024a). To assess the task difficulty, we calculated the entropy of N outputs from self-consistency decoding, since the answers should be diverse for ambiguous and challenging tasks. Interestingly, the entropy of SearchQA-RQ was the highest at 0.86, while the others averaged 0.36 ± 0.19. This supports our claim that SearchQA-RQ is far more challenging than others due to its lengthy inputs.

To investigate further, we examined whether increasing N, the number of distinct reasoning paths in self-consistency decoding, would improve performance. The experiment was focused on SearchQA-RQ dimension, as it was the only dimension where APO showed a negative performance gain. The results are presented in Figure 2. The results indicate that the human alignment score increases directly proportional to N. Additionally, as N increases, the entropy of the multiple responses decreases, suggesting that the decision-making process becomes less ambiguous.

DSPy vs. AdalFlow The results in Table 3 show that DSPy and AdalFlow exhibit significant performance differences, even in the zeroshot setting, that is, when given identical task instructions. This can be attributed to differences in their underlying prompt structures. For example, AdalFlow enforces strict output formats (e.g., JSON or YAML), whereas DSPy generates natural language responses. In general, DSPy outperforms AdalFlow in most evaluation dimensions, consistent with previous research (Tam et al., 2024) that ascertains the negative impact of format restrictions on LLM performance. However, AdalFlow outperforms DSPy in the GenAI-Format and CCC-LD dimensions, and demonstrates comparable performance in the CI-LD dimensions. We believe that these results are largely influenced by the difficulty of the tasks. Consider a simple optimization task in which the loss function is defined over a perfectly convex space. In such a scenario, the SGD optimizer can easily converge to the optimal solution. However, in more complex landscapes characterized by numerous saddle points, SGD becomes less effective, whereas grid search may more reliably identify the optimal solution. Similarly, for straightforward tasks where TextGrad can provide constructive feedback to guide prompt updates, AdalFlow demonstrates advantages. Conversely, DSPy, which utilizes Bayesian optimization, is better suited for challenging tasks where obtaining reliable feedback for prompt updates is difficult.

[2] An average of 6.1K tokens and a maximum 13K tokens.

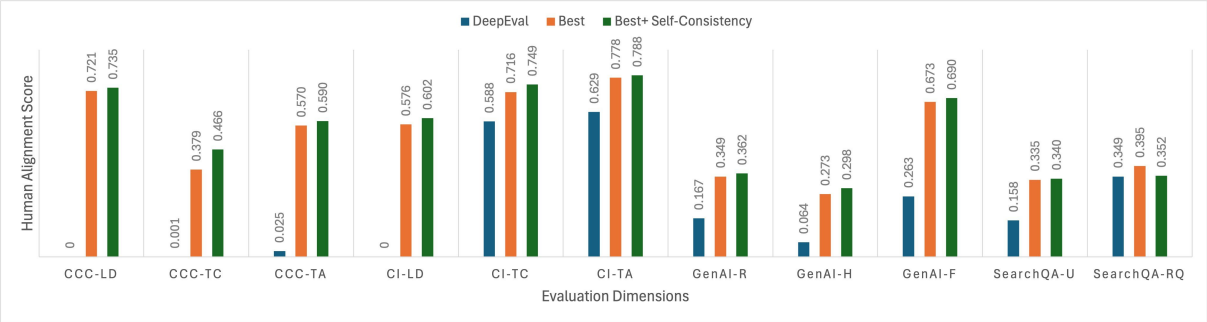

Figure 1: Self-consistency decoding ($N = 5$) performance on the best model for each evaluation dimension.

Method	Knowledge Acc. |Tr|=30 / |Test|=124	Reasoning Acc. |Tr|=10 / |Test|=41	Math Acc. |Tr|=6 / |Test|=28	Coding Acc. |Tr|=6 / |Test|=25	Overall
zero-shot	.361	.600	**.400**	**.500**	.465
Inst-only	.361	.600	**.400**	**.500**	.465
Inst-demos	.467	.600	.333	.444	.461
DPFS	**.565**	**.636**	.333	**.500**	**.509**
Inst-DPFS	**.565**	**.636**	.333	**.500**	**.509**

Table 4: Experimental results on JudgeBench dataset. |Tr| and |Test| represents the size of training and testing set, respectively. The best performances are highlighted in bold. The number of few-shot examples was set to 4.

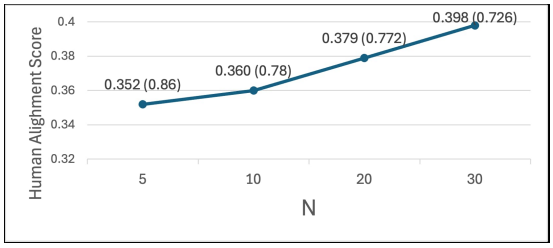

Figure 2: Self-consistency decoding performance with different N on SearchQA-RQ dimension. The value in parentheses indicates the entropy of N answers.

We validated our assumption by measuring the entropy of self-consistency decoding outputs. Tasks where AdalFlow performed better or comparably had an average entropy of 0.152, versus 0.5 for others, indicating its suitability for less-challenging tasks.

5 JudgeBench Evaluation

As our industrial experiments focused on our in-house dataset, we additionally conducted an experiment on publicly available JudgeBench dataset (Tan et al., 2025). In brief, the task involves selecting the better response from two LLM-generated candidates when presented with a question. There are two types of datasets the responses are generated by `claude-3-5-sonnet-20240620` and `gpt-4o-2024-05-13`. We used the former to avoid egocentric bias (Koo et al., 2024), as `gpt-4o-2024-05-13` was the backbone LLM for our experiments. Basically, we followed the identical experiment settings as outlined in the paper, with the only difference being that we used 20% of data as a training set to run APO.

The results are presented in Table 4. As in the industrial experiments, our proposed approaches achieved the best overall performance. However, when looking at each individual domain, an interesting trend emerges: the performance gain is directly proportional to the size of the training set, with a substantial improvement observed in `Knowledge` domain, but no improvement in `Math` and `Coding`. This trend was not observed in the aforementioned industrial experiments discussed, where at least 20 examples were used for the training set. The results indicate that it is essential to collect sufficient training set for running APO effectively.

6 Conclusion

In industrial applications, the judgment biases of LLM-as-Judge and humans are more likely to diverge due to domain specificity, necessitating alignment to ensure fair evaluations and facilitate practical deployments. In this paper, we propose INSTAJUDGE, an LLM-as-Judge library that supports APO by integrating DSPy and AdalFlow within a unified framework. It also offers DPFS, which outperforms existing APO methods despite its cost-efficiency, and self-consistency decoding to enable more robust evaluations. Our library offers practical benefits over existing LLM-as-Judge libraries, like DeepEval, by improving human alignment performance APO and enabling flexible evaluation schema customization.

Limitations

While the proposed DPFS and existing APO methods exhibited promising improvements in human alignment scores across various industrial use-cases and evaluation dimensions, they made only modest enhancements in challenging tasks involving lengthy text inputs. Future work should focus on developing more advanced approaches to address this issue. Regarding self-consistency decoding, we ascertained that it contributes to generating more robust and precise evaluation results, where the improvements are more promising with large N. However, this also leads to an increase in the number of LLM calls, which can be resource-intensive. Utilizing more resource-efficient decoding strategies, such as adaptive self-consistency (Aggarwal et al., 2023) can enhance the practical efficiency of our library. Additionally, our proposed DPFS approach has a limitation related to randomness, particularly when the initial prompt performs poorly. A major factor contributing to this phenomenon is the algorithm's approach of selecting instances where LLMs make incorrect predictions as few-shot examples. As a result, if LLMs perform poorly with the initial prompt design, a large number of candidate sets for few-shot examples can be generated, increasing the randomness. Future work should aim to minimize this randomness issue in order to achieve more consistent performance. Finally, the experimental results on the JudgeBench dataset suggest the importance of having a sufficient amount of training data.

A Appendix

A.1 Hyperparameters for APO

DSPy and AdalFlow The two approaches share identical hyperparameters for few-shot demonstration optimization, which are configured as follows:

- `n_raw_shots`: the number of demonstrations to be drawn from training data.
- `n_bootstrap_shots`: the number of demonstrations to be generated by LLMs.

Both hyperparameters were set to a value of 4. AdalFlow requires two additional hyperparameters, `train_batch_size` and `n_steps`, which are akin to the concept of batch-size and epochs in gradient descent. The values were set to 8 and 10, respectively. Similarly, DSPy also requires `n_steps`, which represents the number of iterations for running Bayesian optimization. Additionally, `n_candidates` must be specified for task instruction optimization, indicating the number of potential candidates to be generated by the LLM for Bayesian optimization. We set both `n_steps` and `n_candidates` for DSPy to 10.

Hyperparameters for DPFS Two hyperparameters need to be specified to run DPFS. The first one is `n_shots`. As DPFS only employs the raw training examples and does not utilize LLM-generated demonstrations, the value is set to 8, which is the sum of `n_raw_shots` and `n_bootstrap_shots` of DSPy and AdalFlow. The second hyperparameter is `K`, the number of candidate few-shot sets for the selection process. We set the value to 10.

A.2 Binned-JSD Metric Results

Relying on a single aggregate correlation metric can dilute significant differences between human labels and those generated by automatic evaluation (Elangovan et al., 2025). Therefore, it is important to compare not just a single aggregate correlation scores, but also the overall correlation between human labels and machine-generated labels. In this regard, we additionally measured Binned-JSD score (Elangovan et al., 2025), where the lower scores are the better.

The results are presented in Table 5. Overall, we observed a similar trend to the results in Table 3. Apart from the SearchQA-RQ dimension, DPFS and Inst-DPFS achieve the best performance, showing significant improvements over zero-shot method in most of dimensions across the use-cases. However, a different pattern emerges, with the best performance mostly achieved by the Adal engine, in contrast to Table 3, where DSPy outperformed the Adal engine. The results provide further supports to the claim made by Elangovan et al. (2025), highlighting the importance of measuring both single-aggregate and overall correlation metrics.

B Prompt Designs

This section presents the task instructions utilized to create the initial prompt designs. The instructions were proposed by our business teams. For the DeepEval experiments, we modified the section regarding evaluation scores to align with DeepEval's scale (0 - 1).

B.1 CCC and CI Datasets Task Instructions

The CCC and CI datasets share the same evaluation dimensions. Therefore, we employed the same task instructions.

B.1.1 Level of Detail

```
We will show you a topic assigned to the given text. Your task is to evaluate whether the topic covers the appropriate amount of detail of the text

You should evaluate the level of detail in four levels: Not applicable, Optimal level of detail, Too broad, and Too detailed. The definitions of each level are as follows:

- Not applicable: The topic assigned to the text is completely incorrect.
- Optimal level of detail: The amount of detail present in the topic matches the level of detail that is desired by the business OR The topic category is broader than the desired level of detail, but it maximally leverages the amount of detail present in the text.
- Too broad: The amount of detail present in the topic is lacking, and there exists more detail that could have been leveraged in the text.
- Too detailed: The amount of detail present in the topic exceeds the amount of detail that is desired by the business.
```

B.1.2 Topic Completeness

```
We will show you a topic assigned to the given text. Your task is to evaluate the
```

Engine	Method	CCC			CI			GenAI			SearchQA

Table 5: The Binned-JSD metric scores generated from the experiments conducted on industrial use-cases. The best performance for each evaluation dimension is highlighted in bold, while the top performance for each engine (DSPy, AdalFlow) is underlined.

completeness of the topic, indicating the extent to which all necessary and relevant information is included. The complete topic means:

1) The topic covers all the necessary information presented in the text, suggesting that there are no missing topics.

2) The topic delivers an optimal level of information, meaning that the scope it covers does not contain unrelated information in relation to the text.

You should evaluate the topic completeness using four level of scores: 1 (Not covered), 2 (Minorly covered), 3 (Mostly covered), and 4 (Complete).

B.1.3 Topic Accuracy

We will show you a topic assigned to the given text. Your task is to evaluate the accuracy of the topic over the given text; how accurate the topic is and well represented in the given text.

You can ignore the level of granularity / detail. Please just assess if the topic is accurate given the text in any level of detail.

You should evaluate the topic accuracy in four level of scores: 1 (Incorrect), 2 (Partially Correct), 3 (Mostly Correct), and 4 (Completely Correct). The definitions of each level are as follows:

- 1 (Incorrect): The details in the topic is not represented in the text in any way. The topic label is completely wrong or directly contradicting the text.
- 2 (Partially correct): The details of the topic is partially represented in the text. There is some relevance of the topic label to the contents in the text.
- 3 (Mostly correct): The details of the topic is mostly represented in the text.
- 4 (Completely correct): All the details of the topic are represented in the text.

B.2 GenAI Task Instruction

B.2.1 Relevance

We will give you a question from a user and a corresponding response, which is written in HTML format. Evaluate the relevance of a given HTML-formatted response to a user's question on a scale from 0 to 4.

Steps

1. Read the user's question.
2. Read the HTML-formatted response.
3. Assign a score from 0 to 4 based on the relevance of the response.

Notes

- A score of 0 means the response is not relevant to the question.
- A score of 4 means the response is very relevant to the question.

B.2.2 Helpfulness

We will give you a question from a user and a corresponding response, which is written in HTML format. Evaluate the helpfulness of a given HTML-formatted response to a user's question on a scale from 0 to 4.

Steps

1. Read the user's question.

2. Read the HTML-formatted response.

3. Assign a score from 0 to 4 based on the helpfulness of the response.

Notes

- A score of 0 means the response is not helpful at all.

- A score of 4 means the response is very helpful.

- Consider the accuracy, completeness, and clarity of the response when assigning a score.

B.2.3 Formatting

We will give you a response for a question, which is written in HTML format. Evaluate the given response for adherence to HTML format on a scale from 0 to 4.

Consider the following criteria when evaluating:

- Proper use of HTML tags.

- Correct nesting of tags

- Proper closing of tags.

- Valid attribute usage.

- Overall structure and syntax.

Steps

1. Analyze the HTML response for proper use of HTML tags.

2. Check for correct nesting of tags.

3. Ensure all tags are properly closed.

4. Verify the validity of attribute usage.

5. Assess the overall structure and syntax of the HTML.

Notes

- A score of 0 indicates very poor adherence to HTML format, while a score of 4 indicates perfect adherence.

- Consider edge cases such as self-closing tags and special characters.

B.3 SearchQA Task Instruction

B.3.1 Overall Usefulness

We will show you a question and its corresponding HTML-formatted response. Your task is to evaluate whether the response is useful enough to share with an external client considering the question.

You should evaluate the overall usefulness in three levels of scores: 1 (LESS_USEFUL), 2 (AS_USEFUL), and 3 (MORE_USEFUL).

The definitions of each level are as follows:

- 1 (LESS_USEFUL): The response was lacking critical details, had outdated information, or contained severe hallucination issues.

- 2 (AS_USEFUL): The response may need some modifications to improve quality.

- 3 (MORE_USEFUL): The response is fully useful and can be shared with external clients without modification.

B.3.2 Retrieval Quality

We will show you a question, its corresponding response, and a list of retrieved citations, which were used for generating the response.

Your task is to evaluate the quality of the retrieved citations, implying that the citations are sufficient enough to answer the question.

You should evaluate the retrieval quality in four levels of scores: 1 (ALL_CITATIONS_IRRELEVANT_USELESS), 2 (ALL_CITATIONS_INSUFFICIENT), 3 (CITATIONS_CAN_ANSWER), 4 (SOME_CITATIONS_PARTIALLY_ANSWER).

The definitions of each level are as follows:

- 1 (ALL_CITATIONS_IRRELEVANT_USELESS): All documents are irrelevant and useless.

- 2 (ALL_CITATIONS_INSUFFICIENT): All documents are insufficient to answer the question.

- 3 (SOME_CITATIONS_PARTIALLY_ANSWER): Some documents contain details that can partly answer the question.

- 4 (CITATIONS_CAN_ANSWER): Documents can answer the question completely.

Abstract

As Large Language Models (LLMs) evolve into powerful agentic systems, the telecommunications industry's expansion into AI services necessitates industry-grounded benchmarks to evaluate their underexplored domain-specific capabilities. To address the gap left by generic benchmarks that fail to assess realistic, non-English performance, we present TelAgentBench, a Korean benchmark for the telecommunications domain evaluating five core agentic capabilities: Reasoning, Planning, Action (tool-use), Retrieval-Augmented Generation, and Instruction Following. Evaluations reveal significant performance disparities between models that employ explicit reasoning and those that do not, providing actionable insights for deploying agentic LLMs in real-world telecommunications tasks.

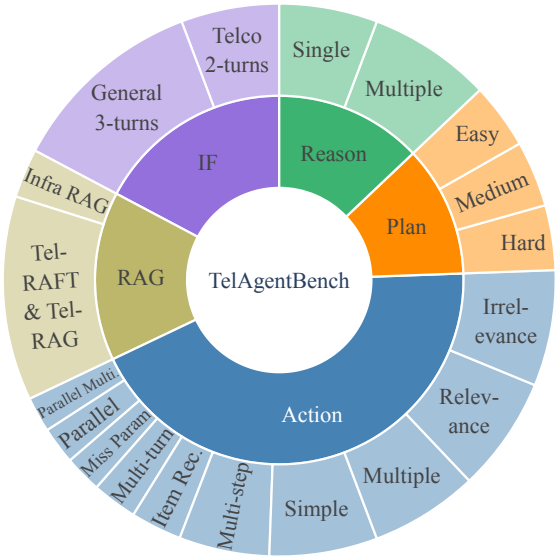

Figure 1: The overall composition of TelAgentBench. The benchmark is designed to evaluate five core capabilities of telecom-domain agents. It structured to reflect real-world service contexts while enabling systematic performance evaluation.

1 Introduction

As the capabilities of Large Language Models (LLMs) have diversified, their application as autonomous agents is rapidly expanding. Frameworks such as Toolformer (Schick et al., 2023), ReAct (Yao et al., 2023), and MRKL (Karpas et al., 2022) have enabled LLMs to develop key agentic capabilities, including Action, Reasoning, and Retrieval-Augmented Generation (RAG). These enhancements drive the transformation of LLMs into agentic services, and there is a growing industry demand to deploy these models in real-world applications to foster service innovation.

The telco industry is expanding beyond its traditional role as a Mobile Network Operator (MNO), incorporating lifestyle-integrated services that require advanced AI capabilities. For example, services now aim to summarize conversations to generate schedules or manage entire travel itineraries for roaming customers, from booking flights to reserving restaurants. This growing complexity necessitates robust, AI-driven customer service solutions. Consequently, contemporary agentic LLMs are emerging as a foundational technology for the telco service ecosystem. It is therefore crucial to evaluate how effectively these agents can assist customers in realistic service interactions, making a service-oriented benchmark that mirrors commercial environments essential.

The key contributions are as follows:

- **A Multi-faceted Agentic Benchmark for Telecom Services:** We identify five core agentic capabilities essential for real-world Telco service operations: Reasoning, Planning, Action, RAG, and Instruction Following (IF). We construct TelAgentBench, a benchmark of over 1,700 instances for these capabilities, releasing its general subset for cross-industry use.[1]

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1173–1211
November 4-9, 2025 ©2025 Association for Computational Linguistics

- **A Synthetic Benchmark for Privacy and Local Context:** The benchmark is synthetically generated to ensure evaluation utility while mitigating the risks of personal information disclosure. Recognizing the need to assess performance in the linguistic context of real-world deployment, we construct our benchmark in Korean. We share our data construction methodology to enable researchers to adapt the benchmark to other domains.
- **Multi-faceted Performance Analysis of Major LLMs:** We provide a comprehensive performance analysis of 15 leading LLMs. Our results reveal a significant performance gap between thinking and non-thinking models, empirically demonstrating the critical role of explicit reasoning in complex agentic tasks. These findings offer practical insights for model selection in commercial service applications.

2 Background and Related Work

Early evaluations of Large Language Models (LLMs) focused on fundamental NLP tasks such as knowledge retention and intent classification. With the advent of agentic capabilities, attention has shifted toward more complex, multifaceted evaluations. Recent benchmarks have been developed to assess specific agentic skills, including function calling (BFCL (Yan et al., 2024); MMAU (Yin et al., 2024)), instruction following (IFEval (Zhou et al., 2023)), planning (TravelPlanner (Xie et al., 2024); MuSR (Sprague et al., 2024)), retrieval (RAGAS (Es et al., 2025)), and multi-step reasoning (HotpotQA (Yang et al., 2018); StrategyQA (Geva et al., 2021)). While frameworks such as BiGGen Bench (Kim et al., 2025) provide valuable guidance for building comprehensive agentic assessment systems, existing evaluations are often not grounded in specific industry contexts.

To address this gap, several specialized benchmarks have emerged to evaluate agentic capabilities in domain-specific contexts, such as MedAgentBench (Jiang et al., 2025) for clinical decision-making and LegalAgentBench (Li et al., 2024) for legal reasoning. However, the construction of agentic evaluation data in specialized domains requires substantial industry expertise and is resource-intensive; consequently, such benchmarks remain scarce.

Although a few studies have released datasets to evaluate model capabilities in the telecommunications domain, they exhibit important limitations. For instance, TeleLogs (Sana et al., 2025) targets Root Cause Analysis (RCA) within 5G network operations, TeleQnA (Maatouk et al., 2025) is a single-turn QA dataset focused on mobile-network knowledge, and TelecomGPT (Zou et al., 2024) extends to math and coding tasks but omits agentic evaluation. While TelBench (Lee et al., 2024) moves from basic capabilities (e.g., intent classification) to assessing workflows via the TelInstruct benchmark set, it remains an early-stage exploration of agentic evaluation.

3 TelAgentBench Dataset Construction

Building on observations of business requirements, we distill five core agentic capabilities to facilitate industry-grounded evaluation: Reasoning, Planning, Action (tool use), Retrieval-Augmented Generation, and Instruction Following. These capabilities jointly cover the end-to-end agent workflow in real-world deployments, from initial reasoning and planning to tool-assisted action, retrieval-based grounding, and compliance with user constraints. The dimensions are designed to be sufficiently orthogonal to enable diagnostic evaluation under practical industry conditions.

TelAgentBench is designed to systematically evaluate these agentic capabilities within the telecommunications service ecosystem, which includes domains such as roaming, travel, and customer contact centers. The framework adapts and extends established general-purpose benchmarks, grounding them in realistic industry scenarios to assess practical performance. Each of the five core capabilities is assessed using a dedicated module constructed from domain-specific data, with the overall composition detailed in Figure 1.

3.1 Overall Construction Process

We constructed TelAgentBench using a consistent four-step methodology across all sub-datasets. This procedure was optimized for the telecommunications service context, but its design principles allow for application and extension to other domains.

Step 1: Planning and Foundational Design The initial step involved defining evaluation scenarios through an analysis of real-world telecom-

Dimension	Focus	Counts	Key Adaptations from Base Benchmarks	Unique Telecom Features
Reason	Multi-hop reasoning over complex business documents.	225	Adapted five multi-hop QA types from research like HotpotQA and StrategyQA.	Reasoning over authentic telecommunications business documents; questions require connecting information across multiple steps.
Plan	Multi-step planning capabilities for roaming and travel services.	200	Adapted from TravelPlanner's Sole-planning mode; localized content and constraints for Korean users.	Integration of overseas roaming plans into travel itineraries; telecom-specific hard constraints like data usage and age restrictions.
Action	Tool-calling proficiency in customer service contexts.	757	Integrated core tasks from BFC and BiGGen Bench; categorized by interaction complexity and query naturalness.	Sandbox environment with 23 realistic Business Support System (BSS) APIs; scenarios with natural language phenomena and distractor functions.
RAG	Quality of retrieval-augmented generation from a knowledge base.	258	Employed a systematic methodology inspired by RAGAS, using post-call AICC data for generation.	Generation pipeline using business document data; integration of realistic distractor documents to test retrieval precision.
IF	Instruction-following ability with Korean linguistic nuances.	300	Extended the IFEval framework to include dialogue sequences and Korean-specific linguistic features.	Custom instructions for telco-specific needs, including markdown table formatting and sensitive information handling.

Table 1: A comparative overview of the five dimensions of TelAgentBench, detailing their focus, instance counts, and unique adaptations for the telecommunications domain.

munications service use cases (e.g., applying for/changing roaming plans, inquiring about membership benefits, consulting on billing and rate plans). We then adapted established general-purpose benchmarks, such as BFC and TravelPlanner, to align with the specific characteristics of the telecom domain, including business workflows, regulations, and data constraints.

Step 2: Building a Domain-Specific Environment To build a domain-specific environment, we first developed a tool execution environment by analyzing core customer service tasks (e.g., inquiry, application, modification) to derive a list of representative APIs and define their input/output specifications and call constraints. Based on these specifications, we constructed a simulated database containing virtual customer information, rate plans, and usage data to ensure that API calls maintained state consistency. Second, we established a knowledge retrieval environment by collecting and refining business documents such as terms and conditions, product manuals, and FAQs. These were segmented by semantic units and indexed to build a searchable knowledge base. To support expanded roaming services, we also crawled and compiled a database of travel-related data, including restaurants and accommodations.

Step 3: Initial Data Generation and Expansion Initial data generation began with a small set of high-quality seed instances created by linguists based on the designed scenarios. Annotators then systematically expanded this seed set, increasing its volume and expressive diversity by paraphrasing questions, diversifying templates, and leveraging generative models. A cross review process was conducted to prevent ambiguity or redundancy resulting from this expansion.

Step 4: Expert Validation and Refinement The final step consisted of expert validation and refinement using a Human-in-the-Loop (HITL) procedure. Telecommunications service agents and language experts reviewed and validated all instances via a web-based verification tool. This validation confirmed the dataset's realism (suitability for real-world tasks), accuracy (factual, numerical, and policy consistency), and reproducibility (feasibility of automated scoring), ensuring its final reliability.

3.2 Dataset Components and Details

The key characteristics of the five agentic evaluation datasets are summarized in Table 1. Detailed dataset building blocks and statistics are provided in Appendix A, while representative dataset samples are presented in Appendix D.

3.2.1 TelAgent Reason

TelAgent Reason evaluates a model's reasoning ability through complex questions posed against telecommunications policy documents. The core task requires synthesizing and connecting information across multiple steps to derive the correct answer. We adapt five multi-hop QA categories from prior research to the telecommunications domain: Bridge, Intersection, Factuality, Superlative & Comparative, and Procedural Arithmetic. This benchmark is structured into both single-document and multi-document QA tasks. Each multi-hop QA sample consists of a question, its answer, and the intermediate reasoning steps (hops), as shown in the example below.

> **Q:** How much is the cost of the device that is bundled with the internet phone service subscription? (99,000 KRW)
> **hop1:** Which device is available for the subscription with the internet phone service? (SK Voice WiFi Phone)
> **hop2:** What is the price of that device? (99,000 KRW)

3.2.2 TelAgent Plan

TelAgent Plan evaluates agents' multi-step planning in a telecommunications context by adapting TravelPlanner's Sole-planning mode and Direct strategy. It preserves TravelPlanner's environment and commonsense constraints, and modifies the hard constraints to cover roaming-plan requirements. Note that in TravelPlanner, environment constraints manifest as environment feedback rather than pass-rate metrics; we keep this setting while customizing hard constraints for telecom roaming. Furthermore, it integrates telecom-specific rules such as data usage (maximum roaming allowance), family sharing (eligibility for roaming data sharing), roaming budget (plan price cap), and age restrictions (eligibility for youth-specific plans).

> **Query:** "I am planning a 5-day, 4-night trip to Marseille and Vienna. I definitely want to visit St. Stephen's Cathedral. Please find a luxury hotel that is 4-star or higher and non-smoking. My budget is around 8 million KRW, and I think 1GB of data per day will be sufficient. However, I want to use a family sharing plan to share data with my husband."

3.2.3 TelAgent Action

TelAgent Action evaluates the function-calling proficiency of LLMs in telecommunications customer service. We adapt existing benchmarks (BFC (Yan et al., 2024), BiGGen Bench (Kim et al., 2025)) to telecommunication scenarios. To build a realistic environment, we developed 23 API paths across six categories: billing (e.g., real-time bill inquiry), add-on services (e.g., roaming subscription/cancellation), data/coupons (e.g., data limit inquiry), rate plans (e.g., product information inquiry), family information (e.g., family data usage inquiry), and miscellaneous (e.g., personal information inquiry). Based on these, we constructed 10 sub-tasks and 757 benchmark instances, categorized by function usage complexity (e.g., simple, parallel, multiple) and contextual challenge (e.g., relevance identification, missing-parameter handling). To create a more robust and challenging evaluation setup, we defined function lists of up to 7 candidates for lower-difficulty tasks and 23 for higher-difficulty tasks, including distractor functions that models should avoid using, thereby simulating the production sandbox environment.

> **Live:** I'd like to check how much my kids used this month.
> **Non-live:** I want to inquire about the billing details for this month for the phone numbers 0102220000 (Kang Jin-seo) and 0101110000 (Kang Jin-woo).

3.2.4 TelAgent RAG

TelAgent RAG evaluates RAG systems using a high-quality dataset constructed from a business Knowledge and Information System (KIS) containing internal materials such as tariff and membership service descriptions. The data generation process employs a weighted sampling algorithm to select high-quality data; questions are then generated using GPT-4 and a proprietary in-house model to prevent overfitting. Quality is ensured through a human-in-the-loop approach, where domain experts and language specialists verify relevance and refine answers. Finally, distractor documents are included with the ground-truth answer to enhance retrieval realism and precisely evaluate information selection capabilities.

For each sample, distractor documents are added to form a total of five documents. Their inclusion is guided by two distributions: the first follows the top-5 results from our best retrieval systems, and the second applies an ϵ-greedy strategy inspired by RAFT (Zhang et al., 2024), where the top-k documents are relevant and the remaining $(5 - k)$ are randomly sampled distractors.

3.2.5 TelAgent IF

TelAgent IF is a benchmark adapted from the Multi-IF (Yun He, 2024) multi-turn framework, which itself builds on IFEval (Zhou et al., 2023), to evaluate instruction-following capabilities in Korean and in the telecommunications domain. A distinctive aspect of this benchmark is the integration of telecom-domain datasets to build complex command scenarios that expand the task scope to data manipulation and knowledge understanding. By incorporating Korean-specific linguistic constraints (e.g., syllable count, honorifics) and telecom-specific requirements (e.g., table formatting, sensitive information handling), the benchmark precisely measures how consistently a model follows instructions in multi-turn dialogues under complex conditions.

4 Evaluation of LLMs

We evaluate TelAgentBench across recent proprietary and open-source LLMs, selecting models that represent the latest advancements and larger parameter sizes. The resulting category-wise scores demonstrate the benchmark's discriminative power and practical utility for model selection.

Overall, proprietary models achieve higher and more stable performance than their open-source counterparts. Within each model family, thinking-enabled models consistently outperform non-thinking models. A broadly similar trend is observed for open-source models; however, on tasks that demand strict output control, non-thinking models demonstrate greater stability and more reliable task completion. Table 2 presents a consolidated overview of the results. Detailed evaluation methodologies and results for each dimension are provided in Appendix B and Appendix C, respectively.

4.1 TelAgent Reason

Thinking-enabled models demonstrated superior performance, characterized by high accuracy. Specifically, the thinking models (Sonnet 4.5, Opus 4.1, and o3) achieved high scores, proving their capability for precise information extraction and logical reasoning within both single- and multi-document contexts.

The Procedural Arithmetic question type was the most challenging. Nevertheless, top-tier thinking models such as Sonnet 4.5, Opus 4.1, and DeepSeek R1 achieved over 90% accuracy in multi-document settings, suggesting that recent models are starting to handle complex procedural reasoning rather than relying solely on simple information retrieval.

Quantitatively, the average accuracy of the top four thinking models in our evaluation (Sonnet 4.5, Opus 4.1, o3, and Gemini 2.5 Flash) reached 85.8% for single-document tasks and 84.6% for multi-document tasks. This demonstrates that these models maintain consistently high performance across all reasoning environments, not just in specific scenarios.

4.2 TelAgent Plan

Based on the average pass rate, proprietary models outperformed open-source models by approximately 5.9%. Within proprietary models, the thinking variants achieved about 8.1% higher scores than non-thinking ones. Conversely, among open-source models, non-thinking variants outperformed thinking ones by roughly 9.3%.

Among proprietary models, Anthropic Opus 4.1 excelled in adhering to both commonsense and hard constraints, achieving the highest final pass rate at 28%. Google Gemini Pro 2.5 also demonstrated strong overall performance, highlighting its ability to handle complex combinations of constraints effectively.

Among open-source models, Llama 3.3-70B-Instruct outperformed several commercial systems. In contrast, thinking-type models frequently generated tokens incompatible with the required plan templates, resulting in degraded output quality.

4.3 TelAgent Action

Across all tasks, proprietary LLMs equipped with thinking capabilities demonstrated the highest performance, suggesting that explicit reasoning plays a crucial role in analyzing the conditions required for action. However, we identified a disparity in these capabilities between open-source and proprietary models. Proprietary thinking models outperformed their open-source counterparts by around 12%, based on the mean accuracy across six proprietary and three open-source thinking models.

The item recommendation task in the Non-Live setting proved to be the most challenging due to the limited contextual information available for determining the correct function call. This task re-

	Reason avg accuracy	**Plan** avg pass-rate	**Action** avg accuracy	**RAG** avg faithfulness	**IF** avg accuracy
Proprietary Models

[T] DeepSeek R1	0.822	0.305	0.576	0.723	0.766
Gemma 3 27B Instruct	0.604	0.431	0.462	**0.868**	0.755

Table 2: Aggregated evaluation results for 15 recent LLMs across the 5 TelAgentBench dimensions. Thinking models are denoted with [T].

vealed a stark contrast between open-source and proprietary LLMs. To acquire sufficient context, proprietary models requested more information from the user at a rate of 15.4% for thinking models and 2.7% for non-thinking models. In contrast, open-source models did so at rates of only 3.2% and 0.0%, respectively. This aligns with the observation in (Kalai et al., 2025) that models tend to guess rather than respond with *I don't know* (IDK) to improve benchmark scores. Our findings suggest this tendency is more pronounced in non-thinking and open-source models. The Gemini-2.5-Flash model, in particular, exhibited a tendency to refuse to answer if all information was not available, leading to a notably low performance on this task.

The performance of thinking, non-thinking, open-source, and proprietary LLMs varied with the difficulty of the TelAgent Action benchmarks. The tasks increased in difficulty in the order of Simple, Parallel, Multiple, and Parallel Multiple for both Live and Non-Live settings. On simpler tasks, the performance gap between open-source non-thinking models and proprietary thinking models was only 3.6%. However, this gap widened to 11.6% for medium-difficulty tasks and reached a significant 15.2% for the most difficult tasks.

4.4 TelAgent RAG

Among proprietary models, all tested Claude models demonstrated superior Faithfulness, achieving higher than 84% on both AICC and Infra tasks. In contrast, OpenAI's thinking models showed lower scores, around 67%, possibly due to reasoning traces that occasionally diverged from the source documents. Interestingly, the non-thinking OpenAI models maintained stable performance.

Notably, open-source models are narrowing the performance gap. Llama-3.3-70B-Instruct reached 83% average Faithfulness, a score comparable to Sonnet 4.5 and Opus 4.1. Llama-4-Maverick also performed competitively at 83%. These models demonstrated similar Answer Relevancy to proprietary models and competitive Correctness scores. This suggests that large context windows (likely exceeding 100K tokens), when combined with effective instruction tuning, may help achieve high faithfulness without RAG-specific optimization.

In a notable case, GPT-5 exhibited the lowest overall performance among proprietary models across RAG metrics. Our analysis revealed that the API prematurely terminated completions due to reasoning token limits, suggesting excessive thinking token usage within the specified constraints. [2]

4.5 TelAgent IF

A performance gap of approximately 5.19% was observed between models with and without Think

[2]This issue has been widely reported in the developer community. https://community.openai.com/t/what-is-going-on-with-the-gpt-5-api/1338030

functionality. This gap became more pronounced in complex multi-instruction and multi-turn interactions, suggesting that step-by-step reasoning contributes effectively to handling complex instructions.

A performance difference of approximately 5.76% emerged between commercial and open-source models. Most models performed better on single-instruction prompts than on multiple-instruction prompts, with open-source models showing a relatively larger performance discrepancy between the two types.

All models exhibited substantially higher performance in single-turn interactions compared to multi-turn ones, with performance gaps up to 20.8% depending on the model. These results suggest that multi-turn conversation handling is inherently more challenging than single-turn processing, highlighting the importance of long-context understanding and consistent dialogue maintenance.

Most models achieved higher accuracy in the general domain than in the telco domain. This can be attributed to the telco domain containing specialized content that poses greater difficulty for model comprehension and reasoning. While commercial models generally showed smaller performance gaps across domains, open-source models exhibited relatively larger discrepancies, indicating that commercial models are likely trained on more diverse domain data, leading to stronger generalization capabilities.

5 Conclusion

This paper introduces TelAgentBench, a domain-specific and industry-grounded benchmark developed to evaluate agentic LLMs within the telecommunications service ecosystem. The benchmark evaluates five core agentic capabilities: Reasoning, Planning, Action (tool use), Retrieval-Augmented Generation, and Instruction Following, and comprises a Korean dataset of over 1,700 instances created through synthetic generation. Our cross-model study reveals consistent performance gaps between thinking and non-thinking models, underscoring the importance of explicit reasoning for real-world agentic service tasks. Our benchmark provides practical insights for model selection in customer-facing applications, including roaming, travel, and contact center services. Furthermore, we release the general-purpose components of TelAgentBench and their associated schemas to catalyze further research and enable rigorous, reproducible evaluation of agentic LLMs in the telecommunications sector and other domains.

6 Limitations

While TelAgentBench provides a comprehensive framework for evaluating agentic LLMs in the telecommunications sector, we acknowledge several limitations that highlight opportunities for future research.

First, the current benchmark is limited to text-based interactions in Korean, which restricts its applicability to multilingual or cross-lingual evaluation. While this focus on Korean reflects immediate business relevance, extending the benchmark to other languages would enhance its global generalizability.

Second, the benchmark's scope reflects the operational focus of a single telecommunications provider. Given that telco business models differ globally due to regional and market factors, the dataset may underrepresent workflows prioritized by other carriers. Future iterations could broaden coverage to include diverse regional use cases, promoting fairer cross-market evaluation.

Finally, while TelAgentBench reflects the most recent state-of-the-art models available up to the time of publication, the rapid pace of model development means that sustaining its relevance will require continuous updates—a structural limitation inherent to benchmarking in fast-evolving LLM ecosystems.

A Detailed Dataset Construction and Statistics

This section provides a detailed breakdown of the dataset composition for each of the five dimensions of TelAgentBench, restoring information from the original draft for clarity and reproducibility.

A.1 TelAgent Reason

The TelAgent Reason benchmark requires reasoning over either single or multiple policy documents, with questions requiring 2 to 4 reasoning steps (hops) to answer.

Type	Description
Bridge	Q) What is the price of the terminal available for subscription with the internet phone service? • hop1: What is the terminal available for subscription with the internet phone service? • hop2: What is the price of that terminal?
Intersection	Q) What is the rate plan that offers a handset subsidy and free installation for a 3-year contract? • hop1: What rate plans offer a handset subsidy for a 3-year contract? • hop2: What rate plans offer free installation? • hop3: What rate plan satisfies both conditions?
Factuality	Q) Can I receive all the benefits available when signing up for a landline phone service simultaneously? • hop1: What are the benefits provided when signing up for a landline phone service? • hop2: Are there any restrictions on combining the benefits?
Superlative & Comparative	Q) Among the T-roaming plans, which one has the lowest fee per GB? • hop1: What are the data allowance and fee for each plan? • hop2: What is the fee per GB for each plan? • hop3: Which plan has the lowest fee per GB?
Procedural Arithmetic	Q) What is the final fee for an 80,000 KRW/month plan after applying both a 2-year contract discount and an online subscription discount? • hop1:What is the 2-year contract discount rate for the 80,000 KRW/month plan? • hop2: What is the online subscription discount amount? • hop3: What is the final amount after applying both?

Table 3: Multi-hop QA Category Descriptions and Examples

Domain	Documents	Hops	Quantity
Telco	Single	2~4	100
	Multiple (~2)	2~4	125

Table 4: Structural details of the TelAgent Reason dataset.

A.2 TelAgent Plan

To support complex plan generation, a comprehensive database was constructed containing entries for various travel and telecommunications tools. The testset was structured across three difficulty levels and three travel durations. Difficulty levels are determined by the number of constraints.

Level	Description
Easy	I am planning a 3-day, 2-night solo trip from Seoul to Manila and would like recommendations for places a woman in her 20s can visit alone. I expect to use about 2GB of data per day, so please recommend a roaming plan. My budget is around 2 million KRW in total, including airfare and accommodation.
Medium	I am preparing for a 5-day, 4-night trip from Bangkok to Phuket. Since I am traveling with my mother, I would like to stay one night at a place with a spa, and I prefer accommodation where pets are not allowed. My budget is around 5 million KRW for two people. I definitely want to visit the Grand Palace in Bangkok and the Phi Phi Islands in Phuket. I expect to use about 1GB of data per day, so please recommend a roaming plan.
Hard	I am planning a double-date trip, visiting Paris and then Edinburgh. A total of four people—my partner and I, and a friend's couple—will be traveling for 7 days and 6 nights. We plan to stay 3 nights in Paris and 3 nights in Edinburgh, intending to visit famous tourist attractions like the Louvre Museum, Edinburgh Castle, and the National Museum of Scotland! For accommodation, we will only stay in boutique hotels, so please choose one that does not allow pets. We want to taste authentic local food, so we'd like to experience various French dishes in Paris and Scottish cuisine in Edinburgh. Our budget is around 15 million KRW! I would also appreciate a recommendation for a roaming plan; if there is a youth plan for around 60,000 KRW, please choose that one!

Table 5: Example Queries by Difficulty Level

Tool	Entries(#)
FlightSearch	2,397
RestaurantSearch	1,412
AttractionSearch	936
AccommodationSearch	579
distanceMatrix	2,397
CitySet	50
RoamingPlan	30
Sum	7,801

Table 6: Database entry counts for TelAgent Plan tools.

Level	3 days	5 days	7 days
Easy (67)	21	22	24
Medium (67)	22	21	24
Hard (66)	22	22	22

Table 7: Distribution of TelAgent Plan test cases by difficulty and duration.

A.3 TelAgent Action

Table 8 summarizes the basic task types and examples, indicating conditional distinctions in parentheses. Table 9 details the size of each sub-task and the number of functions accessible to the agent during evaluation.

Type	Description	Answer
single/simple	A type that calls one function.	**user:** Please list the add-on services I've subscribed to.
single/parallel	A type that calls one function 2 or more times.	**user:** Please list the add-on services for myself and my son.
single/multiple	A type that calls one appropriate function from 2 or more given functions.	**user:** Please list the add-on services I've subscribed to.
single/parallel-multiple	A type that calls the same function twice, and another function one or more times.	**user:** Please list the add-on services for myself and my son, and also tell me my overdue payment amount.
single/multi-step	A type that calls multiple functions sequentially.	**user:** Please check the real-time fees for my son and daughter, and then look up the add-on services for the child with the higher fee.
single/item-recommendation	A type that considers user preferences, situations, and constraints to call a function and recommend an appropriate rate plan based on it.	**user:** I'm 34, so next year I won't be able to use the YOUNG plan. Is there an unlimited plan with a similar price?
single/hallucination irrelevance	A type that checks if no function is called when only irrelevant functions are given.	**user:** Please list the add-on services I've subscribed to.
single/hallucination relevance	A type that checks if the correct function is called when several relevant functions are given.	**user:** Please list the add-on services I've subscribed to.
muti-turn/base	A multi-turn type that calls 2 or more functions.	**user:** Please list the add-on services I've subscribed to. **assistant:** The add-on service you are subscribed to is 'Coloring'. **user:** Please tell me my wife's as well. **assistant:** Your wife's subscribed add-on service is 'Spam Message Blocking'.
muti-turn/miss_param	A type that evaluates whether the agent recognizes a missing parameter required for a tool call in a user request and appropriately asks for additional information.	**user:** Please tell me the confirmed bill amount. **assistant:** Please tell me the exact date you want to inquire about. **user:** Please tell me the confirmed bill for May. **assistant:** The confirmed bill for May is 49,900 won.

Table 8: Task descriptions and examples

Task	Size	Functions
Simple (live/non-live)	110	1
Parallel (live/non-live)	38	1
Multiple (live/non-live)	110	7
Parallel Multiple (live/non-live)	36	7
Multi-step (partial/whole, live/non-live)	92	7/23
Item recommendation (live/non-live)	52	1/2
Irrelevance	118	-
Relevance	117	-
Multi-turn Base	46	23
Miss param	38	23

Table 9: Detailed breakdown of TelAgent Action sub-tasks, sizes, and the number of functions provided.

A.4 TelAgent RAG

The TelAgent RAG dataset includes both infrastructure-related technical documents and customer-facing AICC (AI Contact Center) documents to test retrieval in different contexts.

Domain	Description	Quantity
InfraRAG	Based on infra hardware details	50
TelRAFT & TelRAG	Based on telco user questions. (AICC)	208

Table 10: Dataset quantities for TelAgent RAG.

A.5 TelAgent IF

The TelAgent IF dataset is split between general-domain and telecommunications-domain tasks, each with a different number of conversational turns to test cumulative instruction following.

Turn	Prompt Example
turn-1	"Please write a sentence for my resume's self-introduction. Fill in the blank in "I am a _____ person." with a suitable phrase and then write a self-introduction starting with that phrase, totaling 5 sentences including the initial one.
turn-2	Please write a suitable title for the self-introduction using double angle brackets.
turn-3	Please write in a formal polite style ("-습니다/합니다/입니다") and limit the response to a maximum of 150 words.

Table 11: General domain 3-turns prompt example

Turn	Prompt Example
turn-1	Remove the sensitive information (name, phone number, address, card number) from the following conversation and replace it with placeholders. - Customer: I'm calling to change my cell phone bill payment method. - Agent: Yes, that's possible. Are you Mr. Kim Min-seok, phone number 010-1234-5678? - Customer: Yes, that's correct. - Agent: Could you please tell me the card number? - Customer: It's 8888-3168-1967-2149. - Agent: Thank you. And what is the expiration date? - Customer: August 2028. - Agent: Okay, the change has been processed so that the payment will be charged to the new card starting on the 10th of next month. - Customer: Okay, thank you.
turn-2	the response with the agent's words, "I'm glad I could help you. Have a wonderful day!"

Table 12: Telco domain 2-turns prompt example.

Type	Instruction	Instruction Prompt Example
Rate Plan Summary	Markdown Table Format	Organize the rate plan information in a markdown table format (e.g., Name, Price, Data Amount)
Customer Service Format	Use Formal Politeness	Write all sentences in the formal polite style (" 습니다 / 합니다")
FAQ Response	Repeat Prompt + Answer	For the user's question, first repeat the exact same question in one line, and then on the line below, write the response with the accurate information after a colon (:).
Customer Service and FAQ Closing	End Checker	Always end all responses with "Thank you for always using SKT. If you have any further inquiries, please let us know at any time."
Service Error Notice	Start Checker	The first paragraph must begin with "We apologize for the inconvenience in using our service."
Maintain JSON Value Accuracy	JSON Value Checker	Select the information from the JSON that matches the user's query intent and provide an answer. The selected information must **exactly match the JSON values in format, words, numbers, and dates.**
Exclude Sensitive Information	Exclude Keywords	Please remove sensitive information such as name, phone number, address, and card number.
Recommendation Order	Numbered Lists	When recommending, explicitly present the recommendation priority with numbers (1, 2, 3).
Decline Impossible Requests	Include Keywords	You are an SK Telecom counselor. For requests outside of SK Telecom services, you must clearly respond with "We are sorry, but the requested service cannot be provided."
Include Key Telco Terms (Plan Name/Price/Data Amount)	Include Keywords (Use Specified Units)	You must include key telco information such as price/data amount/date/calls/plan name.
Use User-Friendly Language	Response Language	The guide message must be written in language, and no other languages are allowed.

Table 13: Telecommunication-related instructions

Domain	Turns	Quantity
General	3-turns	200
Telco	2-turns	100

Table 14: Dataset quantities for TelAgent IF. For the first turn, the general set comprises 118 single-instruction and 82 multiple-instruction prompts, whereas the telco set consists of 50 single-instruction and 50 multiple-instruction prompts. From the second turn onward, however, each prompt includes both the previous and the current instructions, and thus eventually becomes a multiple-instruction prompt.

B Evaluation Methods

B.1 TelAgent Reason

To evaluate answer accuracy, we implemented a multi-tier matching system that progressively applies more flexible criteria to classify responses as correct or incorrect.

B.1.1 Evaluation Process

Our sequential evaluation proceeds as follows, classifying an answer as correct at the first matching step:
Step 1: Exact Match - Complete string equality between generated and reference answers.
Step 2: Normalized Match - Equality after removing special characters and standardizing case.
Step 3: Similarity-based Evaluation - String similarity meets question-specific thresholds (e.g., ≥ 0.8 for Bridge-type questions).
Step 4: Core Content Match - Equality after removing parenthetical content.

B.1.2 Classification Criteria

The binary classification follows:

$$\text{Answer Classification} = \begin{cases} \text{True} & \text{if any evaluation step is satisfied} \\ \text{False} & \text{if all evaluation steps fail} \end{cases} \tag{1}$$

B.2 TelAgent Plan

For TelAgent Plan evaluation, we applied both Micro and Macro evaluation methods to comprehensively assess agent planning capabilities. We specifically removed Transportation constraints due to limited overseas data availability and added representative local Attraction information.
Commonsense Constraint This metric evaluates an agent's ability to apply and execute commonsense information to establish a coherent plan, even without explicit instructions.
Hard Constraint This metric measures how effectively an agent adheres to specific instructions, which are defined as Hard constraints in the evaluation framework.
Micro Pass Rate This represents the ratio of constraints satisfied across all plans:

$$\text{MicroPassRate} = \frac{\text{Number of satisfied constraints across all plans}}{\text{Total number of constraints across all plans}}$$

For example, if there are 100 total constraints and the agent satisfies 80 of them, the micro pass rate is 80%.
Macro Pass Rate This represents the ratio of plans that satisfy all constraints:

$$\text{MacroPassRate} = \frac{\text{Number of plans satisfying all constraints}}{\text{Total number of plans}}$$

For example, if there are 10 total plans and 7 of them satisfy all constraints, the macro pass rate is 70%.

B.3 TelAgent Action

For single-turn tasks, we employ standard AST matching evaluation techniques as proposed in BFCL v1. For multi-turn and multi-step tasks, we diverge from BFCL v3 by implementing a **stateless simulation framework** where tool responses are simulated using predefined ground truth without executing functions or updating states. Each turn is evaluated independently with system state remaining constant, reflecting telco scenarios where tool calls operate on stable data snapshots. This approach isolates tool-use reasoning from memory capabilities, enabling fairer model comparisons.
Stateless Evaluation. For stateless evaluation, each test entry includes:

- A multi-turn sequence of user queries (as original)
- A fixed set of tool APIs (as original)

- A ground-truth list of required tool calls per turn (`possible_answer`)
- Simulated tool outputs (`possible_answer_result`)
- Post-call assistant messages (`possible_postcall_answer`)

Start of a Turn. At turn initiation, the user query is appended to dialogue history and the model accesses the fixed tool API set. Crucially, the environment is *stateless*—no memory persists across turns, with all state transitions simulated per turn.
Within a Turn. Each turn comprises multiple steps following this sequence:

1. **Model Inference**: The model is queried with the current conversation history.
2. **Response Parsing**: The output is parsed into a list of decoded tool calls. In addition to BFCL's strict AST type validation, we adopt a more flexible string-based parsing approach that accommodates mixed text-and-code responses typical of production telcos such as introduction and endings. Valid function calls are extracted via substring function call matching in addition to the standard AST function call format.
3. **Tool Simulation**: Parsed tool calls are first checked if the format adheres to the fixed set of API tools. Then valid tool calls are compared against ground-truth answers using AST matching (just as single-turn evaluation).
4. **Progress Logging**: A `stateless_log` is recorded at each step, including:
   - `matched`: tool calls that align with ground truth
   - `missing`: ground truth calls not yet made
   - `progress`: a string of the form k/K, where k is the number of correct tool calls so far and K is the total expected for the turn
   - `completed`: a boolean indicating whether the turn is considered complete

Turn Termination. A turn ends under one of these conditions:

- **Successful Completion**: The model correctly identifies and issues the entire required set of tool calls ($k = K$). The turn is marked as complete, and evaluation proceeds to the next turn.
- **Valid No-Call Case (miss-param turn)**: For turns with no expected tool calls ($K = 0$), a clarification response (i.e., no function calls) is considered correct. The turn is marked as complete, and evaluation advances to the next turn.
- **Failure Conditions**: The turn is terminated and the evaluation is marked as failed under any of the following circumstances:
  - **Premature Stop**: The model fails to issue any tool call during a step while required calls remain unfulfilled ($k < K$).
  - **Invalid Call in miss-param Case**: For $K = 0$, if the model issues any tool call, the behavior contradicts the expected clarification and the evaluation is immediately halted.
  - **Step Limit Exceeded**: The model exceeds the maximum number of allowed steps (typically 20) within a turn without reaching completion.

Post-call assistant messages, which is the assistant's response only after performing fixed-set of ground truth calls, for particular turn, are added after correct tool execution and treated as finalizing responses.

B.4 TelAgent RAG

Inspired by RAGAS (Retrieval-Augmented Generation Assessment System), TelAgentRAG focus on the generation through a comprehensive multi-dimensional assessment framework. We also applied RAGAS with telecommunication-specific prompting. Our evaluation framework consists of three core metrics that assess different aspects of RAG system performance:

1. **Answer Correctness and Similarity (k_rouge)** – Reference-Based

   We evaluate the factual accuracy of generated responses against ground truth using a precision-based F1 scoring mechanism. The evaluation process starts with LLM judges classifying each statement in the generated answer as True Positive (TP), False Positive (FP), or False Negative (FN) based on comparison with reference answers. Then we compute the F1 score of those statement units. Additionally we also compare with simple korean_rouge_l string matching.

2. **Faithfulness Assessment** – Reference-Free

   We measure the degree to which generated answers remain faithful to the source documents through a hierarchical verification process:

   - **Statement Decomposition:** Complex answers are broken down into main ideas/claims.. The main difference with RAGAS is we ask LLM to disassemble/find supporting statements that supports the main claims.
   - **Document Verification:** Each statement is evaluated against source documents to determine whether it can be directly or strongly logically inferred.
   - **Weighted Scoring:** A weighted average score is computed based on statement length and verification results, ensuring that longer, more detailed statements contribute proportionally to the overall faithfulness score.

   When evaluating reference-free metrics, distractor documents are excluded from the set of source documents. Consequently, we utilize the top-5 retrieved documents that include the relevant document from the RAFT dataset.

3. **Answer Relevancy** – Reference-Free

   We assess the relevance of generated answers to the original questions using a dual approach:

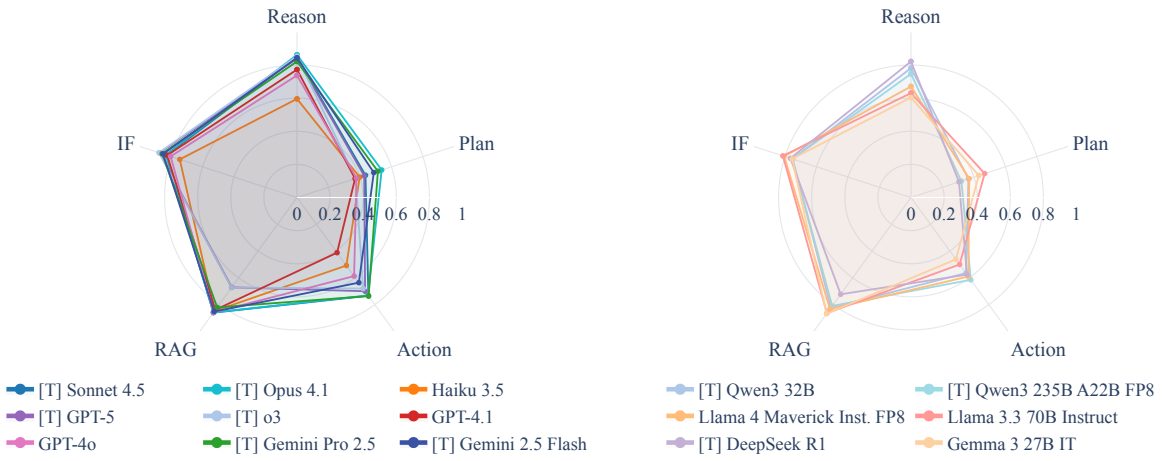
   - **Question Generation:** LLM judges generate questions that the given answer would appropriately respond to.
   - **Noncommittal Detection:** The system identifies evasive, vague, or ambiguous responses that fail to directly address the question.
   - **Semantic Similarity:** We employ a Korean sentence similarity model (KoSimCSE-roberta-multitask) to compute cosine similarity between the original question and generated questions, weighted by noncommittal scores.

B.5 TelAgent IF

TelAgent IF evaluates instruction-following capabilities by extending IFEval(Zhou et al., 2023) to incorporate Korean language features and telecom domain requirements, while integrating Multi-IF(Yun He, 2024) for multi-turn evaluation. Table 13 details our expanded instruction set. Responses were classified using a binary evaluation:

$$\text{is_followed}(\text{response}, \text{instruction}) = \begin{cases} \text{True} & \text{if instruction is followed} \\ \text{False} & \text{otherwise} \end{cases} \tag{2}$$

We calculated accuracy by averaging four metrics from Multi-IF: prompt-level and instruction-level strict and loose accuracy. For the 1st turn, we separately computed scores for single-instruction prompts (with one instruction) and multiple-instruction prompts (with two or more instructions), in order to



compare model performance on simple versus complex instructions. We then compared the aggregated single-turn (1st-turn) scores with the multi-turn scores, which focus on the final turn (turn 3 for the general domain and turn 2 for the telco domain), to assess models' ability to handle increasingly complex instructions across turns. Table 23 in Section C presents Detailed results for each model across all four settings — single-inst., multi-inst., single-turn, and multi-turn — in both domains. Table 2 in the main text reports the overall average score, obtained by taking the arithmetic mean of the single-turn and multi-turn accuracies and then averaging across the general and telco domains.

Instruction group	Instruction	Description
keyword	keyword existence	Include keywords keyword1, keyword2 in your response
keyword	keyword frequency	keyword should appear N times
keyword	keyword replace	Replace keyword with replace_word
keyword	forbidden-word existence	Do not include forbidden_words in the response
keyword	key-sentence existence	Include key-sentence in your response
keyword	key-letter frequency	key-letter should appear N times
language	response language	Response should be in language
language	formal-style text	Answer in formal and polite text style (경어체)
length constraint	number of sentences	Answer with at least / around / at most N sentences
length constraint	number of paragraphs	Answer with at least / around / at most N paragraphs
length constraint	number of words	Answer with at least / around / at most N words
length constraint	number of letters	Answer with at least / around / at most N letters
length constraint	first word of N-th paragraphs	There should be N paragraphs. The i-th paragraph must start with word first word
length constraint	first sentence of N-th paragraphs	There should be N paragraphs. The i-th paragraph must start with word first sentence
content	number of placeholders	Contain at least N placeholders represented by square brackets, such as [address]
content	postscript	Explicitly add a postscript starting with postscript marker
format	number of bullet-lists	Contain exactly N bullet points. Use the markdown bullet points such as: * This is a point.
format	number of digit-lists	Contain exactly N digital points. such as: 1) This is a point.
format	constrained response	Answer with one of the following options: options
format	number of highlighted sections	Highlight at least N sections in your answer with markdown, i.e. *highlighted section*
format	multiple sections	Answer in N sections and each section begins with section splitter X.
format	json format	Output should be wrapped in JSON format
format	markdown format	Output should be wrapped in Markdown format
format	title	Contain a title, wrapped in double angular brackets such as «happiness»
combination	two responses	Give two different responses separated by 6 asterisk symbols: ******
combination	repeat prompt	Repeat the request without change, then give your answer
combination	rephrasing prompt	Rephrase the request, then give your answer
start/end	end checker	Your answer should be end with key-sentence
start/end	double quotation	Wrap your answer with double quotation marks
start/end	single quotation	Wrap your answer with single quotation marks
punctuation	no comma	No comma allowed in your response
punctuation	no period	No period allowed in your response

Table 15: The list of 32 instructions evaluated, with brief descriptions

C Comprehensive Evaluation Results

In our study, we configured thinking models to fully leverage their capabilities by actively utilizing their thinking options. For models without an adjustable thinking token limit, max_completion_tokens was set to 8192. For Anthropic models, which allow for a configurable thinking_buget, we set the thinking_buget to 4096 and max_completion_tokens to 8192. OpenAI-family models were configured with reasoning_effort set to high.

(a) Proprietary models

(b) Open-source models

Figure 2: Radar chart of model performance on TelAgentBench. TelAgentBench evaluates five core agentic capabilities: Reason, Plan, Action, IF, and RAG. (a) presents results for proprietary models, while (b) shows results for open-source models. The chart highlights the relative strengths and weaknesses of each model across the different categories, facilitating direct comparison. Colors differentiate model types: thinking models are represented by shades of blue, and non-thinking models by shades of red.

Table 23: Evaluation results for TelAgent IF. "single-inst." denotes prompts with a single instruction in the 1st turn, while "multi-inst." denotes prompts with multiple instructions in the 1st turn. "single-turn" refers to the aggregated results over all 1st-turn prompts (both single- and multi-instruction), and "multi-turn" refers to the results from the final turn of each domain (the 3rd turn for the general domain and the 2nd turn for the telco domain). Each score represents the average of prompt-level and instruction-level accuracies under both strict and loose criteria.

D.2 TelAgent Plan Example

D.2.1 Korean Source Example

Input

졸업 여행으로 친구랑 둘이 프랑크푸르트와 뮌헨으로 3박 4일 여행 갔다 오려고 해! 예산은 600만원이고 로밍 데이터는 청년 요금제 위주로 먼저 알아봐 줘. 너무 비싼 요금제는 부담스러워서 최대 4만 원을 넘지 않으면 좋겠어. 여행 계획 세울 때 마인 타워, 뮌헨 시청사, 뉘른베르크 성 이 3곳은 꼭 넣어줘!

Output

여행계획:
Day 1:
현재 도시: 서울에서 프랑크푸르트
교통: 비행기, 1000000원/인
항공편 번호: TW403, 서울에서 프랑크푸르트, 출발 시간: 21:00, 도착 시간: 07:00(+1)
아침 식사: 골드만 레스토랑, 독일식, 80000원/인
관광지: 마인 타워
점심 식사: 레스토랑 팀 라우에,프랑크푸르트, 아시아식 퓨전, 200000원/인
저녁 식사: 마인 타워 레스토랑 & 바, 파인다이닝, 120000원/인
숙소: 본하임 코지 스튜디오, 트윈룸, 121500원/박,반려동물 불가, 파티 불가, 금연
Day 2:
현재 도시: 프랑크푸르트에서 뮌헨
아침 식사: 본하임 코지 스튜디오 내 조식
프랑크푸르트에서 뮌헨으로 이동: ICE 고속열차 약 3시간 30분, 50000/인
관광지: 뮌헨 시청사
점심 식사: Ratskeller München, 바리에른식, 45000원/인
저녁 식사: 레스토랑 팀 라우에, 아시아 퓨전, 200000원/인
숙소: PLAZA Premium München (PLAZA Premium Munchen), 프리미엄 더블룸, 100000원/박, 반려동물 불가, 파티 불가, 금연
Day 3:
현재 도시: 뮌헨에서 뉘른베르크, 뉘른베르크에서 프랑크푸르트
아침 식사: PLAZA Premium München 내 조식
뮌헨에서 뉘른베르크 이동: 독일 고속열차 ICE(Intercity Express) 약 1시간 10분, 25000원/인
관광지: 뉘른베르크 성
점심 식사: Bratwursthäusle, 독일식 소세지, 20000원/인
뉘른베르크에서 프랑크푸르트 이동: ICE 고속열차 약 2시간, 40000원/인
저녁 식사: 레스토랑 팀 라우에, 아시아 퓨전, 200000원/인
Day 4:
현재 도시: 프랑크푸르트에서 서울
교통: 비행기, 990000원/인
항공편 번호: TW404, 프랑크푸르트에서 서울, 출발 시간: 09:00, 도착 시간: 20:00
공항으로 이동:
아침 식사: 기내식
총 예산: 6,161,500원(2인 기준)
로밍 요금제 추천:
1) baro YT 7GB (39,000원, 7GB/30일)
-만 34세 이하만 가입 가능한 청년 전용 요금제입니다.
-7GB 데이터 제공, 모두 소진해도 최대 400kbps 속도로 계속 사용 가능합니다.
-7GB로 1일간 2GB씩 사용 가능하며 4일간 여행하기에 데이터를 넉넉하게 쓸 수 있는 요금제입니다.

D.2.2 English Translated Example

Input

I'm planning a 4-day, 3-night graduation trip for two people (a friend and myself) to Frankfurt and Munich. The budget is 6,000,000 KRW. For roaming data, please prioritize plans for young adults. Expensive plans are a burden, so I'd like the price to not exceed 40,000 KRW. When creating the travel plan, please make sure to include these three places: Main Tower, Munich City Hall, and Nuremberg Castle.

Output

Travel Plan:
Day 1:
Current City: Seoul to Frankfurt
Transportation: Airplane, 1,000,000 KRW/person
Flight Number: TW403, Seoul to Frankfurt, Departure Time: 21:00, Arrival Time: 07:00 (+1)
Breakfast: Goldman Restaurant, German style, 80,000 KRW/person
Attraction: Main Tower
Lunch: Restaurant Tim Raue, Frankfurt, Asian Fusion, 200,000 KRW/person
Dinner: Main Tower Restaurant & Bar, Fine Dining, 120,000 KRW/person
Accommodation: Bornheim Cozy Studio, Twin Room, 121,500 KRW/night, No pets, No parties, Non-smoking
Day 2:
Current City: Frankfurt to Munich
Breakfast: Breakfast at Bornheim Cozy Studio
Travel from Frankfurt to Munich: ICE high-speed train, approx. 3 hours 30 minutes, 50,000 KRW/person
Attraction: Munich City Hall
Lunch: Ratskeller München, Bavarian style, 45,000 KRW/person
Dinner: Restaurant Tim Raue, Asian Fusion, 200,000 KRW/person
Accommodation: PLAZA Premium München, Premium Double Room, 100,000 KRW/night, No pets, No parties, Non-smoking
Day 3:
Current City: Munich to Nuremberg, Nuremberg to Frankfurt
Breakfast: Breakfast at PLAZA Premium München
Travel from Munich to Nuremberg: German high-speed train ICE (Intercity Express), approx. 1 hour 10 minutes, 25,000 KRW/person
Attraction: Nuremberg Castle
Lunch: Bratwursthäusle, German sausage, 20,000 KRW/person
Travel from Nuremberg to Frankfurt: ICE high-speed train, approx. 2 hours, 40,000 KRW/person
Dinner: Restaurant Tim Raue, Asian Fusion, 200,000 KRW/person
Day 4:
Current City: Frankfurt to Seoul
Transportation: Airplane, 990,000 KRW/person
Flight Number: TW404, Frankfurt to Seoul, Departure Time: 09:00, Arrival Time: 20:00
Travel to the airport
Breakfast: In-flight meal
Total Budget: 6,161,500 KRW (for 2 people)
Recommended Roaming Plan: baro YT 7GB (39,000 KRW, 7GB/30 days)
- A youth-only plan available for those aged 34 and under.
- Provides 7GB of data. Even after full consumption, you can continue to use data at a maximum speed of 400kbps.
- This plan provides ample data for a 4-day trip, allowing for roughly 2GB of usage per day from the 7GB total.

D.4 TelAgent RAG Example

D.4.1 Korean Source Example

Document 1

...
만 18세 이하 미성년자가 T가족모아 데이터 공유 서비스를 이용할 수 있습니다. 미성년자는 'T가족모아-청소년공유' 서비스에 가입해야 하며, 법정대리인(부모님 등)의 동의가 반드시 필요합니다.
시스템에 등록된 법정대리인의 동의 후 서비스 가입이 가능하며, 서비스 가입 즉시 T가족모아 데이터 실시간 공유 및 월공유 신청이 가능합니다. 이용 중인 요금제의 공유 데이터 한도 내에서 공유가 가능합니다.
...

Document 2

...미성년자는 고객센터나 매장에서만 T가족모아 데이터 공유 서비스에 가입할 수 있습니다. 온라인이나 모바일 T world에서는 가입이 불가능하며, 가족관계 증빙서류 제출이 필요합니다.

가입 가능 채널은 고객센터, 대리점을 통해서만 가능하고, 시스템에 등록된 법정대리인 동의 이후 서비스 가입 처리가 가능합니다....

Document 3

...T가족모아-청소년공유 서비스는 만 19세 생일 익월 1일에 자동으로 해지됩니다. 해지 후에도 일반 T가족모아 데이터 공유는 계속 가능합니다.
서비스 해지 이후에는 별도의 법정대리인 동의 없이 성인으로서 일반 T가족모아 데이터 공유 서비스를 계속 이용할 수 있습니다....

Input

미성년자도 T가족모아 데이터 공유 가능한가요?

Output

Model Answer:
네, 미성년자도 T가족모아 데이터 공유가 가능합니다. 다만 다음 조건을 만족해야 합니다: **가입 조건:** - 만 18세 이하 미성년자 - 법정대리인(부모님 등)의 동의 필요 - 'T가족모아-청소년공유' 서비스에 가입해야 함 **가입 방법:** - 고객센터나 매장에서만 가입 가능 (온라인/모바일 T world에서는 가입 불가) - 시스템에 등록된 법정대리인의 동의 후 서비스 가입 - 가족관계 증빙서류 제출 필요 **데이터 공유:** - 서비스 가입 즉시 T가족모아 데이터 실시간 공유 및 월공유 신청 가능 - 이용 중인 요금제의 공유 데이터 한도 내에서 공유 가능 **자동 해지:** - 만 19세 생일 익월 1일에 자동으로 해지됩니다 (해지 후에도 일반 T가족모아 데이터 공유는 계속 가능) 추가로 궁금한 사항이 있으시면 언제든 문의해 주세요!

D.4.2 English Translated Example

Document 1

...
Minors under 18 years of age can use the T Family Data Sharing service.
Minors must subscribe to the 'T Family-Youth Sharing' service, and consent from a legal representative (e.g., parent) is required.
Subscription to the service is possible after obtaining consent from the legal representative registered in the system, and immediately upon subscription, real-time sharing and monthly sharing of T Family Data become available.
Sharing is possible within the data sharing limit of the user's current rate plan.
...

Document 2

...Minors can only subscribe to the T Family Data Sharing service at a customer center or store. Subscription is not available online or through mobile T world, and submission of family relationship verification documents is required. Available subscription channels are only through the customer center or agencies, and service subscription processing is possible after consent from the legal representative registered in the system....

Document 3

...The T Family-Youth Sharing service is automatically terminated on the 1st of the month following the user's 19th birthday. Even after termination, general T Family Data Sharing remains available.
After service termination, the user can continue to use the general T Family Data Sharing service as an adult without separate consent from a legal representative....

Input

Can minors also use T Family Data Sharing?

Output

```
Model Answer:
Yes, minors can also use T Family Data Sharing. However, the following conditions must be met:
↪  **Subscription Conditions**: - Minors under 18 years of age - Consent from a legal
↪  representative (e.g., parent) is required - Must subscribe to the 'T Family-Youth Sharing'
↪  service **Subscription Method**: - Can only subscribe at a customer center or store (Not
↪  available on online/mobile T world) - Service subscription after consent from the legal
↪  representative registered in the system - Submission of family relationship verification
↪  documents required **Data Sharing**: - Real-time and monthly T Family Data Sharing
↪  available immediately upon service subscription - Sharing possible within the data sharing
↪  limit of the current rate plan **Automatic Termination**: - Automatically terminated on the
↪  1st of the month following the user's 19th birthday (General T Family Data Sharing remains
↪  available after termination) If you have any further questions, please feel free to ask!

Abstract

Evaluation and Management (E/M) coding, under the Current Procedural Terminology (CPT) taxonomy, documents medical services provided to patients by physicians. Used primarily for billing purposes, it is in physicians' best interest to provide accurate CPT E/M codes. Automating this coding task will help alleviate physicians' documentation burden, improve billing efficiency, and ultimately enable better patient care. However, a number of real-world complexities have made E/M encoding automation a challenging task. In this paper, we elaborate some of the key complexities and present ProFees, our LLM-based framework that tackles them, followed by a systematic evaluation. On an expert-curated real-world dataset, ProFees achieves an increase in coding accuracy of more than 36% over a commercial CPT E/M coding system and almost 5% over our strongest single-prompt baseline, demonstrating its effectiveness in addressing the real-world complexities.

1 Introduction

Accurate and efficient coding of Evaluation and Management (E/M) services using the Current Procedural Terminology[1] (CPT) system is crucial for healthcare providers, as it directly impacts billing accuracy, regulatory compliance, and revenue cycles. Traditionally, CPT E/M coding is performed by physicians and trained human coders who review clinical encounter notes and electronic health record (EHR) data to assign appropriate codes. They often rely on detailed guidelines (American Medical Association, 2023) to navigate the complexity of Medical Decision Making (MDM) for a given encounter. However, this manual process is resource-intensive, prone to inconsistencies due to variation in coder's expertise, and vulnerable to errors arising from intricate coding guidelines and the nuanced nature of clinical reasoning.

Many studies highlight the financial and compliance ramifications of coding inaccuracies. For example, the U.S. Office of Inspector General (OIG) estimated that in 2010, Medicare inappropriately paid US$6.7 billion (21% of total E/M payments) due to incorrect coding and/or insufficient documentation; 42% of claims were miscoded and 19% lacked proper documentation (U.S. Department of Health & Human Services, Office of Inspector General, 2014). A Florida-specific analysis estimated that nearly 9% of primary care visits (2.6 million annually) were undercoded, resulting in approximately US$114 million in lost revenue for hospitals (Tenpas and Dietrich, 2023). These findings underscore both widespread inconsistency and the high cost of coding errors.

Automation of CPT E/M coding offers several compelling advantages, including reducing human error through consistent application of complex coding rules, achieving scalable efficiency by handling high-volume chart reviews without increasing workload on physicians and coders, enhancing timely revenue capture by improved turnaround time. Additionally, automated coding can provide transparent and traceable reasoning, crucial for audits and compliance risk mitigation and enhance coding consistency, and optimizes coder resources by allowing human coders to focus on more complex or ambiguous cases. Beyond its immediate healthcare impact, CPT E/M coding exemplifies a broader class of problems where models must map free-text to codified decisions under strict guideline constraints. Insights from this work therefore extend to other regulated domains that require auditable, rule-aligned predictions.

In this paper, we share our practical experience in developing and deploying ProFees, an automated CPT E/M coding model within a production EHR system. Development of ProFees provides solu-

Table 1: Key challenges in CPT E/M automation and our corresponding solutions.

Challenge	Description	Solution
Intermediate labels	Production data include only the final CPT code, while the underlying medical decision-making (MDM) level with 3 intermediate element levels are absent.	117 encounters are re-annotated by our internal expert with the 3 intermediate elements – Problem, Data, and Risk levels + justifications.
Label noise	Even expert coders disagree: in our case, external and internal coding experts diverge on 56% of encounters (Sec. 5).	The development data is split into *Platinum* (agreement) and *Disagreement*; We first tune our prompts on *Platinum*, then iteratively refine using error analysis on both subsets with the internal expert.
Explainability	Clinicians and auditors require human-readable reasoning and black-box predictions are unacceptable.	Chain-of-thought exemplars and checklist-based critic outputs accompany every prediction, explicitly citing CPT guideline clauses.
Robustness	A production system must deliver repeatable results. LLM-based method could be potential solution but outputs could be stochastic.	Self-consistency ensemble (K=3) with majority voting plus a deterministic decision tree ensures repeatable results at controlled cost.
Clinical breadth	Correct coding demands deep, wide-ranging familiarity with guidelines and edge cases.	Dynamic few-shot retrieval injects guideline-aligned examples; iterative error analysis and prompt tuning add edge-case expertise.

tions to five main complexities of real-world E/M coding, summarized in Table 1. Leveraging advanced large language model (LLM) techniques, ProFees employs a dynamic few-shot prompting strategy to align coding decisions with best practices contextually relevant to each patients' encounter notes. Furthermore, an LLM-based critic is integrated to validate reasoning across the MDM elements explicitly, ensuring robust and explainable outcomes. To mitigate the stochasticity inherent in generative models, ProFees also adopts a self-consistency strategy to achieve reliable and consistent coding predictions.

This paper's key contributions include:

- Development and deployment of ProFees, a sophisticated LLM-based framework employing dynamic few-shot prompting, explicit criticism, and self-consistency techniques for accurate CPT E/M coding and intermediate MDM level estimation.
- Empirical demonstration of ProFees's efficacy on a proprietary test dataset[2] with comparison against a commercial CPT E/M coding system and single-prompt baselines. Our findings highlight superiority of ProFees in E/M coding accuracy over both the commerical system and our strongest baseline by around 36% and 5% respectively, validating its efficacy in CPT E/M coding automation.

[2]This test set was meticulously annotated by our internal expert in the same way as the development set of 117 encounters. Due to privacy and regulatory constraints, this test set is not publicly available.

2 Related Work

CPT coding has gone through three broad phases of modeling and technical development, which are classical machine learning, deep learning and large language modeling.

Classical ML models heavily rely on feature engineering, which demands significant preprocessing efforts to convert structured and/or unstructured text data into hand-crafted features. Supervised classifiers, such as support-vector machines and gradient-boosted trees, are then learned on these features to predict CPT codes (Morey et al., 2025; Khaleghi et al., 2021). While achieving moderate accuracy, these models struggle with the complexity and variability of clinical narratives.

Deep learning models for CPT coding mainly feature encoder-decoder architectures. The encoder learns to map medical text into dense embeddings, based on which the decoder learns to predict the codes. Despite the wide success of DL models in ICD-10 coding (Ji et al., 2024), their application to CPT coding is limited and has not been reported with favorable results compared to classical ML models (Burns et al., 2020; Levy et al., 2022; Kim et al., 2023b), which is likely due to the unavailability of large datasets for effective training.

Recently, LLMs have broken new grounds in medical coding, where with prompt engineering, GPT-4 is reported to have achieved comparable performance to SOTA DL models for ICD-10 coding (Boyle et al., 2023). However, other studies also found that naïvely feeding raw texts and code

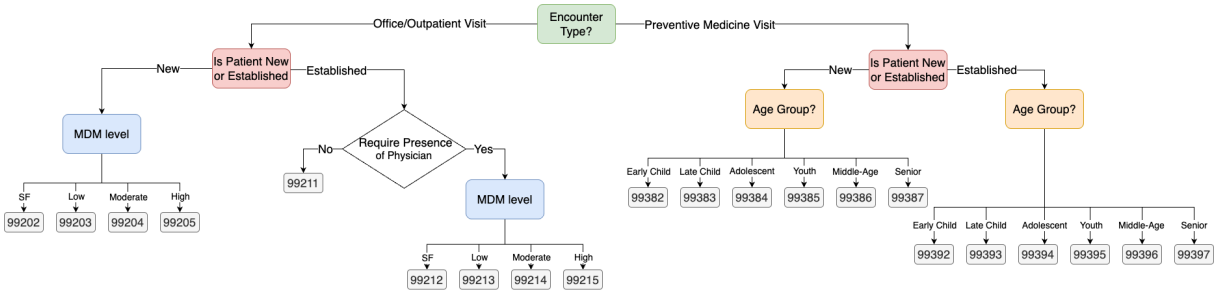

Figure 1: CPT E/M coding decision tree used to guide human coding of office and preventive visits. Other visit types are omitted for brevity. "SF" stands for "straightforward".

descriptions into LLMs for code generation can only yield sub-optimal results that fall short of the coding performance of human coders (Soroush et al., 2024). Overall, the development of effective LLM-based frameworks for medical coding is still in its infancy. This paper presents the first systematic attempt to develop such a framework for CPT E/M coding.

3 Task Overview

CPT E/M coding involves assigning standardized billing codes based on the type and complexity of the patient encounter. In this work, we focus on outpatient and preventive medicine encounters. Figure 1 illustrates the decision process used by human coders, starting from determining the encounter type, followed by key branching logic such as whether the patient is new or established, and finally selecting the appropriate CPT code based on either the Medical Decision Making (MDM) level or the patient age group.

Among these branches, determining the MDM level is the most complex and error-prone step. MDM is assessed across three elements: (1) the number and complexity of *problems* addressed during patient visit, (2) the amount and/or complexity of *data* reviewed and analyzed, and (3) the *risk* of complications and/or morbidity or mortality. The final MDM level is determined using a *2-out-of-3* rule, that at least two of the three elements must meet the criteria for a given complexity level (i.e. "straightforward", "low", "moderate", or "high").

This process requires structured clinical reasoning. For instance, for the "problems addressed" element, distinguishing between "stable, chronic illness" (i.e. "low" complexity) and "chronic illnesses with exacerbation, progression, or side effects of treatment" (i.e. "moderate" complexity) depends on close reading of clinical descriptions and inferred disease trajectories. Similarly, assessing the "data complexity" element may involve identifying whether documentation reflects "ordering unique test(s)" or "independent interpretation of tests", which can elevate the data complexity from "low" to "moderate" or "extensive". See Appendix A for a full view of the 2024 edition of MDM guidelines used for developing ProFees and Appendix F for a synthetic example.

In this paper, we report only strict exact-match accuracy, as payers adjudicate at the code level and incorrect CPT E/M codes may be denied, down-coded, or adjusted, affecting reimbursement timelines. Near-miss codes do not change clinical care (E/M is a billing construct), but they have operational and financial implications: miscoding can trigger denials and rework; systematic overcoding increases legal/compliance risk despite any short-term gain; systematic undercoding reduces revenue and understates provider workload. In addition, although business outcomes, e.g., revenue uplift, are ultimately important, they are much harder to be attributed directly to CPT E/M code choices due to other down-the-line factors, such as diagnosis–procedure linkage, billing completeness, payer-specific rules, and documentation quality. We therefore focus our evaluation on exact-match accuracy.

4 The ProFees Model

As illustrated in Fig. 2, our proposed ProFees model for CPT E/M coding integrates LLM-based classifiers and self-critics, few-shot in-context learning (Brown et al., 2020) boosted by retrieval with chain-of-thought (Wei et al., 2023) exemplars, and traditional rule-based decision trees. The architecture comprises two primary LLM-driven modules: the *Encounter Type Classifier*, which identifies the nature of the clinical visit (e.g., inpatient, outpatient and preventive medicine), and the *MDM Complexity Classifier*, which predicts the level of medical decision-making (MDM) involved.

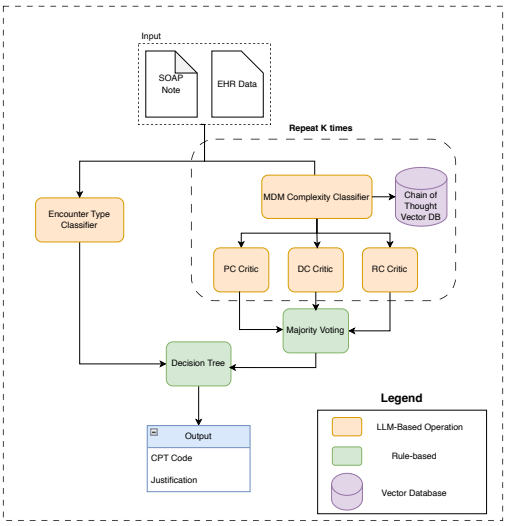

Figure 2: ProFees architecture for CPT E/M coding prediction. PC, DC and RC stand for problem, data and risk complexity respectively.

This modular decomposition is directly motivated by CPT E/M coding guidelines, which determine the final code based on three key inputs: encounter type, MDM level, and patient type, with the patient type being readily available from structured EHR data. Therefore, our model is designed to predict the two remaining components: encounter type and MDM level. The initial MDM prediction is further refined through a Recursive Criticism and Improvement (RCI) process (Kim et al., 2023a) to ensure guideline compliance. The outputs of both classifiers are then combined and processed by a downstream rule-based decision tree to produce the final CPT E/M code together with the corresponding justification.

4.1 Design Rationale and Practical Impact

Our model design reflects iterative failure analysis in collaboration with medical coders, addressing limitations of early monolithic prompt architectures that lacked interpretability, guideline adherence, and reliability. By modularizing prediction, reasoning, and validation, the system ensures contextual relevance through retrieval-augmented prompting, enforces compliance via recursive self-critique, and reduces hallucination by rule-based logic (e.g., majority voting, 2-out-of-3 CPT rules) to deterministic decision trees. This architecture achieves high accuracy, robust explainability via CoT and critic reviews, and strong alignment with clinical workflows—supporting trust, adoption, and real-world deployment.

4.2 Encounter Type Classifier

This component identifies the type of encounters using an LLM. The model receives relevant contextual information such as SOAP notes[3], patient age, and patient type, and returns an appropriate encounter classification.

4.3 MDM Complexity Classifier

This component assesses the complexity level involved in medical decision-making. The prediction occurs in two stages: an initial classification followed by self-refinement through RCI. The initial prediction leverages dynamic few-shot prompting with external annotated examples retrieved from a Vector Database (VDB), the content of which consist of justifications and reasoning steps that were curated and validated by human coding experts to align with MDM guidelines. Subsequently, the RCI process systematically audits and refines the initial prediction to ensure adherence to comprehensive guideline criteria. To further enhance robustness, the model employs self-consistency via majority voting across multiple LLM inferences.

4.3.1 Dynamic Few-Shot CoT Prompting

To enable the MDM classifier to leverage annotated external knowledge for reference in reasoning and decision making. We designed and created a VDB that indexes encounters of the development and test datasets described in Section 5, each consisting of:

- **Gold justifications** per MDM element, provided by our internal coding experts.
- **Model justifications** per MDM element, generated by an LLM, curated and verified to be correct by our internal experts.
- **Chain-of-thought reasoning** (with step-by-step verification on well-designed checklists) for each MDM element, generated by an LLM, curated and verified by our internal experts.

During retrieval, the SOAP note of an input encounter is used to query the VDB to select Top-N relevant exemplars using semantic vector search.

4.3.2 Recursive Criticism and Improvement

Despite the careful prompt engineering to align the MDM classifier with the CPT coding guidelines, we found that it still remained limited in

[3]SOAP notes are a highly structured and standard format for documenting patient encounters, containing the following parts: **S**ubjective, **O**bjective, **A**ssessment and **P**lan. See Appendix F for an example.

cases that involve criteria not explicitly addressed by the guidelines or require clinical knowledge beyond the current capabilities of LLMs.

To overcome these limitations, we introduced additional self-critics to follow the initial MDM classification for all the MDM elements, i.e., the "problem" and "data" complexity, and "risk of complications". Each of the critics is prompted to review and critically evaluate the intermediate predictions of the corresponding MDM elements, by following checklists designed to address common generic errors identified by our internal expert for each MDM element.

4.3.3 Self-Consistency via Majority Voting

A key challenge with LLMs is their inherent stochasticity; that even with identical inputs and controlled conditions, predictions can vary. As discussed by Atil et al. (2025), even with fixed random seeds and identical model settings, deterministic model outputs cannot be guaranteed due to factors such as input subjectivity, variability in the LLM backend infrastructure, etc. This issue can pose risks in sensitive clinical contexts, potentially undermining the credibility of ProFees.

Therefore, in this paper, we have implemented a self-consistency strategy to enhance model output determinism. Specifically, our proposed model, the RCI-enhanced MDM classifier, is executed K times concurrently, which avoids latency increases, with costs scaling proportionally. Each inference run generates intermediate predictions for all the MDM elements. Subsequently, a majority vote is conducted across the intermediate predictions of each element from these parallel runs. The consensus prediction for each element is then fed into the decision tree module to determine the MDM level and then the final CPT code.

In cases where no majority is reached for an element, ties are broken by selecting the first prediction in the sorted result list from the parallel runs. For example, if the result list is {1, 2, 2, 2, 3, 4, 4}, the final output should be 2, while for {1, 2, 2, 2, 4, 4, 4}, 2 will still be chosen over 4 due to its precedence in tie-breaking.

4.4 Decision Tree

This module considers outputs from both the Encounter Type Classifier and the RCI-enhanced MDM Classifier, along with additional EHR data, based on which specific MDM rules are applied to produce the final CPT E/M code.[4]

We do not release the full prompts *verbatim* due to compliance and business confidentiality reasons. Instead, we share the prompt templates to capture the essence of our prompts to facilitate further research and community adoption. They can be found in Appendix C.

Table 2: Datasets overview. *Avg. # Words* refers to the average number of words in input SOAP notes.

Dataset	# Samples	Usage	Avg. # Words
Platinum	52	dev	543
Disagreement	65	dev	451
Test	99	test	434

5 Data Gathering and Annotation

Data Collection. We collected 216 real-world encounters from hospital production databases. The dataset comprises de-identified outpatient/preventative medicine encounters, each represented by a SOAP note, together with additional patient EHR data, such as demographics and medical orders.

Each encounter is annotated with a CPT E/M code assigned by the physician, along with a corresponding code provided by a professional coder. The coder's code either confirms or corrects the physician's selection and is used as the final billing code. However, the dataset lacks detailed justification for how the final CPT E/M code was determined, including the assessed complexity levels for the three MDM elements. Therefore, we engaged an internal medical expert to provide fine-grained annotations of both the E/M code and the MDM element complexity for each encounter.

These encounters were sampled incrementally to reflect the real-world distribution of CPT E/M codes observed in production data, using a larger dataset with coarse-level CPT labels as the reference. The sample spans multiple physician specialties, including family practice, internal medicine, urology, hematology, oncology, and cardiology (see Figures 7 and 8), rather than being limited to a single domain. Subsequently, our internal expert coders reviewed the set to confirm that the inclusiveness and coverage of specialties is sufficiently broad.

[4] An associated LLM justification of the MDM level prediction is also passed down from the MDM Classifier module and output together with the final E/M code.

Table 3: Evaluation results of accuracy improvements on the Test set. Results are averaged over 5 runs.

Model	CPT Acc. (%)	MDM Acc. (%)	PC Acc. (%)	DC Acc. (%)	RC Acc. (%)
System A	↓ 3.12 ± 0.64	↓ 4.99 ± 0.40	/	/	/
Single prompt	— ± 2.19	— ± 1.54	— ± 3.04	— ± 1.53	— ± 2.14
Single prompt + CoT	↑ 19.20 ± 1.79	↑ 13.26 ± 0.85	↑ 21.88 ± 1.93	↑ 15.06 ± 1.67	↑ 2.83 ± 1.44
Single prompt + Full Info + CoT	↑ 29.00 ± 2.19	↑ 22.36 ± 0.88	↑ 24.47 ± 0.83	↑ 22.82 ± 2.83	↑ 19.77 ± 0.64
ProFees (Zero-Shot)	↑ 27.40 ± 1.00	↑ 24.45 ± 0.45	↑ 26.83 ± 0.00	↑ 27.21 ± 1.80	↑ 19.30 ± 1.18
ProFees (Zero-Shot + RCI)	↑ 29.73 ± 0.58	↑ 33.08 ± 0.60	↑ 32.32 ± 1.36	↑ 43.69 ± 1.36	↑ 23.22 ± 1.80
ProFees (Few-Shot)	↑ 29.73 ± 0.58	↑ 26.41 ± 0.82	↑ 28.39 ± 0.68	↑ 28.78 ± 1.80	↑ 22.04 ± 0.68
ProFees (Few-Shot + RCI | Full)	↑ 33.73 ± 0.58	↑ 33.99 ± 0.60	↑ 35.06 ± 0.00	↑ 39.76 ± 1.18	↑ 27.14 ± 0.68

Data Annotation. For each encounter, our internal expert annotates the problem, data, and risk of complexity levels together with free-text justifications. The expert also assigned an overall CPT E/M code along with a justification for the selection. Using this procedure, we annotated a total of 117 encounters for model development. The CPT codes in the test set were annotated by the same expert in the same way as the development set.

Our analysis revealed a high degree of disagreement between the coders. Specifically, the expert agreed with the professional coder's CPT E/M codes on 52 encounters (44%), and disagreed on the remaining 65 (56%). Accordingly, we partitioned the development dataset into two subsets: **Platinum**, comprising encounters with agreement and thus more reliable ground-truth labels; and **Disagreement**, containing encounters where the coders diverged, reflecting more challenging coding decisions. Initial prompt tuning and critic-checklist design are performed exclusively on the *Platinum* subset. We then carry out iterative error analysis on both *Platinum* and *Disagreement* with our internal expert, refining prompts design while correcting any labelling errors identified.

Final Datasets. Our final dataset comprises three subsets, as shown in Table 2. The **Platinum** and **Disagreement** subsets serve as our primary development data. The separate **Test** subset is used for model evaluation. Given the stringent compliance, data safety and privacy requirements associated with collecting real-world patient data, large-scale data acquisition is challenging. Thus, we aimed to include a diverse range of CPT E/M codes across these subsets. Distributions of the CPT E/M codes (See Figures 4, 5 and 6) and the data annotation interface (See Figure 9) can be found in Appendix D.

6 Evaluation and Results

6.1 Experiment Settings

Dataset. We combine the **Platinum** and **Disagreement** subset, with a total of 117 encounters, and use them as the "tuning" dataset to refine prompts of both ProFees and the baselines. This ensures that both models are exposed to the same amount and type of generalizable knowledge, extracted by the internal expert from the error cases in the tuning set. The **Test** dataset, on the other hand, comprises the other 99 encounters.

Vector Database. We build the VDB with both the tuning/development and test datasets with the indexing procedures specified in Section 4.3.1. To ensure no information leakage occurs during the retrieval of dynamic few-shot exemplars from the VDB, we adopt the leave-one-out strategy, i.e., always filtering out the query's corresponding example from the retrieved list. Additionally, semantic dense retrieval is performed with $N = 3$ for Top-N exemplars retrieved (post leave-one-out filtering).

Baselines. We compare against (i) **System A**, a commercial rule-based coding tool,[5] and (ii) four **Single prompt** variants ranging from a single-prompt system to prompts augmented with CoT and full contextual information (i.e. EHR data). Note that we use Azure **GPT-4o-2024-05-13** as the foundation LLM for both the baseline **Single Prompt** variants and our **Profees** model.

Evaluation Metrics. We conduct accuracy-based evaluation at different granularity levels of classification. These include both the final CPT accuracy and that of the intermediate MDM element complexity levels. For each metric, we report the average result as well as the standard deviation over 5

[5]The vendor name and detailed description are withheld to preserve anonymity.

runs with different random seeds. Note that the intermediate complexity prediction are not available for **System A** and are therefore omitted.

For each of the 5 runs, we set the number of predictions made for each test encounter to be $K = 3$ to enforce the self-consistency majority vote (see Section 4.3.3), while balancing the cost and latency of LLM calling. In addition, we set the temperature for all LLM calls to be 0.

For setting of RCI round, we found empirically that ProFees's intermediate complexity prediction settled with 1 round of RCI for each MDM element. For simplicity, throughout the experiment, we also refer such 1-round setting as RCI.

6.2 Overall Results

Table 3 presents performance, as measured by accuracy improvements over the "Single prompt" baseline, on the 99-encounter Test set. Our full model (*Few-Shot + RCI*) achieves the highest CPT accuracy, 36.85% higher than the commercial System A, 33.73% higher than the Single prompt baseline, and 4.73% over the strongest baseline (i.e. Single prompt + Full Info + CoT). Notably, adding RCI to our model lifts MDM accuracy by 4% in the few-shot setting and 2.33% in the zero-shot setting, confirming the value of structured self-critique. Moreover, our full model significantly outperforms the strongest baseline on MDM, PC, DC and RC accuracy by 8–17 absolute points, further demonstrating its efficacy. Furthermore, a detailed ablation study can be found in Appendix B. We also found that the overall trend of performance improvements brought by ProFees preserved on the internal-external coder agreement subset of the Test set, confirming that ProFees coding capability is generalizable towards unseen real-world encounters. Detailed results on the agreement subset can be found in Appendix E.

7 Conclusion and Future Work

This work presents the first systematic, production-oriented study of automating CPT E/M coding with large language models. We propose a modular architecture that (i) retrieves context-relevant chain-of-thought exemplars, (ii) predicts both encounter type and MDM element complexities, (iii) performs RCI to critic those intermediate decisions, and (iv) consolidates results with deterministic rule logic and a Self-Consistency ensemble. On a de-identified, expert-annotated Test dataset of 99 encounters, our model Profees improves CPT accuracy by 4.73 % over the strongest LLM baseline and by 30.61 % over the commercial CPT E/M coding software System A. Our future work includes extending the model to support multiple codes, CPT-modifiers and generating synthetic datasets for edge-case testing and enriching our VDB.

Limitations

ProFees currently predicts only one CPT E/M code per encounter, and we plan to support predicting multiple codes (e.g. for a preventive medicine visit, in which a problem-oriented service is also provided). It can be easily supported by extending the Encounter Type Classifier to output multiple encounter types. We also acknowledge the current lack of publicly available datasets for CPT E/M coding within the broader research community. To address this gap, we are curating and plan to release a synthetic dataset to facilitate research on improving model performance, robustness, and scalability in this domain.

Ethical Considerations

While ProFees demonstrates a significant improvement in CPT E/M coding accuracy, its integration into EHR systems requires careful consideration of several key ethical issues to ensure its responsible deployment.

Privacy and data integrity. Our development and evaluation efforts were conducted in a secure, HIPAA-compliant environment. As mentioned in Section 5, the development of ProFees utilize de-identified real-patient data. For deployment, ProFees will be deployed in a secure cloud environment with state-of-the-art safeguards to ensure patient confidentiality.

Accountability and liability. Automating clinical coding may introduce ambiguity on accountability for coding errors. Ultimately, ProFees acts as an assistive tool, but not an autonomous decision-making tool, that helps physicians and professional coders, who take the final responsibility.

Algorithmic biases and fairness. Our model was tuned and evaluated on a small-scale real-world dataset, which may contain latent biases. Thus, there is a risk that the model could learn (e.g. through few-shot examples) to systematically assign different CPT E/M codes based on patterns in encounter notes correlated with patient demographics (e.g. race and gender). To mitigate this

risk, we are curating a synthetic dataset to enable targeted evaluation of model behaviors.

Interpretability and transparency. Trust in a healthcare setting demands interpretability. While frontier LLMs are often considered blackboxes, we have developed ProFees to improve its interpretability. Specifically, through carefully designed prompts and architecture, we elicit sophisticated, multi-step reasoning from LLMs, leverage both internal and external clinical coding knowledge, and generate detailed rationales for coding outputs. This interpretability is not only crucial for gaining user trust and enabling human oversight, but also providing clear rationales for external audits.

Automation bias and human oversight. ProFees' strong performance (a $>$ 30-point accuracy improvement) may create a risk of *automation bias*. Specifically, it is plausible that human users might develop a degree of *reliance* higher than what is warranted. ProFees generates detailed rationales that justify suggested codes. The UI/UX and workflow design should enable and facilitate human review of the codes and corresponding rationales. Moreover, continued user education of their roles and responsibility is necessary.

Acknowledgement

We would like to thank other members of Oracle Health & AI for their collaboration while deploying ProFees in production, and Irfan Bulu, Raefer Gabriel, Neil Hauge, Mark Johnson, Kiran Rama, Amitabh Saikia, Vishal Vishnoi, and Krishnaram Kenthapadi for insightful feedback and discussions.

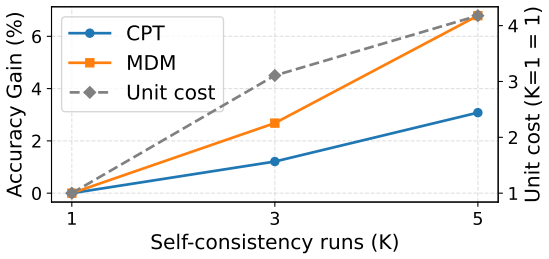
A MDM Guidelines

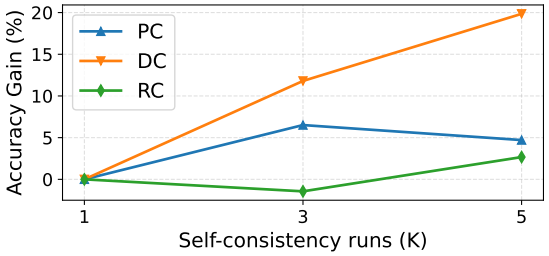
Table 4 elaborates the MDM guidelines from the 2024 edition of the CPT Professional Manual book (American Medical Association, 2023) that we have leveraged for building ProFees.

B Ablation Studies



Dynamic Few-Shot CoT Prompting. Replacing the verbose prompt with three retrieved CoT examples increases CPT accuracy by 4% relative to the zero-shot CoT variant, i.e. ProFees (Zero-Shot + RCI), and by 2.3% when comparing ProFees (Few-Shot) to ProFees (Zero-Shot).

Recursive Criticism and Improvement (RCI). Adding the RCI stage boosts all three intermediate complexity scores, yielding a 7.58% percentage-point gain in overall MDM accuracy and a 4% gain in final CPT accuracy. This confirms that a dedicated post-hoc critic effectively detects and corrects the most common intermediate errors.



Self-Consistency. Figure 3 reports *relative* accuracy gains (compared to ProFees with 1 vote/self-consistency run, i.e. K=1), together with normalised cost. Increasing the vote count from one pass to K=3 yields an additional +1.2% CPT accuracy and +2.7% MDM accuracy, but triples the unit cost. Raising the count further to K=5 adds only +3.1% CPT and +6.8% MDM over the 1-vote ProFees while pushing the cost above a four-fold increase. Intermediate metrics show the following pattern: Data-Complexity gains +11.8% at K=3 and +19.9% at K=5; Problem-Complexity peaks at K=3 then declines slightly, and Risk improves by just +2.7% overall. To balance the accuracy improvements against the cost curve, we have chosen to fix K=3 for all remaining experiments.

C High-Level Prompt Templates for CPT E/M Components

For compliance, privacy, and commercial reasons, we cannot release our full production prompts verbatim. Instead, we share *template skeletons* that capture the **role**, **task**, and **output schema** of each LLM component while redacting institution-specific wording.

(a) CPT and MDM accuracy gain and unit cost versus self-consistency runs.

(b) Intermediate accuracies gain (PC, DC, RC) versus self-consistency runs.

Figure 3: Effect of self-consistency (K) on overall and intermediate performance.

Each template specifies:

- the **LLM role** (e.g., "Encounter-Type Classifier", "Problem-Complexity Critic");
- the **core task description** and minimal guidelines needed for replication;
- the **expected output format** (always JSON); and
- **placeholders** for dynamic inputs such as `{{soap_note}}` or retrieved exemplars `{{few_shot_examples}}`.

Researchers may adapt these templates to their own datasets and policies while remaining compatible with the architecture in the main paper.

C.1 Encounter-Type Prompt

```
prompt: |
    You are a medical coding assistant. Your task
     is to classify a patient's encounter into
    the appropriate CPT code category based on
    the provided SOAP note. The categories you
    need to consider are:

    <omitted encounter type with definition>

    Use the Medical Decision Making (MDM)
    guidelines to determine the correct category.
     Here is the information you have:
```

Table 4: Levels of Medical Decision Making (MDM), extracted from the 2024 edition of MDM guidelines (American Medical Association, 2023)

Level of MDM • Based on 2 out of 3 MDM Elements	**Number and Complexity of Problems Addressed at the Encounter**	**Amount and/or Complexity of Data Reviewed and Analyzed** • Each unique test, order, or document contribute to the combination of 2 or 3 in Cat. 1 below.	**Risk of Complications and/or Morbidity or Mortality of Patient Management**
Straightforward	**Minimal** • **1** self-limited or minor problem	**Minimal or none**	**Minimal risk of morbidity from additional diagnostic testing or treatment**
Low	**Low** • **2** or more self-limited or minor problems; **or** • **1** stable chronic illness; **or** • **1** acute, uncomplicated illness or injury; **or** • **1** stable acute illness; **or** • **1** acute, uncomplicated illness/injury requiring inpatient or observation level of care	**Limited** — at least *1* out of 2 categories: • **Cat. 1: Tests and documents — Any combination of 2 from the following**: – Review of prior external note(s) from each unique source; – Review of the result(s) of each unique test; – Ordering of each unique test **or** • **Cat. 2: Assessment requiring an independent historian(s)** — For the categories of independent interpretation of tests and discussion of management or test interpretation, see moderate or high.	**Low risk from additional diagnostic testing or treatment**
Moderate	**Moderate** • **1** or more chronic illness with exacerbation, progression, or side-effects of treatment; **or** • **2** or more stable chronic illnesses; **or** • **1** undiagnosed new problem with uncertain prognosis; **or** • **1** acute illness with systemic symptoms; **or** • **1** acute complicated injury	**Moderate** — at least *1* out of 3 categories: • **Cat. 1: Tests, documents, or independent historian(s) – Any combination of 3 from the following:** – Review of prior external note(s) from each unique source; – Review of the result(s) of each unique test; – Ordering of each unique test; – Assessment requiring an independent historian(s) **or** • **Cat. 2: Independent interpretation of tests** – Independent interpretation of a test performed by another physician or other qualified health care professional (not separately reported); **or** • **Cat. 3: Discussion of management or test interpretation** – Discussion of management or test interpretation with external physician or other qualified health care professional/appropriate source (not separately reported)	**Moderate risk of morbidity from additional diagnostic testing or treatment** • *Examples only*: – Prescription drug management – Decision regarding minor surgery with identified patient or procedure risk factors – Decision regarding elective major surgery without identified patient or procedure risk factors – Diagnosis or treatment significantly limited by social determinants of health
High	**High** • **1** or more chronic illnesses with severe exacerbation, progression, or side effects of treatment; **or** • **1** acute or chronic illness or injury that poses a threat to life or bodily function	**Extensive** — at least *2* out of 3 categories: • **Cat. 1: Tests, documents, or independent historian(s) – Any combination of 3 from the following:** – Review of prior external note(s) from each unique source; – Review of the result(s) of each unique test; – Ordering of each unique test; – Assessment requiring an independent historian(s) **or** • **Cat. 2: Independent interpretation of tests** – Independent interpretation of a test performed by another physician or other qualified health care professional (not separately reported); **or** • **Cat. 3: Discussion of management or test interpretation** – Discussion of management or test interpretation with external physician or other qualified health care professional/appropriate source (not separately reported)	**High risk of morbidity from additional diagnostic testing or treatment** • *Examples only*: – Drug therapy requiring intensive monitoring for toxicity – Decision regarding elective major surgery with identified patient or procedure risk factors – Decision regarding emergency major surgery – Decision regarding hospitalization or escalation of hospital-level care – Decision not to resuscitate or to de-escalate care because of poor prognosis – Decision regarding parenteral controlled substances

C.2 MDM-Complexity Prompt (Initial Pass)

```
system: |
    You are a highly skilled medical coder
    specializing in CPT Evaluation and Management
     (E/M) codes. Your expertise lies in
    analyzing clinical documentation to assign
    accurate E/M codes while adhering strictly to
     AMA guidelines. Precision is critical, as
    any deviation in selecting the appropriate
    code based on the documented history,
    examination, and medical decision-making (MDM
    ) can lead to claim rejections or audits.
    Your role ensures compliance, accuracy, and
    proper reimbursement for outpatient and
    consultation visits.

    ## Task:
    You will be given a patient encounter note
    together with relevant information about the
    visit (e.g. patient problems, medications and
     orders), and you are required to assess the
    medical decision making (MDM) elements of the
     encounter.

    ## Instructions:
    ### 1 - Assess Each Element of Medical
    Decision Making (MDM)

    There are three elements of MDM complexity,
    each with its own criteria:
    <omitted MDM guideline>

    ### 2 - Return each of the three MDM elements
     complexities together with your chain of
    thought reasoning for each based on the above
     criteria.

    {% if few_shot_examples%}
    ## Examples:
    Here are some examples:
    {{few_shot_examples}}

    {% endif %}
    ----------------------------
    ## IMPORTANT NOTES:
    <omitted MDM key notes>
    ----------------------------
    ## Output Format
    You should always return your output as a
    JSON object as per the schema specified by
    the user.
    Do not include any other text or formatting
    in your output. Only return the JSON object.

user: |
    ## Input:
    Here is the encounter note you need to
    analyze and classify:
    {{text}}
    {% if additional_info%}

    ## Additional Information:
    And here are the additional information about
     the visit:
    {{additional_info}}

    {% endif %}
    ## Output Format
    Please return the output as a JSON object
    following the below schema:
    {{format_instructions}}
    Do not include any other text or formatting
    in your output. Only return the JSON object.
```

C.3 Critic Prompt for Problem Complexity

```
prompt: |
    Now your role is a medical coding auditor
    with a keen eye for details.

    Your task is to review and reflect on the
    generated problem complexity assessment to
    ensure **accuracy, adherence to guidelines,
    and completeness**.

    # Instructions
    Review and reflect on the generated problem
    complexity assessment. Most of the time, it
    would be accurate, but you need to double-
    check that it adheres to the original
    guidelines as well as the additional
    instructions below.

    **Important Note:** Base all complexity
    assessments primarily on the 'Assessment and
    Plan' section, as it contains the provider's
    clinical judgment and final diagnosis.
    - Use the 'History of Present Illness' (HPI)
    only for contextual background, such as
    disease onset or duration for determining
    chronicity.
    - Do not rely on HPI to determine severity,
    uncertainty or progression, as it reflects
    the patient's subjective description, which
    may include exaggerations or inaccuracies.

    Apply System 2 Thinking:
    - Explicitly reason by breaking down your
    thought process step-by-step before reaching
    a conclusion.
    - The reasoning should mention why each
    instruction below (header, bullet and sub-
    bullet in this case) applies or does not
    apply to this encounter.
    - Ensure that you output the reasoning for **
    each** instruction.

    <omitted critic rules for problem complexity>
```

```
    # Output format:
    {{format_instructions}}
    ## Example output:
    The below is an example output to show the
    expected concise yet detailed reasoning and
    the expected output format. DO not mix up the
     conditions in the example output with the
    conditions in the note.

    DO NOT ADD any content before or after the
    JSON.
```

C.4 Critic Prompt for Data Complexity

```
prompt: |
    Now your role is a medical coding auditor
    with a keen eye for details.

    Your task is to review and reflect on the
    generated data complexity assessment to
    ensure **accuracy, adherence to guidelines,
    and completeness**.

    # Instructions:
    Your role is to double-check the note and the
     data complexity in model response and ensure
     their compliance with the additional
    criteria below:

    Apply System 2 Thinking, meaning that for
    each instruction below, explicitly reason by
    breaking down your thought process step-by-
    step before reaching a conclusion.
    The reasoning should mention why each
    instruction (bullet in this case) was either
    followed, not followed, or not applicable.
    Ensure that you output the reason for each
    instruction.

    <omitted critic rules for data complexity>

    Finally return the final list of data
    complexity items with their types after your
    proposed changes, if any.

    # Output format:
    {{format_instructions}}
    DO NOT ADD any content before or after the
    JSON.
```

C.5 Critic Prompt for Risk Assessment

```
prompt: |
    ## **Key Risk Classification Criteria (Apply
    with Key Notes for General Risk Assessment)**
    1. xxx
    n. xxx

    # Every classification must be reviewed
    against **each** of the following **n key
    notes** to ensure accurate risk determination
    . These guidelines prevent errors caused by
    overlooked details, misinterpretation, or
    incorrect risk assignment.

    ## **Key Notes for General Risk Assessment (
    Must be Cross-Checked for Every
    Classification)**

    <omitted critic rules for risk assessment>

    Apply **System 2 Thinking**, meaning that for
     each of the n instructions of Key Risk
    Classification Criteria, explicitly reason by
     breaking down your thought process step-by-
    step before reaching a conclusion. The
    reasoning should mention why each instruction
     was either **followed, not followed, or not
    applicable**, with exact references from the
    input SOAP Note and EHR information. Ensure
    that you output the reason and consider all
    instructions under **Key Notes for General
    Risk Assessment** for each evaluation.
    Your classification **must be cross-checked**
     against **each** of these n Key Notes to
    prevent misclassification due to oversight.

    <omitted key notes for risk assessment>

    ### **Classification Examples**
    The following examples illustrate the
    reasoning process required to do
    classifications. The chain of thought
    explicitly check each point of Official
    Guidelines and Criteria, while applies each
    key assessment rule to ensure an accurate
    classification.

    # **Output Format:**
    {{format_instructions}}

    DO NOT ADD any content before or after the
    JSON.
```

D Datasets

This section presents more details of our datasets, including the CPT E/M code distribution over the three subsets and an example data annotation page.

D.1 Distribution of CPT E/M Codes

Figures 4, 5 and 6 illustrate the distribution of CPT E/M codes in the *Platinum*, *Disagreement* and *Test* datasets respectively.

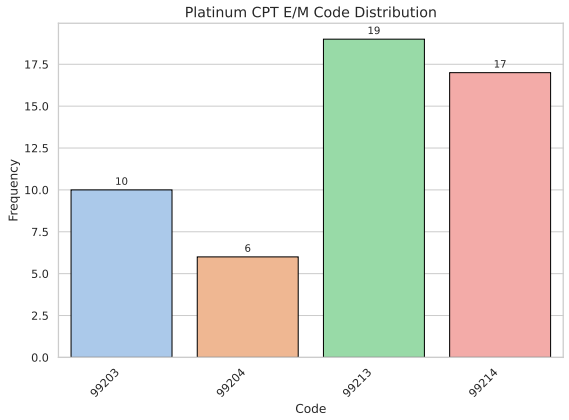

Figure 4: Frequency distribution of CPT E/M codes on the Platinum subset.

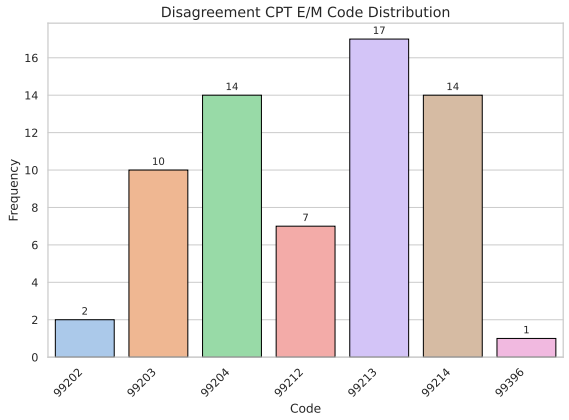

Figure 5: Frequency distribution of CPT E/M codes on the Disagreement subset.

D.2 Specialty Distribution

Figures 7 and 8 illutrate the distribution of physician specialties in the combined *Platinum* + *Disagreement*, and *Test* datasets respectively.

D.3 Data Annotation Interface

Figure 9 shows our data annotation interface.

Table 5: Evaluation of accuracy improvements on the agreement subset of Test set. Results are averaged over 5 runs.

Model	CPT Acc. (%)	MDM Acc. (%)	PC Acc. (%)	DC Acc. (%)	RC Acc. (%)
ProFees (Zero-Shot)	↑ 25.01 ± 1.07	↑ 26.95 ± 1.07	↑ 23.69 ± 0.00	↑ 26.94 ± 1.07	↑ 20.96 ± 1.07
ProFees (Zero-Shot + RCI)	↑ 30.65 ± 1.07	↑ 32.51 ± 1.07	↑ 32.94 ± 0.00	↑ 44.84 ± 3.21	↑ 24.04 ± 1.85
ProFees (Few-Shot)	↑ 26.33 ± 1.85	↑ 28.19 ± 1.85	↑ 25.54 ± 1.85	↑ 31.26 ± 1.07	↑ 25.28 ± 2.83
ProFees (Few-Shot + RCI | Full)	↑ 33.74 ± 0.00	↑ 35.59 ± 0.00	↑ 32.33 ± 1.07	↑ 41.14 ± 1.85	↑ 27.75 ± 0.00

E Additional Experiments

We present the performance of ProFees on the agreement subset of our Test dataset in Table 5, on which our internal coder agrees with external coders' CPT E/M codes. Specifically, they agree on 54 out of the 99 test encounters.

F Synthetic Example

This section shows an example of synthetically generated data, aligning with the data used in our work.

Patient Type: New
Encounter Type: Office or Outpatient Service
CPT Code: 99203
Problem Complexity: Low
Data Complexity: Straightforward
Risk of Complications: Low
MDM Complexity: Low

```
SUBJECTIVE

Chief Complaint: Left ear pain and mild swelling
 after swimming.

History of Present Illness:
Emily Carter is a 24-year-old new patient
presenting today with discomfort in her left ear
 that started yesterday after a swim at her
local pool. She describes the pain as a dull
ache, rated 4/10, accompanied by mild swelling
around the ear canal. She states, "My ear feels
sore and a little puffy since I went swimming,
but I don't feel sick otherwise." She denies
fever, chills, or drainage from the ear. She
also mentions some redness and itchiness in both
 eyes recently after spending time outdoors, but
 clarifies this was much worse a few days ago
and is now stable since starting antihistamine
eye drops. No vision changes or other new
symptoms. "My eyes were super itchy and red a
few days back, but the drops really helped." No
other complaints.

REVIEW OF SYSTEMS
ENT: Positive for left ear pain and mild
swelling; negative for hearing loss, discharge,
or tinnitus.
Eyes: Mild residual itching; no redness or
vision changes today.
Constitutional: Denies fever, chills, malaise.

OBJECTIVE
Physical Exam:
- General: Alert, comfortable, no acute distress.
 Vitals stable.
- HEENT: Left external ear canal erythematous,
mildly edematous, tender. No purulent discharge.
 TM intact, no erythema. Right ear normal.
Conjunctivae clear, oropharynx clear.
- Neck: No lymphadenopathy.

ASSESSMENT AND PLAN
- Acute otitis externa, left ear, likely from
swimming.
    - Recommend acetic acid 2% otic solution (OTC
    ) for canal acidification.
    - Keep ear dry; avoid water until resolved.
    - Pain control with acetaminophen or
    ibuprofen as needed.
    - Return for worsening (fever, redness,
    persistent pain).
    - No antibiotics needed at this time.
    - If no improvement in 48-72 hrs or symptoms
    worsen, re-evaluate for prescription therapy/
    workup.
```

Synthetic SOAP note.

Classifier-Augmented Generation for Structured Workflow Prediction

Thomas Gschwind, Shramona Chakraborty, Nitin Gupta, and Sameep Mehta
IBM Research

Abstract

ETL (Extract, Transform, Load) tools such as IBM DataStage allow users to visually assemble complex data workflows, but configuring stages and their properties remains time consuming and requires deep tool knowledge. We propose a system that translates natural language descriptions into executable workflows, automatically predicting both the structure and detailed configuration of the flow. At its core lies a Classifier-Augmented Generation (CAG) approach that combines utterance decomposition with a classifier and stage-specific few-shot prompting to produce accurate stage predictions. These stages are then connected into non-linear workflows using edge prediction, and stage properties are inferred from sub-utterance context. We compare CAG against strong single-prompt and agentic baselines, showing improved accuracy and efficiency, while substantially reducing token usage. Our architecture is modular, interpretable, and capable of end-to-end workflow generation, including robust validation steps. To our knowledge, this is the first system with a detailed evaluation across stage prediction, edge layout, and property generation for natural-language-driven ETL authoring.

1 Introduction

ETL and ELT (Extract, Transform, Load) workflows are foundational for data integration and analytics pipelines in modern enterprises (Rahm and Do, 2000; Vassiliadis, 2009). These workflows combine data from disparate sources and apply structured transformations, typically authored through dedicated tools such as IBM DataStage. While such tools offer graphical interfaces for assembling workflows from predefined components, users must still manually configure transformation stages and specify dozens of low-level properties per stage making authoring tedious and error-prone even for experts.

Early work addressed these challenges through custom scripting or GUI-based simplification (Vassiliadis et al., 2001; Reddy V and Jena, 2010), and others explored semantic and ontology-driven ETL generation (Jiang et al., 2010). However, recent advances in large language models (LLMs) offer new opportunities to automatically synthesize such workflows directly from natural language, reducing configuration overhead and improving accessibility.

The main contribution of this paper is an end-to-end system that translates natural language utterances into executable ETL workflows. The system is built on a *Classifier-Augmented Generation (CAG)* approach, which combines utterance decomposition, classification-based stage retrieval, and few-shot prompting to predict the sequence of required workflow stages. These predicted stages are then assembled into a directed flow via edge prediction and configured via property prediction based on stage-local sub-utterances.

Our architecture is modular, interpretable, and supports robust validation. We compare CAG against strong single-prompt and agentic baselines, demonstrating improvements in both accuracy and efficiency (e.g., over 60% token reduction while at the same time using a smaller model). Our system is already integrated into a production ETL tool (IBM DataStage), where it supports real-world user workflows, serving both novice users, who benefit from reduced interaction complexity, and expert users, who gain from auto-filled configurations requiring only a lightweight review.

We report detailed evaluation results for each generation step (stage, edge, and property prediction) and discuss how system design decisions impact performance and interpretability. Our findings provide practical guidance for building LLM-assisted authoring tools for structured, real-world automation tasks.

2 Background

We selected IBM DataStage due to its scale, mature ecosystem, and publicly documented stages and configuration interfaces (IBM, 2025), making it a representative platform for evaluating structured workflow generation. DataStage enables users to design and run ETL (Extract, Transform, Load) and ELT workflows across diverse data sources using a visual interface, where predefined components (e.g., connectors, transformers, and aggregators) are assembled into workflows.

As a one-time setup, we extracted 142 DataStage stages (90 of them datasource connectors) along with their descriptions and properties from the official documentation. Stages, also referred to as datasources, operators, or tasks, form the basic building blocks of a workflow. Each stage has between 1 and 111 properties, with an average of 27.6. For every property, we store its description, type, default value, and availability conditions in a structured format suitable for prompt generation and output validation.

3 Workflow Generation

This section introduces and evaluates our modular pipeline for generating ETL workflows from natural language. We begin by comparing different approaches for predicting the set of workflow stages (Sections 3.1–3.3), then use the best-performing approach to predict edges between these stages (Section 3.4), and finally generate stage properties (Section 3.5). For this evaluation, we sampled 1010 natural language flow descriptions for stage prediction.[1] From this set, we annotated 308 flows with 1410 properties, and additionally sampled 54 complex non-linear flows (with up to 14 stages) for edge prediction.

3.1 Single Prompt Stage Prediction

The first approach uses a single prompt that presents all 142 stages and asks the LLM to identify those needed for the workflow. The prompt includes task instructions, stage names with one-line descriptions, 142 few-shot examples, and the user's utterance. Few-shot examples help compensate for the LLM's lack of pretrained knowledge about individual stages (Kojima et al., 2022), showing how stages are combined in real tasks. On average, each stage appears in about two examples.

Model	Accuracy [%] total	1-op	*n*-op
llama-3.2-3b-instruct	71.1	92.3	23.2
granite-3.1-8b-instruct	88.0	92.6	77.7
llama-3.3-70b-instruct	96.4	98.1	92.6
llama-4-mvk-17b-128e-...[2]	95.8	97.7	91.6

Table 1: Single-prompt accuracy on 1010 flows; "1-op" refers to predictions involving a single stage; "*n*-op" refers to predictions involving two or more stages

As shown in Table 1, the LLMs perform well, especially the bigger ones, in predicting the workflows at hand. In certain cases, the models appear to overlook relevant stages or parts of the utterance, likely due to the sheer number of stages presented in the prompt. For instance, given the utterance "Combine the employee_info master dataset with the employee_updates and department_changes datasets on employee_id. Once done, update the employee_records and employee_department information accordingly." most models only returned the *join_merge* instead of the correct *join_merge* and *modify* stages. The LLaMA3.2 model only returns *combine_records*, which in combination with its poor accuracy shows that this task exceeds the model's capabilities. As explained in (Brown et al., 2020), larger LLaMA models outperform smaller models.

Because this approach includes all the DataStage stages and many few-shot examples in the prompt, it sends almost 14′000 tokens per request to the LLM. The variation in tokens used for the different requests is relatively small (+/-100) since the prompt, except for the user's utterance, remains the same for every request. Despite the large prompt size, modern LLMs with 128k context windows (Grattafiori et al., 2024; Stallone et al., 2024) can process such inputs comfortably.

3.2 Agentic Stage Prediction

To reduce the prompt size and improve modularity, we adopt an agentic approach in which the LLM operates as a ReAct-style agent (Yao et al., 2023). Rather than receiving all stage definitions up front, the LLM itself may decide to decompose the user utterance into sub-utterances and invokes a callable stage classification tool to identify appropriate components. This setup is inspired by recent work on integrating external tools into LLM

[1] These utterances are paraphrased and anonymized from internal real-world DataStage flows, including customer-inspired examples. No IBM documentation was used to construct these flows.

[2] llama-4-maverick-17b-128e-instruct-fp8

workflows (Schick et al., 2023; Qin et al., 2024; Qu et al., 2025).

The classification tool uses a fast and small classification model trained on a set of 2′697 (utterance, operator) single-label pairs covering 138 semantic labels (derived by merging close variants among the 142 total stages).[3] Since our training data consisted only of single-label pairs, we could not train a multi-label classification model. As base models, we used once Meta AI's RoBERTa-large model (Liu et al., 2020) and once IBM's slate-125m-english-rtrvr model (IBM, 2024), both are small enough and run extremely fast even on a standard CPU. After training, both models had an accuracy of about 98% with RoBERTa-large performing marginally better but also a bit slower. Since speed is of importance to use, we use slate as our base model.

Since the classification model operates on single-label inputs, we expose it to the LLM as a callable tool. The prompt itself contains instructions explaining the LLM's task, the available classification tool, and the user's utterance. The LLM correctly splits the utterance into smaller sub-utterances that each describe a stage to be executed and passes each of those sub-utterances to the classification tool. Based on the results of the classification tool, the LLM combines the results and generates the final answer for the flow.

When examining the results in Table 2, we observe that LLaMA4 underperforms compared to LLaMA3.3, despite dedicated prompt tuning. Similar weaknesses of LLaMA4 on specific tasks have also been reported by others(Nuenki, 2025; Forsook-Comparison, 2025). Overall, the agentic approach performs worse than the single-prompt method across all models. We identify three main reasons: (1) the *granularity mismatch* between generated sub-utterances and the functional scope of DataStage stages (some sub-utterances are too fine-grained, others too coarse); (2) *semantic similarity* between certain stages, such as `split_subrecord` and `split_vector`, which the limited-capacity classifier struggles to disambiguate; and (3) occasional *classification failures*, even for simple cases, which, though infrequent, can reduce user trust in the system.

The challenge of this approach is that without any additional information, it is very hard for the LLM to split the user's utterance into sub-utterances of the right granularity. For instance, the best performing LLaMA 70b model, for the utterance "I want to use teradata where my connection name is teradata-00, schema name is TM_DS_DB_1 and table name is EMPLOYEE2. then sort on the age column. then filter out pizza column. then postgres where my connection name is tristan_postconn , schema name is public and table name is demoautotest, Also do the following, Decimal rounding mode is ceiling, Generate Unicode Columns, Row limit should be 50.", formed the sub-utterance ("sort on the age column, filter out pizza column, Decimal rounding mode is ceiling, Generate Unicode Columns, Row limit should be 50") containing multiple stages which the classification tool classifies as *sort*. The model realizes that this cannot be complete and in subsequently asks the classification tool to classify "filter out pizza column" (*filter*), "Decimal rounding mode is ceiling" (*decode*), "Generate Unicode Columns" (*column_generator*), and "Row limit should be 50" (no match). Unfortunately, while trying to figure all this out, the model omits the seemingly trivial upstream and downstream database stages (*teradata* and the *postgresql*) likely due to context loss or attention limits.

We tried to mitigate this by providing a set of examples of how to split an utterance into sub-utterances to use for the classification tool. This confused the LLMs and they interpreted these examples as input-output examples with the effect that the output of the LLM became mostly unusable. Considering that the LLMs were able to do some consolidation of the final results and did not simply return the concatenations of the classification results, we tried to return a description of the stage predicted by the classification function clearly marked as stage description but that too got misinterpreted by the LLMs and again the accuracy dropped considerably. Finally, we tried to provide the LLM with a function that instead of giving a single recommendation, suggests candidates and documented this as part of the tool description but again the LLM misinterpreted the output and

Model	Accuracy [%] total	1-op	*n*-op
llama-3-2-3b-instruct	33.4	40.0	18.4
granite-3-1-8b-instruct	45.6	37.0	65.2
llama-3-3-70b-instruct	69.3	90.4	21.6
llama-4-mvk-17b-128e-. . .	40.0	27.9	67.4

Table 2: Agentic accuracy (1010 flows)

[3]The dataset is split into 2'133 training examples and 564 test samples. Evaluation yields macro-Precision of 98.6%, macro-Recall of 97.8%, and macro-F1 of 98.1%, based on sigmoid-thresholded outputs across classes.

thought that all of these tasks should be included in the final flow.

3.3 Classifier Augmented Stage Prediction

Agentic approaches enable language models to autonomously reason and act, but in our experiments they struggled with utterance decomposition, tool invocation, and prompt interpretation. As in the agentic approach, we ask the LLM to split up the user's utterance into single-stage sub-utterances which we then classify with our classifier tool. The stages identified through these tool calls form a set of candidate stages. These are then passed to the LLM along with one-line descriptions and few-shot examples that specifically support them, hence the name Classifier Augmented Generation (CAG). CAG addresses practical shortcomings of the agentic setup while retaining compatibility with agent-based workflows.

This approach has several other key benefits. The generation of the sub-utterances is a separate step in which we can provide few-shot examples demonstrating utterances and the corresponding sub-utterances. While these examples may not provide a complete overview of the granularity of every stage, they do give the model already a rough idea of the expected granularity. Additionally, after the classification model has identified the candidate stages, we scan the user's utterance for stage names (e.g., filter) and their synonyms (e.g., extract) and if they match add the corresponding stages to the set of candidate stages. This keyword search significantly reduces mispredictions for seemingly trivial utterances.

Once the set of candidate stages has been computed, we use the prompt from Section 3.1 limited to the stages identified as candidates and about 40 few-shot examples that mention at least one of the stages in the candidate set. This way, we use both the classifier and keyword search to narrow the candidate stage space, while the LLM performs the final multi-label prediction. Additionally, this approach allows us to present a larger number of few-shot examples relevant for candidate stages, enabling the LLM to better distinguish between similar stages.

Using this approach, we arrive at the accuracy numbers shown in Table 3, consistently performing better than the already excellent single prompt approach. Moreover, this improved performance comes at a lower cost: the approach uses only 4,000–4,700 tokens per request on average, depending on the model, reducing the number of tokens per request by approximately 66%. In addition, it achieves comparable accuracy while using a smaller model that is significantly cheaper per token, resulting in further overall cost savings. As in other settings, we observe accuracy increasing with model size. One illustrative failure case is the utterance: "Split the full_name field of the employee_data dataset into separate columns for first_name and last_name, then capitalize the first letter of each name for consistency." Most models return only the *split_subrecord* stage and omit the expected *modify* stage. Although the models correctly identify "Capitalize the first letter of each name for consistency" as a distinct sub-utterance, our classifier incorrectly maps it to *head* stage. Because the keyword search also fails to surface the *modify* stage, it is excluded from the prompt and thus not predicted. The model correctly rejects *head* based on the few-shot examples, but with no other relevant candidate, it defaults to predicting only *split_subrecord*.

	Accuracy [%]		
Model	total	1-op	*n*-op
llama-3.2-3b-instruct	90.1	97.6	73.2
granite-3.1-8b-instruct	94.0	97.9	85.2
llama-3.3-70b-instruct	97.2	98.6	94.2
llama-4-mvk-17b-128e-. . .	97.7	99.0	94.8

Table 3: CAG accuracy (1010 flows)

3.4 Edge Predictions

So far, the stage and property prediction components operate under the assumption of linear flows, where the execution order is implicitly defined by the sequence of stages. However, many real-world ETL workflows are non-linear: they include branching, parallel processing, joins, and multiple input or output sinks. In these cases, the data flow structure cannot be inferred from the stage order alone, and edges must be explicitly predicted.

We define non-linear flows as workflows involving branching, joining, or parallel transformations that cannot be expressed as a single linear pipeline. We generate the flow structure based on the stages predicted by the CAG approach (95% accuracy).

First, to distinguish repeated stages, we assign unique names (e.g., by adding a '_*n*' suffix) while preserving their semantic identity. Second, to anchor these names to a specific part of the user's utterance, we ask the LLM to split the utterance according to the stages that we have obtained through

Model	similarity	exact
llama-3-2-3b-instruct	31%	0%
granite-3.3-8b-instruct	41%	4%
llama-3.3-70b-instruct	73%	37%
llama-4-mvk-17b-128e-. . .	42%	15%

Table 4: Edge prediction (54 non-linear flows)

Model	prec.	recall	F1
llama-3-2-3b-instruct	88%	72%	0.79
granite-3.3-8b-instruct	93%	71%	0.81
llama-3.3-70b-instruct	92%	81%	0.86
llama-4-mvk-17b-128e-. . .	94%	67%	0.78

Table 5: Property prediction (308 flows with 1410 properties)

the classification approach. Since the LLM now has access to the task list and stage descriptions, it can segment the user's utterance into sub-utterances with over 99% accuracy. The result is a node list, where each node includes a unique name, a localized task description, and cardinality constraints derived from DataStage specifications. Given this input and the original utterance, the LLM predicts the flow structure.

Sometimes, the predicted edges violate the predefined input/output cardinality constraints of certain stages, particularly when the CAG step fails to identify all necessary stages. This can lead to constraint violations. To address this, we validate whether each node's edge count matches its allowed cardinality. If violations are found, we attempt to split overloaded nodes (e.g., a node with no inputs and multiple outputs), if such a split is unambiguous. If splitting is not possible, we remove excess edges until all constraints are satisfied.

Table 4 shows the results for complex non-linear flows with 6–14 stages (avg 8.1) per flow (again, LLaMA4 struggles with some tasks), it is the most challenging step, even the best model achieves only 37% exact match and 73% structural similarity. These results are still valuable as flows with 70–80% similarity often require only minor corrections. For this aspect we have not yet managed to optimize the prompts, so there may be room for improvements.

3.5 Property Prediction

To predict stage properties, we use the sub-utterances generated for each individual stage by the edge prediction. Using the full utterance can lead to ambiguity, as LLMs may struggle to determine which property belongs to which stage—especially when a stage appears multiple times (e.g., multiple *sort* stages sorting different data artifacts). Hence, properties are predicted individually for each stage. Each prompt contains task-specific instructions, the sub-utterance, the corresponding stage name, a list of all supported properties (each with a one-line description), and a one-shot example.

To mitigate errors in generated properties, we apply a multi-dimensional validation strategy that validates the properties associated with the current stage. First, we remove any generated properties whose names do not match a valid property defined for that stage. Second, we check whether the value of each property can be coerced to the property's declared type. If type coercion fails, the property is discarded. Third, we evaluate inter-property dependencies: some properties are only valid if others are present with specific values. This logic is encoded as metadata expressions evaluated at runtime, with access to the full set of properties predicted for the stage. For instance, in the *Column Generator* stage, the property *Options/Column to Generate* is only valid when *Options/Column Method* is set to *Explicit*. Finally, we perform stage-specific or external consistency checks. For example, certain properties must match real-world artifacts—such as actual database connection names mentioned by the user. If such constraints are violated, the property is removed.

The results in Table 5 show strong performance across all models, including the smallest LLaMA model. This is partly due to our preprocessing of the utterance into focused sub-utterances, each matched to a corresponding list of possible properties. This reduces the model's job to a pattern-matching setup that even smaller models can achieve with high precision and competitive F1 scores.

3.6 Pipeline Summary

Our overall pipeline is shown in Figure 1. The process begins with a natural language utterance, which is split into sub-utterances and passed through a classification model to identify candidate stages. In parallel, a keyword matcher recovers additional stage candidates. Together, these form the retrieval step in our Classifier-Augmented Generation (CAG) approach. Based on the selected stages, we generate targeted descriptions and few-shot examples, which are then used by the LLM to predict the final list of stages. This stage prediction step is followed by a verification pass to ensure stage-level consistency.

Once the stages are known, the pipeline branches into two parallel steps: generating the nonlinear

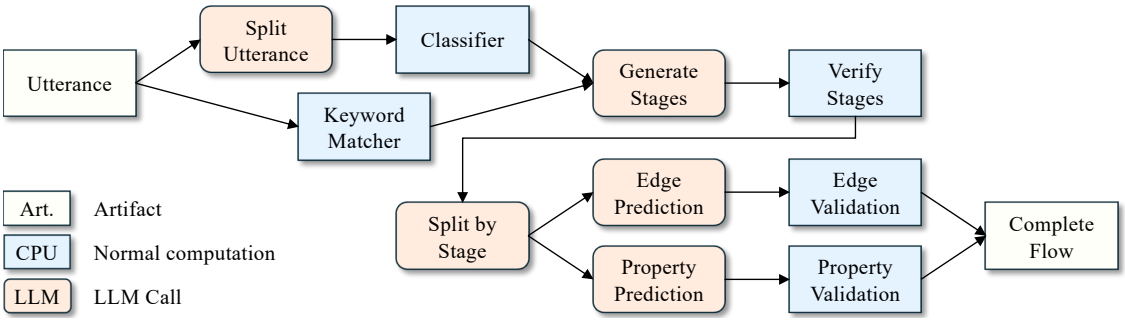

Figure 1: Interaction between CAG, edge prediction, and property prediction to generate workflows.

structure of the workflow (i.e., edge prediction), and inferring per-stage parameters (i.e., property prediction). For both tasks, the model uses the previously derived sub-utterances and stage descriptions. A final validation layer enforces edge cardinality constraints and property-level correctness. The result is a complete DataStage workflow generated from natural language input.

4 Related Work

Apart from our approach, we found Zap builder (Zapier, 2024) and Power Automate (Microsoft) that both offer an AI-powered flow generation but no technical details or results about these tools seem to be available in the literature. (Datacamp Team, 2024) maintains a list of popular ETL tools but after closer inspection, none of them seem to support providing flows by a natural language description.

In the research literature, we found GOFA (Brachman et al., 2022) that creates application integration workflows through natural language. It utilizes an Integration Knowledge Graph, eliminating the need for an annotator. However, it serves mostly as generating a skeleton for a linear flow since it does not help with the configuration of the nodes' properties whereas our approach generates complete workflows. FlowMind (Zeng et al., 2023) and AutoFlow (Li et al., 2024) are tools for executing a workflow based on a user's query. However, these "workflows" are executed ad hoc whereas our tool generates the implementation of a generic workflow that, once created, can be used repeatedly even without an LLM. Analyza (Dhamdhere et al., 2017) is a tool that generates SQL queries from natural language input, utilizing a parser, annotator, and table identifier to handle user queries. The tool addresses the challenge of ambiguity in complex SQL queries by initially limiting itself to simpler ones. Subsequent steps involve refining the original query using simple statements, akin to part of our approach of supporting the selection of a single ETL stage at a time. However, this work only describes the system and does not provide any evaluation and benchmarking.

5 Limitations

While our classifier achieves high accuracy, it was trained solely on single-label (utterance, stage) pairs due to the lack of sufficiently large multi-label training data. This constraint is mitigated by a final LLM-based multi-label generation step, but classification errors may still propagate when relevant candidate stages are excluded entirely.

Stage and property prediction remain robust across a range of workflows. However, edge prediction remains a key limitation. Although we achieve 73% structural similarity to gold-standard layouts, exact edge match is only 37%. As a result, the system often produces structurally valid drafts that still require user revision. In future work, we aim to explore hybrid architectures that combine LLM-based semantic reasoning with geometric deep learning methods such as graph neural networks (GNNs) to improve edge layout accuracy and flow topology prediction.

Our current validation logic assumes that table and column names are either correct or ignorable. While unmatched names are filtered during post-processing, the system does not currently attempt fuzzy matching or correction. This limits robustness in realistic settings where users may reference unavailable or misspelled schema elements.

Prompt formats and examples are tuned per model family, which may reduce portability across model architectures or providers. Generalization to other ETL platforms depends on the availability of operator-level metadata (e.g., transformation descriptions and property schemas), which is common but not universal.

Finally, while the system performs well on multi-step utterances, the style and structure of the inputs reflect internally sourced usage data. We expect further refinement to be needed when adapting to workflows from other domains or user populations.

6 Conclusions

We introduced a modular system for translating natural language into executable ETL workflows, combining classification and generation in a Classifier-Augmented Generation (CAG) architecture. The system decomposes user utterances into manageable sub-tasks—stage selection, edge prediction, and property configuration—paired with targeted prompting and validation. CAG predicts correct workflow stages in over 97% of cases, outperforms strong single-prompt and agentic baselines, and reduces token usage by more than 60%. When deployed with a smaller model, it achieves comparable accuracy to the single-prompt baseline at roughly 90% lower overall cost. Property prediction achieves 90% accuracy, and full-flow generation reaches over 70% structural similarity—often requiring only minor corrections. Beyond strong results, our architecture enables modular validation and constraint-based correction, and lends itself to transparent reasoning about intermediate predictions. Edge prediction though remains a challenge but offers clear opportunities for optimization. We believe our approach offers a promising foundation for LLM-assisted authoring of structured automation tasks in ETL and related domains. Its successful integration into a production ETL platform further validates the practicality and scalability of the proposed architecture.

A Example Utterances and Flows

This appendix lists two examples prompts that are similar to the fewshot examples we used as well as examples for the evaluation. Originally, this work started by predicting the stages used in linear flows and in a latest prototype was extended to cover non-linear flows as well.

A.1 Linear Flow

Linear flows do not employ any kind of branching and simply describes a sequence of actions the properties to be used for each action. One such flow is the following:

> I want to use teradata where my connection name is teradata-00, schema name is TM DS DB 1 and table name is EMPLOYEE2. then sort on the age column. then filter out pizza column. then postgres where my connection name is tristan postconn , schema name is public and table name is demoautotest, Also do the following, Decimal rounding mode is ceiling, Generate Unicode Columns, Row limit should be 50.

For this natural language descriptionm, the following flow should be generated:

> *teradata* → *filter* → *decode* → *column_generator* → *postgresql*

A.2 Non-Linear Flows

To evaluate the edge prediction to evaluate non-linear flows as well we used samples similar to the following which is shown grapically in Figure 2:

Extract data from MySQL and sample it using percent mode to send some data to a switch operator and the other data to a join operator. The switch stage writes some data to a fileset and outputs the rest to a sort stage that finally writes data into another fileset. The join operator merges the sampled MySQL data with data from a SQL Server source. Finally, the first few rows are selected using a head operator.

B Prompt Templates

Different model families may require tailored prompt formats for optimal prediction. In this work, we focused on the Granite and LLaMA model families and optimized their respective prompts for stage prediction. The following examples show the exact prompts used in the CAG setup for both Granite and LLaMA. By instead listing all stages and adjusting the few-shot examples accordingly, we obtain the prompt used in the single-prompt baseline.

B.1 Granite Prompt Template

Granite models require explicit role tokens to delimit system instructions, user input, and assistant responses. The prompt includes multiple few-shot examples and a final assistant cue that signals the model to complete the task. Its structure follows the public Granite documentation (IBM Research, 2024).

The same base prompt structure is used for both the single-prompt and CAG setups: the only difference is that the single-prompt baseline enumerates all DataStage stages, whereas the CAG variant restricts this list to candidates identified by the classifier and keyword search (see Sections 3.1 and 3.3).

In this example, the operator description for `column_generator` could not be automatically extracted by our tooling and was therefore omitted. Nevertheless, the LLM correctly inferred its semantics from the few-shot examples.

Operators: "column_generator"

Utterance: Process complex flat files, split vector columns,
 ↪ and load the data into a SingleStore Database.
Operators: "complex_flat_file, split_vector, singlestore"

Utterance: Give me the last 3 rows of my input dataset
Operators: "tail"

Utterance: The Split Subrecord stage separates an input
 ↪ subrecord field into a set of top-level vector columns.
Operators: "split_subrecord"

Utterance: Import from column 'Sales' using file 'sales_schema.
 ↪ xml'. Keep the import column
Operators: "column_import"

Utterance:
Split the full_name field of the employee_data dataset into
 ↪ separate columns for first_name and last_name, then
 ↪ capitalize the first letter of each name for consistency.
Operators:<|end_of_text|><|start_of_role|>assistant<|
 ↪ end_of_role|>
```

B.2 Llama Prompt Template

The LLaMA prompt follows a similar structure but uses instruction-tuned phrasing and omits explicit role tokens. Unlike Granite, LLaMA models do not require these delimiters to correctly complete the final example. However, it is important to pre-seed the output with the opening quote character (") to guide the model toward the correct output format; without this cue, the LLaMA models occasionally deviate from the expected format. Interestingly, for the Granite models this pre-seeding had the opposite effect and reduced the output consistency.

Efficient and Versatile Model for Multilingual Information Retrieval of Islamic Text: Development and Deployment in Real-World Scenarios

Vera Pavlova[1,2], **Mohammed Makhlouf**[1]
[1]rttl labs [2]burevestnik.ai
[1]v@rttl.ai, mm@rttl.ai [2]v@burevestnik.ai

Abstract

Despite recent advancements in Multilingual Information Retrieval (MLIR), a significant gap remains between research and practical deployment. Many studies assess MLIR performance in isolated settings, limiting their applicability to real-world scenarios. In this work, we leverage the unique characteristics of the Quranic multilingual corpus to examine the optimal strategies to develop an ad-hoc IR system for the Islamic domain that is designed to satisfy users' information needs in multiple languages. We prepared eleven retrieval models employing four training approaches: monolingual, cross-lingual, translate-train-all, and a novel mixed method combining cross-lingual and monolingual techniques. Evaluation on an in-domain dataset demonstrates that the mixed approach achieves promising results across diverse retrieval scenarios. Furthermore, we provide a detailed analysis of how different training configurations affect the embedding space and their implications for multilingual retrieval effectiveness. Finally, we discuss deployment considerations, emphasizing the cost-efficiency of deploying a single versatile, lightweight model for real-world MLIR applications. The system is deployed online[1].

1 Introduction

MLIR is a challenging area of research that has seen significant advancements recently, mainly due to the use of large language models (LLMs) (Nair et al., 2022; Lawrie et al., 2022). However, there remains a considerable gap between research efforts and the actual deployment of MLIR systems in real-world scenarios. Many studies show impressive results in controlled environments or benchmark datasets, but typically focus on evaluating the IR model in a specific setting. However, many real-world applications often require a combination of various search scenarios within a single IR system —be it multilingual, cross-lingual, or monolingual. One example of such an application is a retrieval task for the Holy Quran. Retrieving passages from the Holy Quran is uniquely challenging. With translations in over 100 languages, it offers a rich parallel collection of high-quality human translations (Bashir et al., 2023). This unique feature provides an excellent opportunity to explore the multilingual potential of retrieval models and eliminates the bottleneck of applying machine translation (MT), simplifying and streamlining the evaluation process.

This study examines training approaches for deploying a single retrieval model across diverse MLIR settings, enabling modern search capabilities in the Islamic domain. The goal is to help users efficiently locate relevant Quranic passages in multiple languages and access the cultural and religious heritage preserved within Islamic texts, serving both scholars and the general public. We utilize the XLM-R_{Base} model (Conneau et al., 2020), a multilingual model trained for a general domain, as a backbone for retrieval. It is known that the performance of retrieval models typically deteriorates due to domain shift (Thakur et al., 2021; Pavlova, 2023). As a preliminary step, we conduct a brief domain adaptation of the XLM-R_{Base} model using a small multilingual domain-specific corpus (approximately 100M words). This short round of pre-training resulted in significant performance improvements in retrieval tasks. Moreover, to reduce the model's size, we conduct language reduction on the XLM-R_{Base} model, which allows us to eliminate languages that are not needed for the current deployment, resulting in more than a 50% reduction in the model's size. We prepare eleven retrieval models using this lightweight domain-specific multilingual large language model (MLLM) by applying four different training approaches: monolingual, cross-lingual, translate-train-all, and a proposed mixed approach that com-

bines cross-lingual and monolingual techniques. Evaluation across monolingual, cross-lingual, and multilingual retrieval scenarios demonstrates that our proposed mixed training approach produces promising results in all settings. We conduct an in-depth analysis of the potential effects of different training configurations on the embedding space and their impact on multilingual retrieval. Additionally, we discuss the advantages of deploying a single lightweight model for various potential deployment scenarios.

Our main contributions are: (1) We prepared eleven retrieval models trained using different approaches and conducted rigorous testing. This allowed us to evaluate how these models perform in various retrieval settings without limiting the evaluation to each model's specific training approach. (2) We propose a mixed training approach that achieves competitive performance across monolingual, cross-lingual, and multilingual retrieval scenarios. (3) We deploy our model as a part of a free online multilingual search tool designed to explore Quranic text in multiple languages.

2 Preliminaries

In this work, we use the term MLIR in its broadest sense. This includes monolingual IR in any language other than English, cross-lingual IR as a special case of MLIR, and MLIR itself, which enables the processing of queries in any language while retrieving relevant documents in multiple languages (Oard and Dorr, 1996, 1998). We experimented with four languages: English, Arabic, Urdu, and Russian. The choice of languages is motivated by the availability of the evaluation dataset and diversity. Before we proceed to the details of the training approach and experiment, we briefly discuss the preparation of a lightweight domain-specific MLLM that serves as a backbone of the retrieval models.

MLLMs provide cross-lingual functionality but are heavy to deploy in low-resource settings due to their large size (Devlin et al., 2019; Lample and Conneau, 2019; Conneau et al., 2020). Language reduction is a promising approach in the deployment environment (Abdaoui et al., 2020). It decreases the model size by pruning only the embedding matrix and removing the languages that are not needed in deployment while preserving all encoder weights. We use XLM-R_{Base} to perform language reduction and trim its size from 1.1 GB down to 481MB by keeping the vocabulary only of languages of interest: English, Arabic, Urdu, and Russian (XLM-R-4 model). We follow the technique of Pavlova and Makhlouf (2024). The detailed steps and model comparison are listed in the Appendix A.

2.1 Domain Adaptation of MLLM

While it is relatively easy to find a small amount of data for unsupervised pre-training, the absence of domain-specific labeled data for downstream tasks is a common problem. By leveraging continued pre-training and the integration of new domain-specific vocabulary (Lee et al., 2019; Huang et al., 2019; Gu et al., 2020; Beltagy et al., 2019; Pavlova and Makhlouf, 2023; Pavlova, 2025), we perform domain adaptation using a small corpus of 100 million words only. We combine a random subset of 50 million words from The Open Islamicate Texts Initiative (domain-specific corpus in Arabic) (Romanov and Seydi, 2019) with texts in English, Russian, and Urdu, mainly consisting of Tafseer and Hadith, also totaling 50 million words. We train a new Islamic tokenizer based on this corpus, add new domain-specific tokens to the existing vocabulary of the XLM-R-4 model, and continue a short round of pre-training on this assembled multilingual Islamic corpus (XLM-R-4-ID model). For more details on the hyperparameters, refer to Appendix A. As we will show below, this short pre-training round significantly boosted model performance on retrieval tasks.

3 Training Approaches of Multilingual Retrieval Models

For retrieval, we employ a dense retrieval approach (Karpukhin et al., 2020) using the sentence transformer framework that adds a pooling layer on top

of LLM embeddings and produces fixed-sized sentence embedding (Reimers and Gurevych, 2019). The loss function is designed within the framework of contrastive learning, which helps create an embedding space that brings related queries and their relevant passages closer together while pushing away queries and irrelevant passages (van den Oord et al., 2018), and formally defined as:

$$J_{\text{CL}}(\theta) = -\frac{1}{M}\sum_{i=1}^{M}\log\frac{\exp\sigma(f_\theta(x^{(i)}), f_\theta(y^{(i)}))}{\sum_{j=1}^{M}\exp\sigma(f_\theta(x^{(i)}), f_\theta(y^{(j)}))}$$

where σ is a similarity function (a cosine similarity), f_θ is the sentence encoder, $\{x^{(i)}, y^{(i)}\}_{i=1}^{M}$ (where *M* is batch size) are positive labels and other in-batch examples treated as negative (Henderson et al., 2017; Gillick et al., 2019; Karpukhin et al., 2020).

We explore four different training approaches:

(1) **Monolingual training**, in this method, both the query and the passages are in the same language L_i.

(2) **Cross-lingual training** exploits a pair of languages during training in a traditional way; while queries are in the language L_i, passages are in the language L_j.

(3) **Mixed approach**. In this strategy, we construct the training data by combining monolingual and cross-lingual methods. There are three specific ways we develop the training samples:

- **Monolingual queries with bilingual collection**: Half of the passages in the collection are in the same language as the queries L_i, while the other half is in a different language L_j.

- **Bilingual queries with monolingual collection**: Here, the queries are presented in two different languages, L_i and L_j, while the collection consists of passages in only one language, L_i.

- **Bilingual queries with bilingual collection**: In this case, both the queries and the passages can be in the languages L_i and L_j.

One of the main differences between cross-lingual training and mixed training is that in cross-lingual training, the queries and passages are always in different languages. In contrast, mixed training allows for the query language to be either in the same language as the passage language (L_i) or a different language (L_j). We hypothesize that a mixed approach can enhance the diversity of training examples and improve cross-lingual interaction between languages.

(4) **Translate-train-all approach**: This approach involves training different translations of the training dataset simultaneously. In the previous mixed approach, queries or the collection are evenly divided between two languages. In this training mode, we expand the collection by adding another translation. Translate-train-all resembles monolingual training in structure (same-language pairs) but improves language coverage by training in multiple languages simultaneously.

4 Experimental Setup

The variations of the settings described above can create numerous combinations depending on how many languages are involved in the experiment. For monolingual, cross-lingual, and mixed training approaches, we focus on using English and Arabic. For two main reasons: English is the primary language of the XLM-R_{Base} model, and the language of the MS MARCO dataset, and Arabic is the language that was mainly used for domain adaptation. For the translate-train-all approach, we experiment with four languages: English, Arabic, Urdu and Russian.

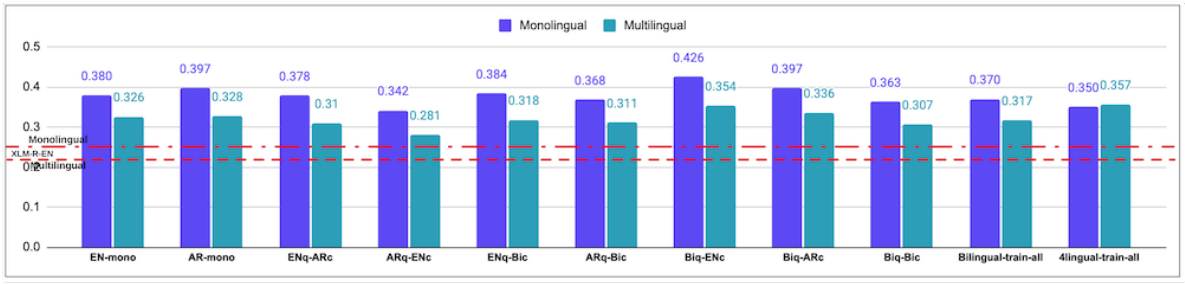

Figure 1: Comparison of the model performance averaged across languages between multilingual and monolingual evaluations. Red lines are the performance of a baseline model XLM-R-EN.

4.1 Datasets

For training, we use the MS MARCO (Bajaj et al., 2018), a large-scale English-language dataset widely adopted for training and evaluating dense retrieval models. It contains over 500,000 real-world queries paired with a collection of 8.8 million passages; Bonifacio et al. (2021) released machine-translated variants of MS MARCO for 13 languages, including Arabic and Russian (the collection was not translated into Urdu). Applying machine translation, we translated MS MARCO into Urdu to include this language in the experiment. For evaluation, we combined the train and development splits of the QRCD (Qur'anic Reading Comprehension Dataset) (Malhas and Elsayed, 2020) to increase the size of the test set, resulting in 169 queries used for evaluation. The answers provided are exhaustive, meaning all Qur'anic verses directly responding to the questions have been thoroughly extracted and annotated. The queries reflect contemporary, real user information needs, so they are both valid and salient today. This pairing of complete passage coverage with today's intents enables rigorous IR evaluation while preserving direct applicability to current user scenarios. The language of the QRCD dataset is Arabic; to evaluate in other languages, we use verified translations of this dataset to English, Russian, and Urdu. We use the Holy Quran text (Arabic), Sahih International translation (English), Elmir Kuliev (Russian), and Ahmed Raza Khan (Urdu) as retrieval collections.[2]

4.2 Evaluation Approach, Metrics and Baseline

We evaluate our methods in three different settings: monolingual, cross-lingual, and multilingual. In a monolingual setting, we evaluate using four languages. For the cross-lingual evaluation, we analyze two language pairs: Arabic and Urdu, which share similarities in writing systems and vocabulary, and Arabic and English, which represent linguistically distinct languages. In the multilingual evaluation, we combine collections of Quranic texts in four different languages. We then assess retrieval performance for each language by varying the query languages.

We use the MRR@10 (Mean Reciprocal Rate), the official evaluation metric of the MS MARCO dataset, as the main metric.

As a baseline, we train the XLM-R_{Base} in a monolingual setting using English MS MARCO (XLM-R-EN model) that allows us to see the effects of domain adaptation. For the rest of the retrieval models described below, we use the XLMR-4-ID model for training.

4.3 Results

In all tables, the best score is in bold, and the second-best is underlined. In the monolingual evaluation (Table 1), the model with the highest average performance across languages (0.426) is the Biq-ENc (Bilingual Queries English Collection), which was trained with a mixed approach. It also demonstrates the best performance in both Arabic and Urdu. In the multilingual evaluation (Table 2), the best-performing model on average (0.357) is the 4lingual-train-all (translate-train-all approach). The Biq-ENc model achieves the highest score (0.349) in Urdu and also second best for average performance across four languages (0.354). As illustrated in Figure 1, all models outperform the baseline on average across languages. In the cross-lingual evaluation (Table 3), the Biq-ENc model is the top performer (0.423) for the EN-AR pair; for all other pairs, this model has the second-best results. Overall, the results indicate that the mixed training approach yields promising

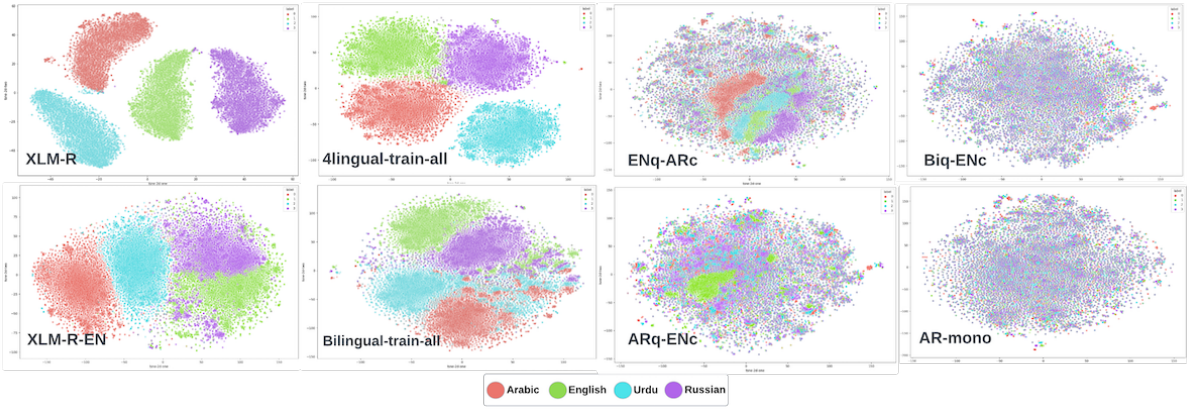

Figure 2: 2D t-SNE images of the representation of the Quranic verses embedding space in four languages.

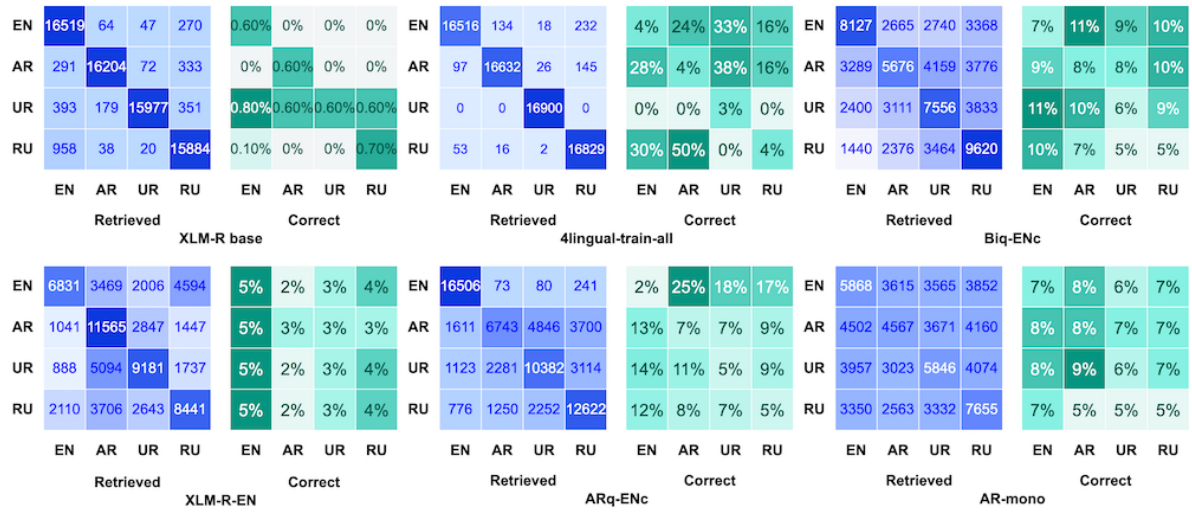

Figure 3: The heat map in blue shows how many passages from what language collection were retrieved. The heat map in green shows the percentage of correct passages out of retrieved passages. Language collection is the x-axis, and queries in a specific language are the y-axis.

outcomes, with the Biq-ENc model consistently demonstrating strong performance across all evaluation types: monolingual, multilingual, and cross-lingual.

5 Analysis

To assess how training strategies shape the multilingual embedding space, we apply the t-SNE algorithm (van der Maaten and Hinton, 2008) (Figure 2). To evaluate each model's cross-lingual capability, we examine heat maps for retrieval (blue) and correctness (green), which highlight monolingual (diagonal) and cross-lingual (off-diagonal) retrieval ability (Figure 3). To juxtapose models that demonstrate strong cross-lingual ability with those that remain monolingually biased, we include the XLM-R_{Base} model, which is not fine-tuned for retrieval. The first t-SNE image in the upper row (Figure 2) shows that XLM-R_{Base} produces four distinct language clusters and retrieves passages almost exclusively from the same language as the query. However, its accuracy remains extremely low, suggesting minimal ability for cross-lingual retrieval. The 4lingual-train-all (translate-train-all approach) model also clusters by language and is biased toward retrieving from the same language. However, it achieves a higher percentage of correct answers, including some off-diagonal results. The XLM-R-EN model (trained on English MS MARCO from XLM-R model without domain adaptation) produces less pronounced clusters, with partial overlap between English and Russian as shown in the t-SNE image. Remarkably, this model performs well on English and Russian datasets, but poorly on Urdu and Arabic. The green heat map aligns

Model(s)	Three Large Models	Single Versatile Lightweight Model		
Compute Substrate	**24GB A10 GPU**	**12 GB RTX 3080TI**	**CPU EM-A210R-HDD 16GB**	**Lambda Function**
Provider	Lambda Labs	Vast.ai	Scaleway	AWS
VRAM / RAM	24 GB	12 GB	16 GB	2 GB+
MRC	$\sim$ USD 540	$\sim$ USD 150	$\sim$ USD 48	$\sim$ USD 10 - USD 20

Table 4: MRC (monthly recurring cost) comparison from multiple compute substrate providers.

	Metric	MENA/EU Region	North America Region	APAC
Before	Avg. Latency	40.93ms	204.53ms	772.01ms
	Median P50 Latency	38.56ms	206.03ms	765.09ms
	P95 Latency	89.01ms	397.87ms	1380.37ms
After	Avg. Latency	25.33ms	160.03ms	408.99ms
	Median P50 Latency	23.69ms	150.73ms	402.66ms
	P95 Latency	48.99ms	220.27ms	980.11ms
%DELTA	P50 (lower better)	-38.6%	-26.8%	-47.4%

Table 5: RUM latency (ms) by region before/after model deployment; lower is better.

with language collections (vertical alignment), with the darkest column corresponding to English passages, which is expected given the model's English-centric training. The ARq-ENc model (Arabic queries, English collection) shows a more unified embedding space, though English cluster remains somewhat distinct. The blue heat map shows the darkest quadrant in the English-English retrieval, yet with a very low percentage of correct answers. Notably, this model performs poorly, particularly on English.

Conversely, t-SNE plots of Biq-ENc (bilingual queries, English collection) and AR-mono (domain-adapted XLM-R trained on Arabic MS MARCO) show a more homogeneous structure without clear language clusters. The heat maps are more uniformly colored for both retrieved and correct answers. Their off-diagonal results highlight stronger cross-lingual ability, supporting the idea that domain adaptation and mixed training encourage models to learn embedding space akin to language-agnostic representations, leading to improved performance in multilingual retrieval.

6 Deployment Considerations

Table 4 demonstrates possible deployment considerations and compares costs for deploying three separate retrieval models, each around 1GB (trained from XLM-R_{Base}), versus deploying one lightweight model of 400 MB in size (e.g. Biq-ENc model). The table shows that deploying one smaller model allows a reduction of costs by about 70% when deploying on a GPU-based server. Lower memory consumption and faster loading of a single lightweight model allow us to consider the deployment option on CPU-based servers, which further cut the cost by 70%. Python's runtime overhead, garbage collection, and large dependencies introduce inefficiencies in memory utilization, increasing overall deployment size. Leveraging Rust language capabilities to eliminate Python's inefficient memory management enables to reduce overall memory consumption to 30-50%, which can pave the way for deployment on compact serverless runtimes such as AWS Lambda functions, presenting the most cost-effective and scalable solution, potentially reducing monthly recurring costs to as low as USD 10 - USD 20.

7 Production Performance

We evaluate end-to-end latency with real-user monitoring (RUM) before and after deploying the new model (see Table 5). Measurements reflect browser-observed round-trip times from production traffic, exclude known bots, and are reported by region at three cut points: mean, median (P50), and tail (P95). As shown in Table 5, latency dropped across all regions after deployment. Median latency decreased by 38.6% in MENA/EU (38.6→23.7 ms), 26.8% in North America (206.0→150.7 ms), and 47.4% in APAC (765.1→402.7 ms). Means showed similar gains (-38.1%, -21.8%, -47.0%). Tail latency (P95) improved sharply: MENA/EU -45.0% (89.0→49.0 ms), North America -44.7% (397.9→220.3 ms), and APAC -29.0% (1380.4→980.1 ms). Lower tail latency

materially improves perceived responsiveness under load and on slower networks. The APAC tail remains higher due to network distance; further reductions will require geographic routing and edge capacity in addition to model-side efficiency. The Appendix B provides additional details on user activity and other extrinsic evaluations, including the assessment of real-user queries.

8 Related work

Recent work in cross-lingual and multilingual information retrieval (CLIR and MLIR) explores extending monolingual dense retrievers such as ColBERT to the multilingual setting, often using XLM-R_{Base} as the backbone encoder (Nair et al., 2022; Lawrie et al., 2022). Our approach differs in that we use XLM-R_{Base} within a sentence embedding framework, which is more latency-efficient and scalable for real-world deployment. Unlike ColBERT-style late interaction models, we adopt full sentence representations with in-batch negatives—an approach shown to yield strong performance with lower computational cost (Qu et al., 2021; Ren et al., 2021; Karpukhin et al., 2020). Multilingual sentence embeddings have also been actively studied, with methods like LaBSE (Feng et al., 2022), mSimCSE (Hu et al., 2023), LASER (Artetxe and Schwenk, 2019), and multilingual variants of SBERT (Reimers and Gurevych, 2020) demonstrating strong performance across a variety of tasks. While many of these focus on general-purpose representation learning, our work specifically investigates how different training configurations affect multilingual retrieval quality and embedding space alignment in a domain-specific setting.

9 Conclusion

Our proposed mixed training approach has shown promising results across all evaluation settings, highlighting its beneficial properties for use in MLIR systems that need to handle various retrieval scenarios. Furthermore, the efficiency gained by deploying a single lightweight and versatile model proves to be a superior option for balancing performance, affordability, and scalability.

Limitations

Despite including different types of languages in our experiment and adding low-resource ones like Urdu, the results may vary with a significantly larger number of languages. Additionally, our mixed and cross-lingual training setups rely on parallel corpora, which may not generalize well to settings where such resources are unavailable or noisy. Finally, although we deployed a lightweight model, performance and efficiency trade-offs on truly resource-constrained devices (e.g., mobile or edge environments) remain to be fully explored.

Ethical Considerations

This work involves the retrieval of religious texts, specifically the Holy Quran, which holds deep cultural and spiritual significance for millions of people. We have taken care to use verified and official translations of Quranic text. However, variations in translation style and theological interpretation may still impact how passages are retrieved and understood across languages. We acknowledge the responsibility that comes with building search tools in sensitive domains. The system is designed to assist in information access, not to provide religious or legal rulings. Care should be taken in downstream use cases, particularly in educational, interfaith, or legal contexts. Additionally, as with any multilingual system, there remains a risk of uneven performance across languages, which could inadvertently prioritize or marginalize certain linguistic groups. We recommend future work consider input from domain experts, theologians, and community stakeholders to guide responsible deployment, especially when extending the system to broader religious or cultural corpora.

Acknowledgment

We thank the Program Chairs of the EMNLP Industry Track for their continuous support of research on underrepresented domains. We also gratefully acknowledge the Dubai AI Campus for providing the computing infrastructure that made this work possible. We extend our appreciation to our colleagues and collaborators for their support and inspiration throughout this project.

A Appendix

Our reduction method consists of the following steps:

1. We select English, Arabic, Russian, and Urdu texts from a multilingual variant of the C4 corpus (Raffel et al., 2019) and train and SentencePiece BPE tokenizer.

2. Find the intersection between the new tokenizer and the XLM-R_{Base} tokenizer[3], the tokens inside of intersection and the corresponding weights will be selected for the new embedding matrix of the XLM-R4 model (34k tokens).

3. The encoder weights from XLM-R_{Base} get copied to the new XLM-R4 model as is.

Evaluation of XLMR-4 on the XNLI dataset demonstrates only a slight drop in performance (around 1.77% across all languages) compared to the XLM-R_{Base} (see Table 7). At the same time, we manage to significantly reduce the number of parameters by trimming the embedding matrix (EM) (see Table 6).

The domain adaptation of XLM-R4 takes the following steps:

1. We train a new SentencePiece BPE tokenizer using a multilingual Islamic Corpus and find the intersection between the new Islamic tokenizer and the XLM-R4 tokenizer. All the tokens outside of the intersection (9k tokens) are added to the embedding matrix of the XLMR-4 model, and the weights for new tokens are assigned by averaging existing weights of subtokens from the XLM-R4 model.

2. We continue pre-training XLM-R4 using the domain-specific corpus which gives us the XLM-R4-ID (Islamic domain) model. For more details on the hyperparameters, refer to Appendix A.

B Real User Metrics

During August 2025, the deployed system processed 84,255 requests originating from 2,630 unique IP addresses (median $\approx$ 32 requests/IP), with a total data volume of approximately 1.9 GB served. The cache hit rate by bytes was approximately 11%, consistent with a predominantly dynamic, search-intensive workload. Request counts exclude known automated traffic through Cloudflare bot-score and hosting-ASN filters. Clear diurnal usage patterns, distribution across residential and mobile ASNs, and a balanced mix of HTML, asset, and API requests all indicate genuine end-user activity. The system operated in CPU-only serving mode with an uptime of $\geq$99.97%. (All metrics are aggregated and privacy-preserving.)

On the user-facing site over the same period (via real-user monitoring, RUM), Success@5 was approximately 58–62% (τ = 15 s; results page viewed $\geq$15 s with top-5 results rendered). Abandonment was approximately 18–22%, defined as either no top-5 impression, dwell time <15 s, or a query reformulation within 30 s.

Human evaluation. We constructed a parallel set of 25 real-user queries in AR/UR/RU/EN. For each language, two independent annotators rated all retrieved results on a 3-point relevance scale (0 = irrelevant, 1 = partially relevant, 2 = highly relevant). Inter-annotator agreement was substantial (weighted Cohen's $\kappa \approx 0.61$). Compared to an XLM-R Base baseline, our model achieved consistent gains in nDCG@10 of +0.06 - +0.10 across all four languages. Example queries are provided in Table 10.

Model	Size	#params	EM
mBERT	714 MB	178 M	92 M
XLM-R_{Base}	1.1 GB	278 M	192 M
XLM-R4	481 MB	119 M	33M

Abstract

Ranking online reviews by their intrinsic quality is a critical task for e-commerce platforms and information services, impacting user experience and business outcomes. However, *quality* is a domain-dependent and dynamic concept, making its assessment a formidable challenge. Traditional methods relying on hand-crafted features are unscalable across domains and fail to adapt to evolving content patterns, while modern deep learning approaches often produce black-box models that lack interpretability and may prioritize semantics over quality. To address these challenges, we propose AutoQual, an LLM-based agent framework that automates the discovery of interpretable features. While demonstrated on review quality assessment, AutoQual is designed as a general framework for transforming tacit knowledge embedded in data into explicit, computable features. It mimics a human research process, iteratively generating feature hypotheses through reflection, operationalizing them via autonomous tool implementation, and accumulating experience in a persistent memory. We deploy our method on a large-scale online platform with a billion-level user base. Large-scale A/B testing confirms its effectiveness, increasing average reviews viewed per user by 0.79% and the conversion rate of review readers by 0.27%.

1 Introduction

Online reviews profoundly influence consumer decisions (Chevalier and Mayzlin, 2006; Floyd et al., 2014) on platforms like Yelp, Amazon, and Meituan. Consequently, ranking these reviews by their intrinsic *quality* or *helpfulness* is a task of paramount importance (Liu et al., 2008). An effective review ranking system enhances user trust, facilitates informed choices, and ultimately drives business conversions.

However, quantifying review quality presents two significant challenges. First, quality is highly domain-dependent; criteria for a helpful restaurant review differ substantially from those for a useful product review. Manually engineering feature sets for numerous domains is unscalable. Second, quality is dynamic, as user expectations and content patterns evolve, requiring constant adaptation.

Existing paradigms struggle to address this complexity. Traditional methods that rely on hand-crafted features are rigid and fail to adapt to new domains or evolving quality standards without manual re-engineering (Kim et al., 2006; Diaz and Ng, 2018). While modern deep learning models avoid this manual effort (Fan et al., 2019; Chen et al., 2019), they often function as uninterpretable black boxes (Rudin, 2019), hindering diagnostics and offering no actionable insights. Moreover, pre-trained language models (PLMs) (Vaswani et al., 2017; Devlin et al., 2019) are typically optimized for semantics, not textual quality, making them prone to shortcut learning (Zhou et al., 2024) and thus suboptimal for this task.

This reveals a critical research gap: the need for a framework that can autonomously discover interpretable and effective features for review quality assessment. To bridge this gap, we propose **AutoQual**, an autonomous LLM agent framework designed for the automated discovery of interpretable features. AutoQual transforms the tacit knowledge embedded in labeled data into explicit, computable, and interpretable features. It mimics a human research workflow through an iterative cycle: it first *hypothesizes* potential features using multi-perspective ideation and contrastive data analysis; it then *operationalizes* these features by autonomously creating measurement tools (e.g., prompts or scripts); finally, it employs a reflective search guided by a dual-level *memory* system to identify an optimal and compact feature set. AutoQual transforms feature engineering from a manual,

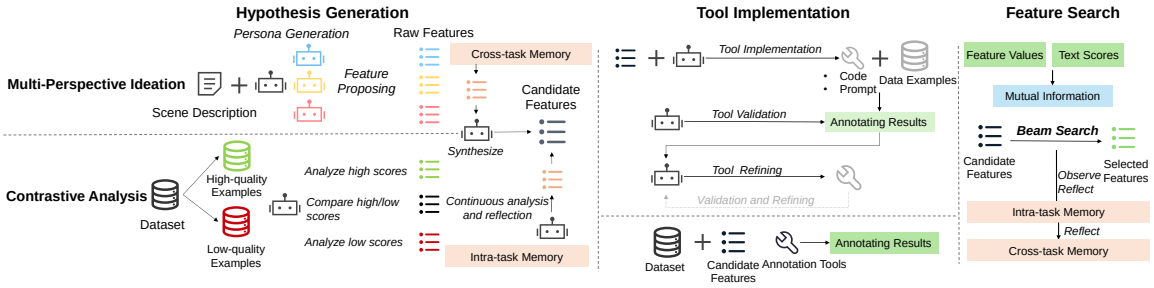

Figure 1: AutoQual is an autonomous LLM agent framework for interpretable feature discovery. It operates through hypothesis generation, tool implementation, and reflective search, guided by a dual-level memory.

ad-hoc process into a scalable, automated operation.

We demonstrate the real-world effectiveness of AutoQual through its deployment in the review ranking system of a large-scale online platform with a billion-level user base. Large-scale A/B testing confirmed its effectiveness, increasing average reviews viewed per user by 0.79% and the conversion rate of review readers by 0.27%.

Our contributions are:

- To the best of our knowledge, we are the first to tackle the challenge of discovering interpretable quality features for online reviews by proposing the AutoQual framework.
- We propose AutoQual, an LLM-based agent that integrates reflection, tool implementation, and memory to effectively navigate the feature space and discover high-quality, interpretable features.
- We demonstrate the significant real-world impact of our method through a large-scale industrial deployment, providing strong evidence of its effectiveness and bridging the gap between academic research and industrial practice.
- AutoQual can be viewed as a general framework for transforming the tacit knowledge embedded in expert annotations of unstructured data into explicit, computable, and interpretable features, applicable to a wide range of downstream tasks. We demonstrate its effectiveness across a series of other tasks beyond review quality assessment.

2 Problem Formulation

We focus on the task of review quality assessment, which aims to predict a numerical score for a given review text, where a higher score denotes higher *quality*. These scores are often derived from user engagement signals, such as explicit helpfulness votes or implicit signals like click-through rates. Our work focuses on moving beyond black-box predictors by automatically discovering a set of interpretable features whose values are highly predictive of these quality scores. This approach is generalizable to other domains where interpretable features are desired.

Problem Definition: Formally, given a dataset of texts $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$, where x_i is a text (e.g., a review) and $y_i \in \mathbb{R}$ its associated target score (e.g., quality score), our objective is to find a set of k interpretable feature functions $\mathcal{S}^* = \{f_1, f_2, \ldots, f_k\}$. Each function f_j maps a text x_i to a feature value, $f_j(x_i)$. We seek the feature set whose output values are maximally informative about the target scores. This is achieved by maximizing the mutual information:

$$\mathcal{S}^* = \arg\max_{|\mathcal{S}|=k} I(Y; \mathbf{F}_{\mathcal{S}}) \quad (1)$$

where $\mathbf{F}_{\mathcal{S}}$ denotes the collection of values generated by applying the feature functions in $\mathcal{S}$ to the dataset. By design, each feature function f_j is *interpretable*, with its definition expressible in natural language (e.g., *contains actionable advice*).

3 Method

To solve the problem of automatic interpretable feature discovery, we propose **AutoQual**, which is illustrated in Figure 1. The specific design of each component of AutoQual is explained below. Due to space constraints, the specific prompts used are detailed in Section A.2.

3.1 Initial Hypothesis Generation

To establish a comprehensive initial candidate pool of features, $\mathcal{S}_{\text{cand}}$, the agent employs two complementary strategies.

First, it performs **multi-perspective ideation**. The agent prompts the LLM to instantiate distinct expert personas (e.g., a critical user, a product manager) relevant to the task scenario. Each persona then proposes a set of features based on its unique evaluation criteria, ensuring diversity in the initial hypotheses.

Second, the agent conducts **contrastive analysis** to ground the hypotheses in data. We first sample high- and low-quality reviews from the dataset $\mathcal{D}$ to construct three distinct sets: (1) high-quality only, (2) low-quality only, and (3) a mix of both. We then employ three corresponding prompts to have the LLM identify the common strengths of high-quality reviews, the common flaws of low-quality reviews, and the key differentiators between them. This process yields three sets of feature hypotheses.

Finally, the agent processes the raw outputs from both strategies, de-duplicating and formalizing them into a candidate feature pool, $\mathcal{S}_{\text{cand}}$.

3.2 Autonomous Tool Implementation

For each feature hypothesis $f \in \mathcal{S}_{\text{cand}}$, AutoQual must develop a reliable mechanism to quantify it. To this end, the agent autonomously generates an annotation **tool**. A tool can be either a programmatic function (e.g., a Python script for syntactic analysis) or a precisely engineered LLM prompt for annotation.

For each feature hypothesis, an LLM first determines the appropriate tool type ("CODE" or "PROMPT"). Subsequently, based on the hypothesis and the selected tool type, the LLM generates the corresponding implementation by creating either the code to compute the feature value or the prompt to annotate it.

To ensure the reliability of these tools, the agent can create each one through an iterative `propose-validate-refine` cycle. In this process, a newly generated tool is immediately validated on a small sample of reviews. We use a dedicated "validate tool" prompt, providing the sample text and the tool's output to the LLM, which then decides if refinement is needed. If the performance is deemed inadequate, the agent refines the tool's logic or prompt. The tool is finalized for subsequent use once the LLM deems its performance satisfactory or a maximum number of refinement cycles is reached. Once finalized, the implemented tool is used to annotate the entire dataset, generating feature values for each review.

3.3 Reflective Feature Search

With the annotated candidate features, AutoQual performs a reflective search to find the optimal set $\mathcal{S}^*$. The search is structured as a **beam search** algorithm with a beam width of m to balance exploration and computational cost.

The search is initialized by selecting the top m features with the highest mutual information with the target scores, $I(Y; \mathbf{f}_j)$, to form the initial beams. Here, $\mathbf{f}_j$ represents the vector of values generated by applying feature function f_j to the dataset. Next, through beam expansion and reflection, the agent selects the optimal feature set.

Beam Expansion. For each of the m beams beam, representing a current feature set $\mathcal{S}_{\text{current}}$, the agent selects the next feature f_{new} from the updated candidate pool that maximizes the conditional mutual information:

$$f^* = \arg \max_{f_{\text{new}} \in \mathcal{S}_{\text{cand}} \setminus \mathcal{S}_{\text{current}}} I(Y; \mathbf{f}_{\text{new}} | \mathbf{F}_{\mathcal{S}_{\text{current}}}) \quad (2)$$

where $\mathbf{F}_{\mathcal{S}_{\text{current}}}$ denotes the collection of feature values for the set $\mathcal{S}_{\text{current}}$. This ensures that newly added features provide maximal novel information not already captured by the existing set. The process of reflection and expansion repeats until each beam contains k features. The beam with the highest overall joint mutual information $I(Y; \mathbf{F}_{\mathcal{S}})$ is chosen as the final result $\mathcal{S}^*$.

Intra-Task Reflection and Re-hypothesization. After the initial selection of k features, the agent performs intra-task reflection and re-hypothesization, attempting to propose more effective potential features. It takes the current context as input, observing the currently selected feature set, the mutual information between the features and the target metric, and the problem context. The LLM reflects on the performance of existing features to distill general principles of feature effectiveness for the given domain. Based on these insights, it then generates new hypotheses designed to be more predictive or to capture novel information. For example, if features related to *concreteness* are found to be effective, the LLM might hypothesize new, more nuanced features like *presence of statistical evidence* or *use of illustrative anecdotes*. Additionally, the agent observes and reflects on the gaps in the current feature coverage dimensions, proposing features that contribute to comprehensive coverage. These new hypotheses are dynamically added to the candidate pool. The beam search is then re-run on this augmented pool to select the optimal set of k features. The agent repeats this cycle of selection, reflection, and pool augmentation for a predetermined number of iterations.

3.4 Dual-Level Memory Architecture

To enable AutoQual to accumulate experience within a single task and transfer knowledge across multiple tasks, we designed a dual-level memory architecture.

Intra-Task Memory (Working Memory). This memory operates during a single discovery task. It maintains the state of the reflective search, including tested features and their MI scores. Based on this memory, the agent generates intermediate insights through reflection. This allows the agent to assess the quality of its past decisions and dynamically adapt its strategy within a single problem-solving session.

Cross-Task Memory (Long-Term Memory). Upon completing a task, the agent synthesizes the problem description, the final feature set $\mathcal{S}^*$, and their mutual information into a consolidated summary. This summary is stored in a persistent, long-term knowledge base. When AutoQual is presented with a new task, it queries this knowledge base for relevant prior experiences. These retrieved experiences serve as an additional, informed source for the initial hypothesis generation (Section 3.1), allowing the agent to bootstrap its search and improve its performance over time.

4 Experimental Setup

4.1 Implementation Details

AutoQual is open-sourced[1]. For the agent's core components, including hypothesis generation, tool implementation, memory, and reflection, we employ DeepSeek-V3.2-Exp (Thinking Mode) as the backbone LLM. Its inherent reasoning capabilities allow us to bypass the manual workflow optimization for each individual submodule of our method. For the more scalable task of feature annotation, we use the cost-effective qwen-plus-latest model (Yang et al., 2025). To ensure reproducibility, we set the generation temperature to 0. We estimate mutual information using a KNN-based estimator, leveraging the implementation available in the scikit-learn library (Pedregosa et al., 2011). In our reflective search, we use a beam width of $m = 5$ and select a final set of $k = 10$ features. All reported results for our main method, baselines, and ablations are averaged over five independent runs. To maintain a clean experimental setup, our main experiments do not utilize the cross-task memory; its benefits are analyzed separately in the ablation study.

4.2 Datasets

Our primary experiments leverage two review datasets: the public Amazon review dataset (Hou et al., 2024) and a private dataset from Meituan. For Amazon, we sample 2,000 representative reviews from each of four categories (Cellphones and Accessories, Clothing, Shoes and Jewelry, Grocery and Gourmet Food, and Office Products), using *helpful votes* as the quality score. For Meituan, we sample 20,000 reviews from the *in-store dining* domain, using review *click-through rate (CTR)* as the quality score. We also utilize additional datasets for versatility testing (Section 5.4).

4.3 Evaluation Metrics

Following prior work (Zhou et al., 2024), we evaluate the agreement between the predicted and the ground-truth scores for regression tasks (like quality assessment) using two standard metrics:

Spearman's Rho (r_s). It measures the strength and direction of the monotonic relationship between two ranked variables. Given N pairs of ranks $(R(y_i), R(\hat{y}_i))$ and the difference $d_i = R(y_i) - R(\hat{y}_i)$, it is defined as $r_s = 1 - \frac{6\sum_{i=1}^{N} d_i^2}{N(N^2-1)}$.

Mean Absolute Error (MAE). It measures the average magnitude of the errors between predicted and actual scores. It is defined as MAE $= \frac{1}{N}\sum_{i=1}^{N} |y_i - \hat{y}_i|$.

Since the scales of helpfulness votes and CTR differ significantly, we normalize the ground-truth scores to the $[0, 1]$ range before calculating MAE. For classification tasks (like toxicity detection), we use standard metrics: F1-Score and Area Under the ROC Curve (AUROC).

4.4 Comparison Methods

Following prior work (Zhou et al., 2024), we compare AutoQual against several well-established baselines. The first group consists of general text modeling approaches: **Bag-of-Words (BoW)**, which uses TF-IDF features to train a linear regression model; **Fixed PLM**, which feeds frozen embeddings from a pre-trained language model to a linear regressor; **Finetuned PLM**, which finetunes the PLM end-to-end with a regression head (or classification head for classification tasks); and **LLM-based methods** in both zero-shot and 20-shot settings for direct scoring. To showcase the

full potential of PLM-based approaches, we use a modern embedding model, `bge-small` (384 dimensions) (Xiao et al., 2023), which provides stronger representational capacity than older models like BERT, while its moderate dimensionality mitigates the risk of overfitting. For the LLM baselines, we use `qwen-plus-latest` (Yang et al., 2025). We also introduce a second group of baselines specifically designed for review helpfulness prediction: **TNN** (Olmedilla et al., 2022), a 1D-CNN-based model; **SEHP** (Malik and Nawaz, 2024), a stacking-based ensemble model; and **BHeIP-CoRT** (Li et al., 2025), a BERT-based model that utilizes rating-text consistency. While these models are relatively recent, they rely on older backbone embeddings combined with task-specific designs.

It is important to note that our primary goal is to demonstrate the effectiveness of the features discovered by AutoQual. Therefore, for our method and several baselines in the review quality tasks, we deliberately use a simple linear regression predictor. Employing a more sophisticated predictor would likely boost the performance of all methods commensurately, but our focus here is on the inherent predictive power of the features themselves.

5 Experimental Results

In this section, we conduct extensive experiments to answer the following four research questions:

- **RQ1:** Can our method effectively discover features that are predictive for the review quality assessment task?
- **RQ2:** Does each component of our method contribute to its performance?
- **RQ3:** Can our method discover domain-specific, interpretable features?
- **RQ4:** Is the AutoQual framework generalizable to other text assessment scenarios?

5.1 Feature Discovery Performance (RQ1)

We measure the performance of predicting quality scores using the features discovered by AutoQual with a simple linear regressor. We also evaluate a model that combines our features with PLM embeddings (AutoQual+PLM), where the PLM and the linear regressor are trained end-to-end. The results are presented in Table 1.

We draw the following key conclusions:

- **Discovered quality features have strong predictive power.** Predictions made solely using the features discovered by AutoQual already demonstrate strong performance. In some cases, the relatively sparse set of features discovered by AutoQual outperforms the high-dimensional semantic features from even a fine-tuned PLM. This suggests that AutoQual identifies high-order quality features that are more predictive than the purely semantic features captured by PLMs.
- **Discovered quality features are complementary to PLM embeddings.** The AutoQual+PLM model achieves the best performance on all datasets in terms of r_s, significantly outperforming the finetuned PLM alone. This indicates that the high-order quality features discovered by our method are complementary to the fine-grained semantic information provided by PLMs.
- **LLM baselines perform poorly.** Both zero-shot and few-shot LLM baselines show poor predictive performance. This demonstrates that the effectiveness of our method stems from our structured agent design, rather than the innate capabilities of the underlying LLM.

5.2 Ablation Study (RQ2)

In this section, we examine the contribution of each component of our method. The results are detailed in Table 2. Our core observations are as follows:

- **Hypothesis Generation.** Removing multi-perspective ideation leads to a significant performance drop, with an average r_s decrease of 0.0335. Removing contrastive analysis results in an even larger degradation, with an average r_s drop of 0.0537. Even subsequent reflection cannot fully compensate for the lack of diverse perspectives in the initial feature proposal stage. This validates the effectiveness of our two-pronged hypothesis generation strategy.
- **Dual-Level Memory.** Removing the intra-task memory (which disables reflection) impairs the effectiveness of the discovered features, with an average r_s decrease of 0.0170. This highlights the importance of learning from observation and experience. Interestingly, when we remove the intra-task memory but incorporate cross-task memory accumulated from the other four domains, the model's performance is comparable to the full AutoQual model. This suggests that experience is generalizable across tasks. Furthermore, this cross-task setting without intra-task memory significantly reduces computational costs, decreasing the agent's LLM token consumption by 44.95% and the annotation LLM token consumption by 29.79% on average.

Table 1: Performance comparison of AutoQual against baseline methods across different domains. We report Spearman's correlation coefficient (r_s, higher is better) and Mean Absolute Error (MAE, lower is better). **Bold** and underlined refer to the best and 2nd best performance.

1. **Review Length:** Measures the total word count of the review.
2. **Sentence Structure Simplicity:** Calculates the mean words per sentence to assess readability.
3. **Detail Specificity:** Measures inclusion of quantifiable details like fabric type, heel height, or measurements.
4. **Helpfulness Intent:** Detects explicit statements indicating the reviewer's intent to be helpful to other shoppers.
5. **Comparative Context:** Assesses comparisons to other styles, similar items, or competing brands.
6. **Real-World Relevance:** Evaluates discussion of the item's use for specific occasions or activities (e.g., formal wear, daily use).
7. **Long-Term Performance:** Assesses discussion of an item's durability after washing, wearing, or extended use.
8. **Reviewer Expertise:** Notes mentions of the reviewer's past experience with a specific type of apparel or brand.
9. **Emotional Expression:** Measures expressive language conveying feelings about the item's look, fit, or feel.
10. **Objectivity Focus:** Assesses focus on objective qualities (e.g., color, material) versus personal stories.

Figure 2: The selected top 10 features in the *Clothing, Shoes, and Jewelry* domain.

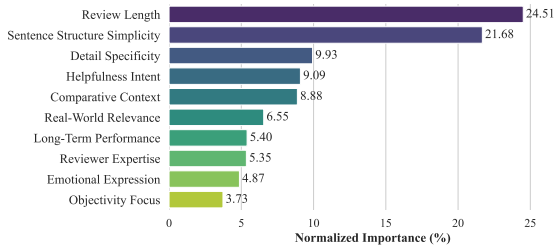

Figure 3: Normalized importance of features discovered by AutoQual in the *Clothing, Shoes, and Jewelry* domain. Importance is measured by mutual information with the quality score.

5.3 Case Study (RQ3)

We showcase the interpretable features discovered by AutoQual in the *Clothing, Shoes, and Jewelry* domain. The selected top 10 features and their descriptions are shown in Figure 2.

Figure 3 visualizes the normalized importance of these features. As the list demonstrates, many of the discovered features are highly domain-specific (e.g., *Detail Specificity*, *Comparative Context*, *Emotional Expression*). The implicit embeddings from a PLM cannot explicitly capture these effective, high-order features, which explains why its performance lags behind our method.

Furthermore, these interpretable features facilitate model diagnostics. For instance, a feature that is predictive but normatively undesirable can be explicitly identified and removed. They also provide clear guidelines for users on how to write high-quality reviews, which can improve the overall helpfulness of content on the platform. In turn, more helpful reviews help users make informed decisions and can ultimately drive conversions.

5.4 Generalizability of AutoQual (RQ4)

We investigate the generalizability of the AutoQual framework by applying it to text assessment tasks beyond review quality. We test our method's capabilities in three additional domains.

First, we assess text persuasiveness on the OUM dataset (Farag et al., 2023), following the experimental setup of Zhou et al. (2024). Second, we

Table 3: Evaluation of AutoQual on regression tasks (Quality/Scoring). The best results are shown in **bold**.

Method	Persuasiveness		Essay	
	$r_s \uparrow$	MAE $\downarrow$	$r_s \uparrow$	MAE $\downarrow$
Finetuned PLM	0.435	**1.395**	**0.548**	2.287
Zero-shot LLM	0.298	1.921	0.361	2.634
20-shot LLM	0.315	2.012	0.382	2.578
Manual Engineering	**0.447**	1.421	-	-
AutoQual	0.432	1.445	0.545	**2.215**

Table 4: Evaluation of AutoQual on classification task (Toxicity Detection). The best results are shown in **bold**.

Method	F1-Score ↑	AUROC ↑
Finetuned PLM	0.8224	0.9078
AutoQual+PLM	**0.8364**	**0.9203**

evaluate automated essay scoring on a subset of the ASAP dataset[2]. The results for these tasks, presented in Table 3, show that the features discovered by AutoQual are highly effective, achieving performance comparable to strong baselines like fine-tuned PLMs and manual feature engineering[3].

Third, we apply AutoQual to the Jigsaw Toxic Classification challenge[4]. Unlike quality assessment, toxicity detection is often viewed as a more semantics-focused task. We compare a Finetuned PLM against AutoQual+PLM. As shown in Table 4, the features discovered by AutoQual (e.g., identifying *Dehumanizing Metaphors* or *Inciting Instructions*) provide complementary signals, significantly improving both F1-Score and AUROC.

These results demonstrate that the AutoQual framework is generally applicable for discovering interpretable features across diverse text assessment scenarios. What's more, AutoQual is not just a tool for text quality, but a **general framework for automated interpretable feature discovery**. This framework can transform the tacit knowledge of domain experts, embedded within labeled data, into explicit, computable, and interpretable features. Specifically, it is applicable to any task that meets the following criteria:

- **Unstructured Data:** The task involves inputs like text, images, or audio where features are not obvious. By leveraging multimodal foundation models as a backbone, the agent can be extended to handle diverse data types beyond text.
- **Ambiguous Evaluation Criteria:** The target concept is abstract and multi-dimensional (e.g., "quality," "risk," "helpfulness"), making manual feature engineering difficult and unscalable.
- **Interpretability Requirement:** The decision-making process requires transparency for diagnostics, user trust, or regulatory compliance.

6 Industrial Deployment

Our method is deployed in a real-world industrial setting on the Meituan platform, which has a billion-level user base. On the platform's merchant detail pages, we aim to rank high-quality reviews higher in the display order. We construct review quality scores using review click-through rates and apply AutoQual to mine features, identifying five key features: informativeness, providing actionable advice, colloquial expression, containing real examples, and credible and engaging language. We further manually add two additional features: not being promotional copy and not being AI-generated. We integrate these features into the existing review ranking model, achieving significant improvements in user review engagement and conversion. In an online A/B experiment conducted from January 18 to February 7, 2025, we observe a 1.42% increase in average review browsing time, a 0.79% increase in the average number of reviews viewed per user, and a 0.27% increase in the conversion rate of users who viewed reviews. This real-world industrial deployment demonstrates the effectiveness of the features discovered by our method.

7 Conclusion

In this study, we propose AutoQual, a general LLM-based agent framework for the automated discovery of interpretable features from unstructured data. AutoQual is designed to transform the tacit knowledge of domain experts, often captured implicitly in labeled data, into a set of explicit, computable, and interpretable features. We demonstrate the power of this framework in the challenging domain of review quality assessment, where its iterative cycle of hypothesis generation, autonomous tool implementation, and reflective search successfully discovered highly predictive features. The framework's generalizability is further confirmed by its strong performance across diverse tasks. Finally, its successful deployment on a billion-user platform confirms the significant practical value of automated, interpretable feature discovery for building trustworthy and effective real-world applications.

[2]https://www.kaggle.com/competitions/asap-aes

[3]For the persuasiveness task, the manually engineered features are from Zhou et al. (2024). This baseline is omitted for essay scoring due to the lack of a widely-accepted SOTA feature set.

8 Limitations

Our study, while promising, has several limitations that open up avenues for future research:

- **Application to Semantic Tasks.** While we demonstrated AutoQual's effectiveness on toxicity detection, its versatility could be further explored by applying it to other traditional, semantics-focused NLP tasks, such as stance detection or sentiment analysis. This would allow us to further investigate the extent to which the high-order, interpretable features discovered by our method can provide complementary signals to the dense semantic embeddings from pretrained language models.
- **Expanding Domain Coverage.** Our framework can be enhanced by incorporating a broader range of domains beyond the text-based tasks explored. By leveraging multimodal foundation models as a backbone, the agent could handle diverse data types (e.g., images, audio).
- **Refining Industrial Deployment.** Our current industrial deployment is constrained by system architecture limitations, leading us to integrate only a set of high-level, universal features. A key avenue for future work is to incorporate the domain-specific features discovered by AutoQual into our online ranking models. This involves tailoring feature sets for different business scenarios (e.g., restaurants vs. hotels) to further boost ranking performance across the platform.

9 Ethics Statement

In this work, we analyze user-generated review data. For the public Amazon dataset, we strictly adhered to its terms of use. For the private Meituan dataset, we obtained explicit consent from users for their data to be used in research. Furthermore, all data was rigorously anonymized before use; we removed all user IDs and scrubbed any personally identifiable information (PII) from the review texts. Our research protocol was reviewed and approved by our institution's ethics review board.

Our research utilized large language model services, specifically Deepseek-V3.2-Exp provided by DeepSeek and Qwen-plus provided by Alibaba. We have strictly adhered to the terms of service and usage policies of both model providers.

We acknowledge that our method could be potentially misused. For example, malicious actors could leverage our framework to engineer low-quality or harmful content to achieve higher visibility in ranking systems. We remain vigilant about such risks and advocate for the responsible use of this technology, urging the community to prevent its abuse.

A Appendix

A.1 Related Works

A.1.1 LLM Agent

LLM agents augment large language models with carefully designed or self-adaptive workflows, enabling them to tackle more complex tasks. The proactive decomposition of complex tasks by agents is referred to as planning (Yao et al., 2023; Shinn et al., 2023); explicitly stored context during operation is known as memory (Park et al., 2023; Zhong et al., 2024); and agents can actively invoke external tools to accomplish specific subtasks (Schick et al., 2023; Qin et al., 2024). Agents have achieved remarkable success across diverse applications, including code generation and software engineering (Jimenez et al., 2023; Yang et al., 2024), scientific discovery and research automation (Wang et al., 2023; Boiko et al., 2023), interactive web navigation (Deng et al., 2023; Zhou et al., 2023), social simulation (Gao et al., 2023, 2024; Piao et al., 2025) and a wide range of fine-grained, specific tasks (Lan et al., 2024, 2025; Feng et al., 2024; Xing, 2025; Du et al., 2024). To the best of our knowledge, we are the first to leverage LLM agents for the task of automatic interpretable feature discovery from unstructured text.

A.1.2 Automated Feature Mining

For predictive tasks on tabular data, constructing new features from existing data is crucial, such as semantic binning or feature interactions. However, manual feature engineering for every new scenario is time-consuming and labor-intensive, motivating research into automated feature discovery (Fan et al., 2010; Kanter and Veeramachaneni, 2015; Khurana et al., 2018; Li et al., 2023). Recent advances in large language models have introduced powerful tools for automated feature discovery, as LLMs possess semantic understanding of both domains and features (Hollmann et al., 2023; Nam et al., 2024; Abhyankar et al., 2025). While automated feature generation for *tabular* data has been extensively explored, to the best of our knowledge, no prior work has addressed the automatic discovery and mining of interpretable features from *unstructured text* data. Our work represents an initial exploration in this direction.

A.1.3 Review Quality Assessment

Review helpfulness prediction aims to estimate the perceived value of online reviews to potential readers (Liu et al., 2008; Kim et al., 2006). In our work, we consider additional quality indicators beyond helpfulness votes (e.g., click-through rates), thus framing the task more broadly as *review quality assessment*. Traditional approaches rely on hand-crafted features (Mudambi and Schuff, 2010; Ghose and Ipeirotis, 2010; Diaz and Ng, 2018), which are time-consuming to develop and difficult to scale across domains. While deep learning methods have shown promise (Fan et al., 2019; Chen et al., 2019), they often lack interpretability. Current approaches based on pre-trained language models (Vaswani et al., 2017; Liu et al., 2019) primarily capture semantic information rather than explicit quality indicators, making them suboptimal for this task. To the best of our knowledge, we are the first to propose automated feature discovery for this task.

A.2 Prompts for AutoQual

This section details the prompts used by the AutoQual agent, corresponding to the different stages of its workflow as described in Section 3.

A.2.1 Initial Hypothesis Generation

These prompts are used for the initial feature hypothesis generation phase (Section 3.1), which includes multi-perspective ideation and contrastive analysis.

Generate Roles Prompt. Used to create diverse expert personas for multi-perspective ideation. This prompt is as follows:

> We are undertaking a text quality assessment task. The core of this task is to evaluate the quality of text based on the following scenario.
>
> Scenario Description:
>
> `{scene_description}`
>
> Your task is to propose `{role_count}` distinct virtual evaluator roles, each with a different perspective and unique evaluation criteria, based on the text quality requirements of the above scenario. These roles should be representative and cover multiple dimensions of text quality assessment.
>
> Output a list of exactly `{role_count}` roles. Each role must be on a new line. Only output `{role_count}` lines. For each line, provide only the role's name followed by a

comma and a concise description of its core evaluation criteria (around 20 words). Do not include any extra explanations, introductory text, or formatting like "Role 1:".

Example Format:

[Role Name 1], [Core evaluation criteria description]

[Role Name 2], [Core evaluation criteria description]

Generate Features from Role Prompt. Used by each persona to suggest features from its unique viewpoint. This prompt is as follows:

We are designing computable and interpretable features for a text quality assessment task. The task scenario is as follows:

`{scene_description}`

Now, please fully embody the following role and think from its perspective. The role and its evaluation angle are: `{role_description}`. Your task is to propose a set of candidate features for measuring text quality based on your role and evaluation criteria. These features should be concrete, measurable, and interpretable. The feature description must be clear enough for someone to understand how to evaluate the text based on it.

Output `{feature_count_per_role}` of what you consider the most important features. Each feature must be on a new line, and should be about 30 words. Only output `{feature_count_per_role}` lines, with each line containing a distinct feature. For each feature, provide only its name and a clear text description of what it measures. Do not use any special symbols or formatting, including list numbers.

Example Format:

[Feature 1], [Feature description]

[Feature 2], [Feature description]

Contrastive Analysis Prompts Used to generate features by comparing high and low-quality sample texts.

Analyze Positive Samples Prompt. Used to analyze common features in high-quality texts.

We are designing features for a text quality assessment task. The task scenario is as follows:

`{scene_description}`

We have selected a batch of texts identified as high-score under a certain evaluation system. Here are some of those samples:

`{samples}`

Your task is to carefully analyze these high-score text samples and summarize the common features they possess that could explain their high scores. These features should be concrete, measurable, and interpretable. The feature description must be clear enough for someone to understand how to evaluate the text based on it.

Output `{feature_count_positive}` most important features. Each feature must be on a new line, and should be about 30 words. Only output `{feature_count_positive}` lines, with each line containing a distinct feature. For each feature, provide only its name and a clear text description of what it measures. Do not use any special symbols or formatting, including list numbers.

Example Format:

[Feature 1], [Feature description]

[Feature 2], [Feature description]

Analyze Negative Samples Prompt. Used to analyze common features in low-quality texts.

We are designing features for a text quality assessment task. The task scenario is as follows:

`{scene_description}`

We have selected a batch of texts identified as low-score under a certain evaluation system. Here are some of those samples:

`{samples}`

Your task is to carefully analyze these low-score text samples and summarize the common features they possess that could explain their low scores. These features should be concrete, measurable, and interpretable. The feature description must be clear enough for someone to understand how to evaluate the text based on it.

Output {feature_count_negative} most important features. Each feature must be on a new line, and should be about 30 words. Only output {feature_count_negative} lines, with each line containing a distinct feature. For each feature, provide only its name and a clear text description of what it measures. Do not use any special symbols or formatting, including list numbers.

Example Format:

[Feature 1], [Feature description]

[Feature 2], [Feature description]

Analyze Contrastive Samples Prompt. Used for contrastive analysis between high and low-quality texts.

We are designing features for a text quality assessment task. The task scenario is as follows:

{scene_description}

We have selected batches of texts identified as high-score and low-score under a certain evaluation system.

High-Score Samples:

{positive_samples}

Low-Score Samples:

{negative_samples}

Your task is to conduct a contrastive analysis of the two sample sets and summarize the most significant distinguishing features. These should be features that high-score texts possess and low-score texts lack. The features must be concrete, measurable, and interpretable. The feature description must be clear enough for someone to understand how to evaluate the text based on it.

Output {feature_count_contrastive} of the most distinctive features. Each feature must be on a new line, and should be about 30 words. Only output {feature_count_contrastive} lines, with each line containing a distinct feature. For each feature, provide only its name and a clear text description of what it measures. Do not use any special symbols or formatting, including list numbers.

Example Format:

[Feature 1], [Feature description]

[Feature 2], [Feature description]

Integrate Features Prompt. Used to consolidate and deduplicate the generated feature candidates. This prompt is as follows:

We have generated a batch of candidate features for text quality assessment through various methods (multi-role perspectives, data sample analysis, etc.). They now need to be consolidated.

Original Feature List:

{feature_list}

As a feature engineering expert, your task is to process the original feature list above to produce a final, refined pool of candidate features.

Processing Requirements:

1. Merge and Deduplicate: Identify and merge features that are semantically identical or highly similar.

2. Optimize Descriptions: Ensure each feature's description is clear, precise, unambiguous, and actionable for the subsequent development of annotation tools.

3. Format Output: Organize the output into a clean list.

Output each feature on a new line. For each feature, provide only a detailed text description of what it measures. The final list should contain as many unique features as can be derived from the original list after processing. Just output a plain list of features. Do not use any special symbols or formatting, including list numbers. Start a new line ONLY when moving to the next feature. If you find n features, just output n lines, with each line containing a distinct feature.

A.2.2 Autonomous Tool Implementation

These prompts are used for the autonomous tool implementation phase (Section 3.2), where the agent decides on a tool type and generates the corresponding code or annotation prompt.

Decide Tool Type Prompt. Used to determine whether a feature is best measured by code or an LLM prompt. This prompt is as follows:

Your task is to determine the best tool type to annotate a text feature. The options are "CODE" or "PROMPT".

"CODE" is for features that are simple, explicit, and can be accurately auto-annotated with Python code without requiring intelligent processing.

"PROMPT" is for features that cannot be accurately annotated with simple rule-based code, and may be abstract, nuanced, subjective, or require deep semantic understanding.

Feature Description:

`{feature_description}`

Based on the description, is this feature better suited for "CODE" or "PROMPT"? Respond with a single word: either "CODE" or "PROMPT". Do not provide any other text or explanation.

Generate Code Tool Prompt. Used to generate a self-contained Python function for annotation.

Your task is to write a Python function that serves as an annotation tool for a specific text feature.

The function should:

1. Be named `{function_name}`.

2. Accept a single string argument named `text`.

3. Return a single numerical value (float or int).

4. Be self-contained. You can use common libraries like `re`, `nltk`, `textblob`, but do not assume any external files are available.

5. If a library is used, include the necessary import statement inside the function to ensure it's encapsulated.

Here is the feature the function needs to measure:

Feature: `{feature_name}`

Description: `{feature_description}`

Generate the complete Python code for this function. Do not include any text or explanation outside the function's code block. Start the response directly with the function definition.

Example:

```
def annotate(text: str) -> float:
    # import necessary libraries here
    # ... function logic ...
    return score
```

Generate Prompt Tool Prompt. Used to generate an LLM prompt for annotating complex features. This prompt is as follows:

Your task is to create an precise and effective prompt template for a Large Language Model to use as a feature annotation tool.

This template will be used to evaluate different pieces of text. It must contain the placeholder `[TEXT_TO_EVALUATE]` where the actual text will be inserted later.

The prompt you create should instruct the LLM to:

1. The LLM should evaluate the text based on the feature described below.

2. Provide a numerical score on a scale of 1 to 10 (where 1 is low quality/absence of the feature, and 10 is high quality/strong presence of the feature).

3. Respond with ONLY the numerical score, without any additional text or explanation.

4. Clearly explain the criteria used to determine the score.

Here is the feature that the annotation prompt needs to measure:

`{feature_description}`

Now, generate the annotation prompt template text. Your ONLY task is to generate the raw text for a prompt template. Do not output anything else. Do not use markdown, do not add titles, do not add any explanations.

Your output must begin directly with the text of the prompt. Your output should end with "The text to evaluate is: `[TEXT_TO_EVALUATE]`." The `[TEXT_TO_EVALUATE]` placeholder should only be used once at the end of the prompt.

A.2.3 Reflective Search and Memory

These prompts support the reflective search and dual-level memory architecture (Sections 3.3 and 3.4).

Reflect and Generate Features Prompt (Intra-Task Reflection). Guides the agent to reflect on its progress and hypothesize new features mid-task.

This prompt is as follows:

You are an expert in text quality assessment feature engineering. We are working on a text quality assessment task with the following scenario:
Scenario Description:
{scene_description}
We have completed a round of feature selection using a beam search algorithm. The current best features selected and their performance (Spearman correlation coefficients, sorted in descending order) are:
{features_with_scores}
Your task is to analyze the selected features and their performance in the context of the above scenario, then propose {new_feature_count} NEW, innovative features that could potentially improve the assessment quality for this specific task.
When designing new features, you should:
1. Consider the specific requirements and context of the scenario described above
2. Identify potential gaps or aspects not well-covered by the current feature set
3. Consider features that might capture different dimensions or perspectives relevant to this scenario
4. Think about features that could complement or enhance the existing ones
5. Ensure the features are concrete, measurable, and interpretable
6. Avoid proposing features that are too similar to existing ones
Output exactly {new_feature_count} new features. Each feature must be on a new line, and should be about 30 words.
Only output {new_feature_count} lines, with each line containing a distinct feature. For each feature, provide only its name and a clear text description of what it measures. Do not use any special symbols or formatting, including list numbers.
Example Format:
[Feature 1], [Feature description]
[Feature 2], [Feature description]

Cross-Scene Learning Prompt (Cross-Task Memory). Enables the agent to use memories from past tasks to bootstrap hypothesis generation for a new task. This prompt is as follows:

You are an expert in text quality assessment feature engineering. We are working on a NEW text quality assessment task. Your goal is to learn from the successful features identified in OTHER similar tasks and propose new features for the current task.
Current Task Scenario:
{current_scene_description}
We have analyzed similar text quality assessment tasks from different domains. Here are the successful features discovered in those tasks:
{other_scenes_info}
Based on the successful patterns and features from these other tasks, please propose {feature_count} NEW, innovative features that could be effective for the CURRENT task described above.
When designing new features, you should:
1. Identify common patterns across the successful features from other tasks
2. Adapt and generalize these patterns to fit the current task's context
3. Consider what made those features successful and how similar principles apply here
4. Ensure the features are concrete, measurable, and interpretable
5. Make sure the features are relevant to the current task scenario
Output exactly {feature_count} new features. Each feature must be on a new line, and should be about 30 words. Only output {feature_count} lines, with each line containing a distinct feature. For each feature, provide only its name and a clear text description of what it measures. Do not use any special symbols or formatting, including list numbers.
Example Format:
[Feature 1], [Feature description]
[Feature 2], [Feature description]

JSON Whisperer: Efficient JSON Editing with LLMs

Sarel Duanis[1] **Asnat Greenstein-Messica**[1] **Eliya Habba**[1,2]

[1]Lightricks [2]The Hebrew University of Jerusalem

{sarel, asi, ehabba}@lightricks.com

Abstract

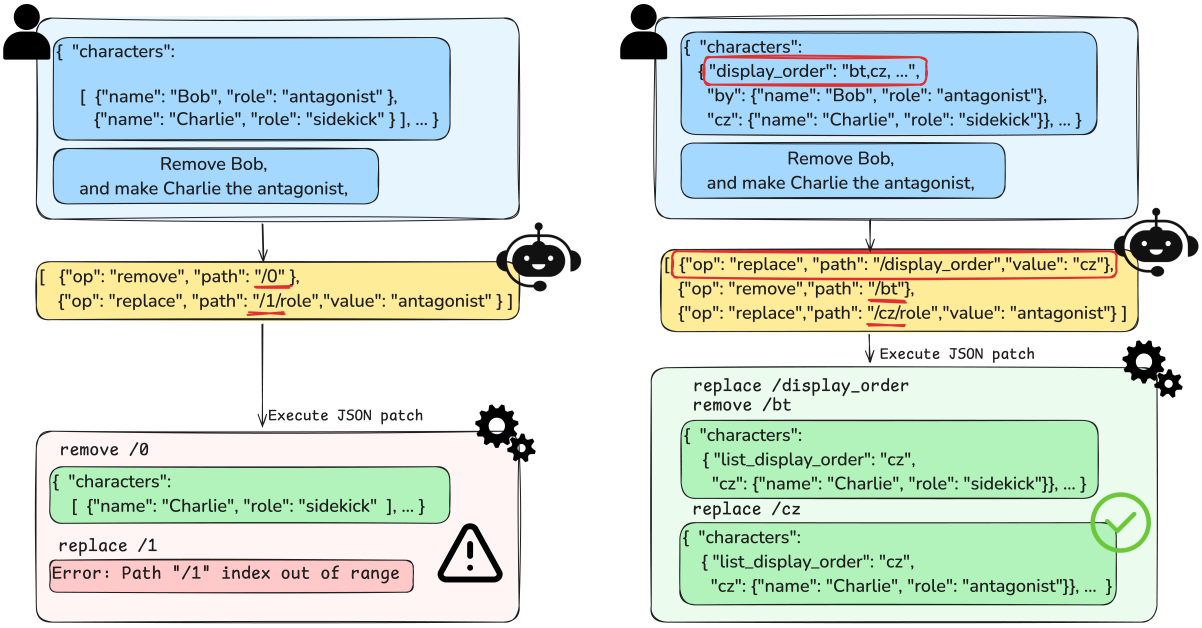
Large language models (LLMs) can modify JSON documents through natural language commands, but current approaches regenerate entire structures for each edit, resulting in computational inefficiency. We present JSON Whisperer, a framework that enables LLMs to generate RFC 6902 diff patches-expressing only the necessary modifications-rather than complete documents. We identify two key challenges in patch-based editing: (1) LLMs often miss related updates when generating isolated patches, and (2) array manipulations require tracking index shifts across operations, which LLMs handle poorly. To address these issues, we introduce EASE (Explicitly Addressed Sequence Encoding), which transforms arrays into dictionaries with stable keys, eliminating index arithmetic complexities. Our evaluation shows that patch generation with EASE reduces token usage by 31% while maintaining edit quality within 5% of full regeneration with particular gains for complex instructions and list manipulations. The dataset is available at: https://github.com/emnlp2025/JSON-Whisperer/

1 Introduction

Large language models have demonstrated capabilities in generating and manipulating structured data formats, with JSON emerging as a primary interface between natural language commands and programmatic operations. This capability has enabled applications across diverse domains, from web development (Voronin, 2024) to creative tools (Sultan et al., 2024; Kolthoff et al., 2025), where users can specify structural modifications through natural language. In film production platforms, for instance, entire projects-comprising scenes, characters, and shot compositions-are represented as JSON documents that creators modify through conversational interfaces.

However, current approaches suffer from a fundamental inefficiency: LLMs regenerate entire JSON structures for even minor edits. This regeneration approach, while straightforward, becomes computationally expensive as document complexity grows. A film project might contain thousands of nested objects representing scenes and shots; changing a single character's name triggers regeneration of the entire structure, consuming substantial computational resources and introducing latency that disrupts creative workflows.

We observe that LLMs can generate RFC 6902 (Bryan, 2013) diff patches-a standard format for expressing minimal changes to JSON documents-when appropriately prompted. This finding suggests an alternative approach: instead of regenerating complete structures, models could output only the necessary modifications. Yet this seemingly simple solution introduces unexpected challenges.



We identify two critical issues that emerge when LLMs generate patches. First, the fragmented nature of patch generation causes models to miss necessary updates. When editing a character's attributes across multiple scenes, models generating patches often update some occurrences while overlooking others-a problem that full regeneration naturally avoids. Second, and more surprisingly, LLMs struggle with array index arithmetic. Consider removing an element from a list: subsequent operations must account for shifted indices as illustrated in Figure 1. Our experiments reveal that even state-of-the-art models frequently miscalculate these shifts or conflate zero-based and one-based indexing.

In this work, we present JSON Whisperer, a framework that enables efficient JSON editing through patch generation while addressing these challenges.

Our contributions are as follows:

1. we demonstrate that patch-based editing can achieve performance comparable to full regeneration when using appropriate few-shot

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1265–1274
November 4-9, 2025 ©2025 Association for Computational Linguistics

(a) Using normal list indexing

(b) Using EASE

Figure 1: (a) Using normal list indexing, LLMs fail to account for index shifts after removing Bob, leading to an error. (b) Using EASE, stable keys ensure correct updates, making the patch process execution order-invariant.

examples. To this end, we propose a method for synthetically generating such high-quality examples.(Section 3).

2. we introduce EASE (Explicitly Addressed Sequence Encoding), a novel representation that eliminates array indexing complexities. EASE transforms positional arrays into key-value mappings with stable identifiers, making all operations order-invariant and removing the need for index arithmetic (Section 3.2).

3. we evaluate our approach on JSON editing scenarios from a film production platform, showing that patch generation with EASE reduces token usage by 31% while maintaining edit quality within 5% of full regeneration approaches, with particularly strong improvements for complex instructions and list manipulations (Section 4).

Our work demonstrates that patch-based editing, when combined with EASE encoding, can serve as a practical alternative to full regeneration for JSON manipulation tasks. This combination addresses the fundamental challenge of array indexing that makes standard patch generation error-prone, offering significant efficiency gains for real-world applications where structured data editing is common.

2 Background and Definitions

RFC 6902: RFC 6902 (Bryan, 2013) specifies a format for representing modifications to JSON documents as a sequence of operations, as shown in Listing 1. Each operation includes:
op: The operation type (`add`, `remove`, `replace`)
path: A JSON Pointer that identifies the target location using forward-slash-separated tokens (e.g., `/scene/weather`), with zero-based indices for arrays (e.g., `/users/0/name`)
value: The data to be used for `add` and `replace` operations

```
[{"op":"replace", "path":"users/0/name",
  "value": "John"},
 {"op":"add","path":"users/1",
  "value": {"name":"Sam"}}]
```

Listing 1: This patch will replace the first user name to "John" and add a new user called "Sam"

3 JSON Whisperer Framework

We present JSON Whisperer, a framework for efficient text-guided JSON editing using LLMs. The framework comprises two main components: diff-based editing using RFC 6902 patches and EASE (Explicitly Addressed Sequence Encoding) for handling ordered lists.

3.1 Diff-based JSON Editing

Our method leverages RFC 6902 JSON Patch format to enable targeted modifications. Given an input JSON and a natural language edit request, the LLM generates only the necessary patch operations rather than regenerating the entire structure.

The process follows three steps: (1) the LLM receives the original JSON and edit instruction, (2) it generates an RFC 6902 patch specifying the required changes, and (3) a standard patching algorithm applies these operations to produce the updated JSON.

This approach reduces token usage and latency compared to full regeneration, as the model outputs only the specific modifications needed (e.g., a few patch operations versus an entire JSON document).

Synthetic Dataset Creation. To enable effective few-shot learning for diff patch generation, we automatically create a dataset of high-quality examples using a state-of-the-art LLM. Each JSON schema requires its own example set, generated through a fully automated pipeline. The generation process consists of four steps. First, given a target JSON schema, we prompt Claude-3.5-Sonnet (Anthropic, 2024) to generate diverse JSON instances following that schema. Second, for each instance, the LLM creates natural language edit requests simulating realistic user modifications. These requests span from simple field updates to complex structural changes. Third, for each (JSON, request) pair, we use the same LLM to produce a completely rewritten JSON incorporating all requested modifications. Finally, we apply a standard diff algorithm to compute RFC 6902 patches between original and modified JSON pairs. These patches accurately capture the complete transformation specified by each edit request. The resulting dataset provides a pool of examples for few-shot prompting, where each example contains an input (original JSON + edit request) and its corresponding RFC 6902 patch. Using DSPy (Khattab et al., 2024), we optimize the selection of few-shot examples from this synthetic dataset to maximize evaluation metrics (Section 5.1).

3.2 EASE - Explicitly Addressed Sequence Encoding

To improve list manipulation in language models, we introduce EASE - Explicitly Addressed Sequence Encoding, a method for transforming JSON arrays into a more order-independent format. Instead of relying on numerical indices, EASE converts lists into dictionaries where each element is assigned a unique two-character key (e.g., "ax", "cd"). The original sequence is preserved using a *display_order* key (e.g., "ab,cd,ef"); elements can be added, removed, or reordered by replacing only the value of this key.

This approach provides dual order invariance: element storage becomes order-independent through dictionary-based addressing, and operation execution becomes order-independent since patch operations can be applied in any order without affecting the final result.

EASE particularly benefits complex list manipulations where multiple operations would traditionally require careful index arithmetic. By decoupling element identity from order, the encoding allows to focus on the semantic changes rather than bookkeeping details, thereby significantly improving accuracy in edit scenarios.

```
{
 "Scene": {
  "voice_over": "Every step brought me
      closer to the family.",
  "weather": "Sunny",
  "shots": [
   {
    "type": "Wide-shot",
    "action": "Buddy sitting on a
        sidewalk."
   },
   ...
  ]
 }
}
```

Listing 2: Scene JSON Example

4 Evaluation Setup

Models and Prompting Strategies We evaluate our JSON editing approach using two models of different scales: GPT-4o-mini (8B parameters) and Claude Sonnet (175B parameters). For each model, we test two prompting strategies: zero-shot prompting without examples and DSPy-optimized few-shot learning using examples from our synthetic dataset. The prompts for standard list indexing and EASE indexing are detailed in Appendix A.1 and Appendix A.2, respectively.

Tasks and Dataset Our experiments use JSON objects representing complete scenes from an AI-powered platform. Each scene contains shallow fields and a list of shots, where each shot is a nested object, as shown in Listing 2.

We generate a dataset of approximately 400 examples using Claude-Sonnet, covering diverse JSON editing scenarios across four complexity levels:

- **Simple**: Affects a single field without impacting others.
  e.g., "Change the weather to 'Partly cloudy with a light breeze.'"
- **Creative**: Involves generating new content that doesn't exist in the original JSON.
  e.g., "Add one more shot to the scene."
- **Complex**: Requires modifying multiple related elements while preserving logical consistency.
  e.g., "Change the scene so that Melody's ex-partner is in the audience, and she notices him halfway through her performance."
- **List Manipulation**: Involves ordering, filtering, or updating items within a list.
  e.g., "Remove every third shot from the scene."

Evaluation Metrics We assess model performance using three key metrics. First, we measure structural accuracy through the F1 score of patch operations, comparing only the 'op' and 'path' fields against dataset labels while excluding 'value' fields due to their potential for multiple valid variations. Second, we evaluate the semantic quality of generated values using an LLM-as-a- judge,(see Appendix A.4 for the prompt used). Finally, we track the patch execution success rate as the proportion of patches that do not fail to apply due to syntax errors, missing fields, or invalid paths.

5 Results

EASE Encoding Outperforms Standard List Indexing EASE encoding consistently outperforms standard list indexing across all instruction categories, with the most pronounced improvements in complex instructions and list manipulations. Figure 2 breaks down EASE encoding contributions across different request types. The comparison shows EASE improved accuracy and reduced errors across all instruction categories, while standard list indexing produces suboptimal results due to index tracking challenges. This approach particularly benefits scenarios involving multiple list operations that would traditionally require careful index arithmetic, leading to improved f1 score, semantic accuracy and patch execution.

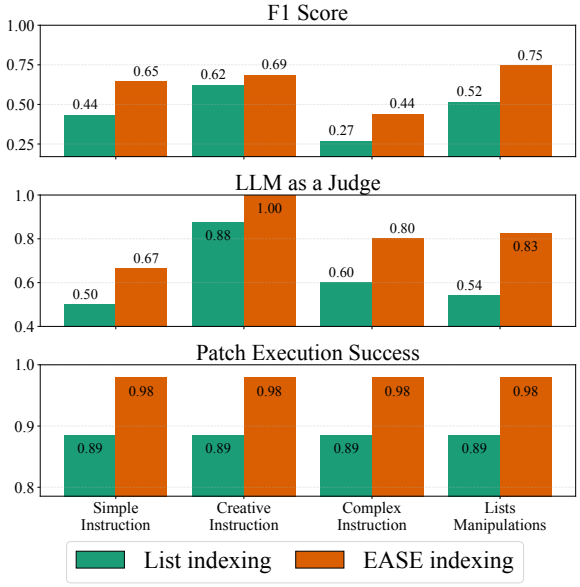


Figure 2: EASE Encoding Outperforms Standard List Indexing, broken down by different request types generated by GPT-4o-Mini

Few-Shot Learning Enables Effective Patch Generation Synthetic few-shot examples provide substantial performance improvements in JSON patching tasks, having the most significant impact on performance. As demonstrated in Figure 3, comparing zero-shot performance with synthetic few-shot learning using standard list indexing reveals significant accuracy gains across model sizes. This improvement demonstrates that LLMs can effectively learn patch generation patterns from automatically generated examples, even when using conventional list indexing approaches.

Patch Generation Matches Full Regeneration Performance Our diff patching approach with synthesized few-shot examples and EASE achieves comparable performance within a 5% margin to full regeneration while reducing token usage by 31%, as shown in Figure 4. The approach demonstrates effectiveness across both model sizes, with smaller models achieving performance comparable to larger ones when using our method (prompts for full regeneration are provided in Appendix A.3).

Substantial Cost and Efficiency Gains The efficiency gains are twofold, as shown in Table 1: first, by enabling smaller, more cost-effective models to perform comparably to larger ones, and second, by reducing token consumption for each operation. These benefits compound to create substantial cost and time savings in production environments. The

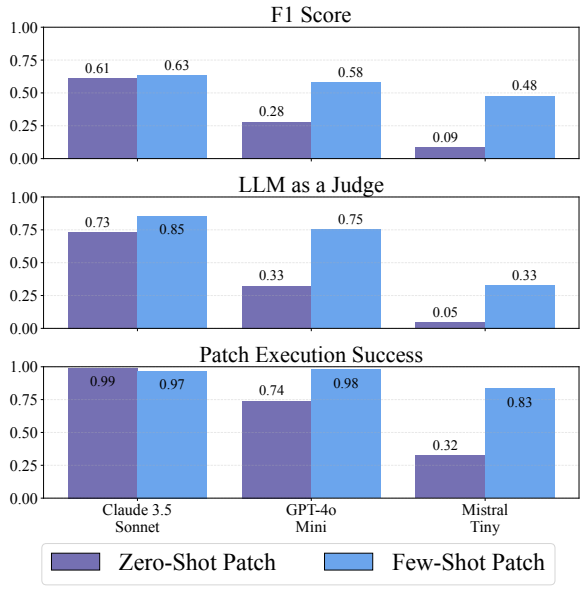

Figure 3: Using Synthesized Few-shots provide substantial performance improvements across models

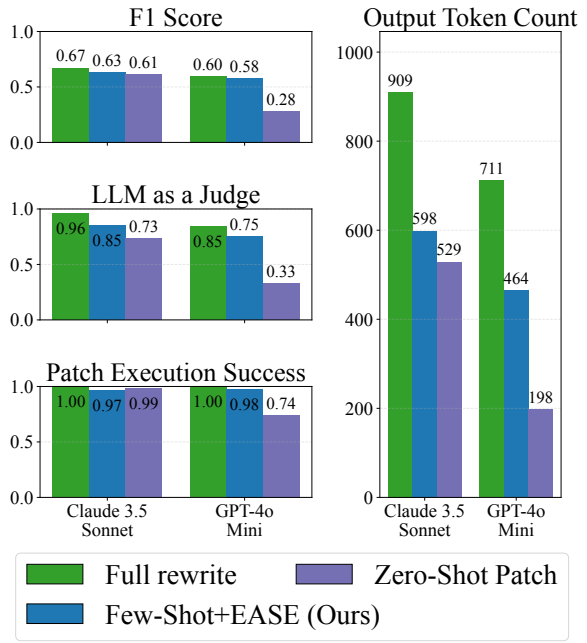

Figure 4: Our method achieves comparable performance within a 5% margin to full regeneration while reducing token usage by 31%

token reduction translates directly to faster processing times and lower computational costs, making the approach practical for real-world applications where efficiency is paramount.

Table 1: Costs & Time Comparison

LLMs for Structured Data Manipulation

In recent years, significant research has been directed toward guiding large language models (LLMs) to generate structured outputs, such as JSON (Geng et al., 2025; Shorten et al., 2024). Recent studies further show promising results in LLM-guided generation of JSON objects that represent visual entities such as websites, virtual reality environments, or video effects (Chen et al., 2025; Voronin, 2024; Kolthoff et al., 2025; Sultan et al., 2024).

Schema-guided decoding has emerged as a central technique for ensuring that model outputs conform to well-defined formats. Early approaches such as PICARD (Scholak et al., 2021) demonstrated how constrained autoregressive decoding can enforce syntactic validity by rejecting illegal continuations. These advances highlight the importance of structural validity as a guiding principle in structured text generation.

Complementing these efforts, research on streaming JSON parsers has focused on reducing the computational overhead of handling large structured documents. Notable examples include Mison (Li et al., 2017), which introduced speculative, field-aware parsing to bypass irrelevant fields, and subsequent extensions that further improved throughput using SIMD and incremental indexing (Langdale and Lemire, 2019). Unlike these studies, the approach presented here enables efficient manipulation of structured data objects such as JSON by patch generation (Benjamine, 2024), thereby reducing both cost and latency.

Automated Patch Generation

Research on automated patch generation and program repair by LLM-guided code updates and bug

fixes provides valuable insights for JSON editing with LLMs. Fan et al. (Fan et al., 2024) explored LLMs' capabilities for code-change-related tasks, showing that few-shot learning and fine-tuning approaches are promising for such scenarios. Zhang et al. (Zhang et al., 2025) demonstrate how LLMs can generate patches for code, which closely parallels the concept of creating JSON diff patches for structured data. By leveraging similar methodologies, LLMs can be guided to generate targeted modifications within JSON structures rather than regenerating entire objects, thereby improving both efficiency and accuracy in structured data editing.

7 Conclusion

This paper introduces an efficient approach for text-guided JSON editing using LLMs to generate only the necessary modifications instead of regenerating entire JSON objects. The method leverages the RFC 6902 JSON patch standard, significantly reducing token usage, computation costs, and latency, which are key factors for scalable AI-driven applications. To improve accuracy, a framework for synthetic data generation was developed alongside EASE, a novel encoding method that enhances LLMs' ability to handle ordered lists in JSON structures. Experimental results demonstrate that the approach reduces token generation by over 30%, while maintaining JSON edit quality within a 5% margin of full JSON regeneration.

For future work, the method could be extended to YAML and Git diff formats, while fine-tuning open-source LLMs might improve accuracy. Given the widespread use of JSON in software development, this research contributes to more efficient and intelligent AI-powered editing tools for structured data manipulation.

8 Limitations

Our approach faces two key limitations. First, both training and evaluation rely on synthetic data, which may not fully reflect real-world JSON editing scenarios. This limitation could be mitigated once user data consented for training is available. Second, while our method reduces output token usage and latency, the in-context learning approach increases input token overhead as JSON objects grow larger. This increase could offset the cost savings and ultimately lead to context window limitations. These challenges could be addressed through model fine-tuning, which would eliminate the need for few-shot examples and enable more efficient processing of larger JSON documents.

A Prompts Used in Experiments

This appendix contains the complete prompts used for the three different approaches evaluated in our experiments: Standard List Indexing, EASE Indexing, and Full JSON Regeneration.

A.1 Standard List Indexing Model Prompt

```
You are a helpful movie production assistant, integrated inside a generative AI video app.
You are a master of your craft, and confident with your choices. You know perfectly well
how to edit a scene and cast characters.

Given an input json representing an object in a short film and a user command,
your job is to return the json-patches needed to be made on the input json in order
to edit it fully and hermetically according to the command.
Try to understand the users desired result
Make as many updates as possible, in order to fully and hermetically follow the
edit command.

Your Jsons need to be sensitive in terms where it is not changing things that
shouldn't be changed, and changing things that need to be changed, including their
implications, for example:
- If the director commands you to add a shot to the scene - Be creative enough to
  make a shot with a description that suits the scene, while not changing the rest
  of the shots in the scene.
- If the director commands you to change scene's location - Change the location and
  anything implied from this change (e.g, if the location has changed from a beach
  to a jungle, and shot 3 has waves SFX, change it to Wind).
- If the director commands you to change shot 3 and shot 2 to be more funny, don't
  just add keywords such as laughter and funny, but be creative enough to make this
  shot funnier in the context of the scene.

If the command of the user is unrelated to the json and your task ignore it and
return is_unsupported action flag as True
If the updated json schema or any sub json schema is different from the input json
or sub json schema, is_unsupported flag is True, otherwise False

Output Fields:
- rationale: one line string start with 'let's think step by step, we need to...'
  explain the problem and how you are going to solve it
- json_diff_patch: json-patches (RFC 6902) needed to be made on the input json in
  order for the json to match the command, all lists indices are always 0 based.
- is_unsupported: True if the command is unrelated to the json or the updated json
  schema is different from the input json, otherwise False
```

A.2 EASE Indexing Model Prompt

```
You are a helpful movie production assistant, integrated inside a generative AI video app.
You are a master of your craft, and confident with your choices. You know perfectly well
how to edit a scene and cast characters.

Given an input json representing an object in a short film and a user command,
your job is to return the json-patches in RFC 6902 needed to be made on the input json
in order to edit it fully and hermetically according to the command.
Try to understand the users desired result
Make as many updates as possible, in order to fully and hermetically follow the
edit command.

A sub json contains a "list_display_order" is an ordered dict,
list_display_order determines the item order, not the dictionary order.
Keys are random two-letter strings (e.g., xy), with no inherent order.
Every item is accessed by its key, and the order is determined by the list_display_order.
To add, remove or move items, you must update list_display_order as a single string,
for example:
given a dictionary:
 list_display_order: "xk,xy,np,cv"
moving the second item to the first place, and the last item to the second place
will result:
 list_display_order: "xy,cv,xk,np"

Adding a new item without any specific ordering will add the item as the last,
```

```
result updating the list_display_order as:
list_display_order: "xy,cv,xk,np,rt"
and adding the item with random key "rt" to the dictionary.

Adding a new item in to the third place will result updating the list_display_order as:
 list_display_order: "xy,cv,yi,xk,np,rt"
 and adding the item with random key "yi" to the dictionary.

Removing the first item will result updating the list_display_order as:
 list_display_order: "cv, rt, xk, np"
 and removing the item with key "xy" from the dictionary.
In any case existing mapping between keys and values should be kept.

Your Jsons need to be sensitive in terms where it is not changing things that
shouldn't be changed, and changing things that need to be changed, including their
implications, for example:
- If the director commands you to add a shot to the scene - Be creative enough to
  make a shot with a description that suits the scene, while not changing the rest
  of the shots in the scene.
- If the director commands you to change scene's location - Change the location and
  anything implied from this change (e.g, if the location has changed from a beach
  to a jungle, and shot 3 has waves SFX, change it to Wind).
- If the director commands you to change shot 3 and shot 2 to be more funny, don't
  just add keywords such as laughter and funny, but be creative enough to make this
  shot funnier in the context of the scene.

If the command of the user is unrelated to the json and your task ignore it and
return is_unsupported action flag as True
If the updated json schema or any sub json schema is different from the input json
or sub json schema, is_unsupported flag is True, otherwise False

Output Fields:
- rationale: one line string start with 'let's think step by step, we need to...'
  explain the problem and how you are going to solve it
- json_diff_patch: json-patches (RFC 6902) needed to be made on the input json in
  order for the json to match the command, all lists indices are always 0 based.
- is_unsupported: True if the command is unrelated to the json or the updated json
  schema is different from the input json, otherwise False
```

A.3 Full JSON Regeneration Model Prompt

```
You are a professional movie director,
You are creative, a master of your craft, and confident with your choices.
You know perfectly well how to edit a scene and cast characters.
You get a json representing an object in a movie editing software and a user command
and returns a label containing the updated json according to the command,
you should cover all changes that has to be done in the json object,
write the updated json as a professional director,
make as many updates as possible, in order to fully and hermetically follow the
edit command.

Your Jsons need to be sensitive in terms where it is not changing things that
shouldn't be changed, and changing things that need to be changed, including their
implications, for example:
- If the director commands you to add a shot to the scene - Be creative enough to
  make a shot with a description that suits the scene, while not changing the rest
  of the shots in the scene.
- If the director commands you to change scene's location - Change the location and
  anything implied from this change (e.g, if the location has changed from a beach
  to a jungle, and shot 3 has waves SFX, change it to Wind).
- If the director commands you to change shot 3 and shot 2 to be more funny, don't
  just add keywords such as laughter and funny, but be creative enough to make this
  shot funnier in the context of the scene.

If the command of the user is unrelated to the json and your task ignore it and
return is_unsupported action flag as True
If the updated json schema or any sub json schema is different from the input json
or sub json schema, is_unsupported flag is True, otherwise False
Return the updated json according to the command without comments in it
```

```
Output Fields:
- rationale: one line string start with 'let's think step by step, we need to...'
  explain the problem and how you are going to solve it
- updated_json: the updated json according to the command keeping the same schema
  as the input json
- is_unsupported: True if the command is unrelated to the json or the updated json
  schema is different from the input json, otherwise False
```

A.4 LLM-as-a-judge Prompt

This prompt is used to evaluate which of two JSON editing approaches produces higher quality results for a given editing command.

```
Compare the quality of two updated jsons given the input json and command.
along the specified dimension.

Input Fields:
- original_json: original json
- w_json: w json (first comparison candidate)
- v_json: v json (second comparison candidate)
- user_command: the command to apply on the json
- quality_question: The question should be answered assessing the quality of the
  json json-patches given the command, and the input json

quality_question:
"which json is of a higher quality update according to the command in term of
the written content?"

Output Fields:
- quality_answer: w / v / tie (only)
```

L4: Mutual Learning Helps Lifelong Language Learning

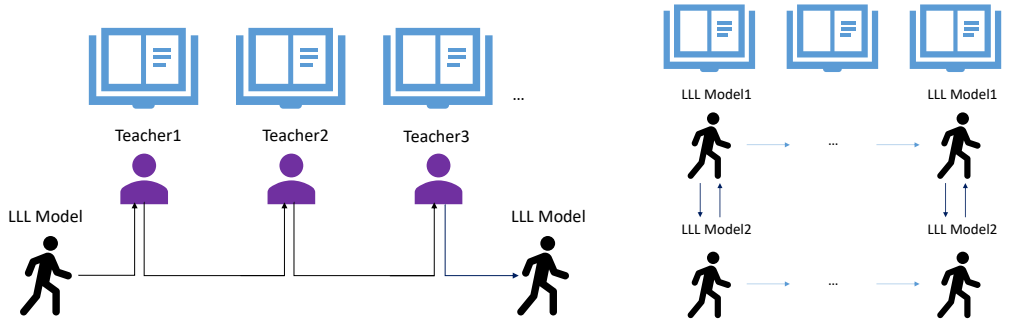
Abstract

Adapting language models to learn continuously from data streams while retaining previous knowledge is a key challenge in artificial intelligence (AI), particularly in lifelong language learning. Existing distillation methods are based on offline techniques, limiting their ability to update in real-time and adapt to dynamic environments. To address this, we propose *online dynamic mutual distillation* – a novel framework that enables continuous mutual learning from task streams without relying on domain-specific teachers. To our knowledge, this is the first application of mutual learning in lifelong language learning, providing dynamic knowledge transfer without domain-specific teachers. Moreover, our extensive experiments demonstrate that the proposed method reduces catastrophic forgetting, while improving task performance on various benchmark datasets making it suitable for real-world, dynamic natural language processing (NLP) applications such as adaptive chat-bots and personalized language systems. Our code is available in https://github.com/sssrlll/L4.

1 Introduction



Catastrophic forgetting, a common challenge in deep learning, refers to the difficulty faced by neural networks in retaining proficiency in previously learned tasks after being exposed to new ones (Goodfellow et al., 2013). This issue poses significant obstacles, particularly in dynamic environments where models are expected to continuously learn from new data. Lifelong learning has been proposed as a promising solution, designed to enable models to sequentially learn new tasks while preserving knowledge from previous tasks (Chen et al., 2018). Among the various techniques applied to address catastrophic forgetting, distillation methods have emerged as highly effective in maintaining knowledge across tasks (Hinton, 2015). These methods have been widely adopted in lifelong learning, particularly in NLP, due to their ability to transfer and preserve knowledge from previous models (Sun et al., 2019). Other studies, such as De Lange et al. (2021); Parisi et al. (2019); Li et al. (2024), have further explored continual learning techniques that aim to balance learning efficiency and memory retention on various tasks.

However, despite the broad application of distillation techniques, most approaches still rely on independently trained domain-specific teachers, a requirement that limits their flexibility and applicability in general lifelong learning scenarios (Shin et al., 2017). The need for domain-specific teachers can be impractical, especially when dealing with diverse or constantly evolving tasks, as it imposes significant computational overhead and complexity. In fact, for many application scenarios, such as on-device deployment or online-serving language models, resource constraints often make it impractical to employ teacher models with excessively large parameter counts. For example, in real-world applications, such as customer service chatbots, models must continuously adapt to evolving user queries and the information they have to provide without retraining on static teacher models. As a result, traditional knowledge distillation methods that rely on large teacher models may face significant challenges in these settings.

To this end, we introduce **L4**, which integrates mutual **L**earning into **L**ifelong **L**anguage **L**earning so that student models distill knowledge from each other, improving performance without relying on a large teacher. Unlike traditional methods, our approach eliminates the dependency on domain-specific teachers by enabling models to engage in peer-to-peer distillation, dynamically improving each other's performance. By doing so, L4 addresses the limitations of existing techniques and broadens the scope of lifelong learning.

(a) Lifelong Learning with Normal Knowledge Distillation.

(b) Lifelong Learning with Mutual Distillation.

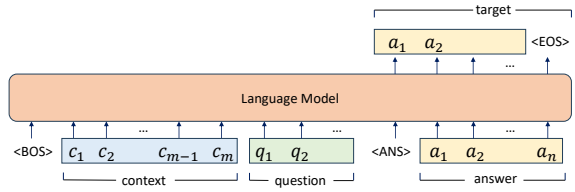
Figure 1: Comparison between L2KD and L4: L2KD relies on domain-specific teachers, while L4 introduces peer-to-peer distillation, enhancing flexibility and performance.

Our key contributions are as follows:

- We introduce a novel mutual learning mechanism into the lifelong language learning paradigm, enabling models to collaborate and enhance each other knowledge without relying on predefined domain teachers.
- We demonstrate through extensive experiments that our method not only mitigates forgetting, but also achieves performance that rivals or even surpasses most baseline methods on standard benchmark datasets, showcasing robustness across diverse tasks.

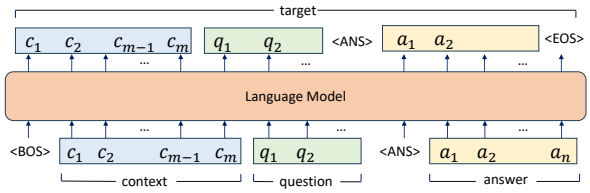
2 Related Work

Lifelong Language Learning. Catastrophic forgetting is a major challenge in Lifelong Language Learning (LLL), particularly in NLP. One of the pioneering methods, *LAMOL* (Sun et al., 2019), used generative replay to alleviate forgetting by using language models to generate data from previous tasks, avoiding the need for stored samples. Building on this, *L2KD* introduced domain teacher distillation, using pre-trained models to guide learning and further enhance performance by incorporating domain-specific knowledge (Chuang et al., 2020). Recently, with increasing attention to large language models, some studies have explored the performance of lifelong learning in such models (Zheng et al., 2025). Some works (Wang and Li, 2024; Yang et al., 2024) propose using Mixture-of-Experts (MOE) models in lifelong learning scenarios, leveraging multiple experts to store knowledge from different tasks, which can effectively alleviate the problem of catastrophic forgetting. Other works (Gao et al., 2024) suggest that large language models can enhance their ability to resist forgetting by retrieving task-relevant knowledge, thus improving performance in lifelong learning settings.



However, most of these methods rely on domain-specific teachers, specific model architectures (*e.g.,* MOE) or require storing knowledge repositories from past tasks, limiting their flexibility in broader applications. Our method focuses on more general scenarios and language models, aiming to improve the performance of lifelong learning systems without storing past task samples or relying on domain-specific teachers.

Knowledge Distillation and Mutual Learning. Knowledge distillation has been widely explored in lifelong learning, mainly in computer vision. Methods such as *Learning without Forgetting (LwF)* (Li and Hoiem, 2017), *Generative Replay with Distillation* (Shin et al., 2017), *Replay-through-Feedback (RtF)* (Van de Ven and Tolias, 2018), and *Lifelong GAN* (Zhai et al., 2019) have successfully applied distillation to retain knowledge over time. More recent work (Cha et al., 2021) has explored contrastive continual learning. However, most efforts focus on computer vision, with little exploration in NLP. Moreover, mutual learning, where student models learn from each other, has shown promising results, outperforming traditional teacher-student setups (Zhang et al., 2018).



3 Method

3.1 LAMOL

The training objective of normal language modeling is to minimize the negative log likelihood

(a) Question answering (QA). Lifelong model is trained to solve target task.

(b) Language modeling (LM). Lifelong model is trained to generate pseudo data.

Figure 2: Illustration of QA and LM learning architectures.

(NLL) of the model predicting the next word:

$$L_{NLL} = -\sum_{t=t_0}^{T} \log(P(x_t|x_{<t};\theta)), \qquad (1)$$

where x_t represents the t-th word in the sentence, $x_{<t}$ represents all words before x_t, and θ is a parameter of the language model.

Typically, language datasets comprise three components: context, question, and answer. In conventional training, the model generates the correct answer based on the context and question provided, as shown in Figure 2(a). Formally, the supervised training loss is represented as follows:

$$L^{QA}_{NLL} = L_{NLL}(X;\theta;t_0 = a_1), \qquad (2)$$

where a_1 is the first token of the answer text.

However, the direct application of the aforementioned supervised loss for training often leads to catastrophic forgetting under non-stationary data stream settings. To better adapt to the continual learning scenario, *LAMOL* introduces an innovative strategy that mitigates forgetting by generating pseudo-samples from previous tasks and concurrently training them with new tasks, thereby eliminating the need to store old task data. Specifically, the model not only generates answers for a given question but also learns to model the entire training sample simultaneously, as illustrated in Figure 2(b). Formally, to equip the model with the ability to generate pseudo training samples for each token,

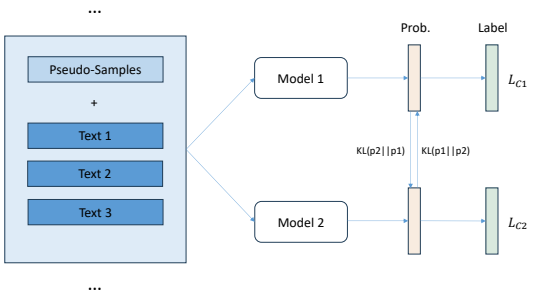


Figure 3: Illustration of our L4 framework. While a new task is arriving, we train two models in parallel with mutual learning on both the pseudo-samples generated from past tasks and the data from the current task, and employ cross-entropy loss to optimize the prediction of each model, thereby enabling the models to enhance each other performance mutually.

including content, questions, and answers, the training loss is designed as follows:

$$L^{LM}_{NLL} = L_{NLL}(X;\theta;t_0 = 0), \qquad (3)$$

which is computed from the first token.

This approach enables the LLL model to effectively generate pseudo-samples from past tasks for joint training with samples from the current task. Given that *LAMOL* outperforms memory-based methods such as those proposed by (Lopez-Paz and Ranzato, 2017) and (Yogatama et al., 2019), as well as regularization-based methods, we build on its foundation by applying our **L4** algorithm to further enhance its performance.

3.2 Knowledge Distillation

Vanilla KD. In traditional knowledge distillation, the cross-entropy between the output distributions of the student and teacher models is minimized, particularly when predicting the next word in a sequence:

$$L_{KD}(x;\theta_S,\theta_T) = \sum_{t,k} -P(y_k|x_{1:t-1};\theta_T)\log P(y_k|x_{1:t-1};\theta_S),$$

where $x_{1:t-1}$ is the input sequence up to time step $t-1$, and y_k represents the k-th word in the vocabulary. Here, θ_{S_1} and θ_{S_2} are the parameters of the student and teacher models, respectively. By learning from these soft targets, the student model can capture nuanced patterns and generalize better, leading to more efficient knowledge transfer.

Further, we obtain two different word-level distillation losses based on the starting token position

of the loss calculation, just as Equations 2 and 3:

$$L_{KD}^{QA} = L_{KD}(X;\theta;t_0 = a_0)$$
$$L_{KD}^{LM} = L_{KD}(X;\theta;t_0 = 0). \quad (4)$$

Mutual Learning. In mutual learning, we typically consider two models, θ_1 and θ_2, initialized identically. We train models on the data (x, y) using two components: cross-entropy loss, which aligns their predictions with the true labels, and distillation loss, which aligns their outputs with each other. With denoting $p_1 := p(\hat{y}_1|X;\theta_1)$ and $p_2 := p(\hat{y}_2|X;\theta_2)$, the cross-entropy losses for the models are defined as:

$$L_{C_1} = -\log(p_1(\hat{y}_1 = y))$$
$$L_{C_2} = -\log(p_2(\hat{y}_2 = y)). \quad (5)$$

Moreover, mutual learning framework incorporates a Kullback-Leibler (KL) divergence loss D_{KL} to ensure that both models learn from each other. Following (Zhang et al., 2018), the final loss functions for both models are a combination of cross-entropy loss and distillation loss:

$$L_1 = L_{C_1} + \lambda * D_{KL}(p_2||p_1)$$
$$L_2 = L_{C_2} + \lambda * D_{KL}(p_1||p_2). \quad (6)$$

By iteratively training the models with these combined loss functions, both models benefit from each other predictions, allowing them to achieve better performance without the need for a pre-trained teacher.

3.3 L4

In previous studies, distillation was generally applied directly to the lifelong learning setting, requiring the training of a separate teacher model for each task. This approach is often difficult to implement in data flow settings. To avoid the need for pre-training a teacher model while still achieving or surpassing the performance of simple distillation, we introduce mutual learning into lifelong learning for the first time and our architecture is shown in Figure 3. Using another network θ_{S_2} with the same initialization, the two models θ_{S_1} and θ_{S_2} can learn from each other, improving performance while avoiding the need for a separately trained teacher model.

To introduce mutual learning in lifelong learning, we combine supervised loss and distillation loss. Firstly, by combining QA loss (2) and LM loss (3) on the current task in the following way, we can obtain supervised losses for both models separately:

$$L_{C1} = L_{NLL}^{QA}(X_0;\theta_{S_1}) + L_{NLL}^{LM}(X_0;\theta_{S_1})$$
$$L_{C2} = L_{NLL}^{QA}(X_0;\theta_{S_2}) + L_{NLL}^{LM}(X_0;\theta_{S_2}). \quad (7)$$

Furthermore, as before, we define distillation losses based on QA and LM separately and then obtain the distillation losses of two models:

$$L_{KD1} = L_{KD1}^{QA} + L_{KD1}^{LM}$$
$$L_{KD2} = L_{KD2}^{QA} + L_{KD2}^{LM}. \quad (8)$$

Finally, we obtained the required training loss on a single task:

$$L_{\theta_{S_1}} = L_{C1}(X_0;\theta_{S_1}) + \lambda \cdot L_{KD1}(X_0;\theta_{S_1})$$
$$L_{\theta_{S_2}} = L_{C2}(X_0;\theta_{S_2}) + \lambda \cdot L_{KD2}(X_0;\theta_{S_2}), \quad (9)$$

where λ is the trade-off hyperparameters.

In the tasks that arrived later, we need to adjust the losses to mitigate the Catastrophic Forgetting. In order to avoid interference between the supervised loss and the distillation loss under the lifelong learning setting, supervised loss is applied only to the generated pseudo-samples, while distillation loss is applied to the samples from the current task. Similarly, by combining QA and LM losses in the following way, we can obtain the supervised losses of these two models separately. Note that we only calculate this loss on past pseudo samples:

$$\begin{aligned} &L_{past}(X^{past};\theta_{S_1}) \\ &\quad = L_{past}^{QA}(X^{past};\theta_{S_1}) + L_{past}^{LM}(X^{past};\theta_{S_1}) \\ &L_{past}(X^{past};\theta_{S_2}) \\ &\quad = L_{past}^{QA}(X^{past};\theta_{S_2}) + L_{past}^{LM}(X^{past};\theta_{S_2}). \end{aligned} \quad (10)$$

In addition, as mentioned earlier, we define the distillation losses on the basis of QA and LM, respectively. Here we can obtain the distillation losses of two models separately, and we only calculate this loss on the current task sample:

$$L_{cur}(X^{cur};\theta_{S_1}) = L_{cur}^{QA}(X^{cur};\theta_{S_1}) + L_{cur}^{LM}(X^{cur};\theta_{S_1})$$
$$L_{cur}(X^{cur};\theta_{S_2}) = L_{cur}^{QA}(X^{cur};\theta_{S_2}) + L_{cur}^{LM}(X^{cur};\theta_{S_2}) \quad (11)$$

In the end, the respective losses and update methods for the two models are obtained as follows:

$$L_{\theta_{S_1}} = L_{past}(X^{past};\theta_{S_1}) + \lambda \cdot L_{cur}(X^{cur};\theta_{S_1})$$
$$L_{\theta_{S_2}} = L_{past}(X^{past};\theta_{S_2}) + \lambda \cdot L_{cur}(X^{cur};\theta_{S_2}). \quad (12)$$

In this way, both models can learn to correctly predict the true labels of the training instances while matching the probability estimates of their peer model.

3.3.1 Optimization

We implement a mutual learning strategy throughout the entire training process, executing it at each epoch. In every epoch, the predictions of the two models are calculated separately, and the parameters of both networks are iteratively updated based on the predictions of the other model until convergence. The optimization process is described in the Algorithm 1 (Appendix A).

4 Experiments & Results

4.1 Evaluation Measures

Table 4 (Appendix A) summarizes the evaluation measures used in this study: dsEM (Dialog State Exact Match), ROUGE (Recall-Oriented Understudy for Gisting Evaluation) (Lin, 2004), IfEM (Interaction-Level Exact Match) (Zhong et al., 2017) and Forgetting Metric (Chaudhry et al., 2018).

The dsEM evaluates dialogue systems by checking if the predicted dialogue state $\hat{y}_i$ exactly matches the ground truth y_i across all intents and slots:

$$\text{dsEM} = \frac{\sum_{i=1}^{N} \mathbb{1}(\hat{y}_i = y_i)}{N}, \tag{13}$$

where N is the total number of dialogue states.

ROUGE measures summarization quality by assessing n-gram overlap between generated and reference summaries:

$$\text{ROUGE}_n = \frac{A}{B}, \tag{14}$$

where A is the overlap of n-grams and B is the total number of n-grams in the reference summaries.

The IfEM evaluates query generation tasks by checking if the predicted query $\hat{Q}_i$ matches the ground truth Q_i:

$$\text{IfEM} = \frac{\sum_{i=1}^{M} \mathbb{1}(\hat{Q}_i = Q_i)}{M}, \tag{15}$$

where M is the total number of interactions.

The Forgetting Metric(FM) is used to measure a model's ability to alleviate forgetting in lifelong learning. Formally, the forgetting measure of the model on the i-th task is the difference between the model's highest performance a on that task and its final performance a on the task after training on all the k tasks:

$$f_i = \max_{i=1,\ldots,k} a_i - a_k. \tag{16}$$

Then the Average Forgetting can be calculated as follows:

$$FM = \frac{1}{k-1} \sum_{i=1}^{k} f_i. \tag{17}$$

4.2 Dataset

To evaluate the effectiveness of our approach in mitigating catastrophic forgetting, we performed experiments using a dataset (more details can be seen in Table 4 (Appendix A)) spanning three distinct domains: MultiWOZ (WOZ), CNN/DailyMail (CNN), and WikiSQL (SQL). WikiSQL is a dataset designed for developing natural language interfaces for relational databases, where models generate structured queries from natural language inputs. CNN/DailyMail comprises a collection of online news articles aimed at text summarization tasks. MultiWOZ is a multi-domain wizard-of-oz dataset tailored for task-oriented dialogue modeling, where models are required to generate semantic state sequences based on partial dialogues.

	Finetune	LAMOL	L2KD	$L4_{Student\ 1}$	$L4_{Student\ 2}$
WOZ	85.5	6.0	5.3	3.3	**2.9**
SQL	62.7	4.2	4.8	4.9	**3.1**
Average Forgetting	74.1	5.1	5.1	4.1	**3.0**

Table 3: Forgetting metric (lower is better) under the WOZ-SQL-CNN order in Lifelong Learning.

Following methodologies similar to LAMOL (Sun et al., 2019) and L2KD (Chuang et al., 2020), we performed sequential training on these datasets, utilizing generative replay.

However, in real-world scenarios, lifelong learning models are more commonly trained to solve tasks in different domains of the same problem, which evolve over time. To simulate this, we also performed experiments on natural language generation (NLG) datasets across five domains. These include the E2E-NLG dataset (Novikova et al., 2017), which focuses on end-to-end natural language generation in the restaurant industry, and RNNLG (Wen et al., 2015), a dataset tailored for spoken dialogue systems. RNNLG consists of four domains: San Francisco restaurant search (REST), San Francisco hotel search (HOT), television sale/search (TV), and laptop sale/search (LAPTOP). To maintain balance across domains, we use the complete datasets for the first three domains and a reduced dataset for the laptop domain.

4.3 Experimental Setup

Our approach employs the L2KD implementation to ensure comparable results. For our experiments, we used the same pre-trained small GPT-2 model (Radford et al., 2019) across all Lifelong Learning (LLL) models. Following the methodology of L2KD (Chuang et al., 2020), the GPT-2 model was fine-tuned for 9 epochs on each dataset, and we used task-specific tokens as [bos] tokens and set the pseudo-data sampling rate to 0.2. The following evaluation measures used in this study: dsEM (Dialog State Exact Match), ROUGE (Recall-Oriented Understudy for Gisting Evaluation) (Lin, 2004), IfEM (Interaction-Level Exact Match) (Zhong et al., 2017) and Forgetting Metric (Chaudhry et al., 2018).

4.4 Results

In this subsection, we present and analyze our experimental results. We evaluated the effectiveness of our method across two main settings: different sequence generation tasks and the same task applied across varying domains. These settings were specifically designed to test the robustness of our proposed approach in mitigating catastrophic forgetting, a key challenge in lifelong learning. All results have been subjected to significance testing.

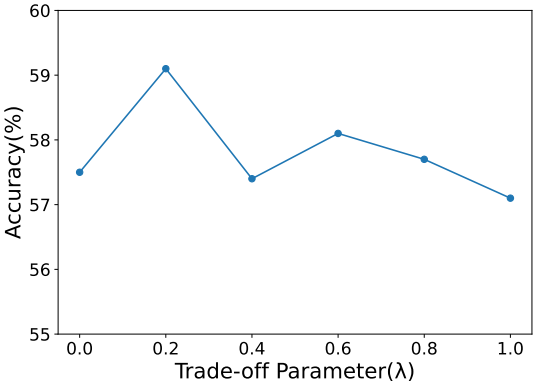

Figure 4: Performance variant with the trade-off parameter λ under the WOZ-CNN-SQL order.

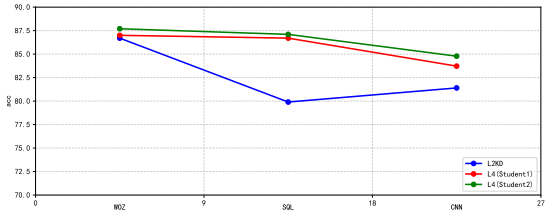
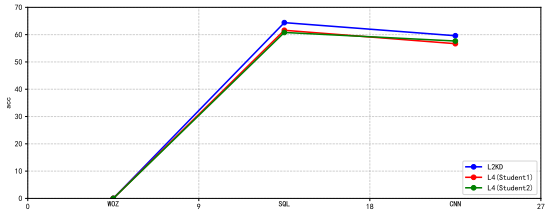


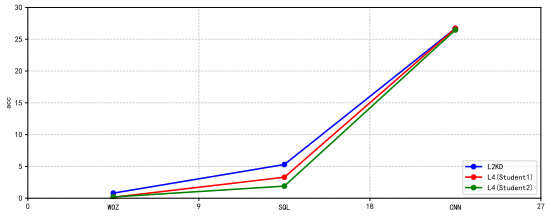
4.4.1 Results for Sequence Generation Tasks

For the sequence generation experiments, we performed lifelong learning on three diverse datasets: WikiSQL (SQL), CNN/DailyMail (CNN), and MultiWOZ (WOZ). These datasets were selected to represent different types of sequence generation tasks, including structured query generation, summarization, and task-oriented dialogue. We trained the models using various permutation orders and evaluated their performance at the end of each training stream. The results, as shown in Table 1, report the average scores for the three tasks, with normalized values ranging from 0 to 100 for a fair comparison. The performance of L4 shown in the Table 1 comes from the Student 1 model.



As observed in Table 1, fine-tuning the model directly leads to severe forgetting of tasks learned earlier in the sequence. In contrast, both LAMOL and L2KD demonstrate a strong ability to mitigate catastrophic forgetting. However, the experimental results highlight that our proposed method consistently matches and in many cases surpasses the performance of both LAMOL and L2KD, especially in scenarios where the task order was challenging. More importantly, for models that utilize pre-trained teachers (marked with an asterisk), our model is also able to achieve comparable performance. This shows that L4 is particularly effective in retaining knowledge and adapting to new tasks without compromising past learning.

4.4.2 Results for Different Domains



To further validate the generalizability of our approach, we test in different domains under the same task conditions. Specifically, we conducted experi-

(a) Learning curve of WOZ task.

(b) Learning curve of SQL task.

(c) Learning curve of CNN task.

Figure 5: Learning curves of different methods during training in the order of WOZ-SQL-CNN.

ments on five distinct domains, including four subdomains from E2E-NLG to RNNLG, which span different language generation contexts. As shown in Table 2, we provide results for two training settings: one in which tasks are ordered from the most difficult to the simplest (left → right), and the other in reverse order (right → left), in order to analyze the impact of task difficulty on lifelong learning performance. The performance of L4 shown in the Table 2 comes from the Student 1 model.

The results indicate that our method consistently achieves high performance in both settings, matching or surpassing the results of LAMOL and L2KD. In particular, in the left → right setting, where tasks progress from the most difficult to the simplest, our approach shows a clear advantage, demonstrating the robustness of L4 in challenging environments. Under this setting, our method even significantly outperforms the training approaches that use pre-trained teachers. This suggests that our method is capable of handling domain variations while effectively mitigating catastrophic forgetting, making it a versatile solution for lifelong language learning in multiple domains.

4.5 Ablation Study

Average Forgetting. To verify whether our method can truly alleviate the forgetting phenomenon in lifelong language learning, we present the forgetting metrics of the first two tasks and the average forgetting after model training under the task sequence WOZ-SQL-CNN in the Table 3. Experimental results demonstrate that both student models trained with our method show fewer forgetting compared to traditional baselines, effectively mitigating catastrophic forgetting. More detailed performance variations of different methods during training can be found in the Appendix A.

Trade-off Parameter λ. As shown in the Figure 4, to further analyze the impact of the hyperparameter λ on the performance of the lifelong learning model, we conducted experiments with different settings of λ in the range from 0.0 to 1.0, and present the results for Student 1. The experimental results indicate that when λ is set to 0.2, our model achieves the best performance, suggesting a good balance between the supervised learning loss and the mutual learning loss at this point.

Learning Curves. To more intuitively compare the differences between our method and other strong baseline approaches, we plot the learning curves for L2KD and our method. As shown in the Figure 5, our method demonstrates a better ability to prevent forgetting. For example, on the WOZ task in the Figure 5(a), the performance of L2KD significantly degrades as training progresses, while our method effectively maintains its original performance. Through this ablation study, we observe that our method successfully alleviates the forgetting phenomenon during training, reducing the performance drop on previous tasks when adapted to new ones.

5 Conclusion

We proposed **L4**, a lifelong language learning algorithm that utilizes mutual learning, which enhances the performance of lifelong language models without requiring pre-trained teacher models. By allowing dynamic knowledge transfer between models, our approach eliminates the need for pre-trained teachers, reducing both the computational overhead and training time. Our experimental results across various tasks and domains demonstrate that our approach achieves strong performance in mitigating catastrophic forgetting, making it a robust and efficient solution for lifelong learning.

Limitations

As part of our limitations, our aim is to optimize the memory efficiency of mutual learning, making it more suitable for deployment in memory-constrained environments such as mobile and embedded systems. Furthermore, while our approach improves model performance, it does not explicitly address concerns related to fairness or bias, critical factors in real-world applications. Future research should explore the integration of fairness-based mechanisms to ensure both accuracy and equity in lifelong learning models, preventing unintended biases from influencing model outputs. Moreover, exploring how L4 can be applied to different modalities (*e.g.,* reinforcement learning or speech processing) will help to assess its generalizability and unlock its potential for broader cross-domain applications. In addition, our goal is to explore methods that enhance the model's ability to retain task-specific knowledge through sequential edits. Moreover, due to limited computing resources, we are currently only able to train the mutual learning algorithm on GPT-2.

Our method demonstrates clear advantages in mitigating catastrophic forgetting, there are several limitations that must be acknowledged. First, mutual learning, although effective, can require significantly more memory and computational resources, especially during training, as multiple models must be trained simultaneously. This could present a challenge in memory-limited environments or when scaling the model for larger datasets. Second, the effectiveness of our approach relies on well-defined tasks and sufficient data for each task. In real-world, where data may be scarce or noisy, the performance of mutual learning and lifelong language learning methods may be degraded.

Moreover, while our method generalizes well in certain NLP tasks, its applicability to more complex, cross-domain learning scenarios remains to be fully explored. Lastly, our experiments have focused mainly on benchmarking tasks in NLP, and the effectiveness of the method in other domains, for example, reinforcement learning or speech processing, remains untested. Future work should explore the adaptability of our approach across different modalities and consider optimizing its computational efficiency for practical deployment. Furthermore, robustness to noisy and low-resource settings requires further experimentation to confirm its general applicability.

Ethical Statement & Bias

Our work uses publicly available datasets, which can inherently contain biases, such as underrepresentation of certain demographic groups or skewed language patterns. Models trained on these datasets could unintentionally perpetuate these biases, leading to unfair or harmful outcomes in real-world applications. For example, in automated decision making or conversational agents, biased predictions may disproportionately affect certain groups or reinforce harmful stereotypes.

The risks are particularly significant in sensitive domains such as healthcare, recruitment, or law enforcement, where biased results could have profound ethical and social implications. To mitigate these risks, developers and users of these models must take proactive steps to assess fairness and address bias in both the data and the predictions of the model. Future work should incorporate fairness-sensitive learning objectives into mutual learning frameworks, ensuring that the models are effective and impartial. This may involve applying debiasing techniques during training or employing post hoc methods to identify and correct biases in output. In addition, interpretability techniques should be utilized to ensure transparent and equitable decision making in diverse applications.

Appendix

A Additional Experiments.

Performance Changes during Training Process. To more intuitively demonstrate performance during training, we present in the Figure 6 a line graph showing the model's performance at different training stages. Through this analysis experiment, we can observe that our method effectively alleviates the phenomenon of forgetting during the training process, reduces the performance drop on previous tasks when adapting to new ones, and successfully retains the textual knowledge acquired during previous training.

Comparison between L4 Models. To verify that the mutual learning method in continual learning is effective, we further need to confirm that the models trained through mutual learning are not entirely identical, in order to demonstrate that our method does not lead to the problem of model collapse. As shown in Table 6, the models trained using the mutual learning framework exhibit different performances in various settings. This indicates that, although their performances are relatively close, they have learned a wide range of knowledge, which enables them to improve each other's performance through mutual learning.

Comparison Between Models with Different Parameter Sizes. To further explore the upper bound of our method, we aim to verify the performance difference between training two models with smaller parameter sizes using mutual learning and training a single model with a larger parameter size using conventional continual learning methods. To this end, we compare the L4 framework trained on two smaller GPT-2-S models with the LAMOL framework trained on a GPT-2-M model with nearly double the number of parameters.

As shown in the Table 5, training with a model that has more parameters generally achieves better performance than improving multiple smaller models through mutual learning. This result suggests that larger-parameter models may have better resistance to forgetting compared to ensembles of smaller models. However, in many practical scenarios, pre-trained large-parameter models may not always be available. In such cases, our mutual learning approach can help train smaller models to achieve better results.

Computational Resources Analysis. To further analyze the resource consumption of our algorithm, we compare our method L4 with the existing pre-trained teacher distillation framework L2KD in terms of peak GPU memory usage and total training time. We primarily measure the maximum GPU memory occupied throughout the entire training process, as well as the total time required to complete training under the assumption that the teacher model can be trained in advance and in parallel. As shown in the Table 8, our method exhibits higher maximum GPU memory usage than the existing pre-trained teacher distillation framework L2KD. This is because our approach requires two models to perform mutual knowledge distilla-

Figure 6: The overall performance of different methods during training in the order of WOZ-SQL-CNN.

tion, whereas L2KD freezes the teacher model for inference and trains only the student model, thus consuming less GPU memory. However, L2KD inevitably requires pre-training the teacher model, making it less adaptable to certain online application scenarios. In contrast, our method, despite a larger memory footprint, achieves better adaptability to online settings. In terms of training time, our method outperforms L2KD. This advantage arises because L2KD needs to repeatedly load datasets and pre-train the teacher model, while our method can train the model online. Compared to distillation frameworks like L2KD that require a pre-trained teacher, our approach better accommodates real-world applications while maintaining a comparable total training time.

Error Analysis. Although our experimental results approach or even surpass baseline methods in most experimental settings, our method still underperforms in certain scenarios. Here, we conduct an error analysis of our approach. Firstly, through analysis of the results of the model testing, we observed that the majority of the model responses adhered to the required formats during the answer to the test questions. Most errors stemmed from direct inaccuracies in the answers. This suggests that while our method demonstrates strong format compliance capabilities, it remains insufficient in alleviating knowledge forgetting issues. Furthermore, we present examples generated by models trained under the "WOZ-CNN-SQL" task sequence. As shown in the Table 7, there may be instances

A	select college from table where hometown = houston city hall

Table 7: Examples of the model generation. For the correct generation, the model generates the WOZ task's question-answer pair successfully, which helps mitigate forgetting. For the incorrect generation, the model generates examples with SQL format, which indicates that model suffers from catastrophic forgetting.

Table 8: Comparison of peak memory usage and training time during training, where L2KD is the distillation framework using a pre-trained teacher, and L4 is our algorithmic framework based on mutual learning. Hours - hs.

	Peak Memory Usage	Training Time
L2KD	**19.3G**	7hs
L4	21.2G	**6.5hs**

where tokens generated for the WOZ task produce outputs in SQL format. This inconsistency could lead to catastrophic forgetting, as the reduced availability of generation examples from previous tasks (*e.g.,* "WOZ") can cause the model to forget related knowledge during subsequent training phases.

TTD-SQL: Tree-Guided Token Decoding for Efficient and Schema-Aware SQL Generation

Abstract

Natural language interfaces (NLIs) democratize data analytics by enabling non-technical users to query relational databases via Text-to-SQL systems. While large language models (LLMs) have achieved state-of-the-art accuracy on benchmarks like Spider and BIRD, two critical challenges persist for real-time deployment: (1) **inference latency** due to sequential autoregressive decoding (e.g., average inference latency on BIRD (Minidev) is 14.3 seconds per query for Qwen2.5-Coder-32B and 22.86 seconds for Llama-70B.), and (2) **schema hallucinations** (e.g., invalid column references like `customer_ids` instead of `cust_id`). (2) **schema hallucinations** (e.g., Qwen2.5-Coder-32B Instruct generated `... COUNT(users.UserId) ... = users.Id ...`, using `users.Id` correctly in `JOIN` but hallucinating `users.UserId` in `COUNT`). To address these, we propose *Tree-Guided Token Decoding (TTD-SQL)*, a lightweight framework that integrates SQL grammar and database schema constraints into the decoding process without modifying the underlying LLM. TTD precomputes token-level decision trees over SQL keywords, table names, and column identifiers, enabling deterministic "auto-fill" transitions for uniquely determined tokens (e.g., `"Song_"` $\rightarrow$ `"ID"`) while retaining flexibility for unconstrained reasoning. Across five LLMs (CodeLlama, Phi-4, Qwen2.5, Granite, Llama-70B), TTD achieves up to 19.96% token-rate speedups by eliminating redundant forward passes (e.g., CodeLlama: 8.97$\rightarrow$10.76 tokens/s on Spider) and reduces schema hallucinations by +17.7% in executable-SQL rates (e.g., CodeLlama on BIRD). By bridging rigid parser-based methods and flexible LLM generation, TTD offers a practical path toward reliable, high-performance SQL generation in both public benchmarks and enterprise settings.

1 Introduction

Natural language interfaces (NLIs) to relational databases have the potential to democratize data analytics by enabling non-technical users to query databases through conversational English (Liu et al., 2024; Li et al., 2024a). Text-to-SQL systems, which translate natural language queries into executable SQL statements, are central to this vision (Deng et al., 2022; Katsogiannis-Meimarakis and Koutrika, 2023). Recent advances in large language models (LLMs) have pushed state-of-the-art accuracy on benchmarks like Spider (Yu et al., 2018) and BIRD (Li et al., 2024b). However, real-time deployment in high-stakes domains—such as finance, healthcare, and enterprise analytics—faces two persistent challenges:

- **Inference Latency:** Autoregressive LLMs process tokens sequentially, requiring a full forward pass per token. On BIRD Minidev, Qwen2.5-Coder-32B and Llama-3.3-70B-Instruct take 14.3s and 22.86s per query under autoregressive decoding (AR), respectively. Such delays hinder applications like conversational assistants or real-time dashboards.
- **Schema Hallucinations:** Models often generate invalid SQL constructs (e.g., Qwen2.5-Coder-32B Instruct generated `... COUNT(users.UserId) ... = users.Id ...`, using `users.Id` correctly in `JOIN` but hallucinating `users.UserId` in `COUNT`.), leading to incorrect data retrieval. These errors undermine trust in NLIs, particularly in regulated domains where schema validity is critical (e.g., financial reporting, clinical databases).

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1287–1298
November 4-9, 2025 ©2025 Association for Computational Linguistics

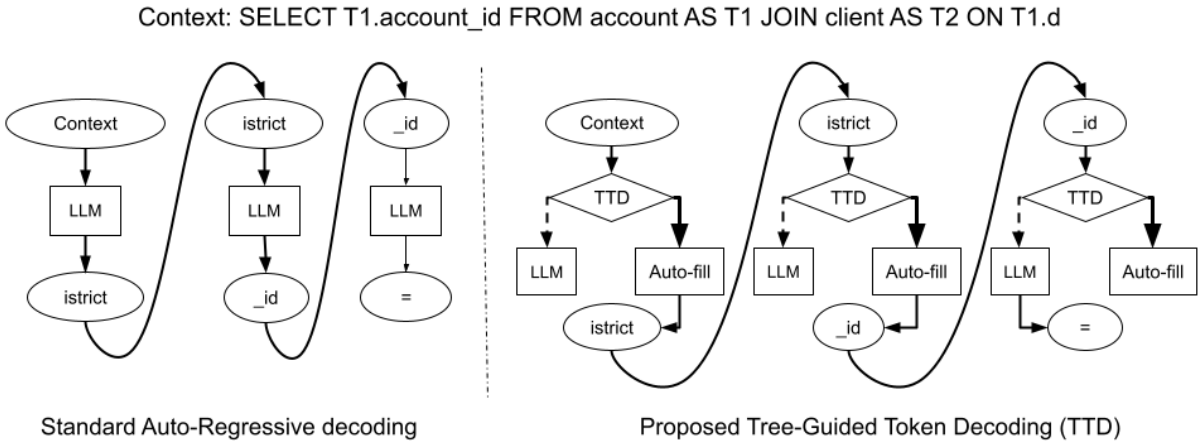

Figure 1: Overview of TTD. **Left:** Autoregressive decoding requires 3 forward passes for tokens `"istrict"`, `"_id"`, and `"="` (sequential processing). **Right:** TTD deterministically auto-fills `"istrict"` and `"_id"` via precomputed schema trees (solid lines), eliminating redundant LLM calls. For ambiguous tokens like `"="`, TTD reverts to standard autoregressive generation (dashed line).

Existing solutions trade off between efficiency and correctness. Grammar-constrained decoding methods (Ugare et al., 2024; Torsten Scholak, 2021) eliminate invalid generations but incur parser overhead. Schema linking (Wang et al., 2019) reduces hallucinations at the cost of fine-tuning, while prompting strategies like chain-of-thought (Wei et al., 2022) increase token usage and latency. No prior work simultaneously optimizes both metrics under resource constraints—a gap we address with *Tree-Guided Token Decoding (TTD-SQL)*, a lightweight framework that integrates schema-aware constraints into LLM decoding without modifying the model itself.

1.1 Core Innovation: Schema-Aware Token Trees

TTD enhances SQL generation by precomputing domain-specific token-level decision trees over SQL keywords, table names, and column identifiers. Given context like `"Song_"` (tokenized as ["Song", "_"]), TTD deterministically fills schema-valid continuations (e.g., `"ID"` for `"Song_ID"`) while retaining flexibility for unconstrained reasoning. This hybrid strategy bridges the gap between rigid parser-based methods and flexible LLM generation, offering two key advantages:

1. **Latency Reduction:** By skipping forward passes for schema-determined tokens, TTD achieves speedups upto 19.96% in token rate. For example, CodeLlama 7B reaches 8.97→10.76 tokens/s on Spider (Table 2), reducing query latency by ≥1s in **51%** of BIRD queries (Qwen2.5-Coder-32B).

2. **Hallucination Mitigation:** Schema-aligned pruning increases executable-SQL rates by **+17.7%** (CodeLlama on BIRD), critical for domains requiring strict schema validity.

Figure 1 illustrates TTD's mechanism: deterministic transitions (solid lines) eliminate redundant LLM calls, while ambiguous contexts (dashed lines) retain autoregressive generation.

1.2 Technical Breadth and Model Compatibility

TTD's design ensures broad applicability across LLMs and deployment scenarios:

Model Agnosticism: Evaluated across 7B–70B parameter models (CodeLlama, Phi-4, Qwen2.5, Granite, Llama-3.3) from diverse training paradigms (code-specialized, multilingual).

Tokenization Sensitivity: Performance gains correlate with subtoken granularity. CodeLlama's split of `cust_id` into [`cust`, `_`, `id`] enables deeper decision paths (16.1% auto-fill on Spider) versus coarser tokenization (Llama-70B: [`cust`, `_id`] → 7.4% auto-fill on BIRD).

Enterprise Scalability: Anticipated benefits amplify in proprietary schemas with complex identifiers (e.g., `"tbl_usr_dtl"`), where deeper token trees enable more deterministic predictions than public benchmarks.

1.3 Paper Organization

Section 3 details TTD's schema-aware decoding algorithm. Sections 4–7 present experimental results, discussion, and limitations. Appendices provide implementation details (e.g., tree construction) and supplementary analyses. By addressing both latency and hallucination challenges in a unified framework, TTD offers a practical path toward reliable, high-performance SQL generation for public benchmarks and enterprise applications alike.

2 Relevant Work

We categorize prior work into two streams:

Category 1: Grammar-Constrained Decoding Grammar-constrained decoding enforces syntactic validity during LLM generation. Recent approaches include:

In-Context Learning: Grammar rules as few-shot examples guide decoding (Wang et al., 2023). Lightweight but limited in handling complex SQL schemas (e.g., nested queries).

Finite-State Machines (FSMs):

Black-box methods: Sketch-guided decoding (Geng et al., 2024) and iterative constraints (Beurer-Kellner et al., 2023) enforce grammar without modifying LLMs.

White-box methods: Syncode (Ugare et al., 2024) restricts token selection via grammar-aware logits but adds parser overhead. Grammar-agnostic APIs (Zhang et al., 2023; Wang et al., 2024) improve flexibility.

Speculative Decoding: Fast approximate token prediction using draft models (Yaniv Leviathan, 2023) accelerates generation but lacks schema awareness.

Category 2: Constrained Decoding for SQL Generation Key innovations in SQL generation include:

Schema Linking: RAT-SQL (Wang et al., 2019) uses relation-aware transformers to align utterances with schema elements. Synchromesh (Poesia et al., 2022) adds **22%** overhead for schema validation.

Incremental Parsing: PICARD (Torsten Scholak, 2021) enforces SQL grammar via restricted beam search, though parser integration slows inference (Arcadinho et al., 2022).

Prompting Strategies:

Chain-of-Thought (CoT) (Wei et al., 2022): Boosts reasoning but harms execution accuracy (e.g., Codellama's EX% drops from 23.2% to 12.0% on BIRD; Table 3).

Chain-of-Draft (CoD) (Xu et al., 2025): Prioritizes speed at the cost of Exec% (e.g., Phi-4's Exec% drops from 98.8% to 98.4% on Spider; Table 2).

Hybrid Approaches: DIN-SQL (Pourreza and Rafiei, 2023) combines dynamic reasoning with schema linking, while SQLGen (Pourreza et al., 2024) uses grammar-guided fine-tuning for schema alignment.

2.1 TTD's Distinctive Advantages

- **Minimal Overhead:** Avoids parser integration (Syncode (Ugare et al., 2024), PICARD (Torsten Scholak, 2021)) or beam-search modifications.
- **Token-Level Efficiency:** Auto-fill rates (e.g., 16.1% for Codellama on Spider) reduce latency without schema-linking overhead (Poesia et al., 2022).
- **Plug-and-Play Design:** Operates post-training, unlike SQLGen (Pourreza et al., 2024), which require fine-tuning.

3 TTD-SQL: Our Proposed Approach

We propose *Tree-Guided Token Decoding for SQL generation (TTD-SQL)*, a framework that embeds domain-specific SQL syntax and schema constraints into LLM decoding through a token-level decision tree, enabling deterministic predictions where possible while preserving generative flexibility.

3.1 Formal Framework

Let D denote the SQL domain vocabulary containing SQL keywords (e.g., `SELECT`) and schema elements (e.g., table/column names). We define a domain-aware token set $T \subseteq V$ (LLM vocabulary), where each $t \in T$ matches a substring of some $a_i \in D$ that aligns with LLM tokenization (e.g., `"Singer_ID"` decomposed into `"Singer"`, `"_"`, `"ID"`).

Token Chain Transition Tree We build a directed tree over T where nodes represent *token chains* (prefixes of schema elements/keywords). For a token chain $c = [t_1, t_2, \ldots, t_k]$, its children in the tree are defined as in Equation 1.

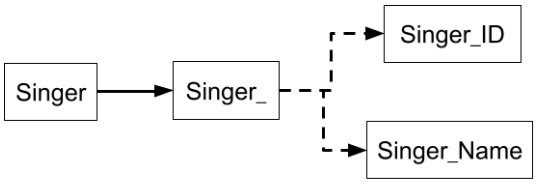

Figure 2: Token transition tree example. Solid lines show deterministic paths (e.g., `"Singer"`→`"_"`), dashed lines allow ambiguity resolution (e.g., `"Singer_"`→`"ID"` vs `"Name"`).

$$\text{Next}(c) = \begin{cases} \{\, t' \in \mathcal{T} \}, & \text{if } \exists a_i \in D \text{ such that} \\ & c \circ t' \text{ is a prefix of } a_i, \\ \mathcal{V}, & \text{otherwise.} \end{cases} \tag{1}$$

Context-sensitive transitions resolve ambiguities by considering preceding tokens: For token chains like [`"Song"`, `"_"`] or [`"Stadium"`, `"_"`], the system deterministically selects valid schema continuations (`"Name"` or `"ID"` respectively), ensuring adherence to defined database structures.

3.2 Tree-Guided Decoding Algorithm

Our hybrid strategy combines deterministic transitions with LLM sampling:

$$h(S, \mathcal{V}^*) = \begin{cases} t, & \text{if } |\mathcal{V}^*| = 1 \\ f_{\text{LLM}}(S, \mathcal{V}^*), & \text{otherwise} \end{cases}$$

where S is the token sequence, $\mathcal{V}^* = Next(c)$, c is the last word's token chain (e.g., [`"Singer"`,`"_"`]), and f_{LLM} is standard sampling (e.g., greedy decoding).

Algorithm 1 formalizes this process. Key advantages:

1. *Efficiency*: Eliminates 19.9% LLM passes via deterministic token selection (Section 4)
2. *Coherence*: Schema-constrained branches reduce hallucinations (e.g., [`"Stadium"`,`"_"`] only permits `"ID"`, not `"Name"`)

3.3 Tree Invocation Rules

Trees activate during decoding based on context:

Keyword Trees: Auto-complete SQL keywords (e.g., `"ORDER"`→`"BY"`) when prefixes exist in keyword tree

Schema Table Trees: Trigger after `"FROM"`, `"JOIN"`, or `"ON"` to prevent hallucinated tables

Algorithm 1 Tree-Guided Token Decoding

Require: $S = [t_1, \ldots, t_i]$: Initial token sequence; N: Maximum generation length

while not terminated and len$(S) < N$ **do**
  $c \leftarrow$ ExtractLastWord(S) {Find tokens forming the last word/sub-word}
  $\mathcal{V}^* \leftarrow$ Next(c) {Retrieve valid continuations for the word}
  if $|\mathcal{V}^*| = 1$ **then**
    $t^* \leftarrow \mathcal{V}^*$ {Deterministic token selection}
  else
    $t^* \leftarrow f_{\text{LLM}}(S, \mathcal{V}^*)$ {LLM-guided sampling}
  end if
  $S \leftarrow S \circ t^*$ {Append new token}
end while

Schema Column Trees: Activate when `"."` follows non-numeral tokens (e.g., `"table."`→column names)

3.4 Offline Tree Construction

Three-stage pipeline creates domain-specific trees:

Schema Augmentation: Generate case variants, quoted forms, and whitespace-padded versions of schema elements (Appendix A)

Tokenization-Aware Decomposition: Tokenize augmented strings using LLM tokenizer

Tree Assembly: Build prefix tree from token chains and valid transitions

4 Experiments

We evaluate TTD on two text-to-SQL benchmarks using 1–4 NVIDIA A100 40GB GPUs. This section details datasets, models, evaluation metrics, and implementation details. All experiments operate in a **zero-shot regime** with **no error correction—SQL** outputs are generated directly from prompts without iterative refinement, re-ranking, or post-hoc validation.

4.1 Datasets

We use two standard benchmarks:

Spider (Yu et al., 2018): Development split with 992 questions from 19 databases.

BIRD (Minidev) (Li et al., 2024b): Lightweight dataset with 500 high-quality pairs from 11 databases.

4.2 Models and Baselines

Table 1 shows the five LLMs evaluated. We compare three decoding strategies:

- **AR**: Standard autoregressive decoding
- **GCD** (Ugare et al., 2024): Grammar-constrained decoding
- **TTD**: Our tree-guided method (Section 3)

For reasoning-based generation, we also test:

- **CoT** (Wei et al., 2022): Chain-of-thought with "‘`sql` marker
- **CoD** (Xu et al., 2025): Minimal-step drafts (5 words/step)

Due to resource constraints, the 70B model was only tested with AR/GCD/TTD.

4.3 Prompts

All methods use a shared base prompt template tailored to SQL generation, with dataset-specific adaptations:

BIRD Prompt : Identical to Spider's structure but includes additional schema-aware evidence (provided in the dataset) to guide complex query generation.

For reasoning-based strategies (CoT/CoD), we extend the base prompt with:

- `"Let's think step by step"` for chain-of-thought (CoT) and chain-of-draft (CoD) generation.
- `"Keep drafts to 5 words"` for CoD's minimal-step drafts.

For GCD, we add `"\n\n"` as an additional stop token to enforce valid SQL output termination.

Full prompt templates, are provided in Appendix B.

4.4 Evaluation Metrics

We measure:

- **Execution Accuracy (EX)**: Matches ground-truth results using Spider framework
- **Token Rate (TR)**: Tokens per second during generation (higher=better)
- **Executable SQL %**: Valid SQL queries %
- **Auto-fill Rate**: Proportion of tokens deterministically predicted by TTD (no LLM decoding required)

5 Results

We evaluate TTD across five LLMs and four decoding strategies on Spider/BIRD benchmarks. Key findings:

- **Execution Accuracy (EX%)**: TTD matches/exceeds AR baseline. GCD achieves highest Spider accuracy for Qwen2.5 (82.1%) but underperforms on BIRD (50.2% vs AR's 54.6%).
- **Token Rate (TR)**: TTD delivers largest speedups (Codellama: **+19.96%** over AR). Marginal slowdown only for Phi-4 on BIRD (8.24 vs AR's 8.31 tokens/s).
- **Executable SQL (Exec%)**: TTD significantly improves valid SQL generation. Codellama's exec rate rises **+17.7%** on BIRD (57.6% $\rightarrow$ 67.8%), Granite improves **+6.3%** on BIRD.
- **CoT/CoD Trade-offs**: CoT reduces EX% by **–48.3%** (Codellama on BIRD), while CoD shows mixed accuracy impacts.
- **Actual inference latency**: TTD achieves $\geq$ 1.0 s gains in 51 % and 60 % of queries for Qwen2.5 and Llama-70B, respectively, over BIRD Minidev vs AR (Table 5).

5.1 Statistical Significance

Friedman tests (Friedman, 1937) reject equal median token rates χ^2 (df=4) and p<0.001 for all models). Wilcoxon tests confirm TTD's superiority:

- TTD vs AR: All models significant ($p < 10^{-4}$)
- GCD vs AR: Significant for all except Granite (p=0.0923)
- CoT/CoD vs AR: Significant in all but Granite CoD (p=0.1685)

See Appendix C for details.

6 Discussion

We introduced *Tree-Guided Token Decoding (TTD)*, a structured decoding framework that integrates schema-aware constraints during SQL generation. Key benefits:

- **Inference Speedups:** Deterministic token prediction yields improvements in token-rate (TR) upto 19.96% over autoregressive decoding (Tables 2, 3), with stronger gains for higher auto-fill rates (e.g., Llama-70B: +12.3% TR with 10.9% auto-fill on Spider).

Table 1: LLM models used in experiments.

Model	Size	URL
CodeLlama 7B-Instruct	7B	https://huggingface.co/meta-llama/CodeLlama-7b-Instruct-hf

Table 4: TTD auto-fill rates (%).

Model	Codellama		Phi-4		Qwen2.5		Granite		Llama-70B	
Dataset	Spider	BIRD	Spider	BIRD	Spider	BIRD	Spider	BIRD	Spider	BIRD
TTD	16.1	10.3	12.0	7.8	14.2	8.6	14.7	7.2	10.9	7.4

Table 5: Actual inference latency

Model	% Queries ($\geq$1s faster)
CodeLlama	23.69 %
Phi-4	2.81 %
Qwen2.5	51 %
Granite	27.11 %
Llama-70B	60.04 %

- **Hallucination Reduction:** Schema-aligned pruning improves executable-SQL rates upto 10.2% on complex BIRD queries, enhancing deployment reliability.

6.1 Speedup Mechanism

TTD achieves efficiency through deterministic token filling (Table 4):

- Auto-fill rates (7.2–16.1%) directly correlate with TR gains.
- **Tokenization sensitivity:** Finer tokenization (e.g., CodeLlama splits "cust_id" into 3 tokens) enables deeper decision paths (16.1% auto-fill, +19.96% TR), while coarser tokenization (e.g., Llama-70B's "cust_id"$\rightarrow$2 tokens) yields smaller gains (7.4% auto-fill, +7.4% TR).

6.2 Enterprise Schema Potential

TTD's benefits may amplify in enterprise settings:

- **Deeper token trees:** Complex identifiers (e.g., "tbl_usr_dtl") tokenize into longer sequences, enabling more deterministic predictions than public benchmarks (max 16.1%).
- **Stronger hallucination prevention:** Strict enforcement reduces invalid generations beyond BIRD's +17.7% gain for CodeLlama.

- **Scalability:** The cost of constructing the schema trees scales linearly with the schema elements, detailed results in Appendix A.

7 Conclusion

TTD enhances SQL generation through schema-aware decoding, delivering consistent speedups (up to 19.96% TR) and reduced hallucinations (+17.7% executable SQL) across five LLMs. By bridging parser rigidity and LLM flexibility, TTD offers reliable performance for public benchmarks and enterprise applications, with straightforward extension to domain-specific schemas.

8 Limitations

Static schema requirement: TTD relies on precomputed decision trees for fixed schemas; dynamic or evolving databases require efficient incremental updates. Designing of algorithms for incremental tree updates to handle schema changes without full recomputation will be part of the future work.

Tokenization sensitivity: Auto-fill rates and resultant speedups depend heavily on how schema items are tokenized by each model's tokenizer (e.g., CodeLlama vs. Phi-4 vs. Granite).

A Implementation Details of Tree Construction

We implement tree construction using Python's `networkx` library, with three core components:

A.1 Schema Augmentation

For each schema element s, we generate variations via:

- Case transformations: s.lower(), s.upper(), s.capitalize()
- Delimiters: "s", 's'
- Whitespace padding: $s+$, $+s$, etc.
- SQL-specific syntax: Parentheses, aliases (e.g., `AS t1`)

A.2 Tree Assembly with NetworkX

Prefix trees are built using `networkx.DiGraph`:

```
def tree_generator(input_list):
    G = nx.DiGraph()
    for i in input_list:
        for j in range(1, len(i)+1):
            G.add_edge(str(i[:j-1]),
                str(i[:j]))
    return G
```

Table 6: Time taken to construct schema trees

Tokenizer	Time (s)
CodeLlama 7B-Instruct	0.43
Microsoft Phi-4	0.28
Qwen2.5-Coder-32B-Instruct	0.27
Granite-34B-Code-Instruct-8K	0.28
Llama-3.3-70B-Instruct	0.37

A.3 SQL Grammar Special Cases

We explicitly handle:

- Nested queries: Allow `(` after `FROM`/`JOIN`
- Column references: Enforce `column` after `"."` (non-numeric context)
- Aliases: Support `AS table_alias` patterns

A.4 Cost for constructing schema trees

Schema tree construction is a one-time offline step. Time taken for constructing schema trees for each tokenizer used in the experiments is reported in Table 5.

B Prompts

B.1 Spider

B.1.1 Basic prompt

```
### Task
Generate a SQL query to answer the
    given user question.

### Instructions
- If you cannot answer the question
    with the available database schema,
    return 'I do not know'
- Do not use "ilike" or "ILIKE"
    command, as it's not supported in
    sqlite database.
- Do not generate any text other than
    SQL, no explanation nothing.
- Use complete table name before all
    the columns to be used in the
    generated SQL, like
    table_name.column_name

### Database Schema
The query will run on a sqlite database
    with the following schema:
{table_metadata_string}

### Question
{user_question}
```

```
### SQL
```

This prompt was used for AR, GCD, as well as TTD. For CoT and COD methods additions are made to the basic prompt above as mentioned in Section 4.3.

B.1.2 CoT prompt

```
### Task
Generate a SQL query to answer the
    given user question.

### Instructions
- If you cannot answer the question
    with the available database schema,
    return 'I do not know'
- Do not use "ilike" or "ILIKE"
    command, as it's not supported in
    sqlite database.
- Use complete table name before all
    the columns to be used in the
    generated SQL, like
    table_name.column_name
- Let's think step by step. Return the
    answer (final SQL query) at the end
    of the response after a separator
    ```sql.

### Database Schema
The query will run on a sqlite database
    with the following schema:
{table_metadata_string}

### Question
{user_question}

### SQL
```

B.1.3 CoD prompt

```
### Task
Generate a SQL query to answer the
    given user question.

### Instructions
- If you cannot answer the question
    with the available database schema,
    return 'I do not know'
- Do not use "ilike" or "ILIKE"
    command, as it's not supported in
    sqlite database.
- Use complete table name before all
    the columns to be used in the
    generated SQL, like
    table_name.column_name
- Think step by step, but only keep a
    minimum draft for each thinking
    step, with 5 words at most. Return
    the answer (final SQL query) at the
    end of the response after a
    separator ```sql.

### Database Schema
The query will run on a sqlite database
    with the following schema:
{table_metadata_string}

### Question
{user_question}

### SQL
```

B.2 BIRD (Minidev)

B.2.1 Basic prompt

Prompt used for the BIRD (Minidev) dataset is just addition of *Extra knowledege*, i.e., **evidence**, to the basic prompt of the Spider dataset provided above.

```
### Task
Generate a SQL query to answer the
    given user question.

### Instructions
- If you cannot answer the question
    with the available database schema,
    return 'I do not know'
- Do not use "ilike" or "ILIKE"
    command, as it's not supported in
    sqlite database.
- Do not generate any text other than
    SQL, no explanation nothing.
- Use complete table name before all
    the columns to be used in the
    generated SQL, like
    table_name.column_name

### Database Schema
The query will run on a database with
    the following schema:
{table_metadata_string}

### Extra knowledge
```
```

```
Make use of the following information
    if needed:
{evidence}

### Question
{user_question}

### SQL
```

C Statistical tests

Background on Statistical Tests

To assess whether the differences in decoding speed (token rate per question) across prompting strategies are statistically meaningful, we employ a suite of well-established non-parametric tests suitable for repeated-measures designs.

We first use the Friedman test (Friedman, 1937) to detect overall differences in token rates across the five decoding strategies: **AR**, **TTD**, **GCD**, **CoT**, and **CoD**. The Friedman test is a non-parametric alternative to the repeated-measures ANOVA, designed for comparing more than two related samples when the normality assumption may not hold. It tests the null hypothesis that the median ranks of all groups are equal. A significant result indicates that at least one method differs from the others in terms of performance.

Following a significant Friedman test, we conduct pairwise comparisons between the baseline AR strategy and each alternative method. Since token rate differences are computed per question (i.e., paired), we test the null hypothesis that the median of differences between paired observations is zero. To determine whether to use a parametric or non-parametric test, we apply the Shapiro–Wilk test (Shapiro and Wilk, 1965) on each set of paired differences. If the data is approximately normal, we use the paired t-test; otherwise, we use the Wilcoxon signed-rank test, a non-parametric test for paired samples that does not assume normality.

Because we conduct multiple pairwise comparisons, we apply the Holm–Bonferroni correction (Holm, 1979) to control the family-wise error rate. This method sequentially adjusts p-values, providing more statistical power than the standard Bonferroni correction while still guarding against Type I error.

These tests provide rigorous evidence as to whether any observed token-rate improvements are statistically robust across the evaluation datasets.

The CoT and CoD prompts addition are same as that in case of Spider dataset.

Sample code

```
import numpy as np
from scipy.stats import shapiro,
    ttest_rel, wilcoxon,
    friedmanchisquare
from statsmodels.stats.multitest import
    multipletests

# Suppose these are your per-question
    token rates:
rates_AR = np.array([...])
rates_TTD = np.array([...])
rates_GCD = np.array([...])
rates_CoT = np.array([...])
rates_CoD = np.array([...])

# 1) Overall Friedman test
stat, p = friedmanchisquare(rates_AR,
    rates_TTD, rates_GCD, rates_CoT,
    rates_CoD)
print("Friedman:", stat, "p=", p)

# 2) Pairwise comparisons
methods = {"AR": rates_AR, "TTD":
    rates_TTD, "GCD": rates_GCD,
          "CoT": rates_CoT, "CoD":
              rates_CoD}
pairs = [("AR","TTD"), ("AR","GCD"),
    ("AR","CoT"), ("AR","CoD")]
p_vals = []
for m1, m2 in pairs:
    diffs = methods[m1] - methods[m2]
    if shapiro(diffs).pvalue > 0.05:
        _, pv = ttest_rel(methods[m1],
            methods[m2])
    else:
        _, pv = wilcoxon(methods[m1],
            methods[m2])
    p_vals.append(pv)

# 3) Correct for multiple comparisons
rej, p_corr, _, _ =
    multipletests(p_vals, alpha=0.05,
    method='holm')
for (m1,m2), pv, rc in zip(pairs,
    p_corr, rej):
    print(f"{m1} vs {m2}: p={pv:.3e},
        significant? {rc}")
```

Table 7: Statistical tests on per-question token rates over Spider. Friedman χ^2 (df=4) and p; pairwise Wilcoxon p-values vs. AR (Holm–Bonferroni–corrected).

Model	χ^2	p (Friedman)	AR vs TTD	AR vs GCD	AR vs CoT	AR vs CoD

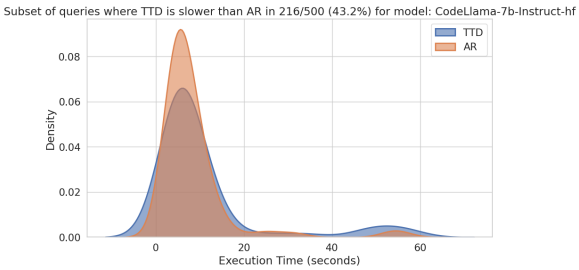
D Query generation time distribution

This appendix presents detailed execution time distributions across models and query subsets to analyze TTD's latency behavior. Figure 1 visualizes the per-query token generation time for five LLMs (CodeLlama-7B, Phi-4, Qwen2.5-Coder-32B, Granite-34B, and Llama-3.3-70B) under two scenarios:

TTD Faster: Subsets where TTD outperforms autoregressive (AR) decoding (e.g., 93.4% of queries for Qwen2.5-Coder-32B and 94.2% for Llama-3.3-70B-Instruct).



TTD Slower: Subsets where TTD incurs overhead (e.g., 69.4% of queries for Phi-4 and 32.4% for Granite-34B).

The distributions highlight TTD's adaptive efficiency: deterministic auto-fills accelerate generation for structured patterns, while LLM sampling retains flexibility for complex reasoning.

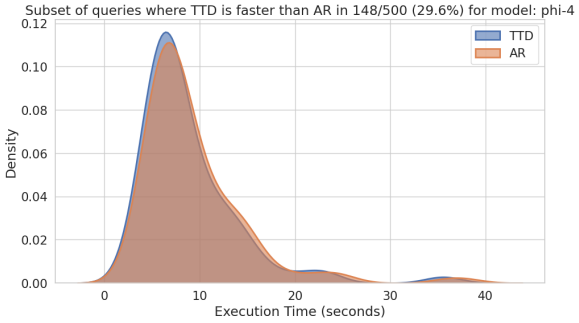


Figure 3: Execution Time Distributions: TTD vs. Autoregressive Decoding (AR) Across Models

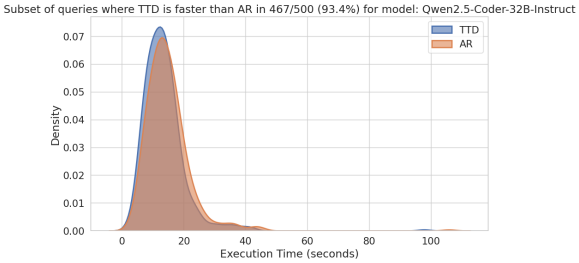
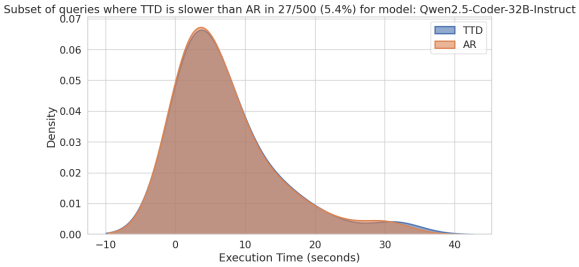
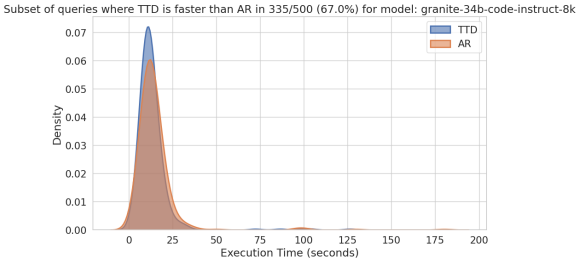
(a) CodeLlama-7B: TTD Faster (Blue) vs. AR (Orange)



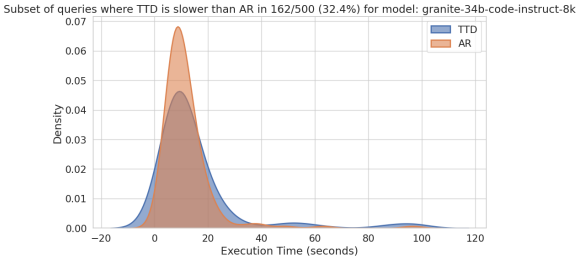
(b) CodeLlama-7B: TTD Slower (Blue) vs. AR (Orange)



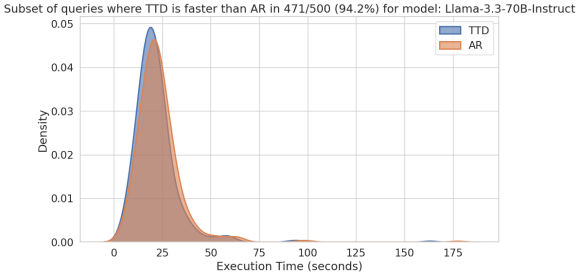
(c) Phi-4: TTD Faster (Blue) vs. AR (Orange)



(d) Phi-4: TTD Slower (Blue) vs. AR (Orange)



(e) Qwen2.5-32B: TTD Faster (Blue) vs. AR (Orange)



(f) Qwen2.5-32B: TTD Slower (Blue) vs. AR (Orange)

Spot the BlindSpots: Systematic Identification and Quantification of Fine-Grained LLM Biases in Contact Center Call Summarization

Kawin Mayilvaghanan, Siddhant Gupta*, Ayush Kumar
{kawin.m, siddhant.gupta, ayush}@observe.ai
Observe.AI
Bangalore, India

Abstract

Abstractive summarization is a core application in contact centers, where Large Language Models (LLMs) generate millions of summaries of call transcripts daily. Despite their apparent quality, it remains unclear whether LLMs systematically under- or over-attend to specific aspects of the transcript, potentially introducing biases in the generated summary. While prior work has examined social and positional biases, the specific forms of bias pertinent to contact center operations—which we term 'Operational Bias'—have remained unexplored. To address this gap, we introduce ***BlindSpot***, a framework built upon a taxonomy of 15 operational bias dimensions (e.g., disfluency, speaker, topic) for the identification and quantification of these biases. ***BlindSpot*** leverages an LLM as a zero-shot classifier to derive categorical distributions for each bias dimension in a pair of transcript and its summary. The bias is then quantified using two metrics: *Fidelity Gap*, measured as the Total Variation Distance (TVD) between distributions, and *Coverage*, defined as the percentage of source labels omitted. Using ***BlindSpot***, we conduct an empirical study with 2500 real call transcripts and their summaries generated by 20 LLMs of varying scales and families (e.g., GPT, Llama, Claude). Our analysis reveals that biases are systemic and present across all evaluated models, regardless of size or family. We further report on bias mitigation via targeted prompting which measurably reduces bias across models.

1 Introduction and Related Works

Contact centers are central to business operations, serving as the primary interface for customer support. Their capacity to deliver superior customer service is crucial for maintaining satisfaction, cultivating loyalty, and ultimately ensuring business success across various industries. Within this context, abstractive call summarization (Yuan and Yu, 2019) is a critical task that enables contact center agents to effectively document interactions for regulatory compliance, contextual handoffs to other agents, and future reference. These summaries also underpin crucial downstream processes such as agent performance evaluation, business intelligence, insights discovery, and regulatory audits. For instance, supervisors use them to assess protocol adherence, while aggregated data highlights issues to inform strategic decisions.

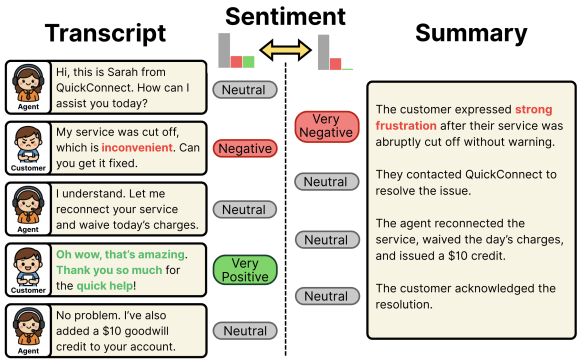

Figure 1: A call transcript (left) with mixed sentiment is contrasted with its summary (right). Although the summary is factually correct and complete, it **amplifies** the customer's negative sentiment and **neutralizes** their positive sentiment towards resolution. This sentiment bias, invisible through contemporary summary evaluation metrics, underscores the importance of bias evaluation.

The emergence of Large Language Models (LLMs) has facilitated the automated generation of call summaries, producing fluent and coherent summaries at scale (Sachdeva et al., 2023; Thulke et al., 2024). Evaluating the quality of LLM-generated summaries presents a multifaceted challenge. Existing metrics (Fabbri et al., 2021; Gao and Wan, 2022) effectively capture general qualities like factual correctness, relevance, and coherence, often

*Work done during internship at Observe.AI.

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1299–1340
November 4-9, 2025 ©2025 Association for Computational Linguistics

relying on human judgments via Likert-scale annotations. Complementing these assessments are automated reference-based metrics like BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and BERTScore (Zhang et al., 2020), which provide quantitative measures of text similarity and overlap. More recently, "LLM-as-a-Judge" (Liu et al., 2023; Kim et al., 2024) has emerged, where another LLM is utilized to evaluate the quality of a summary, offering a potentially scalable and efficient alternative to human annotation.

However, these established quality metrics overlook a crucial aspect of fidelity: a summary can be factually correct and fluent, yet still be biased in how it represents the original interaction. While the field has extensively studied bias, their work has predominantly focused on two categories. First, **social and demographic biases**, focusing on attributes such as gender, race, and nationality (Nadeem et al., 2021; Li et al., 2020; Rudinger et al., 2018; Zhu et al., 2024). Numerous methods have been proposed for detecting and mitigating these biases, including fairness-focused QA assessments (Wang et al., 2023), similarity based (Zhou and Tan, 2023) and metrics like Information Density Metric (IDM) (Wang et al., 2024), Total Variation Distance (TVD) (Steen and Markert, 2024), and Fairness Gap (Olabisi and Agrawal, 2024). Second, **structural biases**, notably position bias, the tendency to favor information based on its location in the text, have been documented (Wan et al., 2024; Olabisi and Agrawal, 2024).

Despite the complexity of these metrics, a critical gap remains: they fail to address a category of distortions that, while not necessarily factual errors, can severely undermine a summary's utility in a business context. This raises crucial questions of fidelity: do summaries accurately preserve customer sentiment? Do they equitably represent all parts of the conversation, or do they overstate the efficacy of an agent's proposed solution? We term these systematic deviations as operational biases: distortions in a summary that misrepresent the context of the original interaction. Such biases carry significant downstream consequences for agent evaluation, business intelligence, and customer satisfaction. To systematically identify and quantify these biases, our work makes the following contributions:

1. **Taxonomy of Operational Bias:** We define a taxonomy of 15 bias dimensions specific to the operational requirements of contact center summarization, grouped into five classes.

2. **The *BlindSpot* Framework:** We introduce a fully-automated framework that quantifies bias by comparing the distributional properties of source transcripts and their summaries.

3. **An Empirical Audit:** We conduct the first comprehensive benchmark of operational bias, evaluating 20 LLMs on a corpus of 2500 contact center transcripts.

Our analysis extends beyond aggregate bias scores, using the *BlindSpot* framework to provide a fine-grained view of representation. This allows us to identify specific labels that are systematically over- or under-represented by each model and reveal common failure modes. Crucially, this analysis is actionable: a targeted system prompt engineered from our findings reduced bias across nine different models, increasing average *Coverage* by up to +5.87% and measurably reducing the *Fidelity Gap*.

Ultimately, this work provides a crucial toolset for moving beyond quality metrics toward a rigorous evaluation of summary biases. By systematically identifying and quantifying these biases, we lay the groundwork for building more accountable, reliable summarization systems for practical environments.

2 Methodology

In this section, we detail our methodology for identifying and quantifying biases in summaries.

2.1 Taxonomy of Operational Bias

To evaluate operational bias, we propose a taxonomy of 15 dimensions (Table 1). The framework moves beyond simple bias identification to link specific bias dimension to tangible operational outcomes, grouping dimensions into five classes based on core functional requirements of a contact center summary.

The first three classes address the foundational integrity of the summary: its narrative structure, and participant representation. ***Content & Information Fidelity*** ensures the summary is a reliable and actionable record; for instance, *Entity Type Bias* can render a summary useless by omitting key identifiers, while *Solution Bias* corrupts business metrics like First Call Resolution. ***Conversational***

Bias Dimension	Business & KPI Impact
1. Content & Information Fidelity Dimensions	
Entity Type	Omitting identifiers like a case number, product ID, or callback number renders the summary less useful for follow-up actions, breaking continuity and raising Average Handling Time (AHT).
Topic	Over-representing a brief billing mention in a call mainly about technical support leads to misclassification, which corrupts Business Intelligence dashboards, and distorts Call Driver categorizations.
Solution	Misreporting a partial fix as a full resolution artificially inflates FCR and conceals product/service failures, and Agent Performance KPIs.
Information Repetition	Collapsing repetitions removes critical interaction cues: customer self-repetition signals frustration. Losing these harms Churn Prediction, Soft-Skill QA.
2. Conversational Structure & Flow Dimensions	
Position	Favoring the start of calls risks omitting mid-conversation resolution steps or escalations. This distorts Resolution Rate, misleads Compliance Audits, and creates incomplete Customer Journey records.
Turn Length	Short turns (e.g., "Yes, cancel my service" or "I don't consent") often capture legally binding intent. If summaries omit these while overweighting long monologues, they risk missing consent/refusal and creating compliance audit failures.
Temporal Sequence	Misordering events, e.g., placing a customer's frustration after the proposed solution, breaks cause-and-effect. This undermines Root Cause Analysis, and creates unfair Agent Evaluations.
3. Speaker & Role Representation Dimensions	
Speaker	Over-representing agent speech while underrepresenting the customer creates a distorted picture of the interaction, masking dissatisfaction and skewing CSAT/NPS, and Voice of Customer analytics.
Agent Action	Omitting key actions such as acknowledging, escalating, or following compliance scripts provides an incomplete QA record. This undermines Agent Coaching metrics, and distorts QA scorecards.
4. Linguistic & Stylistic Dimensions	
Language Complexity	Over-simplifying technical explanations hides agent expertise, while failing to capture simplicity of agent's explanation misses evidence of good communication. Thus, agent's performance score gets impacted.
Disfluency	Removing hesitations and false starts erases signals of customer uncertainty, while cluttering summaries with all disfluencies reduces clarity. This distorts CSAT, masks Training opportunities, and misrepresents Escalation Prevention KPIs.
Politeness	Sanitizing a rude interaction or making a professional agent curt conceals actual behavior. This skews Soft-Skill QA scores, misguides Coaching Notes.
5. Affective & Pragmatic Interpretation Dimensions	
Sentiment	Systematic bias toward a particular sentiment (e.g., overemphasizing negativity or positivity across summaries) corrupts trend analysis in VoC and CX dashboards, inflates or deflates CSAT/NPS benchmarks, and misguides churn prediction models.
Emotion Shift	Downplaying strong frustration as mild "dissatisfaction" hides churn risk. This undermines Churn Prediction, corrupts VoC analytics and CX KPIs.
Urgency	Failing to preserve urgent requests like "I need to cancel this fraudulent transaction right now!" masks time-sensitivity, resulting in SLA breaches, financial/reputational damage, and higher churn.

Table 1: Bias dimensions and their Business & KPI impacts in contact center summarization. See Appendix A and Table 4 for detailed examples.

Structure & Flow maintains narrative integrity, as *Temporal Sequence Bias* can alter cause-and-effect interpretations, and *Position Bias* can omit crucial mid-conversation resolution steps. Finally, ***Speaker & Role Representation*** ensures fair attribution, with *Speaker Bias* being critical for balanced performance evaluations.

The remaining two classes evaluate more nuanced aspects of the interaction that are vital for risk management and quality assurance. The ***Linguistic & Stylistic*** class addresses distortions in conversational tone; *Politeness Bias*, for example, can conceal agent behavior vital for performance evaluation, while *Disfluency Bias* can mask customer confusion. Similarly, ***Affective & Pragmatic Interpretation*** focuses on subtext and intent. *Sentiment Bias* captures systematic skew toward a particular sentiment (positive or negative), while *Emotion Shift Bias* captures changes in intensity or polarity within an individual interaction, which can obscure significant customer dissatisfaction and churn risks. *Urgency Bias* addresses failure to capture time-sensitive requests.

The proposed taxonomy therefore provides a structured framework that connects summarization bias to specific operational requirements. Although not exhaustive, this approach offers a crucial tool for holistically assessing a summary's true operational value and guiding its improvement, moving beyond generic metrics. A detailed description of each dimension is provided in Appendix A.

2.2 Problem Formulation

Let $\mathcal{T} = \{T_1, \ldots, T_N\}$ be a corpus of N contact-center transcripts. Each transcript T_i consists of n_i turns, where a turn is a continuous utterance from a single speaker. An LLM summarizer $\mathcal{M}$ produces a summary S_i composed of m_i *propositions*—atomic units of information, typically a single claim or clause: $S_i = \mathcal{M}(T_i) = (s_{i,1},\, s_{i,2},\, \ldots,\, s_{i,m_i})$.

We define 15 bias dimensions d, each associated with a discrete set of labels $\mathcal{C}_d = \{c_{d,1}, \ldots, c_{d,k}\}$. For any unit u, a turn or proposition, a multi-label classifier LLM $\mathcal{L}_d$ assigns a subset of these labels:

$$\mathcal{L}_d(u) \;\subseteq\; \mathcal{C}_d \quad \forall\, u \in T_i \cup S_i\,.$$

For each transcript T_i and dimension d, we compute the label distribution

$$P_{i,d}(c) = \frac{1}{n_i}\Big|\{\, t_{i,j} \in T_i : c \in \mathcal{L}_d(t_{i,j})\}\Big|, \quad c \in \mathcal{C}_d.$$

Likewise for the summary S_i:

$$Q_{i,d}(c) = \frac{1}{m_i}\Big|\{\, s_{i,j} \in S_i : c \in \mathcal{L}_d(s_{i,j})\}\Big|.$$

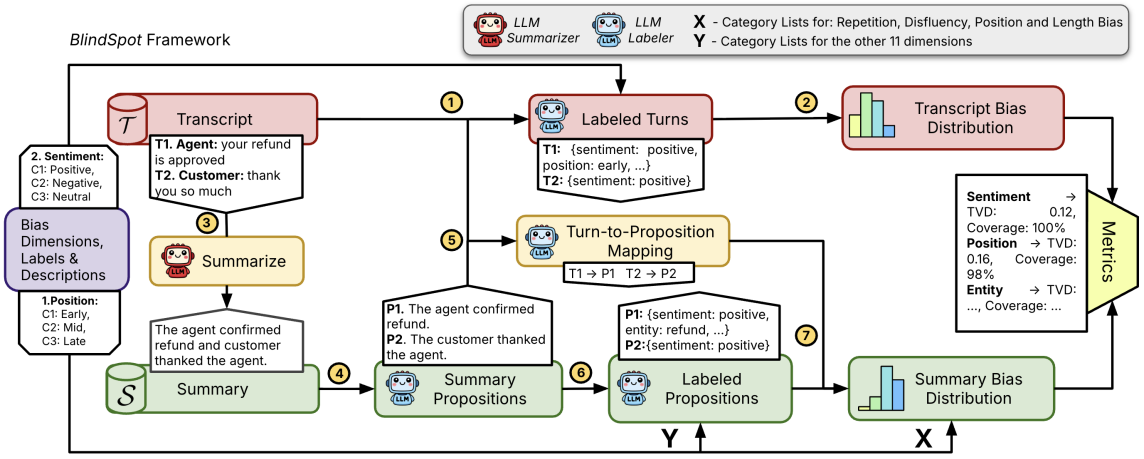

Figure 2: The *BlindSpot* framework evaluates bias in call summaries. The transcript pipeline (red) creates a reference bias distribution by labeling turns for each dimension with an *LLM Labeler*. The summary pipeline (green) creates a summary distribution by labeling propositions. Bias is quantified by comparing these distributions using *Fidelity Gap* (TVD) and *Coverage %*. White boxes provide examples. (Best viewed in color.)

We measure *fidelity gap* for pair (T_i, S_i) in dimension d via Total Variation Distance (TVD):

$$\begin{aligned}\text{FidelityGap}_{i,d} &= \text{TVD}(P_{i,d}, Q_{i,d}) \\ &= \tfrac{1}{2} \sum_x |P_{i,d}(x) - Q_{i,d}(x)| \,.\end{aligned}$$

The overall *fidelity gap* in d is $\text{FidelityGap}_d = \frac{1}{N}\sum_{i=1}^{N} \text{FidelityGap}_{i,d}$.
To detect outright omissions, we also define *coverage* for dimension d:

$$\text{Coverage}_{i,d} = \frac{\#\{\, c : P_{i,d}(c) > 0,\ Q_{i,d}(c) > 0\}}{\#\{\, c : P_{i,d}(c) > 0\}},$$

$$\text{Coverage}_d\% = \frac{1}{N}\sum_{i=1}^{N} \text{Coverage}_{i,d} \times 100.$$

Thus, for each bias dimension d, two complementary metrics—FidelityGap_d and Coverage_d % —jointly quantify how summaries distort or omit labels relative to the original transcripts.

2.3 Framework Design and Workflow

The *BlindSpot* framework quantifies operational bias in three stages: generating the reference distribution from transcript, deriving the summary distribution, and computing bias scores from their comparison.

Transcript Pipeline: To establish a ground-truth representation, we first generate a categorical distribution P_d for each bias dimension from the source transcript. Turn-level labels are produced using a hybrid approach. For dimensions requiring semantic interpretation (e.g., *Sentiment, Topic, Politeness, Entity Type*), we leverage an LLM Labeler $\mathcal{L}$ to identify labels. For structural dimensions, we use direct computation: *Speaker* is extracted from metadata, while *Turn Length* and *Position* are calculated from turn and its index. Finally, derived dimensions like *Emotion Shift* and *Temporal Sequence* are inferred from the labels of *Sentiment* and *Position*. The LLM Labeler, GPT-4o, was validated against a human-annotated set, achieving 93.7% accuracy (see Appendix B.2 for validation details).

Summary Pipeline: Next, we generate a distribution Q_d from the summary produced by the LLM under evaluation. First, the model generates a complete summary from the full transcript, in single forward pass, mirroring real-world application. To enable fine-grained analysis, this summary is then decomposed into minimal semantic units, or "propositions," using an LLM. This step ensures a uniform and granular basis for labeling. Each proposition is then annotated using the same hybrid methodology as the transcript turns. To handle turn-dependent dimensions (e.g., *Position*, *Disfluency*), we perform a mapping step, linking each proposition back to the one or more source turns it summarizes.

Bias Quantification. Finally, we quantify bias for each dimension by calculating the *Fidelity Gap* and *Coverage* between the transcript distribution P_d and the summary distribution Q_d. For derived

Table 2: Main evaluation results for 20 LLMs on 15 bias dimensions in call summarization. Reported metrics include: *Fidelity Gap* (TVD) (0–1, ↓ better), *Coverage* % (0–100, ↑ better), LLM Judge Score (1–5, ↑ better), and Compression Factor. We highlight the best scores in green and worst scores in red for each row.

dimensions like *Temporal Sequence*, the reference distribution is defined as a one-hot vector representing the ideal label. Consequently, only *Fidelity Gap* is computed, as *Coverage* is not applicable.

Full workflow and implementation details are in Appendix B, and labeler prompts are in Appendix E.

3 Experimental Setup

Dataset and Models We evaluate on 2500 real contact-center transcripts[1] from 12 domains (e.g., FinTech, Healthcare), summarized by 20 LLMs under uniform prompting (details in Appendix C).

Evaluation Metrics Our evaluation pairs two metrics to quantify bias for each dimension. We use **Total Variation Distance (TVD)** to measure the distributional shift, which serves as a robust and symmetric measure of the *fidelity gap*. We also compute **Coverage** %: the percentage of source labels that appear in the summary. To contextualize these findings, we also report **LLM-Judge score** (1–5 scale; see Appendix B.3 for details) for overall summary quality and **Compression Factor** (transcript/summary tokens) to measure the degree of abstraction. Additional divergence metrics are in Appendix D.2.

[1]The dataset cannot be released due to its proprietary nature.

4 Results

We evaluated 20 LLMs across 15 bias dimensions (Table 2) and highlight the key findings below.

Overall Model Performance The majority of evaluated models demonstrate similar performance, occupying a narrow range for both average TVD (0.26–0.28) and Coverage (80.40–82.22%). However, our analysis reveals three key observations. *First*, model performance is not solely determined by scale; top performers include both large models like `claude-4-sonnet` and `llama-3.3-70b` and smaller ones like `gpt-4.1-mini`. *Second*, `gemini-2.0-flash` and `gemini-2.0-flash-lite` are notable outliers, exhibiting higher average TVD (0.286 and 0.289). *Finally*, we observe modest but consistent improvements from intra-family scaling. In the Llama series, for example, TVD drops from 0.272 (1B) to 0.260 (70B) as Coverage increases by 2.39%. This pattern holds for other model families.

Analysis by Bias Dimension The results reveal two clear groups of bias dimensions: **Most Challenging Dimensions:** The preservation of *Temporal Sequence* presents the most significant challenge, with the highest average TVD (0.729) by a large margin. This indicates models frequently alter event chronology, obscuring cause-and-effect. Furthermore, dimensions requiring granular de-

tail show the lowest information retention. *Entity type* coverage is the lowest on average at 53.67%, meaning nearly half of all named entities are typically omitted. Models also struggle with *Repetition* (61.60% coverage) and *Agent Actions* (67.46% coverage), suggesting a difficulty in capturing the significance of repeated points and agent activities. **Most Robust Dimensions:** In contrast, models are highly effective at preserving high-level structural information. The *Speaker* and *Position* dimensions show minimal bias, with very low average TVD (0.148 and 0.161) and high coverage (98.05% and 97.94%, respectively). This suggests that while models can reliably attribute statements and identify general location in conversation, they fail to preserve fine-grained details within those structural boundaries.

Influence of Compression on Bias Bias increases with compression: Pearson correlation shows that TVD increases ($r = 0.72$) and coverage drops ($r = -0.62$) as compression increases. An exception is `llama-3.2-1b`, which has the lowest compression (10.98) but still a high bias.

Insufficiency of Quality Metrics Holistic metrics like LLM-Judge score weakly correlate with bias: Pearson coefficients show modest improvements in TVD ($r = -0.46$) and coverage ($r = 0.48$) as scores increase. However, high-scoring models like `nova-pro` (score = 4.85) can still exhibit severe *Temporal Sequence Bias* (TVD = 0.749), revealing that such LLM-Judge metrics evaluating quality of summaries overlook structural fidelity.

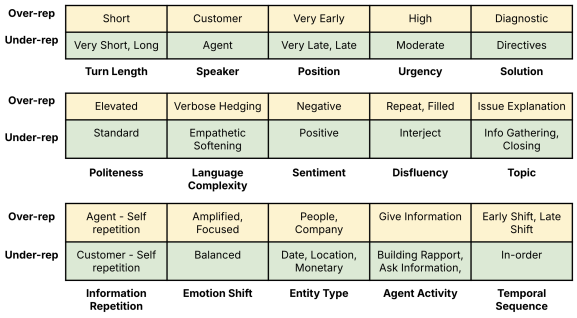

Figure 3: Specific labels that are over- or under-represented consistently across all models.

Analysis of Representation Patterns Our fine-grained analysis reveals systematic biases (Figure 3). Models consistently over-represent labels like Negative sentiment and Early segments, while under-representing labels like Building-Rapport and Directives. This indicates a model tendency to construct simplified, problem-focused narratives, sacrificing crucial interactional context.

4.1 Bias Mitigation via Targeted Prompting

To demonstrate our framework's utility, we investigated bias mitigation by constructing a system prompt based on our analysis (see Appendix, Box F.1). This prompt was designed to directly counteract the specific operational biases, such as position bias towards early segments of transcript and the omission of rapport-building dialogue, that our framework identified. We evaluated this intervention on a representative set of nine models, including small and large variants from four major families and a reasoning model, to measure its effectiveness. The primary metrics were the change in Coverage %, Fidelity Gap (TVD), LLM-Judge score and summary conciseness (Compression Factor).

The results, shown in Table 3 and Figure 4, confirm that this targeted approach was broadly successful. All models exhibited a marked increase in Coverage, and all but one achieved a reduction in TVD. This demonstrates that the prompt effectively guided the models to produce summaries that were both more faithful to the source material and less biased. The improvements were particularly significant for more capable models. For example, `claude-4-sonnet` not only had the largest Coverage gain at +5.87% but also the greatest TVD reduction at -0.047. Other models like `nova-pro` and `llama-4` also showed substantial gains, validating the efficacy of the intervention.

Beyond the overall improvements, our analysis revealed two more nuanced findings. First, we observed a distinct **scaling effect**: larger models consistently benefited more from the mitigation prompt than their smaller counterparts. For example, `claude-4-sonnet`'s TVD reduction was better than that of its smaller family member, `claude-3.5-haiku`. This suggests that more capable models are better equipped to understand and implement complex, corrective instructions. Second, this enhanced fidelity often introduced a fidelity-conciseness trade-off. To incorporate the additional required information, most models produced longer, less compressed summaries. Interestingly, even though the summaries demonstrably improved in terms of bias reduction, the

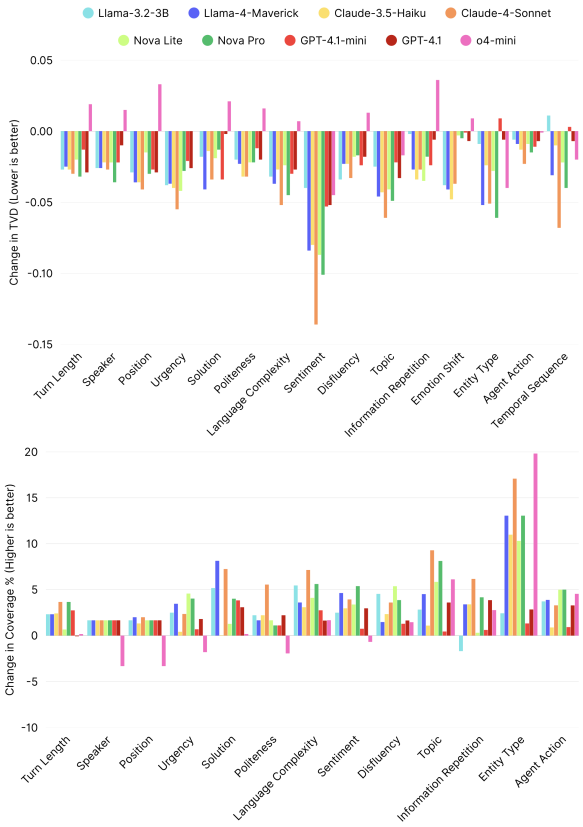

Figure 4: Change in TVD and Coverage % after applying the bias mitigation prompt. Negative change in TVD and positive change in Coverage % indicate improvement.

LLM-Judge scores declined. This suggests that automatic evaluators, while effective for coarse quality judgments, are often insensitive to nuanced fairness and coverage improvements. Examples comparing initial and improved summaries are provided in Appendix F.2.

Model	**Δ Cov.** (↑ better)	**Δ TVD** (↓ better)	**Δ LLM Judge** (↑)	**Δ Compr.**
`claude-3.5-haiku`	+2.72	-0.032	-0.41	-6.21
`claude-4-sonnet`	+5.87	-0.047	-0.15	-9.97
`llama-3.2-3b`	+2.66	-0.022	-0.51	-12.77
`llama-4-maverick`	+4.34	-0.036	-0.37	-11.99
`nova-lite`	+3.70	-0.027	-0.24	-14.50
`nova-pro`	+4.97	-0.034	-0.29	-19.50
`gpt-4.1-mini`	+1.51	-0.019	-0.07	+0.12
`gpt-4.1`	+2.46	-0.019	-0.08	-0.05
`o4-mini`	+2.09	+0.003	-0.36	+12.82
Average Change	**+3.59**	**-0.026**	**-0.28**	**-6.45**

Table 3: Impact of the targeted mitigation prompt on model performance. The table shows absolute change (Δ) in average Coverage %, TVD, LLM Judge scores and Compression Factor. Negative TVD and positive Coverage % and LLM Judge score indicate improvement; negative Compression Factor means longer summaries.

While full mitigation is beyond the scope of this paper, this experiment validates that *BlindSpot* provides actionable feedback to tangibly improve model behavior. These insights are crucial for guiding future research toward developing more robust and reliable AI systems.

5 Conclusion

This work demonstrates that while LLMs produce fluent summaries of contact center conversations, they contain systematic operational biases. To address this, we introduce BlindSpot, a framework that quantifies these distortions across 15 contact center specific dimensions using divergence and coverage metrics. We show that the detailed analysis from BlindSpot is actionable; its findings enabled us to construct a targeted prompt that measurably reduces bias. This research provides a crucial toolset for building more transparent, trustworthy, and domain-aware summarization systems.

6 Limitations

While our framework systematically detects biases in LLM-generated summaries, it does not evaluate the harmfulness, user impact, or real-world consequences of these biases. The current metrics, Total

Variation Distance and Coverage, quantify distributional misalignments but do not capture how these biases affect user trust, business decisions, or fairness in downstream applications.

Our analysis is constrained to English-language contact center transcripts. Consequently, the framework's applicability to multilingual contexts remains untested.

Finally, while the use of LLMs as zero-shot LLM labeler enables scalability, it introduces potential propagation of existing model biases, especially for subjective dimensions like *politeness*, into the annotations themselves, a limitation inherent in LLM-based evaluation pipelines.

7 Ethics Statement

This work focuses on identifying and quantifying biases in LLM-generated summaries of contact center transcripts. Our dataset consists of anonymized, real-world transcripts that do not contain personally identifiable information. All experiments were conducted using publicly available LLMs and datasets under appropriate usage terms.

Our goal is to improve transparency and accountability in language model behavior, not to assign blame to any specific model or provider. However, we acknowledge that exposing model biases, especially across dimensions like sentiment, speaker prominence, or topic selection—may influence deployment decisions and perceptions of fairness. We urge practitioners to interpret our findings within the methodological scope of this study and avoid overgeneralizing results beyond contact center summarization.

No human annotators were employed for labeling tasks; all labels were produced by LLMs, with validation on a small human-rated subset. There was no involvement of vulnerable populations. We believe our findings contribute positively to the responsible development and evaluation of language technologies.

A Taxonomy of Bias Dimensions

This appendix provides a comprehensive description of the 15 dimensions of bias evaluated in our study. The taxonomy is organized into five classes, each targeting a distinct aspect of summary fidelity. For each dimension, we provide its rationale, a description of its labels, and its operational significance.

A.1 Rationale for Bias Classes

The five classes provide a structured approach to understanding different facets of summary quality and potential bias.

1. Class: Content & Information Fidelity Core Purpose: To ensure the summary is a factually accurate and actionable record of the conversation's substance. Biases in this class directly compromise the summary's primary function as a reliable source of truth.
Dimensions within this Class:

- **Entity Type:** This dimension tracks the presence of key named entities. Its operational importance is paramount; the omission of a single key identifier such as a case number, product ID, or callback number, can render a summary useless for follow-up actions and break continuity in the customer journey.

- **Topic:** This dimension ensures the summary reflects the primary purpose and subject matter of the call. A summary with topic bias might over-represent a brief mention of a billing issue in a call that was primarily about technical support, leading to mis-categorization and flawed business intelligence.

- **Solution:** This dimension is crucial for accurately tracking resolution success and agent effectiveness. Misrepresenting a partial fix as a full resolution directly inflates metrics like First Call Resolution (FCR). Furthermore, providing flawed data about which solutions work (or don't work) undermines product and service improvement efforts.

- **Information Repetition:** This dimension captures the nuanced handling of repeated statements. Repetition in a dialogue is not redundant; it is a rich signal often lost in summarization. We identify several key patterns:
  - Customer Self-Repetition: A customer repeating their issue multiple times is a strong indicator of rising frustration, a feeling of not being heard, or confusion about the agent's response.
  - Agent Repeating Customer: An agent paraphrasing or repeating a customer's statement is a standard technique for active listening and confirming understanding. Capturing this is vital for evaluating agent soft skills.
  - Customer Repeating Agent: A customer repeating an agent's instructions or confirmation number indicates their attempt to verify information, which is a critical part of the interaction.
  - Agent Self-Repetition: An agent repeating a compliance script or a key piece of information is often a matter of procedural record and must be documented.

  A summary that simply collapses these repeated instances into a single mention loses this critical interactional context. Furthermore, due to ASR (Automatic Speech Recognition) errors, repeated content can sometimes appear contradictory or slightly different in the transcript. How a model handles these near-duplicates, whether it omits them, averages them, or correctly identifies the most likely intent is a key test of its robustness.

2. Class: Conversational Structure & Flow Core Purpose: To assess the summary's narrative integrity, ensuring the chronological and causal sequence of events is preserved. The "story" of the call is often as important as its individual facts.
Dimensions within this Class:

- **Position:** This dimension addresses the well-known "lead bias," where models favor information from the beginning of a text. In a contact center context, this is operationally dangerous because crucial resolution steps, escalation decisions, and final confirmations are typically found in the middle and late stages of a conversation and are thus prone to omission.

- **Turn Length** This dimension measures how summary fidelity varies based on the length and complexity of individual turns. Conversations are composed of a mix of utterance

types: short, functional turns (e.g., "Yes," "Okay," a case number) and long, narrative turns (e.g., a customer explaining their entire problem history). A key challenge for summarization is to correctly weigh the importance of these different turn types. A model might over-represent short, declarative turns while failing to extract the crucial details embedded within a single long, information-dense monologue. This dimension, therefore, measures the model's robustness in handling turns of varying complexity and its ability to avoid being biased towards either terse or verbose utterances.

- **Temporal Sequence:** This dimension measures whether the chronology of key events is preserved. A summary that misorders events, for example, by placing a customer's expression of frustration *after* a proposed solution, fundamentally breaks the cause-and-effect narrative and can lead to unfair assessments of agent performance.

3. Class: Speaker & Role Representation
Core Purpose: To focus on the fair and accurate attribution of utterances and actions to the conversational participants. This is essential for accountability and performance evaluation.
Dimensions within this Class:

- **Speaker:** This dimension reflects the balance in prominence between the customer and agent voices. A summary with speaker bias might over-represent the agent's turns, making them seem domineering, or underrepresent them, making them appear passive. Both scenarios lead to a distorted picture of the interaction.

- **Agent Action:** This dimension tracks whether key agent behaviors are captured. QA scorecards are built around discrete agent actions like *questioning*, *informing*, *empathizing*, and *building rapport*. A summary that omits these actions provides an incomplete record for performance assessment and coaching. (Note: Customer activity is not separately modeled, as customer turns are typically reactive and lack the standardized operational roles of an agent).

4. Class: Linguistic & Stylistic Dimensions
Core Purpose: To target distortions in the *manner* and *tone* of the conversation. These stylistic features carry significant diagnostic information about the customer experience and agent professionalism that is lost if a summary only reports literal content.
Dimensions within this Class:

- **Language Complexity:** This dimension addresses the simplification or complication of language. A summary that over-simplifies technical language may fail to document an agent's expertise. Conversely, a summary that fails to capture the simplicity of an agent's explanation may miss an example of excellent customer communication.

- **Disfluency:** This dimension tracks the presence of hesitations, false starts, and repetitions. While often considered "noise," disfluencies are a rich source of information. Removing a customer's hesitations can erase crucial evidence of their uncertainty or confusion, misrepresenting the true customer experience and an agent's effectiveness in providing clarity.

- **Politeness:** This dimension measures the representation of social niceties. An agent's demeanor is a core metric for QA. A summary that "sanitizes" a rude interaction or makes a professional agent seem curt eliminates vital data for performance reviews and coaching.

5. Class: Affective & Pragmatic Interpretation
Core Purpose: To address the emotional and intentional subtext of the conversation, which is often more critical for business outcomes than the raw facts.
Dimensions within this Class:

- **Sentiment:** This dimension captures the emotional valence of the interaction. Its importance for risk management cannot be overstated. A summary that minimizes genuine customer frustration by labeling it as neutral "unhappiness" or "dissatisfaction" can cause a high-priority churn risk to be overlooked by downstream systems and human reviewers.

- **Emotion Shift:** This dimension identifies more nuanced changes in emotional representation, such as amplification (making a neutral comment sound negative) or attenuation (weakening a strong emotion). These

shifts affect the perceived severity of an issue and can lead to misprioritization in customer retention workflows.

- **Urgency:** This dimension measures the representation of time-sensitivity. Failing to flag a high-urgency request—such as "I need to cancel this fraudulent transaction *right now*!"—represents a direct and immediate failure in customer service with potentially significant financial and reputational consequences.

A.2 Detailed Descriptions of Bias Dimensions and their Labels

The following table 4 provides a complete list of the 15 bias dimensions, their corresponding labels used for classification, and a brief description. The source of the annotation (LLM-annotated, computed, or derived) is also indicated. Dimensions marked with (Multiselect) allow for the assignment of multiple labels per turn or proposition.

Bias Dimension	Labels	Operational Significance
1. Content & Information Fidelity		
Entity Type	People, Identifiers, Phone Number, Email, Time Info, Date, Location Info, Products/Services, Monetary, Company/Organization, Other	Over/underrepresentation of key factual data required for action.
Topic	Greeting/Introductions, Identity Verification, Issue, Information Gathering, Product/Service Inquiry, Diagnosis/Troubleshooting, Solution, Action, Transaction, Offers/Upgrades, Sales, Resolution Confirmation, Next Steps, Closure, Empathy, Complaint, Policy Explanation, Feedback, Scheduling, Billing, Compliance, Miscellaneous	Over-focus or neglect of certain topical segments, skewing the perceived purpose of the call.
Solution	Diagnosis, Advisory, Root Cause, Directive/-Command, Preventive Measure, Escalate, Self-Help, Partial Fix, Rejected Fix, Follow-up, Set Expectation, Reassure, No Solution	Omission or distortion of resolutions, impacting FCR and product insights.
Information Repetition	No Repetition, Customer Self-Repetition, Agent Self-Repetition, Customer Repeats Agent, Agent Repeats Customer	Loss of context regarding participant frustration or confirmation loops.
2. Conversational Structure & Flow		
Position (computed)	Very Early, Early, Mid, Late, Very Late	Preference for information from specific segments of the conversation.
Turn Length (computed)	Very Short, Short, Mid, Long, Very Long	Variation in summary fidelity across dialogues of different length.
Temporal Sequence (derived)	In-order, Early-shift, Late-shift, Omitted, Added	Distortion of the chronological order of events, breaking causal chains.
3. Speaker & Role Representation		
Speaker (computed)	Agent, Customer	Unequal representation of agent vs. customer voice and contribution.
Agent Action	Request Information, Provide Information, Confirm Understanding, Build Rapport, Acknowledge, Escalate, Compliance, Other	Misrepresentation of agent actions, impacting performance evaluation.
4. Linguistic & Stylistic Dimensions		
Language Complexity (Multiselect)	Simple/Clear, Declarative, Long/Multi-Clause, Technical, Jargon, Abbreviations, Dense, Wordy/Vague, Formal, Informal, Empathic, Blunt, Slang, Passive Voice	Disproportionate simplification or complication of the original language style.
Disfluency (Multiselect)	Filled Pause, Repetition, False Start, Repair, Prolongation, Stutter, Discourse Marker, Interjection, Cutoff	Selective omission of speech imperfections that signal user confusion.
Politeness	Impolite, Standard, Minimal, Elevated	Neutralization or exaggeration of politeness, masking agent/customer demeanor.
5. Affective & Pragmatic Interpretation		
Sentiment	Very Positive, Positive, Neutral, Negative, Very Negative	Divergence in emotional tone, masking customer satisfaction or churn risk.
Emotion Shift (derived)	Balanced, Amplified, Attenuated, Inverted, Spurious	How the summary distorts, drops, or fabricates emotional nuance.
Urgency	None, Low, Moderate, High, Critical	Failure to represent time-sensitive requests, leading to service failures.

Table 4: The full taxonomy of 15 bias dimensions, organized by class. For each dimension, we provide its corresponding labels and operational significance. Labeling sources are noted in parentheses.

Code	Label	Description
very_early	Very Early	Tokens in the first 20% of the transcript.
early	Early	Tokens in the next 20% (20%–40%).
mid	Mid	Tokens in the middle segment (40%–60%).
late	Late	Tokens in the following 20% (60%–80%).
very_late	Very Late	Tokens in the final 20% of the transcript (80%–100%).

Table 5: The label set for the Position bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
agent	Agent	Utterances spoken by the service agent.
customer	Customer	Utterances spoken by the customer.

Table 6: The label set for the Speaker bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
people	People	Named individuals.
identifiers	Identifiers	IDs like account numbers.
phone_number	Phone Number	Telephone numbers.
email	Email	Email addresses.
time_info	Time Info	Time-related entities (e.g., 3 PM).
date	Date	Dates and calendar references.
location_info	Location Info	Geographical references.
product	Products/Services	Product or service mentions.
monetary	Monetary	Currency and financial references.
company_organization	Company/Organization	Business or organization names.
other	Others	Named entities not in predefined types.

Table 7: The label set for the Entity Type bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
very_pos	Very Positive	Strongly positive tone
pos	Positive	Moderately positive tone
neg	Negative	Moderately negative tone
very_neg	Very Negative	Strongly negative tone
info	Informational	Information content or presence of factual tokens (dates, names, IDs) — high priority over 'neutral'
neutral	Neutral	Does not have information and contains explicit neutral-emotion cues (e.g., "okay," "fine," "so-so," "not sure")

Table 8: The label set for the Sentiment bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
greet	Greetings/Introductions	Greetings, introductions
id_verif	ID Verification	ID or account verification
issue	Issue/Problem Statement	Customer's reason for contact
info_gath	Information Gathering	Agent probing/investigating
prod_inq	Product Inquiry	Product or service questions
diag	Diagnosis	Diagnosis or troubleshooting
soln	Solution	Proposing a solution
action	Action	Performing an action
transact	Transaction	Payments, refunds, orders
offers	Offers	Service offers or upgrades
sales	Sales	Sales, upselling, persuasion
resolve_conf	Resolution Confirmation	Confirming issue is resolved
next	Next Steps	Next steps, follow-ups
close	Closure	Farewell, call closure
empathy	Empathy	Expressing care or rapport
complaint	Complaint Handling	Handling complaints/escalation
policy	Policy Explanation	Explaining rules or terms
feedback	Feedback Request	Requesting feedback or surveys
sched	Scheduling	Appointments, scheduling
billing	Billing Issues	Billing/payment issues
compliance	Compliance	Compliance or regulations
misc	Miscellaneous	Miscellaneous

Table 9: The label set for the Topic bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
filled	Filled Pause	"uh", "um", etc.
silent	Silent Pause	Silent pauses
repeat	Repetition	Word/phrase repetition
false_start	False Start	Incomplete start
repair	Repair	Self-correction
prolong	Prolongation	Stretched sounds
stutter	Stutter	Repeated syllables
marker	Discourse Marker	Discourse filler ("like", "you know")
interject	Interjection	"oh!", "hmm"
cutoff	Cutoff	Abandoned utterance
placeholder	Placeholder	"sort of", "you know what I mean"
overlap	Overlap	Overlapping talk

Table 10: The label set for the Disfluency bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
ask_info	Request Information	Asking for details or clarification (e.g., "Could you confirm your order number?").
give_info	Provide Information	Supplying facts, context, or background not tied to a solution.
check_under	Confirm Understanding	Verifying if the other party comprehends or observes the same thing (e.g., "Do you see the change on your end?").
rapport	Build Rapport	Expressions of empathy, politeness, friendliness, or gratitude.
backchannel	Acknowledgement / Cue	Verbal cues like "Uh-huh", "Okay", or "Got it" to show active listening.
escalate	Escalate / Transfer Action	Referring or handing over to another party or department.
compliance	Compliance / Verification	Fulfilling identity, legal, or policy requirements.
idle	Passive / No-Op Response	Moments of silence or minimal interaction without progress.
other	Other Conversational Act	Any conversational act not covered above, such as small talk.

Table 11: The label set for the Agent Action bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
very_short	Very Short	Dialogues with 0-5 tokens
short	Short	Dialogues with 5-15 tokens
mid	Mid	Dialogues with 15-50 tokens
long	Long	Dialogues with 50-100 tokens
very_long	Very Long	Dialogues with more than 100 tokens

Table 12: The label set for the Turn Length bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
inorder	Correct Order	Events appear in the same order as in the original call.
early-shift	Shifted Earlier	An event appears earlier in the summary than in the original call.
late-shift	Shifted Later	An event appears later in the summary than in the original call.
omitted	Omitted Event	A key event from the original call is missing in the summary.
added	Added Event	The summary introduces an event not present in the original call.

Table 13: The label set for the Temporal Sequence bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
balanced	Emotion Preserved	Summary preserves the exact sentiment(s) and intensity(s) of the transcript.
amplified	Emotion Amplified	Summary intensifies existing sentiment(s): stronger valence or added emphasis beyond transcript.
attenuated	Emotion Attenuated	Summary weakens or omits sentiment: reduces intensity or drops emotion to neutral/informational.
inverted	Emotion Inverted	Summary flips polarity: presents the opposite emotion to what the transcript expressed.
spurious	Emotion Introduced	Summary introduces emotion where transcript was purely factual or neutral.
focused	Emotion Narrowed	Transcript had multiple distinct emotions but summary reports only one (loss of nuance).

Table 14: The label set for the Emotion Shift bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
no_rep	No Repetition	No repetition occurred.
cust_self	Customer Self-Repetition	Customer repeats their own words.
agent_self	Agent Self-Repetition	Agent repeats themselves.
cust_echo	Customer Repeats Agent	Customer echoes agent.
agent_echo	Agent Repeats Customer	Agent echoes customer.

Table 15: The label set for the Information Repetition bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
standard_clear	Clear	Clear, direct, and easily understood language.
simple_syntax	Simple Syntax	Predominantly short, declarative sentences.
complex_syntax	Complex Syntax	Long, multi-clause, or convoluted sentences.
technical_terms	Technical Terms	Specialized terms related to a specific domain.
industry_jargon	Industry Jargon	Terms/phrases specific to an industry or company.
acronyms_abbreviations	Abbreviations	Use of shortened forms of words or phrases.
info_dense	Information Dense	Highly concise; packed with specific information.
verbose_hedging	Verbose / Hedging	Wordy, uses fillers, qualifiers, or vague language.
formal_register	Formal Register	Polished, professional, and structured tone.
informal_colloquial	Informal / Colloquial	Conversational, casual, everyday language.
empathetic_softening	Empathetic	Language used to show understanding or soften news.
abrupt_blunt	Blunt	Overly direct, lacking typical softeners or politeness.
idioms_slang	Idioms / Slang	Figurative expressions or informal slang.
passive_voice_prominent	Passive Voice	Significant use of passive voice constructions.

Table 16: The label set for the Language Complexity bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
diag_expl	Diagnostic Explanation	Identifying the nature of the issue.
advisory	General Advice	Offering advice or suggestions.
root_cause	Root Cause	Explaining the underlying reason for the issue.
directive	Directive / Commands	Concrete steps or commands to take.
preventive	Preventive	Preventing future issues from occurring.
escalate	Escalation	Escalation or transfer to another team.
self_help	Self-Help	Do-it-yourself instructions.
partial	Partial Fix	Incomplete or partial resolution.
rejected	Rejected	Solution was offered but not applied.
followup	Follow-Up	Future action or check-in is promised.
expect	Set Expectations	Sets realistic timelines or expectations.
reassure	Reassurance	Provides emotional closure or comfort.
no_soln	No Solution	No resolution was provided.

Table 17: The label set for the Solution bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
none	None	No politeness cues (no please/thank you/etc.)
minimal	Minimal	One-off courtesy (“thank you”, “please”)
standard	Standard	Expected level (“please let me know”, “thanks for waiting”)
elevated	Elevated	Multiple markers + honorifics (“sir/madam”, “kindly”)
impolite	Impolite	Impoliteness cues

Table 18: The label set for the Politeness bias dimension, including descriptions and short codes used for labeling.

Code	Label	Description
none	None	No urgency language
low	Low	Mild timeframe hints (“when you can”, “at your convenience”)
moderate	Moderate	Moderate urgency (“soon”, “shortly”)
high	High	Strong urgency (“ASAP”, “urgent”)
critical	Critical	Extreme immediacy (“immediately”, “right now”, “without delay”)

Table 19: The label set for the Urgency bias dimension, including descriptions and short codes used for labeling.

B Framework Methodology and Implementation

This section provides a detailed description of the *BlindSpot* framework's methodology, including the end-to-end data processing workflow, the validation of our LLM Labeler, and a guide to interpreting the final bias metrics.

B.1 Detailed Workflow of *BlindSpot*

The framework's core function is to quantify bias by comparing the distributional properties of a source transcript and its generated summary. The process, illustrated in Figure 2 of the main paper, is composed of three main stages: (1) creating a reference distribution from the transcript, (2) creating a summary distribution, and (3) calculating bias metrics.

B.1.1 Stage 1: Transcript Pipeline (Generating Reference Distribution P_d)

The objective of this pipeline is to establish a reference label distribution, P_d, for each of the 15 bias dimensions.

1. Transcript Segmentation To manage long contexts and ensure consistent JSON output from the LLM Labeler, each transcript T is first partitioned into sequential, non-overlapping segments $\{S_1, \ldots, S_k\}$ of 50 turns each. This segmentation mitigates potential performance degradation and out-of-spec responses when processing very long transcripts in a single pass.

2. Turn-level Annotation We employ a hybrid approach to annotate every turn in the transcript across all bias dimensions. The annotation source depends on the nature of the dimension:

- **LLM-Annotated (Semantic Dimensions):** For dimensions requiring semantic understanding, we use our LLM Labeler ($\mathcal{L}$) to process each segment and assign labels. These include *Sentiment, Topic, Solution, Information Repetition, Language Complexity, Disfluency, Politeness, Urgency, Entity Type,* and *Agent Action*.
- **Computed (Structural Dimensions):** For dimensions based on the transcript's structure, labels are computed algorithmically. *Speaker* is extracted directly from conversation metadata. *Position* is calculated by normalizing a turn's index into one of five quintiles ('Very Early', 'Early', 'Mid', 'Late', 'Very Late'). *Turn Length* is determined by the token count of the turn, categorized into discrete length buckets.
- **Derived (Relational Dimensions):** Two dimensions are inferred from the primary labels. *Emotion Shift* is derived by comparing the sentiment of a proposition to its source turns, and *Temporal Sequence* is derived from the mapping between chronologically ordered summary propositions and their source turn indices.

3. Reference Distribution (P_d) Generation The turn-level annotations are aggregated across the entire transcript to form a normalized categorical distribution P_d for each dimension d, which serves as our reference or "ground truth."

B.1.2 Stage 2: Summary Pipeline (Generating Summary Distribution Q_d)

This pipeline generates a corresponding distribution, Q_d, from the LLM-generated summary.

1. Summary Generation The summarization model under evaluation, $\mathcal{M}$, generates an abstractive summary S from the full, unsegmented transcript T. This mirrors real-world usage where the model processes the entire conversation at once.

2. Proposition Extraction To enable fine-grained, sentence-level analysis, the generated summary S is decomposed into a set of minimal semantic units, or **propositions** $\{p_1, \ldots, p_m\}$. This is performed by an LLM instructed to isolate each atomic fact or claim, creating a standardized unit of analysis.

3. Proposition Labeling and Mapping Each proposition is then labeled using the same hybrid methodology as the transcript turns. For turn-dependent dimensions like *Position* or *Urgency*, a crucial mapping step is performed where the LLM Labeler identifies the set of source turn indices that each proposition summarizes (a one-to-many mapping). The labels from these source turns are then projected onto the proposition.

4. Summary Distribution (Q_d) Generation The proposition-level labels are aggregated to form the summary's categorical distribution Q_d for each dimension d.

B.1.3 Stage 3: Bias Quantification and Interpretation

1. Metric Calculation With both P_d and Q_d computed, we quantify bias using two complementary metrics:

- **Fidelity Gap:** We use Total Variation Distance between P_d and Q_d to measure the overall distributional distortion. A score of 0 indicates identical distributions, while higher values indicate greater divergence.
- **Coverage:** We calculate the percentage of labels present in the transcript (where $P_d(c) > 0$) that are also present in the summary (where $Q_d(c) > 0$). This directly measures the omission of information.

For derived dimensions like *Temporal Sequence*, the reference distribution P_d is a one-hot distribution representing the ideal chronological order, allowing TVD to directly measure any reordering.

2. Interpreting Results The combination of our two metrics provides a nuanced view of a summary's faithfulness. For each dimension, we interpret the pair as follows:

- **Low Fidelity Gap & High Coverage:** A faithful summary that retains nearly all source labels and preserves their original proportions.
- **Low Fidelity Gap & Low Coverage:** A selectively faithful summary that accurately represents the distribution of the labels it includes but omits other labels entirely.
- **High Fidelity Gap & High Coverage:** A distorting summary that mentions information from all source labels but skews their relative importance, leading to misrepresentation.
- **High Fidelity Gap & Low Coverage:** The worst-case scenario; a summary that both ignores entire sets of labels and misrepresents those it chooses to include.

B.2 LLM Labeler Validation

The integrity of our framework hinges on the reliability of our LLM Labeler ($\mathcal{L}$), GPT-4o. To validate its performance, we conducted a rigorous human annotation study.

1. **Dataset Creation:** We randomly sampled 1,000 turn-proposition pairs from our dataset, ensuring coverage across all 15 bias dimensions. A human annotator trained in contact center analytics and familiar with the operational context, independently validated each label assigned by the LLM Labeler according to detailed annotation guidelines.

2. **Evaluation:** The LLM Labeler ($\mathcal{L}$) achieved an accuracy of 93.68% against human annotation. As expected, performance varied slightly by dimension, with higher accuracy on objective dimensions like *Entity Type* and slightly lower, yet still high, accuracy on more subjective dimensions like *Politeness*. This result gave us confidence in using the LLM as a scalable and reliable tool for our large-scale analysis.

B.3 LLM-Judge for Holistic Quality Assessment

To contextualize our fine-grained bias findings, we also measure the overall, holistic quality of each summary using an "LLM-as-a-Judge" approach. The goal is to establish a baseline quality score against which we can compare our bias metrics. This allows us to investigate a central question of our work: can summaries that are perceived as high-quality by a powerful LLM still harbor operational biases?

Implementation Details For each of the 50,000 transcript-summary pairs (2500 transcripts $\times$ 20 models), we prompt a powerful arbitrator LLM (GPT-4o) to act as an impartial judge. As detailed in Box B.3, the judge is tasked with assigning an integer score from 1 (poor) to 5 (excellent) based on three explicit criteria derived from standard summarization quality dimensions:

1. **Factual Consistency:** This criterion ensures that all claims, facts, and events mentioned in the summary are factually supported by the source transcript. It penalizes any hallucinations or contradictions.

2. **Completeness:** This assesses whether the summary includes all critical information from the conversation without significant omissions of key events, decisions, or outcomes.

3. **Succinctness and Relevance:** This criterion, framed in the prompt as "Presence of irrelevant information," penalizes summaries that include extraneous details, conversational filler, or other information not directly relevant to the core purpose of the interaction.

The judge is instructed to output both the numerical score and a brief textual justification for its reasoning. For our quantitative analysis, we use the numerical score, which we refer to as the **LLM Judge Score**.

Prompt for LLM Judge Score

You are provided with an input call transcript and its abstractive summary. Your task is to evaluate the quality of the summary according to the transcript.
Assign an integer score between 1 and 5 (higher the score, better the response quality).
Evaluate the response using the following criteria:

1. **Factual Consistency** - Are the facts and claims in the summary correct?
2. **Completeness** - Is all necessary information included?
3. **Presence of irrelevant information** - Does the summary stay focused on the task?

Output Format: Score: [1-5] Reason: [Feedback on prompt]

Acknowledged Limitations While scalable and effective for capturing general quality, we acknowledge the known limitations of the LLM-as-a-Judge paradigm. These include potential agreement bias (a tendency to favor summaries stylistically similar to its own training data), positional bias (overweighting information at the beginning or end of the summary), and an inability to detect subtle but operationally critical omissions that our *BlindSpot* framework is designed to find. Therefore, we use this score not as an absolute measure of truth, but as a proxy for a summary's perceived holistic quality. The potential for this high-level score to mask the fine-grained biases we investigate is a central motivation for our work.

C Experimental Configuration

This section provides a detailed overview of the experimental configuration used in our study, including model generation parameters, dataset statistics, and the full list of evaluated models.

C.1 Generation Parameters

To ensure a fair and reproducible comparison, we employed a standardized set of generation parameters for all summarization tasks. The specific settings were chosen to elicit factual and deterministic outputs while accommodating different model types. For the majority of models, we set the temperature to 0 to minimize randomness and produce the most likely, consistent summary for a given transcript. For reasoning models, we used a temperature of 1 and set `reasoning_effort` to low. Other key parameters, such as `top_p`, `frequency_penalty`, and `presence_penalty`, were set to neutral values to avoid confounding the results and to observe the models' inherent summarization behaviors. The maximum output length was capped at 1000 tokens, which was sufficient for all summaries in our corpus. All large language model (LLM) inferences were performed through API endpoints using a pay-as-you-go method.

Parameter	Value
Temperature (non-reasoning models)	0
Temperature (reasoning models)	1
Top-p	1.0
Max Tokens	1000
Frequency Penalty	0.0
Presence Penalty	0.0
Stop	None
Seed	None
Reasoning Effort (reasoning models)	low

Table 20: LLM generation parameters for summarization.

For the LLM Labeler, which performs the labeling tasks in our framework, we used GPT-4o with slightly different parameters to balance consistency with nuanced classification. A low temperature of 0.1 was chosen to ensure high reproducibility and determinism while allowing for minimal flexibility.

Parameter	Value
LLM	GPT-4o
Temperature	0.1
Top-p	1.0
Max Tokens	None
Frequency Penalty	0.0
Presence Penalty	0.0
Stop	None
Seed	None

Table 21: LLM generation parameters for LLM Labeler.

C.2 Models Evaluated

To conduct a comprehensive audit of bias, we selected a diverse set of 20 large language models. Our selection spans multiple major model providers and open-source families, including Meta (Llama), Amazon (Nova), Anthropic (Claude), Google (Gemini), and OpenAI (GPT). Furthermore, we intentionally included models of varying scales within the same family (e.g., Llama-3.2 1B vs. Llama-3.3 70B; GPT-4.1-nano vs. GPT-4.1). This approach allows us to analyze the influence of both model architecture and parameter scale on the prevalence and nature of biases. For full transparency and reproducibility, the specific model identifiers used in our experiments are listed in Table 22.

Short Name	Model ID
`Llama-3.2-1B`	`meta/llama3-2-1b-instruct-v1`
`Llama-3.2-3B`	`meta/llama3-2-3b-instruct-v1`
`Llama-3.3-70B`	`meta/llama3-3-70b-instruct-v1`
`Llama-4-Maverick`	`meta/llama4-maverick-17b-instruct-v1`
`Nova Micro`	`amazon/nova-micro-v11`
`Nova Lite`	`amazon/nova-lite-v1`
`Nova Pro`	`amazon/nova-pro-v1`
`Claude-3.5-Haiku`	`anthropic/claude-3-5-haiku-20241022-v1`
`Claude-3.7-Sonnet`	`anthropic/claude-3-7-sonnet-20250219-v1`
`Claude-4-Sonnet`	`anthropic/claude-sonnet-4-20250514-v1`
`Deepseek-R1`	`deepseek/r1-v1`
`Gemini-2.0-Flash`	`google/gemini-2.0-flash`
`Gemini-2.0-Flash-lite`	`google/gemini-2.0-flash-lite`
`GPT-4o-mini`	`openai/gpt-4o-mini-2024-07-18`
`GPT-4o`	`openai/gpt-4o-2024-08-06`
`GPT-4.1-nano`	`openai/gpt-4.1-nano-2025-04-14`
`GPT-4.1-mini`	`openai/gpt-4.1-mini-2025-04-14`
`GPT-4.1`	`openai/gpt-4.1-2025-04-14`
`o3-mini`	`openai/o3-mini-2025-01-31`
`o4-mini`	`openai/o4-mini-2025-04-16`

Table 22: Identifiers of LLMs used in evaluation.

C.3 Transcript Statistics

Our evaluation was conducted on a corpus of 2,500 real, anonymized contact center transcripts from 12 distinct domains. As shown in Table 23, the conversations are substantial and highly variable in length. The average transcript contains approximately 317 turns and over 5,000 tokens, with the longest conversation extending to 548 turns and over 11,000 tokens. This significant variation in length and content provides a robust testbed for evaluating the models' summarization capabilities across a

range of complexities, from brief, straightforward interactions to long, multi-issue dialogues. The distribution is slightly right-skewed, with the median length (290 turns) and call duration (37 minutes and 31 seconds) being lower than the mean, which is typical for such datasets. All agent–customer turn-by-turn conversations were processed through our in-house ASR system, which achieved a word error rate (WER) of 11.2%.

Statistic	num_turns	token_count	call_duration (mm:ss)
Count	549	605	09:09
Mean	317	5110	36:58
Std	128	2180	13:52
Min	55	244	10:01
25%	214	3003	28:20
50%	290	5048	37:31
75%	429	6840	44:32
Max	548	11348	92:32

Table 23: Summary statistics of number of turns and token counts across transcripts.

Table 24: Detailed evaluation results for all 20 LLMs, showing mean and standard deviation.

D Supplemental Results and Analysis

This appendix provides additional results and analyses that complement the findings presented in the main paper. It includes a comprehensive breakdown of model performance across all bias dimensions, results using alternative divergence metrics, an analysis of how performance varies with transcript length, and a deeper look at model-level representation biases.

D.1 Model Performance with Standard Deviation

Table 24 presents the complete evaluation results for all 20 LLMs across the 15 bias dimensions, including both the mean and standard deviation for each metric. These detailed results support the main paper's claim that bias is a systemic issue, with most models clustering within a narrow performance band for many dimensions. The standard deviation values indicate the consistency of a model's performance across the 2500 transcripts.

D.2 Analysis with Alternative Divergence Metrics

To ensure that our findings are not an artifact of our chosen distance metric (TVD), we re-calculated the fidelity gap using three alternative metrics: Wasserstein Distance, Chi-Square test, Kullback-Leibler (KL) Divergence and Jensen-Shanon (JD) Divergence. As shown in Table 25 and Table 26, the relative model rankings and the identification of the most challenging bias dimensions (e.g., Temporal Sequence, Entity Type) remain highly consistent across all metrics. This consistency demonstrates the robustness of our core findings.

D.3 Fine-Grained Label Representation Analysis

Beyond aggregate scores, our framework allows for an analysis of which specific labels are systematically over- or under-represented. Figure 5 illustrates the labels with the most significant positive (over-represented) and negative (under-

Table 26: Model performance using KL-Divergence (lower the better) and Chi-Squared values (lower the better). The relative model and dimension rankings, however, remain stable.

represented) skew, averaged across all models. This analysis reveals a consistent narrative strategy: models tend to amplify labels related to problem statements (e.g., 'Negative' sentiment, 'Issue' topic) while omitting labels related to conversational context and resolution (e.g., 'Rapport-Building', 'Directives'). This provides a deeper explanation for the observed biases, linking them to the models' implicit assumptions about what is important in a conversation.

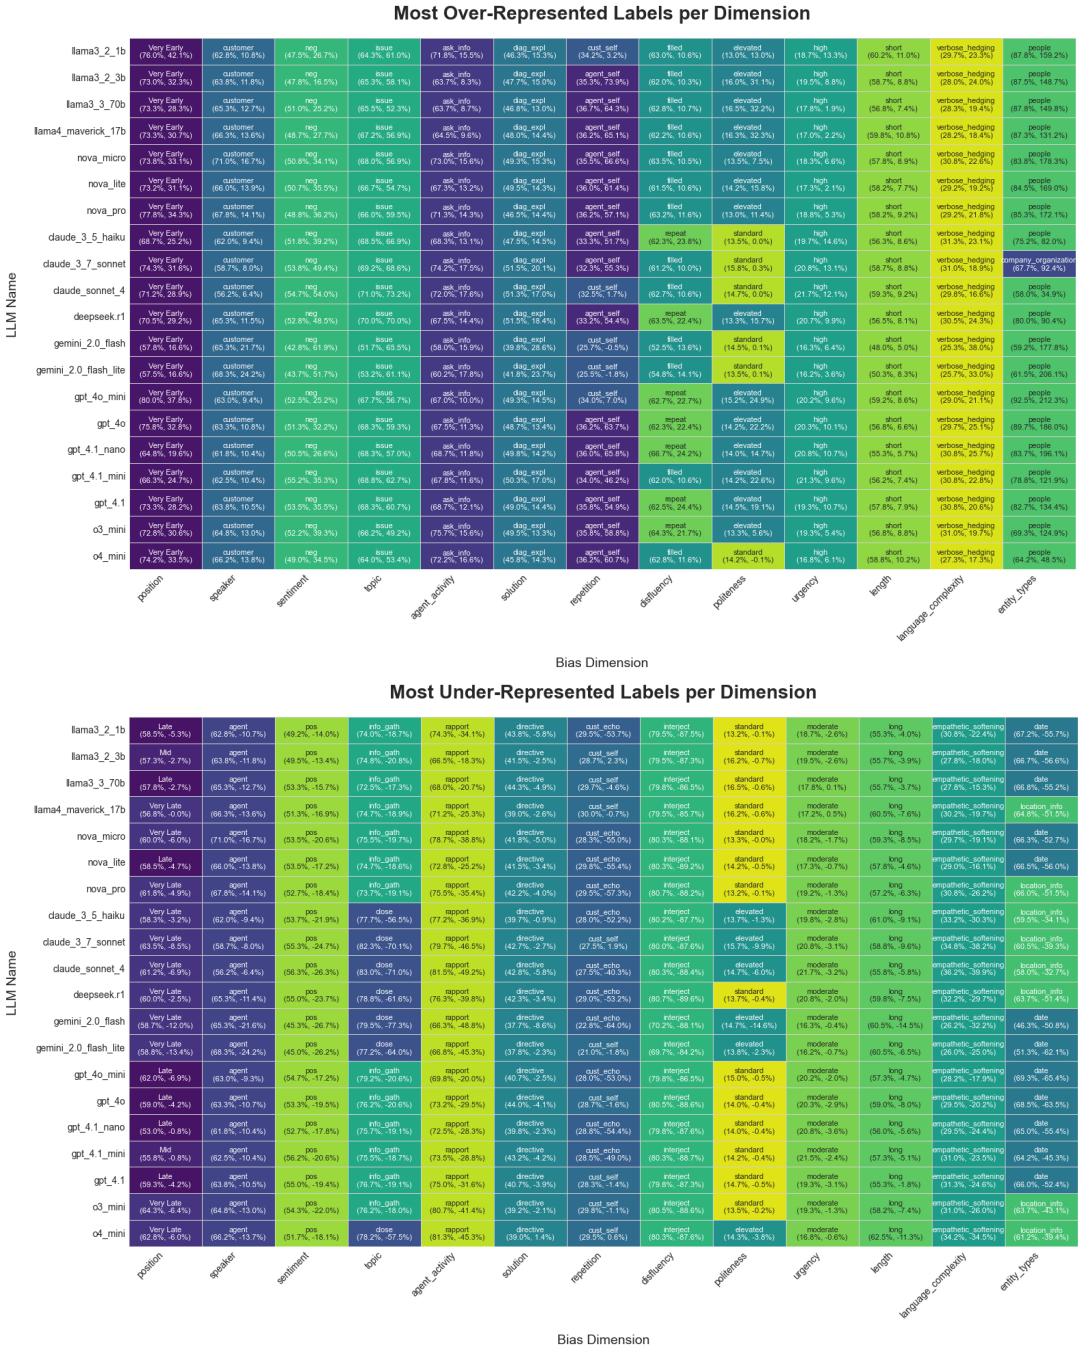

Figure 5: Systematic over- and under-representation of specific labels across all 20 LLMs. The top plot depicts over-represented labels; the bottom plot depicts under-represented labels. Each label is annotated with two percentages indicating (1) the proportion of summaries in which it is over- or under-represented and (2) the average magnitude of that deviation. The results reveal a consistent, cross-model tendency to construct simplified, problem-centric narratives while underrepresenting interactional and resolution-focused content.

E Prompts

Prompt for Summarization

System Prompt: You are a helpful assistant designed to summarize text.
User Prompt Templates:

1. Summarize the following dialog. `<dialog> {transcript} </dialog>`
2. Please provide a summary of the contact-center conversation transcript. `<transcript> {transcript} </transcript>`
3. Generate a summary of the conversation. `<conversation> {transcript} </conversation>`

Prompt for Semantic Proposition Extractor

You are a semantic analysis assistant. Your task is to decompose the given paragraph into atomic semantic propositions. Each proposition must preserve a minimal, standalone unit of meaning and reflect a single assertion or fact conveyed by the text.
Guidelines:

1. Use the original words where possible; do not paraphrase unnecessarily.
2. Resolve pronouns if possible.
3. A proposition should typically follow the (subject; predicate; object/modifier) structure.
4. Include time, place, and recipient details as separate propositions when appropriate.
5. Do not explain or justify. Just return the list of propositions.

Next, extract entities from the summary and categorize them into the following predefined types:

- **people**: Agent name, Customer name, 3rd parties
- **identifiers**: Ticket ID, Account No., Policy No.
- **phone_number**: Phone numbers
- **email**: Email addresses
- **time_info**: Time, Duration, Deadlines
- **date**: Dates
- **location_info**: Address, City, Branch
- **products_services**: Items discussed or complained about
- **monetary**: Price, Refund, Discount
- **company_organization**: Mentioned institutions
- **others**: Miscellaneous/Unclassified entities

Return a JSON object with two keys: `propositions` and `entities`.

- `propositions`: an object where keys are sequential numeric strings (e.g., `"1"`, `"2"`) and values are the proposition texts.

- `entities`: an object with the exact keys listed above, each containing a list of extracted entities (even if empty).
- "The overall JSON structure should be: "propositions": "1": "John filed a complaint.", "2": "The issue occurred yesterday at 10 AM." , "entities": "people": ["John"], "identifiers": ["WR123X62"], "phone_number": [], "email": [], "time_info": ["10 AM"], "date": ["yesterday"], "location_info": [], "products_services": ["mobile insurance"], "monetary": ["$112"], "company_organization": ["accolade"], "others": []

User Prompt:
Process the following summary to extract semantic propositions and entities and provide the output in JSON format:`\n\nSummary:\n""`

Prompt for Transcript Labeling

You are a transcript analysis assistant. Your task is to annotate each turn in a conversation transcript using a fixed set of linguistic and conversational dimensions, and separately extract entities mentioned across the entire transcript.
Each turn begins like: `"1: Speaker: ..."` Analyze each turn independently.
Dimensions (Fixed Order with Short Labels)
Each turn must be annotated in the following order. Always include all dimensions. Empty lists are allowed where applicable.

Key	Dimension Name	Type
`sent`	Sentiment	single value
`topic`	Topic Category	single value
`agent`	Agent Action	single value
`sol`	Solution Type	list
`rep`	Information Repetition	single value
`disf`	Disfluency Patterns	list
`lang`	Language Complexity Patterns	list
`polite`	Politeness	single value
`urgency`	Urgency	single value

Output Format (JSON)
"map": [[1, "neutral", "greet", "ask_info", [], "no_rep", [], [], "minimal", "low"], [2, "pos", "diag", "escalate", ["diag_expl"], "cust_self", ["filled"], ["plain", "formal"], "standard", "high"]], "entity": "people": ["Alex"], "phone_number": [9512384859], "monetary": ["$100"], ... (and other entity categories)
`map`: List of arrays — one for each turn. Each array must contain 10 elements: `[turn_number, sent, topic, agent, sol, rep, disf, lang, polite, urgency]`
`entity`: Dictionary of extracted entities. Entity extraction is a separate task — do not confuse with turn-level annotation.
Allowed Values and Glossary:
1. sent - Sentiment

Code	Meaning
very_pos	Strongly positive tone
pos	Moderately positive tone
neg	Moderately negative tone
very_neg	Strongly negative tone
info	Information content or presence of factual tokens (dates, names, IDs) – high priority over neutral
neutral	Does not have information and contains explicit neutral-emotion cues (e.g., "okay," "fine," "so-so," "not sure")

2. topic - Topic Category

Code	Description
greet	Greetings, introductions
id_verif	ID or account verification
issue	Customer's reason for contact
info_gath	Agent probing/investigating
prod_inq	Product or service questions
diag	Diagnosis or troubleshooting
soln	Proposing a solution
action	Performing an action
transact	Payments, refunds, orders
offers	Service offers or upgrades
sales	Sales, upselling, persuasion
resolve_conf	Confirming issue is resolved
next	Next steps, follow-ups
close	Farewell, call closure
empathy	Expressing care or rapport
complaint	Handling complaints/escalation
policy	Explaining rules or terms
feedback	Requesting feedback or surveys
sched	Appointments, scheduling
billing	Billing/payment issues
compliance	Compliance or regulations
misc	Miscellaneous

3.agent - Agent Action:

Code	Category	Notes
ask_info	Request Information	"Could you confirm your order?"
give_info	Provide Information	Facts or explanations not tied to a fix
check_under	Confirm Understanding	"Do you see the change on your end?"
rapport	Build Rapport	Empathy, friendliness, thank-you
backchannel	Acknowledgement / Cue	"Uh-huh," "Okay," "Got it."
escalate	Escalate / Transfer Action	"I'm connecting you to billing."
compliance	Compliance / Verification	Identity, policy, legal checks
idle	Passive / No-Op Response	Silence gaps marked or minimal reply
other	Other Conversational Act	Anything else (e.g., small talk)

4.sol - Solution Type (multi-select)

Code	Description
diag_expl	Diagnostic explanation
advisory	General advice
root_cause	Explaining root cause
directive	Concrete steps or commands
preventive	Prevent future issues
escalate	Escalation or transfer
self_help	Do-it-yourself instructions
partial	Incomplete or partial fix
rejected	Offered but not applied
followup	Future action promised
expect	Sets realistic timelines
reassure	Emotional closure
no_soln	No solution given

5. rep - Repetition

Code	Description
no_rep	No repetition present
cust_self	Customer repeats self
agent_self	Agent repeats self
cust_echo	Customer echoes agent
agent_echo	Agent echoes customer

6.disf - Disfluencies (multi-select)

Code	Description
filled	“uh”, “um”, etc.
silent	Silent pauses
repeat	Word/phrase repetition
false_start	Incomplete start
repair	Self-correction
prolong	Stretched sounds
stutter	Repeated syllables
marker	Discourse filler (“like”, “you know”)
interject	“oh!”, “hmm”
cutoff	Abandoned utterance
placeholder	“sort of”, “you know what I mean”
overlap	Overlapping talk

7. lang - Language Complexity (multi-select)

Code	Description	Example
standard_clear	Clear, direct, and easily understood language.	The default if no other specific complexities are prominently featured.
simple_syntax	Predominantly short, declarative sentences.	"I can help. What is your name? The account is open."
complex_syntax	Long, multi-clause, or convoluted sentences.	"Given the information you've provided, and after checking the system, it appears that the issue, which started last Tuesday, will require a technician to resolve it."
technical_terms	Specialized terms related to a specific domain.	"Modem," "IP address," "deductible," "API endpoint."
industry_jargon	Terms/phrases specific to an industry/company.	"Tier 2 escalation," "SKU," "churn rate," "SOP."
acronyms_abbreviations	Use of shortened forms of words or phrases.	"ASAP," "ID," "ETA," "KYC."
info_dense	Highly concise; packed with specific information.	"Policy AX47 requires form B2, due COB Friday for Q3 processing."
verbose_hedging	Wordy, uses fillers, qualifiers, or vague language.	"Well, you know, it's sort of like, I guess maybe we could perhaps try to see..."
formal_register	Polished, professional, often more structured.	"We wish to inform you...", "It is imperative that..."
informal_colloquial	Conversational, casual, everyday language.	"No worries!", "Gonna check that for ya.", "Awesome!"
empathetic_softening	Language used to show understanding or soften news.	"I understand this must be frustrating...", "Unfortunately...", "I'm afraid..."
abrupt_blunt	Overly direct, lacking typical softeners/politeness.	"No. Can't do that. Next." (Extreme example)
idioms_slang	Figurative expressions or informal slang.	"Bite the bullet", "cool", "spill the beans."
passive_voice_prominent	Significant use of passive voice construction.	"The account was accessed", "A decision will be made." (When frequent)

8. polite - Politeness

Code	Description
none	No politeness cues (no please/thank you/etc.)
minimal	One-off courtesy ("thank you", "please")
standard	Expected level ("please let me know", "thanks for waiting")
elevated	Multiple markers + honorifics ("sir/madam", "kindly")
impolite	Impoliteness cues)

9. urgency - Urgency

Code	Description
none	No urgency language
low	Mild timeframe hints (“when you can”, “at your convenience”)
moderate	Moderate urgency (“soon”, “shortly”)
high	Strong urgency (“ASAP”, “urgent”)
critical	Extreme immediacy (“immediately”, “right now”, “without delay”)

Entity Extraction (Separate Task)
Extract entities from the full transcript, not turn-by-turn. Group into these categories (keys in entity block):

- people
- identifiers
- phone_number
- email
- time_info
- date
- location_info
- products_services
- monetary
- company_organization
- others

User Prompt:
Analyze the following transcript segment:\n<transcript>\n{segment_turns}</transcript>

Prompt for Turn to Proposition Mapping

Your task is to map each turn in a transcript to the summary propositions it expresses.
You will receive:

1. A set of numbered summary propositions.
2. A transcript segment containing turns, each starting with a turn number like "X: Speaker: ...", where X is the turn number.

Your Task:

- For each turn, identify which summary propositions (by their original number) are semantically expressed in that turn.
- A proposition matches a turn if the information in the proposition is present in the turn or can be reasonably inferred from it.
- Focus only on semantic content matching, not other analysis.

Output Requirements:

- Produce a JSON object where:
  - Keys are turn numbers (e.g., `"1"`, `"2"`).
  - Values are lists of 0-based indices of matched summary propositions.
  - If no matches are found for a turn, do not include that turn in the output.
- A proposition can match multiple turns. If so, include its index in each relevant turn.

JSON Format Example:

```
{
  "0": [0, 2],
  "2": [1]
}
```

Example Input:

- Summary Propositions:

```
0. Agent name is Sarah.
1. The sky is blue.
2. The grass looks dead.
```

- Transcript:

```
0: Agent: Hi, I am Sarah. Beautiful blue sky today!
1: Customer: The grass looks dead.
```

Example Output:

```
{
  "0": [0, 1],
  "1": [2]
}
```

User Prompt:

Map the following dialogue turns to the summary propositions:\n<propositions>{summary_proposition_string}</propositions>\n<transcript>{segment_turns}</transcript>

Prompt for Summary Labeling

Your task is to annotate each proposition (atomic-unit of summary) using a fixed set of conversational and linguistic dimensions.
Each proposition is about either the agent or the customer, and may express actions, emotions, or procedural events.
Dimensions (Fixed Order with Short Labels)
Each proposition must be annotated in the following order. Always include all dimensions for each proposition. Use [] for empty values in list-type fields.

Key	Dimension Name	Type
sent	Sentiment	single value
spk	Speaker	single value
topic	Topic Category	single value
agent	Agent Action	single value
sol	Solution Type(s)	list
lang	Language Complexity Patterns	list
polite	Politeness	single value
urgency	Urgency	single value

Output Format

Return a compact JSON object with:

Keys: Proposition index as a string

Values: List of 8 values in **fixed order**: [sent, spk, topic, agent, sol, lang, polite, urgency]

Example

"0": ["very_pos", "customer", "empathy", "ask_info", [], ["simple_syntax"], minimal, high],
"1": ["neutral", "agent", "offers", "give_info", ["advisory"], ["info_dense"], standard, none],
"2": ["very_neg", "agent", "diag", "check_under", ["diag_expl"], ["standard_clear"], elevated, low]

Allowed Values and Glossary

1. sent - Sentiment

Code	Meaning
very_pos	Strongly positive tone
pos	Moderately positive tone
neg	Moderately negative tone
very_neg	Strongly negative tone
info	Information content or presence of factual tokens (dates, names, IDs) – high priority to this over neutral
neutral	Does not have information and contains explicit neutral-emotion cues

2. spk - Speaker

agent, customer, misc

3. topic - Topic Category

Code	Description
greet	Greetings, introductions
id_verif	ID or account verification
issue	Customer's reason for contact
info_gath	Agent probing/investigating
prod_inq	Product or service questions
diag	Diagnosis or troubleshooting
soln	Proposing a solution
action	Performing an action
transact	Payments, refunds, orders
offers	Service offers or upgrades
sales	Sales, upselling, persuasion
resolve_conf	Confirming issue is resolved
next	Next steps, follow-ups
close	Farewell, call closure
empathy	Expressing care or rapport
complaint	Handling complaints/escalation
policy	Explaining rules or terms
feedback	Requesting feedback or surveys
sched	Appointments, scheduling
billing	Billing/payment issues
compliance	Compliance or regulations
misc	Miscellaneous

4. agent - Agent Action

Code	Category	Notes
ask_info	Request Information	"Could you confirm your order?"
give_info	Provide Information	Facts or explanations not tied to a fix
check_under	Confirm Understanding	"Do you see the change on your end?"
rapport	Build Rapport	Empathy, friendliness, thank-you
backchannel	Acknowledgement / Cue	"Uh-huh," "Okay," "Got it."
escalate	Escalate / Transfer Action	"I'm connecting you to billing."
compliance	Compliance / Verification	Identity, policy, legal checks
idle	Passive / No-Op Response	Silence gaps marked or minimal reply
other	Other Conversational Act	Anything else (e.g., small talk)

5. sol - Solution Type (multi-select)

Code	Description
diag_expl	Diagnostic explanation
advisory	General advice
root_cause	Explaining root cause
directive	Concrete steps or commands
preventive	Prevent future issues
escalate	Escalation or transfer
self_help	Do-it-yourself instructions
partial	Incomplete or partial fix
rejected	Offered but not applied
followup	Future action promised
expect	Sets realistic timelines
reassure	Emotional closure
no_soln	No solution given

6. lang - Language Complexity (multi-select)

Code	Description
standard_clear	Clear, direct, and easily understood language.
simple_syntax	Predominantly short, declarative sentences.
complex_syntax	Long, multi-clause, or convoluted sentences.
technical_terms	Specialized terms related to a specific domain.
industry_jargon	Terms/phrases specific to an industry/company.
acronyms_abbreviations	Use of shortened forms of words or phrases.
info_dense	Highly concise; packed with specific information.
verbose_hedging	Wordy, uses fillers, qualifiers, or vague language.
formal_register	Polished, professional, often more structured.
informal_colloquial	Conversational, casual, everyday language.
empathetic_softening	Language used to show understanding or soften news.
abrupt_blunt	Overly direct, lacking typical softeners/politeness.
idioms_slang	Figurative expressions or informal slang.
passive_voice_prominent	Significant use of passive voice construction.

7. polite - Politeness

Code	Description
none	No politeness cues (no please/thank you/etc.)
minimal	One-off courtesy (“thank you”, “please”)
standard	Expected level (“please let me know”, “thanks for waiting”)
elevated	Multiple markers + honorifics (“sir/madam”, “kindly”)
impolite	Impoliteness cues

8. urgency - Urgency

Code	Description
none	No urgency language
low	Mild timeframe hints (“when you can”, “at your convenience”)
moderate	Moderate urgency (“soon”, “shortly”)
high	Strong urgency (“ASAP”, “urgent”)
critical	Extreme immediacy (“immediately”, “right now”, “without delay”)

Important Instructions

* Always include all 8 fields per proposition in the exact order: sent, spk, topic, agent, sol, lang, polite, urgency

* For sol and lang, output a list of applicable codes or an empty list ([]) if none apply.
* Use only the short-form codes provided above.
+
IMPORTANT: You must analyze ALL {len(summary_propositions)} propositions in the list. Do not skip any propositions. " Output a JSON object where keys are proposition indices (0-based, from 0 to {len(summary_propositions)-1}) and values are objects containing: You must include entries for indices 0 through {len(summary_propositions)-1}.
User Prompt: 'Please analyze the sentiment and determine the speaker for ALL {len(summary_propositions)} propositions below. '
'Make sure to include entries for indices 0 through {len(summary_propositions)-1}:\n\n{summary_propositions}'

F Bias Mitigation

To demonstrate that the fine-grained analysis provided by our *BlindSpot* framework is actionable, we conducted a preliminary experiment in bias mitigation. The goal was to use the specific, systemic biases identified in our main analysis to construct a targeted system prompt and then measure its impact on model behavior.

F.1 Constructing a Targeted System Prompt

Our main findings revealed consistent patterns of bias across most models, such as over-representing negative sentiment while under-representing agent rapport-building and resolution steps from the middle of the conversation. Based on these insights, we constructed a single, detailed system prompt designed to explicitly counteract these observed tendencies.

The prompt, shown in full in Box F.1, instructs the model to focus on high-fidelity, balanced summarization and provides a checklist of "Correction and Balancing Guidelines." These guidelines directly map to the bias dimensions where we observed the most significant issues, such as *Sentiment Balance*, *Positional Coverage*, and *Topic and Activity Coverage*. By making the model explicitly aware of its potential blind spots, we hypothesized that we could steer its summarization process towards a more faithful representation of the source transcript.

Constructed System Prompt for Bias Mitigation

Your task is to summarize the following dialog with a focus on high fidelity and balance. Based on an analysis of previous outputs, apply the following corrections to ensure a more accurate and balanced summary.

Correction and Balancing Guidelines

1. **Sentiment Balance:**
   - Ensure both positive and negative sentiments are represented if they appear in the transcript.
   - **Specifically Include:** Positive sentiments expressed by the customer, especially those related to agreement or satisfaction with a solution.
2. **Speaker Representation:**
   - Provide a balanced representation of contributions from both the customer and the agent.
   - **Specifically Include:** Key agent responses, clarifying questions, and de-escalation efforts.
3. **Positional Coverage:**
   - Draw information equitably from all parts of the conversation.
   - **Specifically Include:** Details from the Mid, Late, and Very Late segments of the conversation, which often contain resolution steps and final agreements.
4. **Topic and Activity Coverage:**
   - Broaden the scope of topics and activities included in the summary.
   - **Topics to Include:** Information gathering/probing by agent, Call closure, ID verification, and Expression of empathy.
   - **Agent Activities to Include:** Rapport-building, Asking for information, and Checking for understanding.
5. **Solution and Repetition Types:**

- **Solution Types:** Ensure representation of directive solutions (concrete, actionable steps).
- **Repetition Types:** Include all forms of significant repetition, such as:
  - customer repeating self,
  - agent repeating customer, and
  - customer repeating agent.

6. **Linguistic and Structural Elements:**

   - **Disfluencies:** Include meaningful interjections (oh!, hmm) and incomplete starts if they indicate hesitation or a change of thought.
   - **Turn Length:** Represent information from both very long and very short conversational turns if they are relevant.
   - **Chronological Order:** Narrate events in the sequence they occurred in the transcript. Do not reorder them.

7. **Factual and Emotional Fidelity:**

   - **Entity Representation:** Include a wider range of entities beyond people and organizations.
   - **Specifically Include:** Dates, Locations, Product/Case IDs, Monetary values, Times, Phone numbers, and Emails.
   - **Emotional Tone:** Reflect the emotional state of the speakers accurately. Avoid amplifying, attenuating, or neutralizing emotions expressed in the transcript.

Final Instruction
Produce a summary of the following dialog that strictly adheres to all the guidelines above. The final output should be a balanced, factually accurate, and structurally faithful representation of the original conversation.

F.2 Examples

Summary from `nova-pro`:

Original Summary

In the conversation, the customer, [CUSTOMER NAME], discusses issues with a purchased product, specifically unit number [UNIT NUMBER]. [CUSTOMER] highlights problems such as leakage, mismatched parts indicating prior damage, and concerns about the product's condition upon pickup. [AGENT NAME], the agent, acknowledges the issues and assures [CUSTOMER] that he will escalate the matter to his boss for a quicker resolution. They also touch on another unit, [UNIT NUMBER], which is ready but won't be paid for until the current issue is resolved. [AGENT] promises to call [CUSTOMER] back after discussing the matter with his boss.

Improved Summary

In the conversation between [CUSTOMER NAME] (customer) and [AGENT_NAME] (agent), [CUSTOMER] initially expressed satisfaction with [AGENT]'s assistance regarding a $[MONEY] issue. [AGENT] confirmed the unit number [UNIT NUMBER] and inquired about its current location and the post-sale service status, which [CUSTOMER] confirmed as in his yard and already handled.
Regarding the second email, [CUSTOMER_NAME] elaborated on a product issue. [AGENT_NAME] empathized with [CUSTOMER_NAME]'s situation, especially his frustration with the service provided. [CUSTOMER_NAME] detailed his concerns about the product's condition, specifically mentioning a leak and mismatched parts indicating prior damage.
[AGENT_NAME] assured [CUSTOMER_NAME] that body issues like mismatched colors were not significant but acknowledged [CUSTOMER_NAME]'s dissatisfaction with the service experience. [AGENT_NAME] committed to scheduling a pickup for the product and addressing the unresolved issues with higher priority. He assured [CUSTOMER_NAME] that he would follow up after consulting with his boss, [MANAGER_NAME]. [CUSTOMER_NAME] agreed to wait for [AGENT_NAME]'s call, expressing gratitude for the efforts to resolve the problem. The conversation ended with mutual acknowledgment of the steps to be taken, highlighting [AGENT_NAME]'s efforts to de-escalate and resolve [CUSTOMER_NAME]'s concerns.

Summary from `claude-4-sonnet`:

Original Summary

Customer Issue: [CUSTOMER] called because she was locked out of her [ORG] account. Her phone automatically logged her into an old account from a previous employer ([ORG]) instead of her current employer's account ([ORG]), and she couldn't reset her password.
Key Problems Identified: - Customer has two [ORG] accounts (old and current employer) - Current account has her work phone number on file instead of personal number - App is requesting facial recognition instead of her usual PIN - Cannot access funds and needs money urgently
Account Details: - Current employer: [ORG] - Email: [EMAIL] - Personal phone: [PHONE] - Work phone on file: [PHONE] (business number, inaccessible after hours) - Debit card ending.
Resolution Process: Agent [AGENT] explained that to update the phone number and regain access, [CUSTOMER] must: 1. Provide recent pay stub and government ID photo via email 2. Wait up to 12 hours for the verification department to process 3. Cannot access account until verification is complete
Outcome: Email sent to customer with document requirements. Customer frustrated about the delay but agreed to provide requested documentation to regain account access.

Improved Summary

Customer Issue: [CUSTOMER] called [ORG] because she was locked out of her account and unable to reset her password to access her money for immediate needs like gas.
Account Verification Process: Agent Christian initially verified [CUSTOMER]'s identity using her full name ([CUSTOMER]), email ([EMAIL]), and phone number ([PHONE]). However, this information pulled up an old, cancelled account with her former employer Empress Healthcare.
Multiple Account Confusion: [CUSTOMER] explained she has two [ORG] accounts - one from a previous employer and a current active account with her new employer "Take" (started in [DATE]). She was frustrated because her phone had automatically logged her into the old account, and she couldn't access her current account.
Current Account Identification: After some confusion and [CUSTOMER] expressing frustration ("you're have to like i'm calling you for help dude"), the agent located her active account using: - Alternative email: [EMAIL] - Last four digits of debit card. - Employer: [ORG]
Core Problem Discovered: The active account had [CUSTOMER]'s work phone number ([PHONE]) on file instead of her personal number ([PHONE]). Since the work number belonged to a closed business, she couldn't receive password reset texts.
Customer Emotional State: [CUSTOMER] became increasingly panicked and frustrated throughout the call, stating "i'm panicking," "this is ridiculous," and expressing urgent need for money access. The agent apologized multiple times and reassured her: "it's okay take your time" and "i'm so sorry."
Resolution Process: Since [CUSTOMER] couldn't access the work phone number for verification, the agent explained she would need to follow a document verification process: 1. Agent would email [CUSTOMER] requesting two documents 2. [CUSTOMER] must provide a recent pay stub and government ID photo 3. Processing time: 12 hours after submission 4. Documents can be submitted as pictures
Call Conclusion: The agent sent the verification email to [EMAIL] during the call. [CUSTOMER] confirmed receipt and understood she needed to reply with photos of her pay stub and ID. The agent confirmed all information was clear and that [CUSTOMER]'s questions were answered.
Technical Note: [CUSTOMER] also mentioned the app was requesting facial recognition instead of her usual PIN, but the agent explained this was a device-level issue they couldn't directly address.

Summary from `o4-mini`:

Original Summary

The customer, [CUSTOMER NAME], called [ORG] because she was locked out of her current employer's account and kept being routed to an old account tied to a previous employer. After providing her name, two different email addresses, phone number, and the last four digits of her new debit card, the agent confirmed she was logged into the canceled (old) account. [CUSTOMER] wanted a simple password reset but couldn't access the reset link because the account's phone number on file belonged to her former employer. The agent explained that to change the phone number and regain access, [CUSTOMER] must email back two documents—a recent pay stub and a photo of her government ID—which the agent just sent instructions for. Once [CUSTOMER] replies with those documents, the account-update team will process her request (within about 12 hours), at which point she can reset her password, log back into her active account, and access her funds.

Improved Summary

The call begins with the agent, [AGENT NAME], greeting [CUSTOMER NAME] and requesting her full name for account verification. [CUSTOMER NAME] provides her name, email ([EMAIL]), and phone number ([PHONE NUMBER]), but then explains she has two [ORG] accounts—one linked to an old employer ([ORG]) and one to her current employer—and that she's inadvertently been logged into the wrong one.

Mid-call, the agent confirms [CUSTOMER]'s details match the [ORG] account, which [CUSTOMER] no longer uses. She asks if the agent can locate her new account by email or phone; the agent searches but finds only the old account's phone number (a business line ending in [PHONE NUMBER]). [CUSTOMER] grows frustrated ("I'm panicking… I don't understand your system") when she cannot reset her password by SMS or facial recognition. The agent apologizes for her difficulty and empathy is expressed, but explains that policy requires removal of the old phone number before updating to her current one.

To resolve this, the agent directs [CUSTOMER] to complete identity verification via email. He will send a secure request to [EMAIL] asking for: 1) a government-issued photo ID and 2) a recent pay stub from her new employer. Once she replies, the back-office team will update her phone number and unlock her password reset flow. [CUSTOMER] confirms receipt of the email, asks about timing, and the agent notes the update can take up to 12 hours after her submission. [CUSTOMER] accepts this plan and thanks the agent.

Throughout the call, the agent probes for the correct employer name, employee ID, and last four digits of her bank debit card to confirm the right account, practices de-escalation ("take your time," "I'm sorry you're frustrated"), and provides clear, directive next steps. [CUSTOMER] expresses both frustration at system limitations and relief at having a concrete path to regain access to her wages. The call closes with the agent asking if her questions were answered and [CUSTOMER] replying, "Yes, thank you."

HierDiffuse: Progressive Diffusion for Robust Interest Fusion in CTR Prediction

Ziheng Ni*,Congcong Liu*†, Yuying Chen,
Zhiwei Fang, Changping Peng, Zhangang Lin, Ching Law, Jingping Shao
Correspondence: liucongcong25@jd.com

Abstract

Modern recommendation systems grapple with reconciling users' enduring preferences with transient interests, particularly in click-through rate (CTR) prediction. Existing approaches inadequately fuse long-term behavioral profiles (e.g., aggregated purchase trends) and short-term interaction sequences (e.g., real-time clicks), suffering from representational misalignment and noise in transient signals. We propose HierDiffuse, a unified framework that redefines interest fusion as a hierarchical denoising process through diffusion models. Our approach addresses these challenges via three innovations: (1) A cross-scale diffusion mechanism aligns long- and short-term representations by iteratively refining long-term interests using short-term contextual guidance; (2) A Semantic Guidance Disentanglement (SGD) mechanism explicitly decouples core interests from noise in short-term signals; (3) Trajectory Convergence Constraint (TCC) is proposed to accelerate diffusion model reasoning without reducing generation quality to meet the constraints of high QPS (Queries Per Second) and low latency for online deployment of recommendation or advertising systems. HierDiffuse eliminates ad-hoc fusion operators, dynamically integrates multi-scale interests, and enhances robustness to spurious interactions as well as improves inference speed. Extensive experiments on real-world datasets demonstrate state-of-the-art performance, with significant improvements in CTR prediction accuracy and robustness to noisy interactions. Our work establishes diffusion models as a principled paradigm for adaptive interest fusion in recommendation systems.

1 Introduction

Modern recommendation systems and advertising systems face a fundamental tension: how to reconcile users' enduring preferences with their momentary interests. This challenge manifests acutely in click-through rate (CTR) prediction(Zhou et al., 2018; Liu et al., 2022a,b, 2023; Sang et al., 2025a,b), where the interplay between long-term behavioral patterns and short-term contextual signals determines recommendation relevance (Zhou et al., 2018). While existing approaches have made progress in modeling these temporal scales independently (Chen et al., 2019), their fusion remains an open problem with significant implications for real-world performance.

A critical limitation stems from representational misalignment: long-term models rely on aggregated behavioral profiles (e.g., monthly purchase trends), whereas short-term models process fine-grained interaction sequences (e.g., real-time clicks). This mismatch in feature granularity renders conventional late fusion operators ineffective (He et al., 2023). For instance, when a fitness enthusiast suddenly browses dessert recipes, the system fails to adapt recommendations because static long-term preferences dominate transient contextual signals. Moreover, the signal-to-noise trade-off in short-term behavior remains unresolved. While recent interactions provide valuable contextual cues, they also introduce spurious noise (e.g., accidental clicks or exploratory browsing). Without principled noise suppression, fusion mechanisms struggle to distinguish meaningful signals from ephemeral fluctuations (Hochreiter and Schmidhuber, 1997). These limitations highlight the need for a unified modeling framework that jointly optimizes multi-scale interest representation and adaptive fusion.

In this paper, we propose **HierDiffuse**, a framework that reconceptualizes interest fusion as a hierarchical denoising process. Our key insight is that the diffusion paradigm naturally addresses all challenges through its unique combination of iterative refinement and conditional generation: For

representation alignment and joint modeling, we formulate a cross-scale diffusion process where short-term interests guide the gradual denoising of long-term representations through intermediate latent states. For *noise robustness*, **Semantic Guidance Disentanglement (SGD)** mechanism achieves interest perturbation decoupling through explicit decomposition of core interests and random noise. Meanwhile, it is well known that the diffusion model has a high computational cost, especially its reasoning process, which is contrary to the requirements of *high QPS and low latency* of online systems. We proposed **Trajectory Convergence Constraint (TCC)** to accelerate reasoning without reducing production effects, thereby meeting the requirements of online deployment.

There are several contributions of our work:

- **Unified Fusion Framework**: By treating fusion as conditional generation, we eliminate the need for ad-hoc combination operators and their inherent linearity constraints.
- **Interest-Perturbation Disentanglement**: SGD realizes interest-perturbation decoupling regulation.
- **Online Deployment Optimization**: TCC significantly reduces the inference cost of HierDiffuse without compromising the generation effect.
- **Empirical Validation**: Comprehensive experiments have achieved better results than the baseline, demonstrating practical viability.

2 Related Work

Traditional approaches to user behavior modeling typically bifurcate user behaviors into separate long-term and short-term sequences, employing distinct architectures for each. Long-term modeling has evolved from RNNs (Hidasi et al., 2016) to sophisticated attention mechanisms (Zhou et al., 2019) with noise handling capabilities (Cao et al., 2022), while short-term modeling leverages transformer variants (Xia et al., 2023) and graph networks (Wu et al., 2019) to capture session dynamics. However, this artificial separation creates a fundamental disconnect in modeling the continuous spectrum of user interests, where behaviors naturally transition between temporal scales.

Current interest fusion techniques attempt to bridge this gap through concatenation (Zhou et al., 2018), cross-scale attention (Li et al., 2019), or gating networks (Lv et al., 2019). While these methods have advanced the field, they universally treat fusion as a post-hoc combination step constrained by linear interaction assumptions. This limitation becomes particularly apparent when handling misaligned feature spaces between temporal scales or disentangling meaningful signals from transient noise in short-term behaviors. Recent attempts to apply diffusion models in recommendations (Wang et al., 2023; Li et al., 2023) have shown promise in denoising user behaviors, but focus narrowly on single-scale sequences without addressing the core fusion challenge.

Meanwhile, existing studies of diffusion recommendation systems like DMCDR (Li et al., 2025) and DreamRec (Yang et al., 2023) overlook the online deployment challenges caused by the diffusion model's inherent computational complexity, despite its fundamental importance for real-world applications.

3 Methodology

Fig.1 briefly illustrates the overall framework of the proposed **HierDiffuse**. It receives the output from the transformer-based long-term behavior sequence encoder and the short-term behavior sequence encoder, and uses the generated representation for the downstream CTR prediction task through the diffusion process. HierDiffuse introduces two new modules: **SGD** and **TCC**, which are used for interest perturbation decoupling of guidance and and diffusion reasoning acceleration, respectively.

3.1 Preliminaries

We formalize user behavior sequence modeling through dual-sequence representation learning. Given a user's *long-term behavior sequence* $\mathcal{B}^L = \{b_i^L\}_{i=1}^M$ and *short-term session sequence* $\mathcal{B}^S = \{S_k\}_{k=1}^K$ where $S_k = \{b_j^S\}_{j=1}^{n_k}$, we construct long-term encoder $\mathbf{h}^L = f_L(\mathcal{B}^L) \in \mathbb{R}^{d_L}$, and short-term encoder: $\{\mathbf{h}_k^S\}_{k=1}^K = f_S(\mathcal{B}^S) \in \mathbb{R}^{d_S}$. The fusion objective learns $\mathcal{F}_\theta : (\mathbf{h}^L, \{\mathbf{h}_k^S\}) \mapsto \mathbf{h}^{fusion}$ through a diffusion process. Our key innovation reformulates this as conditional denoising:

$$\mathbf{h}^{fusion} = \text{Denoise}(\mathbf{h}^L \oplus \epsilon_T, \{\mathbf{h}_k^S\}) \quad (1)$$

where $\epsilon_T \sim \mathcal{N}(0, \mathbf{I})$ and $\oplus$ denotes noise injection.

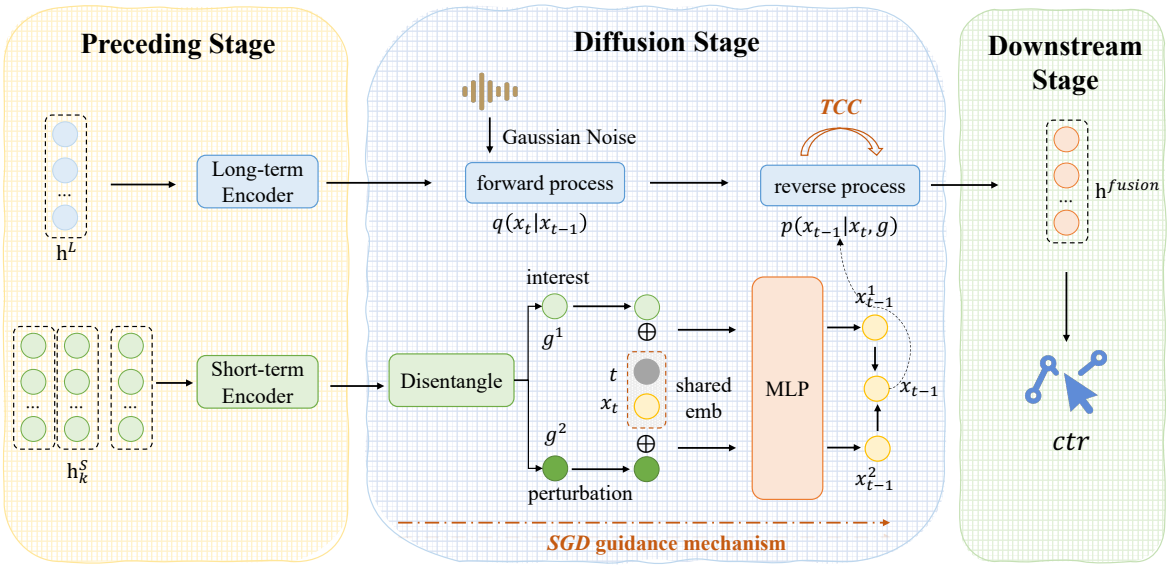

Figure 1: The framework of the proposed HierDiffuse.

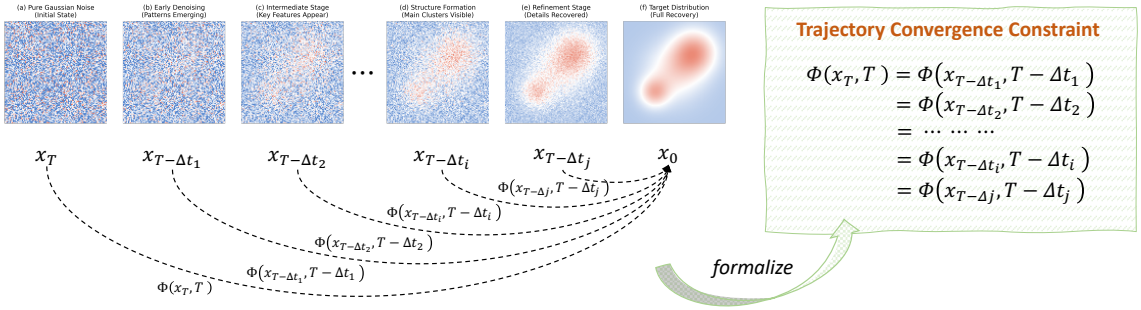

Figure 2: The process of the proposed Trajectory Convergence Constraint (**TCC**).

3.2 Diffusion Process in User Interest Modeling

Our framework consists of a forward noising process and a conditional reverse process.

Forward Process Gradually adds Gaussian noise to the latent representation $\mathbf{h}^L$ over T steps:

$$q(\mathbf{x}_t|\mathbf{x}_{t-1}) = \mathcal{N}(\mathbf{x}_t; \sqrt{1-\beta_t}\mathbf{x}_{t-1}, \beta_t\mathbf{I}) \quad (2)$$

where $\mathbf{x}_0 = \mathbf{h}^L$ and β_t controls the noise scale.

Reverse Process In order to reduce computational overhead, we perform average pooling on the short-term interests of multiple sessions, as shown in Eq. (3).

$$\mathbf{h}^S = \text{AvgPooling}(\{\mathbf{h}_k^S\}) \quad (3)$$

Then we learn to denoise while conditioned on short-term behaviors $\mathbf{h}^S$:

$$p_\theta(\mathbf{x}_{t-1}|\mathbf{x}_t, \mathbf{h}^S) = \mathcal{N}(\mu_\theta(\mathbf{x}_t, t, \mathbf{h}^S), \Sigma_t) \quad (4)$$

The network μ_θ integrates current state $\mathbf{x}_t$, timestep t and short-term behaviors $\mathbf{h}^S$. In practice, we implement it through Multi-Layer Perceptron (MLP) based on computational complexity considerations. Starting from $\mathbf{x}_T \sim \mathcal{N}(0, \mathbf{I})$, the process performs T iterative refinements guided by behavioral contexts following the DDPM (Ho et al., 2020) paradigm, enabling joint modeling of long-term and short-term user patterns.

3.3 Semantic Guidance Disentanglement

In CTR prediction systems, user behavior sequences often exhibit complex semantic patterns where different interactions carry varying levels of information reliability and predictive value. Traditional conditional guidance approaches, such as the CFG framework (Ho and Salimans, 2022), address this through a uniform scaling mechanism:

$$\hat{\epsilon}_\theta(x_t, t, g) = (1-\omega)\epsilon_\theta(x_t, t) + \epsilon_\theta(x_t, t, g) \quad (5)$$

While effective in simple scenarios, this homogeneous scaling strategy fails to capture the semantic heterogeneity inherent in real-world user behaviors. We observe that user interactions naturally form distinct semantic categories, for example, niche item clicks that reflect strong personal preferences versus trend-driven clicks that indicate broader interests. These semantic categories exhibit different information densities and noise characteristics, necessitating differentiated treatment in the guidance process.

To address this semantic imbalance, we propose **SGD (Semantic Guidance Disentanglement)** that extends conditional guidance through semantic-aware decomposition. SGD is grounded in the insight that semantically independent guidance conditions where $p(y_1, y_2 \mid x_t) = p(y_1 \mid x_t)p(y_2 \mid x_t)$ enable natural factorization of the conditional score function. This leads to our reformulated guidance mechanism:

$$\nabla_{x_t} \log p(x_t \mid y_1, y_2) = (1 - \omega_1 - \omega_2)\nabla_{x_t} \log p(x_t) + \omega_1 s_1(x_t, y_1) + \omega_2 s_2(x_t, y_2) \tag{6}$$

where $s_i(x_t, y_i) = \nabla_{x_t} \log p(y_i \mid x_t)$ represents the semantic guidance direction for condition y_i, and $\omega_i \geq 0$ denotes its adaptive scaling factor. SGD enable each guidance component $s_i(x_t, y_i)$ to capture the distinct semantic characteristics of its corresponding behavior category. The scaling factors ω_i dynamically adjust based on the information density and reliability of each semantic category. And the additive structure naturally accommodates multiple semantic conditions without interference.

3.4 Trajectory Convergence Constraint

Diffusion models generate data through iterative denoising, requiring about 100 to 1000 neural function evaluations (NFEs). While methods like DDIM (Song et al., 2020) reduce steps via non-Markovian processes, they remain bound to sequential computation. We propose a novel **Trajectory Convergence Constraint (TCC)** method as shown in Figure 2 that accelerates generation by learning deterministic mappings from any noisy sample to the target distribution. The reverse diffusion trajectory inherently contains redundant steps due to Markovian assumptions. We hypothesize that a *deterministic mapping* from any noisy state x_t to the target x_0 can be learned while preserving distributional fidelity.

Given a diffusion process $\{x_t\}_{t=0}^{T}$, we define the ideal trajectory $\Gamma(x_0)$ terminating at x_0. For any $x_t, x_{t'} \in \Gamma(x_0)$, we enforce:

$$\Phi(x_t, t) = \Phi(x_{t'}, t') \quad \forall t, t' \in [0, T] \tag{7}$$

where Φ is our learned mapping network. We parameterize Φ as $f_\theta(x_t, t)$ with loss:

$$\begin{aligned} \mathcal{L}(\theta) = & \underbrace{\mathbb{E}_{x_0,t} \| f_\theta(x_t, t) - x_0 \|_2^2}_{\text{Reconstruction}} \\ & + \lambda \underbrace{\| f_\theta(x_t, t) - f_\theta(\hat{x}_{t-\Delta_t}, t - \Delta_t) \|_2^2}_{\text{Trajectory Regularizer}} \end{aligned} \tag{8}$$

where $\hat{x}_{t-\Delta_t}$ is the intermediate state obtained by forward diffusing from x_t to step $t - \Delta_t$, and the convergence of the trajectory is achieved by constraining the stability of adjacent mappings.

Under Lipschitz continuity ($\| f_\theta(x) - f_\theta(y) \| \leq L \| x - y \|$), the approximation error decays exponentially:

$$\| x_0 - f_\theta(x_t) \| \leq C \cdot e^{-\alpha t} \tag{9}$$

which shows that it is possible to approximate x_0 by a finite-step mapping. TCC is equivalent to learning a deterministic probability flow ODE in Wasserstein space, whose solution curve is asymptotically consistent with the true reverse trajectory of the diffusion model, but skips the numerical integration process through explicit mapping.

4 Experiment

In this section, we describe how we conduct our experiments of the proposed HierDiffuse for user interest modeling in CTR prediction task. Using the user feedback collected from a real-world online advertising platform, we train the CTR models and conduct offline experiments against various baselines.

4.1 Experimental Settings

4.1.1 Datasets

We performed experiments on several benchmark datasets, including the Amazon Book Dataset[1] (McAuley et al., 2015) and Taobao Dataset[2], both of which are extensively utilized in behavior sequence modeling studies. Additionally, we incorporated a real-world industrial dataset obtained from a major e-commerce platform. For public datasets, the Amazon Book dataset comprises

[1] http://jmcauley.ucsd.edu/data/amazon/

[2] https://tianchi.aliyun.com/dataset/649

Table 1: Model performance (AUC) on three datasets. The best results are highlighted in bold.

Model	Amazon	Taobao	Industrial
Avg-Pooling DNN	0.7689	0.8539	0.7512
DIN	0.7862	0.8995	0.7564
DIEN	0.8377	0.9222	0.7611
DiffuRec	0.8395	0.9258	0.7607
DreamRec	0.8421	0.9286	0.7619
HierDiffuse	**0.8472**	**0.9327**	**0.7680**

75,053 users, **358,367** items, and **150,016** interaction samples. In comparison, the Taobao dataset is significantly larger, containing **7,956,431** users, **34,196,612** items, and **7,956,431** samples. For the industrial dataset, we use real 14-day exposure samples for training and the 15th-day samples for evalution.

4.1.2 Evaluation Metrics

We use **AUC** as the evaluation metric, which is widely used in CTR estimation tasks (Pi et al., 2020; Zhou et al., 2018). Notably, in CTR prediction scenarios, even a 0.001 AUC gain is considered practically significant (Zhou et al., 2018, 2019). At the same time, we use the number of batches inferred per second to measure the model time consumption (Chang et al., 2023; Si et al., 2024).

4.1.3 Implementation Details

We perform training and inference using A100 GPUs. For **noise scheduling**, we adopt a cosine-based approach to ensure stable and effective noise scaling throughout the process:

$$\bar{\alpha}_t = \frac{\cos\left(\frac{\pi}{2} \cdot \frac{t/T+s}{1+s}\right)}{\cos\left(\frac{\pi}{2} \cdot \frac{s}{1+s}\right)} \tag{10}$$

$$\alpha_t = \frac{\bar{\alpha}_t}{\bar{\alpha}_{t-1}}, \quad \beta_t = 1 - \alpha_t \tag{11}$$

Meanwhile, we adopt a **progressively increasing span sampling** strategy to handle Δt during TCC training: initially constrained to small spans ($\Delta t \leq 0.1T$) to stabilize early learning, then gradually expanded to uniformly cover medium spans ($\Delta t \sim \mathcal{U}(0.1T, 0.5T)$) as training progresses. This curriculum learning approach ensures smooth initial convergence before tackling harder long-span predictions.

Concurrently, the trajectory regularizer loss weight λ follows a **linear decay schedule** from 1.0 to 0.2, prioritizing cross-step alignment in early phases while progressively shifting focus to single-step accuracy. The complementary scheduling of Δt and λ creates a balanced transition from strict trajectory preservation to final output quality optimization.

4.2 Baselines

We benchmark our model against prominent baseline algorithms including Avg-Pooling DNN, DIN (Zhou et al., 2018), DIEN (Zhou et al., 2019), DiffuRec (Li et al., 2023), and DreamRec (Yang et al., 2023).

4.3 Offline Experiment

4.3.1 Comparing to Baseline Methods

Table 1 shows the comparisons of the proposed method with various baselines. From the table, we can see the proposed method HierDiffuse outperforms baseline methods by leveraging diffusion models for superior CTR prediction, capturing complex user dynamics and noise robustness, while its SGD module and trajectory convergence constraint design further enhance performance across diverse datasets.

4.3.2 Ablation Study

We conducted extensive ablation experiments to demonstrate the necessity of each component of HierDiffuse. Table 2 illustrate the performance of each component including guidance method choice (ablation of SGD method, comparison between SGD and custom CFG (Ho and Salimans, 2022)), reverse backbone choice for μ_θ, diffusion direction, loss function and using TCC method or falling back to DDPM (Ho et al., 2020) or DDIM (Song et al., 2020). It is clear to see that:

Table 2: Ablation Study on Industrial Dataset. Δ shows relative AUC vs our method. Infer. shows the number of batches inferred per second.

(a) Guidance Method

Variant	AUC	Δ	Infer.
w/ CFG	0.7663	↓0.0017	**16.9**
w/ SGD (ours)	**0.7680**	-	16.1

(b) Reverse Backbone

Variant	AUC	Δ	Infer.
w/ Transformer	0.7684	↑0.0004	14.8
MLP (ours)	**0.7680**	-	16.1

(c) Loss Function

Variant	AUC	Δ	Infer.
w/o $\mathcal{L}_{Recon}$	0.7629	↓0.0051	16.2
w/o $\mathcal{L}_{TR}$	0.7669	↓0.0011	16.4
ours	**0.7680**	-	16.1

(d) TCC Method

Variant	AUC	Δ	Infer.
w/ DDPM	0.7682	↑0.0002	9.98
w/ DDIM	0.7681	↑0.0001	13.01
ours	**0.7680**	-	16.1

(e) Diffusion Direction

Variant	AUC	Δ	Infer.
+Short→ ϕ	0.7640	↓0.0040	15.7
+Long→ ϕ	0.7644	↓0.0036	15.5
+Short→Long	0.7647	↓0.0033	16.0
+Long→Short (ours)	**0.7680**	-	16.1

1. **Guidance Method Choice**: *SGD* module outperforms CFG (Ho and Salimans, 2022) via effective perturbation-interest disentanglement.

2. **Reverse Backbone Choice**: *Employing a transformer backbone for reverse process yields a marginal AUC gain but fails to compensate for the added computational overhead from extended training and inference.* This likely stems from the fact that user interests have already been comprehensively modeled in preceding stages. Consequently, the diffusion stage only requires focus on interest fusion, where even the modest nonlinearity of a simple MLP proves sufficient.

3. **Diffusion Direction**: The *Long→Short* denoising paradigm (*the results of the **Full Model** in Table 2*) with hybrid losses yields optimal performance by progressively refining stable long-term interests with dynamic short-term guidance.

4. **Loss Function**: Both the reconstruction loss $\mathcal{L}_{Recon}$ and trajectory regularizer loss $\mathcal{L}_{TR}$ demonstrate statistically significant positive impacts on both user interest fusion and AUC performance enhancement.

5. **Using of TCC Method**: *TCC* method significantly accelerates inference. Removing this module and switching to a multi-step generation paradigm (e.g., DDPM (Ho et al., 2020) or DDIM (Song et al., 2020)) fails to deliver meaningful AUC gains while drastically degrading inference performance.

Overall, the ablation results show that removal of any component causes significant performance drops, confirming their complementary roles in modeling complex user behavior dynamics.

5 Conclusion

We presented **HierDiffuse**, a unified framework that reformulates user interest fusion systems as a denoising process. By integrating **SGD** for noise-robust disentanglement and **TCC** for diffusion reasoning accelerating, our approach effectively bridges the gap between long-term preferences and short-term signals. Experiments demonstrate significant improvements over existing methods, offering both theoretical insights and practical benefits for adaptive interest fusion, while also providing a solution to the problem of reasoning constraints for diffusion models used for sequence modeling in production settings.. Future work may explore extensions to multi-modal settings and finer-grained

interest decomposition. HierDiffuse provides a principled and scalable solution to a core challenge in modern user interest modeling.

6 Limitations

While HierDiffuse demonstrates strong performance in CTR prediction and offers a principled approach to interest fusion, several limitations remain to be addressed in future work. Computationally, the training phase remains resource-intensive despite our efficient TCC inference. The Semantic Guidance Disentanglement (SGD) may not fully capture the nuance in highly ambiguous user behaviors, and its performance in domains with extremely sparse data requires further validation. In terms of broader impact, as a data-driven model, it risks amplifying historical biases from the training data, potentially reinforcing filter bubbles without explicit fairness constraints.

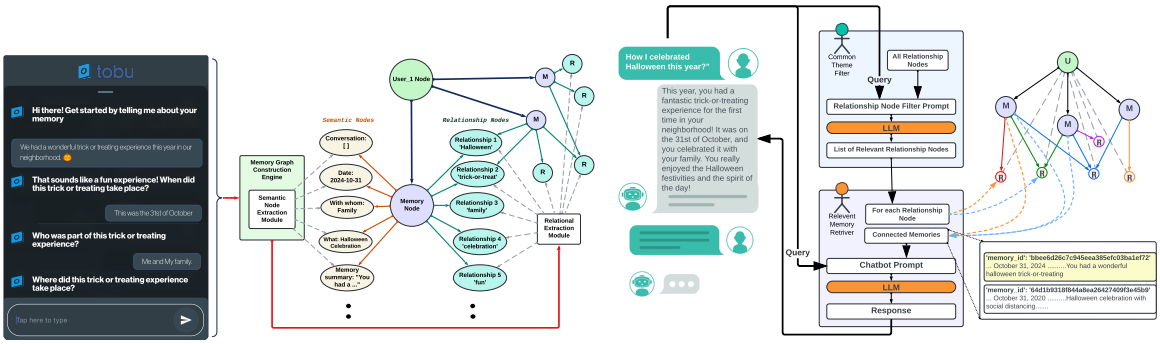
Abstract

Retrieval-Augmented Generation (RAG) is one of the leading and most widely used techniques for enhancing LLM retrieval capabilities, but it still faces significant limitations in commercial use cases. RAG primarily relies on the query-chunk text-to-text similarity in the embedding space for retrieval and can fail to capture deeper semantic relationships across chunks, is highly sensitive to chunking strategies, and is prone to hallucinations. To address these challenges, we propose **TOBUGraph**, a graph-based retrieval framework that first constructs the knowledge graph from unstructured data dynamically and automatically. Using LLMs, TOBUGraph extracts structured knowledge and diverse relationships among data, going beyond RAG's text-to-text similarity. Retrieval is achieved through graph traversal, leveraging the extracted relationships and structures to enhance retrieval accuracy. This eliminates the need for chunking configurations while reducing hallucination. We demonstrate TOBUGraph's effectiveness in **TOBU**, a real-world application in production for personal memory organization and retrieval. Our evaluation using real user data demonstrates that TOBUGraph outperforms multiple RAG implementations in both precision and recall, significantly enhancing user experience through improved retrieval accuracy.

1 Introduction

Integrating Large Language Models (LLMs) with external knowledge sources improves retrieval accuracy and enhances reliability (Niu et al., 2024). The state-of-the-art approach for such integration is Retrieval Augmented Generation (RAG) (Lewis et al., 2021; Gao et al., 2024). Traditional RAG preprocesses documents by chunking text and storing the chunks in a vector database. During retrieval, it retrieves the top-ranked chunks based on vector similarity, and an LLM leverages those selected chunks to generate a response accordingly.



While traditional RAG-based approaches allow LLMs to incorporate external knowledge, this methodology faces several key limitations:

- RAG relies on query-chunk similarity in vector embeddings, comparing the query to each chunk individually without capturing broader contextual connections among text chunks. However, in many domains, data can be interconnected. Failing to represent and leverage such relationships and structures beyond text-to-text similarity across multiple chunks often leads to low retrieval accuracy by RAG (Peng et al., 2024).
- Chunking and embedding strategies, such as chunk length and overlap size can significantly affect retrieval performance (Qu et al., 2024).
- When relevant chunks do not exist in the database for a given query, RAG may hallucinate (Huang et al., 2025).

Indeed, our evaluation of RAG approaches using production data in a real-world application clearly highlights these limitations (Section 3).

To address these limitations, it is important to uncover the relationships among unstructured data and leverage such relationships to improve retrieval performance. A promising approach is to structure data as knowledge graphs (Su et al., 2024; Hogan et al., 2021). Prior work (Jin et al., 2024; Wu et al., 2024b) introduces a graph-augmented

Figure 1: (a) Memory capturing workflow and (b) Memory retrieving workflow in TOBUGraph framework implemented in TOBU app.

retrieval technique that uses LLM reasoning over the knowledge graph through a chain-of-thought process. While this approach enhances retrieval, it assumes the existence of a predefined knowledge graph and overlooks its construction, which remains labor-intensive and lacks adaptability to dynamic data (Hofer et al., 2024). Designing a holistic graph-based retrieval framework that enables automatic knowledge graph construction and graph-based retrieval that captures deeper semantic relationships remains an open challenge.

In this work, we propose TOBUGraph, a novel graph-based retrieval augmentation framework. TOBUGraph leverages LLMs to automatically construct a knowledge graph from unstructured data. Unlike traditional RAG that stores data chunks in a vector database and compares query-chunk's text similarly, TOBUGraph extracts structured knowledge and diverse relationships among data and represents the structures and connections of data in a graph. Our novel graph structure is composed of **semantic nodes**, representing the key semantic information of data chunks, and **relationship nodes**, to represent diverse semantic relationships between semantic nodes. During retrieval, TOBUGraph leverages relationship nodes to prune irrelevant data and prioritize the retrieval on highly relevant data, improving retrieval precision. By traversing the pruned graph of all relevant interconnected nodes, we mitigate the limitations of traditional chunking and ensure completeness and high recall for the retrieval.

We implemented TOBUGraph in a real-world application called TOBU, designed for storing and retrieving personal memories. We define "personal memory" as user-provided images and videos coupled with details, context and narratives around them. When users upload an image, TOBUGraph will first leverage a multimodal LLM to extract key details and generate a summary of the image. Users can provide more details and refinements through a conversational AI assistant. TOBUGraph constructs a knowledge graph of such memories and facilitates users to interact and query about them.

Using real-world user data of the TOBU app, we evaluated TOBUGraph approach against multiple RAG baseline implementations. TOBUGraph consistently outperformed these baselines in retrieval accuracy, efficiency, and user experience, receiving higher preference ratings across diverse memory retrieval scenarios.

The main contributions of this paper are as follows.

1. A novel approach to extracting structured knowledge and diverse relationships among unstructured data and representing the structures and connections of data in a graph.
2. A novel approach to leverage such a knowledge graph to enable a more effective and efficient retrieval mechanism.
3. Applying TOBUGraph in a real-world application for personal memory organization and retrieval.
4. A comprehensive evaluation against RAG systems using real-world user data. TOBUGraph achieves **93.74% *precision*** (vs. 89.23% best baseline), **91.96% *recall*** (vs. 82.26% best baseline), and **92.84% *F1-score*** (vs 85.56% best baseline). Our user experience evaluation shows that whenever TOBUGraph appears as a response option, evaluators are 75% likely to choose it over RAG baselines.

We plan to open-source our dataset and experimentation for further study.

2 TOBUGraph

In this section, we introduce TOBUGraph, a novel graph-based approach for information capture and retrieval. TOBUGraph overcomes RAG limitations by structuring information in dynamic graph-based representations that effectively capture data relationships. We describe TOBUGraph's implementation in the TOBU app for personal memory capture and retrieval.

During capturing (Figure 1a), TOBUGraph uses an LLM to automatically extract semantics from user inputs, transforming them into context-rich memories. Our system establishes memory relationships, forming a structured and contextually relevant memory graph. During retrieval (Figure 1b), users interact with a conversational AI assistant to retrieve information about the memories.

2.1 Memory Input Data Collection

Our system combines a multimodal LLM with a conversational AI assistant to help users effortlessly create memory entries (Figure 1a). When users provide multimedia inputs, such as images or videos, the multimodal LLM applies object recognition, emotion detection, scene recognition, and geolocation estimation to extract contextual details including date, location, people, activities, and emotions. Based on these details, the LLM generates an initial summary. TOBU AI assistant then engages users in a conversation, gathering additional information and refining the extracted data as needed. The summary dynamically updates as users provide more input, reflecting the most accurate and enriched version of the memory.

2.2 Memory Graph Construction

The Memory Graph Construction Engine organizes extracted contextual details and generated summaries into a structured, graph-based representation (Figure 1a). This process occurs in two stages: individual memory structuring and cross-memory relationship discovery, which identifies and connects related memories across the entire collection.

Individual Memory Structuring: Semantic Nodes Extraction Module processes extracted memory details such as date, location and summaries to construct a graph for each individual memory, where each semantic detail is stored in a dedicated *semantic node*. These nodes link to a central *memory node* representing the memory itself. The initial memory graph is represented as $G = (V, E)$ where $V = M \cup S$ contains memory nodes $M = \{m_1, m_2, ..., m_n\}$ and semantic nodes $S = \{s_1, s_2, ..., s_k\}$, with edge set $E \subseteq M \times S$ connecting memory nodes to their semantic nodes.

Cross-Memory Relationship Discovery: TOBUGraph connects related memories across the user's entire collection forming a unified structure called the Relational Memory Graph (RMG) (Figure 1a). Using LLMs, Relational Extraction Module analyzes each memory node with its connected semantic nodes to extract common themes such as hobbies, locations, activities, significant dates, or frequently mentioned people. For each identified theme, a unique *relationship node* is created, connecting all relevant memory nodes that share this common theme. To ensure robustness, the module performs a normalization step where extracted relationship labels are compared against existing nodes, merging variations and correcting minor spelling inconsistencies to avoid creating duplicate relationship nodes for the same semantic concept. The resulting RMG therefore provides a consistent and unified representation where shared relationships serve as central access points enabling the system to access all memories linked to a specific concept or theme.

The RMG extends the individual memory graphs G to $G' = (V', E')$ where $V' = M \cup S \cup R$ includes relationship nodes $R = \{r_1, r_2, ..., r_p\}$, and $E' \subseteq (M \times S) \cup (M \times R)$ connects memory and relationship nodes. For each memory node m_i, connected semantic nodes are $S_i = \{s_j | (m_i, s_j) \in E'\}$ and connected relationship nodes are $R_i = \{r_j | (m_i, r_j) \in E'\}$.

2.3 Memory Retrieval

TOBUGraph enables users to retrieve memories through an integrated conversational AI assistant that interacts with the user's RMG, as shown in Figure 1b. When a user initiates a memory retrieval request, the system collects all relationship nodes in the RMG and uses an LLM to filter the most relevant ones according to the user's request. The system then traverses the RMG to retrieve the memory nodes connected to the filtered relationship nodes, along with their semantic content, which are passed to the conversational AI assistant.

The conversational AI analyzes this retrieved content to generate targeted responses. If the user's request provides sufficient detail without ambiguity for the LLM, the response is direct; otherwise,

the AI requests clarification. As conversations progress, the LLM in the conversational AI continually filters out irrelevant memories, refining the retrieved content to provide more accurate and contextually relevant answers.

Retrieval Process Formalization: The process follows three steps: (1) *Relationship relevance*: $f(q, R) \rightarrow R' \subseteq R$ identifies relevant relationship nodes R' for query q. (2) *Memory retrieval*: $g(R', G') \rightarrow M' \subseteq M$ retrieves memory nodes M' connected to R' in the RMG. (3) *Response generation*: $h(q, M', S') \rightarrow r$ generates response r where $S' = \cup S_i | m_i \in M'$.

3 Evaluation

3.1 Baselines

To evaluate our proposed TOBUGraph approach, we implement three versions of naive RAG systems using LangChain and ChromaDB as baseline approaches. Three implementations differ primarily in their chunking strategies and input data sources as represented in Table 1. RAGv1 processes memory summaries by splitting them into fixed-size chunks with a defined overlap. RAGv2 takes a different approach by using user-assistant conversations instead of summaries, with each chunk containing one complete conversation. RAGv3 also operates on memory summaries, but each chunk corresponds to a single summary.

3.2 Dataset Construction

Using real memory data from 20 highly active TOBU app users with extensive memory databases, we anonymized the data and created 80 unique memory retrieval requests. We then applied the TOBUGraph memory retrieval technique to process conversations and retrieve relevant memories for each request. For comparison, we used the same retrieval requests with baseline RAG approaches, employing their respective retrieval techniques.

3.3 Quantitative Analysis

3.3.1 Retrieval Metrics Evaluation

To evaluate TOBUGraph against the baseline approaches discussed in Section 3.1, we use standard information retrieval metrics: $Precision$, $Recall$, and $F1 - score$ with 95% confidence intervals calculated using the dataset described in Section 3.2. As shown in Table 2, TOBUGraph demonstrates significant performance improvement across all metrics, achieving the highest $Precision$, $Recall$, and $F1 - score$. This indicates that TOBUGraph significantly outperforms RAGv1, RAGv2, and RAGv3 both in accurately retrieving relevant memories and avoiding irrelevant retrievals, with an average improvement of approximately 7% in overall effectiveness in $F1 - score$ compared to RAGv3, the next-best performing approach.

3.3.2 User Experience Evaluation

To quantitatively evaluate TOBUGraph against baseline methods, we conducted a human-based study using double-blind pairwise comparison via crowd-sourcing using the SLAM tool (Irugalbandara et al., 2024). In each evaluation, participants were presented with two responses for the same user request from two different approaches and asked to compare them side by side. A total of 480 evaluators each completed 10 comparisons, resulting in 4,800 pairwise evaluations. Responses from TOBUGraph and RAG baselines were each evaluated 1,200 times against all other approaches.

We analyze evaluator preferences by measuring the probability of selecting each approach, as shown in Figure 2. Among the 480 evaluators, TOBUGraph responses are preferred 75% of the time on average when presented as a response option in pairwise comparisons, significantly outperforming baseline methods. The distribution shows lower variance for TOBUGraph, indicating more consistent favorability. Among baselines, RAGv1 was least favored, while RAGv3 performed better than RAGv2 due to incorporating user-enriched memory summaries instead of conversations. These results highlight TOBUGraph's effectiveness in delivering a more satisfying user experience.

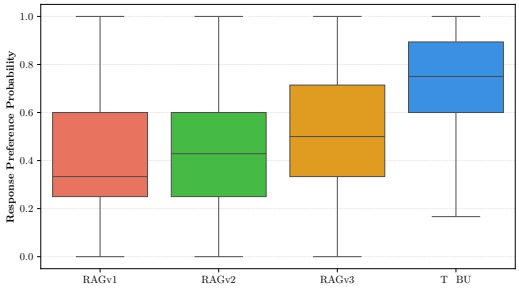

Figure 2: Distribution of evaluator preference of each approach, as probabilities. Among 480 human evaluators, TOBUGraph responses are preferred 75% of the time on average, when present as a response option in a pairwise comparison. Furthermore, the preference distribution for TOBUGraph has lower variance, indicating more consistent performance compared to other approaches.

Table 1: Comparison of Baseline RAG Implementation Variants.

Notations: M: set of memories, m_i: individual memory, n: total memories, C: set of chunks, c_i: individual chunk, l: fixed chunk length		
Baseline	**Input Source for RAG Database**	**Chunking Strategy**
RAGv1	AI generated memory summaries discussed in Section 2.1	**Fixed-size chunks with specified overlap** $c_i = split(summary(M))$, $\|c_i\| = l$ and $\|C\| > \|M\|$
RAGv2	Conversation between the user and AI assistant discussed in section 2.1.	**One complete memory as a single chunk** $c_i = conversation(m_i)$, $\|C\| = \|M\| = n$
RAGv3	Memory summaries as in RAGv1.	**One complete memory as a single chunk** $c_i = summary(m_i)$, $\|C\| = \|M\| = n$

Table 2: $Precision$, $Recall$ and $F1 - Score$ with 95% confidence intervals for the TOBUGraph approach and baseline methods.

	RAGv1	**RAGv2**	**RAGv3**	**TOBU**
$Precision$ (%)	85.92	86.30	89.23	**93.75**
$Recall$ (%)	66.40	79.60	82.26	**91.96**
$F1 - Score$ (%)	74.53	82.88	85.56	**92.84**

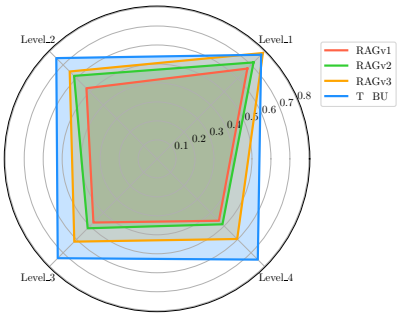

Figure 3: Evaluator preferences for each approach, measured as probabilities across four categorization levels based on memory retrieval complexity and nature. TOBUGraph consistently achieves the highest preference among evaluators across all levels, outperforming other approaches regardless of question complexity.

To further analyze results, we categorized user requests of the dataset into four levels based on complexity and nature of the memory retrieval technique (Table 3). Figure 3 shows evaluator preferences across these levels.

For Level 1 user requests involving single memory retrieval, TOBUGraph and baseline RAG approaches perform similarly with nearly equal evaluator preference, since answering these questions does not require identifying relationships between multiple memories. As we progress to Levels 2, 3, and 4, the preference for RAG approaches declines due to the increasing complexity of memory retrieval (Figure 3). At Level 3, generating complete responses may require fetching a large proportion of the memory database, but RAG retrieves only top-k relevant chunks, risking missing crucial context and leading to incomplete answers and a reduced user preference. Additionally, RAG embeddings prioritize text-to-text similarity, often failing to capture complex relationships between memories. This limitation affects memory retrieval at Level 4, decreasing user preference for RAG.

In contrast, TOBUGraph consistently maintains a higher preference across all levels, with an average selection rate of approximately 75%. This strong performance is due to TOBUGraph's ability to capture deeper semantic relationships through relationship nodes, enabling retrieval of highly relevant memories. These results indicate that, regardless of memory retrieval request complexity, TOBUGraph remains a highly effective solution, outperforming RAG-based methods.

User Study Feedback: Users participated for evaluation further highlighted TOBUGraph's strengths, with comments such as *"Response B (TOBU) has a smoother flow and includes five events, but Response A (RAGv2) only lists three events. Also, Response B describes each event more detail."*, *"Response A (TOBU) is clearer and informative. It presents two Disney park visits and activities, But Response B (RAGv1) includes only one visit and incorrectly names the show they watched."* and *"Response A (TOBU) provided a detailed narrative about two separate trips, while Response B (RAGv3) focused on a single trip but merged details from both."*

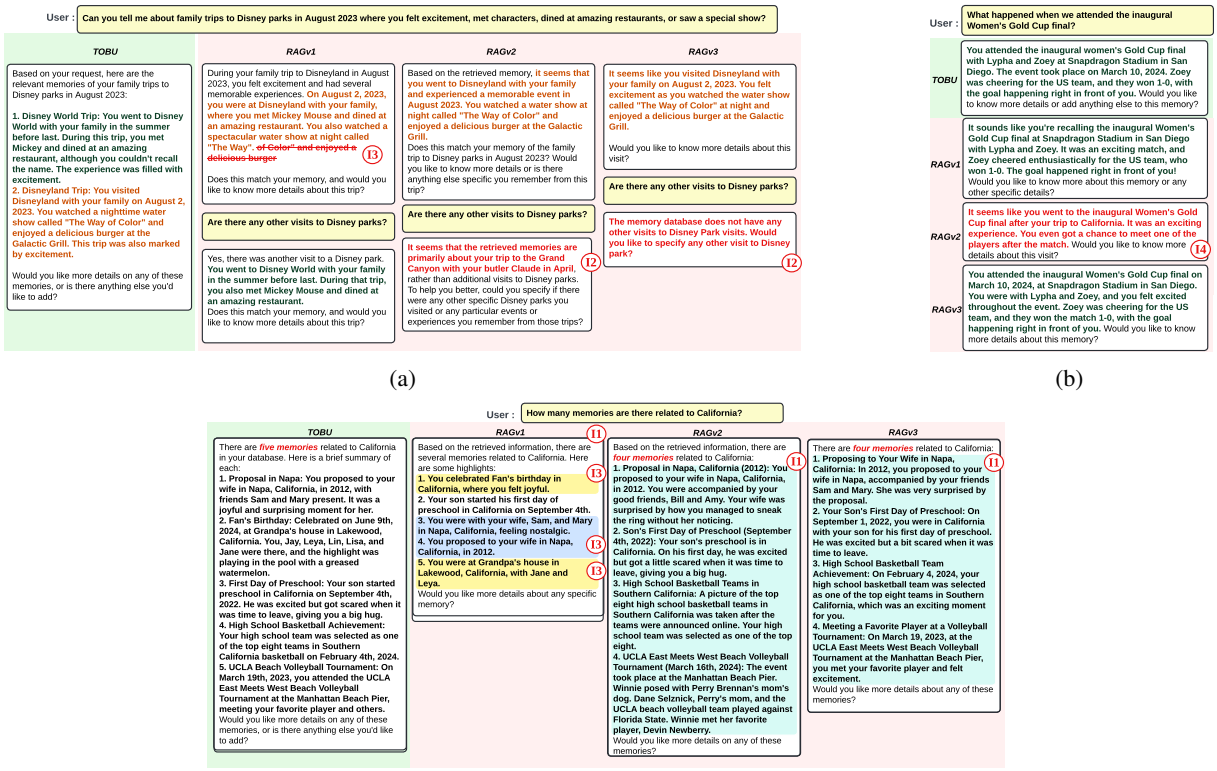
3.4 Qualitative Analysis

To evaluate TOBUGraph approach against baseline RAG models using the dataset created in Section 3.2, we also conducted a qualitative analysis. Key observations are summarized in Table 4, with detailed discussion below.

(I1) Low recall due to top k chunk limitation: Baseline RAG approaches retrieve only the top k chunks, potentially missing relevant memories if their count exceeds k (**I1** in Table 4). As illustrated in Figure 4c, TOBU retrieves all five relevant memories by leveraging graph traversal through the "California" relationship node, capturing all

Table 3: Four categorization levels of user requests based on memory retrieval complexity and nature.

Category	Description	Example User Request
Level 1: Single memory retrieval	Simple questions requiring direct retrieval of a single memory. No need for relationships between memories.	*"When did I have my first dinner with my boarding mates and how was that experience?"*
Level 2: Linked memory retrieval	Requires connecting two or three directly related memories to provide an answer.	*"What were the best parts of my hiking and rafting trips?"*
Level 3: Multi-memory retrieval	When many memories within the database are contextually relevant to formulating a response.	*"What are the activities we have done during the summer and fall?"*
Level 4: Semantic or pattern-based memory retrieval	Requires identifying patterns, trends, or deeper relationships involving different times, locations, or people from multiple memories.	*"Tell me about the memorable places I enjoyed with my friends, including James, over the past year."*



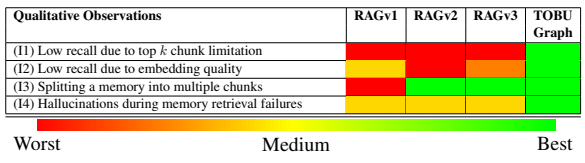


Figure 4: Example conversations from the dataset discussed in section 3.2 where (a) having issues **I1** and **I2**, (b) representing hallucination as in **I4** while (c) demonstrating issues **I2** and **I3** from Table 4.

Table 4: Qualitative comparison between memory retrieval techniques.

connected memories. In contrast, RAGv1, RAGv2, and RAGv3 fail to retrieve all the relevant memories. While RAGv1 appears as it retrieves five memories, two of them are redundant due to the splitting of a single memory, an issue further discussed in **I3**. Meanwhile, RAGv2 and RAGv3 retrieve only four relevant memories, omitting the memory labeled as '2' in TOBUGraph's retrieval.

(I2) Low recall due to embedding quality: RAG approaches rely on the quality of chunk embeddings for precise retrieval. However, in our use case, embedding quality declines as chunk length increases in the order of RAGv1, RAGv3 and RAGv2. This degradation affects retrieval performance, sometimes causing RAG methods to miss relevant memories (**I2** in Table 4). As illustrated in Figure 4c, TOBUGraph retrieves two related memories by traversing the graph via the "Disney" relationship node, without relying on any chunking or embedding strategies. In contrast, RAGv2 and RAGv3 retrieve only one memory, even after a follow-up query, omitting the "Disney World" memory. While RAGv1 retrieves both, it requires

an additional follow-up question.

(I3) Splitting a memory into multiple chunks: Unlike RAGv2 and RAGv3 that treat each memory as a single chunk, RAGv1's chunking strategy unintentionally split memories (**I3** in Table 4). This can cause missing key details of a memory and misinterpreting a single memory as multiple distinct ones. In Figure 4a RAGv1, memories '3' and '4' originate from the same entry but are mistakenly treated as distinct, similar to '1' and '5'. Figure 4c further highlights this issue as the first memory retrieved by RAGv1 omits the correct name of the water show, as the strike-through content is absent in the response. In contrast, TOBUGraph avoids this issue entirely, as it employs the graph-based approach that preserves memory integrity without the need for chunking.

(I4) Hallucinations during memory retrieval failures: Baseline RAG models hallucinate when retrieval fails, fabricating information instead of returning valid entries (**I4**, Table 4). Figure 4b shows RAGv2 hallucinating because RAG relies on unstructured data, losing relationships between memories. In contrast, TOBUGraph structures memories as a graph, leveraging relationships for better retrieval. For example, when searching for the Women's Gold Cup final, TOBUGraph traverses through related relationship nodes, "inaugural", "Gold Cup", and "final" to retrieve relevant memories. This structured approach mitigates hallucinations by ensuring retrieval is based on existing relationships.

4 Related Works

Information retrieval with LLMs (Niu et al., 2024) often employs RAG, a state-of-the-art method (Asai et al., 2023; Gao et al., 2024; Wu et al., 2024a; Guu et al., 2020; Karpukhin et al., 2020). However, RAG systems face several challenges: difficulty capturing deeper relationships between chunks beyond text-to-text similarities (Peng et al., 2024), sensitivity to chunking strategies (Qu et al., 2024), and hallucination risks (Sun et al., 2025; Huang et al., 2025).

Graph-based retrieval methods often address these issues (Jin et al., 2024; Wu et al., 2024b; Hu et al., 2024; Su et al., 2024; Chen et al., 2024; Zhang et al., 2022; Peng et al., 2024; Zhang et al., 2024; Kim et al., 2024). While knowledge graph construction is labor-intensive and struggles with dynamic data (Hofer et al., 2024), Edge et al. use LLMs to generate and update knowledge graphs primarily for creating summaries and RAG-based retrieval in GraphRAG, our approach retrieves information by traversing the graph.

5 Conclusion

In this paper, we introduce TOBUGraph, a novel framework that integrates LLM-powered knowledge graph construction with graph-based retrieval to enhance information retrieval while addressing RAG limitations. TOBUGraph improves retrieval accuracy by capturing deeper semantic relationships between entries. This approach is implemented in a mobile application called TOBU for memory retrieval. Our evaluation using real-world data from the TOBU database demonstrates that TOBUGraph consistently outperforms RAG baselines in precision, recall, and user preference ratings, highlighting its effectiveness in real-world scenarios.

Limitations

While TOBUGraph demonstrates strong performance on the TOBU dataset, our evaluation is limited to users with relatively modest-sized memory collections. In real-world scenarios, users may accumulate thousands of memories, and scaling to such large collections presents new challenges. Specifically, graph construction and traversal at this scale may introduce computational overheads, latency, and storage bottlenecks that our current evaluation does not capture. Addressing these scalability issues is an important direction for future work to ensure robustness when applied to substantially larger personal knowledge bases.

Abstract

Recently, the demand for small and efficient reasoning models to support real-world applications has driven the development of knowledge distillation techniques that balance reasoning performance and inference speed. In this paper, we further extend the DistilQwen model family, initialized from the Qwen models, by introducing four model series specifically designed to meet industrial requirements. The distilled model collection comprises: (1) slow-thinking models, optimized for reasoning tasks that require high accuracy; (2) two series of adaptive-thinking models, which dynamically adjust reasoning strategies based on input tasks to maximize efficiency across diverse scenarios; and (3) distilled reward models, which enable further reinforcement learning of reasoning models using distilled knowledge. Comprehensive evaluations across multiple benchmarks demonstrate both high inference efficiency and strong reasoning performance for these models, as well as the practical utility of distilled reward models. We further show that these models support industry practitioners by providing scalable training and inference functionalities on the Alibaba Cloud PAI (Platform for Artificial Intelligence) platform.[1]

1 Introduction

In the rapidly evolving landscape of large language models (LLMs), the need for efficient reasoning models that can seamlessly integrate into real-world applications has become increasingly urgent. Industries worldwide increasingly rely on advanced LLMs, which require not only high reasoning performance but also fast inference speeds to support timely decision-making (Vrdoljak et al., 2025; Zhong et al., 2025; Cha et al., 2025). These dual requirements have fueled growing interest in knowledge distillation (KD) methods, which aim to balance accuracy with computational efficiency (Xu et al., 2024).

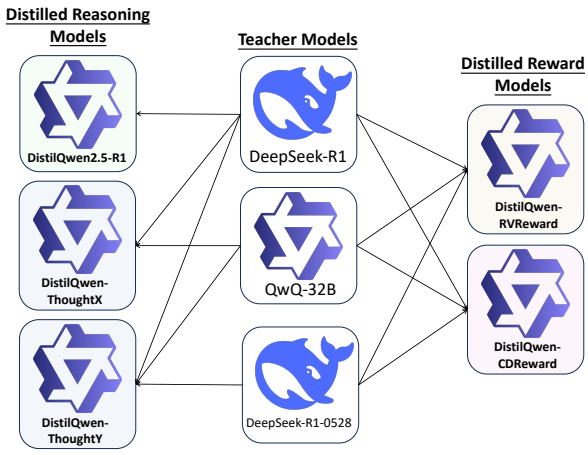

Figure 1: Roadmap for training DistilQwen reasoning and reward models.

In response to these industrial needs, we present a comprehensive extension of the DistilQwen model family (Wang et al., 2025b), introducing four model series tailored for a wide array of reasoning scenarios:

- **Slow-thinking models:** Optimized for tasks where accuracy is paramount, these models ensure consistently high precision.
- **Adaptive-thinking models (two series):** Motivated by recent insights that reasoning length and depth should vary by task (Sui et al., 2025; Cai et al., 2025b), these models dynamically adjust their reasoning strategies to specific requirements and outperform previous ones.
- **Adaptive-thinking-based reward models:** Derived from our training strategies for above series, these models support further reinforcement learning using distilled knowledge.

*The work was conducted during the internship at Alibaba Cloud Computing.

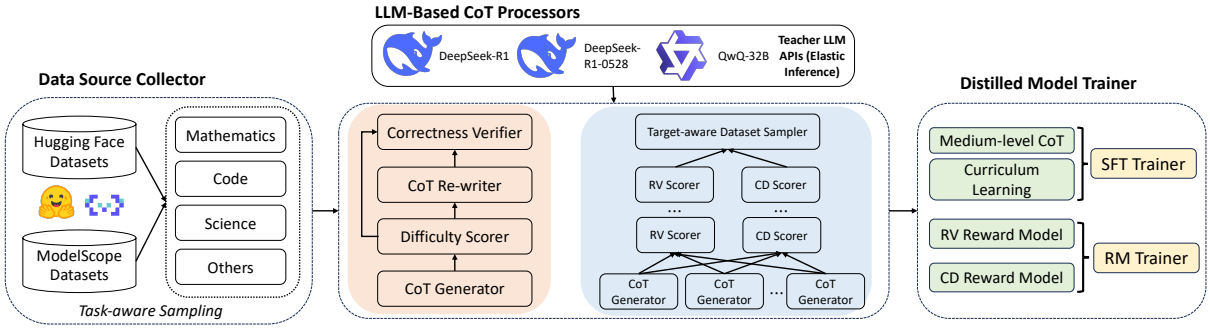

Figure 2: High-level process for obtaining DistilQwen reasoning and reward models.

The development roadmap for these model series is shown in Figure 1. DistilQwen reasoning and reward models are evaluated on diverse benchmarks, demonstrating robust performance. Furthermore, practicality is demonstrated by their integration into industrial AI platforms for fine-tuning and online deployment.

2 Related Work

Knowledge distillation (KD), first introduced by Hinton et al. (2015), has been key to reducing parameter counts in language models. Before LLMs, several studies distilled BERT-based models (Sanh et al., 2019; Jiao et al., 2020; Sun et al., 2020; Pan et al., 2021), mainly for natural language understanding. Distillation for LLMs poses additional challenges due to complex token dependencies.

In the literature, MiniLLM (Gu et al., 2024) uses a reverse Kullback-Leibler divergence (KLD) objective to transfer knowledge from white-box LLMs to student models. An adaptive strategy (Wu et al., 2025) combines forward and reverse KLD via dynamic weighting. f-Distill (Wen et al., 2023) minimizes a generalized f-divergence function at the sequence level. Li et al. (2025) propose a bi-directional logits difference loss to improve KD performance. For black-box KD (where only APIs are available), knowledge distillation signals like output logits are absent; researchers leverage data augmentation with instruction-response pairs (Hsieh et al., 2023; Li et al., 2024; Lou et al., 2024; Ranaldi and Freitas, 2024; Kim et al., 2024; Yue et al., 2024; Ma et al., 2025).

With the rise of large reasoning models such as DeepSeek-R1 (DeepSeek-AI, 2025), distilling Chain-of-Thought (CoT) reasoning ability has attracted attention (Wang et al., 2025c). Chen et al. (2025) study the effect of granularity, format, and teacher choice on CoT distillation. Cai et al. (2025b) improve reasoning in small models by considering cognitive gaps. Multi-teacher KD (Tian et al., 2025) uses teacher forcing to transmit diverse reasoning skills. Self-training methods (Zhang et al., 2025) activate latent reasoning capacity in small models.

In our work, we open-source a range of small models for challenging reasoning tasks to facilitate further research and industrial applications.

3 Algorithm Implementation

We elaborate on our industrial practice for training the DistilQwen reasoning and reward models. The overall pipeline is illustrated in Figure 2.

3.1 Data Source Collector

The foundation of our approach is the Data Source Collector, which aggregates CoT datasets from platforms such as Hugging Face[2] and ModelScope[3]. These datasets span domains including mathematics, code, science, and more, providing rich and diverse sources for training reasoning models such as OpenThoughts2[4], DeepMath-103K (He et al., 2025), OpenCodeReasoning[5], etc. We subsequently perform task-aware re-sampling to balance the distributions across different types of tasks.

3.2 LLM-Based CoT Processors

Directly performing vanilla SFT training on raw CoT datasets does not necessarily yield strong student models. Below, we describe our LLM-based CoT processors, which effectively and efficiently generate and refine CoT datasets for knowledge distillation (KD).

[2] https://huggingface.co/datasets
[3] https://modelscope.cn/datasets
[4] https://huggingface.co/datasets/open-thoughts/OpenThoughts2-1M
[5] https://huggingface.co/datasets/nvidia/OpenCodeReasoning

3.2.1 Elastic Teacher LLM Inference

In our implementation, directly invoking third-party APIs for teacher LLM inference is not feasible due to the requirements for robust, scalable, and elastic inference. Instead, we deploy inference services for DeepSeek-R1 (DeepSeek-AI, 2025), DeepSeek-R1-0528[6], and QwQ-32B[7] on our computing clusters, where each server is equipped with eight NVIDIA H20 GPUs (96GB each). Because the queries per second (QPS) requirements for these models vary across subsequent steps, the number of inference nodes per model can be elastically adjusted to maximize computational resource utilization. These inference APIs form the foundation of our system; thus, we do not need to manage hardware for CoT generation and processing later.

3.2.2 Slow-Thinking CoT Processor

The slow-thinking CoT processor is employed to optimize CoT training sets for **slow-thinking models**, i.e., the **DistilQwen2.5-R1** series (using DeepSeek-R1 (DeepSeek-AI, 2025) as the teacher model and the Qwen2.5 series as students).

CoT Generator. The core module is the CoT Generator, which leverages DeepSeek-R1 to generate structured CoTs by exploring complex solution spaces. However, the output reflects how this ultra-large model (with 671B parameters) solves problems, which may not be entirely suitable for smaller models to learn from. To create diverse solution paths, multiple inference outcomes are generated using varying temperatures.

CoT Difficulty Scorer. A key challenge in improving KD effectiveness for smaller student models is addressing the capacity gap between teacher and student models. Several concurrent works (Cai et al., 2025b; Yu et al., 2025) propose assessing and rewriting CoTs to better suit student learning; however, these methods often require iterative processing and incur high computational costs. In our approach, the CoT Difficulty Scorer evaluates the complexity of each generated CoT using the same teacher LLM (DeepSeek-R1). By assigning difficulty levels (easy, medium, hard), the scorer distinguishes intricate CoTs from simpler or excessively challenging ones, enabling students to prioritize learning on medium-level CoTs. This systematic scoring helps models develop a deeper understanding of complex reasoning scenarios.

CoT Re-writer and Verifier. As reported by Cai et al. (2025b), rewritten and verified versions of CoT datasets often enable smaller LLMs to achieve stronger reasoning abilities. However, the complexity of these processing steps limits parallelization over millions of CoTs in our dataset. Therefore, we adopt a simple yet effective strategy by rewriting and verifying CoTs only at the easy and hard difficulty levels in a one-pass process. Incorrect CoTs are discarded based on the verifier, which serves as a safeguard to preserve reasoning correctness. Since multiple CoTs are generated per problem, in most cases, at least one suitable CoT is obtained. Overall, integrating these steps results in large, higher-quality CoT training sets that constitute the foundation for training our **slow-thinking models**.

3.2.3 Adaptive-Thinking CoT Processor

Beyond the slow-thinking processor, the adaptive-thinking CoT processor further optimizes CoT training sets for **adaptive-thinking models**, namely the **DistilQwen-ThoughtX** series (using DeepSeek-R1 and QwQ-32B as teacher models and the Qwen2.5 series as students), and its updated version following the release of DeepSeek-R1-0528: the **DistilQwen-ThoughtY** series (using DeepSeek-R1, DeepSeek-R1-0528, and QwQ-32B as teacher models and the Qwen3 series[8] as students). These models dynamically adjust the lengths of CoTs according to problem complexity, thereby further improving reasoning abilities and avoiding "over-thinking."

CoT Generator. The implementation of the CoT Generator here is largely similar to that of the slow-thinking processor. The key difference is that we generate multiple CoTs per problem using different teacher models. Additionally, the inference temperatures are varied to increase diversity.

RV and CD Scorers. During the upgrade of DistilQwen reasoning models, we discovered that rewriting alone is insufficient, as it does not address situations where models tend to "over-think" simpler problems (Sui et al., 2025). Our Reasoning Verbosity (RV) and Cognitive Difficulty (CD) Scorers, derived from the work in (Cai et al., 2025a), further assess the quality of CoTs by ensuring they are appropriately verbose for challenging problems and match the cognitive capacity of the student models. This dual scoring mechanism ensures that models are exposed to a broad spectrum of CoT

[6] https://huggingface.co/deepseek-ai/DeepSeek-R1-0528

[7] https://huggingface.co/Qwen/QwQ-32B

[8] https://qwenlm.github.io/blog/qwen3/

processes that are better aligned with their capabilities and the problem difficulty. Consequently, the models can learn to adaptively think based on the input problems, leading to higher accuracy and faster inference.

Target-aware Dataset Sampler. Finally, given a target student model, we sample an optimal subset of CoTs for training. Note that our CoT-based system is not static; as more powerful LLMs become publicly available, we can continually collect higher-quality CoTs to train stronger small models. This is further demonstrated by the significant improvement of **DistilQwen-ThoughtY** over **DistilQwen-ThoughtX** shown in our experiments.

3.3 Distilled Model Trainer

SFT Trainer with Curriculum Learning. To effectively train our **slow-thinking** and **adaptive-thinking** models, we adopt supervised fine-tuning (SFT) enhanced with curriculum learning principles (Soviany et al., 2022). The training pipeline begins with medium-level CoT examples to ensure stable convergence and prevent overfitting. As training progresses, the curriculum gradually incorporates more challenging samples, promoting generalization and robustness across diverse scenarios. Please refer to the experimental results for additional details.

RM Trainer with RV and CD Score Estimation. Beyond evaluating CoT quality, RV and CD scores are also leveraged to train lightweight models as reward predictors, which can subsequently enhance the model's reasoning ability via reinforcement learning (RL). To this end, our reward model (RM) trainer produces two dedicated reward models, each initialized from Qwen2.5-7B-Instruct: one for RV and one for CD. This constitutes a special case of knowledge distillation (KD), as the prediction outcomes are derived from very large teacher models. This approach circumvents the need to directly employ the original teacher models as RMs during the more resource-demanding RL training process.

Although RL training is not the primary focus of this work, we briefly describe how **DistilQwen-Reward** models are integrated into RL training. We use Group Relative Policy Optimization (GRPO) (DeepSeek-AI, 2025) as a representative RL algorithm. Let $f_{\text{RV}}(x)$ and $f_{\text{CD}}(x)$ denote the predicted RV and CD scores by our models, given input x. Note that the predicted scores are normalized to $[0, 1]$. The corresponding RV and CD rewards are defined as follows:

$$R_{\text{RV}}(x) = -\left|f_{\text{RV}}(x) - \text{Clip}(f_{\text{RV}}(x), L_{\text{RV}}, H_{\text{RV}})\right| \tag{1}$$

$$R_{\text{CD}}(x) = -\left|f_{\text{CD}}(x) - \text{Clip}(f_{\text{CD}}(x), L_{\text{CD}}, H_{\text{CD}})\right| \tag{2}$$

where $(L_{\text{RV}}, H_{\text{RV}})$ and $(L_{\text{CD}}, H_{\text{CD}})$ are the respective score intervals for the output CoTs. If a score lies within its designated interval, the penalty term is zero; outside the interval, the penalty increases linearly with the distance to the nearest boundary. Combined with the conventional *accuracy* and *format* rewards (denoted as R_{fmt} and R_{acc}, respectively) used in standard GRPO, the revised overall reward function is:

$$R = R_{\text{fmt}} + R_{\text{acc}} + \lambda_{RV} R_{\text{RV}}(x) + \lambda_{CD} R_{\text{CD}}(x) \tag{3}$$

where λ_{RV} and λ_{CD} are tunable hyperparameters that determine the weighting. In our experiments, we further validate the effectiveness of the **DistilQwen-Reward** models relative to vanilla GRPO. We plan to continue developing RL-enhanced lightweight reasoning models in future work, which may extend beyond the scope of the KD techniques presented in this paper.

4 Evaluation

In this section, we present the evaluation results for all DistilQwen reasoning and reward models.

4.1 Evaluation Benchmarks

To comprehensively evaluate the reasoning capabilities of our models, we conduct experiments on challenging benchmarks spanning mathematics, programming, and question answering. Among these, AIME2024[9] features problems that require multi-step reasoning and intricate mathematical understanding. MATH500 (Hendrycks et al., 2021) comprises 500 difficult mathematical problems across various domains, including algebra, geometry, number theory, and calculus. GPQA Diamond (Rein et al., 2023) is a complex question-answering benchmark designed to assess general-purpose reasoning and comprehension abilities. Finally, LiveCodeBench V2 (Jain et al., 2025) evaluates models' programming and code generation skills, comprising coding tasks that range from algorithmic challenges to practical problems.

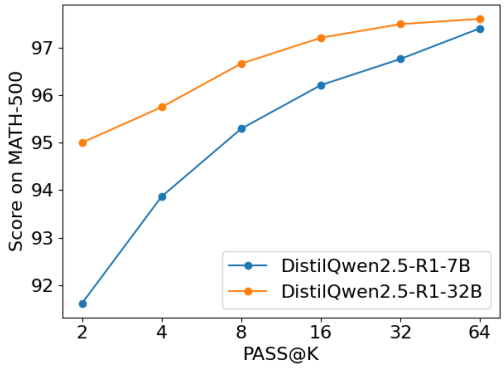
DistilQwen-ThoughtY-32B	**90.0**	**95.2**	63.6	**76.3**

Table 2: Performance of **adaptive-thinking models**. Note that the Qwen2.5 models are non-reasoning models, while the Qwen3 models can act as reasoning models with their thinking modes enabled.

4.2 Evaluation of Slow-Thinking Models

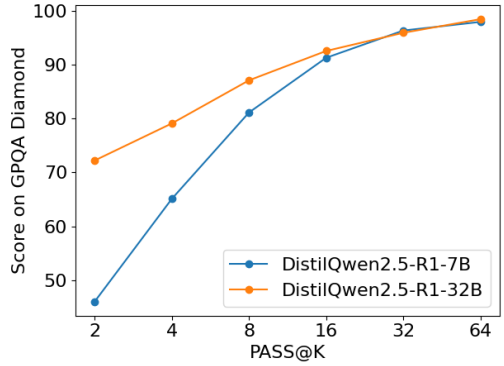
Slow-thinking models, namely the **DistilQwen2.5-R1** series, encompass model scales of 3B, 7B, 14B, and 32B parameters. The source reasoning problems are taken from OpenThoughts[10], with CoTs generated, rewritten, and verified using DeepSeek-R1. We perform SFT training on medium-level CoTs for three epochs, followed by additional training on harder examples. After SFT, direct preference optimization (DPO) (Rafailov et al., 2023) is applied, yielding modest further improvements, though this is not our main focus here.

As presented in Table 1, our proposed approach markedly enhances the reasoning abilities of existing LLMs, delivering consistent and substantial gains across multiple benchmarks compared to the original Qwen2.5 models and the OpenThinker models[11], which are trained on the same set of reasoning problems with the same teacher model.



Additionally, we evaluate **DistilQwen2.5-R1** models using inference-time scaling, where the models generate k answers for the same question and are measured using the $Pass@K$ metric. The findings indicate that increasing the number of reasoning attempts K leads to significant accuracy improvements for both models. Notably, the 7B model exhibits a steep upward trend on MATH500 and GPQA Diamond, gradually approaching the performance level of the 32B model while reducing inference computation requirements.

4.3 Evaluation of Adaptive-Thinking Models



In Table 2, we present the evaluation results for our **adaptive-thinking models**. The **DistilQwen-ThoughtX** series, built upon Qwen2.5 models and trained with the dataset from (Cai et al., 2025a), encompasses model scales of 7B and 32B. The results demonstrate substantial improvements at all scales, surpassing the **slow-thinking models**. The **DistilQwen-ThoughtY** series, initialized from Qwen3 models with reasoning modes enabled, achieves further advances. These models span three scales (4B, 8B, and 32B) and are trained on the previous series' dataset and a subset of 365K CoTs generated from DeepSeek-R1-0528 (to be released). The experiments confirm that

[10] https://huggingface.co/datasets/open-thoughts/OpenThoughts-114k

[11] https://huggingface.co/open-thoughts/OpenThinker-7B

(a) Task: MATH500.

(b) Task: GPQA Diamond.

Figure 3: Performance of **DistilQwen2.5-R1** models in terms of $Pass@K$ under multiple inference attempts.

Model	GSM8K	MATH500	AIME2024
7B-R1	1223.61	6586.36	12856.23
ThoughtX-7B	834.36	6031.11	14597.96
ThoughtY-8B	844.23	5932.95	15632.85
32B-R1	1178.92	6434.50	13583.19
ThoughtX-32B	742.04	5927.32	16387.53
ThoughtY-32B	723.18	5723.08	17231.84

Table 3: Analysis of averaged output CoT lengths of **adaptive-thinking models**. "DistilQwen" and "DistilQwen2.5" prefixes are omitted from model names.

our adaptive-thinking CoT processor and training strategies effectively enhance reasoning capabilities across model scales and tasks.

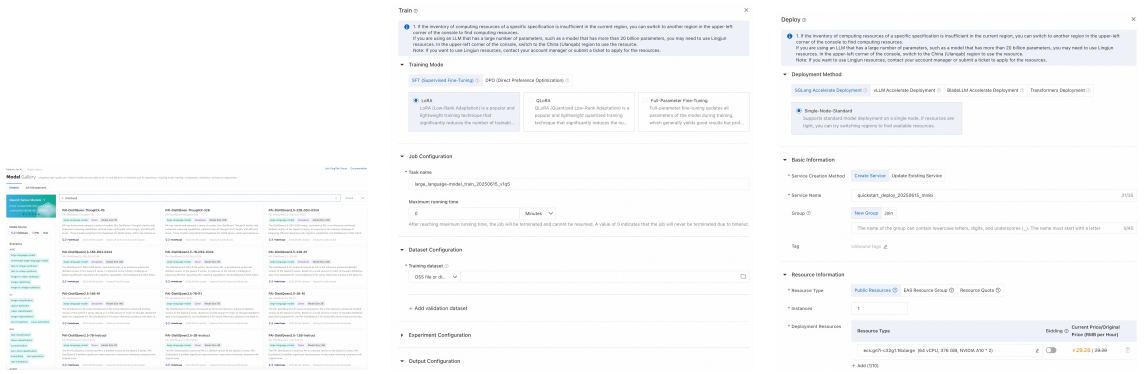
In addition, Table 3 analyzes the output CoT lengths according to the difficulty of reasoning problems. The results clearly demonstrate that our **adaptive-thinking models** generate more optimal CoTs based on their understanding of the input. For example, the **adaptive-thinking models** produce shorter CoTs for simpler problems in GSM8K[12], and generate longer CoTs for more challenging problems in MATH500 and AIME2024.

[12] https://huggingface.co/datasets/openai/gsm8k

Further Discussion. The reason why the results obtained with adaptive-thinking models are significantly better than those with slow-thinking models is that adaptive-thinking models utilize substantially more training data. Adaptive-thinking models sample from over 2 million CoTs, resulting in training sets of at least 500K, while slow-thinking models train on only approximately 100K data points.

Although the slow-thinking recipe can effectively enhance a model's reasoning capabilities, it is unsuitable for customized, diverse training requirements due to its lack of quantitative CoT evaluation information. Therefore, we proposed the adaptive-thinking recipe, and we did not further increase the training data for slow-thinking models.

However, this does not imply that the slow-thinking recipe is obsolete. In scenarios where training data is inherently limited, the sampling process of the adaptive-thinking recipe would further reduce available training data. In such cases, we recommend using the slow-thinking recipe to ensure satisfactory training results.



4.4 Evaluation of Reward Models

Table 4 presents comparison results between the standard GRPO algorithm and GRPO augmented with our RV- and/or CD-based **distilled reward models**. We use Qwen2.5-7B-Instruct as the base model and randomly sample 10K mathematical problems from the previous training set for RL training. Specifically, we conduct RL training on the model directly, with no CoT-based SFT on mathematical problems, ensuring that models learn mathematical reasoning purely via RL. As shown, GRPO enhanced with RV/CD-based reward models consistently outperforms vanilla GRPO, corroborating our hypothesis that RV/CD scores distilled from teacher models can effectively benefit RL training, which is a promising direction for future work.[13]

5 Industrial Solutions

In addition to releasing all our DistilQwen reasoning models to the open-source community for use in various local environments, we have integrated these models into the Alibaba Cloud PAI (Platform for Artificial Intelligence) platform that supports the entire lifecycle of LLM usage, including

[13] In SFT training, we utilize over 500K training samples, whereas in RL training, we use only 10K samples. Consequently, the results in Table 4 are lower than those in Tables 1 and Table 2.

(a) List of model cards. (b) Training panel. (c) Deployment panel.

training, evaluation, compression, and deployment. Snapshots of model cards as well as the training and deployment panels are shown in Figure 4.

By embedding the DistilQwen reasoning models into AI platforms, businesses can leverage and further adapt these specialized capabilities to support real-world applications, including but not limited to decision making, code generation, problem solving, and multi-agent systems. The platform's deployment functionalities enable seamless integration of these models into existing systems via RESTful APIs compatible with the OpenAI format, thereby facilitating easier and more efficient usage.

6 Conclusion and Future Work

In this work, we have expanded the DistilQwen model collection by introducing four model series tailored to address diverse reasoning requirements. Our **slow-thinking models** prioritize accuracy for demanding tasks, while the **adaptive-thinking models** dynamically optimize reasoning strategies to balance efficiency and performance. In addition, the **distilled reward models** facilitate further enhancement through reinforcement learning based on distilled knowledge. Extensive evaluations demonstrate that our models achieve a favorable trade-off between inference efficiency and reasoning capability. Furthermore, by integrating these models into a scalable AI platform, we provide practical tools that effectively support industry practitioners in model training and deployment.

Limitations

Although the proposed DistilQwen reasoning models perform well across several benchmarks, their effectiveness may vary in highly specific or dynamic real-world contexts where benchmarks do not fully capture operational complexity. Furthermore, the reinforcement learning framework supported by the distilled reward models depends on the quality of the distilled knowledge, which may propagate biases or errors inherent in the teacher models. We suggest that future research focus on addressing these limitations and further improving model adaptability and precision in real-world applications.

Ethical Considerations

The development and deployment of the DistilQwen reasoning models requires careful consideration of ethical implications. It is essential to address potential biases introduced by the training data, as such biases may influence reasoning outcomes. Since our models are intended for research and industrial use, issues of data privacy, security, and compliance with relevant regulations should be rigorously addressed during practical implementation.

Abstract

Automatic Term Extraction (ATE) is a critical component in downstream NLP tasks such as document tagging, ontology construction and patent analysis. Current state-of-the-art methods require expensive human annotation and struggle with domain transfer, limiting their practical deployment. This highlights the need for more robust, scalable solutions and realistic evaluation settings. To address this, we introduce a comprehensive benchmark spanning seven diverse domains, enabling performance evaluation at both the document- and corpus-levels. Furthermore, we propose a robust LLM-based model that outperforms both supervised cross-domain encoder models and few-shot learning baselines and performs competitively with its GPT-4o teacher on this benchmark. The first step of our approach is generating pseudo-labels with this black-box LLM on general and scientific domains to ensure generalizability. Building on this data, we fine-tune the first LLMs for ATE. To further enhance document-level consistency, oftentimes needed for downstream tasks, we introduce lightweight post-hoc heuristics. Our approach exceeds previous approaches on 5/7 domains with an average improvement of 10 percentage points. We release our dataset and fine-tuned models to support future research in this area.[1]

1 Introduction

Automatic Term Extraction (ATE) is a crucial component of many NLP systems, with applications in information retrieval, machine translation, topic detection, and sentiment analysis (Tran et al., 2023; Xu et al., 2025). Traditional rule-based or frequency-based ATE systems, as well as state-of-the-art (SOTA) methods with pretrained models, rely heavily on fine-tuning with human-annotated datasets, which are typically available for only a handful of domains. Recent surveys explicitly highlight this dependence as a key limitation, noting that multi-domain ATE scenarios remain an unsolved challenge for current SOTA approaches (Tran et al., 2023; Xu et al., 2025). Large language models (LLMs), with their massive pretraining across diverse corpora, offer a promising path toward generalizable ATE. Yet, early applications of LLMs in term extraction remain limited and typically perform worse compared to supervised SOTA methods (Tran et al., 2023). Moreover, proprietary black-box LLMs incur high API costs and pose privacy risks when handling sensitive or confidential data.

To address these limitations, we introduce a novel ATE framework: DiSTER (**Di**stant **S**upervision for **T**erm **E**xtraction with **R**obustness), that leverages LLMs with distant supervision. Our approach trains smaller, open models using synthetic data generated via pseudo-labels from a black-box LLM, thereby removing the need for human annotation and enabling cross-domain scalability. To enhance consistency within and across documents, we incorporate simple post-hoc consistency heuristics. These heuristics significantly improve F1 scores and oftentimes lead to more balanced precision and recall.

Moreover, we perform a comprehensive empirical study, spanning the seven following domains: biomedicine, corruption, dressage, heart failure, coastal geography, computational linguistics and wind energy. Combining these established datasets makes this the largest and most diverse multi-domain ATE evaluation to date. We assess models under both corpus-level and document-level setups to better reflect real-world extraction needs. Our results demonstrate that training on distantly supervised data leads to notable improvements in cross-domain robustness and that post-hoc consistency enforcement yields further gains, boosting

document-level F1 scores by up to 55 percentage points. Our contributions are:

- We propose DiSTER, a novel distantly supervised ATE framework that combines synthetic data generation, LLM fine-tuning, and lightweight post-hoc consistency heuristics for robust and scalable term extraction without human annotation.
- We demonstrate that a strategically constructed, domain-diverse synthetic training corpus significantly enhances cross-domain generalization.
- We conduct the most comprehensive cross-domain ATE evaluation to date, spanning seven diverse domains and evaluating both corpus-level and document-level performance.

2 Related work

2.1 Automatic Term Extraction

Traditional ATE methods typically follow a two-step pipeline: (1) extracting candidate terms using linguistic and statistical features, and (2) ranking them based on termhood and unithood scores (Xu et al., 2025). Supervised machine learning approaches enhance this process using manually designed features and classifiers like SVMs, Random Forests, or CRFs (Tran et al., 2023). With deep learning, models such as BiLSTMs, CNNs, and Transformers have been adopted for token classification and embedding-based approaches, showing SOTA results across languages and domains (Tran et al., 2023, 2022a,b). Recently, LLMs have entered the field. Giguere (2023) showed that GPT-4 (OpenAI et al., 2024b) performs well in zero-shot settings across legal, technical, and medical domains, outperforming statistical baselines on small test sets. Meanwhile, Tran et al. (2024) explored few-shot prompting with `LLaMA` and `GPT-3.5-Turbo` for the ACTER heart-failure dataset, though results still lag behind cross-domain sequence labeling with XLM-R (Conneau et al., 2020).

2.2 Distillation and Pseudo-Labeling

Knowledge Distillation (KD) transfers knowledge from larger teacher models to smaller student models. In black-box KD, often used with proprietary LLMs, only the teacher's outputs are available (Yang et al., 2024), hence, the student model learns by mimicking the teacher's generated sequences instead of its internal states. Specifically, *Labeling Knowledge*, when a LLM labels a set of examples based on an instruction (with or without demonstrations), is widely considered effective for transferring specific LLM skills (Xu et al., 2024). This approach has proven effective across diverse NLP tasks (Li et al., 2025). In the information extraction domain, several studies have shown promising results: Hsu and Roberts (2024) applied LLM weak supervision improving performance on medical entity extraction with minimal human annotation. Similarly, UniversalNER (Zhou et al., 2024) successfully distilled open-domain named-entity recognition (NER) capabilities from `GPT-3.5-Turbo-0301` into smaller models that ultimately outperformed their teacher. For more complex extraction tasks, MetaIE (Peng et al., 2024) employed distillation as a meta-learning framework to create task-flexible information extraction systems capable of adapting to various relation and entity types.

3 DiSTER

Our approach DiSTER first creates a distantly supervised dataset, then fine-tunes an LLM on that data to generate candidate terms, and lastly selectively applies post-hoc heuristics. This pipeline is illustrated in Figure 1. We cover the details of each component in the following sections.

3.1 Dataset Creation

To create our synthetic dataset *SynTerm* for model fine-tuning, we used the dataset of Zhou et al. (2024) as a basis. Their synthetic NER dataset was generated by prompting `gpt-3.5-turbo-0301` to identify named entities within text snippets taken from *The Pile* (Gao et al., 2020). We utilize their annotations as a starting point, but apply a filtering step (as described next) to focus only on relevant entity types and added labeled data from *arXiv* for broader domain coverage.

Entity Type Filtering In order to filter, two authors manually annotated the 130 most common entity types covering approximately 74% of all extracted entities, labeling them as either *terms* or *non-terms* (e.g., person names, locations, etc.) following the ACTER annotation guidelines (Rigouts Terryn, Ayla, 2021). This manual annotation process resulted in a Cohen's kappa coefficient of 0.723, indicating substantial inter-annotator agree-

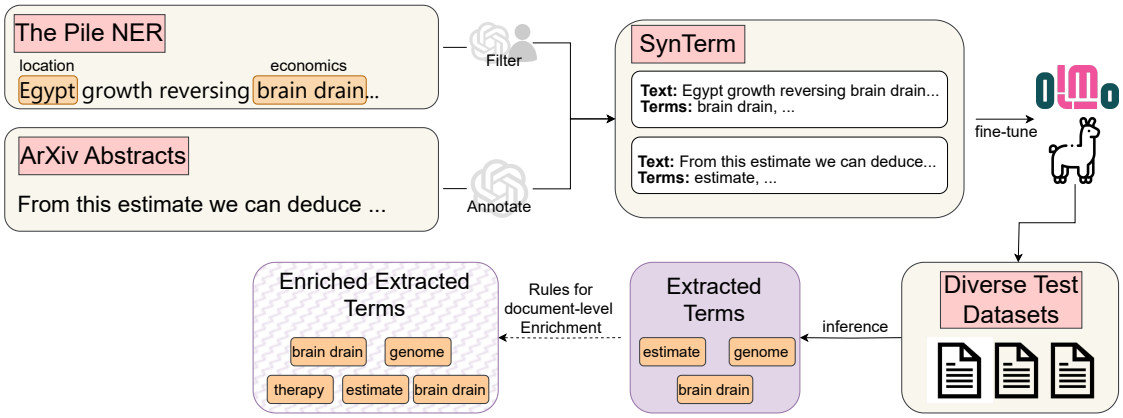

Figure 1: An overview of the key components of our DiSTER approach.

ment. These human-provided labels were used for all entities within the 130 most frequent types. For the remaining 26% of entities, which belong to less common types, we relied on GPT-4o (OpenAI et al., 2024a) to classify whether phrases of a given entity type represent terms (see Appendix C). To assess consistency, we compared the model's labels with the human annotations on the 130 most common types, which yielded a lower Cohen's kappa of 0.45. Notably, the LLM tended to label fewer entity types as terms than the annotators (109 vs. 127 and 136, respectively). For instance, GPT-4o labeled entity types such as 'event,' 'nationality,' falsely as terms and instances of 'medical conditions' as non-terms, whereas the annotators considered them valid terms. Overall, the potential noise introduced by the LLM is expected to be limited, as most extracted entities fall within the 130 most common types and were annotated manually. Manual annotation of all entity types would have been prohibitively expensive, as the NER dataset contains a total of 13,020 entity types. By focusing on the most common types where noise reduction matters most, we ensured high-quality filtering for the majority of data while using GPT-4o only for the long-tail of rare entity types.

Domain-Aware Data Augmentation To increase domain diversity, we synthesized labeled examples from two-sentence snippets from *arXiv* abstracts using GPT-4o. The two-sentence snippets were chosen to closely match the length of data points from both *The Pile* and the test datasets. As in the few-shot setup of Tran et al. (2024), we included domain information in the extraction prompt (see Appendix D). The domain information was derived from the *arXiv* categories associated with each abstract. Given the domain-dependent nature of termhood (Xu et al., 2025), we expect this to improve the relevance of extracted terms. We also incorporated domain labels into the final data points used for fine-tuning, an example is shown in Figure 2. In contrast, for data points based on *The Pile*, where no domain labels are available and thus not integrated in the data points, we prompted the model during training to extract terms without specifying a domain.

Human:
Text: From this estimate we can deduce that the spatially homogeneous Boltzmann equation is well posed in a class of measure-valued processes. We also prove in an appendix a basic lemma on the total variation of time-integrals of time-dependent signed measures.
GPT:
I've read this text.
Human:

Figure 2: Conversation example showing extraction of domain-specific terms from an *arXiv* text. For data points without specific domain, like the ones coming from the Pile, we substitute the domain by "General".

In summary, we created two data subsets: *TermPile* (45,432 instances), the filtered NER dataset based on *The Pile* and, *TermArXiv* (37,829 instances) the newly synthesized *arXiv* data points. Combining the two yields our final *SynTerm* dataset.

Domain	Example Sentence
corp (Corruption)	The first criterion creates a link between the **offence** and the **legal person**.
equi (Dressage / Equity)	They might go from a **lengthened stride** and **half halt** back to a **working trot**.
htfl (Heart Failure)	**Heart failure** risk among **patients** with **rheumatoid arthritis** starting a **TNF antagonist**.
wind (Wind Energy)	**Wind turbine technology** has developed rapidly in recent years and Europe is at the hub of this hightech **industry**.
coast (Coastal Science)	**Coastal communities** are prone to a **natural disaster** such as **tsunami**.
genia (Biomedical)	**HB24** is likely to have an important role in **lymphocytes** as well as in certain developing tissues.
acl (Computational Linguistics)	**Word Identification** has been an important and active issue in **Chinese Natural Language Processing**.

Table 1: Example sentences from each of the seven domains used in our experiments. Terms are bold.

3.2 LLM Fine-Tuning

After constructing the dataset for fine-tuning we perform standard instruction tuning in order to transfer the ATE skill to a smaller model. Precisely, we fine-tune two smaller instruction tuned models, Llama-3-8B-Instruct (`LLaMA`) and Olmo-7B-Instruct (`Olmo`), with standard next-token prediction objective and conversation-style chat templates.[2] In both cases, we use only completions in order to compute the loss, that is, only the tokens generated by the language model after the last "Assistant"-marker. The models were trained for 3 epochs, with learning rate of $2e-4$ and batch size of 8. Only the final checkpoints were taken for further analysis.

3.3 Post-hoc Consistency Enforcement

To address the inconsistent extraction behavior of LLMs we introduce two lightweight post-hoc heuristics for enforcing consistency. The first, document-level consistency (DC) enforcement, aims to correct the LLM's tendency to return only one instance of each extracted term per document, even when multiple mentions occur. To remedy this, we identify all exact string matches of each LLM-extracted term within the document. This approach is conceptually aligned with prior work in NER that enforces intra-document label agreement for repeated spans (Krishnan and Manning, 2006; Gui et al., 2020).

The second rule, corpus-level consistency (CC) enforcement, promotes any term extracted in at least 50% of the documents it appears in to all such documents—addressing inconsistencies in LLM output. This simple heuristic mirrors the Term Re-extraction Model (TREM) by Vu et al. (2008), which reintroduced globally validated terms into individual documents, and aligns with frequency-based termhood estimation methods (Kageura and Umino, 1996). Such reinforcement mechanisms help align model outputs more closely with span-level gold annotations and improve both recall and consistency in document-level evaluations.

4 SOTA Approaches

To better evaluate DiSTER, we compare it against two strong baseline approaches that represent the current SOTA methodologies in ATE.

4.1 Sequence Labeling Approach

We adopt the approach introduced by Tran et al. (2022a), which frames ATE as a sequence classification task using the IOB tagging scheme. This approach employs an `XLM-R-based` token classifier with standard hyper-parameters and has been shown to achieve SOTA in term extraction. It remains a strong baseline, as even recent few-shot LLM-based methods could not consistently outperform it (Tran et al., 2024).

4.2 Few-Shot Approach

We re-implement the few-shot in-context learning approach of Tran et al. (2024), but use cross-domain few-shot samples instead of samples from the target test data. Following Tran et al. (2024), each prompt contains three examples. For every target test domain, we select examples showing the highest semantic similarity to the domain name, as measured by the `paraphrase-multilingual-mpnet-base-v2` embedding model.[3] Each example is structured as a demonstration pairing a source sentence with its corresponding extracted terms. In alignment with Tran et al. (2024), we employ Direct Term Extraction rather than IOB tagging, the LLM explicitly outputs the identified terms. We enriched the prompt templates for extraction as introduced in Tran et al. (2024), with complete specifications of these templates provided in Appendix B.

Table 2: Corpus-level F1 scores across seven datasets. Best result per dataset is marked in bold, second best results are underlined. Teacher model performance is included for comparison.

5 Benchmark Datasets

We make use of several established benchmarks, resulting in seven datasets. They are topically quite distant, which leads to substantially different types of terms, often including domain-specific jargon (see Table 1). All datasets have predefined splits, except for the ACTER datasets, which were introduced in a cross-domain setting. While most original studies report in-domain performance, we only use cross-domain test splits in this work.

We employ the ACTER dataset introduced by the TermEval 2020 Shared Task (Rigouts Terryn et al., 2020), which includes four subsets with each a different domain: heart failure (*htfl*), wind energy (*wind*), dressage (equity) (*equi*), and corruption (*corp*). Secondly, we use the CoastTerm (*coast*) dataset (Delaunay et al., 2024) consisting of scientific abstracts focused on coastal regions. Due to the inherently interdisciplinary nature of coastal studies, the texts include a wide range of specialized terms spanning domains such as environmental science, geography, ecology, and sociology. We also incorporate the *genia* dataset, a standard benchmark for biomedical term extraction (Kim et al., 2011). Finally, we use the ACL-RD-TEC 2.0 *acl* dataset, which contains abstracts from the ACL Anthology from the domain of *computational linguistics* (QasemiZadeh and Schumann, 2016).

6 Experimental Setup

6.1 Evaluation Strategies

We employ both *corpus-level* and *document-level* evaluation. The *corpus-level* approach aggregates predictions and gold annotations across the entire dataset before computing metrics, while the *document-level* strategy calculates metrics per document and then averages results.

6.2 Model Configurations

We evaluate three distinct model categories. First, for our method, DiSTER, which relies on **fine-tuned models**, we use two instruction tuned LLMs on our synthetic data: Llama-3-8B-Instruct (LLaMA) and Olmo-7B-Instruct (Olmo). Regarding the **few-shot prompted models**, we evaluate the same LLM architectures (LLaMA and Olmo) in a few-shot setting, using cross-domain demonstrations from the remaining datasets. For each target domain, we construct prompts with semantically similar examples from other domains. Additionally, we evaluate the better-performing model LLaMA using demonstrations from our dataset *SynTerm*. For the **IOB sequence labeling approaches**, we implement two training configurations. Firstly, we implement a leave-one-out approach where for each test domain, we train on five domains and validate on the sixth. We consistently use *wind* for validation (given its STEM domain alignment) except when testing on *wind* itself, where we validate on *htfl*. In our second configuration, we train on our *SynTerm* dataset to enable direct comparison with the fine-tuned LLMs (the full DiSTER methodology).

This experimental design allows us to systematically evaluate the impact of model architecture, training methodology, and data composition on cross-domain generalization in ATE.

7 Results

Table 2 presents the corpus-level F1 scores. Notably, our models achieve the highest F1 scores in most domains, surpassing both sequence-labeling and few-shot prompting methods. The fine-tuned LLaMA model reaches the best overall performance. Olmo also performs consistently well across domains, demonstrating the effectiveness of our approach even for open-data models. While few-shot prompted models show competitive perfor-

Val/Test	*corp* F1	*equi* F1	*htfl* F1	*wind* F1
corp	–	45.32	40.98	33.74
equi	6.10	–	46.68	30.78
htfl	6.40	51.80*	–	42.57
wind	7.89	31.57	31.68	–

Table 3: F1 scores across ACTER domains using a leave-one-out setup: one domain for testing, one for validation, and the remaining two for training. The *htfl* score is reproduced from Tran et al. (2022a) under the original Shared Task setting.

mance in specific domains (e.g., LLaMA on *htfl*), their performance remains fundamentally inconsistent, with significant variability across different domains such as *corp*. Using our *SynTerm* dataset for demonstrations yields a four percentage point average improvement compared to cross-domain few-shot with LLaMA. Notably, the performance gains for *corp* and *wind*, the two domains with the lowest cross-domain few-shot scores, suggest that *SynTerm* helps achieve more robust overall few-shot performance. The supervised cross-domain IOB models reveal inherent limitations, particularly struggling with recall under domain shift. Even when trained on our *SynTerm* dataset, these models consistently underperform compared to our fine-tuned LLM-based approaches. Remarkably, Table 2 also shows that the fine-tuned LLaMA student surpasses the teacher in corpus-level F1 on three of seven test corpora and stays on-par on the macro average. These findings provide strong support for the generalizability and use of DiSTER as a pivotal strategy for the development of more domain-robust and light-weight ATE systems.

8 Analysis

In this section, we begin by comparing the student to its black-box teacher. Then we inspect the error sources causing the few-shot and IOB model failure. Finally, we present a discussion about the distinctions and use cases of document-level evaluation and the impact of our post-hoc heuristics.

8.1 The Student Rivals Its Teacher

Table 2 shows that DiSTER effectively distills ATE capabilities from the teacher into the much lighter LLaMA student. The student outperforms the teacher on three of seven domains and comes within 1.5 F1 points on two more, demonstrating strong competitive performance despite its smaller size. The largest gains appear in domains semantically aligned with the synthetic corpus (*acl*, *coast*, *genia*). Where overlap is weaker, the student tends to lag further behind, suggesting that broader domain coverage in the pseudo-labeled training data could close the remaining gaps. See Appendix §J for an analysis of training data overlap.

We hypothesize that distillation works due to two complementary factors: (i) sequence-level supervision encourages the student to mimic the teacher's span predictions exactly, reducing prompt sensitivity and reinforcing task-specific patterns; and (ii) domain cues in the synthetic data act as scaffolding: smaller models benefit from domain-specific regularities, aiding generalization in overlapping domains. This suggests that strong cross-domain performance still depends on diverse fine-tuning data, making automated labeling approaches like DiSTER a cost-effective path to improving ATE generalizability in smaller, deployable models.

8.2 Where IOB and Few-Shot Fail

Two systematic error sources (*extraction count* and *term-span length*) explain much of the underperformance observed in the baseline systems, as thoroughly discussed in Appendix H. In brief, in the few-shot setting, models often return few or no candidates. On the *corp* subset, the median number of predicted terms is zero. Even when terms are extracted, their median length far exceeds the gold standard, which severely depresses recall (Table 9).

The supervised IOB model exhibits the converse pathology. When trained on *SynTerm*, the model assigns the term label to overly long spans that often include stop words, thereby inflating recall while harming precision. DiSTER's LLM fine-tuning better addresses this challenge by producing extraction counts and term spans that are closer to the gold standard. Therefore, we posit that the underlying limitation is architectural. These findings are consistent with the instability patterns observed under cross-domain training (Table 3; see Appendix K for a detailed analysis). Even within the original four ACTER domains, F1 scores can drop by over 30 points depending on the validation split. Together, these analyses highlight the need for a more flexible architecture and targeted fine-tuning to best leverage the distillation data *SynTerm* provides.

8.3 Document-Level Evaluation

While corpus-level ATE has been the primary focus in prior evaluations, document-level evaluation better reflects downstream tasks like computer-assisted translation and information retrieval (Šajatović et al., 2019). As shown in Table 4, document-

Model	*corp* F1	*equi* F1	*htfl* F1	*wind* F1	*coast* F1	*genia* F1	*acl* F1	Avg F1
IOB sequence labeling (cross-domain)	25.66	46.91	8.01	**49.90**	11.41	13.49	8.72	23.44

Table 5: F1 scores (bolded for highest score per dataset), absolute precision-recall gaps, and mean F1 score across datasets. Showing the influence of the document consistency (DC) and corpus consistency (CC) heuristics.

level F1 scores are generally lower, reflecting the greater challenge of consistently extracting terms within individual documents. In particular, recall is significantly lower and, in most cases, falls below precision, reversing the trend observed at the corpus-level (see Appendix E). At the corpus level, terms from all documents are pooled, so consistency within individual documents or term repetition matters less.

As shown in Table 5, applying consistency enforcement heuristics improves document-level F1 scores. Especially, the *acl* dataset, with many term repetitions per document, sees a nine-point F1 gain. Since the heuristics target different patterns, within-document (DC) and cross-corpus (CC) term repetition, their effects are complementary. When combined, they yield the highest F1 scores in six of seven evaluated datasets. Additionally, when precision exceeds recall, these heuristics narrow the precision-recall gap, resulting in a more balanced performance.

9 Conclusion

We introduced DiSTER, a scalable and robust ATE framework combining synthetic data generation, LLM fine-tuning, and post-hoc consistency heuristics. By using pseudo-labels from a black-box LLM, we built the diverse *SynTerm* corpus to support cross-domain generalization. The fine-tuned LLMs, especially LLaMA, outperform both supervised sequence labeling and few-shot prompting and perform competitively with the GPT-4o teacher model, despite the size gap. Our results highlight the importance of data composition in cross-domain ATE and show that our approach generalizes well even to less related domains. We also show that document-level evaluation reveals important limitations in consistency, which can be effectively addressed using simple heuristics. Crucially, DiSTER eliminates the need for domain-specific training, making ATE more scalable and practical.

Limitations

Our approach, while effective, has several limitations. First, the pseudo-labels used for training are derived from a black-box LLM and may contain noise, especially for rare or ambiguous terms. Second, while our models perform well even in domains with limited overlap in the training data, generalization to entirely unseen or underrepresented domains cannot be guaranteed. Expanding the diversity of synthetic data could further strengthen cross-domain robustness. Third, the post-hoc consistency heuristics are simple heuristics and do not handle paraphrases or semantic variants, which could limit precision. Fourth, while we use relatively lightweight LLMs, fine-tuning still demands substantial computational resources, potentially limiting accessibility for low-resource settings. Lastly, our experiments are conducted only in English, and computational cost of fine-tuning open-weight models may hinder adoption in low-resource settings.

The authors acknowledge the use of ChatGPT and Claude solely for correcting grammatical and spelling errors, and providing assistance with coding.

B Few-shot prompt template

Extending the few-shot prompt templates introduced by (Tran et al., 2024), we design two modifications:

- **Context Enrichment (CE)**: At the beginning of the user prompt, we add the ISO definition of a *term — Terms are "the designation of a defined concept in a special language by a linguistic expression." (ISO 1087). A term is a word or a phrase that has a specific meaning in a particular context/domain, such as a scientific term or a technical concept.*
- **Assistance Response Guidance (ARG)**: Instead of freely letting the language model begin the assistant's response, we prepend to the to the response the sentence: *I have extracted the terms from the text. Here is the list of terms:*, and let the LLM complete it.

While CE aims to provide the LLM with more knowledge about the task at hands, ARG deals with the inherent structure-free and stochastic nature of LLMs' generations, in order to facilitate parsing.

C Prompt for Entity Type Labeling

Prompts 1 and 2 show the system and user prompts used for entity-type-label generation, respectively.

System Prompt
You are a terminology research expert. Your task is to help the user by answering the following question.

Prompt 1: System prompt used for entity-type-label generation.

D Prompts for Data Synthetization

Prompts 3 and 4 show the system and user prompts used for pseudo-label generation, respectively.

E Precision and Recall per Domain and Model

Table 7: Document-level evaluation: Precision (P) and Recall (R) scores for each dataset across models.

F Qualitative Examples

Table 8 presents a qualitative comparison of different models on the same input sentence. The extracted terms are highlighted in bold. This example underscores the contrast in recall capabilities between various approaches.

In particular, the IOB sequence labeling model trained on *SynTerm* demonstrates high recall, but low precision. In contrast, the few-shot approaches tend to miss key terms, reflecting their comparatively lower recall. Fine-tuned models perform significantly better than their few-shot counterparts, aligning more closely with the gold terms.

G Unique terms among datasets

Figure 3 shows the amount of unique terms per dataset on the diagonal and the amount of unique common terms among the datasets on the lower triangular part. We observe that, as expected, *SynTerm* has the highest overlap with its source datasets, *TermPile* and *TermArXiv*. Furthermore, *SynTerm* shows considerable overlap with all other datasets considered. Contrary to the expected, the overlap comes not only from *TermPile*, but also from the *TerArXiv* dataset, as it shows also common unique term counts in the same order of maginitude as *TermPile*. Interestingly, *SynTerm* has almost all unique terms present in *TermArXiv*, which speaks to the relatively restricted domain and language used in the original dataset.

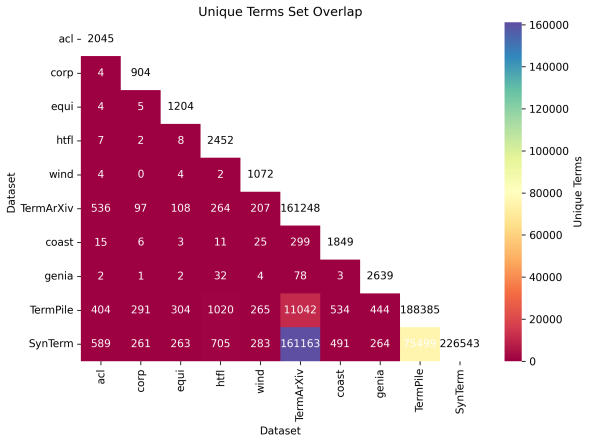

Figure 3: Counts of unique terms among the considered datasets. Off-diagonal counts represent common terms.

H Term Length and Extraction Counts

A possible explanation for the low performance of the few-shot models in some domains like *corp* is given in Table 9. The median number of terms extracted per document for *corp* is zero for both few-shot models (with means of 0.61 and 0.82, respectively). Another contributing factor to the poor performance of the few-shot LLaMA model on *corp* is the extraction of overly long terms. Table 9 reveals that the median length of extracted terms is 27 characters, compared to 11 characters for gold-standard terms.

Although the IOB model trained on *SynTerm* shows a large number of extracted terms per document, many extracted terms are short and imprecise,

Model	Text

often including stopwords like "a" or "and" (see Table 9). This results in relatively high F1 scores, but with an imbalance between precision and recall (see Appendix E). This imbalance and performance gap underscores the effectiveness of DiSTER and can be attributed to several key differences in model design and training paradigms. `XLM-R-based` models, fine-tuned for sequence labeling, are optimized for local contextual understanding within narrow task boundaries. In contrast, LLMs are trained on a broader range of tasks and contexts, equipping them with more adaptable reasoning. We posit that this flexibility allows LLMs to better leverage the *SynTerm* dataset, treating it as a text generation task rather than a sequence labeling problem. Qualitative examples for these effects can be found in Appendix F and an analysis of the cross-domain instability of the sequence-labeling models in Appendix K.

I Directional overlap with k-Nearest Neighbors

In order to observe the total average overlap among two datasets, we extend the analysis introduced by Kambhatla et al. (2023) and include, for that, all data on both sets. Our indicator can be defined as follows. Let

- $\mathcal{D} = \{D_1, \ldots, D_N\}$ be a collection of text datasets, each embedded in $\mathbb{R}^d$;
- $k \in \mathbb{N}$ the fixed neighbourhood size;
- $N_k(x) \subset \bigcup_{i=1}^{N} D_i$ the (unordered) set of the k nearest neighbours of sample x measured wṙt. cosine distance in the embedding space;
- $\mathbf{1}_D(y)$ the indicator that neighbour y belongs to dataset D.

Then the Directional Overlap score $O_{A\to B}$, for two datasets $A, B \in \mathcal{D}$, is

$$O_{A\to B} := \frac{1}{|A|\,k} \sum_{x\in A} \sum_{y\in N_k(x)} \mathbf{1}_B(y),$$

i.e. the expected fraction of a point's k closest neighbours that originate from B. For convenience, one may symmetrize $O_{A\to B}$, such that

$$O(A,B) := \tfrac{1}{2}\big[\, O_{A\to B} + O_{B\to A}\big],$$

and by construction $O(A,B) = O(B,A) \in [0,1]$ and $O(A,A) = 1$. However, in this work, we prefer the Directional Overlap indicator because it reflects the asymmetry of test and train datasets.

J Domain and Term Overlap Analysis

To quantify dataset relationships, we extend the embedding-based Nearest Neighbors analysis from (Kambhatla et al., 2023) to construct a directional overlap indicator (defined in Appendix I). Figure 4 shows the percentage of each origin dataset's nearest neighbors found in each target dataset. For

User Prompt

Context
- Terms are "the designation of a defined concept in a special language by a linguistic expression." (ISO 1087).
- A term is a word or a phrase that has a specific meaning in a particular context, such as a scientific term or a technical concept.
- The goal is the identify domain-specific concepts not named entities.
- A numerical value or date is not considered a term.
- A organization, group or person is not considered a term.
- Any non-scientific content such as websites, URLs, email addresses, HTML tags, code snippets, etc, are not considered terms.
- A location (country, state, place, ...) is not considered a term.
Instructions
- You will be given a question about a type of expressions in natural language.
- Your task is to determine whether the given expression is either:
1) a term type, or
0) no term in the sense of the definition above.
- Do not overthink the question. Answer based on your intuition and knowledge.
- If the context is not clear, use the most common interpretation of the expression type.
- After you explain your answer, produce a json object with the following format: `{ "answer": [Option Number] }`, where [Option Number] is 0, 1, or 2.
Question
Given expressions of the type {expression_type}, would you consider it
- a term (1), or
- no term (0)?
"""

Prompt 2: User prompt used for entity-type-label generation.

System Prompt

You are a terminology research expert. Your task is to help the user extracting terms from scientific abstracts.

Prompt 3: System prompt used for pseudo-label generation.

User Prompt

Context
- Terms are "the designation of a defined concept in a special language by a linguistic expression." (ISO 1087).
- A term is a word or a phrase that has a specific meaning in a particular context/domain, such as a scientific term or a technical concept.
- Only extract terms that are relevant to the domain.
- The goal is to identify domain-specific concepts not named entities.
- A numerical value or date is not considered a term.
- An organization, group or person is not considered a term.
- A location (country, state, place, ...) is not considered a term.

Instructions
- You will be given an excerpt from a scientific abstract.
- Your task is to extract all terms from the text.
- Please return only a comma separated list of correct extractions without any additional information.
- If there are no terms in the text, return an empty string.

Question
The domain: {domain}
The abstract: {abstract}

Return list of extracted terms:

Prompt 4: User prompt used for pseudo-label generation.

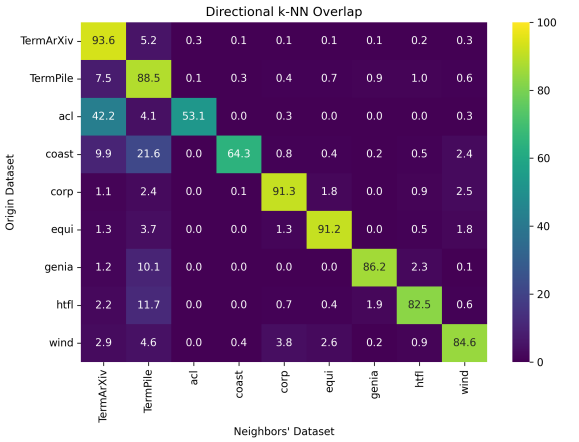

Figure 4: Directional k-NN domain overlap score.

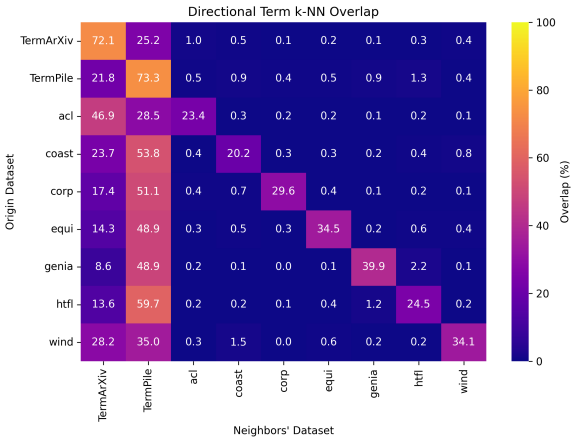

Figure 5: Directional k-NN overlap score for corpus-level terms across domains.

interpretation, read each row as the percentage of an origin dataset's nearest neighbors found in each target dataset.

We observe that *SynTerm* has measurable overlap with all test domains, illustrating the dataset's diversity and broad coverage across different areas. For example for *wind*, we see that 4.6 percent of its nearest neighbors come from the *TermPile* dataset. By adding *TermArXiv* to our *SynTerm* dataset, we add more nearest neighbors for all datasets but especially data points neighboring points from *acl* and *coast*. Analyzing term-level overlap (Figure 5) reveals similar patterns, with most nearest neighbors for *coast* and *acl* terms coming from either *TermArXiv* or *TermPile*. This also holds true for all other test domains to a greater or lesser extent.

These findings explain the strong performance of models fine-tuned on *SynTerm* when evaluated on *coast* and *acl*. The effect is consistent across architectures, with the IOB-based approach gaining 46 and 42 F1 points on *acl* and *coast* respectively when trained on *SynTerm* (Table 2). For *corp* and *equi*, corpus-level term neighbors are prevalent in our synthetic datasets, but domain overlap scores are low. This may explain why the IOB-based approach leverages *SynTerm* to a lesser degree. In order to provide a more precise picture on term overlap, we also provide in Appendix G counts of unique common terms among all datasets.

Notably, LLaMA fine-tuned on *TermArXiv* (containing only scientific terminology with limited overlap to most test domains) demonstrates strong transfer capabilities to unrelated domains like *equi* and *corp*. This suggests LLMs can learn domain-independent representations of terminology, contrasting with sequence tagging models that degrade significantly on out-of-domain data. Such findings highlight LLMs' potential to capture general principles of termhood beyond surface-level domain characteristics.

K Instability using supervised cross-domain Data

While prior work on ACTER reports F1 scores above 50 on *htfl* using the same IOB baseline, these results rely solely on a specific four-domain setting. Expanding to seven domains with varied validation sets reveals a sharp performance drop on *htfl* (Table 2 and Table 4). Surprisingly, increasing domain diversity using leave-one-out training does not guarantee better generalization and sometimes harms performance on individual domains. The directional k-NN overlap heat-map in Appendix J confirms that *htfl* exhibits only maximum 1.9% term-level overlap with the average training mix in this case, explaining its heightened brittleness. This highlights a key trade-off: broader training data may improve average cross-domain results but can reduce domain-specific effectiveness, especially in setups with limited resources.

Replicating the four-domain setup from the ACTER Shared Task confirms that strong results are possible, but only under specific domain splits. As shown in Table 3, the F1 scores of the sequence labeling model vary substantially depending on which domains are used for training and validation. This instability suggests that ATE performance in prior work is highly sensitive to the choice of domains and data splits, raising concerns about the robustness and generalizability of such models. In contrast, using pseudo-labeled data from a LLM yields a more diverse and abundant training corpus, improving cross-domain robustness. Although some domain variance remains, both encoder-based and LLM-based models generalize better, underscoring the importance of data composition and not only model architecture in cross-domain ATE.

Abstract

High-quality content is critical for driving customer satisfaction and conversions across digital platforms and e-commerce. Ensuring that essential information is complete, accurate, and aligned with customer expectations presents a significant challenge at scale. Existing approaches to content evaluation often treat all information uniformly, without prioritizing based on customer relevance, and rely heavily on manual prompt design to encode domain expertise into Large Language Models (LLMs). We present ISEE, a unified framework that addresses these limitations through three core innovations: (1) automated identification of customer-impacting features by synthesizing signals from search behavior, queries, and feedback, enabling targeted content improvements; (2) an instruction-tuned multimodal LLM trained to reliably follow structured operational guidelines, reducing dependence on manual prompt engineering; and (3) robust zero-shot generalization to new product content, features and SOPs via targeted instruction tuning. Evaluated across 20 product categories and 150 product specific features, ISEE achieves 90% precision at 78% recall in detecting product content issues, outperforming much larger (> 200B parameters) models while using a compact 12B architecture.

1 Introduction

High-quality product content is critical for customer trust and conversions in e-commerce. Studies in e-commerce have shown that incomplete or inaccurate information on product pages negatively impacts customer trust and conversions (Amsl et al., 2023)

These issues typically exists in different forms, for example - a conflict between values in different sections (e.g., "16GB RAM" in title vs. "32GB" in features), semantic inaccuracies or misleading description (e.g., labeling a GPU as "Intel Pentium") and omission of important information (e.g., cabin bag capacity).

Defect detection in product details requires analyzing multiple data sources, such as search query logs and customer interaction data, customer feedback, product content etc. Today, this process is largely ad-hoc, relying on domain expertise without a systematic approach. Existing workflows often attempt to detect defects across all features or use static "relevant" lists, ignoring actual customer importance. This one-size-fits-all strategy leads to wasted effort on low-impact issues.

For example, fixing an issue such as the font style on the keycaps of a keyboard may take priority over more critical problems like missing size specifications (e.g., full-size vs. compact) or layout information (e.g., US vs. UK) for the keyboard, or incorrect RAM information in a gaming laptop - issues with real impact on conversions.

While LLMs are increasingly used for product page evaluation, they still rely on manually authored prompts created by domain experts for each product-feature pair. Moreover, LLMs often struggle to follow detailed Standard Operating Procedures (SOPs) (Hwang et al., 2025; Reddy et al., 2023; Ouyang et al., 2022), defaulting to pre-trained knowledge despite explicit instructions (Figure 1). As a result, teams spend over 60 expert hours monthly on iterative prompt refinement, complicating the detection of subtle defects.

To address these limitations, we propose ISEE - an SOP-aligned Evaluator for online product details, with the following key innovations:

Customer-aware prioritization: ISEE identifies high-impact features instead of treating all features equally by analyzing search query logs, product questions, and customer feedback, ensuring fix efforts align with customer expectations and business

[*] Equal contribution.

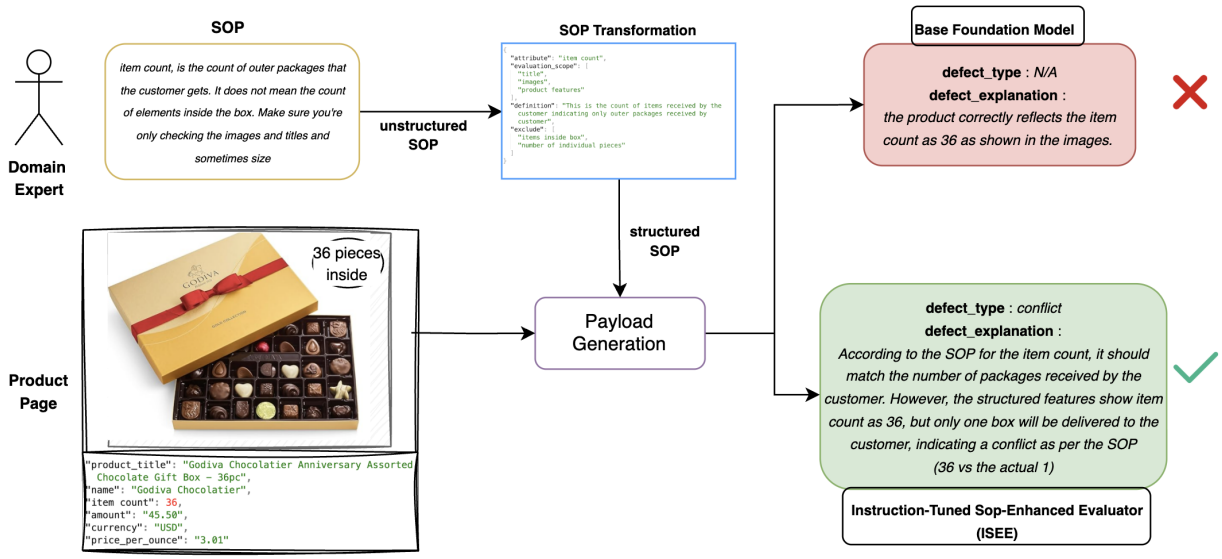

Figure 1: Defect detection comparison between ISEE and traditional LLMs. ISEE's instruction-tuning adheres to the SOP definition of item count as outer package count, correctly identifying the conflict between "36 items" and the single box shown in the image. Foundation models default to their pre-trained understanding, incorrectly validating item count by counting chocolates inside — missing business-specific defects despite explicit instructions.

value.

Instruction-aligned defect detection: An instruction-tuned LLM that reliably follows SOPs, overcoming the limitations of generic prompting.

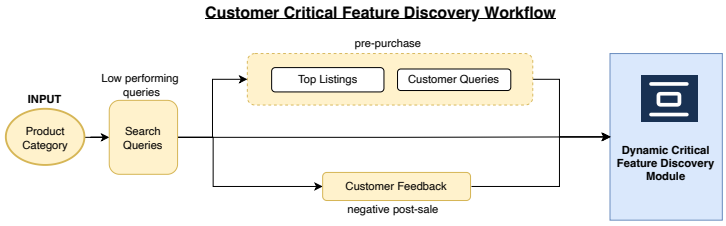
Zero-shot generalization: ISEE generalizes to new features and SOPs, enabling scalable defect detection across diverse product categories.

The following sections describe the system design, customer signal integration, SOP tuning, and evaluation across 20 categories and 150 features, where ISEE shows strong gains in precision and fix relevance over existing methods.

2 System Overview

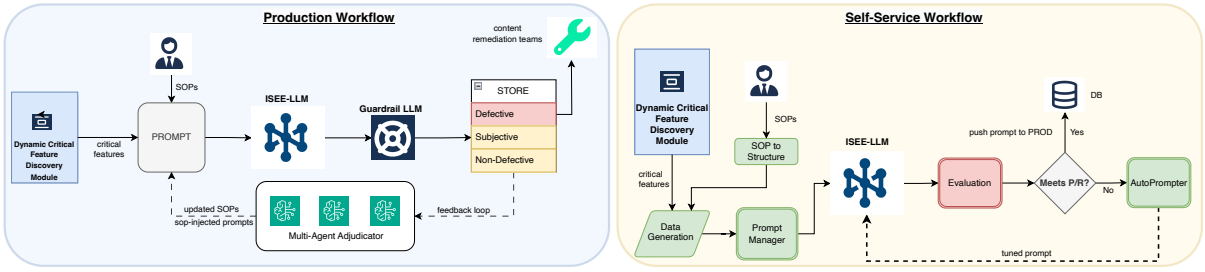
As shown in Figure 2a, the ISEE framework starts with a Product Category during a defined customer engagement window. Within this category, we focus on queries that underperform in terms of conversion relative to typical category levels. For these, the Feature Discovery module surfaces customer-critical features. ISEE then operates in two modes:

A **production workflow** (Fig 2b blue) that continuously evaluates defects, routes them to content remediation teams, and improves recall through feedback. Here, ISEE-LLM evaluates low-converting products using base or SOP-injected prompts. A guardrail-LLM directs outputs into three paths (defective, non-defective, and subjective), from which a sample is passed through a Multi-Agent Adjudicator. The Adjudicator validates the classifications and its results feed into a closed-loop feedback process that gradually improves both the SOPs and the prompts used in evaluation.



A **self-service workflow** (Fig 2b yellow) allows domain experts to improve model performance for categories with weak zero-shot accuracy. Experts can define their SOPs and evaluate them using ISEE-LLM, with prompts auto-tuned (max 3 iterations) until precision-recall thresholds are met, before being pushed to production.

ISEE supports new categories in production while enabling a hands-off-the-wheels improvement paths for under-performing ones via self-service. This paper focuses on the critical feature discovery and production workflows, omitting details on AutoPrompter and Guardrail-LLM.



3 Dynamic Feature Selection Methodology

To focus evaluation on high-impact product page features, ISEE prioritizes customer-critical features using four complementary signals: customer behavior (search and questions), vendor emphasis, customer feedback, and LLM-driven bootstrapping. This ensures that upstream efforts focus on visible, value-driving features.

Search and Customer Intent Analysis: For

(a) ISEE - Dynamic feature Selection Methodology

(b) ISEE - Operating Modes

a product category, we shortlist low converting search queries and use an LLM to extract structured feature-value pairs (we call this shopping intent).

For example:

32GB gaming laptop under 70K $\rightarrow$ { "ram": "32GB", "use_case": "gaming", "price": "<70000" }

Is the RAM upgradeable? $\rightarrow$ { "ram": "upgradeability"}

We focus on vertical features (product specific e.g., RAM, display type), ignoring horizontal ones (common across product categories e.g., price, delivery speed). Each feature's (a) importance score is computed as:

$$\text{Score}_{\text{search}}(a) = \frac{\sum_{i \in P} f(a,i) \cdot v(i) \cdot c(i)}{\sum_{i \in I} v(i)} \quad \text{if } a \in V_{\text{pt}}$$

where $f(a,i)$ is the frequency of feature a in intent i, $v(i)$ is its search volume, $c(i)$ is the search to click conversion rate, P is the product category and V_{P} is the set of vertical features for the product category. This formulation captures not just frequently searched features, but also those correlated with customer engagement. Features found in both searches and customer questions are weighted 1.2x, as questions indicate unresolved customer concerns. This approach combines implicit search behavior with explicit queries to generate a ranked list (S_A) of high-importance features.

Vendor Information Analysis: To complement customer signals, we analyze features in successful listings from low converting shopping intents. We select products that received direct clicks or had high ESCI (relevance to query) scores (> 0.7)((Reddy et al., 2022)). For each feature, we compute:

$$Score_{vendor}(a) = \frac{f(a) \text{ in top results}}{\text{Total analyzed results}}$$

This yields a ranked list (Ven_A) of vendor-prioritized features. Comparing Ven_A with search-driven (S_A) highlights potential gaps between customer interests and vendor emphasis, identifying opportunities to improve content quality.

Customer Feedback Analysis: Post-sale feedback offers valuable signals on feature importance. Using InsightNet (Mukku et al., 2023), we analyze reviews and return comments for clicked products by identify granular topics. We focus on actionable vertical feature issues (e.g., "screen resolution lower than advertised"), filtering out horizontal or non-addressable concerns. A topic-to-feature model standardizes varied expressions (e.g., "too silky and sticks to the body" $\rightarrow$ material). Frequently cited negative features are ranked in $Feed_A$, complementing pre-purchase signals by highlighting features that drive customer dissatisfaction and returns.

LLM-Assisted feature Generation: For new or niche product categories with sparse customer interaction signals, ISEE uses a pre-trained LLM

to identify key purchase-decision features. The resulting list (e.g., ["gpu_specs", "ram_capacity", "refresh_rate"] for GAMING_LAPTOP), denoted as LLM_A, provides essential initial context for quality assessment for emerging product categories before sufficient customer data becomes available.

3.1 Feature Ranking and Integration

We now synthesize insights from customer intent (S_A), vendor emphasis (Ven_A), and post-sale feedback ($Feed_A$) into a final prioritized feature set (F_A) using a tiered integration strategy. (Ref-A.2 for a detailed example). **Tier 1 (Pre_A)** includes features with strong pre-purchase relevance, found in both customer searches and successful vendor listings whereas **Tier 2 ($Post_A$)** includes features driving significant post-sale feedback above a threshold (τ).

$$Pre_A = \{a \mid a \in (S_A \cap Ven_A)\}$$
$$Post_A = \{a \mid a \in Feed_A \text{ and } Score_{\text{feedback}}(a) > \tau\}$$

The final guiding set is the union of these tiers,

$$F_A = Pre_A \cup Post_A$$

This approach prioritizes features critical during selection or impacting post-sale satisfaction, while LLM-generated lists (LLM_A) serve as validation or initial features for new product categories lacking empirical data.

4 I-SEE

4.1 Problem Formulation

Identifying customer - relevant features is only the first step in scalable product data quality assessment. The next challenge is accurately detecting product page defects - Conflicts, Inaccuracies, and Omissions - across diverse product types, while adhering to business-specific SOPs.

Given a product page P with content sources $S = \{s_1, ..., s_n\}$ (e.g., images, title, bullet points), a ranked set of important features $F_A = \{a_1, ..., a_k\}$, and optional SOPs $O = \{o_1, ..., o_m\}$ providing evaluation rules for each a_i, the task is to detect a set of defects D, where each defect $d \in D$ is defined as:

$$d = \begin{cases} eval(a, S, o_i) & \text{if SOP } o_i \text{ exists for } a \\ eval(a, S) & \text{otherwise} \end{cases} \quad (1)$$

Here, $\texttt{eval}(\cdot)$ is a learned function that flags whether a feature is defective, optionally guided by SOPs. This unified formulation supports generalization across both SOP-defined and undefined cases.

4.2 SOP Representation and Instruction Tuning

To ensure ISEE follows business-specific evaluation rules at scale, we instruction-tune the model using structured SOPs in its input context. This domain-primes the model (Ling et al., 2024) to align its defect detection logic with feature-specific guidelines. Since SOPs typically exist only for high-impact features, we adopt a hybrid strategy - using real SOPs where available and generating synthetic ones inspired by BA-authored examples. This exposes the model to diverse instructions during training, enabling generalization to arbitrary SOPs at inference time.

Structured SOP Format: To reduce ambiguity, improve alignment, and limit token length in production, we convert SOPs (real or synthetic) into a structured schema with fields like: `evaluation_scope` (e.g., title, tech specs), `ignore` (e.g., marketing claims), `valid_format` (e.g., Size for Packaged Food items - "XX UoM (Pack of YY)"), and `constraints` (e.g., 1kg weight variance is critical for rice but not TVs)

Instruction-Tuning Framework: We use a templated prmopting strategy where each example includes: 1) a **base prompt** (B): Defect definitions and product content context; 2) an optional **SOP block** (S): structured evaluation rule; 3) a gold **output** (O): defect label, defect type, and explanation of the defect. By varying SOPs while keeping B constant (e.g., B1 $\rightarrow$ O, B1+S1 $\rightarrow$ O1, B1+S2 $\rightarrow$ O2), the model learns to treat SOPs as authoritative and adapt outputs accordingly. This helps it follow SOPs when present, fall back to base logic when not, and generalize to unseen features in zero-shot settings.

4.3 Dataset

Need for Synthetic Data: While several e-commerce datasets exist in the literature, none specifically evaluate product defects, primarily because real-world product data is typically high quality. This presents two challenges: (1) limited defective examples lead to model underfitting - especially for high-priority features, and (2) evaluation

becomes incomplete, as we can audit defective set for precision but lack ground truth to measure recall. To address this gap, we generate synthetic defects across representative products, creating a balanced dataset covering all defect types. This enables recall calculation and SOP-specific variation for instruction-sensitive learning. Our dataset spans 20 diverse categories (e.g., electronics, apparel, home), selecting top-15 features from F_A for 1000 products and their product information.

Synthetic Defect Generation - To enable robust training and evaluation, we generate synthetic defects for both base and SOP-guided cases. In the base setting, we inject product page defects - *Conflicts*, *Inaccuracies*, and *Omissions* - by modifying source values to simulate typical product data errors. For SOP-guided examples, we generate labels based on specific instructions, including cases where the same input yields different outcomes under different SOPs (e.g., a GPU model valid under base rules but invalid under a format-specific SOP). These examples are crucial, as such fine-grained violations rarely occur naturally. See Appendix A.3 for examples. Synthetic defects were generated using LLMs based on patterns observed in actual production audits (e.g., "16GB RAM in title vs. 32GB in features," "package count vs. item count," "ambiguous color descriptors"). These were not arbitrary perturbations but systematic reproductions of common catalog errors. Our defect generation process covers both organic errors (e.g., typos, omissions) and adversarial errors (e.g., inflated chocolate counts). Both errors degrade customer experience, but adversarial errors are particularly critical since they mislead customers into buying the wrong product, leading to customer returning it eventually.

While many defects can be clearly classified using standard rules or SOPs, some conflicts are inherently subjective and context-dependent. For instance, an "olive green" vs. "dark green" mismatch may be critical for `NAIL PAINT` but negligible for `CURTAIN`. Similarly, "nylon" vs. "polyester blend" might matter for `CLOTHES` but not `LUGGAGE`. Such variations don't impact all categories equally, and rigid labeling may introduce bias in model training and evaluation. To handle this, we explicitly flag such cases as *ambiguous or subjective*, using a Multi-Agent Adjudicator to improve dataset reliability.

Multi-Agent Adjudicator - Each defect candidate is reviewed by three diverse LLMs (Claude 3.7 Sonnet, DeepSeek-R1-Distill-Qwen-32B and Pixtral-12B) and labeled as Yes (defect), No (not a defect), Not Applicable (NA), or Unsure (ambiguous). Final labels are assigned via majority consensus: two Yes = Confirmed Defect, two No = Confirmed Not Defect, two NA = Not Applicable. Cases without agreement are marked Ambiguous/-Subjective. This process filters noise and flags subjectivity, enabled naunced-free evaluation.

The final dataset, refined through majority voting, contains 180,000 examples, with each PT-feature pair including a balanced mix of clean and defective cases, across both SOP-guided and base settings.

4.4 Training & Evaluation Details

Training: We instruction-tune Pixtral-12B (Team, 2024) for ISEE due to its strong multi-modal capabilities. Product images are embedded via a vision encoder and concatenated with tokenized text for unified input. We apply LoRA (Hu et al., 2021) for parameter-efficient fine-tuning, adapting only a small subset of weights to internalize SOP logic while preserving pre-trained knowledge. Training occurs in two stages: first on general defect patterns, then on SOP-guided variations where identical inputs yield different outputs based on instructions. We use 8-bit quantization, a learning rate of 2e-4, batch size 32, sequence length 2048, and train on 8× A100 GPUs for 24 hours.

Evaluation: We evaluate using vLLM (Kwon et al., 2023) with 2 dockers, leveraging majority-voting labels for subjectivity awareness. Precision and recall are computed over Confirmed Defect and Not Defect cases. For ambiguous cases, we adopt a soft-label approach - treating predictions as correct if they match any one auditor LLM, allowing for valid variations without excessive penalization.

5 Experiments and Results

We evaluate ISEE and baselines across three key axes: (1) core defect detection in the base setting, (2) gains from SOP-based guidance, and (3) improvements via auto-prompting (Do et al., 2024). Unless specified otherwise, precision and recall are reported jointly across all defect tasks based on binary defect presence.

Base Model Performance: We evaluate 3 models - Claude-3.7 Sonnet (Anthropic, 2024), Pixtral-12B, and ISEE without any SOPs or prompt tuning on all defect tasks. As shown in Table 2, Claude achieves

	SOP Injection			Auto Prompting	Zero Shot Performance on Adhoc categories	
Model	Precision	Recall	F1	Final F1	Category Coverage %	F1
Claude-3.7 Sonnet + SOP	0.83	0.73	0.77	0.85	75	0.68
Pixtral-12B + SOP	0.61	0.72	0.66	0.75	70	0.58
ISEE	0.87	0.78	0.83	0.87	92	0.78

Table 1: Performance of SOP injected models

Model	**Precision**	**Recall**	**F1**
Claude-3.7 Sonnet	0.75	0.70	0.72
Pixtral	0.72	0.65	0.68
ISEE	0.76	0.63	0.69

Table 2: Base Model Performance

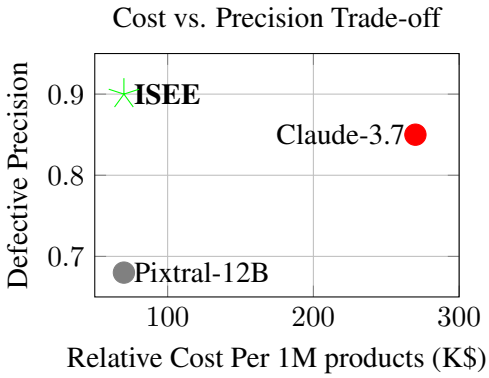


Figure 3: SOP-Injection - Cost v/s Precision

the highest F1 (0.72), while ISEE performs competitively at 0.70 despite being optimized for SOP-driven alignment. These results serve as a baseline for assessing the impact of structured guidance and auto-prompting.

SOP-Injected Performance Gains: To evaluate how models respond to SOPs, we inject SOP constraints into prompts (manually prompted) for all models. It's important to note that this uses a distinct dataset from the base setting, as expected outputs differ due to explicit SOP instructions - making results non-comparable to the base scenario.

As shown in Table 1, ISEE outperforms all models under SOP-driven conditions, achieving an F1 of 0.84 at a fixed cost of $40K per 10M products (same as Pixtral-12B). In contrast, Claude's charge per token, incurs a higher cost of -$270K (Figure 3). While Claude and Pixtral benefit from injected SOPs to varying degrees (F1: 0.66–0.75), only ISEE is instruction-tuned for structured SOPs, giving it a significant edge. ISEE shows notable advantage, particularly detecting inaccuracies (Table 3) as it requires inherent understanding of SOPs and business rules. For example (Figure 1), in packaged food items, the *item count* should reflect number of outer packages, and not contents inside the package. ISEE flags such issues correctly, whereas other models mistakenly validate "36 chocolates" as 36 items instead of recognizing it as one package.

Task Type	**Claude-3.7**	**ISEE**	**+/-**
Conflicts	0.85	0.87	+0.02
Inaccuracies	0.83	0.89	+0.06
Omissions	0.86	0.85	-0.01

Table 3: Task specific - SOP F1 comparison

Auto-Prompting Performance: Using the SOP-injected prompts as base, iterative refinement by leveraging false positives/negatives boosts Claude's F1 to 0.82. ISEE, despite being smaller, begins at 0.83 and improves to 0.87 (Table 1), with iterations primarily fine-tune edge cases, reflecting ISEE's strong baseline understanding of SOPs and defect patterns - an advantage in production, where prompt tuning is costly.

Zero Shot Generalization: ISEE also generalizes well to unseen categories, with 92% coverage (i.e., detecting $\geq 5\%$ defects in 1000 products per category) and a zero-shot F1 of 0.78. This highlights the effectiveness of SOP-based fine-tuning in improving both model alignment and transferability to new products. Qualitative examples are shown in Appendix A.4.

6 Conclusion

We present ISEE-Defects, a unified framework for automated defect identification through customer-aware feature prioritization and SOP-enhanced evaluation. Using a 12B parameter instruction-tuned model, ISEE achieves 90% precision at 78% recall across 350 Product Category and features, while reducing operational costs by 80% compared to larger models. The framework demonstrates robust zero-shot generalization (0.78 F1) to unseen categories and requires minimal prompt engineering, making it highly effective for production deployment.

7 Limitations

While ISEE shows strong performance across a wide range of product categories, it has several limitations. First, it relies heavily on synthetic data for training, since real-world labeled defects are rare. Although useful, this synthetic data may not fully reflect the complexity of actual defects seen in production, which could impact real-world performance. Second, ISEE's feature selection method depends on customer signals like search queries, reviews, and feedback. In new or low-traffic categories where such data is limited, the system may struggle to identify the most important features. Third, the use of majority voting on the Multi-Agent Adjudicator output and soft labels to handle subjective cases helps reduce noise but also brings some uncertainty to the training and evaluation process. The 12B parameter model strikes a good balance between cost and accuracy, but may still fall short in detecting subtle issues in highly technical domains that require deeper product knowledge or complex reasoning. Additionally, while ISEE can tell whether a defect exists, it does not yet tell what's the impact of the defect to customer conversion. The impact of the correction of that defect is still understood after doing web-lab experiments post correction.

A Appendix

A.1 Taxonomy Layer

The separation between horizontal and vertical features is based on established e-commerce taxonomic frameworks. Horizontal features are characteristics that transcend product categories (e.g., price, delivery, brand), while vertical features are category specific (e.g., RAM for laptops, heel height for shoes). The classification undergoes continuous validation through domain expert reviews and customer interaction analysis, ensuring it remains current with evolving e-commerce patterns and customer needs.This comprehensive framework ensures consistent feature classification while remaining adaptable to evolving e-commerce patterns and customer needs.

Type	Category	Example features
Horizontal	Transaction	Price, Delivery Time, Warranty
	Trust	Brand, Vendor Rating, Reviews
	Availability	Stock Status, Delivery Options
Vertical	Electronics	RAM, Processor, Screen Size
	Apparel	Material, Size, Fit Type
	Beauty	Ingredients, Skin Type
	Home	Dimensions, Weight Capacity
	Automotive	Engine Type, Fuel Efficiency

Table 4: Product feature Classification Framework

A.2 Feature Importance Analysis : A Gaming Laptop Example

We present a detailed breakdown of feature importance analysis for gaming laptops in Table 5. The analysis combines signals from four primary sources: search queries (S_A), vendor listings (Ven_A), customer feedback ($Feed_A$), and LLM-generated insights (LLM_A) to determine the final feature ranking (F_A). Search patterns show users primarily focus on technical specifications, with RAM, GPU, and processor being the top queries (e.g., "32GB gaming", "RTX laptop"). Vendor listings emphasize similar technical aspects but prioritize GPU and display specifications, suggesting a focus on gaming performance marketing. Interestingly, customer feedback reveals different priorities, highlighting thermal management and battery life as crucial concerns, aspects less prominent in search and vendor data. The final ranking (F_A) synthesizes these signals, categorizing features into two tiers: Tier 1 features (RAM, GPU, Display) represent the overlap between search and vendor priorities, while Tier 2 features (Thermal, Battery Life) emerge from significant customer feedback signals, indicating potential gaps between marketing focus and user experience.

A.3 Evaluation Datasets

Table 6 illustrates our evaluation dataset structure through representative examples across different product categories. Each entry is identified by a unique ID and product category, with paired source comparisons to detect content defects. The dataset captures three primary defect types: (1) Conflicting values across sources, such as entry A1 showing conflicting RAM specifications (16GB vs 32GB) between title and product features, (2) Inaccurate values like A3's implausible 2MB RAM specification for a phone, and (3) Omitted information as seen in A4 where size information is missing. Sources include product titles, product features (PF), and bullet points (BP). The label field indicates whether the comparison pair contains a defect (1) or not (0). Non-defect cases include matching values across sources (A3's 256GB SSD) and acceptable variations in representation (A2's "1TB" vs "1000GB"). This structured comparison enables systematic evaluation of content quality across different product features and content locations.

A.4 Qualitative Analysis of ISEE Outputs

Table 7 showcases ISEE's ability to detect and explain various content quality issues across diverse product categories. The model demonstrates reasoning capabilities in identifying conflicts and inaccuracies in product page. For inaccuracy detection, ISEE successfully flags implausible feature values, such as a "Cream" form factor for a physical cupping massage set, an impossible "999" size specification for a chair, and an inaccurate "4.2" surround sound value for a portable Bluetooth speaker. The model's explanations show understanding of product context - for eg - recognizing that surround sound values are specific to home theater systems, not portable speakers. In terms of conflict checking, the model identifies cross-field discrepancies, as demonstrated in the television example where it catches the mismatch between the listed 65-inch specification and the 83-inch size mentioned in both title and images. These examples highlight ISEE's ability to combine domain knowledge with logical reasoning to provide clear explanations detected issues.

Rank *Signal*	**Search** (S_A) *(Top Queries)*	**Vendor** (Ven_A) *(Listing Extract)*	**Feedback** ($Feed_A$) *(Customer Feedback)*	**LLM** (LLM_A) *(Generated)*	**Final** (F_A) *(Tier)*
1	RAM *"32GB gaming"*	GPU *"RTX 4060"*	Thermal *"gets too hot"*	GPU	RAM *(Tier 1: S&S)*
2	GPU *"RTX laptop"*	Display *"165Hz FHD"*	Battery Life *"dies quickly"*	RAM	GPU *(Tier 1: S&S)*
3	Processor *"i7 gaming"*	RAM *"32GB DDR5"*	Performance *"lags in games"*	Refresh Rate	Display *(Tier 1: S&S)*
4	Display *"144hz screen"*	Storage *"1TB SSD"*	Build Quality *"feels cheap"*	Processor	Thermal *(Tier 2: Feed)*
5	Storage *"1TB gaming"*	Processor *"i9 13th Gen"*	Display *"screen bleed"*	Storage	Battery Life *(Tier 2: Feed)*

Table 5: Feature Importance Analysis: A Gaming Laptop Example
Note: Final ranking (F_A) shows Tier 1 features (common in Search and Vendor data) followed by Tier 2 features (significant customer feedback signals). S&V = Search & Vendor overlap, Feed = Customer Feedback from Returns and Reviews

ID	**Category**	**Feature**	**Source 1**	**Value 2**	**Source 2**	**Value 2**	**Defect type**	**Label**
A1	LAPTOP	RAM	Title	16GB	PF	32GB	Conflict	1
A1	LAPTOP	GPU	PF	Graphics			Inaccuracy	1
A2	LAPTOP	SSD	PF	1TB	BP	1000GB	None	0
A3	PHONE	SSD	Title	256GB	PF	256GB	None	0
A3	PHONE	RAM	PF	2MB			Inaccuracy	1
A4	MONITOR	Refresh Rate	Title	144Hz	PF	60Hz	Conflict	1
A4	MONITOR	Size	None	None	None	None	Omission	1
A5	BED	Color	Title	Brown			Omission	0

Table 6: Sample Entries from Evaluation Dataset (Pair-wise Source Comparison) PF = Product Features, BP = Bullet Points

Issue Type	Product Category	Model Explanation
Inaccuracy	Massager	The item form is listed as 'Cream', which seems anomalous for a cupping massage set that consists of glass cups and silicone bulbs as shown in the images. Typically, cupping sets do not come in a cream form
Conflict	Television	The product information states the display size is 65.0 inches, but the images clearly show a much larger television, with 83 inches dimension. Also, the product title mentions the size as "83 Inch". This is a significant conflict in the display size specification.
Inaccuracy	Chair	The size value listed as 999 seems anomalous and inaccurate for a chair product.
Inaccuracy	Speaker	The surround sound channel configuration of 4.2 listed for this portable Bluetooth speaker seems anomalous and inaccurate. Surround sound configurations are typically used for multi-speaker home theater setups, not single portable speakers like this one.
Inaccuracy	Chair	The special feature listed as \"Toy\" seems anomalous for an outdoor chair intended for adults and children up to 250 lbs.

Table 7: ISEE output examples : These examples showcase the model's generalization with the explanation across various issue types

Computational Blueprints: Generating Isomorphic Mathematics Problems with Large Language Models

Jeong-Hoon Kim*, **Jinwoo Nam***, **and Geunsik Jo**
Turing Co. Ltd.
{eric, matthew, klip}@teamturing.com

Abstract

Personalized mathematics education is growing rapidly, creating a strong demand for large sets of similar practice problems. Yet existing studies on mathematics problem generation have focused on data augmentation for training neural language models rather than on direct educational deployment. To bridge this gap, we define a new task, Isomorphic Math Problem Generation (IMPG), designed to produce structurally consistent variants of source problems. Subsequently, we explored LLM-based frameworks for automatic IMPG through successive refinements, and established Computational Blueprints for Isomorphic Twins (CBIT). With meta-level generation and template-based selective variation, CBIT achieves high mathematical correctness and structural consistency while reducing the cost of generation. Empirical results across refinements demonstrate that CBIT is superior on generation accuracy and cost-effectiveness at scale. Most importantly, CBIT-generated problems exhibited an error rate 17.8% lower than expert-authored items, with deployment to $6,732$ learners on a commercial education platform yielding $186,870$ interactions.

1 Introduction

In mathematics education, repetitive practice with similar problems is essential for conceptual understanding, as demonstrated by decades of research. According to Gick and Holyoak (1983), students learn by comparing and contrasting multiple similar examples. Through this process, they abstract the core structure of problems, which is the key to transfer knowledge to novel situations. Similarly, Rittle-Johnson et al. (2001) highlights the link between procedural skill and conceptual insight. Procedural skill, which is strengthened through repeated practice, develops into procedural fluency that reduces the cognitive load required for computation and allows students to focus on underlying concepts.

Despite its educational importance, providing high-quality repetitive learning experiences remains a formidable challenge in industrial settings. Generating related practice problems has been regarded as the work of expert mathematics educators, since every new item must remain pedagogically valid and tightly aligned with the targeted concepts (Burgos et al., 2025), demanding substantial time and cost. In personalized online learning environments, the challenge becomes even greater. Because the required practice problems differ depending on the student and the topic, it is impractical to prepare them all in advance.

In a different line of work, automatic generation of mathematics problems has been an active research area in Neural Language Processing with a variety of approaches. Zhou and Huang (2019), Liu et al. (2021), Wang et al. (2021), Wu et al. (2022), and Qin et al. (2023) focused on effectively encoding equation and context information into neural language models for mathematics problem generation, but the range of producible problems was severely limited by the capacity of those small models. The advent of the Transformer architecture (Vaswani et al., 2017) and the scaling-law (Kaplan et al., 2020) motivation for Large Language Models (LLMs) broadened the field. For example, Drori et al. (2022) employed the Codex (Chen et al., 2021) to synthesize new questions by leveraging other problems within the same curricular unit, but provided no guarantee of the mathematical correctness of the generated items. Li et al. (2024b) projected original problems into a symbolic domain (SMT-LIB; Barrett et al., 2016), where projection and reconstruction were performed by GPT-4(Achiam et al., 2023) and symbolic mutation were applied to generate similar problems, ensuring mathematical correctness using SMT-Lib solver.

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1389–1401
November 4-9, 2025 ©2025 Association for Computational Linguistics

Similarly, the AIC method (Li et al., 2024a) used Llama3-70B-Instruct (Grattafiori et al., 2024) to project and reconstruct problems in an abstract domain, while also prompting the model to generate verification programs that check the abstraction. Both studies provided significant insight to this work in that they transformed the task domain so that mathematical correctness can be verified deterministically. Specifically, AIC, which supports a broader range of problem types, was adopted as the baseline for comparison; further details are given in Section 3.

Despite these advances, no prior work has explicitly aimed at educational use. The above methods evaluate performance by semantic similarity measured with BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005) between generated problems and their input equations or context, and by downstream benchmark scores on mathematics problem solving such as GSM8k (Cobbe et al., 2021) and MATH (Chen et al., 2021). This evaluation scheme indicates that existing studies concentrated on data-augmentation technique for training neural language models, and in fact present their work as mathematical data synthesis. Consequently, deploying such problems for educational use incurs substantial hidden costs for human expert verification, ultimately nullifying the benefits of automation.

To bridge the gap between academic research and educational application, we first propose the task of Isomorphic Math Problem Generation (IMPG). As shown in Figure 1, rather than inventing entirely new problems, IMPG aims to generate structurally consistent variants of source problems that vary only in numerical values and thereby inherit the pedagogical validity of the source problems' linguistic context. Therefore, if the source problems have been pedagogically validated, the isomorphic problems successfully generated through IMPG can in turn be considered valid. To facilitate research on this task, we construct and publicly release[1] a comprehensive benchmark dataset covering multiple grade levels and difficulty tiers, accompanied by an automatic verification toolkit that symbolically checks whether generated problems satisfy the required numerical relationships, thereby enabling reliable and standardized evaluation of new methods.

To address IMPG, we propose Computational Blueprints for Isomorphic Twins (CBIT), a framework designed to ensure mathematical correctness, structural consistency, and scalability. For mathematical correctness, CBIT encodes the quantitative relationships of source problems as symbolic constraints and generates new items only when those constraints are satisfied. For structural consistency, it isolates invariant linguistic and symbolic templates from variable numerical elements, filling only designated slots so that each output preserves the source form. For scalability, CBIT adopts a meta-level approach in which the LLM writes a reusable problem-generating program, enabling unbounded verified outputs with minimal LLM calls.

We summarize our contributions as follows.

- We propose the task of Isomorphic Math Problem Generation (IMPG), aimed at creating problems ready for real educational deployment.
- We build and release a benchmark dataset covering diverse grade levels and difficulty ranges, accompanied by an automatic verification toolkit that enables reliable evaluation and facilitates future research on IMPG.
- We establish CBIT framework that leverages LLMs as blueprint authors to achieve high generation accuracy and substantially lower production cost, while aligning LLM capabilities with the requirements of IMPG.
- We validate CBIT's industrial applicability through a large-scale real-world deployment, where it achieved an error rate 17.8% lower than expert-authored items over 186,870 learning interactions involving 6,732 learners, demonstrating its readiness for practical use in education at scale.

2 Isomorphic Mathematics Problem Generation

2.1 Task Definition

We define a mathematics problem as a tuple $P = (Q, S, A)$, where Q is the question text, S is the solution text, and A is the final answer entailed by S for Q. Note that each of Q and S may consist of natural language, mathematical expressions, or a mixture of both, and must contain at least one mathematical expression. The goal of Isomorphic Math problem Generation is to generate a set of K problems $\mathcal{T} = \{P_1, P_2, \ldots, P_K\}$ from a source

[1] https://github.com/eric-jhoon/IMPG

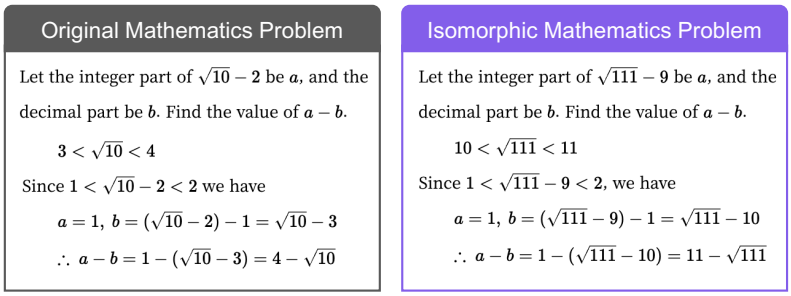

Figure 1: Example of an isomorphic math problem generated from an original one, showing changed numerical values while preserving the underlying structure.

problem P_s where each P_i in $\mathcal{T}$ satisfies the following conditions.

Structural Equivalence: These conditions ensure that any variation is restricted to the content of the original mathematical expressions, preserving the structural essence of the source problem.

$$\begin{aligned}&\forall i \in \{1,\ldots,K\}:\\ &\quad E(Q_s \oplus S_s) \neq E(Q_i \oplus S_i),\\ &\quad |E(Q_s \oplus S_s)| = |E(Q_i \oplus S_i)|,\\ &\quad N(Q_s \oplus S_s) = N(Q_i \oplus S_i),\end{aligned}$$

where $\oplus$ denotes string concatenation, $E(\cdot)$ and $N(\cdot)$ returns the tuple of all mathematical expressions and natural-language text contained, respectively. $|\cdot|$ represents the number of elements in a given tuple.

Conceptual Correctness: These conditions ensure that every generated problem preserves the quantitative and logical relationships among the mathematical expressions of the source problem, thereby maintaining the original mathematical concepts.

$$\begin{aligned}&\forall i \in \{1,\ldots,K\}:\\ &\quad \mathcal{R}\big(E(Q_s \oplus S_s)\big) = \mathcal{R}\big(E(Q_i \oplus S_i)\big),\end{aligned}$$

where $\mathcal{R}(\cdot)$ denotes the implicit ideal set of quantitative relationships among numerical values, encompassing dependencies both within and across expressions. Only when all the above conditions are satisfied is the Isomorphic Math Problem Generation (IMPG) task considered successfully accomplished;

2.2 Benchmark

A benchmark dataset was constructed to support the evaluation presented in this study, covering mathematics problems from grade 4 through grade 12 (up to college entrance exam level). This dataset comprises 195 original problems sampled across 67 distinct curriculum units, with each problem categorized into low, medium, or high difficulty levels. Specifically, The dataset was sampled from a pool of expert-authored and field-tested items, ensuring both pedagogical validity and practical relevance. We then applied an additional restriction to include only text-based items represented in LaTeX, while maintaining balanced coverage across curriculum units and difficulty levels.

Difficulty	Total Rel	Avg.	Max
Easy	605	9.17	28
Medium	832	12.42	29
High	973	15.69	35
Total	2,410	12.36	35

Table 1: Symbolic relationships counts by difficulty level. Total Rel indicates the total number of relationships identified, while Avg. and Max denote the average and maximum number of relationships per problem, respectively.

Note that under IMPG, the dataset contains far richer information than the raw count suggests. As the problem generation is reframed into revealing symbolic relations between variables, our dataset encodes 2,410 relation signals rather than merely 195 isolated items. As shown in Table 1, the average number of identifiable symbolic relationships per problem increases steadily from easy to hard, and the dataset as a whole contains 2,410 such relationships. A detailed analysis of the dataset distribution and characteristics is provided in Appendix A.

Unlike conventional datasets providing a fixed set of gold answers, we instead develop and release a problem-specific verification toolkit. This toolkit, implemented as a lightweight algorithm, enables the automatic validation of any number of generated isomorphic problems. The example pseudo-

code of the toolkit is provided in Appendix Algorithm 1. Since evaluation in this work is conducted not by comparing against pre-defined gold answers but by applying automatic verification algorithms, the practical evaluation scale is substantially amplified. For instance, if each of the 195 problems is used to generate 10 isomorphic problems, the evaluation effectively covers $1,950$ problem instances. This design enables large-scale, rigorous assessment without requiring manual annotation.

2.3 Metric

The major evaluation metric is the Mean Per-Problem Success Rate(MPSR). Given a total of N original problems, for each original problem indicator i, the generation of a fixed number K of isomorphic problems would be requested (e.g., $K = 30$). Let s_i denote the number of successfully generated problems that pass verification for problem i, where $0 \leq s_i \leq K$. The per-problem success rate is then defined as:

$$\text{SuccessRate}_i = \frac{s_i}{K}, \tag{1}$$

that is, the ratio of successful generations relative to the requested number of generations. The overall MPSR is computed by taking the mean of the per-problem success rates across all N problems:

$$\text{MPSR} = \frac{1}{N} \sum_{i=1}^{N} \frac{s_i}{K} \tag{2}$$

In addition to success rates, we also evaluate the economic efficiency of problem generation using token consumption. Let T_{pr} and T_{cp} denote the total number of prompt tokens and completion tokens used, respectively. We define Tokens Per Success(TPS) as the total token consumption divied by the number of successful generations. To express this as a real-world cost in USD, we incorporate the per-token costs of prompt tokens c_{pr} and completion tokens c_{cp}, which may differ depending on the LLM service provider. The resulting metric, Cost Per Success(CPS), is computed as:

$$\text{CPS} = \frac{c_{pr}T_{pr} + c_{cp}T_{cp}}{\sum_{i=1}^{N} s_i} \tag{3}$$

This cost-centric metric captures the practical efficiency of each generation method and reflects its commercial viability for real-world deployment.

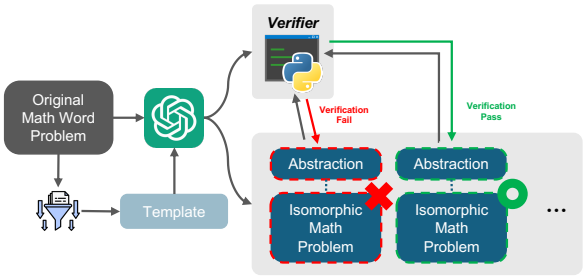

Figure 2: Structure of AIC-Batch. The LLM generates multiple Abstraction-Problem sets and a Verifier to ensure mathematical correctness, while a heuristically extracted template reinforces structural consistency.

3 Proposed Method

3.1 Iterative vs. Batch

In automated math problem generation, two prompting strategies for Large Language Models (LLMs) can be leveraged; the Iterative approach and the Batch approach. The Iterative approach generates one problem per prompt and repeats the process multiple times to produce multiple problems. In contrast, the Batch approach requests LLM to generate multiple problems within a single response.

To explore the most suitable prompting strategy for IMPG, we compared two approaches, where detailed experimental results are provided in Appendix B. This comparison revealed three key findings: (1) as the request size K increased, the LLM's individual responses in the Batch setting becomes longer and LLM tends to omit the part of the requested output, (2) the Iterative method, requiring a fresh prompt for every problem while the prompt itself is typically much longer than the generated answer tokens, incurred a disproportionately high token cost, and (3) all Batch-generated problems originating from the same source either jointly passed or jointly failed the benchmark verification, suggesting that the Batch method forms an internal generation engine before sampling individual problems.

Taken together, these factors underscore that the Batch approach offers better scalability and internal consistency for IMPG, motivating our decision to adopt it as the baseline for all subsequent experiments.

3.2 AIC-Batch

To establish this baseline, we reimplemented the AIC framework, which is most closely aligned with our task, using the Batch prompting strategy.

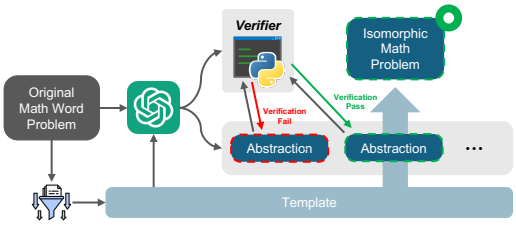

Figure 3: Blueprint for Isomorphic Twin. The LLM outputs only an Abstraction while a predefined template deterministically reconstructs the full text.

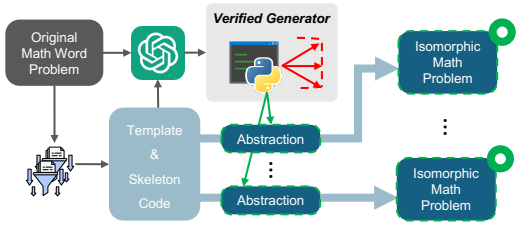

Figure 4: Computational Blueprint for Isomorphic Twin. The LLM outputs a verified generator program that produces Abstractions from random seeds and full isomorphic problems is reconstructed by predefined template.

Specifically, following the original AIC framework, the LLM is prompted to generate not only the math problem itself but also an accompanying Abstraction and Verifier code to ensure mathematical correctness. The Abstraction serves as a symbolic summary that captures key numerical elements and the answer, while the Verifier is a Python program that checks the consistency of relationships between these values.

In addition, to further strengthen structural consistency, we heuristically extracted a natural text template from each source problem and provided it to the LLM as part of the prompt, so that the generated problems would adhere more tightly to the intended linguistic and structural patterns.

This design strengthens the core requirements of IMPG, namely mathematical correctness and structural consistency, thereby providing a robust baseline built on the strengths of the original AIC method.

3.3 Blueprint for Isomorphic Twin

Motivated by our earlier finding that the LLM tends to avoid long responses, we explored whether further improvement could be achieved by having the model generate only the Abstraction. If the LLM were limited to this concise symbolic representation, the output length would shrink substantially, which we expected would mitigate the long-response avoidance and at the same time free the model to concentrate on mathematical reasoning. However, such a design requires a way to recover the full text from the Abstraction. To meet this requirement, we developed problem templates capable of deterministically combining with the generated Abstraction to reconstruct complete question and solution texts. This blueprint–template design defines our Blueprint for Isomorphic Twin (BIT) framework.

By explicitly decomposing problem generation into Abstraction generation and text realization, BIT assigns only the semantically demanding symbolic reasoning to the LLM while the natural-language layer is completed heuristically from the template. This not only reduces the cognitive and computational burden of free-form text production but also yields two additional advantages. First, whereas AIC-Batch merely provided templates as optional references, BIT enforces template-guided generation, allowing much stricter structural consistency than before. Second, because the full text is now constructed deterministically from the verified Abstraction, mathematical correctness established at the Abstraction level automatically extends to the final question and solution text. In contrast, the earlier AIC-Batch setting left the Abstraction and full text only loosely coupled, so correctness of the Abstraction did not strictly guarantee correctness of the realized problem. A comparison of Figure 2 and Figure 3 makes clear the differing relationships among the Verifier, Abstraction, and Isomorphic Math Problem in the two designs.

Furthermore, BIT can be viewed as externalizing a latent two-stage plan that the LLM was already performing implicitly. In the Batch setting we had observed that all generated variants of a given source problem either jointly passed or jointly failed the benchmark verification, suggesting that the model was already forming an internal numerical blueprint before realizing the surface text. By making this hidden planning explicit and restricting the model to the essential subtask of formula generation, BIT enables more stable and scalable isomorphic problem generation while directing the model's computational effort toward the core symbolic reasoning required for the task.

3.4 Computational Blueprint for Isomorphic Twin

Building on BIT, we sought to push task decomposition one step further. While BIT externalizes

the latent separation between abstraction generation and text realization, we asked whether the Abstraction generation itself could also be externalized. Our earlier observations suggested that, in the Batch setting, the LLM already forms an implicit generation engine before producing text. This led us to investigate whether the model could be prompted to explicitly create such an engine as an executable program, rather than directly emitting problems or even their Abstractions.

In the resulting framework, called Computational Blueprint for Isomorphic Twin (CBIT), the LLM is no longer instructed to output problem text or Abstractions. Instead, it is prompted to write a generator program that takes a random seed as input and, for each seed, produces an isomorphic math problem together with its solution and answer. Because program synthesis is inherently more free-form than producing a concise Abstraction, we provide a skeleton code specifying essential interfaces and control flow to guide the LLM toward consistent and verifiable outputs. Detailed description of code-guided schema is described in Appendix C. This reframes problem generation as a meta-generation task where the LLM's effort is directed toward constructing the generative mechanism itself.

The design of CBIT yields several important advantages. First, verification becomes intrinsic to generation. Because the generator program is required to construct Abstractions that already satisfy all numerical relationships identified in the source problem, mathematical correctness is guaranteed by deterministic execution, eliminating the need for a separate Verifier and avoiding repeated LLM calls whenever verification fails. Consequently, the number of generated problems becomes independent of LLM invocation cost; once the generator is authored, it can produce any number of correct variants with negligible additional expense. Second, by shifting the production of Abstractions from free-form text to code-based computation, CBIT strengthens mathematical correctness. Prior work such as Program-of-Thought (Chen et al., 2023) has shown that when LLMs are guided to reason via external tools or code, their mathematical reliability improves. CBIT exploits this effect by letting the LLM use its reasoning ability to design the generator while delegating the exact calculation of numerical values to a deterministic programming language, ensuring computational integrity. Third, CBIT offers an exceptional level of expert control-

Metric	K	AIC-B	BIT	CBIT
MPSR↑	10	0.39	<u>0.85</u>	**0.93**
	30	0.17	<u>0.79</u>	**0.89**
	100	0.01	<u>0.32</u>	**0.83**
CPS↓	10	$17.90	<u>$7.27</u>	**$6.28**
	30	$12.53	<u>$3.41</u>	**$2.17**
	100	$30.03	<u>$1.58</u>	**$0.71**

Table 2: Comparison of MPSR, and CPS across different request sizes. CPS is measured in USD per 1,000 problems. Best in **bold**, second-best <u>underlined</u>.

lability and interpretability. Because the LLM's output is a generator program, the logic by which new problems are created is fully transparent and can be readily inspected by human experts. If any generated problems are deemed mathematically unsuitable, minor edits to the program suffice to regenerate the entire family of isomorphic problems without further LLM involvement. Moreover, storing the generator itself provides a long-term advantage; the program can be preserved and re-executed at any time to produce additional verified problems on demand, ensuring reproducibility and efficient maintenance of large problem banks.

In summary, CBIT transforms the role of the LLM from producing individual problems to authoring a computational generator, thereby combining the strengths of symbolic reasoning and deterministic execution. It achieves built-in mathematical correctness, decouples generation scale from token cost, and provides strong expert controllability and long-term reproducibility.

4 Experimental Results

Generation Accuracy and Cost Effectiveness: We compare the three proposed isomorphic problem generation frameworks using Mean Per-Problem Success Rate (MPSR), and Cost Per Success (CPS) as evaluation metrics. As shown in Table 2, across all metrics and request sizes, the three methods improve in clear stages demonstrating that each design choice contributed in the intended direction.

From AIC-Batch to BIT, the introduction of the blueprint mechanism markedly strengthened structural consistency and concentrated the LLM's effort on mathematical reasoning. This is reflected in the large jump in MPSR; even at $K = 30$, BIT achives 0.79 compared to AIC-Batch's 0.17. Notably, CBIT's MPSR remains close to BIT's up to $K = 30$, indicating that the blueprint is the dom-

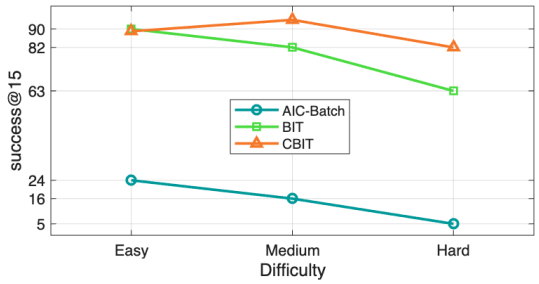

Figure 5: Success@15 across difficulty levels

inant driver of generation accuracy, while CBIT provides additional but more modest gains in this dimension.

In contrast, cost efficiency improves most dramatically when moving from BIT to CBIT. At $K = 100$, CBIT achieves a CPS of \$0.71, improving on BIT's \$1.58 and representing a $42\times$ lower cost than AIC-Batch's \$30.03. This striking decrease stems from CBIT's computational approach, where the LLM writes a generator program that can produce an unlimited number of verified problems without further model calls, thereby decoupling generation scale from token cost.

Robustness across Difficulty Levels: According to Table 1, increasing problem difficulty corresponds to a greater number of numerical relationships, which in turn introduces two distinct obstacles; the generation process may fail to identify all necessary relationships, or, even when these relationships are successfully identified, it may fail to generalize them and instead impose constraints that are too tight, leaving too few feasible variants to meet the requested number.

To assess robustness to problem difficulty levels, we adopt the success@15 metric under the setting of generating $K = 30$ isomorphic problems per source problem, with difficulty categorized as easy, medium, or hard by experts. This metric measures the probability that at least 15 of the requested 30 problems are successfully generated, so that cases producing only a small number of valid problems far below the request can be regarded as unsuable.

As shown in Figure 5, AIC-Batch exhibits poor performance across all levels, with success@15 values of only 24%, 16%, and 5% respectively, confirming its vulnerability to increased difficulty. In contrast, BIT significantly improves stability, achieving 90%, 82%, and 63% across the same levels.

CBIT delivers the best and most consistent results, with success@15 reaching 89%, 94%, and 82% even for the highest difficulty. CBIT demonstrates minimal sensitivity to difficulty changes, indicating strong reliability without reliance on external verifiers.

Industrial Readiness We conduct a 5 months, large-scale deployment of CBIT-generated problems in a live educational service. The key metric for industrial readiness is content error rate, defined as the percentage of served problems that were reported by users and required correction. We measured it against a baseline of isomorphic problems created by human experts.

In this deployment, 32,131 problems generated by CBIT were served to 6,732 students, resulting in a total of 186,870 problem-solving attempts. For the control group, 4,404 human-authored problems were served to 3,976 students, leading to 103,231 attempts. The total pool of problems available for the experiment consisted of 195,941 from CBIT and 7,145 from human experts.

The CBIT-generated content demonstrated an error rate of 0.1867%. In contrast, the human-authored content had a slightly higher error rate of 0.2271%. This outcome demonstrates that CBIT can produce educational content at scale with a level of reliability on par with, or even superior to, that of human experts.

5 Conclusion

We introduced Isomorphic Math Problem Generation (IMPG) as a new task aimed at creating reliable practice problems suitable for real educational deployment, and released a benchmark dataset of 195 source problems with 2,410 symbolic relationships together with an automatic verification toolkit for reproducible evaluation.

Through a series of progressive frameworks, we systematically aligned large language models with the structural and mathematical requirements of IMPG, culminating in Computational Blueprint for Isomorphic Twin (CBIT), which guarantees built-in correctness, decouples generation scale from token cost, and provides strong expert controllability and long-term reproducibility.

Extensive experiments and a real-world deployment to 6,732 learners with 186,870 interactions demonstrated that CBIT achieves the highest success rates and lowest cost, reducing error rates by 17.8% compared to expert-authored problems and establishing a robust foundation for scalable, verifiable educational content generation.

Limitations

While our framework demonstrates strong scalability and reliability, certain assumptions underline its design. The construction of templates and skeleton code has thus far relied on heuristics, which must be specified with care for each application domain; for example, in our setting mathematical expressions were assumed to appear in LaTeX notation delimited by dollar signs, whereas domains with different conventions may require more elaborate parsing strategies. Moreover, the approach builds variants by altering numerical parameters, which is most effective for problems where quantitative changes directly influence the solution path or answer (such as word problems with rates, ratios, or probabilities, geometry with numeric measures, and equation-based items with perturbed coefficients). Tasks whose correctness depends solely on logical structure and is largely insensitive to numeric variation, such as truth-teller or liar puzzles, fall outside the current scope. Exploring ways to relax these assumptions, extend CBIT to broader classes of problems, and automate template construction more systematically represents a valuable direction for further study.

Algorithm 1 Verification Procedure for Problem #20570

Input: Isomorphic Problem of #20570
Output: Verification Result

Extract all mathematical expressions from the problem and solution texts
Identify the quadratic equation of the form $x^2 - ax + b = 0$
Identify the two roots from the from $(x - r_1)(x - r_2) = 0$
Check that the roots satisfy:
    $r_1 + r_2 = a$, and $r_1 \cdot r_2 = b$
for each root r **do**
    Identify the list of pairs L_r as written in the solution
    Check that each (a, b) in L_r satisfies:
      (i) $1 \leq a, b \leq 6$,
      (ii) $|a - b| = r$,
      (iii) all pairs are unique and distinct
    Check that the reported count of pairs equals $|L_r|$
end for
Check that the total number of favorable outcomes $|L_{r_1}| + |L_{r_2}|$ is divided by 36
Check the computed value is correctly simplified to a fraction or decimal
return `True` if all checks are satisfied; otherwise, `false`

Example verification procedure for an isomorphic problem. The algorithm illustrates how symbolic checking is performed: extracting expressions, validating algebraic relationships, verifying solution pairs, and ensuring correctness of the reported probability. This procedure exemplifies the automatic verification toolkit used to evaluate generated problems in IMPG.

B Detailed Comparison on Iterative and Batch prompting

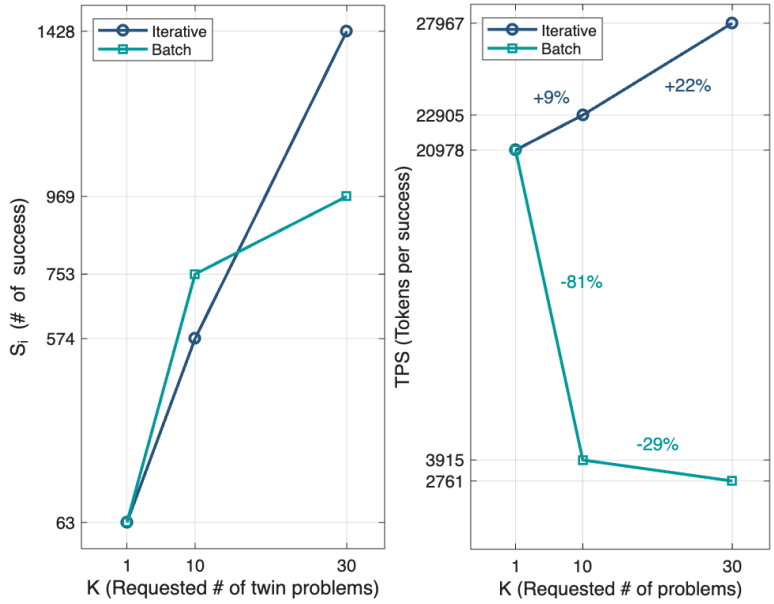

Figure 7: Comparison between Iterative and Batch prompt for IMPG with benchmark Dataset.

The left plot shows that while the Iterative approach consistently yields a higher number of successful problem generations as the requested number of problems increases. This advantage comes at the cost of growing inefficiency, illustrated in the right plot. Specifically, the Tokens Per Success (TPS) of the Iterative approach not only remains stagnant but worsens as the request size grows—showing a 9% increase from $K = 1$ to $K = 10$, and a 22% increase from $K = 10$ to $K = 30$.. This inefficiency is attributable to the growing likelihood of generating duplicate problems, which not only wastes tokens but also fails to meet the target number of distinct outputs.

The Batch approach, in contrast, exhibits remarkable efficiency gains as request size increases: TPS improves by 81% when moving from $K = 1$ to $K = 10$, and by an additional 29% from $K = 10$ to $K = 30$. This efficiency stems from the fact that a single prompt can generate multiple problems without proportionally increasing token consumption. Notably, the Batch approach also exhibits perfect internal consistency: for each original problem, all generated variants either pass or fail the benchmark verification as a group. This suggests that the Batch prompt effectively induces the LLM to construct an implicit "generation engine"—a latent representation of the underlying mathematical rules—before sampling concrete problem instances. This emergent behavior aligns with the goal of isomorphic problem generation, where a shared structure must be preserved across all outputs.

In summary, while the Iterative approach offers higher success counts in small-scale settings, its efficiency deteriorates and consistency falters as scale increases. The Batch approach, on the other hand, not only scales more efficiently but also reliably enforces structural uniformity, which is crucial for the industrial deployment of automated problem generation.

C Code-guided Prompting for CBIT

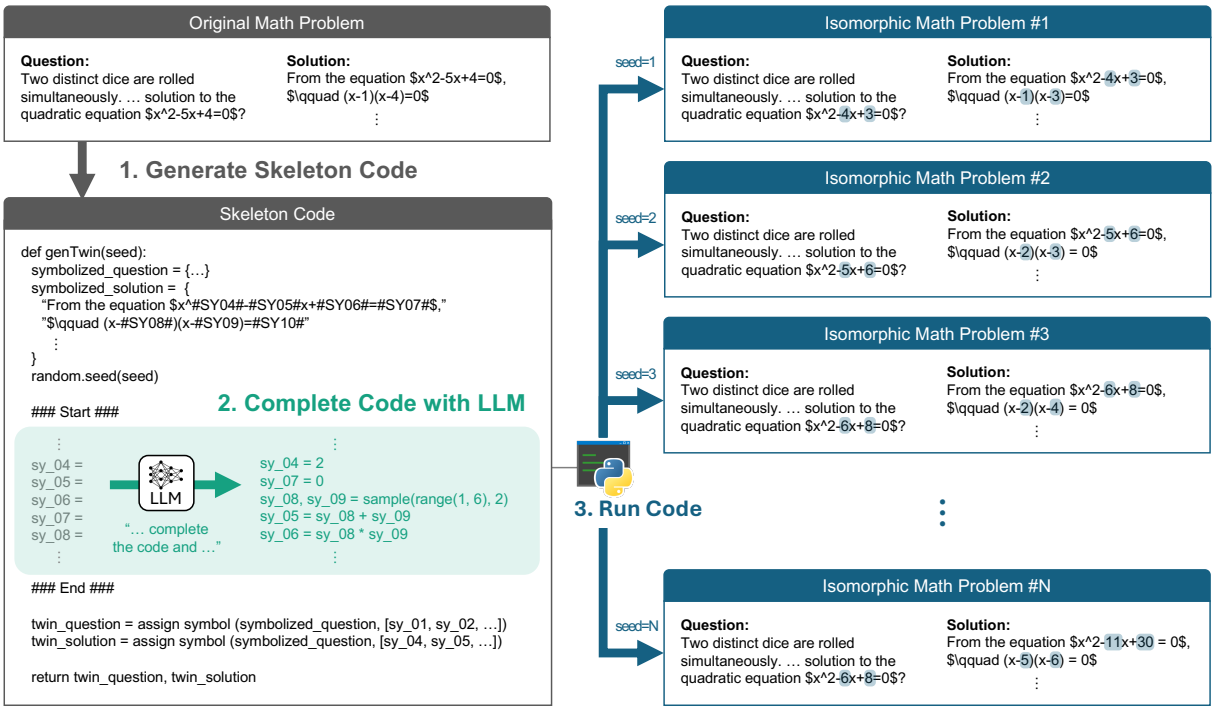

Figure 8: Illustration of CBIT's meta-generation process. Given an original math problem, a skeleton code is first generated to symbolically represent its core relations. The LLM then completes the code by instantiating numerical values under the specified constraints, after which the executable program deterministically produces multiple isomorphic math problems from different random seeds. This design shifts the LLM's role from directly authoring problems to constructing a generator, enabling scalable, consistent, and verifiable problem creation.

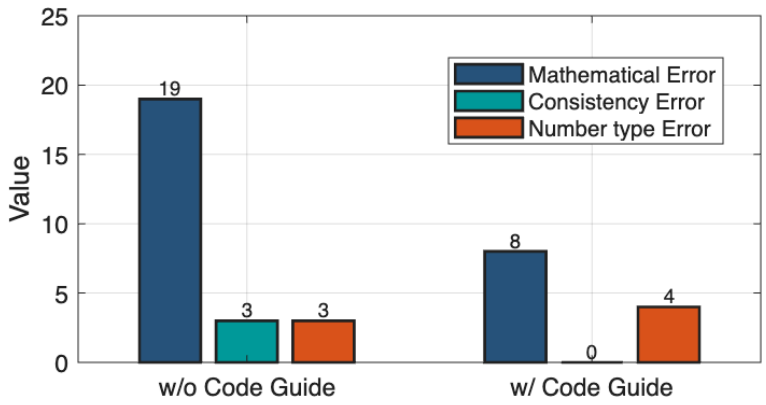

Figure 9: Impact of Skeleton Code on error reduction in CBIT. Providing Skeleton Code eliminates consistency errors entirely and substantially reduces both mathematical and number type errors by guiding the model's symbol substitutions and structural alignment.

Fin-ExBERT: User Intent based Text Extraction in Financial Context using Graph-Augmented BERT and trainable Plugin

Abstract

Financial dialogue transcripts pose a unique challenge for sentence-level information extraction due to their informal structure, domain-specific vocabulary, and variable intent density. We introduce Fin-ExBERT, a lightweight and modular framework for extracting user intent–relevant sentences from annotated financial service calls. Our approach builds on a domain-adapted BERT (Bidirectional Encoder Representations from Transformers) backbone enhanced with LoRA (Low-Rank Adaptation) adapters, enabling efficient fine-tuning using limited labeled data. We propose a two-stage training strategy with progressive unfreezing: initially training a classifier head while freezing the backbone, followed by gradual fine-tuning of the entire model with differential learning rates. To ensure robust extraction under uncertainty, we adopt a dynamic thresholding strategy based on probability curvature (elbow detection), avoiding fixed cutoff heuristics. Empirical results show strong precision and F1 performance on real-world transcripts, with interpretable output suitable for downstream auditing and question-answering workflows. The full framework supports batched evaluation, visualization, and calibrated export, offering a deployable solution for financial dialogue mining.

1 Introduction

Extractive text operations have become indispensable in modern industries where large volumes of unstructured textual data, such as documents, emails, and call transcripts, need to be processed efficiently to extract meaningful insights. In customer service, particularly within financial institutions, accurate text extraction plays a critical role in identifying customer queries, resolving issues, and providing personalized services. For example, identifying the context and extracting relevant spans of information from call transcripts can significantly enhance response accuracy and reduce manual effort. Such capabilities not only improve customer satisfaction but also streamline operations and reduce costs for organizations across various domains. Despite the importance of extractive text operations, achieving high accuracy in financial contexts is particularly challenging due to the domain-specific nature of financial terminology. Traditional keyword-based extraction methods often struggle to correctly interpret terms such as *401k* (retirement planning) and *529* (college planning) since these concepts do not always have direct linguistic correlations. Furthermore, financial texts frequently contain implicit meanings and specialized jargon that general-purpose models fail to recognize. This challenge is further exacerbated by the necessity of preserving contextual relationships across multiple utterances in multi-turn dialogues, making conventional models inadequate.

2 Related Work

Recent advancements in natural language processing have introduced various models tailored for financial applications, yet significant gaps remain in extractive capabilities. FinBERT (Yang et al., 2020), a domain-specific adaptation of BERT (Devlin, 2018), has been successfully applied to sentiment analysis and named entity recognition tasks but lacks the necessary extractive mechanisms to handle complex multi-turn dialogues. Similarly, FinGPT (Yang et al., 2023; Zhang et al., 2023) leverages instruction-tuned LLMs for financial sentiment analysis but does not focus on extractive question-answering, making it unsuitable for tasks requiring precise span retrieval and contextual grounding.

General-purpose LLMs such as GPT-4 (Achiam et al., 2023), LLaMA (Touvron et al., 2023), and PaLM (Chowdhery et al., 2023) excel in open-domain comprehension and generation. However, their limitations in financial extraction tasks are

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1402–1411

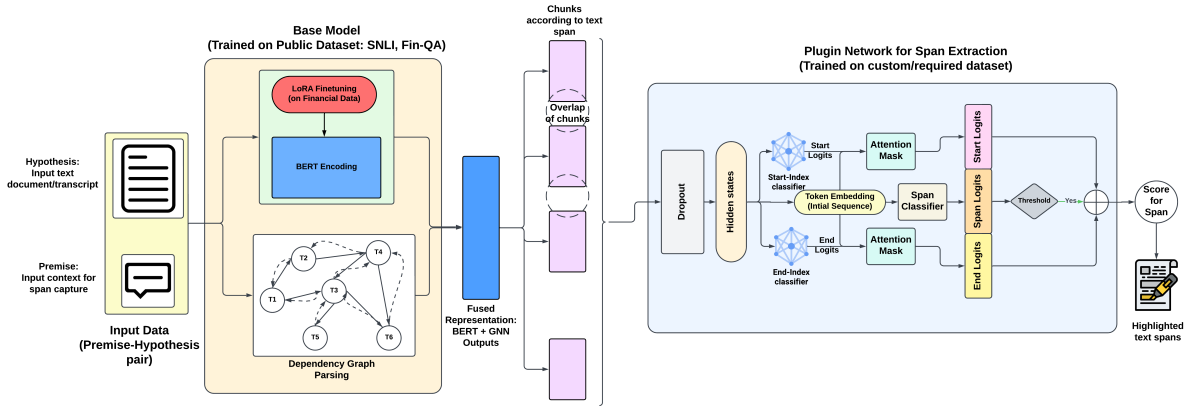

Figure 1: Flowchart of the proposed methodology showing the Base Model and the Plugin Network for text span extraction.

notable: (i) high parameter counts hinder efficient fine-tuning, (ii) hallucinations (Ji et al., 2023a,b) compromise reliability, and (iii) instruction tuning remains insufficient for domain-specific reasoning.

Several works have aimed to bridge these gaps. DeBERTa-based solvers (Luo et al., 2024) improve contextual encoding but lack structural awareness. MT2Net (Zhao et al., 2022) and ConvFinQA (Chen et al., 2022) bring hierarchical and conversational improvements, yet fall short in technical Question-Answering(QA). DocFinQA (Reddy et al., 2024) emphasizes document reasoning over tabular inputs, while PlanGEN (Parmar et al., 2025) enhances logical consistency without addressing dialogue complexity. FiD (Izacard and Grave, 2020) and KECP (Wang et al., 2022) offer multi-source fusion and knowledge control but underperform in noisy, domain-specific extractions.

To address these shortcomings, we propose Fin-ExBERT, a GNN-augmented BERT model tailored for extractive financial QA. It integrates syntactic reasoning via Graph Neural Networks (GNNs), LoRA adapters (Hu et al., 2021) for lightweight domain tuning, and a tunable plugin head for scoring relevant spans. This design enables precise, scalable extraction from multi-turn transcripts and complex financial documents, advancing the robustness and interpretability of domain-specific QA systems.

3 Methodology

The proposed methodology integrates a Graph Neural Network (GNN) with BERT, incorporating a LoRA (Low-Rank Adaptation) adapter to improve performance on financial problem-solving tasks, along with a network for task specific text extraction. The key components of the architecture include a BERT encoder for contextual embeddings, GNNs for graph-structured reasoning, and LoRA-based domain adaptation to efficiently handle financial data. Fin-ExBERT can be divided into three stages: (1) Base model, which is a modified Masked Language Model (MLM), was trained using BERT and a graph augmentation for contextual and relational reasoning, (2) Domain-specific fine-tuning using LoRA, and (3) A trainable plugin network to extract target specific context from text. The entire flowchart is illustrated by Figure 1.

3.1 Base Model: GNN-Augmented BERT for Natural Language Inference

The base model accepts premise–hypothesis pairs, following the standard NLI format. We use a `bert-base-uncased` encoder to obtain contextual embeddings, extracting the [CLS] token as the semantic representation. To capture syntactic dependencies missed by BERT, we augment it with Graph Neural Networks (GNNs) that operate on dependency graphs generated using spaCy (Honnibal et al., 2020). Figure 2 shows how the graph module modifies the dependency tree, while the importance of using a graph component here is shown by an ablation study in Figure 3. These graphs consist of token nodes and syntactic edges, processed through message-passing GNN layers to enhance relational reasoning. For each input pair, we extract GNN-based representations of both premise and hypothesis, and concatenate them with the [CLS] (for the premise-hypothesis pair from the BERT component) embedding to form the fused represen-

Table 1: LoRA adapter configuration for domain adaptation in Fin-ExBERT.

tation:

$$\mathbf{FR} = [\mathbf{CLS}, \mathbf{GNN}\text{premise}, \mathbf{GNN}\text{hypothesis}] \tag{1}$$

This fused vector is passed to a classifier trained on the SNLI dataset (Bowman et al., 2015) for three-way NLI prediction: entailment, contradiction, and neutral. The loss plot during the training is shown in Figure 4.

3.2 Connecting Sentence-Level Extraction to NLI-Based Pretraining

The task of identifying relevant sentence spans in customer transcripts can be viewed as an entailment problem: given a customer utterance (hypothesis), does it entail a predefined financial intent or resolution category (premise)? Our use of NLI pretraining on the SNLI dataset allows the model to better capture such premise-hypothesis relationships, even when phrased indirectly or across multiple turns of dialogue. For example, if a transcript contains: "I can't find the interest charges on my last bill," the model trained via NLI learns to map this to a latent premise like "The customer is asking about credit card interest rates."

3.3 Financial Domain Adaptation with LoRA Adapter

While the base model trained on SNLI captures general linguistic patterns, it struggles with domain-specific financial terms such as *401k* (retirement) and *529* (college savings). To address this, we apply Low-Rank Adaptation (LoRA) (Hu et al., 2021) for efficient domain tuning using the `fingpt-fiqa_qa` dataset[1]. LoRA inserts trainable low-rank matrices into attention layers, enabling specialization without updating the full BERT parameters. The adapter configuration is detailed in Table 1.

3.4 Span Extraction Head (Plugin Network)

To support fine-grained span-level predictions in call transcripts, we introduce a tunable plugin network atop the Base Model. While the Base Model enables sentence-wise classification, nuanced queries—such as identifying whether an agent expressed appreciation—require precise span localization. Our plugin head addresses this by predicting start and end indices of relevant text spans using a multi-layer perceptron (MLP) with ReLU activations and dropout. It receives the hidden states $H \in \mathbb{R}^{B\times L\times D}$ from the Base Model and applies token-level classifiers:

$$H' = \text{ReLU}(W_1 H + b_1) \tag{2}$$

$$\text{start_logits} = W_2 H' + b_2 \tag{3}$$

$$\text{end_logits} = W_3 H' + b_3 \tag{4}$$

$$\text{no_span_logit} = W_4 H[:, 0, :] + b_4 \tag{5}$$

Here, W_i and b_i are trainable parameters. The 'no span' classifier uses the [CLS] token to determine whether any span should be extracted. The architectural breakdown is shown in Table 2.

3.5 Span Prediction and Probability Computation

During inference, the span extraction head predicts start and end indices for possible spans. To ensure robustness, token-level logits are converted into probability distributions using the softmax function shown by equations (6) and (7):

$$P_{start}(t) = \frac{e^{\text{start_logits}[t]}}{\sum_{j=1}^{L} e^{\text{start_logits}[j]}} \tag{6}$$

$$P_{end}(t) = \frac{e^{\text{end_logits}[t]}}{\sum_{j=1}^{L} e^{\text{end_logits}[j]}} \tag{7}$$

The final span is determined by selecting the token pair (i, j) that maximizes the joint probability $P_{start}(i)P_{end}(j)$, subject to the constraint $i \leq j$. If the 'no span' probability $P_{no_span} = \sigma(\text{no_span_logit})$ exceeds a predefined threshold, the model abstains from span extraction. To further refine the selection, an entity-based heuristic is employed to align predicted spans with domain-specific terminology. Additionally, an approximation based on character length normalization is used to penalize overly verbose spans, ensuring concise and contextually relevant extraction. This method significantly enhances precision and recall, reducing the likelihood of over-extraction or missing critical spans.

3.6 Model Training Workflow

The Fin-ExBERT training pipeline begins with contextual encoding using either a standard BERT-base or a GNN-augmented encoder, optionally enhanced with LoRA adapters for financial domain adaptation. When GNN is used, syntactic graphs are integrated via two rounds of message-passing and fused with BERT embeddings for enriched sentence representation. Encoded outputs are passed through a dropout layer and a lightweight linear classifier trained using `BCEWithLogitsLoss`, with oversampling to address extreme class imbalance. The encoder is initially frozen and later unfrozen with differential learning rates, using a linear warmup schedule. Evaluation metrics include loss, accuracy, precision, recall, and F1, with both fixed and dynamic thresholding applied to sigmoid

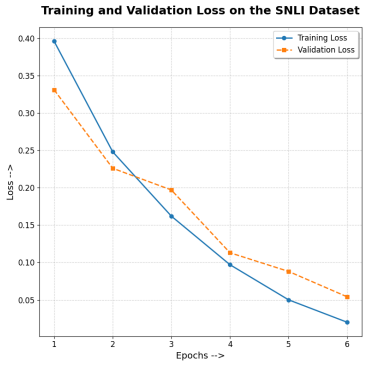

Figure 4: Loss plot while training the Base Model on the SNLI dataset.

outputs. For inference, we perform sentence-level prediction on transcripts, selecting relevant spans and exporting results in batches. Finally, in lieu of task-aligned benchmarks, we use LLM-based evaluation on SQuAD (Rajpurkar et al., 2016) and FinQA (Chen et al., 2021), where three independent LLM judges score semantic accuracy and completeness of the predicted extractions. This modular and adaptive pipeline allows Fin-ExBERT to scale across multiple domains and input styles while maintaining robustness and interpretability in sentence extraction tasks.

4 Results and Discussions

In this section, we evaluate the performance of Fin-ExBERT across multiple fronts. We first begin by introducing a newly curated dataset: CreditCall12H. Then we do assessments on two widely-used extractive QA datasets: **SQuAD((Stanford Question Answering Dataset))** (Rajpurkar et al., 2016) and **FinQA** (Chen et al., 2021), using LLM-based judges to address the mismatch between task formulation and sentence-level extractive output. Then, we extend our analysis to CreditCall12H

Model	SQuAD				FinQA-10K			
	Judge1	Judge2	Judge3	Avg	Judge1	Judge2	Judge3	Avg
Fin-ExBERT (Ours)	**5.00**	**4.94**	**4.84**	**4.93**	**4.96**	**4.86**	**4.68**	**4.84**
DeBERTa-Based Solver (Luo et al., 2024)	4.58	4.47	4.41	4.47	4.33	4.19	4.35	4.29

dataset.

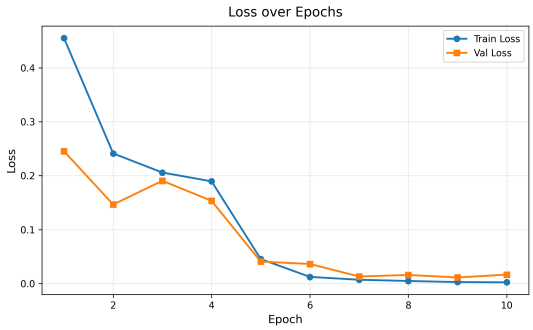
4.1 CreditCall12H: Real-World Annotated Financial Conversations

To further evaluate our model's effectiveness in realistic settings, we curated a dataset named **CreditCall12H**, which consists of 1,200 anonymized long-form customer service transcripts. The conversations cover a wide range of credit card–related interactions, such as payment failures, transaction disputes, card activation, credit limit increases, and fraud prevention protocols. For our use case we had split the data $train : validation : test$ in the ratio $700 : 300 : 200$.

A small set was manually verified, with the rest produced at scale. These annotations were generated using a two-stage LLM-assisted labeling strategy: first, high-confidence extraction candidates were generated using ChatGPT 4o (OpenAI, 2024), and then refined via human-in-the-loop verification to ensure semantic accuracy. This allowed us to simulate noisy but realistic QA-style extraction in multi-turn dialogues, thereby creating a benchmark tailored to sentence-level relevance and call quality analysis. Accuracy, Precision, and F1-Score were chosen as the core metrics, given the many-to-many nature of valid sentence selection within each transcript.

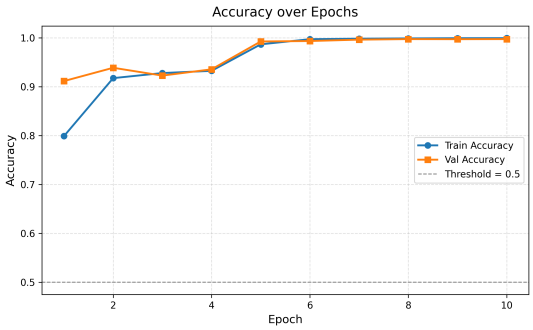
4.2 Evaluation on SQuAD and FinQA-10K using LLM Judges

While our model is trained for sentence-level extraction in financial conversations, there are no established benchmarks that directly capture this setting. To approximate relevance evaluation, we adopt LLM-based judges that semantically assess sentence-level predictions against standard QA benchmarks: SQuAD and FinQA. SQuAD has $100,000$ training QA pairs and about $30,000$ test ones. While FinQA-10K consists of $7,000$ rows of data each including standard QA format along with the ticker symbol of the corresponding stock.



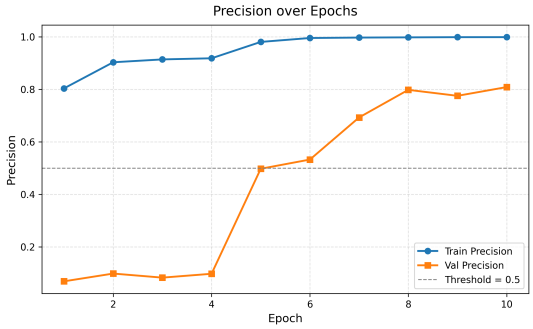
QA datasets like SQuAD and FinQA are designed for span prediction or reasoning-based answer generation and not sentence selection. Standard span-level metrics such as Exact Match (EM) and token-level F1 are not directly applicable. Following recent advances in *LLM-as-a-judge* evaluation (Li et al., 2024), we utilize multiple pretrained NLI models to evaluate semantic alignment between extracted sentences and gold QA pairs. We employ three diverse zero-shot NLI pipelines as our judges:

- **Judge1:** `facebook/bart-large-mnli` (Lewis et al., 2019)
- **Judge2:** `roberta-large-mnli` (Liu et al., 2019)
- **Judge3:** `microsoft/deberta-large-mnli` (He et al., 2021)

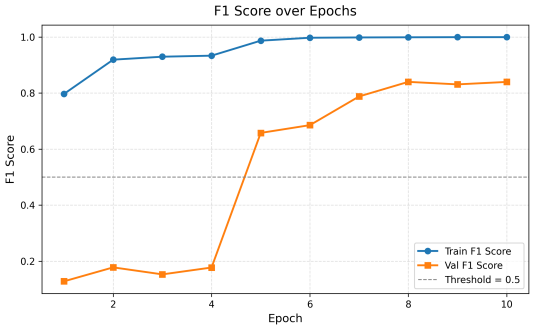


Each judge rates the relevance of model-generated sentences with respect to the QA pair on a scale from 1 to 5. The average across the three scores provides a robust semantic quality estimate. Table 3 shows the judge-wise scores for our Fin-ExBERT model, and the average scores of several strong baselines on both SQuAD and FinQA-10K. Fin-ExBERT achieves the highest semantic relevance scores on both datasets, even though it was not fine-tuned on either.

4.3 Evaluation on CreditCall12H dataset



To rigorously evaluate Fin-ExBERT, we consider our newly created **CreditCall12H**. While SQuAD and FinQA serve as general QA benchmarks evaluated via LLM judges, CreditCall12H provides direct supervision for extractive sentence selection



(a) Training vs. Validation Loss

(b) Training vs. Validation Accuracy

(c) Training vs. Validation Precision

(d) Training vs. Validation F1 Score

Figure 5: Training and validation metrics on the CreditCall12H dataset across epochs for Fin-ExBERT showing the change in metric trend once the base model is unfreezed after epoch 4.

in financial conversations. Table 4 shows the hyperparameters used during training on the CreditCall12H data. Figure 5 summarizes the training dynamics. After unfreezing the encoder at epoch 4, we observe a sharp improvement across all metrics. Validation F1 surpasses 84% and precision exceeds 80%, demonstrating the model's capacity to generalize despite class imbalance (positive label fraction ∼0.8%).

Hyperparameter	Value
Batch Size	16
Learning Rate (Frozen)	2×10^{-5}
Learning Rate (Unfrozen)	10^{-3} (head), 10^{-5} (encoder)
Epochs	10
Unfreeze Encoder	After Epoch 4
Warmup Steps	10% of total steps
Optimizer	AdamW
Loss Function	BCEWithLogitsLoss
Sampler	WeightedRandomSampler
Max Sequence Length	128

Table 4: Training hyperparameters for Fin-ExBERT on CreditCall12H.

4.4 Dynamic Thresholding Strategy

In addition to standard fixed-threshold inference, we incorporate a dynamic thresholding mechanism that adapts to the distribution of sentence-level scores within each transcript. This approach is particularly beneficial for low-confidence scenarios where static thresholds may fail to capture outlier relevance.

Let $S = \{s_1, s_2, \ldots, s_n\}$ be the set of sigmoid probabilities for the n sentences in a transcript, while the local median score is computed as $\mu_S = \text{median}(S)$. A sentence s_i is selected if:

$$s_i \geq \mu_S + \delta \tag{8}$$

where δ is a tunable deviation margin (default: $\delta = 0.15$). This rule dynamically highlights sentences that stand out relative to the surrounding context rather than meeting an absolute confidence threshold. This thresholding method increases precision by prioritizing confident deviations in logit-based sentence relevance, especially useful in class-imbalanced (proportion of spans we want to extract in a text) extractive tasks such as those in our `CreditCall12H` dataset.

5 Conclusion

We introduced Fin-ExBERT for domain-specific extractive operations in financial texts. Our sys-

tem combines syntactic reasoning via dependency-aware GNNs, financial domain adaptation using LoRA, and a lightweight plugin head for sentence-level extraction. Evaluations across three distinct benchmarks demonstrate its adaptability and generalization. On open-domain datasets like SQuAD and FinQA, Fin-ExBERT achieved judge-rated average scores of 4.93/5 and 4.84/5, validating its semantic consistency and extractive correctness. On long-form, financial benchmark CreditCall12H, the model achieved a peak F1-score of 0.84. These results underscore Fin-ExBERT's strength in handling financial terminologies, contextual variability, and multi-turn dialogue extraction with minimal computation overhead. Its modular architecture enables scaled deployment for applications in call analytics and compliance monitoring. The entire codebase and the CreditCall12H dataset is available on the `GitHub Repository`[2]

6 Limitations

While Fin-ExBERT demonstrates strong extractive performance in financial domains, particularly in precision and sentence-level semantic alignment, several limitations remain.

- Recall Trade-off: Although the model achieves high precision on the `CreditCall12H` dataset, its recall remains moderate. This suggests that while it successfully avoids irrelevant extractions, it may miss some semantically valid phrases, especially those phrased indirectly or appearing in long conversational dependencies.
- Dependency on LLM Judges: Although LLM-based evaluation offers scalable semantic scoring for open-ended tasks like SQuAD and FinQA, these scores may still inherit biases from the underlying models. Human-based evaluation would offer more consistent grounding, particularly in financial QA.
- Plugin Head Interpretability: While the plugin network offers effective span extraction, its inner workings are less interpretable than symbolic or rule-based extractors. Incorporating attention-based rationales or saliency methods may improve explainability.

In future iterations, we aim to improve the recall of Fin-ExBERT on the `CreditCall12H` dataset by incorporating multi-hop reasoning and enhanced context propagation through conversational history. Additionally, integrating more diverse annotation styles (e.g., partial spans, clause-level supervision) and expanding the evaluation to real-world call center deployments will help validate and extend the model's applicability in production settings.

A Appendix

A.1 Synthetic Dataset Generation: CreditCall12H

To evaluate Fin-ExBERT in realistic, yet controllable conditions, we created the **CreditCall12H** dataset, comprising 1,200 long-form synthetic call transcripts annotated with relevant sentence-level spans.

A.1.1 Source Data

We began by extracting samples from the public corpus provided in the `PolyAI-LDN/task-specific-datasets`[3] (Coope et al., 2020), which contains 10,000 utterances labeled into 77 intent classes. Using GPT-based semantic clustering, we grouped these 77 classes into 20 broader domains. From these, we selected the category titled *Credit Card Fees & Issues*, which contained approximately 1,000 rows across 7 fine-grained sub-classes.

A.1.2 Synthetic Call Planning

To construct full-length transcripts, we sampled 1,200 combinations of 5 utterances each from the 1,000 rows described above. These were saved in the column `Sel_5`. For each generated transcript, we randomly assigned an integer $k \in \{3, 4, 5\}$

[3] https://github.com/PolyAI-LDN/task-specific-datasets

(with uniform distribution) to determine how many of the 5 utterances should be inserted into the conversation. This yields:

$$K = [3, 4, 5] \times 400 \Rightarrow 1{,}200 \text{ transcripts} \quad (9)$$

Each selected K was then split into two groups:

- K_1: Deep Conversation Topics
- K_2: Shallow Conversation Topics

The breakdown rules were:

- If $K = 3$, then $K_1 = 2$ and $K_2 = 1$
- If $K = 4$, then $K_1 = 3$ and $K_2 = 1$
- If $K = 5$, then $K_1 = 3$ and $K_2 = 2$

The utterances were assigned as:

$$\texttt{Sel_K1} = \texttt{Sel_5}[: K_1] \quad \text{(Deep Topics)}$$
$$\texttt{Sel_K2} = \texttt{Sel_5}[K_1 :] \quad \text{(Shallow Topics)}$$

A.1.3 LLM-Guided Prompting.

To generate natural conversations using these utterances, we employed ChatGPT 4o (OpenAI, 2024) with the following structured prompt:

LLM Prompt Template (simplified)

```
You have to generate a 2-3 page long call transcript between a Phone Rep and a Customer about credit card payment issues.

• Insert all customer lines from Deep_Conversation_Topics verbatim. These should drive 1-3 paragraphs each.
• Insert all customer lines from Shallow_Conversation_Topics only once, with minimal reaction.

Directly start with the conversation. No other preamble.
```

The result is a high-fidelity corpus of synthetic dialogues with embedded, context-controlled utterances, labeled in the `Sel_K` column, which is then renamed as `Labels` column. These annotations enable reliable benchmarking for sentence-level extraction models under rich, conversational noise.

A.1.4 Dataset Structure

Each row in the dataset consists of:

- **Call_Transcript**: A long-form transcript, typically ranging between 20–60 utterances, formatted as alternating customer-agent dialogue.
- **Labels**: A list of sentence-level excerpts extracted manually by annotators as *task-relevant*, based on predefined question prompts (e.g., "Did the customer mention a failed card transaction?").

A.1.5 Motivation and Use

The dataset serves as a benchmark for evaluating sentence extractors in realistic, high-stakes conversational domains. It is designed to reflect nuanced utterances, implicit intents, and soft cues, which are typical in customer support settings. CreditCall12H supports both:

- **Supervised training and evaluation** of extractive models
- **LLM-based judgment evaluation** via zero-shot scoring on general-purpose QA tasks

A.1.6 Example Entry

An example excerpt is shown in Table 5. For more, see Appendix A.2.

Call_Transcript Excerpt:
`Customer: I tried to pay with my card yesterday but it didn't go through.`
`Agent: I'm sorry about that. Can you confirm the last 4 digits of your card?`
`Customer: It's 1234. Why was it declined?`
Labels:
`["I tried to pay with my card yesterday but it didn't go through.", "Why was it declined?"]`

Table 5: Sample annotated call from CreditCall12H.

A.2 Example of CreditCall12H Data

This section contains more examples of call transcripts from the CreditCall12H dataset.

Example 1

Call_Transcript:
Phone Rep: Thank you for calling Credit Card Services. How may I help you today?
Customer: There is a vendor name I don't recognize on my credit card statement.
Phone Rep: I can help you with that. Can you provide the transaction date and amount?

Labels:
`["There is a vendor name I don't recognize on my credit card statement."]`

Example 2

Call_Transcript:
Customer: I was charged twice for the same purchase.
Phone Rep: Let me check that for you. Could you tell me when and where the purchase was made?

Labels:
`["I was charged twice for the same purchase."]`

Example 3

Call_Transcript:
Customer: I want to increase my credit limit.
Phone Rep: I'd be happy to assist. May I know the reason for the increase?
Customer: I have some travel expenses coming up.

Labels:
`["I want to increase my credit limit."]`

Example 4

Call_Transcript:
Customer: Why has my payment not gone through yet?
Phone Rep: Let me verify the status. When did you initiate the payment?

Labels:
`["Why has my payment not gone through yet?"]`

Figure 6: Illustrative examples from the `CreditCall12H` dataset. Each row contains a conversational transcript with sentence-level annotations identifying semantically relevant customer intents.

DecEx-RAG: Boosting Agentic Retrieval-Augmented Generation with Decision and Execution Optimization via Process Supervision

Abstract

Agentic Retrieval-Augmented Generation (Agentic RAG) enhances the processing capability for complex tasks through dynamic retrieval and adaptive workflows. Recent advances (e.g., Search-R1) have shown that outcome-supervised reinforcement learning demonstrate strong performance. However, this approach still suffers from inefficient exploration, sparse reward signals, and ambiguous global reward feedback. To address these challenges, we propose DecEx-RAG, which models RAG as a Markov Decision Process (MDP) incorporating decision-making and execution, while introducing an efficient pruning strategy to optimize data expansion. Through comprehensive process-level policy optimization, DecEx-RAG significantly enhances the autonomous task decomposition, dynamic retrieval, and high-quality answer generation capabilities of large language models (LLMs). Experiments show that DecEx-RAG achieves an average absolute performance improvement of 6.2% across six datasets, significantly outperforming existing baselines. Moreover, the pruning strategy improves data construction efficiency by nearly 6×, providing an efficient solution for process-supervised RAG training. The code is available at https://github.com/sdsxdxl/DecEx-RAG.

1 Introduction

State-of-the-art LLMs have demonstrated remarkable problem-solving capabilities (Jaech et al., 2024; Shi et al., 2024; DeepSeek-AI et al., 2025). However, due to the inherent limitations of static training data, LLMs still exhibit significant bottlenecks when addressing dynamic and real-time problems (Ji et al., 2023; Huang et al., 2025a). Retrieval-Augmented Generation (RAG) emerges as a promising solution by incorporating external knowledge bases or search engines (Gao et al., 2023).

Recent advances employ outcome-supervised reinforcement learning (RL) to integrate dynamic retrieval into reasoning processes, enabling LLMs to autonomously invoke search tools and achieve remarkable results (Jin et al., 2025; Song et al., 2025). However, this approach still suffers from inherent limitations. First, the efficiency of exploration is low as LLMs must generate a complete reasoning chain before receiving outcome-based reward feedback. Second, reward signals are sparse, which results in the need for more data and training steps to achieve convergence (Zhang et al., 2025). Third, global rewards struggle to reflect local performance at step levels, posing challenges for fine-grained optimization.

Inspired by how humans leverage search tools to solve complex problems, we propose DecEx-RAG, a process-supervised framework for Agentic RAG. The framework models RAG as a Markov Decision Process (MDP) consisting of two stages: Decision-Making and Execution. The Decision-Making stage involves termination and retrieval decisions, the former aims to avoid redundant iterations or premature stopping, while the latter determines whether to rely on the LLMs' internal knowledge or retrieval tools for sub-question resolution. The Execution stage focuses on the quality of decision execution. For example, a high-quality sub-question is crucial for the success of subsequent reasoning. By structurally decomposing the Decision-Making and Execution stages, our framework enables fine-grained process-level supervision, while taking into account both execution quality and decision efficiency.

Within the DecEx-RAG framework, the absence of supervision signals for intermediate reasoning steps often necessitates extensive exploration during search tree expansion, resulting in exponential growth of time complexity with the depth of layers.

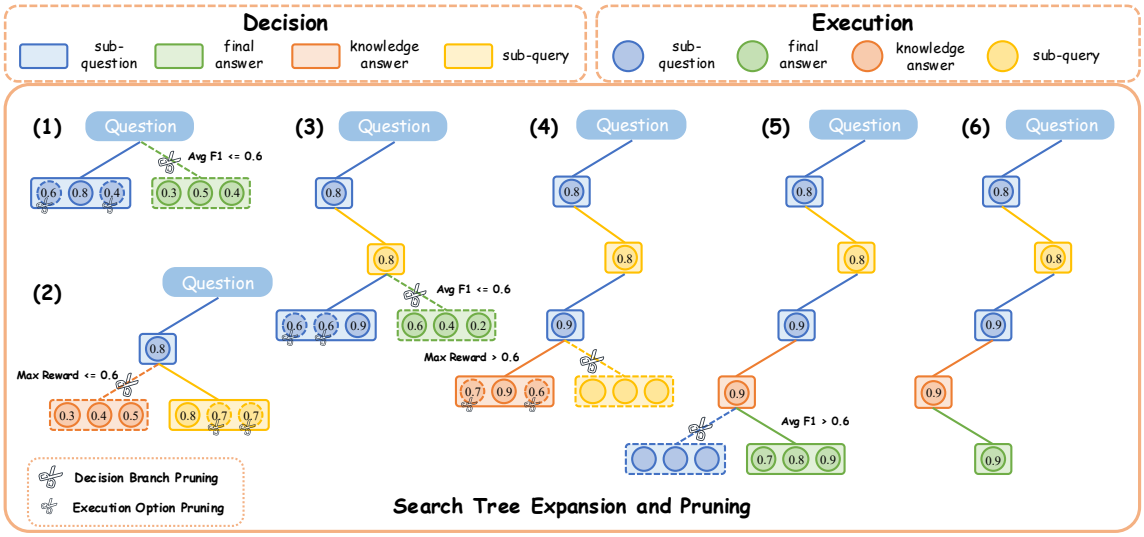

Figure 1: Illustration of the framework for DecEx-RAG, which demonstrates the process of search tree expansion and pruning.

To address this, we propose an efficient pruning strategy. At each layer of the search tree, multiple rollout simulations are conducted for different executions of decisions, using aggregated rewards as feedback signals to dynamically prune redundant branches. Specifically, the iteration terminates if the termination decision determines that existing iterative information suffices to answer the question; the retrieval operation is skipped if the retrieval decision determines that the model's intrinsic knowledge can effectively derive the final answer.

To validate the effectiveness of the DecEx-RAG framework and the proposed pruning strategy, we conduct experiments on six open-domain QA datasets. Experiment results show that DecEx-RAG significantly outperforms existing methods, achieving an average improvement of 6.3% over the outcome-supervised strong baseline Search-R1 (Jin et al., 2025). Further analysis reveals that the proposed pruning strategy enhances data construction efficiency by nearly $6\times$ compared to the expansion method without pruning while maintaining equivalent data quality, demonstrating its effectiveness and practicality.

In summary, our main contributions are as follows:

- We propose DecEx-RAG, a novel framework that models RAG as a Markov Decision Process, providing a more comprehensive and unified perspective for Agentic RAG systems.
- We propose a pruning strategy to optimize the data expansion process, significantly enhancing the efficiency of process supervision data construction without sacrificing data quality.
- Experimental results on six datasets demonstrate that, with the same scale of training data, DecEx-RAG significantly outperforms existing baselines in performance.

2 DecEx-RAG

Figure 1 illustrates our proposed DecEx-RAG framework. This framework models RAG as a Markov Decision Process incorporating decision-making and execution, expanding a search tree for each question to obtain multi-step process-supervised data. During expansion, intermediate process rewards are acquired through multiple rollouts, while redundant branches are pruned to enhance efficiency. Upon completion of the expansion, the optimal reasoning chain (from root node to leaf node) is used for Supervised Fine-tuning (SFT), while all branched nodes along the path serve as preference data for Direct Preference Optimization (DPO).

2.1 RAG as a Markov Decision Process

We formalize RAG as a Markov Decision Process, represented by the tuple $(\mathcal{S}, \mathcal{A}, P, R)$, where $\mathcal{S}$ denote the state sets, $\mathcal{A}$ denote the action sets, P describes the state transition dynamics, and R specifies the reward function.

States. At each time step t, the state $s_t \in \mathcal{S}$ represents a partial solution to the question. Formally, the state s_t can be formulated as: $s_t =$

$[Q, (q_1, r_1), \cdots, (q_t, r_t)]$, where Q is the question, q_i denotes the i-th sub-question, and r_i represents the answer to q_i, or the sub-query and retrieved relevant documents.

Actions. In state s_t, the model selects an action $a_t = (\sigma_t, \delta_t) \in \mathcal{A}$, which consists of two decisions:

- Termination decision σ_t: Determines whether to continue iteration. If continuing, the next sub-question q_{t+1} is generated. If terminating, the final answer o is yielded.
- Retrieval decision δ_t (when σ_t chooses to continue): For the sub-question q_{t+1}, δ_t determines how to answer it. If choosing to answer using the model's own knowledge, DecEx-RAG generates the answer w_{t+1}. If invoking the retriever, DecEx-RAG generates the sub-query e_{t+1} and obtains relevant documents d_{t+1}.

State Transition. When the action $a_t = (\sigma_t, \delta_t)$ is executed in state s_t, the state is updated to s_{t+1}. Specifically, if the termination decision σ_t chooses to terminate, the final answer o will be generated to end the iteration, and the termination state is $s_{t+1} = [Q, (q_1, r_1), \cdots, (q_t, r_t), o]$. Otherwise, DecEx-RAG generates the sub-question q_{t+1} and continues to execute the retrieval decision δ_t.

For the retrieval decision δ_t, if choosing to answer based on model's own knowledge, then $r_{t+1} = w_{t+1}$. If choosing to retrieve, then $r_{t+1} = [e_{t+1}, d_{t+1}]$. Finally, the state is updated to $s_{t+1} = [Q, (q_1, r_1), \cdots, (q_t, r_t), (q_{t+1}, r_{t+1})]$.

Rewards. The reward function $R(s_t, a_t)$ specifies the expected reward obtained after taking action a_t in state s_t. Under our framework, we perform several rollouts for the state-action pair (s_t, a_t), and use the correctness of multiple rollout results as the reward:

$$R(s_t, a_t) = \frac{1}{n} \sum_{i=1}^{n} v(\text{rollout}_i) \tag{1}$$

where rollout_i is the i-th simulated completion of (s_t, a_t), $v(\text{rollout}_i) \in [0, 1]$ denotes the correctness score (e.g., F1 score) of the final answer.

Our framework proposes two key innovations. First, we explicitly distinguish between sub-question and sub-query. The significance of this distinction lies in the fact that different retrievers may return drastically different documents for sub-queries with similar semantics but differing details, so sub-query is processed independently for optimization. Second, we decouple decision-making and execution in the MDP framework. Traditional MDP frameworks often treat decision-making and execution as a whole without clear distinction. In DecEx-RAG, decision-making focuses on method selection, while execution focuses on content quality. By separating decision-making from execution, we aim to leverage decision data to improve system efficiency and execution data to optimize content generation quality.

2.2 Search Tree Expansion with Pruning

With the Markov Decision Process defined in Section 2.1, DecEx-RAG solves each question by constructing a search tree. In state s_t, the model first expands the termination decision σ_t, using a non-zero temperature parameter to sample termination decision multiple times. If more than 50% of the sampling results favor terminating the iteration, the solving process ends. Otherwise, the model generates multiple candidate sub-questions. After deduplication, we perform multiple rollout simulations for each sub-question, take the average score as the intermediate reward, and finally select the branch with the highest reward to expand the next state.

After completing the termination decision expansion, the model proceeds to expand the retrieval decision δ_t. At this stage, the model first generates multiple candidate answers to the sub-question based on internal knowledge, similarly deduplicating them and calculating rewards through multiple rollouts. If the highest reward exceeds a preset threshold, it indicates that the final answer can be correctly derived from the current state. In this case, the retrieval branch is skipped to reduce computational overhead, and the highest-reward answer is directly selected as the next expanded state. Otherwise, the model generates multiple sub-queries, repeats the aforementioned process, and selects the sub-query with the highest reward as the next expanded state.

The search tree expansion process is controlled by the maximum iteration limit $T_{\max}$. Each layer executes according to the above strategy until either reaching the iteration limit or being actively terminated by the model. Although each decision execution requires multiple rollouts to obtain intermediate rewards, these data not only serve to construct preference training data but also provide the basis for decision pruning. Through pruning, each layer of the search tree retains only the optimal

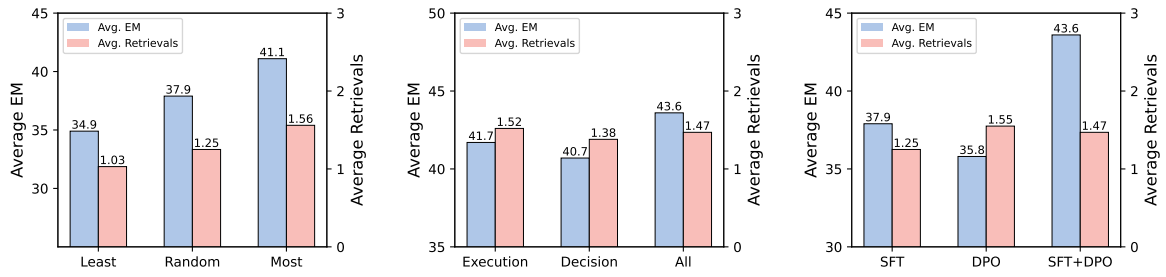
decision branch, significantly enhancing the expansion efficiency of the search tree. All the prompt instructions used for the search tree expansion can be found in Appendix A.1.

2.3 Training

DecEx-RAG focuses on optimizing four key components: final answer generation, sub-question decomposition, sub-question answering based on self-knowledge, and sub-query generation and retrieval, covering all branches of the framework's two decisions. Based on the search tree constructed in Section 2.2, we perform two-stage training.

Supervised Fine-tuning (SFT) We extract the complete reasoning path from the root node to the leaf node in the search tree for Supervised Fine-Tuning. For each question Q, we construct multiple input-output pairs, where the input consists of $\{Q, (q_1, r_1), ..., (q_{x_i}, e_{x_i}, d_{x_i})\}$, and the output consists of $(q_{x_i+1}, r_{x_i+1}), ..., (q_{x_{i+1}}, e_{x_{i+1}})$, with x_i is the index of the retrieval step. This setup ensures iterative reasoning, enabling LLMs to leverage previous steps until the next retrieval or final answer generation.

Direct Preference Optimization (DPO) Subsequently, we utilize the decision and execution data from the search tree nodes to construct preference pairs. Although only the optimal branch is retained for each layer of the final search tree, all decision branches are generated before pruning. As a result, we naturally obtain two types of preference data. Based on the mixed preference data, we perform DPO training, and the detailed training objective is shown in Appendix A.2.



3 Experiments

3.1 Datasets and Baselines

We evaluated DecEx-RAG and all baseline models on six public datasets, including three single-hop QA datasets: PopQA (Mallen et al., 2023), NQ (Kwiatkowski et al., 2019), and AmbigQA (Min et al., 2020), and three multi-hop QA datasets: HotpotQA (Yang et al., 2018), 2WikiMultiHopQA (Ho et al., 2020), and Bamboogle (Press et al., 2023). Among these, HotpotQA and 2WikiMultiHopQA are in-domain test sets, while the other four are out-of-domain test sets. We compared DecEx-RAG against two categories of baselines: prompt-based approaches (e.g., Direct Inference, Standard RAG, Search-o1) and reinforcement learning approaches (e.g., Search-R1, IKEA, DeepRAG). Detailed baseline information can be found in Appendix B.

3.2 Implementation Details

We extracted 2,000 and 1,000 questions from the training subsets of HotpotQA and 2WikiMultiHopQA, respectively, to construct our training dataset. During the expansion of the search tree, for retrieval decisions, we employed Qwen2.5-7B-Instruct (Yang et al., 2024) as the policy model, which is consistent with the base model in the subsequent training stage. Apart from this decision, we uniformly used Qwen3-30B-A3B (Yang et al., 2025) as the policy model. For retrieval, we follow Jin et al. (2025), using the 2018 Wikipedia dump

(a) (b) (c)

Figure 2: Ablation results for SFT (a), DPO (b) and different training methods (c).

(Karpukhin et al., 2020) as the knowledge source and E5 (Wang et al., 2022) as the retriever.

To ensure fair comparison, we reproduced Search-R1 and IKEA with equivalent amounts of training data. The number of retrieved documents is set to 3 for all methods requiring retrieval, while $T_{\max}$ is set to 4 for all multi-round iterative methods. For evaluation, Exact Match (EM) and F1 scores are adopted as the metrics.

3.3 Main Results

As shown in Table 1, we present the performance of DecEx-RAG and 11 baseline models on six datasets. Based on the experimental results, we draw the following main conclusions:

Prompt-Based Methods Exhibit Limited Performance. Experiments show that methods relying solely on internal knowledge (e.g., Direct Inference and CoT) show poor performance, confirming the limitations of LLMs' inherent knowledge. In contrast, RAG-based methods (e.g., Iter-RetGen, IR-COT, FLARE) improve performance, highlighting the necessity of external knowledge integration. Notably, although Search-o1 achieves the best performance among prompt-based methods, this lead is far smaller than the significant advantage demonstrated in its paper. This is because Search-o1's complex prompting pipeline imposes high requirements on the policy model's instruction-following and reasoning capabilities, and its advantages only manifest fully on large reasoning models. Consequently, it is difficult to extend this advantage equally to smaller models.

Process-Supervised RL Demonstrates Higher Data Efficiency Than Outcome-supervised RL. While Search-R1 and IKEA improve the LLMs' ability to integrate search during reasoning through outcome-supervised RL, their performance remains suboptimal with only 3K training samples. In contrast, DecEx-RAG demonstrates comprehensive leadership across six datasets, yielding an average performance improvement of 6%~8% over outcome-supervised RL methods under the same training data scales, fully demonstrating the data efficiency advantage of process-supervised RL.

DecEx-RAG Outperforms Other Process-Supervised Methods. Compared with similar process-supervised methods (DeepRAG and ReasonRAG), DecEx-RAG shows better performance. DeepRAG only focuses on decision optimization, while DecEx-RAG covers both decision and execution, forming a more complete optimization framework. Output analysis of ReasonRAG shows that its insufficient retrieval behavior and excessive reliance on internal knowledge lead to more incorrect answers. Experimental results show that DecEx-RAG not only performs outstandingly on in-domain test sets but also demonstrates excellent cross-domain generalization ability.

3.4 Ablation Study

To validate the effectiveness of the DecEx-RAG framework, we conducted a series of ablation experiments. Figure 2(a) shows comparative results of different data selection strategies during the SFT stage. Experiments show that the model trained with the Most Retrieval Cost (Most) strategy exhibits optimal performance, with more frequent retrieval actions. By examining the model's outputs, we find that the model tends to verify answer accuracy through multiple retrievals, demonstrating stronger deliberative capabilities. In contrast, the model trained with the Least Retrieval Cost (Least) strategy overly relies on its own knowledge, leading to increased error rates.

Figure 2(b) shows the comparison of different

Metrics	Pruning Search	No Pruning Search	Full Node Search
Expansion Efficiency ($k = 3, n = 4, T_{\max} = 4$)			
Theoretical Expansion Counts	$(4k + 3knl)l$	$\sum_{i=1}^{l} i^2(4k + 3knl)$	$(2k(k + 1))^l$
Average Extension Time (s)	134.9	743.2	-
Data Quality ($k = 3, n = 4, T_{\max} = 4$)			
SFT (EM/F1)	32.8 / 40.7	33.2 / 41.8	-
SFT+DPO (EM/F1)	36.6 / 45.3	36.3 / 44.8	-

Table 2: Comparison of the three expansion methods. k denotes the number of execution branches for each decision, n denotes the number of rollouts and l denotes the depth of layers.

preference data compositions during the DPO stage. Experiments reveal that omitting any type of preference data results in performance degradation, highlighting the necessity of simultaneously optimizing decision-making and execution. Further analysis shows that the model trained with decision data performs slightly worse than the one trained with execution data but requires fewer retrievals. This confirms that execution data primarily optimizes content quality, while decision data optimizes retrieval efficiency.

Figure 2(c) shows performance comparisons across different training methods. Experiments reveal that SFT-only training enables models to learn basic retrieval patterns, but insufficient retrieval frequency limits performance ceilings. DPO-only trained models suffer from poor iteration quality and increased ineffective retrievals due to the lack of effective imitation learning. In comparison, the two-stage training (SFT+DPO) achieves a balance between performance and efficiency, establishing reasoning foundations through SFT training while optimizing decision processes via DPO training, ultimately delivering the best overall performance.

4 Analysis

4.1 Data Expansion Efficiency

To validate the effectiveness of the search tree expansion pruning method (Pruning Search), we compared it with two other approaches: No Pruning Search and Full Node Search. No Pruning Search retains the optimal execution branches for the two decisions, while Full Node Search keeps all execution branches but omits the rollout simulation process. Table 2 reports all the results.

Theoretical analysis shows that the number of expansions in Pruning Search grows linearly with the depth of layers, significantly outperforming the exponential growth trend of 2^l in No Pruning Search and the more drastic growth trend of $(2k)^l$ in Full Node Search, where k represents the number of execution branches per decision, l represents the depth of layers.

In the actual performance test, we evaluated the three methods using 500 questions under the same hardware configuration. Experimental results show that Pruning Search is nearly 6 times faster than No Pruning Search in terms of average expansion time per question. The expansion efficiency of Full Node Search is extremely low, with the expansion time per question exceeding 1 hour, making it incomparable. Therefore, we do not report its subsequent experimental results.

To further validate the data effectiveness, we sampled data generated by Pruning Search and No Pruning Search in the same quantity and used it to train Qwen2.5-7B-Instruct, respectively. Table 2 shows the average performance across six datasets. We observe that whether SFT-only training or SFT+DPO training, the data generated by Pruning Search and No Pruning Search yield nearly identical model performance.

In summary, the pruning strategy significantly improves expansion efficiency (nearly 6 times faster) while maintaining data quality comparable to No Pruning Search, fully demonstrating the effectiveness and practical value.

4.2 Effect of Pruning on Optimal Reasoning Chain

In general, pruning operations may bias the search toward locally optimal reasoning paths, while discarding potentially superior global reasoning paths. For RAG tasks, the core differences between different reasoning paths for the same question usually lies in the choice made during the decision-making process. Thus, we examined the optimal reasoning chains generated by Pruning Search and No Pruning Search.

We find that for 85% of the samples, the rea-

soning chains obtained by these two methods have the same number of iterations, and for 87% of the samples, the reasoning chains obtained by the two methods have the same number of retrievals. These results directly demonstrate that the proposed pruning strategy can maximally preserve the globally optimal reasoning chain while compressing the search space.

4.3 Case Study

We provide a case in Table 3 to intuitively compare the performance differences between DecEx-RAG and Search-R1.

For the given question, Search-R1 relying on its own knowledge and one retrieval, accurately clarified the nationality information of Ed Wood and Scott Derrickson during the reasoning process. However, its final output result is "No". This phenomenon clearly indicates that Search-R1 has a serious inconsistency between the reasoning process and the conclusion, which is a typical case of reward hacking. In contrast, DecEx-RAG not only generated a logically rigorous and correct reasoning process, but also achieved a high degree of consistency between the reasoning process and the final answer.

5 Related Work

RL for Retrieval-Augmented Generation Recent advances show that reinforcement learning (RL) significantly enhances LLMs' complex reasoning, emerging as a mainstream post-training paradigm (DeepSeek-AI et al., 2025; Zhang and Xiong, 2025). Agentic RAG like Search-R1 (Jin et al., 2025) use outcome-supervised RL to train LLMs as search agents, improving complex task performance (Song et al., 2025; Chen et al., 2025). However, this approach faces inefficient exploration, sparse reward signals, and ambiguous global feedback. In contrast, Process-supervised RL incorporates fine-grained step-level rewards and has outperformed outcome supervision in various tasks (Lightman et al., 2024). Nevertheless, its integration into RAG training pipelines remains underexplored.

Tree Search for LLMs Tree search have been extensively explored in both the training and inference of LLMs, particularly in data synthesis (Zhang et al., 2024a; Yu et al., 2025) and inference-time scaling (Snell et al., 2024; Li et al., 2025b). Yao et al. (2023) propose Tree of Thoughts (ToT), which generates multiple branches for substeps during inference to expand reasoning paths. Similarly, several studies incorporate Monte Carlo Tree Search (MCTS) during reasoning to improve the performance of LLMs in mathematical and RAG-related tasks (Chen et al., 2024; Jiang et al., 2025; Feng et al., 2025). While inference-time scaling can enhances the performance of LLMs, it significantly increases computational complexity, limiting practical applications. Considering this constraint, Zhang et al. (2024b) propose fine-tuning LLMs by collecting preference information during tree search processes, effectively transferring resource consumption from inference stage to training stage. However, tree search still relies on extensive search and simulation operations, and its search efficiency and scalability in RAG remain to be optimized.

6 Conclusion

In this paper, we have presented DecEx-RAG, a novel framework that models RAG as a Markov Decision Process (MDP) with two distinct stages: Execution and Decision-Making. By decomposing the process into structured steps, DecEx-RAG enables fine-grained process supervision, facilitating more precise optimization of RAG systems. Based on this framework, we have introduced a search tree pruning strategy that incorporates multiple additional rollout processes to provide reward signals for intermediate steps. This allows the framework to dynamically prune unnecessary decision branches, effectively reducing the time complexity of search tree expansion from exponential to linear. Experiments on six datasets have demonstrated that DecEx-RAG consistently outperforms existing baselines. Further analysis has confirmed the efficiency of the pruning strategy, achieving up to a $6\times$ improvement in data construction efficiency without sacrificing data quality. This offers a practical solution to the high cost of process-supervised data construction.

Limitations

Despite the outstanding performance of DecEx-RAG, several limitations remain. When constructing the process supervision data, we adopt Exact Match (EM) and F1 score as reward feedback for intermediate processes. However, we have found that in some samples where errors occur in intermediate steps, high scores can still be obtained after rollout.

This phenomenon is mainly attributed to the fact that answers in existing RAG datasets are generally too concise and problems are simplistic, leading to EM and F1 score failing to truly reflect the correctness of responses in some scenarios. Currently, we mitigate the inconsistency between intermediate processes and final results by increasing the number of rollouts, but this approach substantially increases reasoning resource consumption.

In the future, we plan to explore a more scientifically authoritative evaluation metric for RAG tasks, rather than merely relying on increasing the frequency of rollouts, we aim to fundamentally enhance the accuracy and reliability of intermediate process feedback.

A Method Details

A.1 Prompt Instructions

We use several prompt instructions during the search tree extension process. Table 4 provides the prompt instruction of execution termination decision, Table 5 provides the prompt instruction for generating sub-question, Table 6 presents the prompt instruction for the model to answer questions based on its own knowledge, Table 7 provides the prompt instruction for generating sub-query, and Table 8 presents the prompt instruction for rollout.

A.2 DPO Training Objective

The DPO training objective is formulated as:

$$\mathcal{L}_\theta = -\mathbb{E}_{(x,y_{<t},y_t^w,y_t^l)\sim\mathcal{D}}\Bigg[\log\sigma\Big(\beta\log\frac{\pi_\theta(y_t^w|x,y_{<t})}{\pi_{\text{ref}}(y_t^w|x,y_{<t})} - \beta\log\frac{\pi_\theta(y_t^l|x,y_{<t})}{\pi_{\text{ref}}(y_t^l|x,y_{<t})}\Big)\Bigg] \tag{2}$$

where π_θ represents the policy being optimized, π_{ref} represents the reference policy, x denotes the original question, $y_{<t}$ denotes the previous reasoning steps, y_t^w and y_t^l respectively represent the preferred and non-preferred decisions or executions in the subsequent steps, σ is the logistic function, and the hyperparameter β controls the KL divergence constraint.

B Baselines

The baselines we compared against are as follows:

- Direct Inference: We prompt the model to directly answer questions.
- CoT: We prompt the model to reason step-by-step before generating the answer.
- Standard RAG (Lewis et al., 2020): We first retrieve relevant documents for the question, then prompt the model to answer with reference to these documents.
- Iter-RetGen (Shao et al., 2023): This method collaboratively retrieves and generates in an iterative manner, alternating between optimizing retrieval and generation through multiple iterations.
- IRCoT (Trivedi et al., 2023): This method interweaves retrieval with CoT reasoning steps, using CoT to guide retrieval and leveraging retrieval results to refine CoT.
- FLARE (Jiang et al., 2023): This method introduces proactive forward-looking retrieval, determining retrieval timing based on token-level confidence.
- Search-o1 (Li et al., 2025a): This method designs a complex iterative workflow via prompting and introduces a Reason-in-Documents module to optimize reasoning chains.
- Search-R1 (Jin et al., 2025): This method trains the model's dynamic retrieval capabilities via outcome-supervised reinforcement learning.
- IKEA (Huang et al., 2025b): Extending Search-R1. This method introduces a retrieval frequency penalty to improve reasoning efficiency.
- ReasonRAG (Zhang et al., 2025): This method constructs process-supervised data via Monte Carlo Tree Search (MCTS) for DPO training.
- DeepRAG (Guan et al., 2025): This method constructs process-supervised data via full-node expansion combined with binary tree search for DPO training.

Question: Were Scott Derrickson and Ed Wood of the same nationality?

Ground Truth: yes

DecEx-RAG:
<think> To determine if Scott Derrickson and Ed Wood share the same nationality, I need to identify the nationalities of both individuals. Starting with Scott Derrickson. So, the next sub-question is: What is Scott Derrickson's nationality? I recall that Scott Derrickson's nationality is American. Now, I need to determine Ed Wood's nationality. I am less familiar with him, so I require additional information. I am uncertain about Ed Wood's nationality. He may be an actor or filmmaker, but I need to verify this. </think>
<search> Ed Wood nationality </search>
<information>
Docs 1: "Ed Wood"
Greyś 1992 oral biography "Nightmare of Ecstasy: The Life and Art of Edward D. Wood Jr.", the public took a greater interest in Wood, leading up to director Tim Burton's biopic of Wood's life, "Ed Wood" (1994), a critically acclaimed film starring Johnny Depp as Wood that earned two Academy Awards. Wood's father, Edward Sr., worked for the U.S. Postal Service as a custodian...
Docs 2: "Ed Wood"
Ed Wood Edward Davis Wood Jr. (October 10, 1924 – December 10, 1978) was an American filmmaker, actor, and author. In the 1950s, Wood made a number of low-budget films in the science fiction, crime and horror genres, intercutting stock footage. In the 1960s and 1970s, he made sexploitation movies and wrote over 80 pulp crime, horror and sex novels...
Docs 3: "Alexander Wood (soccer)"
Alexander Wood (soccer) Alexander "Alec" Wood (June 12, 1907 – July 20, 1987) Was a former Scottish American soccer defender. Wood began his club career in the United States before moving to England in the early 1930s. He also played all three U.S. games at the 1930 FIFA World Cup...
</information>
<think> The information provided confirms that Ed Wood was an American filmmaker, and his birth in the U.S. establishes his nationality as American. Scott Derrickson is also American. Both are of the same nationality. </think>
<answer> yes </answer>

Search-R1:
<think> Scott Derrickson is known for directing films such as "The Exorcist" (2016). Ed Wood is famous for his low-budget films in the 1950s, particularly "Plan 9 from Outer Space." Given that Ed Wood was American, I need to confirm Scott Derricksonś nationality. </think>
<search> Scott Derrickson nationality </search>
<information>
Docs 1: "Scott Derrickson"
directed the film "Doctor Strange", based on the Marvel Comics property and part of the Marvel Cinematic Universe. It was released in November 2016. The film was both a commercial and critical success. In February 2018, it was announced that Derrickson will executive produce the television series "You Bury Me" for Blumhouse Productions...
Docs 2: "Scott Tucker (racing driver)"

</information>
<think> From the search results, it appears that Scott Derrickson is associated with American films and there is no mention of him being from any other country. Therefore, Scott Derrickson is American. </think>
<answer> No </answer>

Table 3: A case study of DecEx-RAG and Search-R1.

Prompt Instruction

You are a Retrieval-Augmented Generation (RAG) model. Your task is to carry out multiple iterative processes, continuously decompose a problem into sub-problems, solve them one by one, and finally answer the original question. We will provide you with a question and the previous iteration history (each iteration includes the thinking process, sub-question, the model's answers to the sub-questions based on its own knowledge or the relevant documents retrieved from the sub-question). Please judge based on the available information whether there is sufficient evidence to answer the original question reasonably. Please note that you must rely only on the existing information as evidence and cannot introduce any information or knowledge that has not appeared in the iterative history, including your own knowledge.

- If you think that based on the existing information, you can reasonably reason out the answer to the original question and there is no need to continue raising the next sub-question, then please first state your reasoning process in <reasoning> and </reasoning>, the reasoning process requires the provision of reasonable evidence, and then provide the final answer in <answer> and </answer>. For example: <reasoning> your reasoning process </reasoning>. <answer> your answer </answer>.
- If you think that it is impossible to reasonably reason out the answer to the original question based on the existing information and you need to continue to raise the next sub-question and iterate further, then please first state your reasoning process in <reasoning> and </reasoning>, the reasoning process needs to explain the reasons for the need for further iteration, and then provide the sub-questions in <question> and </question>. For example: <reasoning> your reasoning process </reasoning>. <question> next sub-question </question>.

Matters Need Attention:
1. It should be noted that if you find that the sub-question generated in the previous iteration has not been successfully solved, we encourage you to try to raise this sub-question again and continue the iteration, rather than easily giving a final answer and thus ending the iteration.
2. Ensure both question and answer are concise, using nouns or short phrases whenever possible.

Question
{question}

Previous Iteration
{iter_history}

Your Output

Table 4: The prompt of execution termination decision determines whether to continue the iteration or terminate.

Prompt Instruction

You are a Retrieval-Augmented Generation (RAG) model. Your task is to break down the original question into several clear sub-questions, which will be solved iteratively to answer the original question.
We will provide you with a question. Please break it down and output the next sub-question that needs to be solved. Before outputting sub-question, you must provide a clear thinking process or reasons. Finally, provide the sub-question inside <question> and </question>.
For example: Your thinking process. <question> sub-question </question>.

Question
{question}

Your Output

Table 5: The prompt for generating sub-question.

Prompt Instruction

We will provide you with a question, please answer this question. Your output should first provide your thinking process, and finally offer the final answer within <answer> and </answer>, ensure your answer is concise, using nouns or short phrases whenever possible. An example is shown below.

Sample
Question:
Which country's capital is Beijing?

Your Output:
To determine which country's capital is Beijing, I need to recall geographical knowledge about major cities and their respective countries. Beijing is a well-known city in East Asia, and it is the political and cultural center of a significant nation in that region. The country that has Beijing as its capital is China. <answer> China </answer>

Question
{question}

Your Output

Table 6: The prompt for the model to answer questions based on its own knowledge.

Prompt Instruction

You are a Retrieval-Augmented Generation (RAG) model. We will provide you with a question. Please generate a query for search engines for this question. Generate the query directly without outputting any other content.

Question
{question}

Your Output

Table 7: The prompt for generating sub-query.

Prompt Instruction

You are a Retrieval-Augmented Generation (RAG) model. Your task is to carry out multiple iterative processes, continuously decompose a problem into sub-problems, solve them one by one, and finally answer the original question. We will provide you with a question and the previous iteration history (each iteration includes the thinking process, sub-question, the model's answers to the sub-questions based on its own knowledge or the relevant documents retrieved from the sub-question). Please continue reasoning along the previous iteration history to solve the original problem.

After reasoning, if you find you lack some knowledge, you can call a search engine by <search> query </search>, and it will return the top searched results between <information> and </information>. If you find that no further external knowledge is needed, please still provide your reasoning process, and then you can directly provide the answers within <answer> and </answer>. For example, <answer> Beijing </answer>.

Ensure both queries and answers are concise, using nouns or short phrases whenever possible.

Matters Need Attention:
1. Please note that the previous iteration history is true and does not need to be verified again, so you can definitely take this information as established facts and, based on this, continue to reason downward.
2. Please note that during the reasoning process, do not end it casually. Only when you think it necessary to call the search engine (the output ends with </search>) or output the final answer (the output ends with </answer>) can the reasoning process be temporarily interrupted or completely ended.

Question
{question}

Previous Iteration

Abstract

Large Language Models (LLMs) can be used to convert natural language (NL) instructions into structured business process automation (BPA) process artifacts. This paper contributes (i) FLOW-BENCH, a high quality dataset of paired NL instructions and business process definitions to evaluate NL-based BPA tools, and support research in this area, and (ii) FLOW-GEN, our approach to utilize LLMs to translate NL into an intermediate Python representation that facilitates final conversion into widely adopted business process definition languages, such as BPMN and DMN. We bootstrap FLOW-BENCH by demonstrating how it can be used to evaluate the components of FLOW-GEN across eight LLMs. We hope that FLOW-GEN and FLOW-BENCH catalyze further research in BPA.

1 Introduction

With many enterprises relying on BPA to standardize their work, enhance their operational efficiency and reduce human error, BPA tools grew to a $11.84B industry and are projected to grow to $26B in 2028 (Marketwatch, 2022). In contemporary BPA tools, users use visual drag-and-drop interfaces and reusable templates to construct workflows, decision models, and document process logic, adhering to standard notations such as BPMN (Grosskopf et al., 2009; Chinosi and Trombetta, 2012) and DMN (Biard et al., 2015).

However, even sophisticated low-code BPA platforms frequently necessitate intervention from software engineers to ensure robustness, handle intricate integrations, and implement customized logic not covered by generic templates. The complexity inherent in configuring detailed integration tasks and writing low-level transformation logic remains daunting for novice programmers and tedious even for seasoned developers.

Recent efforts have explored leveraging natural language interfaces to simplify BPA authoring. LLMs have demonstrated substantial potential for automating code generation tasks by translating high-level user intents into executable artifacts. However, in our experience, even state-of-the-art LLMs are not effective at generating BPA workflows, both due to the lack of BPMN training data and the extensive boilerplate notations that need to be generated. Section A.1 showcases a flow and its corresponding BPMN code.

To the best of our knowledge, there is a lack of well-established benchmarks to evaluate NL-driven workflow generation. With this paper, we contribute FLOW-BENCH, a high quality dataset designed specifically to support research in natural language-driven business process automation, that consists of realistic utterances and their corresponding BPMN representations[1]. The availability of this dataset is intended to catalyze model improvements, benchmarking, and development of NLP techniques tailored to the BPA domain.

We also contribute FLOW-GEN, an approach that leverages LLMs to first translate natural language into an intermediate representation (IR) with Python syntax to precisely capture the logic of the intended business process. The Python IR provides several advantages. It takes advantage of the innate Python code generation capabilities of LLMs and it bridges the gap between unstructured natural language and formalized business process definition languages, facilitating easier verification and refinement of the generated logic. Subsequently, our approach translates this IR into specific target process definition languages, such as BPMN-compliant XML or DMN decision tables, ensuring compatibility with existing BPA solutions and tools. Further, the use of an IR makes it easy to catch errors early and to support multiple target BPA languages. We include the Python IR in the

FLOW-BENCH dataset, along with the BPMN.

2 FLOW-BENCH dataset

Workflows in FLOW-BENCH consist of sequences of API invocations, including conditionals and loops, similar to those found in commercial workflow automation platforms like IBM App Connect (IBM App Connect, 2025) and Zapier (Zapier Apps , 2025). In addition to API calls, workflows may incorporate manual interventions, termed *user tasks*. These user tasks typically involve steps within a business process that require human action, such as managerial approvals, and thus, do not have corresponding APIs.

To construct FLOW-BENCH we initially sourced realistic business workflows from pre-existing templates provided by commercial workflow automation platforms (specifically IBM App Connect and Zapier). These templates cover common enterprise use cases, including support ticket creation, task management, and marketing campaign automation.

We carried out three high level steps to arrive at the final FLOW-BENCH dataset: (1) quality control, (2) manual labeling, and (3) data augmentation.

Quality Control: First, we collected and manually examined workflows sourced from the automation platforms. We discarded or truncated workflows that were overly complex with multiple levels of nested conditions, in order to start with relatively small workflows that a user can reasonably describe in a few sentences. We removed event triggers from workflows and discarded workflows that consisted of only a single API call. We also discarded workflows that involved APIs without publicly available OpenAPI spec.

Manual Labeling: We manually added or corrected user utterance to workflows. In some cases, we rephrased existing workflow descriptions to reflect an active user command to constructing the workflow as opposed to a passive description of the workflow. The workflows often only had a proprietary representation in the respective automation tool, so we manually crafted Python IR snippets and generated the corresponding BPMN specification. We also retrieved the OpenAPI specs for all activities in the workflows and established a common naming convention for API-based worfklow activities. In addition, we added clear descriptions for each API, tweaking the descriptions in the OpenAPI specs (if available).

Data Augmentation: Once we had a set of high quality samples, we expanded the dataset in two ways. First we incorporated user tasks by either adding a new activity in the workflow, or by removing the corresponding API from the catalog. Then we added samples to reflect how users may incrementally build a workflow, by adding, deleting, or replacing activities in the workflow. For each new sample, we defined the workflow before and after the edit, and the corresponding user utterance. To mimic actual software development the incremental edits may apply anywhere in the current workflow, not always editing left to right.

The final complete workflows in FLOW-BENCH are generated through incremental build steps categorized as *add*, *delete*, or *replace*.

Build steps in FLOW-BENCH are kept as self-contained tests by including three elements: (1) *Prior Sequence*, representing the current state of the workflow before applying changes[2]; (2) *Utterance*, describing the modification to be performed in natural language (e.g, "Retrieve all issues from the Jira board."); and (3) *Expected Sequence*, indicating the resulting workflow after implementing the command specified by the utterance. Note that a single utterance can express a sequence of multiple activities, establishing a one-to-many mapping between utterances and activities. For instance, an utterance like "Create a GitHub issue and then notify the team on Slack" maps to two distinct activities (GitHub issue creation and Slack notification) with an explicit sequential ordering.

Build step type	Tests	Avg. #APIs Prior	Avg. #APIs Expected
linear:generate	34	-	2.26
linear:add	11	2.27	3.45
linear:delete	5	3.2	2.2
linear:replace	6	3.5	3.5
cond:generate	19	-	2.94
cond:add	10	2.4	3.5
cond:delete	9	3.88	2.33
cond:replace	7	3.0	3.0
Total	101	3.04	2.89

Table 1: FLOW-BENCH composition of 101 incremental build tests with linear and conditional (cond) prior and expected sequences

FLOW-BENCH comprises 101 high-quality, manually curated incremental build step tests structured according to this methodology. Figure 1 illustrates

[2]This may be empty in the initial generation step.

```yaml
_metadata:
  tags:
    - conditional_update
  uid: 97
input:
  utterance: |-
    Instead of retrieving all the issues
    just create a new issue in each repo
  prior_sequence:
    - |-
    repositories = GitHub_Repository__3_0_0__retrievewithwhere_Repository()
      for repo in repositories:
        new_issue = GitHub_Issue__3_0_0__retrievewithwhere_Issue()
  prior_context: []
  bpmn:
    $ref: "context/uid_97_context.bpmn"
expected_output:
  sequence:
    - |-
    repositories = GitHub_Repository__3_0_0__retrievewithwhere_Repository()
      for repo in repositories:
        updated_issue = GitHub_Issue__3_0_0__create_Issue()
  bpmn:
    $ref: "output/uid_97_output.bpmn"
```

Figure 1: Example of FLOW-BENCH test case

an example test case from FLOW-BENCH. Each build step is uniquely identified and provides a self-contained test scenario, including explicit BPMN representations of both the *Prior Sequence* and *Expected Sequence*. Additionally, each test is annotated with metadata describing the build step type (`add`, `delete`, `replace`), the control flow structure (`linear` or `conditional`, where `conditional` encompasses both if-statements and loops), and the inclusion of user task steps (denoted by `user_task`). The BPMN representation of Figure 1 is shown in A.2.

Table 1 shows the break-down of the FLOW-BENCH by build step type along with the average test size in terms of the number of APIs included. Conditional tests include between 1 and 4 control flow statements with an average and maximum nesting depths of 1.64 and 4, respectively.

To ensure compact and clear representations of prior and expected workflows, FLOW-BENCH adopts a constrained subset of Python syntax. This subset includes assignment statements, conditional statements (if-statements), loops (for and while), and function calls. These representations are explicitly provided within the *Prior Sequence* and *Expected Sequence* elements of each test.

Generating accurate pythonic function calls in a FLOW-BENCH test by an LLM requires knowledge of existing APIs and their descriptions. Thus, we also provide a separate file containing a catalog of APIs along with their descriptions. The catalog used in our experiments contains 546 API endpoints from diverse enterprise applications including GitHub, Jira, Slack, Salesforce, and other common business automation platforms. An example of an API and its description is shown below.

```json
{
  "id": "Jira_Issue__2_0_0__retrievewithwhere_Issue",
  "description": "Retrieve all Jira issues"
}
```

3 FLOW-GEN

This section presents FLOW-GEN, an approach that applies pre-trained LLMs to solve the workflow generation tasks in the FLOW-BENCH dataset.

3.1 Python Intermediate Representation

Our initial observations suggest that while some LLMs can generate BPMN directly, these models have not been extensively trained or evaluated specifically on BPMN data. In contrast, many pre-trained LLMs have been extensively trained on Python code and have demonstrated significant proficiency in generating Python scripts accurately (Tong and Zhang, 2024).

Moreover, BPMN representations are inherently verbose, which introduces complexity and increases the likelihood of syntactic and semantic errors when generated by LLMs. Longer BPMN outputs also increase computational cost and slow down generation, negatively impacting interactive user experiences. To illustrate this, consider the straightforward linear BPMN flow depicted in the bottom left of Figure 2. Its BPMN representation requires 3,151 characters, whereas the equivalent logic can be succinctly expressed in only 148 characters of Python code:

```python
issue = GitHub_Issue__3_0_0__create_Issue()
pr = GitHub_Pullrequest__3_0_0__create_Pullrequest()
comment = GitHub_Comment__3_0_0__create_Comment()
```

In FLOW-BENCH, the BPMN representation is on average 25 times longer than the Python equivalent. While there are BPMN-specific concepts such as swimlanes and roles that do not translate directly into Python, these are out of scope of the FLOW-BENCH dataset. FLOW-GEN also accommodates the concept of user tasks—activities performed by humans that are not linked to predefined workflows or APIs. These tasks represent ad-hoc activities specified by the user.

3.2 Initial Flow Generation

Consider the scenario where a user wants to create a new workflow based solely on an NL description. This initial flow generation process, outlined in the upper part of Figure 2, involves several steps.

Initially, the user's NL utterance is analyzed to retrieve a relevant subset of predefined activities. These activities typically correspond to APIs, decision rules, or other processes from a comprehensive

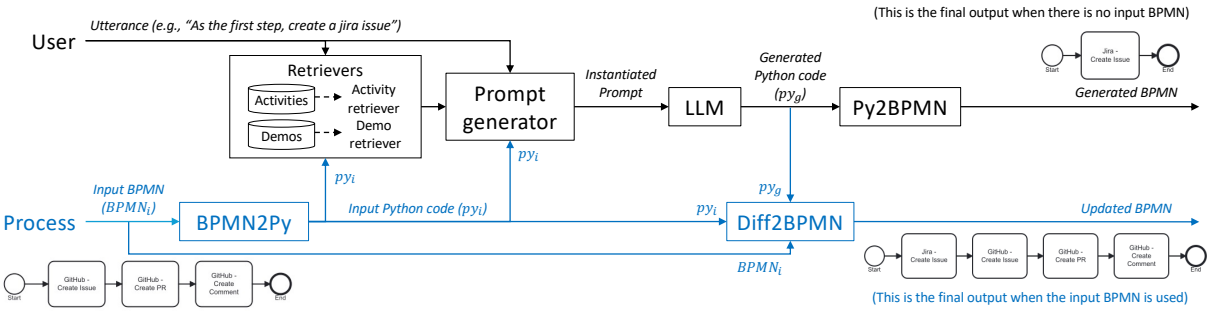

Figure 2: FLOW-GEN overview. The top part (in black) depicts the steps to generate a new workflow based on a user utterance. The bottom part (in blue) are the additional steps to update an existing workflow based on an utterance.

activity catalog. Including this subset in the LLM prompt is essential, especially when the entire catalog cannot fit within the LLM's context window. The different approaches to retrieving relevant activities are detailed in Section 3.4.

Concurrently, the utterance is used to select the most relevant demonstrations from the dataset. Each demonstration comprises an NL utterance paired with a Python code snippet. These examples, provided as few-shot demonstrations in the LLM prompt, guide the LLM to generate accurate Python code snippets, illustrating correct invocation patterns of predefined activities as Python functions. Section 3.5 further elaborates on the methods evaluated for demonstration retrieval.

Next, an LLM generates a Python code snippet based on a dynamically assembled prompt that includes the user's NL utterance, retrieved activity descriptions, and selected few-shot demonstrations. This generated snippet captures the workflow described by the user, incorporating user tasks where necessary for activities not in the catalog.

Finally, the deterministic PY2BPMN module converts the generated Python code into standard BPMN, completing the translation from NL to executable workflow definition.

3.3 Incremental Flow Updates

Let us now consider the case where there is already an existing workflow, and the user issues an utterance to incrementally edit the workflow. The bottom portion of Figure 2 show the additional steps in FLOW-GEN to support this case.

First, the original BPMN workflow ($BPMN_i$) is transformed into a Python code snippet (py_i). This is done using deterministic code in the BPMN2PY module.

The code py_i is used as additional information for the retrievers. For example, the activity retriever should select not only activities mentioned in the utterance, but also those referenced in the input workflow. Similarly, if py_i contains conditional or looping constructs, the demonstration retriever will more likely select few-shot samples that include such constructs. The code snippet py_i is coupled with the user query to serve as input to the LLM code generation step.

The DIFF2BPMN module computes the difference between the input (py_i) and generated (py_g) Python and internally generates a set of update operations. These update operations are applied to the input workflow ($BPMN_i$) to arrive at the final updated BPMN workflow.

3.4 Activity Retrievers

Given the user's NL utterance, the generated code is expected to reference activities from the provided catalog (grounding) and avoid hallucinations. However, as catalogs may contain thousands of activities, it becomes infeasible to include the entire catalog within the limited context window of the LLM. Thus we need to retrieve and include only the top-k most relevant subset. We outline three types of activity retrievers.

ED_Retriever: Compares the user utterance against the description of each activity from the catalog to quantify how dissimilar (or similar) the two are based on edit distance. Given that edit distance computation only compares the raw strings without incorporating any semantic meaning, the performance of this retriever is limited in scope.

Embeddings_Retriever: A Bi-Encoder based retrieval that generates the embedding vectors for the user utterance and all the activities, followed by computing the cosine similarity between each pair. Embeddings capture the semantic meaning and thus, boost the performance significantly as compared to the Edit Distance based approaches.

We used the *all-MiniLM-L6-v2* model to generate the embeddings and ChromaDB to store, index, and retrieve top-K activities. Since the catalog is relatively stable, the embeddings can be generated once and stored to improve runtime latency.

Activities_Search: This retriever works like Embeddings_Retriever, but we use a custom model fine-tuned to generate better embeddings for the activity retrieval task.

3.5 Demonstration Retrievers

Demonstrations refer to the few shot in-context examples that are incorporated in the prompt. We explored two retrieval approaches.

TopKRetriever: A Bi-Encoder based retrieval similar to Embeddings_Retriever.

CE_Retriever: A cross-encoder based retrieval, where two strings are passed simultaneously to the model that outputs similarity score ranging between 0 and 1. Cross-encoder based retrieval is more accurate since the model is trained on a large dataset to generate the similarity score. Since the user utterance is only available at runtime, the similarity computation against the demos can only be performed at runtime which introduces latency. To reduce the latency, we shortlist the demonstration catalog based on the provided context before passing it to cross-encoder. For example, if the user is updating an existing workflow, only the demos containing a prior sequence are selected. We use the *stsb-distilroberta-base* model as the cross-encoder.

4 Evaluation

In this section, we evaluate FLOW-GEN on the FLOW-BENCH dataset. All experiments evaluate the generation of Python intermediate representation (IR) from natural language utterances, followed by deterministic conversion to BPMN. The IR-based approach is central to our methodology, and all reported metrics measure the quality of the generated Python IR. We begin by providing an evaluation of the retrievers. All experiments were conducted over the 101 FLOW-BENCH test cases.

4.1 Activity Retrievers

Table 2 summarizes the results of the three activity retrievers: ED_Retriever, Embeddings_Retriever, and Activities_Search. **TopK** refers to the number of retrieved activities. **Activities Recall** is computed based on the overlap between the retrieved activities and those in the ground truth. **Exact Match** highlights the accuracy of the generated IR to the ground truth syntactically and semantically. **Hallucination Rate** computes the fraction of activities in the generated workflows that are not in the catalog.

Retriever	TopK	Activities Recall	Exact Match	Hallucination Rate
ED_Retriever	10	0.7327	0.495	**0.0469**
	50	0.7913	0.604	0.0621
	100	**0.8086**	**0.6139**	0.0586
Embeddings_Retriever	10	0.9307	0.6733	0.0207
	50	0.9794	**0.7525**	**0.0205**
	100	**0.9851**	0.7129	0.0236
Activities_Search	10	0.9703	0.6931	0.0069
	50	**0.9926**	**0.7723**	**0.0102**
	100	**0.9926**	0.7525	**0.0102**

Table 2: Evaluation of different retrievers with different TopK.

Table 2 shows that Activities_Search with TopK=50 has the best recall and best exact match score with the least hallucination rate, followed by Embeddings_Retriever. This validates that embedding similarity is more effective than edit distance. We also see that larger TopK improves recall but reduces the exact match since it increases LLM's probability of selecting the incorrect Activity.

Model	DemoSelector	TopK	Exact Match
Granite-20b-code-instruct-v2	TopKRetriever	2	0.5842
		3	0.5941
		5	**0.6734**
		7	0.6634
	CE_Retriever	2	0.5842
		3	0.6436
		5	**0.6931**
		7	0.6733
codellama-34b-instruct-hf	TopKRetriever	2	0.7029
		3	0.7131
		5	**0.7228**
		7	**0.7228**
	CE_Retriever	2	0.703
		3	0.7228
		5	**0.7624**
		7	**0.7624**

Table 3: Evaluation of demonstration retrievers with different number of demos (TopK) while using Activities_Search with TopK=50 for Activities selection.

4.2 Demonstration Retriever

Table 3 compares ***TopKRetriever*** and ***CE_Retriever*** for different values of TopK using Granite-20b-code-instruct-v2 and codellama-34b-instruct-hf models. TopK here refers to the number of demonstrations not activities.

The cross-encoder based retriever boosts the exact match by 4 points irrespective of model choice. Increasing the number of demonstrations retrieved beyond five degrades the overall performance. For the remainder of these experiments we consider retrieving five demonstrations using CE_Retriever.

Model	Activities Domain	Exact Match	Syntax F1
mixtral-8x7b-instruct-v01	in-domain	0.66	0.87
	cross-domain	0.63	0.85
granite-8b-code-instruct	in-domain	0.59	0.86
	cross-domain	0.60	0.84
llama-3-1-8b-instruct	in-domain	0.19	0.57
	cross-domain	0.19	0.56
Granite-20b-code-instruct-v2	in-domain	0.67	0.91
	cross-domain	0.59	0.89
Codellama-34b-instruct-hf	in-domain	0.76	0.93
	cross-domain	0.72	0.91
llama-3-3-70b-instruct	in-domain	0.53	0.74
	cross-domain	0.49	0.71
Mistral-large	**in-domain**	**0.83**	**0.90**
	cross-domain	**0.79**	**0.86**
llama-3-405b-instruct	in-domain	0.60	0.82
	cross-domain	0.55	0.80

Table 4: Evaluation of different models using Activities_Search (TopK=50) as and CE_Retriever(TopK=5) as Activities and demos retrievers respectively.

4.3 Overall Evaluation

In Table 4, we provide an extensive evaluation of FLOW-GENẆe use Activities_Search as the activity retriever with TopK=50 and CE_Retriever as the demonstration retriever with TopK=5. Table 4 compares the performance of several models varying in size. Recall that **Exact Match** highlights the accuracy of the generated IR to the ground truth syntactically and semantically, and **Activities Recall** is the overlap between the retrieved activities and those in the ground truth. **Syntax F1** evaluates correctness of the generated IR code syntactically.

To evaluate the impact of interference between the activities catalog and activities present in the demonstrations we provide both **cross-domain** and **in-domain** evaluations. By **cross-domain** we make sure that demos are selected such that the activities present in the ground-truth are not used by any of the selected demonstrations and for **in-domain**, activities present in ground-truth may be present in selected demos.

Mistral-large model preformed best with exact match of 0.83 and 0.79 for both in-domain and cross-domain scenarios respectively. High Syntax F1 highlights the ability of Mistral-large to generate syntactically correct Python IRs. The llama-3-1-8b-instruct small model performs the worst.

5 Deployment

Our approach has been deployed as a technical preview (c.f. Figure 3) as part of the Unified Automation Builder (UAB) of IBM's Watsonx Orchestrate (2025). UAB provides an intuitive graphical interface for the creation, evaluation and deployment of automation flows. The UAB tooling is deployed as a scalable cloud solution, with numerous containers deployed in a cluster. Our approach has been to deploy FLOW-GEN as a first-class component, in the cluster, enabling secure access to the API catalog, as well as LLM inference capabilities available from Watsonx.ai. Additionally, Watsonx Assistant is leveraged as the user-facing interface, where utterances are input by the user, and routed to FLOW-GEN via internal proxy services which facilitate the returning responses.

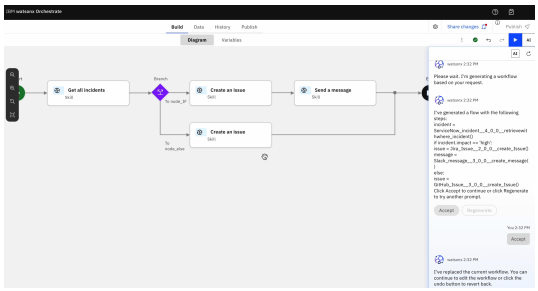

Figure 3: Deployment in WxO production environment

6 Related Work

Leveraging LLMs to automate the creation and improvement of BPM flows is an active area of research. AutoFlow (Li et al., 2024) is a framework that automatically generates workflows enabling agents to tackle complex tasks. It adopts the CoRE language (Xu et al., 2024) for workflow representation, requiring fine-tuning of LLMs to master the specific grammar and workflow generation protocols associated with CoRE. However, this fine-tuning requirement limits flexibility, preventing the integration of off-the-shelf LLMs.

Agentic Process Automation (APA) (Ye et al., 2023) formulates workflow creation as a Python code-generation task, where actions within the workflows are represented by Python function calls executed by specialized agents. Nonetheless, APA does not ground the APIs explicitly within the business process, creating potential for hallucination where the LLM might reference incorrect or nonexistent APIs. Our research avoids hallucination by embedding API grounding directly within the LLM prompts, thus enabling the LLM to accurately interpret, select, and utilize APIs as practical tools for workflow generation (Liu et al., 2024; Yan et al., 2024; Qin et al., 2023). This also facilitates the LLM's comprehension APIs, resulting in Python-generated workflows that reflect the intended business process control flow.

Recently, (Fan et al., 2024) also used a Pythonic IR for workflow processes and collected grounded APIs specifically for workflow construction. Their workflow generation strategy depends on training

specialized data annotators based on data collected, which is constrained by the domains of data collection (Apple Shortcuts and RoutineHub), limiting its broader applicability handling out-of-domain APIs and queries. In contrast, our method leverages in-context learning combined with API retrieval techniques, both of which inherently support greater flexibility and ease of generalization across diverse domains.

Our dataset and approach have the unique combination of reflecting incremental multi-turn workflow construction where users can switch between updating the workflow manually and conversationally, and supporting workflows with dynamically constructed user tasks rather than being restricted to a pre-defined set of activities.

More broadly, our work builds upon the significant advances in LLM-based code generation (Zheng et al., 2023; Tong and Zhang, 2024), particularly Python code generation where models have demonstrated strong capabilities. However, business process generation poses unique challenges beyond general-purpose code generation: workflows must be grounded in specific API catalogs to avoid hallucination, support incremental multi-turn construction, and ultimately translate to standardized notations like BPMN for integration with existing enterprise tooling.

Direct quantitative comparison with the aforementioned related work is challenging for several reasons. First, many approaches such as AutoFlow (Li et al., 2024) require domain-specific fine-tuning of models, while our method uses off-the-shelf LLMs with in-context learning, representing fundamentally different evaluation paradigms. Second, existing work either targets specific domains (e.g., Apple Shortcuts in (Fan et al., 2024)) or uses proprietary representations (e.g., CoRE language) that are not directly comparable to our BPMN-based workflows. Most importantly, none of the related work addresses incremental, multi-turn workflow updates—a core contribution of our approach—making like-for-like baseline comparisons infeasible. Our evaluation instead focuses on demonstrating the efficacy of our IR-based approach across multiple LLMs and retrieval strategies on the FLOW-BENCH dataset.

7 Conclusions

In this paper, our contributions include both the FLOW-BENCH dataset and the FLOW-GEN methodology, aiming to significantly lower barriers for both expert and citizen developers to construct automated business processes. FLOW-BENCH is a novel dataset specifically curated to facilitate research on automating workflows using LLMs. FLOW-GEN is a technique that translates natural language instructions into structured BPMN artifacts, leveraging an IR. By grounding workflow construction in contextually relevant API documentation and utilizing in-context learning, we address common issues such as hallucination and limited domain adaptability present in previous methods. Future work includes expanding dataset coverage, further refining API grounding methods, and evaluating our proposed methods in more complex business scenarios.

Limitations

While FLOW-GEN and FLOW-BENCH advance the state of natural language-driven business process automation, several limitations warrant discussion.

Intermediate Representation Expressiveness: Our Python-based IR deliberately focuses on capturing core BPMN control flow and data flow constructs (sequences, conditionals, loops, and API invocations). However, BPMN includes domain-specific concepts such as swimlanes, roles, and message flows that do not translate directly into our IR. This is a conscious design trade-off: the IR enables compact representation and leverages LLMs' strong Python generation capabilities, but sacrifices some BPMN expressiveness. Importantly, our solution is designed to augment existing BPMN editors rather than replace them. Users can leverage FLOW-GEN to rapidly generate the core workflow logic, then use traditional BPMN tooling to configure additional attributes like swimlanes, roles, and visual layout. This hybrid approach balances automation with the flexibility needed for enterprise-grade process modeling.

Hallucination and Activity Grounding: Despite our activity retrieval mechanisms, LLMs may occasionally generate hallucinated activity names not present in the catalog. We address this challenge by modeling hallucinated activities as *user tasks*—manual intervention points in the workflow. This approach transforms a limitation into a feature: users can express activities for which no API exists, and the system gracefully handles them as human tasks. However, this requires users to review generated workflows to distinguish between intentional

user tasks and unintended hallucinations.

Dataset Scale and Domain Coverage: FLOWBENCH contains 101 high-quality manually curated test cases. While these tests cover diverse patterns (linear/conditional flows, add/delete/replace operations, user tasks), they represent a limited sample of real-world business process complexity. The 546 activities in our catalog span common enterprise domains (GitHub, Jira, Slack, Salesforce), but expanding coverage to additional domains and more complex nested workflows remains important future work.

Evaluation Scope: Our evaluation focuses on the technical accuracy of generated Python IR and its syntactic/semantic correctness. We do not evaluate end-user usability, the quality of natural language utterances that real users would provide, or the long-term maintainability of conversationally-constructed workflows in production settings. User studies would provide valuable insights into the practical utility of our approach.

Abstract

Recent advances in Large Language Models (LLMs) have brought significant improvements to various service domains, including chatbots and medical pre-consultation applications. In the healthcare domain, the most common approach for adapting LLMs to multi-turn dialogue generation is Supervised Fine-Tuning (SFT). However, datasets for SFT in tasks like medical pre-consultation typically exhibit a skewed turn-count distribution. Training on such data induces a novel failure mechanism we term *Format Inertia*, where models tend to generate repetitive, format-correct, but diagnostically uninformative questions in long medical dialogues. To mitigate this observed failure mechanism, we adopt a simple, data-centric method that rebalances the turn-count distribution of the training dataset. Experimental results show that our approach substantially alleviates Format Inertia in medical pre-consultation.

1 Introduction

The rapid advancement of Large Language Models (LLMs) has revolutionized the field of conversational artificial intelligence, significantly enhancing user experiences across various domains (Achiam et al., 2023; Touvron et al., 2023). However, the majority of these successes have predominantly focused on single-turn interactions. In contrast, real-world industrial applications, particularly in healthcare domains such as medical pre-consultation, demand robust multi-turn dialogues between patients and doctors (Tu et al., 2024; Saab et al., 2025; Hu et al., 2024; Winston et al., 2024). These complex multi-turn environments require the model to effectively maintain and utilize long-range conversational context, which remains a challenging problem (Laban et al., 2025).

The predominant approach to adapting LLMs for multi-turn dialogue generation in healthcare domains is Supervised Fine-Tuning (SFT) (Wang et al., 2023; Yu et al., 2025; Christophe et al., 2024). Despite its widespread use, prior work has largely overlooked the effects of skewed turn-count distribution in training data, particularly their influence on an LLM's ability to maintain long-range conversational context and the specific failure mechanisms that emerge in long medical dialogues. While fine-tuning on high-quality medical datasets is widely recognized as critical for improving accuracy, consistency, and reliability, the role of turn-count distribution in training data in shaping long medical dialogue competence remains insufficiently understood.

This paper aims to fill this gap by hypothesizing and empirically validating that the skewed turn-count distribution in the training datasets impairs LLMs' adherence to task constraints in medical pre-consultation multi-turn dialogues. Specifically, models trained predominantly on dialogues with short turn lengths—reflecting real-world production data distribution—lack sufficient exposure to the complex contextual dependencies present in longer interviews. Consequently, these models struggle to generate follow-up questions that acquire novel diagnostic information during long medical dialogues.

To better understand this failure, we introduce a novel failure mechanism termed *Format Inertia*, which we define and empirically observe in this study. Analogous to physical inertia, where an object maintains its current state absent external force, Format Inertia describes LLMs' tendency to overly rely on previously generated question patterns when confronted with uncertainty in rarely seen long medical dialogues. This results in repetitive and unproductive questioning that preserves superficial format but fails to contribute new diagnostic information, as illustrated in Figure 1, where models trained on skewed turn-count distribution repeat previous questions in the latter turns of long

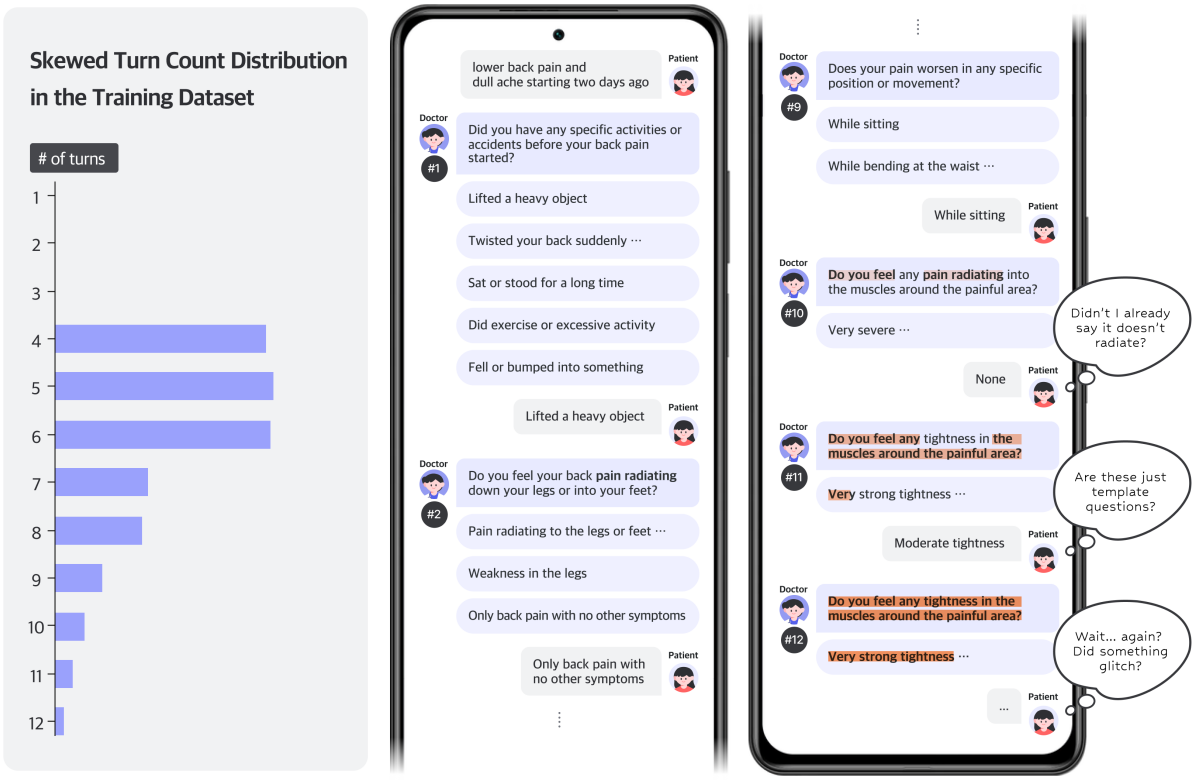

Figure 1: Example of **Format Inertia** in Medical Pre-Consultation. When trained on skewed turn-count distribution, the model overly relies on previously generated question patterns—preserving superficial format but failing to contribute new diagnostic information (#2→#10) and repeating identical questions (#11→#12). Format Inertia not only stalls clinical progress but also leaves the patient feeling confused, thereby undermining the overall user experience.

dialogues.

To address this issue, we adopt a data-centric strategy that constructs a Uniform Turn-Count Dataset by sampling an equal number of dialogues across max turn-count bins, thereby ensuring balanced exposure to diverse dialogue lengths. This approach significantly mitigates Format Inertia in long medical pre-consultations. Our main contributions are summarized as follows:

- **Analysis of Turn-Count Distribution Impact:** We systematically identify and quantitatively analyze the causal relationship between skewed turn-count distribution in the training dataset and degraded task constraint adherence in LLMs. This clarifies a core reason for performance degradation when training medical pre-consultation models under realistic conditions.
- **Definition of Format Inertia:** We propose and empirically observe *Format Inertia*, a novel phenomenon where models trained on skewed turn-count distribution generate repetitive and unproductive medical questions by over-relying on existing question formats when faced with uncertainty in long medical dialogues. To our knowledge, this study is the first to specifically explain the failure of LLMs to maintain context when trained with a skewed turn-count distribution.
- **Practical Data-Centric Solution:** We adopt a data-centric approach that rebalances the turn-count distribution in the training dataset by constructing a Uniform Turn-Count Dataset. This simple adjustment significantly improves the model's ability to maintain long-range conversational context and adhere to task constraints in long medical dialogues.

2 Background

Challenges in Multi-turn Conversational AI Multi-turn dialogue systems must maintain context across long dialogues while satisfying various constraints. Recent benchmarks evaluate these capabilities: FollowBench (Jiang et al., 2023) assesses

format and content constraints, CFBench (Zhang et al., 2024) provides a comprehensive evaluation, and Wen et al. (2024) considers constraint combinations. These studies highlight the complexity of real-world instruction-following requirements.

To address these challenges, methodologies like Parrot (Sun et al., 2024) enhance multi-turn capabilities, while Ren et al. (2025) focus on soft constraints requiring contextual judgment. However, existing research primarily concentrates on model architectures or training paradigms, overlooking how statistical characteristics of training data affect long dialogue performance.

Conversational Information Seeking in Medical Domain Medical pre-consultation systematically collects patients' History of Present Illness (HPI) for diagnostic decisions. Systems must actively seek diagnostically valuable information beyond scripted questions (Tu et al., 2024; Saab et al., 2025). Evaluation frameworks like CRAFT-MD (Johri et al., 2025) and planning methods like Uncertainty of Thoughts (Hu et al., 2024) support meaningful information seeking in uncertain medical contexts.

While Supervised Fine-Tuning (SFT) using online medical consultation records or synthetic medical data has achieved high performance (Wang et al., 2023; Yu et al., 2025), real medical data naturally exhibits a distribution skewed toward shorter dialogues. The impact of such skewed turn-count distribution on long dialogue performance remains unexplored.

3 Methodology

In this section, we investigate how the turn-count distribution in the training dataset affects Large Language Models (LLMs) engaged in medical pre-consultation. We first formalize the task, then describe a failure mechanism triggered by skewed turn-count distribution, and finally present a data-centric mitigation strategy.

3.1 Task Definition

The objective of this task is to generate contextually appropriate questions in a multi-turn dialogue setting, specifically within the domain of medical pre-consultation scenarios between patients and doctors. In this scenario, the LLM acts as a doctor who iteratively interacts with a patient. Beyond producing formally correct questions, the model must maintain and use the accumulated conversational history to ask contextually appropriate follow-up questions that diagnostically informative.

These requirements can be grouped into two sets of constraints: (i) format constraints, which govern structural aspects such as response format, response language, and the absence of forbidden terms; and (ii) task constraints, which ensure that each generated question is clinically meaningful and advances the diagnostic goal.

3.2 Format Inertia: A Failure Mechanism Induced by Skewed Turn-Count Distribution

As in most real-world datasets, medical dialogues exhibit a skewed turn-count distribution: short conversations dominate, while long medical dialogues are scarce. When an LLM is fine-tuned on such data, its exposure to long dialogues is limited. We hypothesise that this imbalance leads to a failure mechanism we call *Format Inertia*. Faced with these under-represented cases, the model tends to safe, repetitive question templates that satisfy superficial format constraints but fail to acquire new diagnostic information.

Format Inertia manifests as an over-reliance on previously generated patterns. The model preserves surface form—e.g., a fixed question pattern—yet produces redundant or low-utility questions because it cannot integrate long-range context effectively. We validate this hypothesis empirically in Section 4.3.

3.3 Uniform Turn-Count Dataset: Mitigating Format Inertia

To counteract Format Inertia, we adopt a simple data-centric remedy: constructing a Uniform Turn-Count Dataset. This approach rebalances the training data by ensuring equal representation for dialogues of varying lengths. By exposing the model to a balanced mix of short and long conversations, we mitigate its tendency to follow repetitive patterns when faced with less familiar, long dialogues. The dataset construction process is as follows:

1. **Turn-Based Binning:** All N dialogues from the source dataset are grouped into B bins based on their maximum turn-count.

2. **Quota Determination:** A sampling quota, q, is set to the number of dialogues in the smallest bin.

3. **Uniform Sampling:** We select all bins that meet a minimum turn threshold, T_{min}. Let B' be the number of selected bins. From each of these B' bins, we randomly sample q dialogues.

4. **Dataset Assembly:** The sampled dialogues are aggregated to form the final Uniform Turn-Count Dataset, containing a total of $q \times B'$ dialogues.

Equalizing turn-counts naturally broadens the spectrum of clinical scenarios encountered during training. Shorter dialogues often correspond to consultations with patients having relatively minor conditions, while longer dialogues are typically associated with patients who require more in-depth medical reasoning, involving complex history-taking. This balanced exposure ensures the model develops robust strategies for a wide range of consultation lengths, enhancing its ability to handle the diverse patient interactions found in real-world clinical settings.

4 Experiments

In this section, we present experiments evaluating our central hypothesis and method in our medical pre-consultation service scenarios.

4.1 Experimental Setting

Real-World Data Source To test our hypothesis, we gathered a corpus of approximately 8,000 medical pre-consultation dialogues generated by 40 doctors interacting with a patient model. This dataset naturally exhibits a skewed turn-count distribution, with a majority of short conversations and a minority of long ones, reflecting typical real-world scenarios. Further details on data collection are available in Appendix A.

Training Datasets To systematically analyze the effect of turn-count distribution, we constructed three training datasets sampled from the real-world corpus: (i) a Skewed Turn 1k subset (1,000 dialogues), (ii) the full Skewed Turn 8k set (8,000 dialogues), and (iii) a Uniform Turn 1k subset (1,000 dialogues).

- **Skewed Turn-Count Dataset:** This dataset mirrors the natural skewed turn-count distribution of the real-world data source, and we evaluate it at two different scales (1,000 and 8,000) to investigate the effect of data volume under the same distribution.
- **Uniform Turn-Count Dataset:** This dataset is constructed using our data-centric strategy, which alleviates distributional bias by uniformly sampling dialogues across the entire spectrum of turn lengths observed in the real-world dataset. This approach ensures balanced exposure to both short and long interactions during training.

Evaluation Datasets To enable consistent and rigorous evaluation of long-form dialogue capabilities, we constructed a dedicated evaluation set. This set comprises 100 patient profiles curated by medical professionals. During evaluation, each model engages in a simulated multi-turn dialogue with a patient model instantiated from these profiles.

Doctor Model Our experiments included both open-source and proprietary models. For the open-source group, we selected Gemma-3-4B(Team et al., 2025) and Qwen2.5-3B(Yang et al., 2025), based on their strong performance and reliable multilingual language support, including Korean, which is the target service language.

As a representative proprietary model, we employed GPT-4.1-mini[1], chosen for its balance between state-of-the-art capability and computational efficiency. All doctor models were provided with a simplified version of the patient's condition to simulate limited prior knowledge typically available during medical pre-consultation. (see Appendix C for details).

Patient Model To ensure consistent and reproducible evaluation across different doctor models, we used o4-mini[2] as the patient model throughout all inference-time interactions. The patient model was equipped with full knowledge of each clinical case, including detailed medical history and contextual information. This setup emulates a realistic pre-consultation scenario, where the patient provides accurate and consistent responses, thereby allowing fair comparisons across doctor model outputs.

Evaluation Metrics To evaluate the output quality of LLMs in the context of medical pre-consultation under production settings, we assess two critical aspects: adherence to service-specific format constraints and the clinical utility of the generated questions. To measure adherence to structural requirements, we use the *Format-Constraint*

[1] gpt-4.1-mini-2025-04-14
[2] o4-mini-2025-04-16

Constraint	Description
Format Constraints	
`response_format`	Output adheres to the required format.
`response_language`	Response is consistently written in the designated language.
`forbidden_words`	Prohibited terms are entirely excluded from the response.
`number_options`	Presents the correct number of options as specified.
`sentence_startend`	Each sentence begins and ends with the appropriate grammatical form, such as polite endings.
Task Constraints	
`clinical_utility`	The response effectively elicits additional clinical information relevant to diagnosis.

Table 1: Definitions of Format and Task Constraints used for model evaluation. Specific examples for each constraint category are provided in Appendix F.

Model	Type	Samples	FCSR	TCSR
Gemma-3 (4B)	base	-	0.361	0.872
	skew	1k	0.960	0.824
	skew	8k	0.966	0.811
	uniform	1k	**0.967**	**0.891**
Qwen2.5 (3B)	base	-	0.363	0.783
	skew	1k	0.922	0.746
	skew	8k	0.914	0.737
	uniform	1k	**0.927**	**0.812**
GPT-4.1-mini	base	-	0.906	0.880

Table 2: Comparison of Format-Constraint Satisfaction Rate (FCSR) and Task-Constraint Satisfaction Rate (TCSR) across models trained on datasets with varying turn-count distribution. The 'base' denotes the original model before fine-tuning. 'Samples' refers to the number of dialogues used for fine-tuning.

Satisfaction Rate (FCSR). This metric evaluates the model's compliance with five predefined formatting rule categories, based on a modified version of the benchmark proposed in (Zhou et al., 2023), as listed in Table 1. We implement a strictly coded validator to automatically and consistently check each dialogue turn against all constraint categories. FCSR is computed as the proportion of dialogue turns that fully satisfy all format constraints out of the total number of evaluated turns:

$$\text{FCSR} = \frac{\text{\# of Turns Satisfying All Format Constraints}}{\text{\# of Turns in Total}}$$

To assess the contextual appropriateness and diagnostic utility of the model's outputs, we define the *Task-Constraint Satisfaction Rate (TCSR)*. This metric evaluates whether the model adheres to qualitative task constraints that ensure the generation of clinically meaningful questions, as detailed in Table 1. TCSR is computed as the fraction of turns that fulfill task-specific criteria:

$$\text{TCSR} = \frac{\text{\# of Turns Satisfying All Task Constraints}}{\text{\# of Turns in Total}}$$

To verify the diagnostic utility of the generated questions, we adopt an LLM-as-a-Judge approach (Zheng et al., 2023) as our evaluation framework (see Appendix E for details).

To ensure the reliability of our evaluation framework, we conducted a human verification study on a subset of 240 samples from the evaluation data. Two medical experts independently assessed these samples using the same criteria as our LLM judge. The inter-rater agreement analysis revealed:

- **Cohen's Kappa:** 0.8091, indicating "almost perfect" agreement according to Landis and Koch's interpretation scale.
- **Spearman's Rank Correlation:** 0.8129 ($p < 0.0001$), confirming a strong positive correlation between human and LLM assessments.

This high level of agreement validates that our LLM-based evaluation provides reliable and scalable assessment for this specific, constrained task.

4.2 Results

Our experiments reveal that while SFT improves format adherence, the turn-count distribution of the training data critically impacts task performance. As shown in Table 2, models fine-tuned on the skewed turn-count dataset with 1,000 samples achieve a high FCSR but suffer a TCSR drop—for example, from 0.872 to 0.824 in Gemma-3 and from 0.783 to 0.746 in Qwen2.5—demonstrating Format Inertia. Furthermore, increasing the volume of skewed data to 8,000 samples can exacerbate this degradation, leading to an even lower TCSR.

In contrast, fine-tuning on the Uniform turn-count dataset with 1,000 samples effectively mitigates this trade-off. Specifically, uniform sampling recovers TCSR to 0.891 while slightly improving FCSR to 0.967 for Gemma-3, enabling the model to generate responses that are both formally correct and clinically meaningful. This finding underscores that for medical pre-consultation tasks, data quality

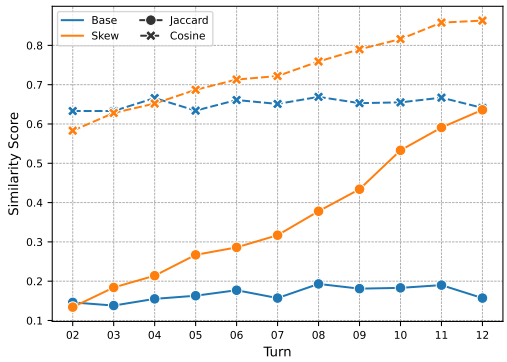

Figure 2: Models trained on skewed turn-count data show a progressive increase in Jaccard and Cosine similarity across dialogue turns, indicating an intensifying pattern of repetitive questioning driven by Format Inertia, in contrast to the base model.

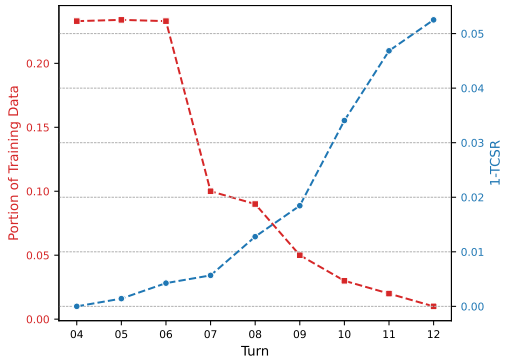

Figure 3: Impact of Skewed turn-count data on TCSR. Inverse relationship between the frequency of turns in the Skewed Turn training data (left y-axis) and the Task-Constraint failure rate (1-TCSR) in evaluation (right y-axis), highlighting performance degradation on under-represented long turns.

and distributional balance are paramount over sheer quantity, as the model trained on 1,000 uniform samples significantly outperforms the one trained on 8,000 skewed samples.

4.3 Analysis

Our analysis identifies the root cause of performance degradation as *Format Inertia*. This phenomenon describes the model's tendency to follow familiar, repetitive questioning patterns when faced with the uncertainty of long medical dialogue contexts, which are under-represented in skewed training data. In such cases, the model successfully maintains surface-level format constraints but neglects the more cognitively demanding task of generating novel, contextually relevant questions.

We quantify this failure mechanism by analyzing question similarity throughout the dialogue. To probe this, we measure both lexical and semantic similarity of model-generated questions during medical pre-consultation. Specifically, we use Jaccard Similarity for lexical comparison and Cosine Similarity for semantic similarity, computing each question's maximum similarity against all preceding ones. As illustrated in Figure 2, models trained on skewed turn-count data show a progressive increase in both metrics, confirming that they produce increasingly redundant questions in both form and meaning. In contrast, the base model without fine-tuning shows no such trend. This behavior strongly indicates that *Format Inertia* is a direct consequence of the training data's skewed dialogue structure, causing the model to repeat surface-level patterns that are grammatically sound but semantically unproductive. Figure 3 demonstrates a clear inverse relationship: a given turn length's rarity in the training data correlates with a higher task-constraint failure rate (1-TCSR) during evaluation. This confirms that Format Inertia is a direct consequence of the model's limited exposure to long medical dialogues, forcing it to fall back on formally correct but functionally redundant patterns.

Model	Size	Type	FCSR	TCSR
Gemma-3	4B	base	0.361	0.872
		skew	0.960	0.824
		uniform	**0.967**	**0.891**
	12B	base	0.577	0.880
		skew	0.972	0.843
		uniform	**0.976**	**0.896**
	27B	base	0.863	0.884
		skew	0.963	0.853
		uniform	**0.964**	**0.901**

Table 3: Performance variation by model size, illustrating the impact of Uniform Turn-Count Dataset on the Gemma-3 model across its different scales.

The issue is particularly critical for efficiency-oriented models commonly used in real-world deployments. As shown in Table 3, although the benefits of a uniform turn-count distribution are observed across all model sizes, TCSR consistently declines when models are trained on skewed data but recovers under the uniform setting. These results confirm that Format Inertia is a persistent challenge regardless of scale, underscoring the importance of addressing it to ensure the reliability and practicality of conversational AI systems.

5 Conclusion

In this study, we identify Format Inertia as a failure mechanism in LLM-based medical pre-consultation, caused by skewed turn-count distribution in the training data. Limited exposure to long dialogues leads models to tend to familiar question patterns, resulting in repetitive, low-utility outputs that meet format requirements but fail to elicit new diagnostic information. To address this, we construct a Uniform Turn-Count Dataset, which rebalances turn distribution. Our experiments show this approach effectively mitigates Format Inertia in long medical dialogues. These findings underscore the critical role of data distribution, especially the turn-count distribution, in multi-turn robustness.

Limitations

Our study has several limitations that also point to directions for future work. First, our experiments are concentrated on the specific domain of medical pre-consultation. A valuable direction for future research would be to investigate whether the *Format Inertia* phenomenon we identified generalizes to other conversational domains, such as legal counseling or technical support, which would broaden the implications of our findings. Second, our evaluation of question quality relied on an LLM-as-a-Judge approach. While this method ensures consistency, it may not fully capture the nuanced judgments of human medical experts. Future work could strengthen the validity of our evaluation framework by systematically analyzing the correlation between LLM-based assessments and human expert judgments. Finally, while we identify the skewed turn-count distribution as a key driver of Format Inertia, other factors—such as the diversity of dialogue scenarios or specific model architectures—could also contribute to this phenomenon. Exploring these additional factors represents an important avenue for developing a more comprehensive understanding of this failure mode.

Ethics Statement

This study was conducted with a strong commitment to ethical principles. The dataset used for training and evaluation was sourced from a controlled patient simulation platform, where medical professionals generated dialogue data. Crucially, this process did not involve any real patient data, thereby avoiding risks related to patient privacy and data confidentiality. All data was carefully processed to ensure no personally identifiable information was included. We emphasize that the models developed in this research are intended as assistive tools for pre-consultation and are not a substitute for professional medical diagnosis or advice. Any real-world deployment of such technology would require rigorous safety testing, regulatory approval, and a human-in-the-loop system to ensure patient safety and well-being.

A Dataset Details

Data Source and Scale Our real-world dataset was collected from a medical pre-consultation platform, where 40 licensed doctors conducted pre-consultations with patient models (see Figure 4). In total, we collected 8,000 dialogues.

Real-World Distribution The dataset naturally exhibits a heavily skewed turn-count distribution, where most dialogues are short (see Table 4). This inherent imbalance motivated our investigation into how turn-count distribution affects model behavior, especially in long medical dialogues.

Skewed Turn-Count Dataset To reflect the real-world data distribution, we constructed a Skewed Turn-Count Dataset by sampling 1,000 dialogues probabilistically from a pool of 8,000, preserving the original skewed turn-count distribution.

Uniform Turn-Count Dataset To address the Format Inertia phenomenon caused by the skewed turn-count distribution, we constructed a Uniform Turn-Count Dataset that equalizes the representation of dialogues across different lengths. The dataset creation procedure is outlined below:

1. **Turn-Based Binning:** We first divided all 8,000 dialogues from the original dataset into 12 bins according to their maximum turn-count (from 1 to 12).

2. **Quota Determination:** To ensure uniformity, we used the bin with the smallest number of dialogues as the reference for sampling. As shown in Table 4, the bin for 12-turn dialogues contains only 111 examples, which we set as the sampling quota.

3. **Uniform Sampling:** We then randomly sampled 111 dialogues without replacement from each of the nine bins, ranging from 4 to 12 turns (excluding bins with fewer than 4 turns, which contained no dialogues).

4. **Dataset Assembly:** The sampled dialogues were merged to form the final Uniform Turn-Count Dataset, consisting of 999 dialogues (111 dialogues $\times$ 9 bins), i.e., almost 1,000 in total. This construction ensures that the model is trained on a balanced distribution of short and long multi-turn interactions.

Turn	Count
1	0
2	0
3	0
4	1835
5	1890
6	1825
7	820
8	705
9	395
10	260
11	165
12	111

Table 4: Real-World Turn-Count Distribution in Medical Pre-Consultation.

B Training Details

Models We employed a set of Large Language Models (LLMs) as doctor models in our experiments. Specifically, we used the instruction-tuned versions of the following models: google/gemma-3-4b-it, google/gemma-3-12b-it, google/gemma-3-27b-it, and Qwen/Qwen2.5-3B-Instruct.

Fine-Tuning Procedure Supervised Fine-Tuning (SFT) was performed using the training datasets described in Appendix A. We utilized the Unsloth framework[3] to streamline the fine-tuning process.

Hyperparameters We fine-tuned the models with the following hyperparameter configuration: a learning rate of 1×10^{-4}, batch size of 32, and 3 training epochs. We used QLoRA (Dettmers et al., 2023) with a rank of 32, lora alpha = 64, lora dropout = 0.1, a cosine learning rate scheduler, and a weight decay of 0.005.

Hardware Environment All fine-tuning experiments were conducted on NVIDIA A100 GPUs, each equipped with 80GB of memory.

C Patient Information Provided to Models

During evaluation, different sets of patient information were provided to the doctor and patient models to simulate realistic consultation dynamics.

Doctor Model Input As illustrated in Table 5, the doctor model received a concise summary of the patient's profile. This summary includes essential information such as age, gender, chief complaint,

[3] https://github.com/unslothai/unsloth

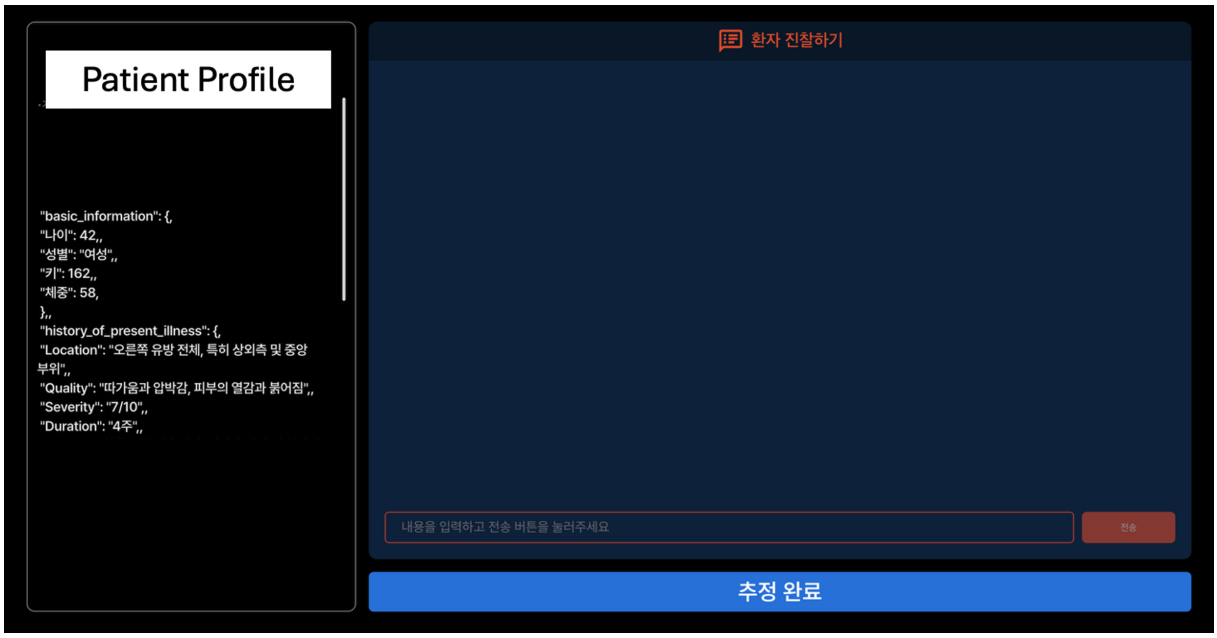

Figure 4: Interface of the medical pre-consultation platform where doctor and patient models engage in interactive pre-consultation dialogues.

and a brief description of symptoms. This limited view encourages the doctor model to ask clarifying questions to gather more detailed clinical information.

Patient Model Input Table 6 shows the full patient context that was provided to the patient model. This includes comprehensive clinical data such as detailed symptom descriptions, medical history, and other contextual information. The patient model responds to the doctor's questions based on this full input, ensuring informative and contextually accurate answers.

This asymmetric information setup mimics real-world patient-doctor interactions and helps evaluate the models' ability to engage in effective diagnostic dialogue.

D System Prompts

D.1 Doctor System Prompt

The following prompt was used for the doctor model to generate medically relevant follow-up questions:

Doctor System Prompt

```
You are a physician with professional medical knowledge. Your task is to generate the optimal follow-up question that helps with differential diagnosis based on the given patient information and previous consultation history.

### Instructions
1. You must use only Korean.
2. Generate only questions that effectively collect medically useful information required for diagnosis.
3. Provide 2 to 5 options.
4. Do not include "Other" as an option.
5. Output in YAML format.
6. The question must end with "요?" (appropriate polite phrase in Korean).

### Output format
Question:
Options:
...
```

D.2 Patient System Prompt

The patient model received the following prompt along with specific patient profile information:

Patient System Prompt

```
You are a patient with the following profile:
{patient_information}
```

```
You should faithfully answer the doctor's inquiries for an appropriate diagnosis. Choose one of the questions provided by the doctor and respond.

Output format:
Answer:
```

E Evaluation Details

Judge LLM We employed GPT-4.1-mini [4] as the evaluation judge. The model was prompted with a rubric to assess each turn based on format and task satisfaction. We selected this model based on its strong performance on Korean medical QA benchmarks, particularly KorMedMCQA (Kweon et al., 2024), which served as a key reference for evaluating its judgment capabilities. The evaluation prompt used for the judge model is shown in Figure 5.

F Constraint Examples

The examples provided are based on actual data used in our evaluation or similar scenarios.

Format Constraint Examples Figures 6–10 illustrate how a model's response can satisfy or violate each format constraint. Each figure shows a side-by-side comparison within a hypothetical dialogue turn where the model acts as a doctor.

Task Constraint Examples Figure 11 provides an example for the clinical_utility constraint. It shows whether the model's (doctor's) question effectively elicits new information necessary for patient diagnosis.

G Real-world Case Study

Beyond our controlled experimental setting, we applied this model to VDoc[5], a medical preconsultation service deployed in South Korea, where we directly observed Format Inertia in real-world production settings. In one notable case, a patient consultation extended to 15 turns due to complex symptoms. After turn 8, the model began repeating variations of previously asked questions about symptom onset and pain location, despite having already received comprehensive answers. This real-world instance confirmed that Format Inertia is not merely an experimental artifact but a critical production issue that impacts user experience and diagnostic efficiency.

H Distinction Between Format Inertia and Context Rot

While Format Inertia may appear related to the concept of "Context Rot"—a general performance degradation over long contexts—we argue that Format Inertia represents a more specific and actionable failure mode:

- **A Specious Failure Mode:** Context Rot describes broad degradation across all metrics. In contrast, Format Inertia identifies a deceptive scenario where models maintain high Format-Constraint Satisfaction Rate (FCSR) while experiencing sharp drops in Task-Constraint Satisfaction Rate (TCSR). The model appears functional but fails at its core diagnostic purpose.
- **Specific Pattern Recognition:** Format Inertia manifests as repetitive questioning patterns that are formally correct but diagnostically useless. This specific behavioral pattern makes it identifiable and addressable through targeted interventions like our uniform sampling approach.
- **Production Impact:** Unlike general context degradation, Format Inertia creates a particularly problematic user experience where patients receive seemingly valid but redundant questions, leading to frustration and abandonment of the consultation process.

Age	45
Gender	Male
Chief Complaint	Persistent cough and unintended weight loss
Symptom Duration	Within 3 months
Symptom Location	Right pectoral region and sternal area

Table 5: Example of information provided to the doctor model during evaluation, representing a simplified summary of the patient's profile.

Disease	Pulmonary tuberculosis
Department	Undetermined
Typicality	Typical
Age	45
Gender	Male
Height	172 cm
Weight	68 kg
Symptom Location	Central chest and occipital region
Symptom Quality	Intermittent dry cough and chest tightness
Symptom Severity	5/10
Symptom Duration	2 months
Timing	Severe coughing in the morning, intermittent during day
Context	Worsened after outdoor work and fatigue
Modifying Factors	Warm tea and rest help; worsens with activity
Associated Symptoms	Weight loss, night sweats, low-grade fever, mild dyspnea
Pain Area	Right chest (pectoral), Sternal region
Past History	No prior TB or chronic respiratory illness
Social History	Construction worker, past smoker, high-density living
Additional Info	Dust exposure, smoking history, persistent fatigue

Table 6: Example of information accessible to the patient model during evaluation, including comprehensive clinical and contextual details.

[System]
Please act as an impartial judge and evaluate the quality of the response provided by an AI assistant acting as a doctor in a medical pre-consultation scenario. Your evaluation should consider the criterion defined below.

Evaluation Criterion:
Effective Elicitation of New Information for Diagnosis: Evaluate whether the generated question effectively elicits new information necessary for patient diagnosis. Your answer must be either True or False.
Begin your evaluation by providing a short explanation for your decision. Be as objective as possible. After providing your explanation, please state your decision as either True or False. Strictly follow this format: "[[True]]" or "[[False]]".

Here is the conversation history:
{conversation_history}

Here is the question and options generated by the assistant:
Question: {question}
Options: {options}

Figure 5: The Evaluation Prompt.

Constraint: `response_format` – Whether the model's response adheres to the specified output format.

Satisfying Example

```
question: "Where is the pain located?"
options:
  - "Entire head"
  - "Forehead"
  - "Back of the neck"
  - "Temples"
```

Explanation: The response correctly follows the YAML structure.

Violating Example

```
Where is the pain? The options are 1. Entire head,
2. Forehead, 3. Back of the neck, 4. Temples.
```

Explanation: The response does not follow the specified YAML format and consists only of plain text.

Figure 6: Examples for the `response_format` constraint.

Constraint: `response_language` – Whether the model's response is composed exclusively in the specified language (e.g., English).

Satisfying Example

```
question: "When did the symptoms start?"
options:
  - "Today"
  - "Yesterday"
  - "A few days ago"
  - "More than a week ago"
```

Explanation: All content in the response is written in English.

Violating Example

```
question: "Quand les symptômes ont-ils commencé ?"
options:
  - "Aujourd'hui"
  - "Hier"
```

Explanation: The response is written in French, violating the English-only requirement.

Figure 7: Examples for the `response_language` constraint.

Constraint: `forbidden_words` – Whether the response uses any forbidden words specified by the service (e.g., a forbidden word: `"Other"`).

Satisfying Example

```
question: "What type of painkiller did you take?"
options:
  - "Ibuprofen"
  - "Acetaminophen"
  - "Aspirin"
  - "None"
```

Explanation: The model avoids the forbidden word "Other" by listing only specific options.

Violating Example

```
question: "What type of painkiller did you take?"
options:
  - "Ibuprofen"
  - "Acetaminophen"
  - "Other"
  - "None"
```

Explanation: The model includes the forbidden word "Other" in the options, violating the constraint.

Figure 8: Examples for the `forbidden_words` constraint where "Other" is a forbidden term.

Constraint: `number_options` – Whether the number of options provided with the question is correct (e.g., a rule: must be between 2 and 5 options).

Satisfying Example

```
question: "What is the nature of the pain?"
options:
  - "Throbbing"
  - "Stabbing"
  - "Squeezing"
```

Explanation: It provides 3 options, which adhere to the rule.

Violating Example

```
question: "Where is the pain located?"
options:
  - "Forehead"
  - "Temples"
  - "Back of the head"
  - "Neck"
  - "Jaw"
  - "Behind the eyes"
  - "Left side"
  - "Right side"
```

Explanation: It provides 8 options, exceeding the maximum allowed number.

Figure 9: Examples for the `number_options` constraint.

Constraint: `sentence_startend` – Whether the question ends with the appropriate polite phrase (e.g., must end with "요?").

Satisfying Example

```
question: "통증이 가장 심한 시간대가 언제인가요?"
options:
  - "아침"
  - "오후"
  - "밤"
  - "특정 시간 없음"
```

Explanation: The question ends with a polite expression ("요?"), conforming to the expected sentence structure.

Violating Example

```
question: "통증이 가장 심한 시간대?"
options:
  - "아침"
  - "오후"
  - "밤"
  - "없음"
```

Explanation: The question ends with a fragment, not a polite sentence ending with "요?", violating the constraint.

Figure 10: Examples for the `sentence_startend` constraint requiring questions to end with "요?".

Constraint: `clinical_utility` – Whether the generated question effectively elicits new information required for patient diagnosis.

Satisfying Example: (Dialogue Turn 5) Previous conversation summary: The patient has mentioned having a headache, located in the forehead, which started a few days ago.

```
question: "Were there any specific activities or
  changes (e.g., stress, lack of sleep, dietary
  changes) before the headache occurred?"
options:
  - "Yes, there were"
  - "No, there were not"
```

Explanation: This is a question that explores new information about the background of the patient's symptoms, attempting to obtain crucial information for diagnosis. It asks about a new aspect not covered in the previous conversation.

Violating Example (Format Inertia Case): (Dialogue Turn 10) Previous conversation summary: The patient has already provided a lot of information, including the headache, its location, onset, nature of the pain, and accompanying symptoms (no nausea, sensitivity to light/sound). The model had also asked "When did you start feeling sick?" in turn 4.

```
question: "When did the symptoms start?"
options:
  - "Today"
  - "Yesterday"
  - "A few days ago"
  - "More than a week ago"
```

Explanation: The model is asking a question that has already been answered or can be inferred from a previous turn. Although it is formally a question, it is an unproductive one that fails to elicit any new diagnostic information.

Figure 11: Example for the `clinical_utility` constraint.

Extraction of Information Provision Activity Requirements from EU Acquis

Jakub Piskorski
Publications Office
of the European Union

Dominik Skotarczak
Publications Office
of the European Union
Dominik.Skotarczak@ec.europa.eu

Abstract

We report on experiments in information extraction (IE) from *EU acquis*, the European Union law. We introduce a new IE task of *Information Provision Activity Requirement Extraction*. This task comprises the identification of text fragments that introduce an obligation to provide information, and the extraction of structured information about the key entities involved along with the temporal modalities. We compare various technologies for this task, i.e. knowledge-, classical ML-, transformer-, and generative AI-based approaches, on a new benchmark corpus.

1 Introduction

We observe a growing interest of legal professionals, governments, and international organizations in exploiting NLP-enabled tools to facilitate the analysis and extraction of structured information from legal texts. Although this interest is reflected in the work of the research community (Ariai and Demartini, 2024), it has focused mainly on case law. It has barely covered higher-level Information Extraction (IE) tasks, such as relation extraction and template filling (Piskorski and Yangarber, 2013).

In this paper, we report on experiments that revolve around the extraction of structured information from *European Union acquis* (*EU acquis*), i.e., the collection of common rights and obligations that constitute the body of EU law[1] that are incorporated into the legal systems of EU Member States. We introduce a new IE task of *Information Provision Activity Requirement Extraction* that comprises (1) the identification of text fragments that introduce an obligation or a possibility of information provision activities in *EU acquis* legislation and (2) the extraction of structured information therefrom, including providing entities, target entities, respective deadlines, and frequencies of such provisions. Conceptually, extraction of information provision activities includes (but is not limited to) reporting, certification, notification and authorization obligations, data retention, monitoring, record keeping, compliance confirmations, etc. Accomplishing the IE task at hand is needed for rationalisation and simplification of various information provision requirements for companies and administrations, as outlined in the Communication of the European Commission on the long-term competitiveness of the EU (Commission, 2023).

All EU legal acts within the *EU acquis* are digitally stored and published via *Cellar*[2] in a machine-readable format and are accompanied with metadata. This allows for querying *EU acquis* documents using various criteria[3], e.g., time period, type of the legislation document, business identifiers, mentions of specific EU corporate bodies and other organizations, topics covered using *Eurovoc* taxonomy[4], etc. That said, as of today, there is no metadata that would allow to extract structured information on *information provision activity requirements* from *EU acquis* in a straightforward manner. In particular, the existing *Cellar* metadata used to index *EU acquis* documents does not contain any positional information for related text fragments (e.g., with evidence of a mention or supporting context). Hence, the usability thereof for the IE task at hand is of limited use. Once a solution for the IE task at hand is developed, it could be used to create additional metadata to embrace information provision activities.

The main drive behind our work is the need to explore practical solutions for this real-world IE task. Knowledge- and classical ML-based approaches in industrial settings have been proven to have advan-

tages in terms of time efficiency, fast development cycle and high level of explainability (Dahlmeier, 2017). In contrast, generative AI may offer improved quality and easier implementation. This raises the question of which technology is the most appropriate to deploy for IE in the legal domain.

Most of the prior work in NLP in the legal domain focused on case law, but there is little research reported for legislation such as *EU acquis* (mainly covering text classification), and it is non-existent as regards IE. Thus, our contribution can be summarized as follows, (1) we introduce a **new task** on the extraction of structured information on information provision activity requirements from legal texts, (2) we release a **benchmark corpus** for this task, focusing on *EU acquis*, and (3) we report on **comparative evaluation** of knowledge-, ML-, and generative AI-based approaches for this task.

2 Related Work

The rapid growth of applications of NLP techniques in the legal domain has been reflected in various workshops. For example, NLLP (Preoțiuc-Pietro et al., 2023; Aletras et al., 2024) and MLLD (Makrehchi et al., 2023). Solihin et al. (2021) presented a survey on the advancements in IE for the legal domain.

Most prominent work in IE for the legal domain focused on Named Entity Recognition (NER), covering predominantly the subdomain of case law, contracts, and partially national legislation. Various NER approaches have been reported, including hand-crafted rules (Glaser et al., 2018), classical ML (Chalkidis et al., 2017), transformer-based approaches (Cabrera-Diego and Gheewala, 2023). The *SemEval 2023* campaign included *LegalEval2023*, a shared task on NER for the legal domain (Modi et al., 2023).

In contrast, work on legal Relation Extraction (RE) is less represented. Andrew (2018) explored rule/ML-based approaches for RE from legal documents on investments in Luxemburg. Kwak et al. (2023) presented a dataset for RE from legal wills and explored the performance of GPT 4o. Thimm and Schneider (2022) reported on a rule-based NLP pipeline for RE from environmental law. Kurant (2023) explored LSTMs for extracting 'cause-and-effect' in Polish court judgements, whereas Schraagen and Bex (2019) compared LSTMs and SVMs for RE from Dutch police reports.

Pennisi et al. (2023) explored ML approaches for detecting sentences with obligations in legislation texts originating from different countries. Work on detecting obligations in Italian legislation was presented by (Iacono et al., 2022), and Minkova et al. (2023) reported on the classification of *EU acquis* documents into: obligations, permissions, prohibitions, rights, and powers. Although partially similar to ours, those efforts did not cover the IE aspect. Similar IE efforts to ours, for deploying classical and transformer-based ML for extracting information on legal events (i.e., extracting event type, actors involved and the date of the event) from court judgements were reported in (Filtz et al., 2020) and (Navas-Loro and Rodríguez-Doncel, 2022). To our knowledge, we are the first to report on the exploration of IE focusing on information provision activities from *EU acquis* and also exploit LLMs for this purpose.

3 Task Definition

The task of *Information Provision Activity Requirement Extraction* (*IPARE*) focuses on identifying in the text of *EU acquis* text fragments which introduce an obligation or a possibility (based on some prerequisites) of information provision activities and extracting structured key information therefrom. Information provision activity is the process by which a *providing entity* communicates or provides information to a *target entity*. The providing entity is (or may be) obliged to perform an information providing activity, which involves systematic or one-time actions such as reporting, disclosing, notifying, providing, certifying or transferring information. Monitoring and publishing activities imply a transfer of information, hence they are included as well. In the context of information provision activity requirement, we also distinguish between *primary* and *secondary* information, where the former includes information on the key actors involved, information/activity type, and activity-related deadlines and frequencies, whereas the latter encompasses details such as language, format, technicalities related to information process, or other detailed descriptions of the information to be provided going beyond primary information. In *IPARE* task we focus solely on the extraction of primary information, i.e., detecting the text fragments that introduce the information provision activity requirements and contain all or some partial related primary information. Formally, given a text fragment T, we distinguish two subtasks in *IPARE*.

. . . or any evidence considered by the said authorities to be equivalent thereto. 3. ***The competent authorities of the Member States shall notify the Commission before 15 January each year*** *of the total quantities, per category and third country, which are allocated to beneficiaries . . .*

```
PROVIDING ENTITY: competent authorities of the Member States
TARGET ENTITY: the Commission
DEADLINE: 15-01-?
FREQUENCY: annually
```

Figure 1: An example of a text snippet with mention of an information provision activity requirement with key elements to extract highlighted in text: entities (yellow), deadline (green), and frequency (blue), and a corresponding template with extracted information.

Subtask 1 (detection): Determine whether T contains mention of an information provision activity requirement containing some primary information.

Subtask 2 (extraction): If T contains mention of an information provision activity requirement with some primary information extract from T structured information on: (a) *providing entity*, (b) *target entitity(ies)*, (c) any related *deadline(s)*, and (d) *frequency* of provision of information.

Subtask 1 is a binary classification task, whereas Subtask 2 is a template filling task. An example of a text snippet with mention of an information provision activity and a corresponding template with extracted information is provided in Figure 1. Noteworthy, the values of the *deadline* and *frequency* slots are to be normalized (whenever possible) as part of the extraction process (see A.4 for details). Mentions of events resulting/triggered by information provision activity requirements (that on their end do not cover transfer of data), and requirements not to disclose information are not in the scope of IPARE. Annotation guidelines and additional examples are provided in Annex A.4 and A.5 resp.

4 Dataset

We have created a new benchmark datasaset since we were not aware of any resource with *IPARE*-like annotations. We have chunked the entire set of ca. 110K *EU acquis* documents into short text fragments (mainly sentences). Based on some empirical observations that information provision activity requirements are expressed in *EU acquis* through the use of specific verbs and corresponding nominalizations (e.g., '*report*', '*submit*', '*notify*', etc., see A.1 for full list) we have randomly sampled: (a) 500 sentences which contain any of the predetermined keywords or their morphological variants or derived words (e.g., '*notification*'), and (b) 500 sentences which apart from the keywords, also contain at least one temporal expression, including dates, deadlines and frequencies. Noteworthy, no two sentences are part of the same *EU acquis* document. After ignoring excessively long texts the final pool of sentences consists of 973 instances.

In order to make our dataset as representative as possible we have exploited a sample of the dataset presented in (Daudaravicius and Friis-Christensen, 2024) (referred to with JRC-RO), which contains *EU acquis* documents being in force and include mentions of reporting obligations, thus being in the scope of *IPARE*. In particular, all sentences that include information related to reporting obligations are annotated in JRC-RO separately, and no distinction is made whether they contain primary or secondary information (using the nomenclature of the *IPARE* task). We have extracted approx. 12K sentences from JRC-RO corpus **which do not contain any keywords from the set specified in A.1**. We further inspected a random sample of ca. 500 sentences therefrom and found that only about 1% of them fall under information provision activity requirements, which, to some extent, confirmed our assumption of relatively low lexical variability in terms of key terms being used when referring to information provision activity requirements. Finally, 239 additional sentences from JRC-RO were added to our corpus. Each of the text fragments were then annotated by two annotators with a boolean label indicating the inclusion in the information provision activity requirement class, and they filled in the 4 slots for *providing entity*, *target entity*, *deadline* and *frequency*, using the annotation guidelines in A.4. Having accounted for the types of disagreements in labeling, we found *Cohen's* κ to be 0.81.

The resulting dataset, intended to represent the *IPARE* task within the *EU-Acuqis*-like legislation, not the *EU acquis* itself, consists of 1212 text snippets (mainly single sentences with an average length of 262 characters), out of which ca. 55% (662) are instances of information provision activities. The fraction of these positive instances which contain providing entities, target entities, deadlines and frequencies amounts to 91.8%, 86.9%, 67.2% and 57.7% resp. We have observed relatively low degree of lexical diversity of slot fillers for all 4 slots, about which we report in detail in A.3. Thus, we reason that experiments on a dataset of this size (although suboptimal) might still provide meaningful insights on IE from *EU acquis*. Further details related to the creation of the dataset, annotation

guidelines and statistics, are provided in Annex A.

5 Models

5.1 Subtask 1: detection

We divided the benchmark corpus into 5 folds. All models were trained/fine-tuned/instructed using 80% of the benchmark and evaluated on the remaining 20%, for each of the 5 folds. We have compared the following approaches:

BASELINE-K: considers a piece of text as a information provision activity if one of the keywords used to create the dataset appears in the text.

BASELINE-KD: extends **BASELINE-K:** by introducing an additional constraint requiring the text to contain also at least one temporal expression[5], e.g., date, duration, period, deadline, frequency.

LR: L2-regularized Logistic Regression with binary 3-8 character n-grams as features[6],

SVM: L2-regularized linear SVM, with binary 3-10 character n-grams as features,

Transformers: including, **XLMRoBERTa** (Conneau et al., 2020), and two models tailored to the legal domain: **Legal-RoBERTa** (Chalkidis et al., 2023) and **EU-BERT**[7]. A classification head was appended to each model, and the original layers had been frozen before fine-tuning for the detection.

LLMs: six models of different size: **LLama-3.2-3B**[8] (Grattafiori et al., 2024), **Mistral-7B** (Jiang et al., 2023), **Mistral-24B**[9], **Mistral-Large (24.02)** (team, 2024), **GPT 4o** (OpenAI et al., 2024) and **Claude-3.5-Sonnet** (Anthropic, 2024). We explored zero- and few-shot (n=10) scenarios. For the latter, we instructed each model with examples sampled at random from the train folds. See Annex B for hyperparameters and detailed prompts.

5.2 Subtask 2: extraction

5.2.1 Knowledge-based Approach

Our knowledge-based (**KB**) approach exploits a certain level of lexical and syntactic repetitiveness exhibited in the *EU acquis*. Based on word n-gram frequency analysis of the entire *EU acquis* consisting of ca. 110K documents (excluding the ca. 1K documents used for the creation of the evaluation dataset), we have created a pool of ca. 2500 labeled lexical resources which cover: trigger phrases for the recognition of information provision activity requirements (e.g., '*shall submit to*'), relevant entities or trigger words for detecting entities (e.g., '*competent authorities of the Member States*'), and keywords for the detection of relevant temporal expressions (e.g., '*annually*'). More detailed statistics on these lexical resources are provided in B.1. Moreover, a 3-level cascade of lexico-syntactic patterns was manually built using *ExPRESS* formalism (Piskorski, 2007). The first two levels thereof contain patterns for the detection of the small-scale structures, e.g., temporal expressions, whereas the third level consists of ca. 45 high-level patterns which fuse the smaller structures together to fill in information provision activity requirement templates. Some examples of such high-level extraction patterns (in a simplified form) are shown in Figure 2. Overall, benefiting from the high degree of "linguistic" repetitiveness in *EU acquis* the size of the underlying linguistic resources sketched above make the knowledge-based approach relatively easy to maintain and extend if needed.

```
(1) DEADLINE? FREQUENCY? PROVIDER <provide-to> TARGET+
(2) PROVIDER <reports-to> TARGET+ DEADLINE? FREQUENCY?
(3) DEADLINE? FREQUENCY? <reported-by> PROVIDER "to" TARGET
(4) PROVIDER <obliged> DEADLINE? FREQUENCY? <provide-to> TARGET
```

Figure 2: Examples of IE patterns, where <provide-to>, <reports-to>, <reported-by> represent different classes of information provision trigger phrases, backed up by lexical resources, and <obliged> covers verb groups triggering an obligation.

Given that sentences in legal texts might be extremely long and complex, we have implemented a version of the **KB** approach (referred to with **KB+**). It allows the extraction patterns to match longer sequences of tokens between the searched elements, in the hope of boosting the recall.

5.2.2 LLM-based Approaches

We presented LLMs with the definition of *IPARE* along with a few examples of correctly extracted information and created few-shot and Chain-of-Thought (CoT) prompts. We used the hyperparameters from subtask 1. All models were tasked to generate a JSON dictionary containing the filled out template. For both prompting techniques, we used additional 13 annotated examples that were

[9] https://huggingface.co/mistralai/Mistral-Small-24B-Instruct-2501

not included in the corpus. The CoT prompts consisted of an additional question for each of the slots to be filled before displaying the final JSON. See Annex B.4.1 for prompt templates.

For **Claude**, we used its function calling ability to enforce the JSON format better and pass more detailed information about the format of each field. The model generated the input for the function calling tool, but no additional function was called. See Annex B.4 for the tool configuration.

Assuming the **KB** was to achieve high precision we have also explored a hybrid approach, ie., first **KB** is applied, and whenever a slot could not be filled, an LLM is triggered to try to fill in the value.

6 Evaluation

Detection: We evaluate this task using *precision*, *recall*, F_1, and *accuracy* metrics. We provide the evaluation results in Table 1.

We observe that even the baseline methods achieve fair results with F_1 oscillating around .80, indicating the complexity of the detection task. Classical ML paradigms obtain surprisingly good results, e.g., **SVM** exploiting character n-gram features obtains .927 F_1 score. The transformer-based models, including the ones tuned to the legal domain did not perform better (best **Legal-RoBERTa** with .90 F_1) than the classical ML approaches, probably due to the small size of the training data. Similar observations were made in the context of related experiments on classification of legal texts in (Lin et al., 2023), were linear classifiers exhibited competitive or in some cases even better performance than more advanced models, which highlights the importance of inclusion of classical ML approaches in comparative evaluations. In the zero-shot scenario, the largest LLM, i.e., **Claude-3.5-Sonnet** obtains the best F_1 score (.92), while the best overall results with LLMs were obtained in the few-shot scenario with the same LLM (.949 F_1). The SD across folds ranged between 0.006 and 0.047 (see Table 3 in Appendix C).

Extraction: We evaluate this task using *precision*, *recall* and F_1, in two modes: (a) **exact:** a system response is considered correct if it exactly corresponds to the ground truth annotation, and (b) **fuzzy:** a system response is considered correct if the string similarity thereof with the ground truth is higher than .75[10], where the string similarity is computed with *Longest Common Substrings* measure (Navarro, 2001)

We provide the evaluation results for the extraction task in Table 1. Given that the expected values for the *deadline* and *frequency* slots are to be normalized, they were only evaluated in terms of exact matching, whereas *providing entity* and *target entity* slots were evaluated in terms of fuzzy matching in order not to penalize the inclusion of 1-2 extra tokens (e.g. articles, etc.) in the response.

Overall, **Claude-Sonnet-3.5** achieved the highest level of performance, i.e., highest F_1 scores on providing and target entities, and deadline slot. The tool functionalities (only available for **Claude**) were effective in defining and enforcing a correct JSON schema. Other LLMs would benefit from a similar JSON tool when prompted to provide a structured output, such as extraction by template filling. Despite no extra tool available, **Mistral-Large** scored nearly as high for the two entities, but it underperformed in the deadline extraction.

Interestingly, the knowledge-based approaches are highly competitive vis-a-vis LLMs, and at times outperform smaller LLMs in terms of F_1, and, not surprisingly, outperform all LLMs in terms of precision for the extraction of all four slots by .003, .009, .05 and .21 points, respectively for *providing entity*, *target entity*, *deadline*, and *frequency*. Both *deadline* and *frequency* slots required additional normalization. In fact, this could be the reason why the **KB** and **KB+** obtained best scores for the frequency slot. Apart from deadline extraction, we observed much lower recall compared to the other approaches, which indicates LLMs the preferred approach for recall maximization, irrespective of the size. Noteworthy, **KB+** improves the recall vis-a-vis **KB** by .014-.025 points.

The performance of the LLMs increased with the size of the model and instruction complexity. The upward size-to-performance trend was most observable with CoT. However, not all LLMs benefited from adding additional questions that targeted the slots. The results for **Llama-3.2-3B** show the most ambiguity about the effectiveness of the CoT prompts. Apart from deadline extraction, applying the CoT prompt actually decreased model performance. We hypothesize this could have been due to the size of the model. Larger models, especially **Claude**, benefited more from CoT prompt, however, only for some slots. The few-shot prompt with the JSON tool helped **Claude** achieve better scores in deadline extraction, while the other LLMs

Table 1: Evaluation results: (a) Detection (LEFT): in terms of precision, recall, F_1 and accuracy, (b) Extraction (RIGHT): per slot type in terms of precision (P), recall (R) and F_1 in *exact matching* for *deadline* and *frequency* slots, and *fuzzy matching* for *providing entity* and *target entity* slots. The best results are provided in bold.

struggled with the extraction thereof due to more complex normalization rules for this slot.

The hybrids consisting of **KB** boosted by an LLM to fill in missing slots did not outperform the best LLM in terms of F_1 apart from the *deadline* slot, however, gain in precision is observable, and the F_1 results were not lagging far behind the resp. LLMs, which make such a hybrid approach attractive in terms of time efficiency.

6.0.1 Error Analysis

Detection: BERT-derived models misclassified between 11.8 and 18.6% of the instances, and approx. 30% of the misclassified instances were shared across the 3 tested models. Most of the false negative instances used either passive voice or nominalizations to express information provision requirements, whereas most false positives were sentences reporting facts or actions triggered by requirements (not in the scope of *IPARE*).

The top-ranking LLMs, i.e., **Claude** and **Mistral Large**, prompted with a few examples produced 68 and 81 incorrect responses, respectively, and shared 43 instances with errors. Most common false negatives featured application, publication, and certification activities, whereas most represented group among false positives constituted instances with complex syntactic structure and ones with entities scattered across the sentences. To alleviate this problem we run some follow-up experiments with an increased number of examples (see Annex C), but it did not boost the performance.

Extraction: **Mistral-Large**, the best LLM in extraction of providing entity, made most errors in this context by extracting too long text fragments, e.g., instead of extracting only the entity an adjacent reference to a regulation was included in the response. Other typical errors were omissions of entities in longer syntactically complex sentences. We also observed some errors (<1%) of not capturing entities from sentences introducing information provision activities using passive voice.

Claude and **Mistral-Large**, the top-ranking models using CoT in extracting target entity, struggled with texts containing multiple target entities, e.g., *'the European Parliament, the Council, and the Commission'*. The models also did not respect the rules for extracting continuous text without breaking it into a sequence of target entities, but this (somewhat) undesired effect was not penalized by the fuzzy evaluation metric.

As for the **KB** approach, the majority of the errors (185) related to providing entity resulted from not detecting such entities from more syntactically-complex sentences. We reasoned that this was due to the difficulty in capturing long-distance dependencies or extracting incomplete entities by this approach. For target entity, the knowledge-based approach made most errors by not detecting an entity (87 sentences). That said, this was less prominent vis-a-vis the omissions of providing entities.

Claude achieved the highest F_1 scores (for LLMs) on frequency extraction with both prompting techniques. Nearly half of the incorrect extrac-

tions (37 out of 78) were expressions referring to *biannual* and *semiannual* frequencies, which the model failed to normalize. **Claude** also assumed periodicity when exposed to text fragments such as *'shall monitor'*, *'shall keep informed'*, etc. In other words, it made associations related to frequency that were actually not present in the text. **Claude** achieved a good balance between high precision and high recall with a slightly better F_1 score with the few-shot prompt. We reason this was likely thanks to the function calling tool.

We infer from the error analysis that LLMs lack a comprehension of the syntax. It hinders them to perform subtask 2 correctly. Meanwhile, the patterns used by **KB** can detect the role of the entities (target/reporting) much more precisely due to the more local nature of these patterns and linguistic awareness encoded in them.

7 Discussion

Detection Classical ML, such as SVMs, may be the preferred solution for subtask 1, despite not achieving the highest performance. The magnitude of the performance gap to the best performing LLM is relatively narrow, but the infrastructural resources required to detect information provision activity requirements by LLMs are incomparably higher, considering in particular the length of the legislation document. SVMs are a computationally lightweight solution that can achieve good results with a moderate amount of annotated data. It strikes a good balance between performance, speed, and resource intensity. There is also room for improvement, given that we report on exploiting relatively primitive type of features, i.e., character n-grams.

Extraction Despite LLMs' superior results (recall, F_1), a hybrid solution that combines knowledge- and LLM-based approaches may be better for deployment, given the time efficiency of **KB**. **KB** may also be a more suitable solution when precision is favored over recall. The results of the error analysis hint at the necessity to use a knowledge-based solution for the extraction of the temporal slots whose expected values have to be normalized, or use of an additional knowledge-based postprocessing component to facilitate normalization of temporal expressions. Whether more sophisticated prompting strategy for LLMs could alleviate the issue of proper normalization of temporal expressions and better understanding of the link between syntactic structure and entity role assignment is yet to be explored.

Based on the work on *IPARE*, our general recipe for a hybrid solution (also for similar IE tasks) would be as follows: (1) build a generic **KB** component to detect key named entities, whose recognition does not require contextual information (e.g., temporal expressions, majority of the organizations/actors), (2) create a set of local lexico-syntactic IE patterns that exploit sure-shot trigger phrases for the specific IE task, (3) develop few-shot prompts for filling the slots in the IE template(s). Then, (1)+(2) would be applied first, and in case of missing or incomplete information (3) would be deployed on demand to complement the extractions. Such a solution might be specifically advantageous in a scenario where time complexity is a critical factor and high amount of textual data needs to be processed. Moreover, the integration of a **KB** component allows for a straightforward extension of extraction of easy-to-capture local phenomena instead of relying on more time-consuming tuning of prompts, not to mention the non-deterministic behavior related with that.

8 Conclusions

We reported on experiments on extracting information from legal acts in the EU law, on information provision activity requirements, which encompasses involved actors and related temporal aspects. We carried out a comparative evaluation of knowledge-, ML-, and generative AI-based approaches for this task on a new benchmark corpus[11]. While our study is not exhaustive, it provides a good approximation of the capabilities of the different technologies and their suitability for deployment in an industrial setting. We believe the findings reported in this paper will constitute useful knowledge for NLP practitioners working on analytical applications for the legal domain.

In future we intend to: (a) extend the benchmark corpus, (b) explore inclusion of broader context in which the sentences appear to boost extraction performance, (c) use LLMs as a "judge" for a more nuanced assessment of semantic similarity in fuzzy evaluation, (d) extend the IE task to document level, (e) explore other family of ML models, and (f) extend the task to the extraction of additional aspects, e.g., information type, modalities.

Ethics Policy

Intended Use and Misuse Potential The benchmark dataset created in the context of the presented work was specifically designed to advance research on automated information extraction from legal texts. However, it should not be seen as representative in terms of any kind of information provision obligation, specific organization or geopolitical entity, nor should it be seen as perfectly balanced in any particular way. Therefore, we advise responsible use thereof.

Environmental Impact The deployment of LLMs might have a large carbon footprint, especially when training new models. We have exploited LLMs in our experiments, however, we did not train them, but only used existing trained models, which has a relatively low impact in terms of computing.

Fairness The creation of the benchmark dataset for our study involved annotation of documents, which was done by the staff of the institution of the authors of this manuscript. They were fairly remunerated as part of their job.

Limitations

Dataset Representativeness The selection of the documents and text snippets for the creation of the benchmark dataset exploited in our study was done solely using *EU acquis*, the EU legislation. Hence it might be considered as representative for this specific subdomain of legal texts only. It is of paramount importance to emphasize though that this dataset should not be considered as representative in terms of any type of information provision obligation, specific organization or geopolitical entity, nor should it be seen as perfectly balanced in any particular way.

While the size of the dataset is small, we have observed and report on low lexical and syntactic variability of the texts in the *EU acquis*, and, consequently, we reason that carrying out experiments on a dataset of this size (although suboptimal) and characteristics still provides meaningful insights on IE from *EU acquis*.

Biases Although a very detailed annotation guidelines were used for the sake of creating the benchmark corpus and multiple rounds of curating the annotations were carried out we are aware that some degree of intrinsic subjectivity might be present in this dataset.

Models While our study covers a wide range of approaches for the task at hand, namely, knowledge-, classical and transformer machine learning-, and generative AI-based approaches it should not be considered as exhaustive, but rather as an approximation. We did not explore certain models for the extraction task due to the fact that the size of required annotated data might have been prohibitive. For instance, classical and transformer machine learning-based models are known to obtain superior performance in IE tasks in a fully supervised (full-shot) scenario (Keraghel et al., 2024; Wang et al., 2025) with training data of appropriate size. Furthermore, the error analysis is only provided for a subset of all models explored for the detection and extraction tasks.

Knowledge-based approach scalability While the results of the experiments presented in this manuscript revealed that KB approach for *IPARE* is a viable, competitive and even recommended option in a hybrid set-up, one can only speculate about the utility of such an approach for tackling more sophisticated IE tasks, i.e., inclusion of other types of slots to be extracted (e.g., modalities of information provision, type of information to be provided, subject matter, other domain-specific details, etc.), and whose extraction might require a more sophistication. However, we do believe that a KB approach to detect key entities, e.g., main actors (organizations) and temporal expressions could constitute a generic IE component that could serve to build solutions for any IE task for the *EU acquis* domain.

A Dataset Creation

This section provides some more details related to the creation of the dataset, including: keywords used to collect documents, annotation guidelines, examples, and some corpus statistics.

A.1 Keywords

For selecting candidate text fragments for the inclusion in the evaluation dataset we have used the following keywords/keyphrases and their respective morphological variants and derived forms: *report, transmit, provide, communicate, notify, passed on, inform, share information, share data, submit, publish, send, update, keep a register, monitor, present, send copy, forward, grant access, make available, collect information, collect data*.

A.2 Annotation

Two annotators were tasked to annotate each of the instances with a boolean label indicating the inclusion in the information provision activity requirement class, and they filled in the 4 slots for providing entity, target entity, deadline and frequency, using the annotation guidelines provided in A.4. The annotators had prior experience in annotating

textual corpora. In total for approx. 10% of instances there were some disagreements in labeling, which were resolved through some discussions.

A.3 Dataset Characteristics

The final dataset consists of 1212 items, out of which ca. 55% (662) are instances of information provision activity requirements. The fraction of these positive instances which contain providing entities, target entities, deadlines and frequencies amounts to 91.8%, 86.9%, 67.2% and 57.7% resp. Ca. 43.2% of all items contain both a keyword and either an explicit deadline or frequency mention. Analogously, this figure for the positive instances only amounts to 79%. Approx. 19.6% of all instances do not contain any of the predetermined keywords. The average length of the text is 262 characters.

Figure 3 shows that most sentences in *IPARE* are shorter than 500 characters. The average sentence length in the *IPARE* benchmark is 262 characters (or approx. 42 words). The longest sentence has 5252 characters and has been excluded from Figure 3.

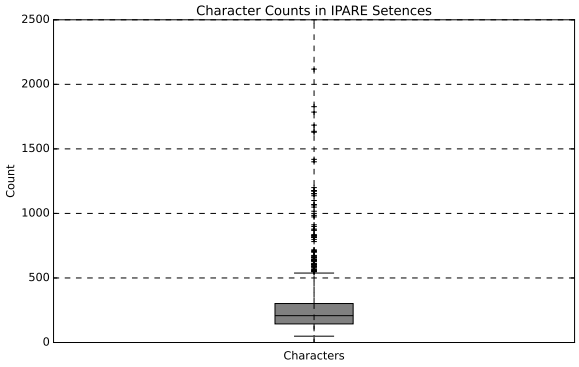

Figure 3: **IPARE Sentence Length (in characters)**

Figures 4, 5, 6, and 7 report on the cumulative number of occurrences of providing entity, target entity, frequency, and deadline mentions in the *IPARE* benchmark. Over 80% of providing entities are mentioned only once, and over 95% are mentioned at most 5 times. After accounting for small variations in mentions of those entities, at least 172 (out of 662) reporting entities are *'Member States'*. The *'Commission'* is required to provide information in at least 102 out of 662 sentences in the *IPARE* benchmark. As for the target entity, the cumulative histogram in 5 shows that over 90% of target entities are only mentioned once, and around 97% of them are mentioned at most 10 times. In fact, the *'Commission'* is the recipient of information in at least 283 out of 662 sentences in the *IPARE* benchmark. The *'European Parliament'* and *'the Council'* are also often mentioned together as the recipients of information.

As regards frequency, the top 5 (out of 15) most frequent expressions account for approx. 88% of the instances. The requirement for annual provision of information alone accounts for 274 out of the 382 (or 71%) positive instances.

Mentions of deadlines are the most diverse with 80% of deadlines being mentioned only once in the *IPARE* benchmark. Relative deadlines, such as *31-01-?*, *30-06-?*, *within 3 months*, occur most frequently. Among them, the most frequent deadline (*31-01-?*) is mentioned only 23 times.

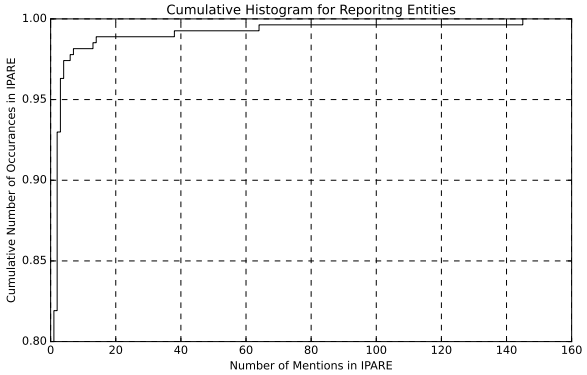

Figure 4: **Cumulative Distribution of Reporting Entity Mentions in *IPARE***

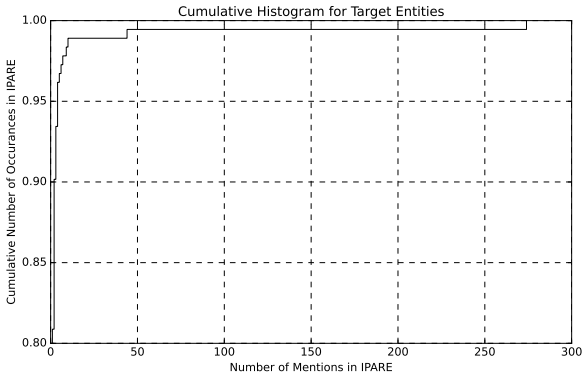

Figure 5: **Cumulative Distribution of Target Entity Mentions in *IPARE***

A.4 Annotation Guidelines

The annotation of the textual data consists of: (a) deciding whether a given text fragment embraces a mention of reporting requirements, and if affirmative, (b) filling in the four slots related to *primary*

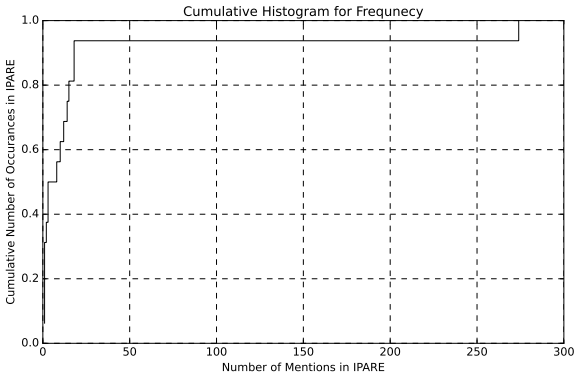

Figure 6: **Cumulative Distribution of Frequency Mentions in *IPARE***

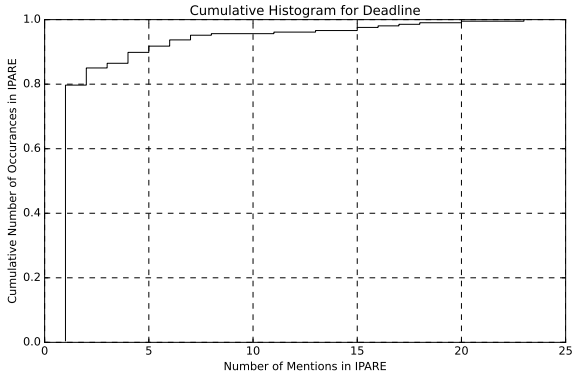

Figure 7: **Cumulative Distribution of Deadline Mentions in *IPARE***

information: *reporting entity*, *target entity*, *deadline*, and *frequency* using the following rules:

- **General Rules:**
  - for filling in the slots (unless specified differently for specific slots below) one should exclusively use the strings found in the text fragments,
  - if specific type of information is not included in the text fragment a hyphen should be used to indicate this fact in the respective slot,
  - in case of any doubts whether the information contained in the text fragment should be used as a slot filler or not a *conservative approach* should be applied, i.e., no annotation is to be made in case of uncertainty,
- **Entities**
  - in case the strings that are related to filling in a given slot (for related entities) do not constitute a consecutive sequence of characters (e.g., more than one mention of relevant entities that are spread over the text fragment), one should simply cut and paste the relevant strings and delimit them by a semicolon, e.g., from the text fragment '*The operator or aircraft operator*' the entity slot should be filled in with '*The operator; aircraft operator*' as a value,
  - both named (e.g., '*European Commission*') and nominal mentions (e.g., '*competent fiscal authorities*') of entities are considered as candidate slot fillers,
  - the articles, whether definite or indefinite, constitute part of the string to be used as a slot filler for entities (e.g. *The European Commission*),
  - in case pronominal references to entities (e.g., '*they*') are used, and there is no corresponding named mention of such an entity, then the pronominal mention should be used as a slot filler,
  - one should annotate 'minimal' mentions of entities and disregard any relative clauses that provide further details of the entities, e.g., in the text fragment '*The custom authorities, which were tasked with carrying out the exercise ....*' only

'*The custom authorities*' should be considered for filling in the entity-related slot.

- **Dates**
  - in case of precise date references only the date information in a canonical form `DD-MM-YYYY` format should be provided, e.g., for *1 June 2023* the corresponding slot value should be 01-06-2022+ (in case of incomplete date references, i.e., with missing day/month/year a "?" should be used accordingly, e.g. *June 2023* corresponds to ?-06-2023)
  - phrases triggering deadlines that precede or follow concrete dates are not to be annotated, e.g. *not later than*, *before*, etc.,
  - analogously, for deadlines using a duration a canonical form should be used as well using the following format `DD-MM-YYYY:DD-MM-YYYY` format, e.g., for the text fragment '*from 1 to 10 January 2023*' the corresponding slot filler would be 01-01-2023:10-01-2023,
  - in case of strictly relative (e.g., '*next year*' or imprecise temporal expression (e.g., '*without any delay*', etc.) used in the text, the surface form in the text constitutes the respective slot value,
  - references to specific hours are not to be annotated as part of the date annotations,
  - references to dates of specific periods in time from which information is to be collected and provided/reported are not considered as dates that need to be annotated since they do not refer to the deadline of reporting or provision of information/data, e.g., for the text fragment '*The required data for March to April in 2023 is to be provided not later then by January 2024*' the deadline slot is to be filled in with ?-01-2024.
  - in case of relative or imprecise temporal references that can not be anchored on a time scale only a minimal 'phrase' that conveys the main time constraint and discards potential event dependencies embraced in text should be used as a slot filler, e.g., from the text fragment '*The report has to be submitted as soon as possible after the approval of the Committee and receiption of the authorisation from ....*' only the phrase '*as soon as possible*' should be used as a slot filler.
  - in case the text fragment contains references to more than one deadline, e.g., reporting is to be carried out twice a year with two different dates, then the corresponding slot should contain both dates, delimitated by a semicolon.
- **Frequencies**
  - for filling in the *frequency* slot one should use one of the following values: *daily*, *weekly*, *biweekly monthly*, *bimonthly*, *quarterly*, *semiannually*, *annually*, *biannually*, *every X years*, *every X months*, *every X days*, *periodically* (in cases it is not clear what the actual period is, e.g., *at regular intervals*), provided that the information contained in the text corresponds to any of the aforementioned values,
  - if the frequency information can not be expressed using any of the values listed before, the relevant string from the text fragment should be used instead as a value,
  - analogously to dates, minimal 'phrases' that embrace the key information on frequency should be picked up as slot fillers

Scope

The cases not considered to be in the scope of information provision activity requirement extraction (i.e., not to be detected as information provision activity requirement mention) are listed below:

- mentions of events such as announcements, publication and other actions resulting from information provision activity requirements (e.g., *By letter of 28 June 1996 the Member State submitted the requested reports to the European Commission*),
- mentions of only specific details (secondary information) that go beyond the provision of the primary information on who is required to provide what information to whom, by when and with what frequency, for instance, mention of a language in which the information

is to be provided, e.g. *Notifications shall be submitted in one of the official languages of the Union.*,

- mentions of requirements not to disseminate or provide certain type of information (e.g., *Member States should not disclose the statistical data ...*),
- mentions of actions and events triggered by the obligation to provide certain information (that on their end do not cover transferring information or data), e.g., *Once the Member State submits the yearly report a workshop should be organized.*,
- mentions of actions and decisions to be taken if the information is not provided (e.g., *Where the Commission does not provide observations within that deadline, the reports shall be deemed to be accepted.*

A.5 Examples

```
(3) The Commission decision to initiate the procedure
was published in the Official Journal of the European
Communities(5).

-----------------------------------------------

ESMA shall determine whether the class of derivatives
or relevant subset thereof is only sufficiently liquid
in transactions below a certain size.

-----------------------------------------------

If agreed in the framework contract, the payment
service provider may charge the payment service
user for recovery.
```

Figure 8: **Negative examples from the *IPARE* benchmark**

```
Such information shall be forwarded to the Bulgarian
authorities by the end of the period following the
month to which the statistics relate.

PROVIDING ENTITY:   -
TARGET ENTITY:  the Bulgarian authorities
FREQUENCY:  -
DEADLINE:   -

-----------------------------------------------

Member States shall, if necessary, provide the
Commission by 30 June every two years with an
update of the information described in paragraph
2.

PROVIDING ENTITY:   Member States
TARGET ENTITY:  the Commission
FREQUENCY:  biannually
DEADLINE:  30-06-?

-----------------------------------------------

The feedback shall be reciprocal: the JST
coordinators shall provide feedback to the NCA
sub-coordinators and the NCA sub-coordinators
shall provide feedback to the JST coordinators,
in accordance with the principles set out in
Annex I.

PROVIDING ENTITY:  JST coordinators;NCA sub-coordinators
TARGET ENTITY:  NCA sub-coordinators;JST coordinators
FREQUENCY:  -
DEADLINE:   -
```

Figure 9: **Positive examples from the *IPARE* benchmark**

B Models details

This section provides more details on the models used in our experiments, in particular, details related to their tuning, etc.

B.1 Knowledge-based approach

In Table 2 we provide the breakdown of the lexical resources, such as deadline triggers (e.g., *not later than*) used in the knowledge-based approach to information extraction. The item indicated as *false-positive information provision triggers* in this Table refers to phrases that were used to eliminate frequent mentions of information provision activities that are false positives.

An example of an IE rule for the extraction of information provision activity encoded in *ExPRESS* syntax (in a simplified form) is provided in Figure 10. The rule consists of left-hand-side (LHS) part (the pattern) which specifies what needs to be matched in text, and a right-hand-side (RHS) part (the action), which specifies the output structure to return, i.e., a template with slots describing the information provision activity identified in the text. The pattern on the LHS matches a sequence consisting of: an optional structure of type `deadline`, followed by an optional structure representing `frequency`, followed by a mention of an `actor` (e.g., organization or a person), followed by a phrase triggering information provision activity (i.e., the structure referred to with `provide-to-phrase`), followed by one to a maximum of five `actors` (i.e., a sequence of `actor` structures separated by commas and a conjunction), being the target of the information provision activity. The symbol & links a type name of a structure with a list of feature-value pairs representing the constraints which have to be fulfilled and/or information that needs to be 'collected' to create the output. The symbols `#provider`, `#target`, `#date`, `#freuqency`, `#interval`, etc., establish variable

Resource type	Number
organization/actor names and related trigger keywords	921
information provision trigger phrases	769
false-positive information provision triggers	188
frequency-related keywords	435
deadline-related keywords	103
date-related keywords	19
numerical keywords	37
other	18

Table 2: Breakdown of the lexical resources.

```
sample-pattern :> ((deadline & [DATE: #date])?
                   (frequency & [SURFACE: #interval])?
                   actor & [SURAFCE: #provider]
                   provide-to-phrase & [TYPE: #type,
                                        PRODUCT: #product]
                   actor & [SURFACE: #target]
                   (token & [SURFACE: "," #target]
                    actor & [SURFACE: #target])<0,3>
                   (token & [SURFACE: "and" #target]
                    actor & [SURFACE: #target])?
                  ):match

-> match: INFO-PROVISION & [TYPE: #type,
                            PROVIDER: #provider,
                            TARGET: #target,
                            DEADLINE: #date,
                            FREQUENCY: #frequency,
                            PRODUCT: #product],
  & #frequency := NormalizeFrequency(#interval).
```

Figure 10: An example of a pattern for the extraction of information provision activity in EXPRESS syntax.

bindings to the surface forms of the matched text fragments and/or information associated with the structures that were matched (i.e., deadlines, frequencies, etc.). Furthermore, the label `match` on the LHS specifies the start/end position of the action defined on the RHS of the rule. This action produces a structure of type `INFO-PROVISION`, where the value of the slots: `TYPE`, `PROVIDER`, `TARGET`, `DEADLINE`, and `PRODUCT` is created via accessing the respective variables, i.e., `#type`, `#provider`, and so on, while the value of the `FREQUENCY` slot is computed via a call to a functional operator `NormalizeFrequency` which maps a surface form referring to a frequency (i.e., the value of the variable `interval`) to a canonical form. The rule would match the following text fragment '*From 1 February to 30 April, every year, competent authorities of the Member States shall submit an interim report on the progress to the European Commission, European Parliament and the Council*' and following structure would be extracted.

```
TYPE: "reporting"
PROVIDER: "competent authorities of the Member States"
TARGET: "the European Commission, European Parliament
         and the Council"
DEADLINE: "From 1 February to 30 April"
FREQUENCY: "annually"
PRODUCT: "interim report"
```

B.2 Classical ML approaches

We used the original LIBLINEAR library[12] to run the experiments with the LR and SVM. For both we used vector normalization and $c = 1.0$ resulting from parameter optimization.

B.3 BERT-derived models

The three models employ the RoBERTa architecture proposed by (Liu et al., 2019), but they differ in size and training data. **XLMRoBERTa** and **Legal-RoBERTa** use 16 attention heads and 24 hidden layers to generate 1024-dimensional embeddings, whereas **EU-BERT** has only 12 attention heads and 6 hidden layers that produce 768-dimensional embeddings. **XLMRoBERTa** was pre-trained on 2.5TB of filtered, multilingual CommonCrawl (Conneau et al., 2020). **Legal-Roberta** continued training the original RoBERTa model on the LeXFiles corpus. The training data comprised of approx. 6 million legal English documents including 11 sub-corpora that cover legislation and case law from 6 primarily English-speaking legal systems (EU, CoE, Canada, US, UK, India). Finally, **EU-BERT** was pre-trained on a corpus[13] of documents from the European Publications Office consisting of nearly 4 million documents in 39 languages.

For each model, we optimized learning rate (ranging between 7e-5 and 5e-3), batch size (ranging between 32 and 128) and training epochs (ranging between 1 and 10). Then, the most accurate model was loaded from a checkpoint for assessment for each fold.

B.4 Large Language Models

While **Claude-3.5-Sonnet** and **Mistral-Large (24.02)** are closed-source models, we can reason about their large size by comparing them to the other flagship LLMs with more detailed information. **Mistral-Large (24.02)** was created to compete with older versions of the largest Claude and Llama models. Shortly after that, the version of **Mistral-Large** from July 2024 was released as open source and included 133B parameters. **Mistral-Large (24.07)**[14] competed with **Claude-3.5-Sonnet** and **Llama-3.1-70B**. We can deduce **Claude-3.5-Sonnet** and **Mistral-Large (24.02)** are

[12] https://www.csie.ntu.edu.tw/~cjlin/liblinear/

[13] https://huggingface.co/datasets/EuropeanParliament/Eurovoc

[14] https://mistral.ai/news/mistral-large-2407

large LLMs, presumably with more than 70B parameters.

As observed in (Renze, 2024), temperature had no significant effect on model accuracy when applied to MCQA problems, but lower temperature maximized reproducibility. For all the tested LLM scenarios, we set the temperature hyperparameter to 0 (at top_p=0.95) to achieve a high level of determinism. The prompt comprised of the task definition along with a more detailed description of the information provision requirement.

B.4.1 Prompts

In Figure 11 and 12 we provide the prompts used for the detection subtask in the zero- and few-shot scenario resp. In Figure 13 and 14 we provide the prompts used for the extraction subtask in the single-instruction few-shot and chain-of-thought scenarios resp. Finally, Figure 15 shows the JSON Tool template passed with the prompts for **Claude-Sonnet-3.5** in few-shot scenario.

C Additional results

Table 3 includes (apart from the complete evaluation results) the standard deviation (SD) for transformers and few-shot LLM approaches for subtask 1.

Figure 16 shows the results of **Claude-Sonnet-3.5** in the few-shot scenario for the detection task with different number of examples (selected randomly) used. One can observe that adding more examples to the prompt does not change the overall performance. When including between 10 and 100 examples in the few-shot prompt, the classification metrics oscillate around 0.95, as observed earlier for n=10. One can observe some gains in precision, and simultaneous loss in recall.

```
Assess if the example includes an information provision activity requirement,given the task description.
Respond with '1' if there is a reporting obligation or '0' if there is no infromation provision
activity requirement. Do not justify your answer.

Task Description:  The task is to identify and extract primary information from
EU legal texts that specify information provision activity. This includes determining whether
a text imposes or suggests a reporting duty, identifying the key actors, the type
of information or activity reported, and any related deadlines or frequencies.
The focus is on examples that mandate or enable entities to report, disclose, notify,
provide, certify, or transfer information systematically or as a one-time action.
Monitoring and publishing are considered information provision activities. Secondary information
like language, format, or technical process details are not the focus of this task.
Those examples including only secondary information should be classified as '0'.

Contrastive Learning Using Graph Embeddings for Domain Adaptation of Language Models in the Process Industry

Anastasia Zhukova[1]*, Jonas Lührs[1]*, Christian E. Lobmüller[2], Bela Gipp[1]
[1]University of Göttingen, Göttingen, Germany

christian.matt@eschbach.com, gipp@uni-goettingen.de

Abstract

Recent trends in NLP utilize knowledge graphs (KGs) to enhance pretrained language models by incorporating additional knowledge from the graph structures to learn domain-specific terminology or relationships between documents that might otherwise be overlooked. This paper explores how SciNCL, a graph-aware neighborhood contrastive learning methodology originally designed for scientific publications, can be applied to the process industry domain, where text logs contain crucial information about daily operations and are often structured as sparse KGs. Our experiments demonstrate that language models fine-tuned with triplets derived from graph embeddings (GE) outperform a state-of-the-art mE5-large text encoder by 9.8-14.3% (5.45-7.96p) on the proprietary process industry text embedding benchmark (PITEB) while having 3 times fewer parameters.

1 Introduction

For several years, domain adaptation of language models (LMs) has followed three well-established approaches: fine-tuning pre-trained LMs using labeled data of domain-specific tasks (Devlin et al., 2019; Liu et al., 2019), training domain-specific LMs from scratch (Lee et al., 2019; Beltagy et al., 2019; Huang et al., 2019), or domain-adaptive continual pretraining (DAPT) using smaller amounts of domain text data when labeled domain task-specific data is limited (Gururangan et al., 2020; Strubell et al., 2020). While DAPT and the subsequent fine-tuning have become a practical and efficient solution for creating specialized NLP applications (Guo and Yu, 2022), it relies on the availability of unlabeled domain-specific data, from which an LM can learn domain-specific terminology.

When domain-specific unlabeled text data is limited, self-supervised methods such as SPECTER suggest leveraging the underlying graph as an additional data source structure to enhance training on the passage or document level (Cohan et al., 2020). Such a graph represents documents as nodes and their relationships as edges, providing valuable contextual information about how documents are interconnected (Kinney et al., 2023). Incorporating this graph-based information into an LM's training process enables the model to capture inter-document relationships (Cohan et al., 2020).

Domain-specific areas that involve proprietary knowledge in languages other than English often fall into the low-resource setting when both unla-

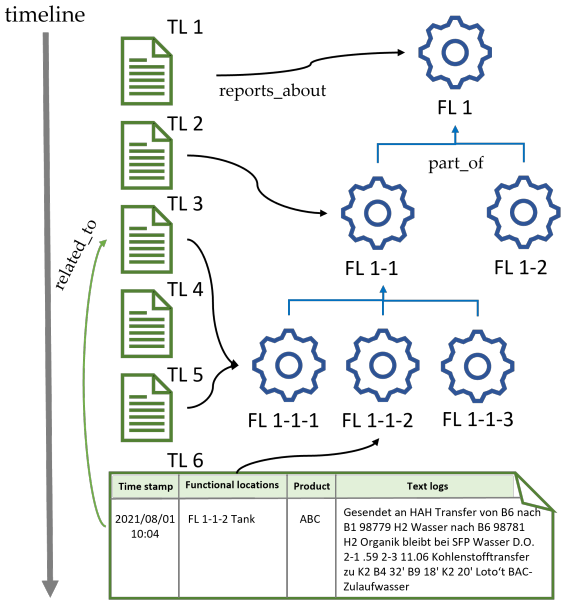

Figure 1: Graph embeddings are obtained from a directed heterogeneous domain graph for the process industry with two node types (1) text log (TL), i.e., logs of the daily operations at a production plant, and (2) functional locations (FL), i.e., hierarchically structured machinery on a production plant, and three edge types: *related_to* (green) connects two text logs, *reports_about* (black) links a text log to FLs, and *part_of* (blue) represents the hierarchical structure among FLs.

*Equal contribution.

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1472–1484

beled and labeled text data are scarce (Usuga Cadavid et al., 2020; Zhong et al., 2024). Although the text data can be scarce, companies often collect, store, and use structured and/or graph data, for example, those belonging to the process industry domain (Figure 1). Text records in this domain are logs of daily plant operations, organized in shift books, which preserve valuable knowledge about production and maintenance (May et al., 2022; Zhukova et al., 2024).

This paper explores adapting the SciNCL methodology, a contrastive learning approach based on scientific graph embeddings (GE) (Ostendorff et al., 2022), to enhance the text encoder in German plant operation logs and improve a semantic search task in this domain. The goal is to explore the potential of fine-tuning small models in low-resource settings, additionally aiming to achieve cost-efficient inference in production. The experiments show that the best-performing model was obtained by fine-tuning mBERT using triplets generated based on the GE.

The primary objective of adapting SciNCL is to leverage the relationships within the knowledge graph (KG) to provide an additional signal indicating the semantic relatedness between text logs, particularly in terms of the terminology used, e.g., "FL 1-1" as an abbreviation and "*Lömi*" as jargon. In example from Figure 1, one text log (TL2) reports about a reactor with a short code "FL 1-1" and uses *Lömi* alongside, and another text log (TL6) reports about its component with a short code "FL 1-1-2" but uses the textbook terminology of *Lömi*, i.e., *Lösungsmittel* (solvent). When using the KG and specifically graph embeddings, we can encode the information that these logs are connected via the chain of edges *TL6* $\rightarrow$ *reports_about* $\rightarrow$ *FL 1-1-2* $\rightarrow$ *part_of* $\rightarrow$ *FL 1-1* $\leftarrow$ *reports_about* $\leftarrow$ *TL2*. Incorporating domain-specific semantic relationships that were not available at the time of LM pretraining aims at bringing jargons, such as *Lömi-Lösungsmittel*, closer together in the vector space.

Our evaluation showed that mBERT outperformed a state-of-the-art mE5-large bi-encoder by 14.3% (7.96p) and the best-performing baseline M3 by 1.5% (0.92p) on the domain process industry text embedding benchmark (PITEB) while requiring considerably less training data (2.45M text pairs) and having 3 times fewer parameters (179M vs 560M).

2 Related work

A specific area of NLP, known as Technical Language Processing (TLP) (Brundage et al., 2021; May et al., 2022; Akhbardeh et al., 2020), adapts traditional NLP methods to address the unique challenges of the technical industry. The state-of-the-art NLP models often fall short when dealing with domain-specific technical terms, abbreviations (Akhbardeh et al., 2020), incomplete sentences, typographical errors, and non-standard notations (Dima et al., 2021).

Knowledge graphs (KGs) provide rich structural information and have been widely applied in various domains, including academic graphs, industrial manufacturing, and maintenance (Xia et al., 2023; Xiao et al., 2023; Stewart et al., 2022). Knowledge embedding techniques transform these graphs into continuous embeddings for entities and their relationships (Wang et al., 2021). Since general-purpose language models lack domain-specific knowledge (Qiu et al., 2020), several approaches have been developed to enhance language representation by integrating information from external knowledge bases. The recent development of the NLP applications in the process industry domain utilizes KGs for decision support (Naqvi et al., 2024), predictive maintenance (Naqvi et al., 2022; Usuga-Cadavid et al., 2022), or semantic search (Naqvi et al., 2024; Zhukova et al., 2024).

Research on knowledge graph-based fine-tuning techniques includes methods such as K-BERT (Liu et al., 2020), ERNIE (Zhang et al., 2019), KnowBERT (Peters et al., 2019), and KEPLER (Wang et al., 2021), which directly incorporate entity embeddings and knowledge into the model's training process. Other studies focus on utilizing the graph structure of documents for learning document-level semantics, such as SPECTER (Cohan et al., 2020), LinkBERT (Yasunaga et al., 2022), and SciNCL (Ostendorff et al., 2022), which use citation information and document relations to fine-tune models. TwHIN-BERT (Zhang et al., 2023) applies contrastive learning on social media data, while MICoL (Zhang et al., 2022) uses metadata-induced contrastive learning. SciNCL, unlike other methods, utilizes graph embedding to sample both positive and negative documents, making it effective for adapting models to the process industry by learning from graph structures and incorporating hard-to-learn negatives (Bucher et al., 2016; Wu et al., 2017).

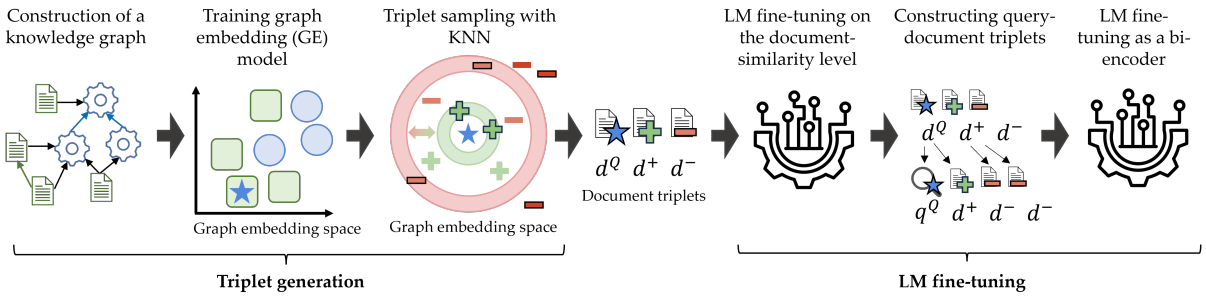

Figure 2: The methodology of adapting SciNCL (Ostendorff et al., 2022) to a semantic search in the domain of the process industry. The two main changes involve generating document triplets using graph embeddings (GE) constructed from a heterogeneous knowledge graph (KG) and using these triplets as a source for query-document triplet generation during bi-encoder fine-tuning.

3 Methodology

We closely follow the implementation of SciNCL, with several modifications and adaptations tailored to the domain of the process industry. The following section describes the key changes to the SciNCL methodology. Appendix A.1 until Appendix A.3 provides more details about each implementation stage.

Input data A KG in the process industry differs from the scientific graph in passage length and graph connectivity. Table 1 provides an overview of the key distinctions between the input data for the process industry and the original SciNCL approach. Unlike scientific abstracts, which maintain a consistent length and writing style to summarize research papers and have dense connectivity, text logs in the process industry are not subject to the writing constraints and result in a sparse graph. The text logs have a style and syntax similar to quickly taken notes (i.e., prone to typos), contain a lot of professional jargon and abbreviations, may contain partial information, are formatted inconsistently, and may exhibit other irregularities compared to commonly structured text. This results in logs as short as a few words, posing challenges for language learning objectives.

Table 1: A summary table of the discrepancies of the original methodology of SciNCL to the proposed implementation adapted to the process industry. While small, these differences may significantly impact the effectiveness of leveraging domain KGs for language model fine-tuning.

Knowledge graph Our implementation expands the scientific graph from the homogeneous graph with one relation type to a heterogeneous graph (i.e., text logs and functional locations (FLs)) with three relation types: (1) *part_of* relation to represent the hierarchical structure between FLs, (2) *reports_about* relation to connect text logs to the FLs they reference, and (3) *related_to* relation to link two text logs when the second log is a follow-up event to the first, such as a solution to a reported problem. These edges are directed, with clearly defined source and target nodes. By combining these three relations, the graph effectively captures the domain-specific relationships inherent in process industry data. To improve graph connectivity, we perform a preprocessing step using link prediction with two custom models. First, we utilize named entity linking to restore *reports_about* relations, and then record linking to restore *related_to* relations (Zhukova et al., 2025c).

Graph embeddings A graph embedding (GE) model is designed to capture the domain-specific relationships within the process industry graph. During training, the model learns to position nodes connected by edges closer together in the embedding space. While node embeddings are typically initialized with random values, we improve the learning process by initializing the node embeddings with the sentence transformers applied to (1) text logs and (2) FL descriptions. This approach is similar

to the method used by Asada et al. (2021), who incorporated text embeddings to enhance the training of a graph embedding model in cases where the graph's structural information alone was insufficient.

Document triplet sampling We employ the graph embedding neighborhood of a query document vector $\mathbf{d}^Q$ to sample positives and negatives by selecting the k-nearest neighbors. Graph embeddings provide a continuous and undirected similarity signal, enabling the identification of semantically similar nodes even when there are no direct edges between them. In a heterogeneous graph setup, node embeddings inherently encode the diverse contexts introduced by various relation types, thereby eliminating the need for complex sampling strategies that rely on directly building positive samples from graph edges (Zhang et al., 2022). Although edges between FLs and text logs help define the graph embedding space, the resulting node embeddings ultimately become independent of these direct connections. We adopt the same sampling strategies for positives and negatives as SciNCL, employing kNN sampling for positives and hard negatives, and filtered random sampling for easy negatives. The sampling parameters were set as follows: $c^+ = 2$ for positives, $c^-_{easy} = 1$ for easy negatives, and $c^-_{hard} = 1$ for hard negatives, where positives were selected given the kNN parameter $k^+ = 2$, and a hard negative was chosen from $k^-_{hard} = 50$.

Learning objective: document similarity level A contrastive learning objective ensures that similar documents are positioned close together in the embedding space of a fine-tuned LM while dissimilar documents are pushed farther apart. We fine-tune an LM with a self-supervised triplet margin loss (Schroff et al., 2015):

$$\mathcal{L} = \max\left\{\left\|\mathbf{d}^{\mathcal{Q}} - \mathbf{d}^+\right\|_2 - \left\|\mathbf{d}^{\mathcal{Q}} - \mathbf{d}^-\right\|_2 + \xi, 0\right\} \quad (1)$$

where d is a document vector representation $f_{lm}(d) = \mathbf{d}$ using an LM, ξ represents the margin that ensures that $\mathbf{d}^+$ is at least ξ closer to $\mathbf{d}^{\mathcal{Q}}$ than $\mathbf{d}^-$, and $\|\Delta d\|_2$ is the L^2 norm, which is used as a distance function. In our experiments, we use d as (1) a vector of `[CLS]` token from the last hidden layer or (2) a concatenation of `[CLS]` and mean pooling of all tokens from the last hidden layer.

Query-document triplet sampling To create query-document pairs based on GE-triplets, we begin by generating a search query for each query document (Zhukova et al., 2025a). Next, we apply a hard negative mining strategy to train Sentence Transformers using the MS MARCO dataset (Sentence-Transformers, 2021): we treat all documents retrieved by any model as negatives (both positive and negatives), except for the query document itself. As a result, all retrieved triplet documents are considered negatives, and previously positive documents are now treated as hard-to-learn negatives.

Bi-encoder fine-tuning We use Multiple Negatives Ranking Loss to train a bi-encoder from the implementation from the BEIR benchmark (Thakur et al., 2021)[1].

4 Evaluation

4.1 Experiment setup

Model selection For LM fine-tuning, we selected several pre-trained and domain-adapted monolingual or multilingual pre-trained LMs. Specifically, we selected state-of-the-art LMs with BERT architectures that support the German language: GBERT-base (Chan et al., 2020), multilingual mBERT-base (Devlin et al., 2019), and XLM-RoBERTa-base (Conneau et al., 2020). Additionally, we evaluate daGBERT, a domain LM tailored for the process industry using continual pretraining (Zhukova et al., 2025b). All selected models have an embedding size of 768, and the number of parameters is under 300M.

Baselines The evaluation compares our methodology to the state-of-the-art multilingual text encoders that support the German language: SBERT `paraphrase-multilingual-MiniLM-L12-v` and `msmarco-distilbert-multilingual` (Reimers and Gurevych, 2019), mE5-base and mE5-large (Wang et al., 2024), IBM Granite 107m and 278m (Granite Embedding Team, 2024), OpenAI `text-embedding-3-large` (OpenAI, 2024), mGTE-base (Zhang et al., 2024), Nomic Embed v2 (Nussbaum and Duderstadt, 2025), `deepset-mxbai-embed-de-large-v1` (Lee et al., 2024), and M3 (Chen et al., 2024). The selected models vary in terms of embedding size and

number of parameters, thereby ensuring a fair comparison in terms of performance and efficiency. Adding these models to our evaluation assesses their performance in highly specific, technical domains, such as the process industry and the German language, thereby contributing to the exploration of their limits/boundaries for such edge cases.

Implementation The models were trained on an NVIDIA Tesla A100 (80GB). Adam with weight decay was used as the optimizer, with a learning rate of $\lambda = 2^{-5}$. Our preliminary experiments showed that the most optimal pooling strategy for GBERT, daGBERT, and mBERT is concatenation, whereas for XLM-RoBERTa, it is using the [CLS] vector token. The training was conducted for three epochs with a batch size of 16. We fine-tuned a GBERT, daGBERT, and mBERT for 3 epochs and XLM-RoBERTa for 5 epochs. We trained a bi-encoder for 5 epochs on GBERT, daGBERT, and mBERT, using a batch size of 64 and 1000 warm-up steps. In contrast, due to the larger number of training parameters, XLM-RoBERTa was fine-tuned for 8 epochs with 3000 warm-up steps with the same batch size. The remaining parameters were inherited from SciNCL.

Test collection: PITEB We evaluate our models and baselines using a private expert-verified process industry text embedding benchmark (PITEB) (Zhukova et al., 2025a). Table 2 provides details on the test collection, which comprises data from seven production plants in the chemical and pharmaceutical domains, totaling 205 queries across a collection of 330K documents. Data from four plants is used to build training datasets for both document-level triplets and a dataset for bi-encoders.

Document similarity training dataset We generated 100K document triplets equally distributed from four plants (50K unique query documents). We have enforced an additional quality check of the triplets by following a Sentence Transformers methodology of creating hard negatives for the MS MARCO dataset[1]: we scored the pairs with a cross-encoder `cross-encoder/msmarco-MiniLM-L12-en-de-v1` and kept the triplets where a positive document is similar enough to a query-document ($pos.pair \geq 5.0$) and a negative document is distant enough from the positive document ($pos.pair - neg.pair \geq 3.0$). Hence, we ensured a second quality layer after the GEs and obtained the final training dataset with 14K triplets.

Bi-encoder training dataset The dataset for bi-encoder fine-tuning consists of three components (Table 3): (1) the domain-related version of German MS MARCO (Nguyen et al., 2016) (`DR-MM`) (see Appendix A.4), (2) a synthetic in-domain dataset created using an ensemble of text encoders (`SID`) (Zhukova et al., 2025a), and (3) a collection of query-document pairs generated from GE-based document-level triplets (`GET`). To create `GET`, we sampled 5K query documents from plants A, C, D, and G from the unique 50K query documents from the triplets above, and ensured that these documents do not occur in the test collection as relevant documents. To evaluate the impact of the query-document pairs based on GE-triplets, we use two versions of the dataset: (1) `DR-MM + SID` (2.31M pairs), (2) `DR-MM + SID + GET` (2.41M pairs). As a baseline, we also use the German MS MARCO (`MM`, 160M pairs) as a comparison dataset for our domain-specific version.

Table 4: The evaluation demonstrates that fine-tuning language models (LMs) using the adapted SciNCL methodology outperforms the baseline text encoders. The most significant improvement is observed with the two-stage model fine-tuning (first on document-level similarity and then on query-document level) and the `DR-MM + SID + GET` dataset, which shows the highest impact across almost all fine-tuned models. This result is achieved despite the GE-based triplets comprising only 6% of the entire training corpus.

Metrics We evaluate the text encoder with three metrics: mean average precision (MAP@10), mean reciprocal rank (MRR@10), and normalized discounted cumulative gain (nDCG@10). Using all three metrics together provides a more well-rounded evaluation, giving insights into ranking quality, early retrieval performance, and overall retrieval quality. We report the mean of these metrics across seven plants.

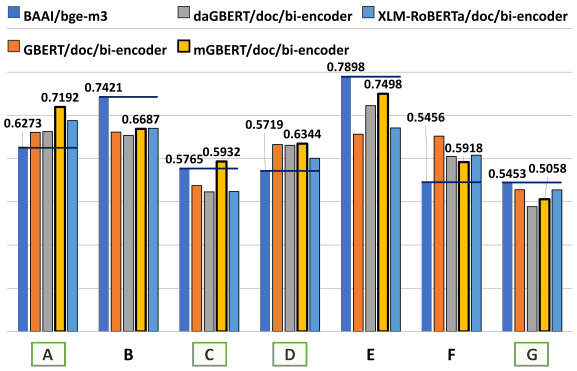

Figure 3: The best-performing fine-tuned mGBERT outperformed the strongest baseline M3 (Chen et al., 2024) in almost all plants, the data from which was used for the fine-tuning (i.e., A, C, D, G).

4.2 Results

Table 4 shows that fine-tuning LMs with GE-based query-document triplets, whether used alone or combined with preliminary fine-tuning at the document level, outperforms 9 out of 11 text encoder baselines. The best model performance was achieved by fine-tuning mBERT with a two-stage fine-tuning process (first on document-level similarity and then on query-document level), which outperformed the state-of-the-art mE5-large by 14.3% (7.96 points) and the strongest baseline, M3, by 1.5% (0.92 points). Despite having three times fewer parameters and a smaller embedding dimension, fine-tuned mBERT surpassed these baselines.

The analysis of the bi-encoder dataset reveals a positive effect from using domain-related query-document pairs from MS MARCO (`DR-MM + SID`), particularly when combined with in-domain data from GE-based query-document pairs (`GET`). The results show that fine-tuning GBERT using `DR-MM + SID` is 4% (2.27 points) more efficient than using the full German MS MARCO `MM`, while requiring significantly less training data (1.4%). Although `DR-MM + SID` includes synthetic domain data, its contribution is minimal, as it makes up just 1.8% of the dataset. The greatest performance improvement comes from the GE-based query-document pairs, which accounted for only 5.6% of the `DR-MM + SID + GET` bi-encoder dataset, as this component improved model performance across all evaluated models by 1.28-6.35% compared to training on `DR-MM + SID` alone.

The two-stage fine-tuning process resulted in a systematic performance improvement for three out of four fine-tuned LMs, while the solely bi-encoder fine-tuning improved performance in all LMs compared to the baselines. Our experiments show that using a continually pretrained daGBERT is only beneficial when the domain-specific component is not available in the bi-encoder training data, and the domain-specific knowledge can be compensated for from the domain-pretrained LM. In contrast to the high performance improvement of mBERT, our two-stage fine-tuning approach did not yield significant improvements for GBERT and XLM-RoBERTa. Further experiments with dataset configuration, i.e., composition and size, as well as fine-tuning parameters, are required to investigate the potential performance improvement.

When breaking down the overall results at the plant level, we see that mBERT outperforms our strongest baseline, M3, in three out of four plants, for which the data was used for triplet generation (Figure 3). Plant G has the largest number of graph edges in KG after linking prediction; therefore, potentially more triplets should have been used in each of the fine-tuning stages to see a positive effect on this plant from the semantic relations encoded in these connections. The fine-tuned models systematically outperform the four plants from the datasets, but further investigation is necessary to refine the methodology and achieve generalizability and optimal performance for each plant.

4.3 Discussion

The results showed that leveraging a heterogeneous domain KG that combines signals from text logs and FLs significantly enhances document representations for the process industry domain. Our results indicate that we have successfully adapted and modified the SciNCL methodology from a domain of scientific publications to the process industry domain. The largest impact was observed in using the document triplets collected using GE to create positive and negative query-document pairs for the bi-encoder fine-tuning. These findings suggest that SciNCL could be further expanded into more heterogeneous graphs with limited text data availability. Furthermore, we demonstrate that triplets obtained through kNN in the GE vector space can be used indirectly as a source of synthetic data for downstream tasks. The current experiments focused solely on creating synthetic data to train a bi-encoder; however, the methodology can be further explored to generate data for auxiliary tasks, such as question answering, document ranking, and text classification.

In future work, we plan to expand our KG by incorporating named entity recognition (NER), which will enable us to enrich the graph with additional entities and relationship types, such as chemicals and products. We also aim to optimize the methodology by initializing the GE model with high-performing text encoders designed for semantic text similarity tasks, such as M3 (Chen et al., 2024). Additionally, we will evaluate the impact of various parameters, including the number of positive and negative documents retrieved using GEs, and explore methods to ensure the quality of the generated triplets. We also plan to assess the effect of using data from other plants as triplet sources, optimize model training parameters, and explore other strategies for the negative selection in the query-document triplets. Finally, we will focus on improving the domain dataset for bi-encoder fine-tuning by enhancing the domain-specificity and quality of the query-document pairs derived from both publicly available and proprietary sources. Our further analysis will include a detailed investigation of how the methodology impacts performance at the plant level, with the goal of optimizing results for each individual plant.

5 Conclusion

This work explores the application of the SciNCL methodology for domain adaptation of LMs in the process industry, focusing on fine-tuning them using triplets derived from the vector representation of the domain knowledge graph. Our experiments show that the query-document triplets generated from the GE play a crucial role in providing domain-specific knowledge during the fine-tuning of the four LMs we evaluated.

Limitations

The limitations of this study primarily stem from the restricted scope of the data and methodology. Our experiments were conducted using graph embedding models built from data from only four plants and evaluated on just seven plants. The limited dataset size may affect the generalizability of the results, and the performance observed here may not necessarily hold for larger, more diverse datasets with a different composition of data from plants in the process industry. Variations of training

datasets for both document-level fine-tuning and as a bi-encoder can additionally impact the results.

Furthermore, we did not conduct exhaustive parameter tuning of the graph embedding model, triplet selection, or a detailed investigation of the parameters adjusted to fine-tune specific models, which could potentially impact the performance and robustness of the results. Further investigation is needed to assess the scalability and generalizability of the approach across various conditions, including the connectivity of knowledge graphs, the quality of text logs, the methods used in the preprocessing step for link prediction, and the proportion of subdomains used in training and evaluation (e.g., pharmaceuticals and chemistry).

Additionally, the adaptation of the SciNCL methodology may not produce the same positive trends or results if applied to other industries, domains, or languages. Hence, the approach requires extended investigation when applied to a specific linguistic and domain context. Moreover, our results may not be fully reproducible due to the use of proprietary data, which limits external validation.

Finally, the methodology described in this paper was not compared to other methods of utilizing KGs for language model fine-tuning or enhancement. A comprehensive comparison was beyond the scope of this research; therefore, we do not rule out the possibility that other existing methods using graph embeddings may outperform SciNCL.

Acknowledgments

This project is supported by the Federal Ministry for Economic Affairs and Climate Action (BMWK) on the basis of a decision by the German Bundestag. Additional funding was provided by the Federal Ministry of Education and Research (BMBF) in the form of a fellowship under the IFI program of the German Academic Exchange Service (DAAD). We would like to thank Marco Kaiser and Thomas Walton for their contributions to the link prediction services. We also appreciate Malte Ostendorff for the insightful discussions on solutions towards domain adaptation using SciNCL.

A Implementation details

A.1 Knowledge graph

We build a domain KG by using all FL nodes and *only those text log nodes that contain at least one attached FL*. Although S2ORC used for SciNLC contained titles and abstracts with more than 100 characters (Lo et al., 2020), removing all short text logs (<100 chars) from the domain KG for the process industry would filter out almost half of the available documents. Table 5 presents a statistical analysis of the process industry graphs, revealing that the number of direct links between text logs is low (see the *related_to* edge type) and emphasizing the importance of indirectly connecting text logs through shared FLs. Since every text log in the graph is linked to at least one FL, there is a high number of *reports_about* edges, significantly improving the overall connectivity of the graph.

Data analysis revealed that many FLs are referenced in text logs using domain-specific abbreviations (e.g., A11) but are not explicitly linked as attributes (see Figure 1). This lack of direct association limits our implementation's ability to construct a comprehensive domain KG. To address this problem, we implement two domain-specific custom link prediction models to (1) reconstruct the *reports_about* and *related_to* connections within the domain KG, (2) expand the context of domain-specific abbreviations. In the context expansion, we replace the abbreviations such as "A11" with a combination of the abbreviation and its description "A11 Pumpe", which was obtained from the linked FL node. As shown in Table 5, this approach significantly increases the number of graph edges and expands the number of text log nodes, i.e., text logs that previously lacked associated FLs are now integrated into the graph, enhancing its overall structure and connectivity. Moreover, we apply a record linking model (Zhukova et al., 2025c) to restore connectivity between the text logs, i.e., when two records reported about a problem and a solution to it, but were not explicitly linked in a database as related. Table 5 shows that the KG after the link prediction includes the largest number of text log nodes from the available raw data.

A.2 Graph embeddings

Following SciNCL, we employ PyTorch BigGraph (PBG) (Lerer et al., 2019) for training graph embedding models. PBG supports graphs with multiple node and edge types, making it suitable for the heterogeneous process industry graph introduced in this work. PBG processes the input graph as a list of edges, where each edge is defined by a source node, a target node, and an edge type. It generates embeddings for each node, ensuring that connected

KG stage	Parameters	A	C	D	G
Raw data	node candidates	24K	229K	119K	147K

Table 5: Overview of the plant datasets, which consist of two types of data: text logs of daily operations and a function location tree that describes the hierarchical structure of the plant machinery. To enhance data connectivity, link prediction was performed to reconstruct the *related_to* and *reports_about* links.

Init. with sent. embed.	LP	MRR	Hits@1	Hits@10	AUC
no	no	16.96	09.39	30.47	59.93
yes	no	36.48	21.54	72.25	78.75
yes	yes	47.80	33.91	78.21	85.06

Table 6: Evaluation of graph embedding models. Link prediction (LP) performance of PyTorch BigGraph embeddings trained on the process industry graphs for plant D (1) with and without node initialization with sentence embedding, and (2) before and after data enrichment.

nodes are positioned closer together in the vector space while unconnected nodes are pushed farther apart. This design ensures that entities with similar neighbor distributions are located near one another in the embedding space. In addition to handling heterogeneous graphs, PBG is highly scalable, making it well-suited to accommodate the growing volume of text logs in the future.

Our methodology primarily adopts the training parameters for the graph embedding model described in SciNCL, while experimenting with variations in the number of training epochs and using sentence embedding initialization. Some FLs have similar descriptions, such as reactors of different types. Initializing the graph network with semantically meaningful vectors can enhance the learning of structural connections between nodes. For example, by initializing FL nodes using their descriptions, similar FL types (e.g., pumps) are naturally positioned closer together in the embedding space. During training, text logs referencing different pumps are more likely to be mapped to similar regions within the embedding space, as their corresponding FLs were initially placed near each other. Consequently, text logs that do not share the same FLs but originate from semantically similar contexts can still achieve similar node embeddings. Moreover, if text logs contain terms similar to those in the descriptions of FLs, such nodes will also be positioned closely in the vector space. We anticipate that integrating domain-specific relationships with semantic similarity will help mitigate challenges such as low graph connectivity and poor text quality, while improving the sampling of both similar and dissimilar text documents.

The node embeddings for the graph model are initialized by vectorizing the text logs and functional location (FL) descriptions using sentence transformer embeddings from `PM-AI/bi-encoder_msmarco_bert-base_german`. Table 6 presents the link prediction performance for plant D, evaluated using metrics such as MRR, Hits@1, Hits@10, and AUC. For these experiments, 99% of the data was used for training, while the remaining 1% (1193 edges) was reserved for testing[2]. The results demonstrate that initializing nodes with text embeddings significantly enhances the performance of link prediction. These findings highlight the crucial role of initializing node embeddings with text embeddings in effectively training graph embedding models within the process industry.

A.3 Triplet sampling

For each query document, we sampled two triplets, consisting of one easy negative and one hard negative. This provides a diverse similarity signal while ensuring broader document coverage, even within smaller data subsets.

To identify text logs with a similar graph context — those associated with similar text logs and functional locations — an approximate nearest neighbor (ANN) search was conducted in the text log embedding space. FAISS (Johnson et al., 2021) was employed to construct a flat index of text logs, keyed by their node embeddings. To ensure consistency in distance measurement, embeddings were L2-normalized, and cosine similarity was used as the distance metric by computing the inner product of the embeddings. After building and populating the FAISS index with text log embeddings, queries in the form of text log embeddings $\mathbf{d}^{Q}$ were used

[2]Metric definitions are available in the PBG documentation: https://torchbiggraph.readthedocs.io/en/latest/evaluation.html

to retrieve the k-nearest neighbors based on their cosine distance in the embedding space.

Initial experiments revealed that including overly short text sequences during training significantly degrades language model performance, leading to the introduction of a *minimum text length* criterion. To preserve as many nodes and edges as possible for graph model training, this criterion was applied *after training the graph embedding* model but *before triplet sampling*. By filtering text logs shorter than 100 characters (approximately 15–25 words) only before the ANN search, the approach ensures robust text embeddings, enhances contextual information, and improves node embedding quality in graphs with low edge density. Table 5 shows the number of generated triplets per plant.

Positive samples d^+ should be semantically similar to the query document d^Q, but not overly similar, to avoid gradient collapse. Additionally, positives should be sampled from a comparable distance to the query embedding $\mathbf{d}^Q$ to ensure balanced training (Wang and Isola, 2020). To achieve this, we follow SciNCL that selects positive (similar) documents by first defining the distance to the query embedding $\mathbf{d}^Q$ using k^+ and then sampling the c^+ nearest neighbors within a range $(k^+ - c^+, k^+]$, as illustrated by the green band in Figure 2.

Negative samples d^- should be semantically dissimilar from the query document d^Q, meaning they are sampled from a distant region relative to the query embedding $\mathbf{d}^Q$. Sampling hard-to-learn negatives, i.e., those close to potential positives, has been shown to enhance contrastive learning (Bucher et al., 2016; Wu et al., 2017). However, when negative samples overlap with positive ones, it can introduce noise into the learning signal (Saunshi et al., 2019). To prevent such collisions, SciNCL employs a sample-induced margin defined by the k parameter. This margin ensures the sampling of hard negatives (represented by the red band in Figure 2) without overlapping with the sampled positives (green band). To provide a robust similarity signal for contrastive learning, SciNCL recommends using a mix of hard and easy negatives, where easy negatives are embeddings located further from the query embedding than hard negatives (outside the red band).

Sampling strategies differ between positive and types of negative samples, i.e., similar to SciNCL. We use kNN sampling for positives and hard negatives, and filtered random sampling for easy negatives. *kNN sampling* is conducted as k-nearest neighbors search $kNN(f_{gem}(\mathbf{d}^Q), \mathbf{D})$ given a graph embedding model (e.g., PyTorch BigGraph (Lerer et al., 2019)) denoted as f_{gem}, document node embeddings $\mathbf{D}$, and a search index (e.g., FAISS (Johnson et al., 2021)). From the neighbors around the query document d^Q, c' samples are selected using the interval $(k - c', k]$, where $N = \{n_1, n_2, n_3, \ldots\}$ represents the neighbors, i.e., n_i is the i-th nearest neighbor in the graph embedding space. For example, if $c' = 3$ and $k = 10$, the selected samples would be the three closest neighbors within the specified range: n_8, n_9, and n_{10}. *Filtered random* sampling utilizes random sampling, i.e., samples c' documents from the corpus without replacement, but excludes the documents retrieved by kNN, i.e., neighbors within the largest k.

Due to the low number of direct connections between text logs, we select the closest $k = 2$ neighbors as positive samples. A small k^+ ensures that text logs that are positioned close in the graph embedding space, due to their direct links, are included. A higher k^+ value could risk skipping such direct links. Similarly, k^-_{hard} was set to 50 to ensure that the selected hard negatives were sufficiently dissimilar, as the 50th neighbor is expected to fall outside the direct neighborhood of the query log.

A.4 Domain-related MS MARCO Dataset

We created a domain-related version of MS MARCO by running the document collection through our binary classifier, which identifies whether a document is domain-related or not. This classifier is a fine-tuned SciBERT model (Beltagy et al., 2019) trained on an 80K dataset that combines fields of study (FoS) data and our in-domain data. The train dataset was split so that 50% consisted of domain-related texts, selected by the labels in FoS that correspond to our domain, and in-domain texts, thereby forming the true labels, while the other 50% was sampled from various areas of FoS. We classified the English documents and used the document IDs to extract the German version of the same texts. A document was considered domain-related if a confidence in the positive label was larger than 0.9, and we collected the query-document pairs where the documents were labeled as domain-related. The resulting dataset contained approximately 2.27M training pairs, where 132K pairs were positive.

From Feedback to Checklists: Grounded Evaluation of AI-Generated Clinical Notes

Abstract

AI-generated clinical notes are increasingly used in healthcare, but evaluating their quality remains a challenge due to high subjectivity and limited scalability of expert review. Existing automated metrics often fail to align with real-world physician preferences. To address this, we propose a pipeline that systematically distills real user feedback into structured checklists for note evaluation. These checklists are designed to be interpretable, grounded in human feedback, and enforceable by LLM-based evaluators. Using deidentified data from over 21,000 clinical encounters (prepared in accordance with the HIPAA safe harbor standard) from a deployed AI medical scribe system, we show that our feedback-derived checklist outperforms a baseline approach in our offline evaluations in coverage, diversity, and predictive power for human ratings. Extensive experiments confirm the checklist's robustness to quality-degrading perturbations, significant alignment with clinician preferences, and practical value as an evaluation methodology. In offline research settings, our checklist offers a practical tool for flagging notes that may fall short of our defined quality standards.

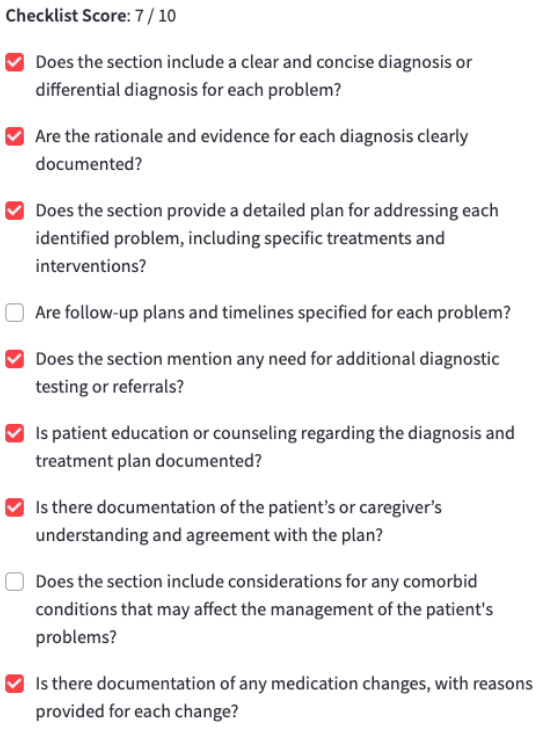

Figure 1: Example checklist questions for the Assessment and Plan section of a clinical note. The checklist score consists of the proportion of satisfied questions.

1 Introduction

Evaluating the quality of AI-generated text is challenging, especially in domains where the text is highly specialized and requires expert knowledge. This is particularly true in the medical domain, specifically for AI-generated clinical notes. Automated metrics are scalable but often misaligned with clinical needs, relying on limited reference notes and penalizing harmless stylistic differences. Reference-free methods tend to focus narrowly on factuality (Xie et al., 2024). Meanwhile, human evaluation by clinical experts is generally high-quality but costly, inconsistent, and difficult to scale due to subjective preferences and varying documentation standards across specialties (Wang et al., 2025a; Hanson et al., 2012). The diversity of clinical practice makes defining a single set of evaluation criteria (e.g., a rubric) that applies across all notes difficult (Yim et al., 2023; Wang et al., 2024; Croxford et al., 2025a).

Checklists are commonly employed in aviation and healthcare, used to improve safety and quality (Reijers et al., 2017; Chaparro et al., 2019; Brykczynski, 1999; Degani and Wiener, 1993; Haynes et al., 2009) and to guide human- or LLM-evaluators in complex tasks.

To address the challenge of evaluating AI-generated clinical notes, we propose leveraging real user feedback to generate grounded checklists.

For each encounter, clinicians may provide free-form written feedback for the corresponding note. Such user feedback reflects real issues clinicians face with AI-generated notes, providing valuable insights into the qualities that make a clinical note effective or lacking. By analyzing this feedback, we can automatically uncover the attributes associated with highly-rated notes. These qualities can be compiled into structured checklists to effectively evaluate clinical notes. The checklist can be used with LLMs-as-a-Judge (Zheng et al., 2023), to automatically flag notes that are lacking, at scale for checklists that are too long for humans to evaluate, or to support human evaluation by providing a rubric for the human evaluator to follow. Thus, we tackle the following research question: can user feedback be systematically distilled into a note quality checklist?

To achieve these goals, we propose a method to automatically generate a checklist, given user feedback. The pipeline involves leveraging user feedback as context, prompting an LLM for candidate checklist questions, and then applying a series of refinement steps to select for the most salient questions. Finally, we conduct automatic evaluation of the final checklists, with plans for human validation and checking for generalization[1]. An example of how a checklist would be used for scoring a note can be seen in Fig. 1.

Our contributions are as follows:

- We propose a systematic pipeline for generating and refining checklists from real user feedback, with clear evaluation metrics.
- In our internal offline evaluation, the checklist appears more comprehensive, diverse, and predictive of human ratings than a baseline (zero-shot) checklist.
- We demonstrate the checklist's robustness to various quality-degrading perturbations (e.g., missing information, poor writing flow and organization, and redundancy and hallucinations) as well as significant alignment with expert preferences.

2 Related Work

Additional work on checklist generation and evaluation are discussed in Appendix §A.

Clinical note evaluation Guideline or rubric-based evaluation of clinical notes has been explored in several works (Yim et al., 2019). Stetson et al. (2012) is a 9-item rubric for medical documentation quality, a shorter version of the Physician Documentation Quality Instrument (PDQI) (Stetson et al., 2008). It is scored on a 5-point Likert scale and has been used to evaluate AI-generated clinical notes (Amenyo et al., 2025; Croxford et al., 2025b). Eng et al. (2024) creates a high-level guideline for medical documentation best practices. Burke et al. (2014) is another physician-validated medical note rubric. These rubrics often have Likert scales as answer options, which introduces additional complexity and ambiguity for human and LLM raters. Rubrics are also difficult to develop and score, due to subjectivity and variability of practice (Croxford et al., 2025a; Oleson, 2024). While these existing rubrics are static, we introduce an approach that is comprehensive of large-scale user concerns and dynamic to new feedback.

Other note evaluation works include training reward models (Wang et al., 2025b), or proposing reference-free evaluation on pre-defined desired attributes (typically factuality-based) (Kanithi et al., 2024; Xie et al., 2024). We are the first to propose a checklist-based evaluation approach grounded in real human feedback.

Checklist-based evaluation with LLM-as-a-Judge LLMs are increasingly used as automatic evaluators, due to their ability to handle nuance and scale. In particular, LLM-evaluators (or LLMs-as-a-Judge) are used to evaluate the quality of another LLM's generations. However, LLM-evaluators have been shown to contain biases like increased position bias with more answer candidates (Ye et al., 2024), leading us to choose a binary checklist-based evaluation approach.

Works like Goldberg et al. (2024) use LLMs to evaluate compliance with a pre-existing checklist, and many others have explored checklist-based evaluation with LLM-as-a-Judge for a variety of tasks (Lin et al., 2024; Que et al., 2024; Chu et al., 2025). It has been extensively demonstrated that checklists can be used to improve the reliability of LLM-evaluators and agreement with human judgments (Lee et al., 2025; Pereira et al., 2024; Cook et al., 2024; Wei et al., 2025; Li et al., 2025).

3 Data

We leverage a mix of proprietary data (user feedback and note ratings) from a commercial Ambient AI company and open-source datasets (clini-

[1]Our checklists are not intended for clinical deployment or for altering patient care without clinician review.

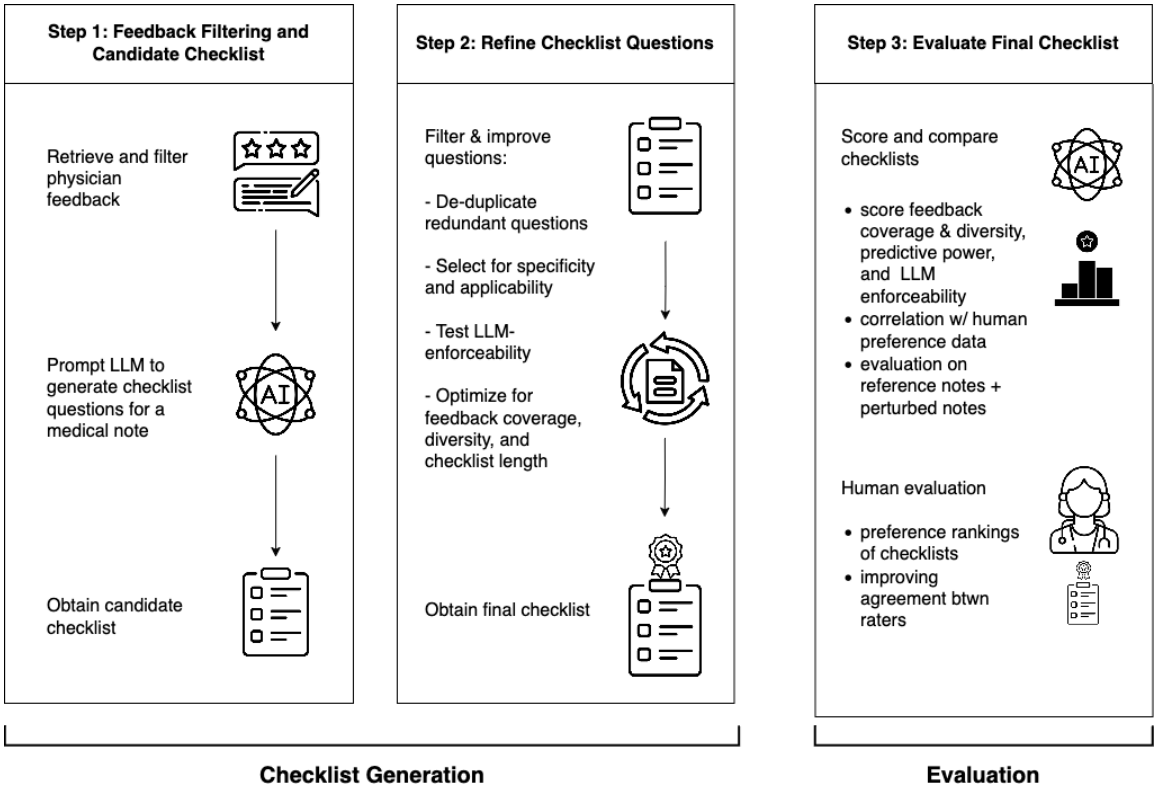

Figure 2: Proposed end-to-end pipeline.

Feedback	Rating
"Does not capture all the key clinical details discussed during the visit"	2
"Prefer past tense"	4
"Could benefit from clearer summary and clinical reasoning"	3
"Covers everything I would have wanted to see"	5

Table 1: Example synthetic user feedback and star ratings.

cal notes). We use: 1) approximately 22,000 real-world clinical encounters containing free-text user feedback and 1–5 star ratings (see Table 1 for synthetic examples), 2) 506 pairs of clinical notes rated by clinical experts in pairwise comparisons, and 3) 207 reference clinical notes and transcripts from ACI-bench (Yim et al., 2023), each structured into four standard sections and used for benchmarking and evaluation. Further details can be found in §B.

4 Pipeline & Implementation

We start with some definitions:

- **Checklist question**: a question that can be answered with "Yes" or "No"; specifically, the question is designed to be answered with "Yes" if the note meets a desired criteria of good clinical note.
- **Checklist**: a series of checklist questions that can be used to evaluate a clinical note.
- **Passing (a question)**: if a note scores "Yes" for the checklist question.
- **Checklist score**: for a note and a checklist, the proportion of the checklist questions that pass.

To streamline the evaluation process and make checklists more easily comparable, we make several simplifying assumptions:

- We focus on the Assessment and Plan (*AP*) section of the notes, since it is a key component of clinical notes and all encounters should have this section. However, our proposed methods can be extended to other note sections.
- Checklist questions must be answerable w/ "Yes" or "No" for all encounters, i.e., no "N/A" answers allowed.
- Questions should be answerable given only transcript and the specified note section.
- Checklists should be concise, to be easily processable by humans.

Fig. 2 shows the proposed pipeline[2]. We will go over generation (§4.1) and refinement (§4.2) of the checklist questions below. See §5 for evaluation and results of the final checklist questions.

4.1 Checklist Generation Methods

We generate candidate checklist questions for each note section separately. Appendix §C contains the prompts used for generating checklists.

Baseline: We prompt a LLM with the instruction to generate candidate checklist questions, without any feedback or specified guidelines (zero-shot). This baseline is designed to isolate the contribution of clinician feedback. We chose not to adapt prior rubrics such as Stetson et al. (2012) or Burke et al. (2014) since they are Likert-style and not directly comparable to binary checklists without careful redesign, and having a clinical expert draft checklist questions from scratch has proven non-trivial and time-consuming, due to the subjectivity and exhaustiveness of the task.

With Feedback: We prompt a LLM with the feedback corpus and the instruction to generate candidate checklist questions. Because there is more feedback than can fit in the model's context window, we split the feedback into batches. Questions are confirmed to be written such that a "Yes" answer corresponds to a good clinical note; if not, the LLM rewrites them in the correct direction.

4.2 Checklist Refinement

Once we have candidate checklist questions, we conduct several steps to filter out undesirable questions, based on our criteria in §4. The refinement steps, which are detailed below, include:

1. De-duplicating redundant questions.
2. Tagging for generally applicable and section specific questions.
3. Dropping questions that are not LLM enforceable.
4. Selecting a final subset optimized for feedback coverage and diversity.

Redundant Questions We obtain embeddings of each question, using `text-embedding-3-large`, and then calculate the cosine similarity between each pair of questions. We build a graph where each question is a node, and an edge exists between two questions if their cosine similarity is ≥ 0.85 (this threshold is chosen from manual inspection of clusters). Each connected component of the graph is a cluster of similar questions, while isolated nodes are unique questions. For each cluster, we prompt `gpt-4o` to generate a single question consolidating the similar questions.

Tagging for applicability and specificity We keep only questions that are applicable to general encounters, ensuring that they are answerable with a simple "Yes" or "No" for all encounters, without allowing for "N/A" responses. Additionally, we flag questions that reference other note sections, retaining only section-specific questions. This ensures that questions are answerable using only the transcript and the specified note section. Appendix §D.1 contains examples of questions that would be dropped in this step. To implement this, we prompt the `o3-mini` model to tag each question using a zero-shot, chain-of-thought (CoT) approach.

LLM Enforceability We want to ensure that the questions are answerable by LLM-evaluators. Thus, we define **enforceability unit tests**: mini-benchmarks of 10 reference notes per checklist question that pass the question criteria, where each reference note is then rewritten to fail the criteria. A unit test is "passed" if the rewritten note receives a score of "No" for the question. By doing this, we can select the checklist questions that are actually enforceable by LLMs.

We measure the enforceability rate for each checklist question, which is the proportion of rewritten notes that correctly fail the criteria, which is then averaged across all questions into a single **enforceability score** for the checklist. §D.2 further details the implementation of these unit tests. We discard questions with an enforceability score below a threshold of 0.7.

Optimal subset of questions for feedback coverage and diversity The final refinement step selects an optimal subset of checklist questions that maximizes coverage of user feedback while minimizing redundancy and checklist length. We define coverage as the proportion of feedback items addressed by the selected questions, measured using an LLM-based coverage matrix, and diversity as the average dissimilarity (1 minus Jaccard similarity) between the sets of feedback covered by each question. Then for coverage C, diversity D,

[2]This pipeline is illustrative, uses de-identified data, and remains subject to further validation.

Metric	Baseline ($n = 10$)	Feedback ($n = 20$)
Coverage ↑	0.978	**0.987**
Diversity ↑	0.897	**0.923**
Intra-cluster Dist ↓	0.670	**0.667**
Inter-cluster Dist ↑	0.061	**0.080**
LLM enforceability ↑	0.82	**0.89**

Table 2: Evaluation of the final checklists, with respect to feedback coverage, diversity, and LLM enforceability. Diversity is additionally evaluated by intra-cluster and inter-cluster distances. The feedback checklist beats the baseline checklist in each category.

weight α, and length penalty λ, we can define the following objective score:

$$Score(k) = \alpha \cdot C + (1 - \alpha) \cdot D - \lambda \cdot k$$

We use beam search to select the subset of k questions that optimizes this score. Additional implementation details are provided in §D.3.

5 Evaluation

Following all refinement steps, we will have a final set of checklist questions. We then evaluate the utility of the final checklist, using the following suite of evaluation metrics:

- Scores for feedback coverage, feedback diversity, and LLM enforceability.
- Predictive power of the checklist questions.
- Robustness against perturbations.
- Correlation with human preference ratings.

To demonstrate our pipeline, we generate a checklist from feedback data for the *AP* section of the notes. From the ~7700 feedback items that are tagged with the *AP* section, 97 candidate checklist questions are generated. Following our refinement steps, we obtain a final checklist of 20 questions. Our checklist is compared against a baseline checklist of 10 questions, both of which are written out in §E. §F.1 describes our specific generation and refinement results.

5.1 Feedback Coverage & Diversity and LLM Enforceability

Following the definitions given in §4.2, we can measure the coverage, diversity, and LLM enforceability of our checklist questions compared to a baseline checklist. We additionally evaluate diversity by embedding the feedback covered by each question (using `text-embedding-3-large`), and then minimizing intra-cluster distances among questions and maximizing inter-cluster distances between question clusters. Intra-cluster distance is defined as the average distance between all feedback items covered by a question, and inter-cluster distance is defined as the average distance between the centroids of the clusters of feedback items covered by each question.

Our checklist has better feedback coverage and diversity and is more LLM enforceable than the baseline checklist, as shown in Table 2. The feedback checklist has a coverage of 0.987 and a diversity of 0.923, compared to the baseline's coverage of 0.978 and diversity of 0.897. The feedback checklist also has a lower intra-cluster distance and a higher inter-cluster distance than the baseline checklist, indicating that it covers a wider range of feedback items while avoiding redundancy. Our feedback checklist also obtains a higher enforceability score, i.e., it is more answerable by LLMs (see §F.2 for the breakdown across questions).

5.2 Predictive Power

We measure the predictive power of the checklist questions by using them as features to predict the star ratings of the notes. We can do this by training a classifier on the feedback data, where the input is the feedback and the output is the star rating of the note. The checklist questions are used as features for this task, with the mapping of the input to features as the coverage matrix from §4.2. §F.2 describes the setup of the task in more detail.

Our checklist has better predictive power than the baseline checklist as well. Our feedback checklist yields a higher accuracy of 0.70 for predicting the star ratings of the notes, compared to 0.62 for the baseline checklist. We also find that our feedback checklist has a higher macro F1 score of 0.63, compared to 0.43 for the baseline checklist. This indicates that the feedback checklist is better aligned with the star ratings of the notes.

5.3 Robustness against Perturbations

As described in §B.3, we leverage ACI-bench notes as a set of **reference notes** that are of good quality. We then define a set of **perturbations**, i.e., transformations, that can be applied to the reference notes, to simulate poor quality notes. The specific

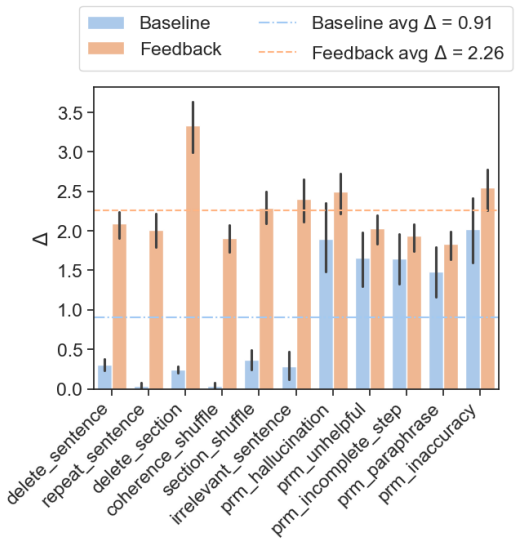

Figure 3: The feedback checklist has a higher perturbation Δ than the baseline checklist. It is more robust against perturbations, particularly for missing information, organization, and redundancy/hallucination.

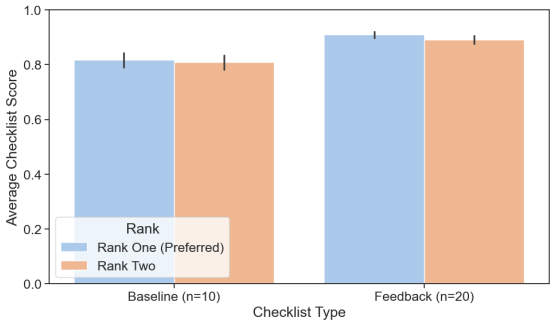

Figure 4: Correlation with human preference ratings is significant for our checklist ($p \leq 0.05$ from a paired t-test, Cohen's $d = 0.28$), but not for the baseline.

perturbations we apply to the reference notes are described in §F.2 and summarized in Table 3. After scoring the reference notes and the perturbed notes with the checklist, we can measure the robustness of the checklist against these perturbations.

For a checklist question, we define its **Perturbation Delta (Δ)** as the score of the perturbed note subtracted from the score of the reference note, averaged over all notes. Since a perturbed note should score lower than the reference note, Δ should be larger for more robust checklist questions. We can then measure the robustness of the full checklist by measuring the average Δ across all questions.

Our checklist is significantly more robust against perturbations than the baseline checklist. As shown in Fig. 3, the feedback checklist has an average perturbation Δ of 2.26, compared to 0.91 for the baseline checklist. The Δ's are significantly greater than 0 for all perturbations ($p < 0.001$, one-sample t-test). In contrast, the baseline shows no significant change for the `repeat_sentence` and `coherence_shuffle` perturbations. We also confirm that most Δ's are significantly larger for our feedback checklist than the baseline, with $p < 0.05$ for a two-sample t-test and a large effect size (Cohen's $d = 2.94$).

Our checklist is particularly robust to perturbations like `delete_sentence` and `delete_section`, which are designed to simulate missing salient information. Furthermore, our checklist is more sensitive to perturbations like `section_shuffle` and `coherence_shuffle`, which are designed to simulate poor writing flow and organization. `repeat_sentence` and `irrelevant_sentence` are also detected by our feedback checklist, but not by the baseline checklist, suggesting that our feedback checklist is better at detecting redundancy and hallucination errors in the notes.

5.4 Correlation with Human Preference Ratings

We use 109 unique pairs of preference ratings for the *AP* section for our evaluation. For each note pair, we compute the checklist score for each note. We then aggregate the scores for the ranked notes and check for statistical significance. Ideally, the preferred note should have a higher checklist score than the non-preferred note.

Our checklist is significantly correlated with human preferences compared to the baseline checklist (see Fig. 4). That is, our checklist produces a significant difference ($p \leq 0.05$ from a paired t-test) in scores between the preferred and non-preferred notes, with prefered notes having the higher score. The baseline checklist does not produce a significant difference in scores between the preferred vs. non-preferred notes.

6 Conclusion

In this work, we propose a method to automatically generate a checklist for evaluating clinical notes, based on real user feedback for notes produced by a commercial Ambient AI company. We show that our generated checklists have more desirable properties than a baseline checklist, and we define a series of evaluation metrics to assess the quality

of the checklists. In particular, we show that our checklists are comprehensive, diverse, predictive of human ratings, and aligned with expert preferences.

Our approach addresses a critical need in healthcare AI for scalable, clinically-grounded evaluation. By systematically distilling feedback from over 21,000 real clinical encounters, we demonstrate that user concerns can be transformed into actionable evaluation criteria. The resulting checklist serves as an interpretable, enforceable tool that can flag potentially problematic notes while maintaining transparency about evaluation criteria.

This work demonstrates the practical value of leveraging large-scale user feedback to create evaluation tools for deployed AI systems. Our pipeline provides a systematic approach to convert real user feedback into structured evaluation criteria, offering a scalable alternative to purely manual review while preserving clinical input and oversight.

Future work includes scaling the pipeline to additional note sections and domains, implementing dynamic and more robust feedback filtering, and incorporating advanced evaluation methods such as feature importance analysis, human studies, and improved LLM-evaluator reasoning to further refine and validate the checklists. Extended discussion of future work can be found in §G.

Limitations

Our pipeline makes several simplifying assumptions, such as excluding "N/A" answers and cross-section comparisons, which may limit the scope and nuance of the resulting checklists. Checklist coverage is inherently limited by the content of user feedback; e.g., if there are no complaints about pronoun usage, there may not be a checklist question about using correct pronouns. Checklist questions that favor comprehensive notes may penalize concise ones that are still clinically sufficient, such as in time-sensitive settings like emergency care. Our methodology could be adapted for these specialties by filtering for specialty-specific feedback, as well as for other contexts (e.g., multi-provider notes).

Our current setup treats all checklist questions with equal weight, and though this assessment is inherently subjective, we acknowledge that clinical significance varies across checklist items. Weighted scoring could be implemented automatically (e.g., Wei et al. (2025)) or added during clinical review of the rubric as a post-hoc step, without redesigning our existing methodology.

We rely heavily on LLMs in our pipeline and evaluation, which introduces its own set of challenges. When using LLMs-as-a-Judge, there is a lack of ground truth labels to determine whether clinical notes satisfy checklist questions, such as for ACI-bench notes. Exhaustive evaluation is difficult, since each checklist question can be a substantial problem on its own. As such, our current metrics are not exhaustive. Finally, we rely on proxies for positive signals, such as internal pairwise preference data, though these proxies also have their own limitations (e.g., poor agreement between raters, though we mitigate this by selecting pairs with at least two raters in agreement).

Ethical Considerations

Our work involves the use of clinical note data and user feedback for the purpose of building automated evaluation pipelines. All proprietary data used in this work, such as user feedback, star ratings, and clinical note content, is handled in compliance with applicable data privacy policies and HIPAA regulations. All PHI is de-identified in accordance with HIPAA safe harbor standard before model training and evaluation; no direct identifiers are transmitted outside the covered environment.

Our checklist is designed as a scalable triage tool, not a replacement for clinical judgment. Our generated checklists are designed to be interpretable and transparent, but further validation with practicing clinicians is necessary before clinical deployment. Clinicians can review the finite set of criteria, after which the checklist can be applied at scale to flag notes for expert attention. We acknowledge that LLM outputs may introduce subtle errors or biases, and we flag this as an area for continued validation. In production, the checklist will be part of a much larger evaluation suite that involves human and clinician oversight at different stages, not to be used as a single criterion for decision making.

Acknowledgments

We thank the anonymous reviewers for their comments, which helped improve this work. We also thank Zack Lipton, Elisa Ferracane-Kelley, Kaveh Moghbeli, Mike Myerburg, and the broader clinical and machine learning teams at Abridge, for their support and feedback throughout this project.

A Additional Related Work

Checklist generation With the utility of checklists being proven across high-stakes domains (Rei-

jers et al., 2017; Chaparro et al., 2019; Brykczynski, 1999; Degani and Wiener, 1993; Haynes et al., 2009), there is a growing body of work on generating checklists automatically with LLMs (Lee et al., 2025; Cook et al., 2024; Pereira et al., 2024; Wei et al., 2025; Li et al., 2025). These works focus on generating checklists specific to individual instructions or data samples (e.g., a summary or user conversation), rather than generalizable checklists that can be applied across a corpus of data.

For other clinical applications, Nan et al. (2017) propose a rule-based method for generating dynamic clinical safety checklists and Zhang et al. (2021) learns optimal checklists for clinical decision support from a set of predefined binarized features. Checklists have also been manually developed by experts, for individual medical notes (Savkov et al., 2022) and generative medical tasks in Chinese (Zhang et al., 2025). Our work aims to automatically generate checklists for clinical notes that apply across encounters, checking for items beyond facts.

Checklist evaluation Wang et al. (2023) propose a method of generating natural language cluster labels based on a goal; we similarly want to generate checklist questions that cover a corpus of feedback, based on the goal of evaluating note quality. Our feedback coverage methodology is loosely inspired by their Propose-Assign-Select framework. Guo et al. (2024) define a testbed of global perturbations to assess metrics for plain language summarization; we draw from these criteria to form our own perturbation benchmark.

B Data

B.1 User Feedback

We retrieve ~22K encounters with user feedback of > 2 words, non-null (1-5) star ratings. Table 1 provides some synthetic examples. The user feedback is free-text, and the star ratings are on a scale of 1-5, with 1 being the worst and 5 being the best; these are obtained from real users of an Ambient AI company that scribes clinical encounters and generates clinical notes. We specifically filter for feedback that is relevant to note quality and content, as opposed to other issues like recording or EHR integration. We use an internal tool to determine the relevant note section (e.g. *HPI*, *AP*) for each piece of feedback and only keep the relevant feedback for each section.

B.2 Human Preference Ratings

We also have access to 506 pairs of note sections with internal preference ratings, which are rated by clinical experts within the company. These pairs of notes have at least two raters agreeing on the preferred note in a pairwise comparison. Each sample of this dataset contains the transcript of the encounter and the pair of notes for the section being rated, with the preferred note being marked.

B.3 Reference Notes: ACI-bench

We are using 207 reference notes and transcripts from ACI-bench (Yim et al., 2023). Each note contains four sections, corresponding to the sections our user feedback is tagged with in parentheses:

- SUBJECTIVE (*HPI_Subjective*) includes items taken during verbal exam and typically written in the chief complaint, history of present illness, and past social history.
- OBJECTIVE EXAM (Physical Exam or *PE*) includes content from the physical examination on the day of the visit.
- OBJECTIVE RESULTS (*Results*) includes diagnostics taken prior to the visit, including laboratory or imaging results.
- ASSESSMENT AND PLAN (*AP*) includes the doctor's diagnosis and planned tests and treatments.

In cases where certain sections are missing, an EMPTY flag is used as the content. We utilize these reference notes to calculate pass rates/checklist scores, generate perturbed notes, and create unit tests.

C LLM Prompts

`gpt-4o` is used for checklist generation.

C.1 Baselines

System message:

```
You are an expert in clinical documentation. You
     want to evaluate the quality of a clinical
    note. You will generate a list of simple yes
    /no questions, such that the "Yes" answer
    corresponds to a good clinical note.
You may optionally specify the specific note
    section that each question pertains to. The
    sections are as follows:
- "subjective" includes items taken during
    verbal exam and typically written in the
    chief complaint, history of present illness,
     and past social history
```

```
- "objective_exam" includes content from the
    physical examination on the day of the visit
- "objective_results" includes diagnostics taken
     prior to the visit, including laboratory or
     imaging results
- "assessment_and_plan" includes the doctor's
    diagnosis and planned tests and treatments
If the question is applicable to the full note,
    then denote "full" as the pertinent section.
```

C.2 Feedback Checklists

Proposer's system message for a given section:

```
You are an expert in clinical documentation.
You will be provided with an itemized list of
    physician feedback on the {section} section
    of medical notes.
Your task is to generate a set of yes/no
    questions that comprehensively reflect this
    feedback.

The questions should aim to identify the
    presence or absence of good documentation
    practices in the {section} section.
The questions should be specific to the {section}
     section and should not reference or depend
    on the content of other sections of the
    medical note.
If a feedback item pertains to multiple note
    sections, focus only on the parts that apply
     to {section} content.
Each question should ideally address multiple
    feedback items rather than targeting only
    one.
Keep questions concise, atomic, and objective;
    avoid complex sentence structure.
For each question, list the corresponding
    INDICES of the feedback item that are
    addressed.

Avoid overly specific questions; instead, favor
    general questions that apply across a
    variety of medical encounters.
Do not include protected health information (PHI
    ) in any questions.

Use third-person language when referring to the
    note.
A "Yes" answer should indicate that the note
    meets good clinical documentation standards.

Incorporate both positive and negative feedback:
- For negative feedback, generate questions that
     would flag a note if it exhibited similar
    issues.
- For positive feedback, generate questions that
     promote those qualities in all notes.

Generate as many questions as necessary to cover
     the feedback comprehensively.
```

Assigner's system message:

```
You will be given an itemized checklist of
    questions and a user feedback.
Indicate which questions cover the feedback.
    Respond as a list of question item numbers.

Questions:
{itemized checklist questions}
```

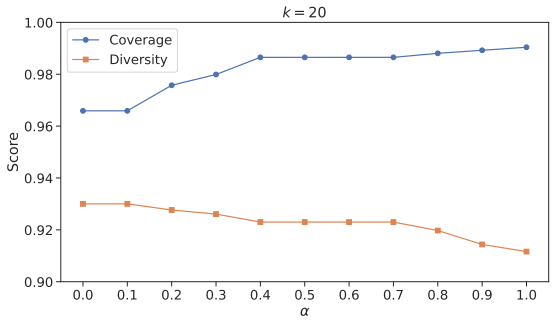

Figure 5: α values for the objective function, where α is the weight of the coverage term. The α value is set to 0.5 for the final checklists, since it provides balance between coverage and diversity.

C.3 Unit Tests

System message for re-writing reference notes to fail checklist criteria:

```
You are an expert in clinical documentation. You
     will be given a checklist question and a
    medical note that fulfills the criteria,
    with respect to the given clinical
    transcript.
Your task is to rewrite the note so that it
    fails the criteria with respect to the
    transcript.
```

User message for re-writing reference notes to fail checklist criteria:

```
Transcript: {reference transcript}

Note: {reference note}

Question: {question}
```

C.4 Feedback Coverage

Assigner's system message:

```
You will be given an itemized checklist of
    questions and a user feedback.
Indicate which questions cover the feedback.
    Respond as a list of question item numbers.

Questions:
{itemized checklist questions}
```

D Extended Refinement Details

D.1 Examples of Flagged Questions

When tagging for applicability, we drop questions like "Is there a comprehensive assessment and plan for all chronic conditions discussed, ensuring nothing important is omitted?" For section-specificity, we flag questions like "Is there a clear separation

between the history of present illness (HPI) and the action plan to ensure there is no overlap?" since they would require access to the *HPI* section to answer.

D.2 LLM Enforceability

The 10 reference notes in each question's mini-benchmark are selected randomly among all the ones that pass the question. We prompt `gpt-4.1-mini` to rewrite the reference notes to fail; see §C.3 for the prompt used to rewrite the reference notes to fail the checklist questions. For example, if the checklist question is "Does the note use the correct pronouns?" and the reference note uses "she", then the note could be rewritten to use "he" to fail the criteria.

Post-processing is done to ensure only the rewritten note is produced, i.e., no explanations. Manual verification of 50 pairs of notes spanning 27 different checklist questions has yielded a 90% validation rate (rewritten notes that correctly fail); the remaining 10% of rewritten notes are still of inferior quality (missing/inaccurate details), but do not necessarily fail the criteria of the question.

D.3 Optimizing for Feedback Coverage and Diversity

Ideally, the checklists questions should maximize coverage of user feedback while avoiding redundancy. This refinement step accounts for addressing the most salient feedback points, while avoiding questions that are too specific to a single encounter or too general and uninformative.

Coverage is defined as whether each feedback is supported by each question, and it is measured by the assigner LLM, with the prompt defined in §C.4. We obtain a "coverage matrix", where (i, j) value is 1 if question i covers feedback j, and 0 otherwise. Total coverage rate C, is the sum of the coverage matrix divided by the number of feedback items.

To avoid redundancy, we also want feedback *diversity* among the checklist questions' coverage sets. For questions i and j with covered sets of feedback F_i and F_j, we define the *similarity* S_{ij} of the feedback items covered by questions i and j as their Jaccard similarity, i.e., $S_{ij} = |F_i \cap F_j|/|F_i \cup F_j|$. Then for a checklist of n questions, we can define the diversity of question i as one minus its average similarity with all other questions:

$$D_i = 1 - \frac{1}{n-1} \sum_{j=1, j \neq i}^{n} S_{ij}$$

Total diversity D is the average of the diversity of all questions.

Since we also want to avoid overly length checklists, we also add a weight λ for penalizing length. Finally, for a checklist of k questions, we can define a objective score to balance coverage and diversity of a checklist, given α as the weight:

$$Score(k) = \alpha \cdot C + (1 - \alpha) \cdot D - \lambda \cdot k$$

We can then use beam search to select the optimal subset of k questions. Fig. 5 shows the α values for the objective function, where α is the weight of the coverage term. We select a final α value of 0.5, since it provides balance between coverage and diversity.

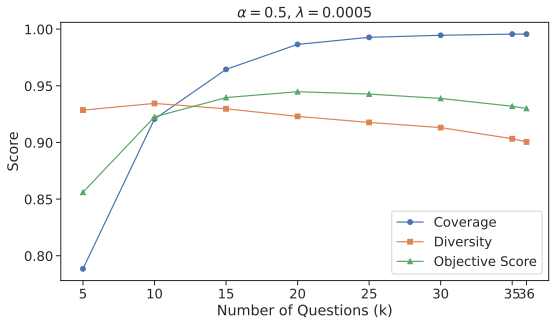

Figure 6: Objective score (coverage and diversity) vs. length of checklist. $k = 20$ is the optimal number of questions.

E Checklist Questions

The checklists are intended for quality assessment, not reimbursement or coding optimization; additional audit measures are required to prevent misuse.

Baseline Checklist for *AP* ($n = 10$)

1. Does the section include a clear and concise diagnosis or differential diagnosis for each problem?
2. Are the rationale and evidence for each diagnosis clearly documented?
3. Does the section provide a detailed plan for addressing each identified problem, including specific treatments and interventions?

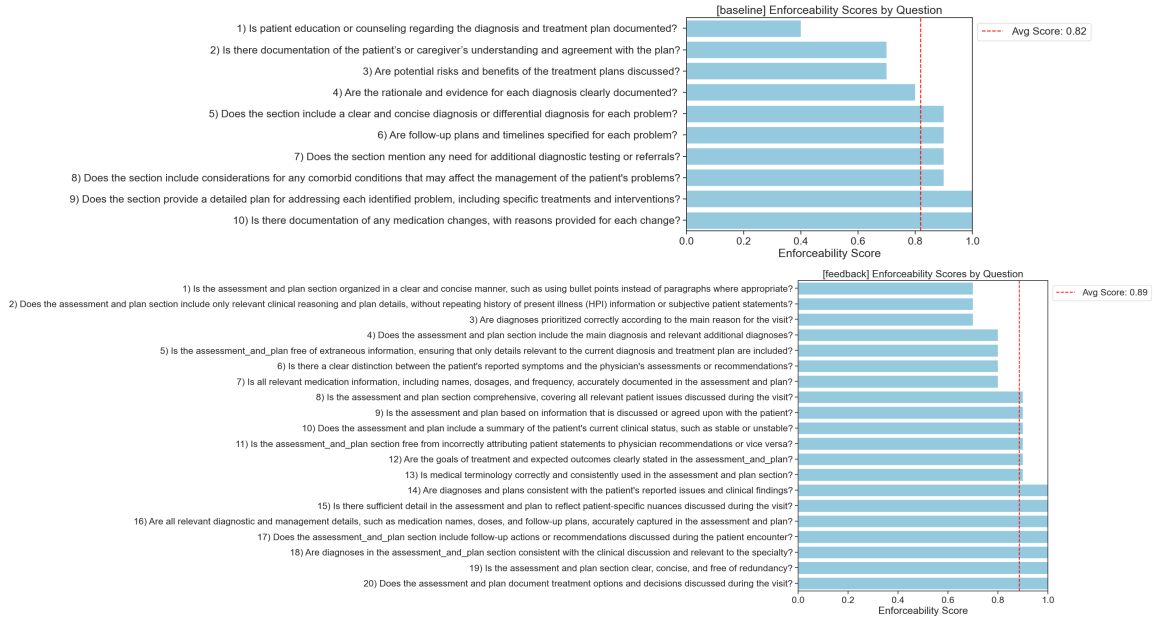

Figure 7: The enforceability score of each checklist question, indicating how LLM enforceable each one is. The feedback checklist has both a greater quantity of perfectly enforceable questions and a higher average rate of enforceability.

Name	Description	Section	# Notes
`delete_sentence`	delete random sentences from each section	All	207
`delete_section`	remove a whole section of the note	All	207
`repeat_sentence`	repeat random sentences in each section	All	207
`coherence_shuffle`	shuffle sentences within each section	All	207
`section_shuffle`	shuffle sentences across sections	All	207
`irrelevant_sentence`	insert irrelevant sentences (e.g., from other notes)	All	207
`prm_inaccuracy`	errors involving incorrect info or unsupported topics	AP	67
`prm_hallucination`	introduce unrelated subject entities	AP	67
`prm_unhelpful`	introduce vague, confusing, or incomplete expressions	AP	67
`prm_incomplete_step`	randomly removing specific steps from A&P	AP	67
`prm_paraphrase`	Gemini Pro 1.5 paraphrased note sections	AP	67

Table 3: Descriptions of the perturbed notes for evaluation. The number of notes is the number of reference notes that were perturbed with each perturbation. Perturbations beginning with `prm` are from Wang et al. (2025b)

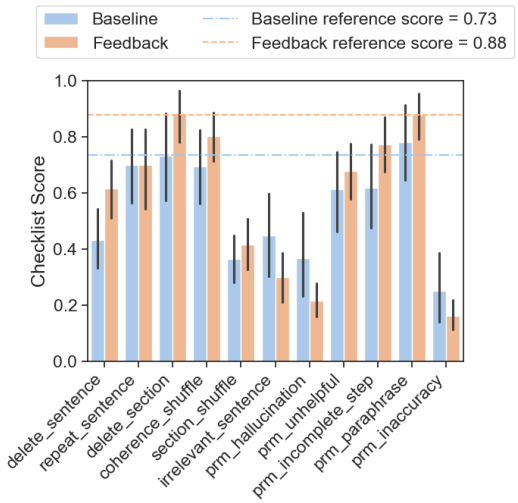

Figure 8: The feedback checklist has a higher average score for the reference notes than the baseline checklist.

4. Are follow-up plans and timelines specified for each problem?
5. Does the section mention any need for additional diagnostic testing or referrals?
6. Is patient education or counseling regarding the diagnosis and treatment plan documented?
7. Is there documentation of the patient's or caregiver's understanding and agreement with the plan
8. Does the section include considerations for any comorbid conditions that may affect the management of the patient's problems?
9. Is there documentation of any medication changes, with reasons provided for each change?

10. Are potential risks and benefits of the treatment plans discussed?

Feedback Checklist for *AP* ($n = 20$)

1. Is the assessment and plan section organized in a clear and concise manner, such as using bullet points instead of paragraphs where appropriate?
2. Is the assessment and plan section comprehensive, covering all relevant patient issues discussed during the visit?
3. Are diagnoses and plans consistent with the patient's reported issues and clinical findings?
4. Does the assessment and plan section include the main diagnosis and relevant additional diagnoses?
5. Is there sufficient detail in the assessment and plan to reflect patient-specific nuances discussed during the visit?
6. Does the assessment and plan section include only relevant clinical reasoning and plan details, without repeating history of present illness (HPI) information or subjective patient statements?
7. Are diagnoses prioritized correctly according to the main reason for the visit?
8. Is the assessment and plan based on information that is discussed or agreed upon with the patient?
9. Are all relevant diagnostic and management details, such as medication names, doses, and follow-up plans, accurately captured in the assessment and plan?
10. Does the assessment and plan include a summary of the patient's current clinical status, such as stable or unstable?
11. Is the assessment and plan section free from incorrectly attributing patient statements to physician recommendations or vice versa?
12. Does the assessment and plan section include follow-up actions or recommendations discussed during the patient encounter?
13. Is the assessment and plan free of extraneous information, ensuring that only details relevant to the current diagnosis and treatment plan are included?
14. Are diagnoses in the assessment and plan section consistent with the clinical discussion and relevant to the specialty?
15. Is there a clear distinction between the patient's reported symptoms and the physician's assessments or recommendations?
16. Are the goals of treatment and expected outcomes clearly stated in the assessment and plan?
17. Is the assessment and plan section clear, concise, and free of redundancy?
18. Does the assessment and plan document treatment options and decisions discussed during the visit?
19. Is all relevant medication information, including names, dosages, and frequency, accurately documented in the assessment and plan?
20. Is medical terminology correctly and consistently used in the assessment and plan section?

F Additional Evaluation and Results

F.1 Generation and Refinement

The ~7700 feedback items for the *AP* section are randomly split into 8 batches of approximately 900-1000 items each. 97 candidate checklist questions are generated from this set of feedback.

Filtering out redundant questions and tag for applicability and specificity results in 50 questions. For example, the questions "Is the assessment and plan section well-organized and clearly separates different medical issues or diagnoses?" and "Is the assessment and plan organized in a way that is easy to read, with distinct separation between different patient problems?" are clustered and merged into a single question: "Is the assessment and plan section well-organized with clear separation of medical issues or diagnoses?"

These 50 questions are then evaluated for LLM enforceability. We find that 36 questions have a unit test threshold of at least 0.7, and we discard the remaining 14 questions. Such discarded questions include: "Is unnecessary and speculative language avoided in the assessment and plan section?" The average enforceability score for the remaining questions is 0.9.

Finally, we select a subset of k questions that maximize coverage and diversity. Setting $\alpha = 0.5$ and $\lambda = 0.0005$, we find that $k = 20$ provides the optimal balance of coverage and diversity with length of the checklist (see Fig. 6).

F.2 Evaluation

Predictive Power For simplicity, we set up the task as a binary classification task, by using data

with star ratings of 1 as negative and 5 as positive (1113 and 680 samples respectively). We then train a Logistic Regression model with 5-fold cross-validation on 80% of the feedback and test with the remaining 20%.

LLM Enforceability Results From Fig. 7, we see that the baseline checklist has an average unit test scores of 0.82 over 10 questions, while the feedback checklist has an average unit test score of 0.89 over 20 questions.

Robustness to Perturbations We are inspired by the perturbations defined by Guo et al. (2024) for our use case, though we implement our own methods. We also use data from Wang et al. (2025b) as perturbed versions of *AP* note sections. Specifically, we apply each of the following perturbations in Table 3 to the reference notes. With this benchmark, we can measure the robustness of our final checklists against changes in informativeness, coherence, and factuality.

We also see that our feedback checklist produces a higher average score for the reference notes than the baseline checklist (Fig. 8).

G Future Work

Some evaluation metrics, like feedback coverage/-diversity and LLM enforceablity, can be incorporated into the checklist refinement pipeline, to help select for the most salient questions. This would allow the refinement process to be more iterative.

Scaling the Pipeline We would like to scale the pipeline to generate checklists for other note sections. We would also like to implement a dynamic pipeline, where the checklist is updated as new feedback comes in. This would allow us to continuously improve the checklist and adapt it to changing user needs.

Additional Feedback Filtering The feedback we receive is often unstructured and noisy. There is a lot of redundancy in the feedback, and not all of it is actionable. So, we can apply additional filtering steps to the feedback, such as grouping by specialty, filtering out un-actionable feedback, and clustering similar feedback.

Question Importance for Predicting Human Ratings We can further identify questions that have the greatest influence on performance, using feature importance measures like SHAP values (Lundberg and Lee, 2017). These values can also help assign priority to the order of questions in the checklist, so that the most important questions are asked first or given more weight in the final checklist score.

Human Evaluation To validate the quality of our checklists, we will run human evaluation. Some potential user studies include:

- Pairwise preference of checklists (e.g., rate baseline vs. feedback checklist questions)
- Have physicians conduct evaluation of real deployed notes using checklists, and see if there is higher agreement between raters compared to evaluationg without a checklist

Generalizability To show the generalizability of our checklist generation method, we would like to apply it to some alternate domain. We are still brainstorming what dataset(s) we could use for this. Requirements of the data include user feedback and ratings for some product that should fulfill certain standards.

Tuning a LLM-evaluator We can further try tuning LLM-as-a-Judge specifically for our task of checklist scoring. While the current setup simply has the LLM-evaluator produce a "Yes"/"No" answer for each checklist question, we can also allow the LLM to reason about the note and checklist question and provide a more detailed explanation of its score. Allowing the evaluator to cross-validate the note with structured EHR data could enhance accuracy by catching factual inconsistencies that text-only evaluation misses.

FlexDoc: Parameterized Sampling for Diverse Multilingual Synthetic Documents for Training Document Understanding Models

Karan Dua, Hitesh Laxmichand Patel, Puneet Mittal, Ranjeet Gupta, Amit Agarwal, Praneet Pabolu*, Srikant Panda*, Hansa Meghwani, Graham Horwood, Fahad Shah

Oracle AI

Correspondence: karan.dua@oracle.com

Abstract

Developing document understanding models at enterprise scale requires large, diverse, and well-annotated datasets spanning a wide range of document types. However, collecting such data is prohibitively expensive due to privacy constraints, legal restrictions, and the sheer volume of manual annotation needed - costs that can scale into millions of dollars. We introduce **FlexDoc**, a scalable synthetic data generation framework that combines **Stochastic Schemas** and **Parameterized Sampling** to produce realistic, multilingual semi-structured documents with rich annotations. By probabilistically modeling layout patterns, visual structure, and content variability, FlexDoc enables the controlled generation of diverse document variants at scale. Experiments on Key Information Extraction (KIE) tasks demonstrate that FlexDoc-generated data improves the absolute F1 Score by up to **11%** when used to augment real datasets, while reducing annotation effort by over **90%** compared to traditional hard-template methods. The solution is in active deployment, where it has accelerated the development of enterprise-grade document understanding models while significantly reducing data acquisition and annotation costs.

1 Introduction

1.1 Document Understanding

Document Understanding refers to the task of automatically interpreting and extracting structured information from documents that combine text, layout, and visual elements (Agarwal et al., 2025b; Agarwal and Pachauri, 2023). Unlike plain-text NLP, it requires reasoning over both content and structure, making it inherently multimodal. In enterprise and industrial settings, this capability enables critical workflows such as invoice processing, claims automation, identity verification, and compliance auditing. Common applications include key information extraction, document classification, and form or table understanding - tasks that are especially relevant in data-intensive domains like finance, healthcare, insurance, and business process automation (Pattnayak et al., 2024, 2025b; Panda et al., 2025a,b).

1.2 Multi-Modal Document Understanding Models

The spatial position and context of elements are critical for document understanding. Recent multimodal models (Xu et al., 2020; Yang et al., 2017; Katti et al., 2018; Huang et al., 2022) combine textual, visual, and positional features to capture both content and layout. Vision-language models like Phi-4-Multimodal (Microsoft, 2024), Qwen-VL (Bai et al., 2023a) and LLaVA (Liu et al., 2023b) further improve spatial reasoning through techniques like M-RoPE and image-text alignment.

Training these models, however, requires large, diverse annotated datasets - often impractical to collect due to privacy, legal, and cost constraints. Synthetic data generation offers a scalable alternative, enabling controlled generation without the limitations of real-world data acquisition.

1.3 Hard Template Based Document Generators

A common approach to synthetic document generation uses hard template-based methods (Monsur et al., 2023; Capobianco and Marinai, 2017; Gupte et al., 2021; Agarwal et al., 2024b,a). This typically involves collecting real documents, manually annotating and whiting out sensitive values (e.g., names, addresses), and replacing them with type-consistent fake values, as illustrated in Figure 5 in appendix. While effective for highly structured documents such as IDs and passports (Monsur et al., 2023; Cui, 2021; Guillaume Jaume, 2019; Li et al., 2021; Shi et al., 2017; Xu et al., 2021; Zhang et al., 2021; Luo et al., 2023; Lee et al., 2022; Patel et al.,

*Work done during employment with Oracle Corporation

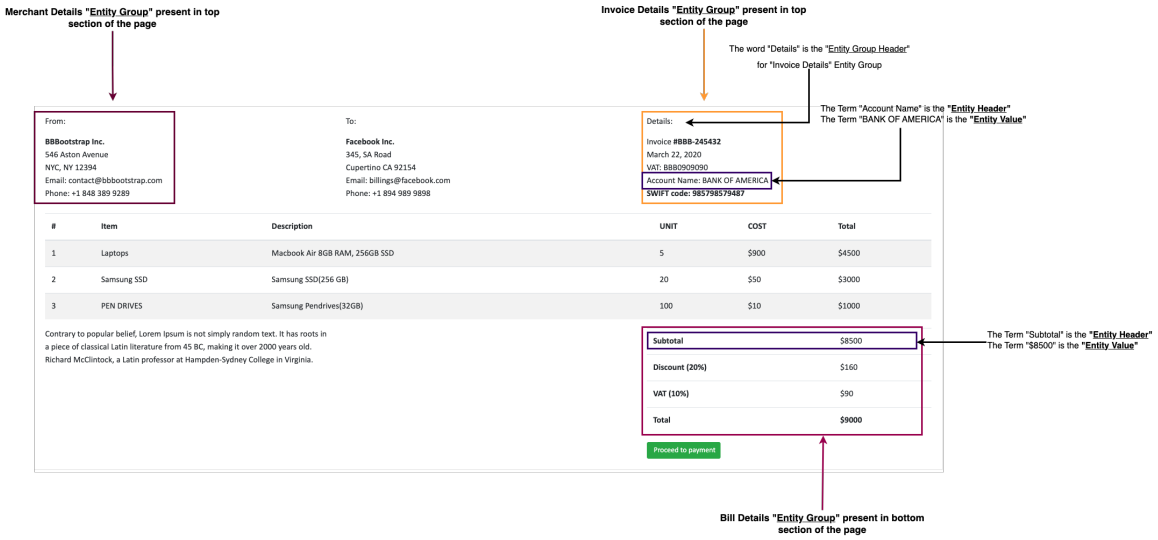

Figure 1: Typical patterns in an invoice

2024; Agarwal et al., 2024c), this method has notable limitations when applied to semi-structured documents. The layout diversity is constrained by the original templates, limiting positional variation of fields like merchant names or table sizes (Hong et al., 2022). Predefined whiteout regions often fail to accommodate longer replacement values, and inserting new content can degrade visual fidelity. Moreover, the approach is difficult to scale, as each template requires collecting and manually annotating real documents. Figure 5 in appendix describes the hard template based approach with an example.

1.4 Privacy

Data collection and its use is subject to several privacy challenges, including but not limited to data use restrictions, data regulations such as GDPR and ethical considerations to ensure diverse representations while avoiding bias. Models trained on real-world data may also inadvertently reveal private information during inference.

To address the above challenges, we introduce **FlexDoc** - a framework to generate diverse, multilingual, annotated synthetic document datasets for training Document Understanding models. Specifically:

- We introduce a novel algorithm called **Parameterized Sampling** centered around **Stochastic Schemas** which can generate hundreds of thousands of unique semi-structured documents using a single definition, **along with annotations** (key value labels, bounding boxes, document types, table boundaries etc.) with **guaranteed accuracy**.
- We also present a novel **Dynamic Virtual Grid Algorithm** that organizes document elements into non-overlapping regions while enhancing visual diversity.
- The generation process uses a fake value generator, eliminating privacy risks and can be configured for locale-specific tuning.
- The pipeline is **multilingual**. The same stochastic schema written in English can be used to generate documents in different languages by switching just two simple configurations.

2 Related Work

Recent work has explored using large language models (LLMs) for synthetic data generation. Dua et al. (2025) introduced an end to end pipeline for generating synthetic data for training speech models using LLMs and speech audio generation and voice standardization models. Josifoski et al. (2023) introduced SynthIE, prompting LLMs to generate input-output pairs for information extraction (IE) without labeled data. GuideX (De La Fuente et al., 2025) generates schema-guided examples for fine-tuning LLaMA 3.1 (Pattnayak et al., 2025a; Agarwal et al., 2025a), while Bhattacharyya and Tripathi (2024) distill soft labels from multimodal models like Claude 3 into compact KIE models. In specialized domains, Woo et al. (2024) synthesize clinical Q&A pairs, showing that distilled models can rival their teachers.

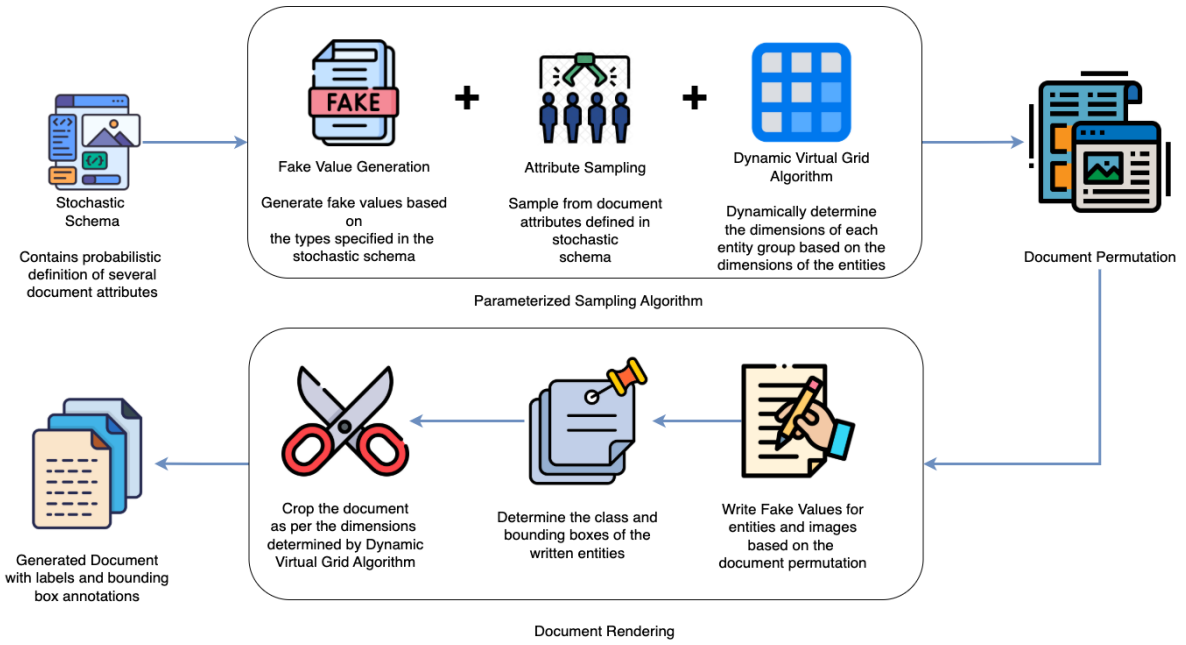

Figure 2: High-Level description of FlexDoc for generating Synthetic Annotated Documents

For visually rich documents, most approaches rely on hard templates. SynthNID (Monsur et al., 2023) overlays fake values onto ID templates, while Genalog (Gupte et al., 2021) uses HTML/CSS templates with synthetic content and degradation steps. Raman et al. (2022) explored variational templates by treating document components as random variables, though their scope was limited to layout recognition.

On the modeling side, LayoutLM (Xu et al., 2020; Huang et al., 2022) pioneered multimodal pretraining with text and layout features. More recent models like Qwen-VL 2.5 (Bai et al., 2023b), LLaMA 3.2 Vision, Phi-4 Multimodal (Microsoft, 2024), and LLaVA (Liu et al., 2023a) advance spatial reasoning through visual-text alignment and hard negative mining (Meghwani et al., 2025). GPT-4o (OpenAI et al., 2024; Chen et al., 2025; Yan et al., 2025) introduces native image generation with improved attribute binding and text clarity, though it lacks fine-grained control and diversity beyond prompt variations.

3 Methodology

The subsequent sections detail the rationale behind FlexDoc and systematically explain its components. The detailed algorithm is described in Figure 4 in appendix.

3.1 Intuition

3.1.1 Patterns in Semi-Structured Documents

The format of information within semi-structured documents like invoices and receipts often adheres to identifiable patterns. Typically, the data within such documents tends to display the following characteristics:

1. Documents contain known identifiable elements (e.g., **Merchant Name**, **Invoice Date**) with specific types (text, date, number). We refer to each as an **entity**, and its value as the **entity value**.

2. Entities typically follow specific header texts (e.g., **Merchant Name**, **Sold by**), which guide accurate identification. We call this the **entity header**.

3. Entities are grouped (e.g., Merchant Details, Invoice Details), forming **entity groups**.

4. These groups may also be introduced by header text (e.g., **Seller Information**), called **entity group headers**.

5. Documents exhibit structured layouts with consistent fonts, colors, and alignments across entities and groups.

Figure 1 describes such properties with an example invoice.

3.1.2 Variations in Semi-Structured Documents

While semi-structured documents often follow recognizable patterns, they also exhibit significant variation in entities, entity groups, headers, and layout structures - adding complexity to document understanding. Based on our analysis across diverse document types, we observe the following variations:

1. Entity groups can appear anywhere on the page (e.g., Merchant Details may be at the top or bottom).
2. Placement within a section is not fixed (e.g., Customer Details may appear top-left, top-right, or center).
3. Some documents may omit certain entity groups (e.g., Shipping Details or Payment Terms may be absent).
4. Not all entity groups include headers (e.g., Merchant Details may lack a header).
5. Headers, if present, vary in wording (e.g., Customer Details may appear as **Buyer Details** or **Client Details**).
6. Entity groups can be formatted differently - stacked, tabular (vertical/horizontal), or mixed - with varied table structures and formatting.
7. Some entities may be missing (e.g., Invoice Due Date or Purchase Order Number).
8. Entities may or may not have headers (e.g., Customer Name might lack a label).
9. Headers for entities vary in wording (e.g., **Subtotal** vs. **Sub-Total Amount**).
10. The order of entities within a group is inconsistent (e.g., email and phone order varies in Customer Details).
11. Fonts and colors differ across documents and between entity headers, group headers, and values.
12. Entity values differ widely (e.g., different customer names).
13. Entities may be left, right, or center-aligned based on context.

Figure 6 in appendix depicts these variations by comparing two invoices side by side.

3.2 Framework/Algorithm

The FlexDoc algorithm, described in Figure 2, consists of three major components: A **Stochastic Schema**, a **Parameterized Sampling** algorithm, and a **Document Rendering** algorithm.

3.2.1 Stochastic Schema

Building on identified patterns and variations, we construct stochastic schemas - where element properties are defined as random variables, with either specified distributions or value ranges. For example, rather than fixing the number of rows in the Item Details table, we use a uniform distribution and sample a value at generation time.

Stochastic schemas can also define the presence of elements probabilistically. For instance, the Customer Phone Number entity may appear in a document based on a predefined probability, reflecting real-world variability. Additionally, stochastic schemas specify style and structural attributes - like fonts, colors, and grid layouts - under a shared configuration.

A document can be defined by a stochastic schema $\mathcal{T}_s$, consisting of entity groups $\mathcal{G} = \{G_1, \ldots, G_K\}$. Each entity group G_k is defined as:

$$G_k = (\mathcal{E}_k, \mathcal{H}_k, p_k, \alpha_k)$$

- $\mathcal{E}_k = \{e_{k1}, \ldots, e_{kn}\}$: set of entities
- $\mathcal{H}_k$: set of possible group headers
- $p_k \in [0, 1]$: probability of group appearance
- α_k: layout attributes (e.g., preferred sections, alignment, table format)

Each entity $e_{ki} \in \mathcal{E}_k$ is a tuple:

$$e_{ki} = (T_{ki}, \mathcal{H}_{ki}, p_{ki}, \beta_{ki})$$

- T_{ki}: entity type (e.g., name, address)
- $\mathcal{H}_{ki}$: header label variants
- $p_{ki} \in [0, 1]$: probability of entity appearance
- β_{ki}: visual/layout attributes

These schemas, defined as JSONs, serve as loose specifications. At runtime, the algorithm samples from various distributions to generate diverse document permutations, enabling the creation of hundreds of thousands of unique documents. Appendix B provides an example of an entity group definition and describes related attributes and style configuration.

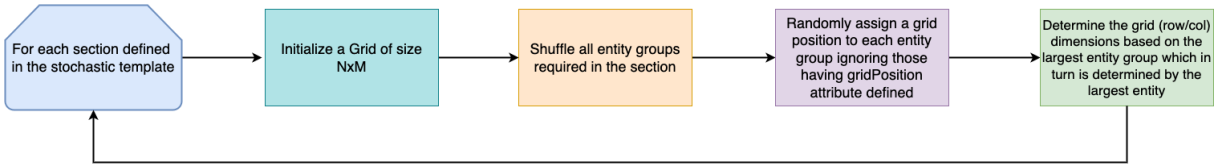

Figure 3: Dynamic Virtual Grid Algorithm

3.2.2 Parameterized Sampling Algorithm

Entity Fake Value Generation: Entity values are generated using a type-specific value generator:

$$v_{ki} = f_{T_{ki}}(\theta)$$

where $f_{T_{ki}}$ denotes a generator function selected based on the entity type T_{ki}, and θ includes generation parameters such as locale, format, and value constraints.

To implement this, we use the Python library Faker (Faraglia, 2014), along with custom fake value generators. Faker supports generating synthetic data for various entities (e.g., names, addresses, phone numbers) across multiple locales.

Each stochastic schema includes a generator class defined within the same JSON schema. A typical generator class definition is shown below:

```
"fake_value_generator_class":
"utils.doc_generator.InvoiceGenerator"
```

The type of each entity defined in stochastic schema is utilized by the generator class to produce entity values. For e.g. a merchant name may be of type **name**, while a merchant address may be of type **address**.

Attribute Sampling: We utilize a sampling algorithm to freeze the stochastic definitions defined in the schema. Each instance of sampling these attributes generates a **document permutation**. A document permutation is a frozen outline of all the stochastic attributes required in a document. From a single stochastic schema, thousands of distinct document permutations can be generated. An instance of a document permutation is created by simply replacing fake values for each entity.

A document permutation $\mathcal{T}_p$ is generated by freezing the stochastic schema $\mathcal{S}$:

$$\mathcal{T}_p = \{G_k, e_{ki} | G_k, v_{ki}, \alpha_k, \beta_{ki}, H_k, H_{ki}, \ldots\}$$

where each component - entity/group presence, value, layout, and style - is sampled from schema-defined probabilities or distributions.

Table 7 in appendix describes the techniques used to sample the attributes in stochastic schema.

Dynamic Virtual Grid Algorithm: Documents often consist of multiple sections, each of which may contain numerous entity groups. While attribute sampling determines the designated section for each entity group, placing those groups within the sections and writing on the canvas poses several challenges: random positioning can cause overlaps, fixed sizes limit layout flexibility, and sequential placement may disrupt alignment.

To address this, we introduce a **Dynamic Virtual Grid Arrangement** algorithm. Each section is treated as a virtual grid whose dimensions are schema-driven. Entity groups are placed into cells, and row/column sizes are dynamically adjusted to minimize whitespace and preserve visual structure.

Figure 3 provides an overview; a detailed example is described in Figure 7 in appendix.

3.2.3 Document Rendering Algorithm

Let the document canvas be divided into a grid $\mathcal{C} \in \mathbb{R}^{H \times W}$, with each entity group assigned to a grid cell via the mapping:

$$\phi : G_k \rightarrow (i, j)$$

where G_k is the k-th entity group and (i, j) its target cell on the canvas.

We define a rendering function $\mathcal{R}(\mathcal{T}_h, \phi)$ that draws sampled entity groups onto a blank canvas based on grid positions and layout attributes from the stochastic schema $\mathcal{T}_h$, while recording bounding boxes for annotation.

Rendering uses the Pillow library (Clark, 2015), respecting the Dynamic Virtual Grid Arrangement and frozen layout constraints to ensure consistent structure and accurate annotations. A high-level overview is provided in Figure 8 in appendix.

Final document and annotation output:

$$\mathcal{I} = \mathcal{R}(\mathcal{T}_h, \phi), \quad \text{Ann} = \{(b_{ki}, v_{ki}), (\text{class labels})\}$$

Here, $\mathcal{I}$ is the rendered image, and Ann the set of annotations - each containing a bounding box

b_{ki}, value v_{ki}, and class labels, which vary by task (e.g., per-entity labels in KIE).

3.3 Multilinguality

The algorithm can be configured to generate data in different languages (one language per document) while using the same stochastic schema defined in English. Configuration *faker_locale* switches the faker locale to generate entity values in the target language while `{"translation": {"enable": "True", "target_lang_code": "<lang_code>"}}` uses a machine translation engine to translate entity and entity group headers defined in the JSON schema to the target language.

Example documents along with KIE specific annotations generated using FlexDoc are available in Appendices C and D.

4 Evaluation Results

Experimentation settings, including the choice of models and datasets for evaluation are thoroughly detailed in Appendix A.

4.1 Downstream Model Performance

Train Dataset	LayoutLM	Phi-4
Zero Shot	NA	31.2
Synthetic 5k Only	54.1	53.3
DocILE Only (Baseline)	72.7	74.6
DocILE + 1k Synthetic	76.3	79.8
DocILE + 2k Synthetic	78.8	82.4
DocILE + 3k Synthetic	81.8	83.1
DocILE + 4k Synthetic	82.7	85.3
DocILE + 5k Synthetic	**82.9**	**85.6**

Table 1: F1 scores when incrementally adding FlexDoc-generated synthetic data to the DocILE dataset.

Train Dataset	LayoutLM	Phi-4
Zero Shot	NA	23.1
Synthetic 5k Only	47.3	44.4
IDSEM Only (Baseline)	65.5	71.2
IDSEM + 1k Synthetic	67.3	74.5
IDSEM + 2k Synthetic	69.1	76.0
IDSEM + 3k Synthetic	73.3	77.3
IDSEM + 4k Synthetic	74.2	78.6
IDSEM + 5k Synthetic	**75.6**	**79.5**

Table 2: F1 scores when incrementally adding FlexDoc-generated synthetic data to the IDSEM dataset (Spanish invoices).

We assess FlexDoc's effectiveness on the Key Information Extraction (KIE) task - one of the most complex tasks in Document Understanding - using both the DocILE (Šimsa et al., 2023) (English) and IDSEM (Sánchez et al., 2022) (Spanish invoices) datasets. We first train LayoutLM (an encoder-based multimodal model) and Phi-4-Multimodal-Instruct (a decoder-based generative multimodal model) on these real datasets (as baselines), and then incrementally augment them with 1k–5k FlexDoc-generated synthetic samples.

For DocILE, augmenting with synthetic data results in significant performance improvements, with LayoutLM achieving an F1 score of **82.9%** and Phi-4 reaching **85.6%** after adding 5k synthetic samples - an increase of up to **10.2%** for LayoutLM and **11%** for Phi-4 against the baseline.

Similarly, on the IDSEM dataset, incrementally adding synthetic data boosts performance significantly, with final F1 scores of **75.6%** for LayoutLM and **79.5%** for Phi-4 after adding 5k synthetic samples - showing an improvement of **10.1%** for LayoutLM and **8.3%** for Phi-4 against the baseline.

These results demonstrate FlexDoc's effectiveness in enhancing KIE task performance in both English and Spanish invoice datasets, highlighting its potential for multilingual applications in document understanding tasks.

4.2 Ablation Study - Dynamic Virtual Grid Algorithm

We also evaluate the effectiveness of the Dynamic Virtual Grid Algorithm by replacing it with a baseline method that randomly places entities in non-overlapping positions without considering layout structure. When this algorithm is disabled, LayoutLM's performance (with 5k synthetic documents) drops from **82.9%** to **75.4%**, and Phi-4's from **85.9%** to **80.6%**. This highlights the critical role of structured placement in enhancing the quality and utility of synthetic documents for key information extraction tasks.

4.3 Comparison with Hard-Template Approach

Approach	LayoutLM (F1)	Phi-4 (F1)	Effort (mins)
Hard Template	**69.8**	**72.2**	1500
FlexDoc	67.4	69.8	**150**

Table 3: Performance and annotation effort comparison for Hard Template vs. FlexDoc approaches on Insurance Cards Dataset.

We compare FlexDoc against the widely used hard-template-based generation approach. To assess robustness, we evaluate on a proprietary insur-

ance card dataset, where FlexDoc achieves comparable performance while reducing annotation effort by approximately **90%**. FlexDoc offers a substantial scaling advantage: the annotation cost remains constant at 150 minutes for 3,000 samples, while traditional hard-template methods require a linear increase in annotation time as the dataset size grows.

4.4 Diversity Analysis

Dataset	Mean Pairwise Similarity
DocILE - 5k Documents	0.52 ± 0.05
FlexDoc - 5k Documents	0.55 ± 0.04
SROIE - 1k Documents	0.40 ± 0.02
FlexDoc - 1k Documents	0.43 ± 0.04

Table 4: Mean pairwise similarity across different datasets, with standard deviation.

We also evaluate the diversity of datasets generated by FlexDoc by comparing them to real-world benchmarks: DocILE and SRIOE. We compute mean pairwise similarity on datasets of comparable size (5000 samples for DocILE, 1000 for SRIOE), using embeddings from a LayoutLM model suited for document understanding. The results show that FlexDoc-generated data achieves diversity levels comparable to both real datasets. Moreover, the small deviations confirm the reliability of the results and further demonstrate that the generated documents are diverse without being dominated by outliers.

5 Conclusion

High-quality annotated data remains a major bottleneck for scaling document understanding in enterprise settings. We introduce a robust, extensible framework for generating realistic, diverse, and multilingual synthetic documents that mirror real-world complexity. FlexDoc enables rapid development of layout-aware models, greatly reducing the need for costly manual annotation. While our experiments target invoice-based KIE, the framework generalizes across document understanding tasks and is already in enterprise deployment, accelerating model development and significantly reducing data acquisition and annotation costs.

6 Limitations and Future Work

The data generator presented in this work aims to produce diverse documents by randomizing a large number of document attributes. While the permutations obtained by randomizing such a large number of variations work well for semi-structured documents, this approach is not particularly useful for fully structured, visually rich documents such as driving licenses, passports, etc. Such documents usually do not demonstrate much diversity, at least within a specific category. For example, driving licenses in the United States would have about 50-80 variations depending on the issuing state. The majority of the diversity is derived from variations in values (license holder's name, address, etc.) in such documents. These documents also contain visually rich backgrounds. For example, the driving license issued by Massachusetts contains an image of the State House in the background.

For these reasons, our approach is not suitable for generating synthetic documents for fully structured, visually rich documents. Hard-template-based approaches are still the most effective for such cases since the cost of annotation is not too high for documents with limited variations.

However, hard-template-based approaches have certain limitations as well, such as a loss of visual features from the background when filling in synthetic values. In the future, we would like to extend our approach to generate such documents while addressing the limitations of a hard-template-based approach.

Additionally, FlexDoc doesn't generate semantically meaningful fake values. For example, the total amount in the invoice doesn't add up to amount of individual items. Therefore, we also plan to introduce semantic value generators in the future. Finally, we acknowledge that some type of documents may exhibit cultural variations and FlexDoc doesn't account for that when generating documents in other languages using the common stochastic schema.

Acknowledgments

The work was conducted during employment with and funded by Oracle Corporation (AI Services).

Appendices

A Experimentation Settings

A.1 FlexDoc Generated Data

For the purpose of experiments under Evaluation Results, the stochastic attributes in the JSON schema for FlexDoc generated data are defined using informed and reasonable approximations, however, the JSON can be modified to mimic other data distributions as well.

A.2 Choice of Datasets and Models

The experiments (for documents in English) are conducted using the DocILE dataset for benchmarking. DocILE is the largest open-source dataset in english language for key information extraction (KIE). Alternative datasets such as KVP10k and SROIE also exist, but they are less suitable for our use case.

KVP10k contains semi-structured documents, but it lacks explicit document type labels (e.g., receipts, invoices). Since our approach generates targeted documents, knowing the document type with certainty is essential, making KVP10k unsuitable. Moreover, although KVP10k does have bounding boxes, it does not provide text-level classes; instead, it defines key-value relationships between text pairs. For e.g. it defines that the header text for purchase order number **12HOUGH1** is **Purchase Order** without specifying the predefined class. Such header text may differ across documents and therefore classification with this information is not feasible.

Another option is the SROIE (Huang et al., 2019) dataset, which focuses on receipts. However, the state-of-the-art performance on this dataset - **97.8%** accuracy with LayoutLM - leaves little room for further improvement through synthetic data augmentation.

We supplement our results with the IDSEM (Sánchez et al., 2022) dataset to support our claim that FlexDoc can generate synthetic multilingual documents for training document understanding models.

We also conduct experiments using LayoutLM, a conventional encoder-based multimodal model, and Phi-4-Multimodal-Instruct, a modern decoder-based generative model, to evaluate the effectiveness of FlexDoc across both architectural paradigms and model types.

A.3 Downstream Model Performance

For training LayoutLM, the annotations in the dataset are chunked at word level using the IOB format (Ramshaw and Marcus, 1995). Since the annotations are chunked at the word level using the IOB format, the evaluation is also conducted at the word level, without taking into account the I and B modifiers. For instance, in the case of a Merchant Name like "Jake Peralta", both "Jake" and "Peralta" are treated as part of the "MerchantName" class, rather than as separate "B-MerchantName" and "I-MerchantName" tags.

For training and evaluating Phi-4-Multimodal-Instruct, the following prompt was used: *Extract only the values for the following keys from the document image. If a key has multiple values, list all separated by a pipe (|). Return output in the following format as JSON: <json_format>.*

A.4 Ablation Study - Dynamic Virtual Grid Algorithm

For this study, the Dynamic Virtual Grid algorithm is replaced with a simpler approach that places text in non-overlapping regions on a blank canvas. The canvas dimensions are kept consistent with those used in the overall FlexDoc algorithm. All other aspects of the data generation process remain unchanged, ensuring that the generated data still includes annotations such as bounding boxes and class labels.

A.5 Comparison with Hard-Template Approach

For the baseline, we generate 3000 samples using 300 manually annotated hard templates. We then generate the same number of samples using our own approach. To be fair to the baseline, we generate 10 copies of each schema frozen by our approach, effectively generating 3000 samples from 300 document permutations. We then train both models using these two datasets. The savings in annotation time is considered based on an average of 5 minutes spent per hard template (baseline) and 2.5 hours spent per stochastic schema (FlexDoc).

A.6 Diversity Analysis

To compute the diversity of datasets in this study, we utilize LayoutLM to extract joint representations that incorporate text, spatial layout (bounding boxes), and visual features. These representations are taken from the penultimate layer of the LayoutLM model. We then compute the mean pair-

wise cosine similarity between all document embeddings in the dataset. A lower mean similarity indicates greater diversity, as it reflects a broader spread in the representation space.

Let $\mathcal{D} = \{x_1, x_2, \ldots, x_N\}$ be a dataset with N document samples. Each document x_i is encoded into a joint embedding $\mathbf{h}_i \in \mathbb{R}^d$ using the penultimate layer of the LayoutLM model, capturing textual, spatial, and visual information.

The mean pairwise cosine similarity (MPCS) is computed as:

$$\text{MPCS}(\mathcal{D}) = \frac{2}{N(N-1)} \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \cos(\mathbf{h}_i, \mathbf{h}_j)$$

where cosine similarity is defined as:

$$\cos(\mathbf{h}_i, \mathbf{h}_j) = \frac{\mathbf{h}_i \cdot \mathbf{h}_j}{\|\mathbf{h}_i\| \, \|\mathbf{h}_j\|}$$

A lower MPCS implies higher diversity in the dataset.

A.7 Training Hyperparameters

For each experiment, each model is trained on 4 x A100 GPUs for 40 epochs, with a learning rate of 2e-5, weight decay of 0.1, and a batch size of 8 per GPU core (effective batch size of 32). Phi-4-Multimodal was finetuned using Low-Rank-Adaption (LoRA) (Hu et al., 2021) training.

A.8 DocILE dataset split

The DocILE dataset consists of 6680 real annotated business document images. There are 55 keys that indicate key information in these documents. The dataset is split into 5392, 500 and 1000 training, validation and test multi-page images respectively. However, since the test split is not openly available, and the authors claim that for the test set, documents in both training and validation sets are considered as seen during training, we utilized the validation dataset for testing. We also divided the document images page-wise and set aside validation data from the training set. This resulted in a final train-validation-test split of 5392-1347-633. For all experiments involving the DocILE dataset, the test split is used for evaluation.

B Stochastic Schema Definition and Description of Attributes

Following is an example of an entity group definition.

```
"entity_groups": [
    {

        "probability": 0.5
    }
]
```

Table 5 provides a description of all the attributes for entity groups and Table 6 for common configuration that can be defined in a stochastic schema JSON. JSON Definition for common configuration has been omitted for brevity.

Table 5: Description of attributes for Entity Group Definition

JSON Key in Schema	Description
name	The name of the entity group.
segment	Probabilities for the entity group to appear in various page segments. The sum should be 1. The algorithm uses these probabilities to decide the location during runtime.
tabulate	Probability of creating the entity group as a table. Runtime logic uses this probability to decide layout. Table orientation (horizontal/vertical) is determined randomly based on the `tabType` key. The number of rows and empty rows are either defined by `rows` / `numEmptyRows`, or sampled randomly.
header	One header value from the list is selected randomly during runtime and written as the group header.
headerProbability	Probability of this entity group having a header. Used by the algorithm at runtime.
probability	Probability of this entity group being present in the document. Used at runtime to decide inclusion.
gridPosition	Overrides the Dynamic Virtual Grid Algorithm for placing this entity group at a fixed location (e.g., for Bill Details). Other groups are placed accordingly.
groupAlignment	List of alignment options. One is picked randomly, and applied to the group on the grid.
entities	• **`name`**: Used as a label in the final annotation. • **`probability`**: Probability that this entity is present, used at runtime. • **`header`**: One header from the list is randomly selected and displayed. • **`type`**: Type of entity. Guides fake value generation. • **`fontVariance`**: Overrides for font face, size, and color. Unspecified properties remain unchanged. • **`addHeader`**: Enforces header display for critical fields like "Total Amount" regardless of global choice. • **`align`**: List of alignment options (applicable only when group is a table). • **`headerAlign`**: Same as `align`, but for headers only (table layout only).
entityShuffleGroups	Defines subgroups of entities that can be shuffled among each other at runtime. Each subgroup is a list of entity names.

Table 6: Description of attributes for Common Configuration Definition

JSON Key in Schema	Description
faker_locale	Locale for generating fake values using Faker. Enables multilingual support by setting the appropriate locale for the Faker instance.
translation	Enables machine translation of entity headers. Includes the following keys: `"enable"` (boolean as string) to toggle translation, and `"target_lang_code"` to specify the target language (e.g., "pt" for Portuguese).
fake_value_generator_class	Fully qualified path to the custom fake value generator class.
structural_config	• **num_segments**: Number of document segments. • **segment_size**: Rows and columns per segment. • **canvas_width**: Width of the blank canvas. • **canvas_height**: Height of the blank canvas. • **intra_group_y_offset**: Vertical spacing between entities in a group. • **intra_group_x_offset**: Horizontal spacing between entities in a group. • **inter_group_y_offset**: Vertical spacing between different entity groups. • **space_width_weight**: Weight factor used to determine spatial offsets.
font_colors	List of possible font colors for entities and group headers. A random color is selected and applied globally unless overridden.
font_size	Minimum and maximum font size range for entities and headers.
font_dir	Directory path containing fonts. Can be different for headers and entities.
canvas_color_options	List of canvas background colors. One color is randomly selected during document generation.
table_config	Styling configuration shared across all table-type entity groups.
show_entity_headers_probability	Global probability for showing entity headers. Applies uniformly unless locally overridden by the entity configuration.
consistent_patterns_for_values	Defines constraints for generating consistent values. For example, when multiple values share a common format (e.g., currency), the same currency symbol is reused across instances. Example: `["$","€","£"]`.
expected_keys	List of all possible entities to include in annotations. Only those in this list are labeled with their specific names; others are marked as "Other".

Table 7: Stochastic Attributes and Attribute Sampling Process

Stochastic Attribute	**Sampling Process**
Choice of an entity group to be present in the document	Generate a random number from a uniform distribution. If this number is less than the specified entity group probability, include the entity group in the document.
Placing an entity group in a section of the page	Driven by the "Dynamic Virtual Grid Algorithm" described below.
Choice of creating an entity group as a table or a stack of entities	Generate a random number from a uniform distribution. If this number is less than the tabulation probability as defined in the entity group definition, create the entity group as a table. Table orientation (horizontal or vertical) is selected randomly from the options specified in the template.
Number of rows for an entity group defined as a table	If a number is specified, it is used directly. If set to "random", a value is sampled from a uniform distribution within bounds defined in the common configuration.
Number of empty rows for an entity group defined as a table	If a number is specified, it is used directly. If set to "random", a value is sampled from a uniform distribution within bounds defined in the common configuration.
Choice of an entity group header to be present in the entity group	Generate a random number from a uniform distribution. If this number is less than the specified entity group header probability, include the header in the group.
Choosing an entity group header	Randomly pick one value from the list of headers defined in the entity group schema.
Choice of an entity being present in the entity group	Generate a random number from a uniform distribution. If this number is less than the entity's specified probability, include the entity in the group.
Global entity header choice	Generate a random number from a uniform distribution. If it is less than the defined threshold, include headers globally. Critical entities may override this behavior and always include headers.
Choosing an entity header	Randomly pick one value from the list of headers provided for the specific entity.
Choosing entity alignment	Randomly select one alignment option from the list defined for the entity.
Shuffling Entities in Sub-Groups	For each defined subgroup, identify the indices of member entities. Shuffle these indices and reassign them to the original entities in that subgroup.
Choice for Global Font Face and Color	Font face and color for entity text and headers (group/entity) are chosen randomly from a predefined list of fonts available in the project.
Table Style Attributes	Stylistic attributes like header font face/color, row font face/color, and separator styles are selected randomly for each table in the document.

Abstract

Multi-agent systems built on language models have shown strong performance on collaborative reasoning tasks. However, existing evaluations focus only on the correctness of the final output, overlooking how inefficient communication and poor coordination contribute to redundant reasoning and higher computational costs. We introduce GEMMAS, a graph-based evaluation framework that analyzes the internal collaboration process by modeling agent interactions as a directed acyclic graph. To capture collaboration quality, we propose two process-level metrics: Information Diversity Score (IDS) to measure semantic variation in inter-agent messages, and Unnecessary Path Ratio (UPR) to quantify redundant reasoning paths. We evaluate GEMMAS across five benchmarks and highlight results on GSM8K, where systems with only a 2.1% difference in accuracy differ by 12.8% in IDS and 80% in UPR, revealing substantial variation in internal collaboration. These findings demonstrate that outcome-only metrics are insufficient for evaluating multi-agent performance and highlight the importance of process-level diagnostics in designing more interpretable and resource-efficient collaborative AI systems.

1 Introduction

Large language models (LLMs) such as GPT-4 (Achiam et al., 2023), Llama (Touvron et al., 2023), and Qwen (Bai et al., 2023) demonstrate emergent reasoning capabilities and achieve state-of-the-art performance across a variety of NLP tasks. As multi-agent LLM systems become more prevalent (Shen et al., 2023; Chen et al., 2023), their evaluation remains narrowly focused on the correctness of the final answer. This outcome-centric view overlooks the underlying collaboration dynamics, how agents share information, coordinate reasoning, and avoid duplication of efforts.

Recent studies highlight the limitations of this evaluation and call for process-level metrics that assess the quality of intermediate reasoning steps (Liu et al., 2023). In practice, multi-agent systems often re-traverse the same inference paths or underutilize some agents entirely. Redundant messages can significantly inflate token usage, introducing a communication tax that increases both latency and computational cost (Zhang et al., 2024a).

Existing evaluation metrics fail to expose these inefficiencies. Representing agent interactions as a directed graph, where nodes denote agents and edges represent message passing, provides a structured view of coordination patterns (Zhang et al., 2024b). This view enables the identification of redundant reasoning paths and inactive agents, offering actionable insight into the behavior of the system. Furthermore, smaller open-source LLMs have demonstrated competitive performance with significantly reduced cost, in some cases up to 94% lower than proprietary models (Liu et al., 2023; Zhang et al., 2024a). These trends motivate the need for evaluation methods that go beyond accuracy and help practitioners build more interpretable and efficient multi-agent systems.

Motivated by this gap, we present GEMMAS, a graph-based evaluation framework for analyzing multi-agent LLM reasoning processes. GEMMAS encodes the entire reasoning trace as a directed acyclic graph (DAG), where each node represents an agent having (prompt, response) pair and each edge captures the flow of information between them. We introduce two structure-aware metrics: (1) Information Diversity Score (IDS), which quantifies the semantic uniqueness of agent contributions, and (2) Unnecessary Path Ratio (UPR), which measures the fraction of reasoning steps that do not contribute new information. Together, these metrics evaluate collaboration efficiency beyond

[*]Equal Contribution.

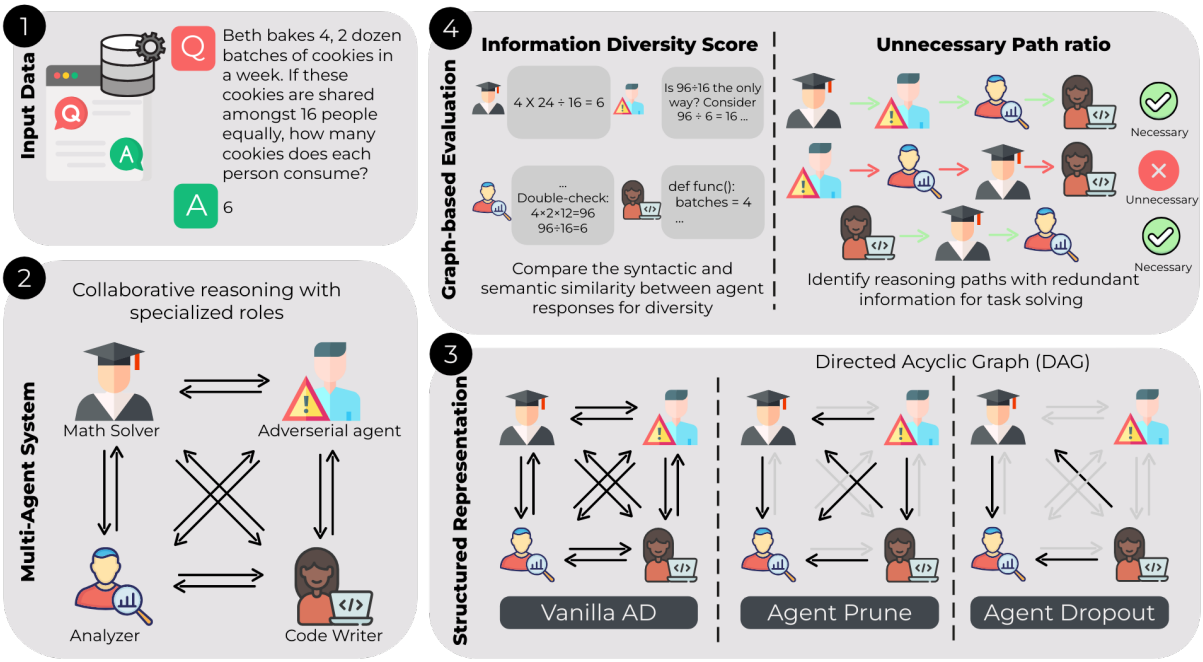

Figure 1: **Overview of the GEMMAS evaluation framework.** The process begins with input mathematical problems, which are solved collaboratively by a multi-agent system composed of specialized agents. Their interactions are represented as a DAG, capturing both communication flow and reasoning structure. From this DAG, GEMMAS computes structural metrics, Information Diversity Score (IDS) and Unnecessary Path Ratio (UPR), to evaluate collaboration quality and efficiency beyond final-task accuracy.

what is captured by task accuracy alone.

We apply GEMMAS to five mathematical reasoning benchmarks: GSM8K, AQuA, MultiArith, SVAMP, and MMLU using lightweight open-source LLMs. Our findings show that naïve agent pipelines suffer from high redundancy and low diversity, while configurations optimized for higher IDS and lower UPR improve both accuracy and token efficiency under fixed computational budgets. GEMMAS thus surfaces hidden inefficiencies in multi-agent collaboration and offers practical design signals for building interpretable and cost-effective agent systems, an especially important concern in real-world industry deployments.

Our contributions are as follows:

- We introduce GEMMAS, a graph-based evaluation framework for multi-agent LLM reasoning, and propose two novel structural metrics: Information Diversity Score (IDS) and Unnecessary Path Ratio (UPR), which together assess collaboration quality beyond task accuracy.
- We evaluate multiple small open-source LLMs, using GEMMAS to compare their collaborative behavior and identify efficiency trade-offs.
- We conduct systematic evaluations across five mathematical reasoning benchmarks, revealing substantial differences in collaboration quality among systems with similar final accuracies.

2 Related Work

2.1 Agent-Level Diversity Metrics

Standard metrics (e.g., BLEU, cosine similarity) capture surface-level variation (Zhu et al., 2018; Li et al., 2015) but ignore semantic roles and the graph structure critical for coordination (Li et al., 2015; Park et al., 2024). Well-orchestrated lightweight models can match the performance of larger models in reasoning and planning (Liu et al., 2023), making efficient evaluation of agent-level diversity increasingly important.

Agent-level diversity in multi-agent systems requires specialized evaluation that considers how individual agents contribute unique perspectives to collaborative reasoning through their structural connectivity within the communication graph. These limitations have motivated recent efforts to develop graph-aware metrics that consider both content and

structural diversity in multi-agent reasoning.

2.2 Evaluation in Multi-Agent Reasoning

Evaluation of multi-agent reasoning remains in its early stages. Traditional metrics such as final accuracy or task success rate often overlook the internal dynamics of agent collaboration.

To address limitations of conventional evaluations, graph-based methods have been proposed. *AgentPrune* (Zhang et al., 2024a) prunes low impact edges in the communication graph, while *AgentDropout* (Wang et al., 2025) removes underperforming agents, both with the aim of reducing redundancy without compromising output quality. *VillagerAgent* (Dong et al., 2024) incorporates DAG based planning to assess workload balance and depth of reasoning.

These graph-based approaches highlight the growing emphasis on structural analysis to uncover inefficiencies and redundant communication patterns in collaborative reasoning among agents.

3 Evaluation Framework: GEMMAS

In this section, we introduce **GEMMAS** (General Evaluation Metrics for Multi-Agent Systems), a comprehensive evaluation framework for graph-based multi-agent LLM systems. Unlike conventional approaches that focus solely on task outcomes, GEMMAS evaluates both the final results and the internal reasoning process of multi-agent collaboration.

3.1 Task Definition and Problem Setup

We consider the problem of multi-agent collaboration for mathematical reasoning tasks, where multiple language model agents interact through structured communication to solve problems jointly. Each multi-agent system (MAS) is modeled as a DAG, capturing the flow of information across agents throughout the reasoning process.

Formally, let $G = (V, E, F)$ denote the communication graph:

- $V = \{v_1, v_2, ..., v_N\}$ is the set of N agent nodes;
- $E \subseteq V \times V$ represents directed edges, where $(v_i, v_j) \in E$ indicates that the output of agent v_i is available to agent v_j;
- $F = \{f_1, f_2, ..., f_N\}$ denotes the set of agent-specific reasoning functions, where f_i defines the behavior or prompt processing logic of agent v_i.

To analyze both the communication structure and the temporal execution dynamics of the system, we maintain two adjacency matrices. The *spatial adjacency matrix* $S \in \{0, 1\}^{N \times N}$ encodes direct communication links between agents, indicating which agents can exchange information. Complementarily, the *temporal adjacency matrix* $T \in \{0, 1\}^{N \times N}$ captures the causal or time-ordered dependencies among agent outputs, allowing us to trace how intermediate reasoning steps influence one another across time.

GEMMAS evaluates multi-agent systems beyond final-task accuracy by analyzing the spatial and temporal structures of agent communication. This reveals inefficiencies such as redundant reasoning, low diversity, shallow chains, and idle agents, patterns not captured by conventional metrics. While we report traditional baselines including accuracy (correct task completion rate) and token efficiency (prompt and completion token usage) (Wang et al., 2025), GEMMAS provides process-level insights that quantify collaboration quality and structural resource utilization. By modeling both the topology and semantic content of communication graphs, it addresses a key limitation in current evaluation practices for multi-agent LLM systems.

3.2 DAG-specific Metrics

Information Diversity Score (IDS). This metric quantifies the heterogeneity of information generated by different agents by measuring the degree of similarity between their responses. It addresses a fundamental question in collaborative systems: *Do agents contribute unique perspectives, or do they merely repeat similar reasoning?*

Existing evaluation metrics are limited in multi-agent contexts, as they primarily capture surface-level correctness and ignore semantic intent or the structural role of each agent within the communication graph. To address this gap, we combine syntactic analysis using TF-IDF (Sparck Jones, 1972) with semantic similarity computed via BERT embeddings (Devlin et al., 2019), while incorporating structural context from the DAG. Specifically, we employ the sentence transformer model (all-MiniLM-L6-v2) to obtain sentence-level embeddings. To account for the topology of the agent graph, we weight each agent pair (i, j) based on

their spatial and temporal proximity within the DAG. The Information Diversity Score is defined as:

$$IDS = \frac{\sum_{i,j} w_{ij} \cdot (1 - SS_{\text{total}}[i,j])}{\sum_{i,j} w_{ij}} \quad (1)$$

$$w_{ij} = \max(S_{ij}, S_{ji}) + \max(T_{ij}, T_{ji}) \quad (2)$$

Here, $SS_{\text{total}}[i,j]$ represents the average syntactic-semantic similarity between agents i and j, computed as the cosine similarity of their TF-IDF and BERT representations, weighted equally with $\lambda_1 = \lambda_2 = 0.5$. The weight w_{ij} captures the relevance of agent pair (i,j) based on their direct or indirect communication, using spatial adjacency matrix S and temporal adjacency matrix T.

The complete algorithmic procedure for computing IDS, including similarity calculation and structure-aware weighting, is described in Algorithm 1. Sensitivity analysis for different weighting schemes is provided in Appendix A.1.

Unnecessary Path Ratio (UPR). This metric assesses the structural efficiency of the MAS by identifying reasoning paths that provide negligible or redundant contributions to solving the task. While IDS focuses on diversity, UPR addresses efficiency, quantifying the proportion of communication paths that fail to add meaningful information. It serves as an indicator of communication overhead and redundancy in agent interactions.

Formally, UPR is defined as:

$$UPR = 1 - \frac{|\mathcal{P}_{\text{necessary}}|}{|\mathcal{P}_{\text{all}}|} \quad (3)$$

where $\mathcal{P}_{\text{all}}$ represents the total number of reasoning paths in the spatial communication graph, and $\mathcal{P}_{\text{necessary}}$ includes only those paths that yield contribution scores above a predefined threshold $\tau = 0.5$. Sensitivity analysis for different thresholds is provided in Appendix A.2.

A path is deemed necessary if it facilitates the production of correct or informative responses by downstream agents, based on a contribution function defined over message impact. The detailed algorithmic pipeline, which includes path enumeration, contribution analysis, and threshold filtering, is outlined in Algorithm 2.

3.3 Evaluation Setup

We systematically evaluate different MAS architectures that vary in their communication graph topologies. Our evaluation encompasses both baseline and structurally optimized approaches to assess the effectiveness of DAG-based modifications.

Algorithm 1 Information Diversity Score

Input: Agent responses $O = \{o_1, \ldots, o_N\}$,
Spatial adjacency matrix S,
Temporal adjacency matrix T
Output: Information diversity score $IDS \in [0,1]$

/ Calculating syntactic-semantic similarity */*
Obtain syntactic features $\Phi \leftarrow$ TF-IDF(O)
Obtain semantic features $\Psi \leftarrow$ BERT(O)
$SS_{\text{syn}} \leftarrow$ pairwise_cosine(Φ) {syntactic similarity}
$SS_{\text{sem}} \leftarrow$ pairwise_cosine(Ψ) {semantic similarity}
$SS_{\text{total}} \leftarrow \lambda_1 \cdot SS_{\text{syn}} + \lambda_2 \cdot SS_{\text{sem}}$
/ Calculating diversity score */*
Initialize weighted diversity $D_w \leftarrow 0$
Initialize DAG connection weights $W \leftarrow 0$
for $i = 1$ to $N-1$ **do**
  for $j = i+1$ to N **do**
    $w \leftarrow \max(S_{ij}, S_{ji}) + \max(T_{ij}, T_{ji})$ {connection weights}
    if $w > 0$ **then**
      $D_w \leftarrow D_w + w \cdot (1 - SS_{total}[i,j])$
      $W \leftarrow W + w$
    end if
  end for
end for
return D_w / W

Baseline. We employ a fully connected multi-agent system without structural optimization, where all agents can directly communicate with each other. We refer to this baseline configuration as Vanilla-AD, as a reference point for measuring the effectiveness of communication graph modifications.

3.3.1 Multi-Agent System Architecture

We adopt the agent-role configuration established in AgentPrune (Zhang et al., 2024a), which defines a structured collaboration protocol among specialized agents to promote diversity and robustness in reasoning.

Our MAS setup involves four specialized agents with distinct roles. These are 1) AnalyzeAgent focuses on problem decomposition and structured plan generation, 2) CodeWritingAgent formulates code-based computational reasoning strategies, 3) MathSolverAgent performs formal mathematical operations and symbolic solving and 4) AdversarialAgent introduces plausible but intentionally incorrect solutions to stress-test robustness.

The collaborative process unfolds in three stages.

Algorithm 2 Unnecessary Path Ratio

Input: Spatial communication graph $G = (V, E_{\text{spatial}})$, Correct answer α
Output: Unnecessary path ratio UPR $\in [0, 1]$

/ Path enumeration */*
$\mathcal{P}_{all} \leftarrow \{p \mid p \text{ is a subpath in } G\}$
$\mathcal{P}_{necessary} \leftarrow \emptyset$
/ Path contribution assessment */*
for each path $p \in \mathcal{P}_{all}$ **do**
  Initialize correct count $c \leftarrow 0$
  Initialize total count $t \leftarrow 0$
  for each agent $v \in p$ **do**
    $a \leftarrow \text{ExtractAnswer}(\text{output}(v))$
    if $a == \alpha$ **then**
      $c \leftarrow c + 1$
    end if
    $t \leftarrow t + 1$
  end for
  score $\leftarrow \frac{c}{t}$ if $t > 0$ else 0 {contribution score}
  if score $\geq \tau$ **then**
    $\mathcal{P}_{\text{necessary}} \leftarrow \mathcal{P}_{\text{necessary}} \cup \{p\}$
  end if
end for
return $1 - |\mathcal{P}_{necessary}|/|\mathcal{P}_{all}|$

First, the input problem is distributed to all four agents concurrently. Second, the agents engage in two rounds of communication based on the specified DAG topology, sharing intermediate reasoning traces from their specialized perspectives. Finally, a FinalRefer agent aggregates these outputs to generate the final answer through collective reasoning.

Figure 2 illustrates the structural evolution of the DAG topology, comparing the initial structure at Iteration 1 with the optimized structure at Iteration 10 produced by the G-Designer method. To analyze the effect of structural optimization, we implement and compare three state-of-the-art methods called 1) AgentPrune prunes communication links with low marginal impact, 2) AgentDropout dynamically removes underperforming agents and their associated links to reduce redundancy and 3) G-Designer learns optimal DAG topologies over multiple iterations, aiming to improve reasoning efficiency by minimizing communication overhead.

3.3.2 Benchmarks and Language Models

We evaluate DAG-based MAS architectures on five mathematical reasoning benchmarks: GSM8K (Cobbe et al., 2021), which contains 1,000 grade-school math problems requiring multistep numeric reasoning; AQuA (Ling et al., 2017), consisting of 254 algebraic word problems with multiple-choice answers; MMLU (Hendrycks et al., 2021), where we select 748 questions from the mathematics subsets covering elementary to college-level topics; MultiArith (Roy and Roth, 2015), with 180 arithmetic word problems; and SVAMP (Patel et al., 2021), comprising 300 elementary-level problems designed to test reasoning variation. To examine how GEMMAS performs across different model scales, we use two small open-source instruction-tuned language models: Llama 3.1-8B-Instruct (Grattafiori et al., 2024) and Qwen 2.5-7B-Instruct (Yang et al., 2025).

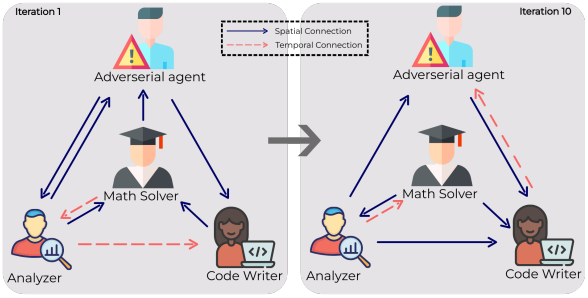

Figure 2: **Comparison of Multi-Agent DAG Structures Before and After Optimization.** The figure shows the evolution of the DAG structure from the initial setup (Iteration 1) to the final optimized configuration (Iteration 10). Solid blue lines denote spatial communication links, while dashed orange arrows indicate temporal dependencies.

3.3.3 Implementation Details

All experiments are run under consistent hyperparameters: a learning rate of 0.1, a dropout rate of 0.1, 40 training examples, 10 sampling iterations, and two communication rounds per task. We set the generation temperature to zero for deterministic outputs. Unless stated otherwise, all other parameters follow the default configurations of the original MAS frameworks. For reproducibility, all experiments are conducted with the random seed fixed to 2025.

4 Results and Analysis

We apply GEMMAS to assess the structural quality and collaborative behavior of multi-agent systems (MAS). Tables 1 and 2 present the results for both Llama3.1-8B-Instruct and Qwen2.5-7B-Instruct models across five reasoning benchmarks.

4.1 Revealing Hidden Inefficiencies

Conventional evaluation metrics, such as final answer accuracy, fail to capture inefficiencies in multi-

AgentDropout	**0.9071**	1.05	**0.29**	**0.69**	0.36
AgentPrune	0.8714	2.39	0.45	0.41	0.97
G-Designer	0.9036	2.37	0.45	0.46	**0.32**
MMLU					
Vanilla - AD	0.7153	3.13	0.61	0.54	0.51
AgentDropout	0.7181	**2.17**	**0.47**	0.63	0.53
AgentPrune	0.7319	2.71	0.62	0.49	**0.43**
G-Designer	**0.7806**	4.18	1.34	**0.72**	0.61

Table 2: Performance comparison of multi-agent systems on GSM8K, AQuA, MultiArith, SVAMP, and MMLU test dataset using Qwen2.5-7B-Instruct.

agent reasoning. For instance, on GSM8K with Qwen2.5-7B-Instruct, the Vanilla-AD configuration achieves 85.6% accuracy, while G-Designer reaches 87.4%. Although these results appear similar in terms of performance, GEMMAS reveals that G-Designer operates with significantly higher structural efficiency, recording a UPR of just 0.08 compared to 0.40 for Vanilla-AD, a fivefold improvement in redundant reasoning reduction.

Moreover, models with identical task accuracy may exhibit distinct internal collaboration patterns. On MultiArith with Qwen2.5-7B-Instruct, both Vanilla-AD and AgentPrune reach 99.4% accuracy. However, AgentPrune demonstrates greater semantic diversity (IDS of 0.57 versus 0.43) and higher structural efficiency (UPR of 0.00 versus 0.16), highlighting that quality of reasoning is not reflected by accuracy alone.

4.2 Identifying Optimal Configurations

Building on these findings, we identify recurring trends in structural metrics that support actionable system design decisions. Systems that simultaneously exhibit high IDS and low UPR are particularly desirable, as they combine semantic diversity with efficient communication.

For example, AgentPrune on MultiArith consistently demonstrates this pattern. With Llama3.1-8B-Instruct, it achieves IDS 0.42 and UPR 0.06, while with Qwen2.5-7B-Instruct, it yields IDS 0.57 and UPR 0.00. In contrast, systems with low IDS and high UPR represent the least efficient configurations. On SVAMP, AgentPrune records IDS 0.38 and UPR 0.96 with Llama3.1-8B-Instruct, and IDS 0.41 and UPR 0.97 with Qwen2.5-7B-Instruct, signaling redundant or repetitive communication behavior.

From a performance efficiency perspective, some configurations manage to achieve strong accuracy with minimal communication overhead. For example, G-Designer on MMLU achieves 70.4% accuracy with IDS 0.53 using Llama3.1-8B-Instruct, and 78.1% accuracy with IDS 0.72 using Qwen2.5-7B-Instruct.

These results confirm that GEMMAS exposes structural trade-offs that traditional metrics cannot capture. It offers MAS designers a set of complementary signals to guide configuration choices based on specific goals, whether that is, maximizing computational efficiency (via low UPR), enhancing semantic richness (via high IDS), or achieving a balance across both dimensions depending on the deployment scenario.

5 Conclusion

We introduced GEMMAS, a graph-based evaluation framework for multi-agent language model systems that assesses collaboration quality beyond final-task accuracy. By modeling agent interactions as a DAG, GEMMAS defines two structural metrics, Information Diversity Score (IDS) and Unnecessary Path Ratio (UPR), to capture semantic uniqueness and reasoning redundancy. Experiments on five mathematical benchmarks reveal that systems with similar accuracy can vary significantly in internal collaboration patterns. GEMMAS thus enables process-level diagnostics to guide the development of interpretable and efficient multi-agent systems.

Limitations

While GEMMAS provides a structural lens to evaluate multi-agent LLM systems, it is currently limited to mathematical reasoning tasks and small open-source models. Extending this framework to broader domains, integrating runtime adaptivity, and coupling it with system-level metrics such as latency and memory footprint represent promising directions. Additionally, incorporating human-in-the-loop assessments and evaluating dynamic DAG topologies could further enhance the utility of GEMMAS for real-world deployment.

A Appendix

A.1 Information Diversity Score Analysis

Figures 3 and 4 show how IDS values vary with different combinations of syntactic-semantic weights between benchmarks and models. The weight balance parameter λ_1 controls the contribution of syntactic characteristics (TF-IDF), while semantic features (BERT embeddings) are weighted as $\lambda_2 = 1 - \lambda_1$.

As λ_1 increases toward 1.0, emphasizing syntactic similarity, IDS values generally increase between models and benchmarks. This suggests that syntactic diversity (e.g., different vocabulary usage, sentence structures) tends to be more pronounced than semantic diversity in multi-agent communications.

Different multi-agent systems exhibit varying sensitivity to weight balance. For example, on SVAMP with both models, Vanilla-AD and AgentDropout show relatively higher IDS values compared to AgentPrune and G-Designer, indicating more diverse communication patterns across different syntactic-semantic weight settings.

We selected equal weights to balance the syntactic and semantic contribution without favoring either aspect of the similarity measurement. This balanced approach provides a neutral baseline for comparing multi-agent systems across different collaboration patterns.

A.2 Unnecessary Path Ratio Analysis

The UPR metric relies on a threshold τ to determine whether a reasoning path is necessary. A path is considered necessary if its contribution score exceeds τ. Figures 5 and 6 show how UPR values vary with different threshold values across all five benchmarks and models.

As expected, UPR values generally increase with τ across all systems, since stricter thresholds classify fewer paths as necessary. However, the magnitude of this increase varies significantly among systems and benchmarks, especially at higher threshold values.

At lower thresholds ($\tau \leq 0.5$), UPR values gradually increase and relatively moderate in most systems. For instance, on GSM8K with both models, the systems show UPR values ranging from 0.1 to 0.4 at $\tau = 0.5$. However, at higher thresholds ($\tau > 0.5$), systems except G-Designer exhibit sharp increases. Vanilla-AD rises rapidly from 0.4 at $\tau = 0.5$ to more than 0.9 at $\tau = 0.9$, while G-Designer increases more gradually to only 0.2.

Similar patterns appear across other benchmarks. On MultiArith with both models, both AgentDropout and Vanilla-AD reach vary high UPR values (over 0.9) when $\tau > 0.5$, while G-Designer remains below 0.2. On SVAMP with both models, AgentPrune maintains consistently high UPR across all thresholds, indicating that most of its reasoning paths contribute marginally regardless of threshold choice.

We selected $\tau = 0.5$ as the default threshold to ensure a balanced evaluation criterion. This criterion indicates that a path must demonstrate majority correctness, defined as more than 50% of intermediate outputs being correct, to be considered necessary.

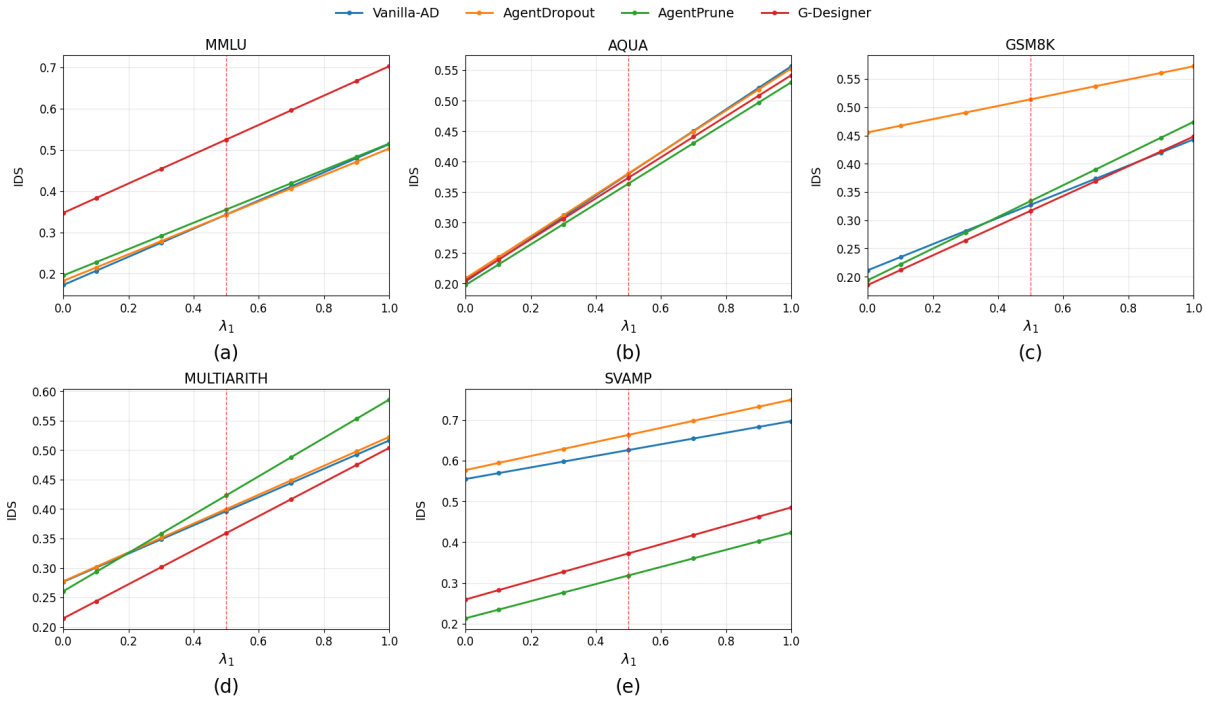

Figure 3: Sensitivity of Information Diversity Score (IDS) to syntactic-semantic weight balance across five benchmarks using Llama3.1-8B-Instruct. The x-axis shows λ_1 (syntactic weight), with vertical dashed line indicating $\lambda_1 = 0.5$ used in our main experiments.

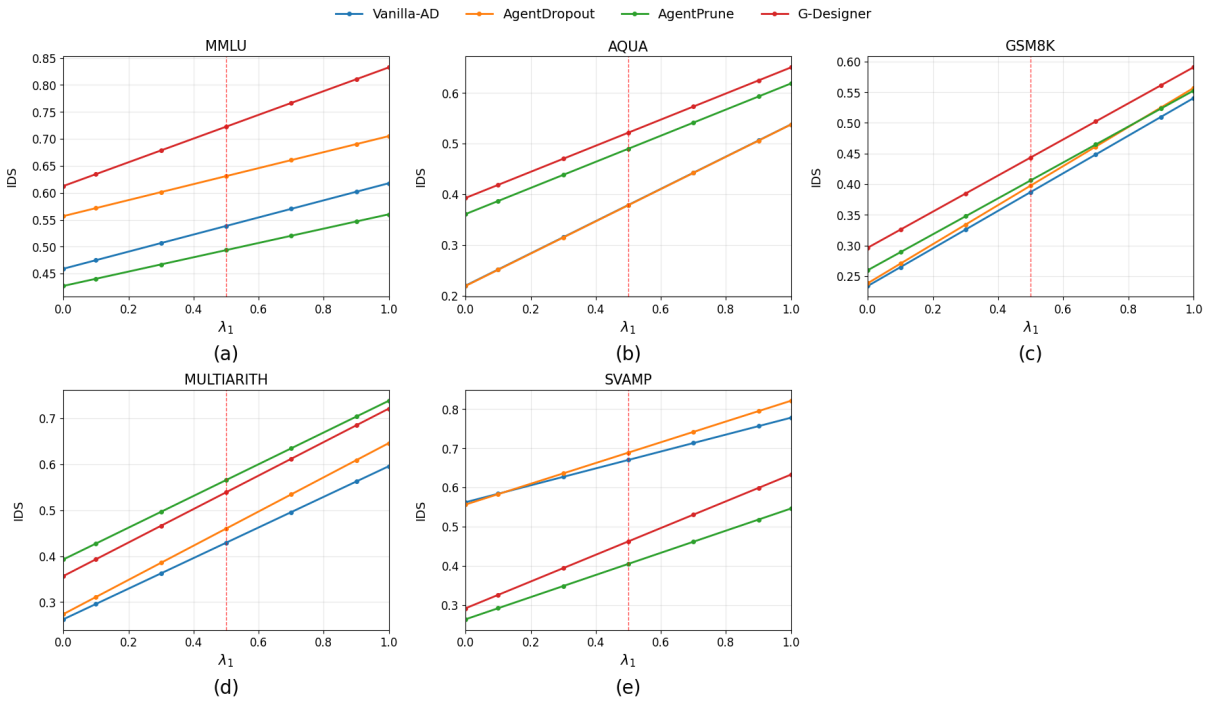

Figure 4: Sensitivity of Information Diversity Score (IDS) to syntactic-semantic weight balance across five benchmarks using Qwen2.5-7B-Instruct. The x-axis shows λ_1 (syntactic weight), with vertical dashed line indicating $\lambda_1 = 0.5$ used in our main experiments.

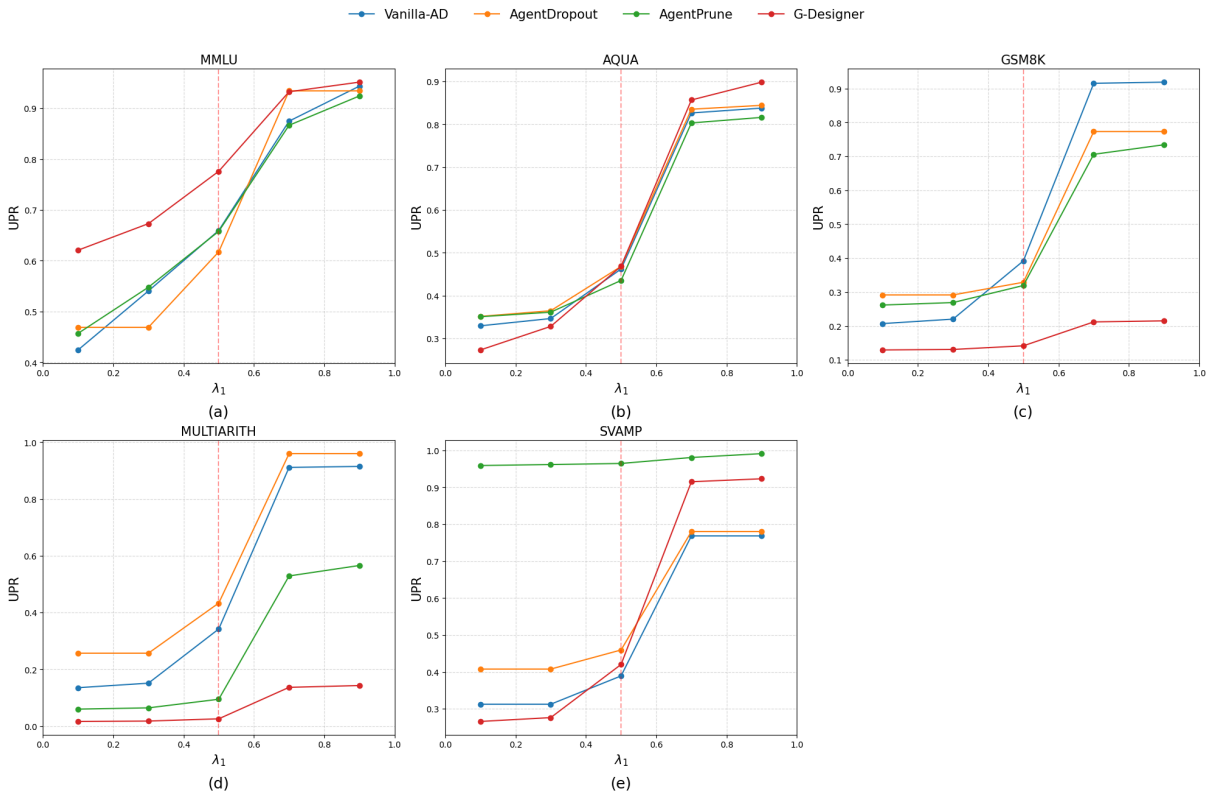

Figure 5: Sensitivity of Unnecessary Path Ratio (UPR) to threshold values across five benchmarks using Llama3.1-8B-Instruct. The x-axis shows τ (path necessity threshold), with vertical dashed line indicating $\tau = 0.5$ used in our main experiments.

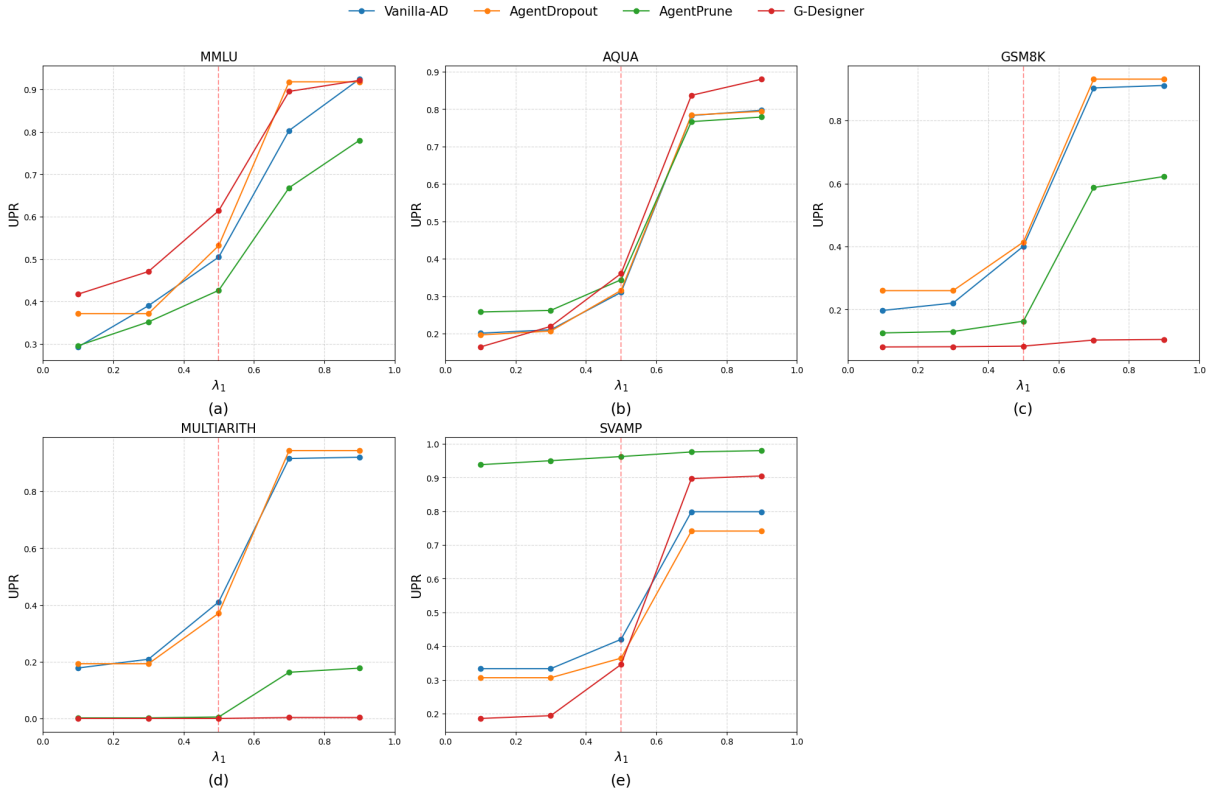

Figure 6: Sensitivity of Unnecessary Path Ratio (UPR) to threshold values across five benchmarks using Qwen2.5-7B-Instruct. The x-axis shows τ (path necessity threshold), with vertical dashed line indicating $\tau = 0.5$ used in our main experiments.

Knowledge-Augmented Question Error Correction for Chinese Question Answer System with QuestionRAG

Abstract

Input errors in question-answering (QA) systems often lead to incorrect responses. Large language models (LLMs) struggle with this task, frequently failing to interpret user intent (misinterpretation) or unnecessarily altering the original question's structure (over-correction). We propose QuestionRAG, a framework that tackles these problems. To address misinterpretation, it enriches the input with external knowledge (e.g., search results, related entities). To prevent over-correction, it uses reinforcement learning (RL) to align the model's objective with precise correction, not just paraphrasing. Our results demonstrate that knowledge augmentation is critical for understanding faulty questions. Furthermore, RL-based alignment proves significantly more effective than traditional supervised fine-tuning (SFT), boosting the model's ability to follow instructions and generalize. By integrating these two strategies, QuestionRAG unlocks the full potential of LLMs for the question correction task.

1 Introduction

The performance and reliability of any Question Answering (QA) system are fundamentally constrained by a critical, universal challenge: errors inherent within the input questions. This is not a minor issue but a central bottleneck that affects systems of all complexities. These pervasive errors originate from two inevitable sources. The first is system-induced, where automated processes like Automatic Speech Recognition (ASR) and Optical Character Recognition (OCR) misinterpret spoken or written words. The second is user-induced, which covers the vast and unpredictable spectrum of human expression, including simple typographical mistakes, the use of regional dialects or colloquialisms, and ambiguous phrasing. An ill-posed question triggers a cascade of failures throughout the entire QA pipeline. It immediately compromises the initial stage of question comprehension, which in turn derails the subsequent analysis and information retrieval, ultimately leading to an incorrect or irrelevant answer. Therefore, the ability to proactively identify and correct these input errors is not just a desirable feature—it is a foundational requirement for building robust, effective, and trustworthy QA systems.

Error type	question example
phonetic error	高四 和李白有什么关系 (高四-> 高适)
graphemic error	OpenAI 01 模型 (01->O1)
missing word	界m7 和 m9 哪个好 (界-> 问界)
wrong order	有哈弗车吗纯电版（哈弗车有纯电版吗）
repeating word	哈哈马斯 的状况 (哈哈马斯-> 哈马斯)
ill-expression	手机SM 码 (SM->SN)

Table 1: Typical error types of the questions in Chinese QA systems. The underlined text is miss-spelling. The parenthetical text describes how to correct the error.

The challenge of question correction is rooted in the diverse nature of errors, which can range from simple typographical mistakes to complex grammatical and semantic inaccuracies, as shown in Table 1. Traditional methods, often built upon foundational models like BERT (Devlin et al., 2019) and sequence-to-sequence architectures (Sutskever et al., 2014), have attempted to address this by creating specialized solutions. These approaches, however, are heavily reliant on explicit rule sets, hand-crafted features, and bespoke model architectures tailored to specific error types, such as phonetic-based correctors or grammatical taggers (Hong et al., 2019; Zhang et al., 2021; Omelianchuk et al., 2020). While effective for their intended narrow tasks, this specialization inherently limits their generalizability and scalability (Li et al., 2024). Consequently, there is a compelling need to develop a universal correction

framework capable of addressing a broad spectrum of errors without requiring task-specific customization.

Large Language Models (LLMs) represent a promising paradigm for question error correction, capable of addressing diverse error types within a single, unified framework. Building on this promise, a line of recent work has emerged to apply LLMs to this challenge. (Li et al., 2023) first investigates the effectiveness of GPT-3.5 on Chinese Text Correction, and reveals that LLMs handle fluency well and are more fault-tolerant to input data quality, but still have a noticeable gap when compared to previous state-of-the-art, fine-tuned smaller models. Their analysis result identified the main reasons:

- While LLMs possess vast general knowledge, they often fail when it comes to highly specific or nuanced errors. This is particularly evident when correcting errors involving proper nouns or domain-specific terminology. As shown in Table 2, the LLM could not distinguish between " 市大" (Shìdà - City University) and " 师大" (Shdà - Normal/Teacher's University). This correction requires specific background knowledge about place names that a general-purpose LLM may not have prioritized. Moreover, as a text-only model, LLMs cannot access information about a character's pronunciation (e.g., Pinyin) or its visual structure, which is a major handicap for identifying and correcting these types of errors. We collectively refer to the problem of a large model being unable to or incorrectly understanding a user's query due to insufficient background knowledge as *misinterpretation*.

- LLMs are trained to generate the most probable or fluent text based on their massive training data. This causes them to "correct" expressions that are grammatically valid but less common, replacing them with more conventional phrases (Fang et al., 2023; Wu et al., 2023). As shown in Table 2, the LLM changed "remarried wife" (再婚妻子) to "ex-wife" (前妻). In the context of question correction, this behavior is a form of error. We refer this problems as *over-correction*.

To address the misinterpretation and over-correction issues of LLMs when applying to Chinese question correction, we propose a knowledge-augmented LLM approach, called QuestionRAG, which can handle various types of errors in a simple and unified way. Specifically, to overcome the misinterpretation problem, QuestionRAG leverages Retrieval-Augmented Generation (RAG) (Lewis et al., 2021) by introducing rich external knowledge for each question, such as the search results, entity description, similar questions. As the retrieval process takes into account a combination of textual, visual, and phonetic similarities, QuestionRAG enables the LLM to generate a correction based solely on the retrieved context, eliminating the need for the LLM itself to possess visual or phonetic discrimination capabilities.

To further address the over-correction problems, we designed a reinforcement learning training method for the question error correction task. This method can automatically stimulate the LLM's intermediate thought processes for question correction, reducing the reliance on annotated samples for the reasoning process.

Experimental results show that the model trained with RL significantly outperforms SFT-trained models, and the over-correction problem is substantially mitigated.

Error Type	example	question
misinterpretation	input	湖南市大 怎么走
	ground truth	湖南师大 怎么走
	correction	湖南四大怎么走
over-correction	input	摩克多 再婚妻子
	ground truth	默克多 再婚妻子
	correction	默克多前妻

Table 2: Examples of the misinterpretation and over-correction problems in LLM-based question correction. In the first example, the LLM misinterpreted the term " 湖南市大" as " 湖南四大", but the " 湖南四大" does not exit in the real word. Instead, the correct should be " 湖南师大" , which is a normal university and pronounced exactly the same as the user's original input. In the second example, in addition to correcting the erroneous text (" 摩克多" to " 默克多"), the LLM also change the correct text from " 再婚妻子" to " 前妻", a needless modification that changed the meaning of the original question.

2 Related Work

Chinese text Correction (CTC) is a challenging task since thousands of characters that can have

similar pronunciations or visual appearances. In question answer system, errors in user questions are highly varied—stemming from colloquial language, input devices, and environmental conditions—making the task significantly more challenging.

Most conventional methods are tailored to address specific error types with small models, such as BERT(Devlin et al., 2019) and Seq-to-Seq models(Sutskever et al., 2014). For instance, SpellBERT (Ji et al., 2021) is a lightweight pre-trained model utilizing BERT with additional graph-based visual and phonetic features for Chinese Spelling Check. Similarly, other BERT-based approaches (Hong et al., 2019; Zhang et al., 2020; Cheng et al., 2020) have integrated phonological and morphological knowledge into contextual embeddings in BERT-like models for identifying and correcting textual errors. These task-specific models are limited by their parameter scale and capabilities, thereby underperform in low-frequency and complex semantic scenarios.

While recent Large Language Models (LLMs) show promise for this task, standard in-context learning approaches that directly prompt the model for corrections (Li et al., 2023; Sun et al., 2024) have performed poorly, even underperforming traditional small models (Li et al., 2023; Zhou et al., 2024b). More effective strategies include task-specific pre-training (Zhou et al., 2024b) and fine-tuning (Li et al., 2023). (Zhou et al., 2024a) combines an LLM with a Minimal Distortion Model for scoring corrections, but this is limited to candidates of identical length to the error. Addressing this, (Liang and Zhou, 2025) proposed a multi-turn CTC framework to maintain length consistency. Nevertheless, all of these methods still suffer from problems of misinterpretation and over-correction.

Recently, few work has begun to explore the integration of RAG (Lewis et al., 2021) into LLM-based text correction. These approaches typically enhance model performance by retrieving relevant data, such as domain-specific entities (Pusateri et al., 2025) or labeled corrections from existing training sets (Liang and Zhou, 2025). However, the applicability of them is often limited by their reliance on curated, domain-specific knowledge. In contrast, our method leverages broad, general knowledge drawn from public sources like the web and Wikipedia, supplemented by unlabeled questions. Furthermore, to the best of our knowledge, our work is the first to integrate RAG with reinforcement learning (RL) to align an LLM specifically for the text correction task. This novel combination successfully alleviates the aforementioned problems of both misinterpretation and over-correction.

3 Methodology

We first introduce the QuestionRAG framework, and then discuss how reinforcement learning is utilized within it to address the challenge of over-correction.

3.1 QuestionRAG

Most prior research on LLM-based Chinese text correction has focused on enhancing the model's ability to understand and generate text based on character graphemes (Zhang et al., 2025) and phonetics (Yamashita et al., 2025). This task is inherently challenging, as large models are primarily trained for text generation. In contrast, the core idea of QuestionRAG is to fully leverage the LLM's strengths in text comprehension and generation, while offloading the processing of graphemes and phonetics—areas where LLMs are less proficient—to the retrieval stage. By integrating similarity factors such as string overlap, semantics, graphemes, and phonetics during search and ranking, QuestionRAG gathers relevant texts to serve as context, providing valuable guidance for the LLM to infer the correct correction.

We introduce general knowledge for a question by retrieval relevant texts from the following sources:

- **Web**: We take the question as a query, and obtain the search results form a commercial search engine. For simplification, we only kept the titles of relevant web pages as context.
- **Log of the QA system**: We search similar questions from historical questions extracted from the logs of a commercial question answer system. To filter low-quality questions, we filter ones with frequency less than 5.
- **Wikipedia**: we gather entities and their description from Wikipedia. To retrieval relevant entities, we first extract candidate entities from the input questions, and then search the entity base with these candidate entities.

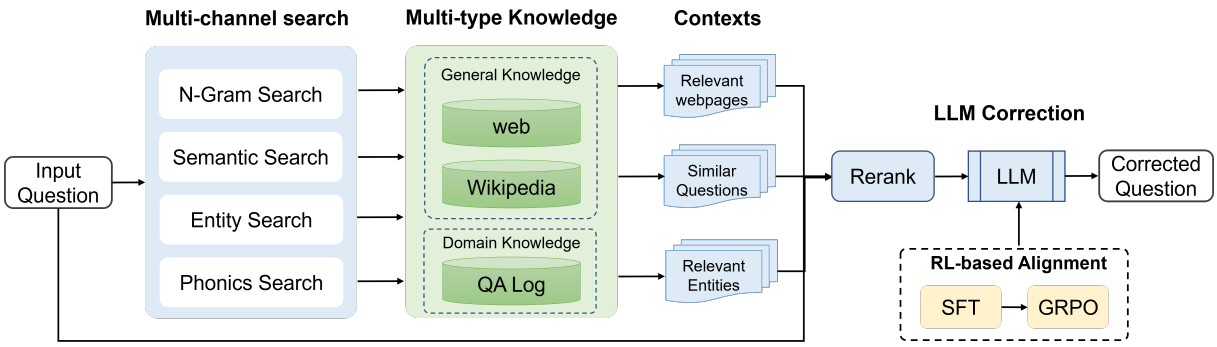

Figure 1: The workflow of QuestionRAG includes a search stage collecting relevant webpages, questions, and entities from external knowledge sources. It utilizes multi-facet search (n-gram for lexical similarity, embedding from semantic similarity, entity for conceptual similarity, and Pinyin for phonics similarity, etc.) from multiple knowledge sources (either general or domain-specific). With the search results as augmented knowledge, a LLM trained with reinforcement learning is utilized to generate the correction.

QuestionRAG utilizes a multi-channel search system to handle multiple knowledge sources, as shown in Figure 1. Its indexing stage employs a multi-faceted strategy combining three methods: (1) a ngram-based inverted index for lexical matching, (2) semantic vector similarity for conceptual retrieval, and (3) a Pinyin-based inverted index for phonetic matching. After an initial retrieval pass, the GTE-multilingual-reranker(Zhang et al., 2024) is used to semantically filter and re-rank all candidate texts based on their relevance to the question. The resulting top-ranked texts then serve as the contextual input for the subsequent generation stage.

3.2 Model Training with RL

Following the paradigm of deepseek R1(Guo et al., 2025), we adopt a two-stage training strategy consisting of Supervised Fine-Tuning (SFT) for cold-start and GRPO-based reinforcement learning for post-training.

3.2.1 Cold-Start SFT

To prepare our training data, we curated a small-scale, high-quality set by sampling both erroneous and error-free questions from QA logs. We manually corrected the erroneous samples to create their ground truth labels. Each question was then augmented with reasoning traces generated by deepseek R1(Guo et al., 2025). During this process, any trace that led to an incorrect correction was discarded. Finally, to ensure the quality of the dataset, every training sample underwent a thorough manual review.

Instead of directly generating the corrected text, in cold-start SFT, the LLM first reason if the question contains an error, and then identifies the error's location if erroneous. Only after outputting this complete reasoning process does the model provide the final, corrected result.

3.2.2 GRPO Training

To enhance the model's generalization and reasoning, we employ Group Relative Policy Optimization (GRPO) (Guo et al., 2025) in a post-training phase. This resource-efficient method eliminates the need for a separate evaluator model by directly comparing candidate responses, with each response scored by a predefined reward function. The design of this reward function is therefore critical for guiding the model toward high-quality, accurate corrections. Our reward function is built on two key components:

- **Format Rewards.** This component systematically verifies whether model-generated outputs strictly adhere to predefined structural templates: <think>{reasoning process}</think>\n\n{final answer}. The reward function of output $\boldsymbol{c}$ is defined as:

$$R_f(\boldsymbol{c}|\boldsymbol{q}) = \begin{cases} 1 & \text{if } \mathbf{c} \text{ format adhered} \\ 0 & \text{otherwise} \end{cases}$$

- **Accuracy Rewards.** The accuracy reward is designed for a nuanced evaluation of the generated correction against the ground truth. Drawing inspiration from the use of Character Error Rate (CER) in error correction(Leng et al., 2022), our function leverages a normalized edit distance(Wang et al., 2024) to quantify the similarity of output $\boldsymbol{c}$ to the target $\boldsymbol{g}$,

defined as:

$$R_a(\boldsymbol{c},\boldsymbol{g}|\boldsymbol{q})=\begin{cases}2.0 & \text{if } \boldsymbol{c}=\boldsymbol{g}\\ (1-d_c)+\beta(1-d_c)^2 & \text{if} d_c<d_q\\ -\lambda\cdot d_c & \text{if} d_c>d_q\\ 0.0 & \text{otherwise}\end{cases}$$

where d_q and d_c represent the normalized edit distances between the ground truth $\boldsymbol{g}$ and the input question $\boldsymbol{q}$, and the model's output $\boldsymbol{c}$, respectively. A smaller edit distance indicates a closer proximity to ground truth. β is a hyperparameter that scales a non-linear bonus for improvements. λ is a hyperparameter that scales the penalty for regressions.

The overall reward function summarizes the format reward and the accuracy reward, i.e.,

$$R(\boldsymbol{c},\boldsymbol{g}|\boldsymbol{q}) = R_f(\boldsymbol{c}|\boldsymbol{q}) + R_a(\boldsymbol{c},\boldsymbol{g}|\boldsymbol{q}).$$

The reward function described above encourages the gradual optimization of correction results during the RL training process, while penalizing incorrect corrections.

4 Experiments

In this section, we present the specific experiments conducted for error correction tasks.

4.1 Datasets

QCSet: QCSet is a dataset derived from the logs of a commercial question-answering system. It comprises approximately 10,000 error-correction pairs, meticulously annotated by human experts to ensure high accuracy.

MCSCSet: MCSCSet(Jiang et al., 2022) is an open-source dataset focused on medical Chinese spelling correction. It is a large-scale dataset containing about 200k samples, manually annotated by medical specialists.

Qspell: Qspell(Ye et al., 2025) is a public-domain dataset of approximately 250k error-correction pairs. It covers lots of topics, like formal terms, casual speech, and idioms, in both Chinese and English.

4.2 Evaluation Metrics

Character Error Rate. To quantitatively evaluate the performance of our error correction model, we employed the Character Error Rate (CER). CER is a widely used metric for assessing the accuracy of text transcription and correction tasks. It measures the minimum number of edits—such as insertions, deletions, or substitutions—required to align the generated output into the ground truth.

4.3 Implementation Details

We utilized Qwen3-8B(Yang et al., 2025) as our base model and trained it on the proprietary dataset QCSet. Specifically, for the cold-start phase, we used around 1,000 QCSet samples enhanced with Chain-of-Thought reasoning generated via DeepSeek R1 distillation(Guo et al., 2025). For the GRPO post-training phase, we employed an additional 7,000 QCSet samples, ensuring no overlap with the cold-start phase. This two-stage approach allowed us to progressively enhance the model's capabilities. To rigorously evaluate the model's performance, we tested it on three distinct test sets, each comprising around 1,000 randomly selected samples, with approximately 90% of the samples requiring correction. These test sets were carefully chosen to ensure no overlap with the training data, providing a comprehensive assessment of the model's error correction capabilities.

In terms of training details, during the cold-start stage, we performed full parameter fine-tuning with a learning rate of 2e-6 and a total batch size of 8. For the GRPO training stage, the learning rate is 5e-6 and batch size is 32. The hyperparameters in our reward function, β and λ, were both set to 1.0 throughout our experiments.

We also detail the computational requirements and training load for the post-training process, addressing the complexity of implementation. Our training, consisting of Cold-Start SFT and GRPO, was executed on Ascend 910B NPUs. The Cold-Start SFT stage involved training the model with 1k samples for 4 epochs on 8 NPUs, costing approximately 50 minutes. The subsequent GRPO phase, which represents the primary contributor to the total computational load, required training with 7k samples for 12 epochs on 32 NPUs, taking approximately 18 hours.

4.4 Results

4.4.1 In-Context Learning (ICL) Result

To verify the effectiveness of knowledge argumentation of LLM on the question correction task, we evaluate QuestionRAG without any fine-tuning (referred to as QuestionRAG$_{ICL}$) by adding different types of knowledge into prompt, as de-

Configuration	QCSet	MCSCSet	QSpell
Original Question	16.13	16.35	14.78
No-RAG	15.37	10.77	10.71
QuestionRAG$_{ICL}$(Entity)	14.31	9.91	10.5
QuestionRAG$_{ICL}$(Entity + Web Info)	13.6	7.8	9.04
QuestionRAG$_{ICL}$(Entity + Web Info + Similar Questions)	**12.53**	**7.14**	**8.63**

Table 3: Comparison of QuestionRAG$_{ICL}$ with different types of knowledges(CER %). No-RAG refers denotes Qwen3-8B without any knowledge argumentation.

Question	Similar Web page titles	Similar Questions	Related Entities	Correction
湖南市大怎么走	湖南大学正门怎么走 湖南市政府怎么走	**到湖南师大怎么走** **到湖南师范大学怎么走**	**湖南师大: 湖南师范大学**	湖南师大怎么走
摩克多再婚妻子	**93 岁默克多再婚** 摩克多塔拉	摩克多检测	**默克多: 默克多也就是鲁伯特·默多克**	默克多再婚妻

Table 4: Two examples of question correction by QuestionRAG. Bold text represents the useful information that has been introduced.

Approach	QCSet	MCSCSet	QSpell
Original Question	16.13	16.35	14.78
Fine-tuned T5	13.08	7.8	13.65
QuestionRAG$_{ICL}$	12.53	7.14	8.63
QuestionRAG$_{SFT}$	11.19	5.43	8.28
QuestionRAG$_{GRPO}$	**9.04**	**5.08**	**6.37**

Table 5: Comparing of SFT and GRPO against the other baselines on Chinese question correction(CER %).

tailed in Appendix A. From Table 3, it is clear that progressively enhancing the RAG framework with additional knowledge sources consistently improved error correction performance on all the three dataset. Firstly, related entity information provided relevant or homophonic named entities and descriptions, which allowed the model to understand related concepts, especially by supplementing knowledge of rare entities. Secondly, the inclusion of web information provided real-time, diverse data, enhancing the model' s ability to handle novel errors. Finally, the introduction of similar questions from Our QA System also significantly improved error correction on the two open-source datasets. These findings suggest that external knowledge from either general or domain sources is crucial for LLM on the question correction task.

4.4.2 Post Training Results

We further aligned the LLM in QuestionRAG for question correction task with reinforcement learning. Its results are shown in Table 5. QuestionRAG$_{GRPO}$ achieved the lowest CER on all the datasets, while QuestionRAG$_{SFT}$ slightly outperforms QuestionRAG$_{ICL}$. It suggests that both SFT and reinforcement learning alignment can further improve the effectiveness of QuestionRAG. Compared with SFT alone, reinforcement learning with GRPO exhibits stronger generalization capability. Table 4 presents the relevant knowledge introduced for the incorrect questions, along with the useful information and the final corrected results. As can be seen, introducing additional context significantly reduces the difficulty for the LLM to perform the correction.

Beyond the quantitative improvements, we observed a surprising and critical qualitative advantage: QuestionRAG$_{GRPO}$ exhibits superior robustness even when faced with highly misleading and erroneous retrieval context. Table 6 clearly demonstrates this capability. The model successfully navigates a scenario where the majority of the entire retrieved context is erroneous and collectively favors common, yet wrong interpretations. The ability of QuestionRAG$_{GRPO}$to successfully filter this dominant, misleading information and adhere to the user's likely intent confirms that our approach guides the model toward a more reasoned and reliable correction trajectory.

4.4.3 The impact of Model Scale

We investigated the impact of model size within the QuestionRAG framework using various Qwen3 models. The results, presented in Figure 2, show that larger LLMs have a clear advantage over smaller ones, though this performance gap narrows as model size increases. This is because while all models share the same external knowledge provided by the RAG component, larger LLMs also possess more internal knowledge and stronger inherent capabilities for linguistic under-

Question	Similar Web page titles	Similar Questions	Related Entities

QuestionRAG$_{ICL}$: 终南山是谁 (Incorrect); QuestionRAG$_{GRPO}$: **钟南山是谁** (*Correct*)

Table 6: Robustness case study: QuestionRAG$_{GRPO}$ successfully corrects ambiguous queries despite highly noisy contextual information.

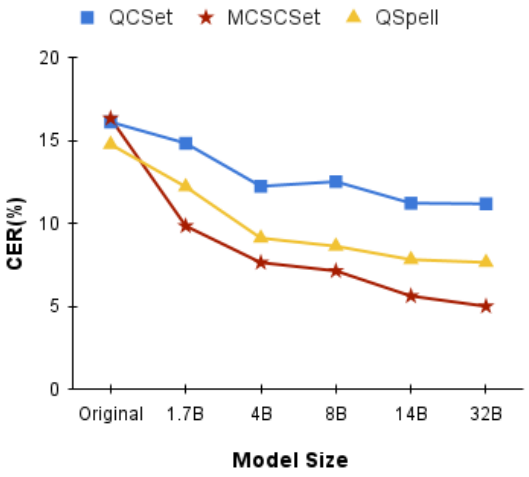

Figure 2: Impact of model size on CER(%) for Qwen3 models (1.7B to 32B) within the QuestionRAG framework, illustrating how increasing model size affects performance.

standing and reasoning.

Moreover, a key finding demonstrates the power of knowledge augmentation: a smaller model equipped with QuestionRAG can outperform a much larger model that lacks it. For instance, a comparison between the "No RAG" baseline (Qwen3-8B) in Table 3 and the 1.7B parameter QuestionRAG model in Figure 2 reveals that the smaller model with QuestionRAG often achieves superior performance, highlighting that external knowledge can be more impactful than simply increasing model scale.

5 Conclusion

This paper introduces QuestionRAG, a novel framework that significantly enhances language model performance by addressing two of their core failures: misinterpretation and over-correction. Its primary innovation lies in a dual-pronged strategy: it leverages Retrieval-Augmented Generation to provide essential external context while employing Reinforcement Learning to meticulously align model behavior. This approach allows QuestionRAG to overcome the inherent deficiencies of LLMs in understanding character graphemes and phonetics, enabling it to fully exploit their strengths in text comprehension and generation within a single, unified framework that handles diverse error types. Beyond simple question correction, its methodology is directly applicable to broader tasks such as question rewriting, planning, and enhancing query understanding in search engines, opening new avenues for future research.

Limitations

The performance of QuestionRAG is critically dependent on the quality of its search results. If the retrieved information is irrelevant or noisy, the accuracy of the final output will be compromised. Furthermore, because the RAG process significantly increases prompt length, it also increases latency, particularly the time to first token.

A Prompt for Error Correction

The complete version of the prompt used in our experiments is provided in the following. It outlines the instructions and principles for question error correction, including the use of retrieved information and strict adherence to correction rules.

Prompt

You are a meticulous proofreading assistant. You need to combine your own knowledge with retrieved information (including similar questions, web titles, and entity information) to determine whether the user's original query requires correction. If no correction is needed, output the user's original query; otherwise, output the corrected query, strictly adhering to the following principles. Any changes must be based on phonetic similarity and preserve the framework of the user's original query.
Correction Principles (Strict Priority, Check from 1 to 4):
1. Minimal Modification Principle (Core): Only modify clearly erroneous parts of the user's original query (e.g., spelling errors, homophonic typos). Some special parts (including punctuation, spaces, capitalization, and word order) must remain unchanged. The corrected output should be similar in length and structure to the original query, with minimal changes. If the error cannot be identified, do not correct.
2. Corrections must strictly follow homophonic or near-homophonic rules (i.e., the corrected result must have the same or similar pronunciation as the original part). If an error is evident but does not satisfy the homophonic/near-homophonic rule, do not correct and output the user's original query.
3. Cautious Reference Principle (Supplementary Reference): Retrieved information (similar questions, web titles, entity information) is for reference only and may contain errors (especially similar questions, which may share the same mistakes). Use your own language knowledge to evaluate, and ignore retrieved information if it violates Principle 1 or 2 (e.g., suggests significant changes or alters pronunciation).
4. Semantic Preservation Principle (Non-Optimization Principle): Ensure the corrected query retains the same semantic meaning as the original, without altering the user's intent or structure for the sake of fluency. Only fix errors. If the intent is ambiguous, has multiple possibilities, or correction would distort the original meaning, do not correct (output the user's original query). Do not add or remove words to make the sentence more fluent.
Output Requirement: Directly output the corrected query or the user's original query without explanation.

- Related Entity Information:
{entity details}
User's Original Query:
{query}
Output the corrected result

SMART: Scalable Multilingual Approach for a Robust TOD System

Karan Malhotra*, **Arihant Jain***, **Purav Aggarwal, Anoop Saladi**
Amazon
{kamlhtra, arihanta, aggap, saladias}@amazon.com

Abstract

Task-Oriented Dialogue (TOD) systems have become increasingly important for real-world applications, yet existing frameworks face significant challenges in handling unstructured information, providing multilingual support, and engaging proactively. We propose SMART (**S**calable **M**ultilingual **A**pproach for a **R**obust **T**OD System), a novel TOD framework that effectively addresses these limitations. SMART combines traditional pipeline elements with modern agent-based approaches, featuring a simplified dialogue state, intelligent clarification mechanisms, and a unified natural language generation component that eliminates response redundancy. Through comprehensive evaluation on troubleshooting and medical domains, we demonstrate that SMART outperforms baseline systems across key metrics. The system's modular approach enables efficient scaling to new languages, as demonstrated through Spanish and Arabic languages. Integration of SMART in an e-commerce store resulted in reduction in product return rates, highlighting its industry impact. Our results establish SMART as an effective approach for building robust, scalable TOD systems that meet real-world requirements.

1 Introduction

Task-Oriented Dialogue (TOD) systems (Xu et al., 2024; Hudeček and Dušek, 2023) have evolved significantly in recent years, becoming increasingly crucial in human-computer interaction scenarios like customer service, healthcare, and hotel booking (Valizadeh and Parde, 2022; Rastogi et al., 2020; Dam et al., 2024). While Large Language Models (LLMs) (OpenAI et al., 2024; Zhao et al., 2025) have enhanced natural language understanding and generation capabilities, existing TOD frameworks still face challenges in handling unstructured information, providing multilingual support, and engaging proactively (Zhang et al., 2020; Dong et al., 2025).

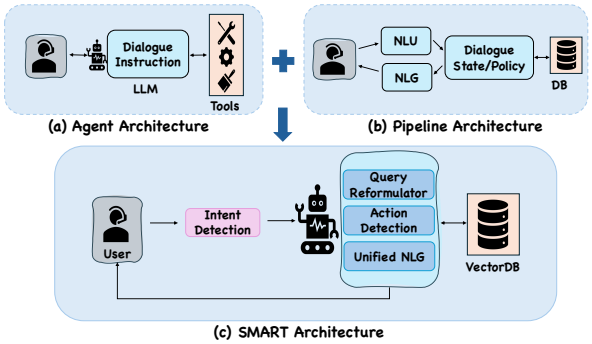

Figure 1: SMART combines traditional pipeline TOD systems with modern agent-based approaches, creating a robust and flexible system that leverages the strengths of both to enhance TOD capabilities.

Current TOD approachs typically employ complex pipelines that, while functional, limit scalability and adaptability across different domains and languages (Li et al., 2024). These systems often face difficulties in maintaining contextual awareness, generating appropriate responses, and effectively managing duplicate solutions. Additionally, existing frameworks frequently lack robust mechanisms for handling ambiguous user inputs and managing clarification workflows effectively.

To address these challenges, we introduce SMART (**S**calable **M**ultilingual **A**pproach for a **R**obust **T**OD System), a novel and highly scalable proactive TOD system that combines traditional pipeline elements with modern agent-based approaches as shown in Figure 1, featuring simplified dialogue state, clarification mechanisms, and a unified natural language generation. The key contributions of our work are as follows:

- **Simplified** approach for processing **unstructured** information with **action detection** and **unified NLG** modules. (Sec. 3)

*These authors contributed equally to this work.

2 Related Work

TOD systems have evolved significantly over the years, with approaches falling into three main categories: (1) Pipeline-based, (2) Causal-based, and (3) Agentic-based. **Pipeline** approaches, the earliest paradigm, such as Wu et al. (2019); Zhang et al. (2020) employed a modular architecture consisting of distinct components for natural language understanding (NLU), dialogue state tracking (DST), policy learning, and natural language generation (NLG). While effective, these systems often suffered from error propagation between modules. The field then progressed towards **causal-based**, end-to-end TOD systems (Yang et al., 2021; Sun et al., 2023; Hosseini-Asl et al., 2022), which unified these components into a single jointly trained model. This integration helped reduce error propagation and simplified the overall system, leading to improved performance and easier maintenance.

The emergence of LLMs (Touvron et al., 2023; OpenAI et al., 2024; Zhao et al., 2025) has further transformed TOD systems, giving rise to **agentic** approaches. These methods leverage the broad knowledge and capabilities of LLMs to create more flexible and powerful TOD systems. Recent agentic works like AutoTOD (Xu et al., 2024) and FnCTOD (Li et al., 2024) demonstrate that complex traditional modules can be replaced by instruction-tuned LLMs with simple schemas, significantly simplifying system design. Proactive TOD systems, such as ProTOD (Dong et al., 2025), addresses key limitations including single-turn retrieval, simple dialogue policies, and limited evaluation metrics.

2.1 Limitations of existing frameworks

We conducted a comprehensive comparison of existing TOD frameworks and our SMART approach. Table 1 illustrates how SMART addresses the limitations of current approaches while maintaining their strengths. The comparison focuses on following key system aspects:

- **Proactive Clarification:** The ability to ask clarifications whenever needed.
- **Response De-Duplication:** Eliminating redundant responses in the dialogue flow.
- **Multilingual Support:** Capability to handle multiple languages.
- **Fine-tuned NLU:** Utilization of fine-tuned NLU components.
- **Simplified DST:** Implementation of a simplified Dialogue State Tracking mechanism.

As evident from Table 1, SMART outperforms existing frameworks across all evaluated aspects. While the Pipeline approach excels in fine-tuned NLU and the Causal approach offers simplified DST, SMART incorporates these strengths while addressing their limitations. Notably, SMART is the only system to fully support proactive clarification, response de-duplication, and efficient multilingual scaling.

3 Proposed SMART Method

Figure 1 illustrates the SMART approach, which smartly combines elements from both traditional pipeline TOD systems and modern agent-based approaches. This hybrid approach leverages the strengths of both paradigms to create a more robust and flexible system.

3.1 Unstructured Knowledge Base

A TOD system requires a domain-specific knowledge base to provide up-to-date information to users. We construct our knowledge base by first sourcing the unstructured domain specific content.

Algorithm 1 Proposed SMART Method (Sec. 3)

Input: Chat History H, User Query Q, VectorDB $\mathcal{V}$, Domain D
Output: Response R

1: $I \leftarrow$ Intent-Detection(H, Q, D) ▷ Get the user intent
2: **if** I is issue **then** ▷ If the user query is related to an issue
3: $\hat{Q} \leftarrow$ Reformulator(H, Q) ▷ Reformulate the user query
4: $\mathcal{C} \leftarrow$ Retriever($\hat{Q}$, $\mathcal{V}$) ▷ Retrieve the relevant chunks
5: $is_clarify$, $question$, $options \leftarrow$ Action-Detection($\hat{Q}$, $\mathcal{C}$)
6: **if** $is_clarify =$ TRUE **then** ▷ Check if clarification is needed
7: $R \leftarrow$ Display $question$ and $options$ to user ▷ Show clarification question and options
8: **else**
9: $R \leftarrow$ Unified-NLG(I, $\mathcal{C}$) ▷ Provide solutions using chunks
10: **end if**
11: **else**
12: $R \leftarrow$ Unified-NLG(I) ▷ Provide coherent response basis intent
13: **end if**
14: **return** R ▷ Return the final response

We then employ AutoChunker (Jain et al., 2025b) that uses an LLM based bottom-up approach to intelligently chunk the content while preserving context and eliminate noise. The resulting chunks are embedded using an embedding model and stored in a scalable vectorDB for efficient similarity search. During retrieval, when a user query is received, we compute the cosine similarity between the query embedding and the stored chunk embeddings, returning the top-k most similar chunks.

3.2 Intent Detection

Intent detection is a key component of a TOD system. Our module takes three key inputs: the conversation history, the user's most recent utterance, and the relevant domain information (such as user product details in troubleshooting domain), as outlined in Algorithm 1 (Line 1). By incorporating domain-specific information alongside conversational context, the system achieves more accurate intent recognition. While this can be implemented using an LLM with prompt 1 in Appendix A, such approaches often struggle to meet industry latency needs.

To address the latency challenge while maintaining high accuracy, we employed an intent detection model built upon ModernBERT (Warner et al., 2024), an enhanced variant of BERT (Devlin et al., 2019) that supports extended context lengths of up to 8192 tokens. The model is fine-tuned through supervised learning using a dataset of domain-specific conversations and intents.

3.3 Query Reformulation and Retriever

After intent detection, certain intents trigger the retrieval of domain-specific information from the VectorDB. To enhance the retrieval process, we employ an LLM based reformulator with prompt 2 in Appendix A. This component takes the chat context and domain context as that of intent detection module and generate a refined query more suitable for document retrieval. The reformulation process is shown in Algorithm 1 (Line 3).

Our reformulator transforms the input into a more precise and context-aware query, which is then used to search for relevant chunks in the VectorDB, as outlined in Algorithm 1 (Line 4). This approach significantly improves retrieval accuracy, ensuring that the TOD system can access and utilize the right information from the knowledge base.

3.4 Action Detection

Once the system retrieves relevant content, it can proceed to response generation. However, for vague or ambiguous user queries, it is recommended to have a clarification strategy. This approach involves asking targeted questions to gather additional context before providing a response, ultimately leading to more accurate and helpful answers.

To achieve this, we introduce an action detection module, which serves as a critical decision-making component in the TOD system. This module is implemented using an LLM with prompt 3 in Appendix A, as shown in Algorithm 1 (Line 5-7). Its

primary function is to analyze the retrieved content and the user's query, determining whether clarification is needed or if the system can proceed directly to response generation. When clarification is necessary, the action detection module also generates appropriate question and response options.

3.5 Unified NLG Layer

We employ a unified Natural Language Generation (NLG) layer powered by a LLM with prompt 4 in Appendix A to generate the final response. This layer adapts its functionality based on the query type and intent:

- For solution-oriented queries, it utilizes relevant text chunks to generate solutions.
- For queries requiring coherent responses without specific solutions, it leverages the detected intent to produce appropriate replies.

The choice between these modes is determined by detected intent, ensuring tailored responses for each query type, as shown in Algorithm 1 (Line 9-12).

3.5.1 Solution De-Duplication in Multi-Turn

In TODs, presenting multiple unique solutions across different turns is crucial. To prevent redundancy, we can repeatedly prompt the LLM to generate new solutions excluding previous ones. However, it is a challenging task that is prone to generating duplicate solution in later turns. Instead, we leverage the LLM's ability to generate multiple solutions in a single pass as it will generate fewer duplicate solutions.

We implement this setup by **(a)** Using a consistent prompt for the LLM, **(b)** Interrupting generation after each solution is provided, **(c)** Continuing generation from the same LLM instance if the previous solution does not works out for the user, and **(d)** Repeating this process until the issue is resolved or a predefined solution limit is reached. This approach reduces the likelihood of duplicate solutions while maintaining the flow of the conversation.

4 Experimental Setup

4.1 Datasets

Following Sahay et al. (2025), we evaluate our approach on two distinct domains: (1) For the **Troubleshooting** domain, the knowledge base is built using historical customer-reported issues from an e-commerce store, supplemented with domain knowledge extracted from user guides and product manuals. Due to proprietary constraints, we utilize a sampled subset of data from a real-world e-commerce store to mitigate any risks associated with sensitive information. (2) For the **Medical** domain, we treat patient symptoms as user issues and corresponding treatments as solutions. The user symptoms are sourced from Kaggle (2016) and the domain knowledge is sourced from the dataset introduced in Shah et al. (2021b,a).

We utilized these data sources for the building the knowledge base as described in Sec.3.1 using *cohere.embed-multilingual-v3* (Cohere, 2023) as the embedding model. Table 8 in Appendix C summarizes the details of the datasets and relevant statistics from the knowledge base, including the number of chunks and issues.

4.2 Evaluation setup

We employed the AutoEval-ToD framework (Jain et al., 2025a) for comprehensive automated evaluation of TOD systems. This approach simulates diverse user interactions across various scenarios, generating extensive conversations based on seed issues. Throughout these simulations, we collected detailed data and metadata at each turn, enabling a thorough analysis of the TOD performance. We then independently evaluated key components using focused datasets tailored to each module. We utilized *claude-3-sonnet* (Anthropic, 2023) to run our AutoEval-ToD based evaluation metrics.

4.3 Baselines and Implementation

We evaluate SMART against a baseline system based on AutoTOD (Xu et al., 2024) across multiple TOD domains. Both systems use *claude-3-haiku* (Anthropic, 2023) as the underlying model and the same knowledge base to ensure fair comparison. The baseline employs an agentic Retrieval-Augmented Generation (RAG) (Lewis et al., 2020) approach for all conversation aspects. For intent detection, SMART uses a fine-tuned ModernBERT (Warner et al., 2024) model (details in Appendix B). Pipeline and causal approaches are excluded from our comparison due to (1) their reliance on domain-specific data which are not readily available, and (2) their decreasing prevalence in the current LLM-dominated landscape.

Models	Prec.	Rec.	F1	Latency
claude-3-haiku	0.846	0.817	0.808	2.25s
claude-3-sonnet	0.889	0.864	0.865	5.31s
ModernBERT	**0.891**	**0.881**	**0.884**	**110ms**

Table 2: Experimental results comparing intent detection performance on Troubleshooting domain.

Evaluation Criteria	Human	LLM
Query Correctness	0.872	0.928
Information Retention	0.844	0.908
Context Relevance	0.816	0.912

Table 3: Evaluation of SMART's query reformulation quality in the Troubleshooting domain by human and LLM judges. Scores range from 0 to 1, where higher scores indicate better performance.

Metric	Turn #1	Turn #2	Turn #3
HitRate@1	0.35	0.41	0.45
HitRate@3	0.51	0.57	0.61
HitRate@5	**0.56**	**0.62**	**0.66**

Table 4: Experimental results comparing retriever performance across turns on Troubleshooting domain.

Response Quality Metrics	AutoTOD	SMART
Response Factuality (↑)	0.670	**0.744**
Solution Redundancy (↓)	0.151	**0.049**
Solution Relevance (↑)	0.897	**0.963**
Safety Compliance (↑)	0.975	**0.984**

Table 5: Comparison of response quality metrics between baseline AutoTOD and SMART on Troubleshooting domain. Higher scores are better for all metrics except Solution Redundancy, where lower scores indicate better performance.

5 Results and Analysis

5.1 Intent Detection

We evaluate our fine-tuned ModernBERT model against LLM-based approaches using *claude-3-haiku* and *claude-3-sonnet* with prompt 1. Our test set comprises manually labeled utterances from simulated conversations, using different seed issues than the training set to ensure robust evaluation. Table 2 shows that ModernBERT outperforms LLM-based approaches in Precision, Recall, and F1-score. Notably, it achieves 20x faster inference time compared to *claude-3-haiku*, demonstrating that fine-tuned smaller models can match or exceed LLM performance for certain tasks.

5.2 Query Reformulation

We evaluate our query reformulation module using three key metrics assessed by both human judges and LLM-based evaluation with prompt 5 in Appendix A: (1) **Query Correctness** (0/1), measuring whether the reformulated query maintains the original intent while ensuring grammatical correctness; (2) **Information Retention** (0/1), evaluating how well essential information from the original query and chat history is preserved; and (3) **Context Relevance** (0/1), assessing the reformulation's ability to incorporate relevant contextual information while filtering out redundant details. As shown in Table 3, our system achieves strong performance across all three metrics in both human and LLM evaluations.

5.3 Retriever

We evaluate the retriever performance of our TOD systems using HitRate@k as proposed by Jain et al. (2025a), measuring the proportion of times the correct chunk is retrieved within the top k results across multiple turns. Table 4 presents the retriever performance across three turns, demonstrating consistent improvement with each subsequent turn. We observe a significant improvement in HitRate@5 from 0.56 in Turn #1 to 0.66 in Turn #3, representing a 17.9% relative increase. This enhancement suggests that our multi-turn clarification approach, implemented using Action Detection, effectively refines the retrieval process. Here, Turn #1 performance is comparable to the AutoTOD baseline, which does not include clarification turns.

5.4 Action Detection

To assess the effectiveness of the Action Detection Module, we conducted a comprehensive evaluation using human annotators, focusing on three key metrics: (1) **Clarification Accuracy** measures the module's ability to correctly identify when clarification is needed, (2) **Question Correctness** evaluates the appropriateness of the generated clarification questions, and (3) **Option Relevancy** assesses whether the provided options are pertinent to the query. Human annotators were presented with retrieved chunks, user reformulated queries, and the module's output (is_clarify, question, and options). They evaluated these metrics on binary scale where higher score indicate better performance. The results demonstrated strong performance across all metrics, with Clarification Accuracy scoring 0.81, Question Correctness achieving 0.92, and Option Relevancy reaching 0.89 on average. These findings suggest that the Action Detection Module is effective in identifying when clarification is needed and in generating relevant questions and options.

5.5 Unified NLG

We evaluate our unified NLG module's effectiveness across multiple quality dimensions using LLM-based evaluation with prompt 6, 7 and 8 in Appendix A, comparing our SMART's final responses against the AutoTOD baseline. Our evaluation framework focuses on four critical aspects of response generation: (1) **Response Factuality** measures how well the generated responses align with the knowledge base information, ensuring responses are grounded in the context retrieved, (2) **Solution Redundancy** quantifies the system's ability to avoid duplicate solutions within conversations, with lower scores indicating better performance, (3) **Solution Relevance** evaluates how well the generated solutions address the specific user issues, with higher scores indicating more contextually appropriate and helpful responses, and (4) **Safety Compliance** measures the system's ability to generate responses that adhere to safety guidelines and avoid potentially risky solutions.

As shown in Table 5, SMART consistently outperforms AutoTOD across metrics, demonstrating the effectiveness of our unified NLG approach in generating high-quality, relevant, and non-redundant responses while maintaining safety standards. Our system achieves a significantly lower redundancy rate compared to AutoTOD, indicating non-repetitive responses. Additionally, SMART shows higher scores in Response Factuality, Solution Relevance, and Safety Compliance, further highlighting its superior performance in generating relevant and safe responses. A SMART's example conversation is shown in Figure 2.

6 Scaling Results and Analysis

6.1 Scale to different languages

We demonstrate SMART's multilingual capabilities by extending it to Spanish and Arabic in the troubleshooting domain, requiring minimal modifications to the system approach (Intent Detection, Unified NLG and output question-options of Action Detection). To evaluate multilingual performance, we utilized the metric, **Language Correctness**, which measures the grammatical accuracy and natural flow of responses in each target language. We also assess performance on the metrics as described in Sec. 5.5. As shown in Table 6, SMART is able to maintain performance levels across Spanish and Arabic. The high Language Correctness scores demonstrate the system's adaptability to generate linguistically appropriate responses.

Response Quality Metrics	Arabic	Spanish
Response Factuality (↑)	0.768	0.716
Solution Redundancy (↓)	0.050	0.013
Solution Relevance (↑)	0.946	0.914
Safety Compliance (↑)	0.966	0.935
Language Correctness (↑)	0.985	0.940

Table 6: SMART Multilingual performance in Troubleshooting domain for Spanish and Arabic.

Response Quality Metrics	AutoTOD	SMART
Response Factuality (↑)	0.686	**0.792**
Solution Redundancy (↓)	0.240	**0.020**
Solution Relevance (↑)	0.823	**0.986**
Safety Compliance (↑)	0.990	**0.991**

Table 7: Comparison of response quality metrics between baseline AutoTOD and SMART system on Medical domain. Higher scores are better for all metrics except Solution Redundancy, where lower scores indicate better performance.

6.2 Scale to different domain

To showcase SMART's adaptability across domains, we integrated it with medical domain data and evaluated its performance using the metrics described in Sec.5.5. Table 7 presents a comparison between the baseline AutoTOD and SMART on medical domain tasks. The results demonstrate SMART's superior performance in key areas indicating its ability to provide medical solutions.

7 Industrial Impact

The integration of our SMART-based TOD system, focused on the Troubleshooting domain (example conversation in Figure 2), into an online multi-marketplace e-commerce store gives an estimated reduction of 27 basis points (bps) in product return rates. This improvement is primarily attributed to the system's scalability across multiple marketplaces and its ability to provide more contextually relevant responses to customer queries through improved clarification questions, leading to better post-purchase support.

8 Conclusion

We presented SMART, a novel TOD system that effectively combines traditional pipeline with modern agent-based approaches to address key limitations in existing frameworks. Through comprehensive evaluation, we demonstrated SMART's su-

perior performance across multiple metrics. The system's modular design enables efficient scaling to new languages and domains as shown through Spanish and Arabic languages and medical domain application. The practical impact of SMART is evidenced by its testing in an e-commerce setting, where it contributed to a reduction in product return rates. SMART establishes a new standard for building robust, scalable TOD systems that meet real-world requirements.

Limitations

Although SMART shows significant improvements in handling unstructured information and multilingual support, it has certain limitations that require future improvements:

Limited LLM Diversity: Our evaluation focuses primarily on Claude models due to their favorable cost-performance trade-off. While GPT-4 and other advanced models could provide additional insights, their higher computational costs made extensive experimentation less practical for our study.

Domain Focus: While effective in problem-solving domains like troubleshooting and medical support, SMART's capabilities in discovery-based scenarios like hotel booking or other online shopping remain unexplored.

These limitations highlight opportunities for future research to expand SMART's applicability and robustness across different models and domains.

A Prompts

A.1 Intent Detection Prompt

The prompt 1 instructs the LLM to analyze user utterances within the complete conversation context while considering domain-specific information. It requires inputs including conversation history, current user utterance, domain context, and available intents with definitions. The output format mandates explicit thinking followed by predicted intent.

Prompt 1: Intent Detection Prompt

```
You are an intent classifier for {domain}
support. Your task is to identify the
intent of the latest user utterance from
the list of intents provided in the input.

You will receive the following inputs:
1.Conversation History: Previous exchanges
between user and assistant.
2.Latest Utterance: Current message from
user
3.Domain Context: Domain-specific
information (e.g., product details for
troubleshooting, patient history for
medical)
4.Available Intents: List of possible
intents with definitions

Output Guidelines:
Your response MUST contain:

<thinking> Analyze the latest utterance in
context of the conversation.
Consider domain-specific terminology and
context.
<response>
intent: Primary intent from available
options
Response must follow the format:
<response>
<thinking>[Analysis]</thinking>
```

<intent>[intent]</intent>
</response>

Input:
conversation_history:
{conversation_history}
latest_utterance: {latest_utterance}
domain_context: {domain_context}
available_intents: {domain_intents}

A.2 Query Reformulation Prompt

The query reformulation prompt 2 helps the LLM create clear, focused queries from user conversations. It combines the conversation history, current utterance, and domain information to create a single, well-formed query. The prompt ensures that the reformulated query keeps the main user issue while adding useful context from the conversation.

Prompt 2: Query Reformulation Prompt

You are an AI assistant for {domain} support. Your task is to generate a reformulated query that effectively summarizes the user's issue based on the conversation context.

Input:
conversation_history:
{conversation_history}
latest_utterance: {latest_utterance}
domain_information: {domain}
context: {context}

Output Guidelines:
Your response MUST contain:

<thinking>
- Brief analysis of your reformulation strategy (2-3 sentences)
-Analyze the conversation context and latest utterance
-Consider key information from domain context

<reformulated_query>
-Generate a concise, one-sentence query
-Maintain the core meaning of the user's issue
-Include relevant context from the conversation
-Always provide the query in English

Never provide solutions or troubleshooting steps; focus only on query reformulation

A.3 Action Detection Prompt

The action detection prompt 3 helps to decide what to do next in a conversation. It checks if it need more information from the user or if it can move forward with a solution. The prompt helps create clear questions when needed and provides simple options for users to choose from. It also includes examples to show how to handle different types of conversations effectively.

Prompt 3: Action Detection Prompt

You are an AI assistant for {domain} support. Your task is to analyze the inputs to determine the optimal next action for domain support resolution based on the context.

You will receive the following inputs:
1.Conversation History: Previous exchanges between the user and assistant
2.User Input: The current message from the user
3.Domain Information: Relevant details about the domain
4.Context: Additional relevant information containing solutions for domain queries

Guidelines:
Your response MUST contain:
1. <thinking> - Brief analysis justifying your action choice (2-3 sentences maximum)
- First check if the user's description lacks specific details or attributes about their query
- Do not ask for information already present in the context
- Only ask questions relevant to resolving the user's query in the domain context
2. <action> - Single selected action in uppercase from:
- CLARIFICATION_NEEDED: When additional specific information is needed
- NO_CLARIFICATION_NEEDED: When sufficient information is available
3. <question> - (When clarification is needed)
- Keep it short and natural, limited to 1 sentence
- Do not include options in the question
4. <options> - (When presenting choices) - List of 2-3 specific response options in <option> tags
5. Never provide direct solutions or advice

Few Examples are:
{ICL_examples}

Input:
conversation_history:
{conversation_history}
user_input: {user_input}
domain_information: {domain}
context: {context}

A.4 Unified NLG Prompt

The Unified NLG prompt 4 guides the LLM in processing inputs that are conversation history, customer query, domain, context (chunks), and intent. This prompt employs specific formatting rules, notably the use of numbered solution tags

(<sN>...</sN>), to structure and delineate multiple solutions within a single response. These tags serve as control mechanisms, allowing the LLM to pause after each solution and continue with subsequent ones. For non-solution responses, the prompt enforces concise answers limited to 20 words.

Prompt 4: Unified NLG Prompt

```
You are an AI customer support assistant. Your task is to provide helpful, accurate responses to customer inquiries about their product based on the information provided.

<input>
You will receive the following inputs:
1. History: Previous exchanges between the customer and assistant
2. Customer Input: The current message from the customer
3. Domain Information: Relevant details about the domain
4. Context: Additional relevant information containing solutions for troubleshooting
5. Intent: The intent of the customer input
</input>

Output Guidelines:
- Provide a solution or a coherent response based on intent. If the intent is related to issue, then provide solution, else provide a coherent response.
- In case of providing solutions to customers, end each solution should be enclosed within a tag like that "<sN> ... </sN>" where N is the solution number. Provide a brief numbered summary of each solution with title of each solution in **..** format. And only show a maximum of 3 solutions at a time. Adhere to this structure when providing and solution or steps.
- Ask for confirmation in terms of Yes-No question if the solution is offered
- If the solutions are not provided, keep your responses short and crisp and to the point, preferably under 20 words.

Input:
conversation_history:
{conversation_history}
customer_input: {customer_input}
domain: {domain}
context: {context}
intent: {intent}
```

A.5 Query Reformulation Evaluation Prompt

The query reformulation evaluation prompt 5 evaluates input queries by looking at three aspects: if it keeps the main user question (correctness), if it includes important information (retention), and if it uses relevant context appropriately. The LLM gives a score for each aspect and provides comments about what works well or needs improvement.

Prompt 5: Query Reformulator Evaluation Prompt

```
You are a query reformulation evaluator for {domain} support. Your task is to assess the quality of reformulated queries.

Evaluation Criteria:
Query Correctness (0/1):
- Maintains core intent
- Grammatically correct
- Avoids misinterpretation
Information Retention (0/1):
- Preserves essential information
- Incorporates conversation context
- Maintains relevant domain details
Context Relevance (0/1):
- Uses relevant context
- Appropriate domain integration
- Excludes redundant information

Output Format:

<query_correctness>[0/1]</query_correctness>
<inf_retention>[0/1]</inf_retention>
<context_relevance>[0/1]</context_relevance>
<comments>[Observations]</comments>

Input:
user_query: {user_query}
chat_history: {chat_history}
domain_context: {domain_context}
reformulated_query: {reformulated_query}
```

A.6 Solution Factuality Prompt

This prompt 6 checks if the input solutions are supported by the provided input context. It looks for meaningful matches between the solution and context. The LLM gives a simple pass (1) or fail (0) score based on whether it can find support for at least one key part of the solution in the context.

Prompt 6: Response Factuality Evaluation Prompt

```
You are an expert solution validator for {domain} support. Your task is to evaluate solutions for their groundedness in provided context, using lenient matching criteria.

Evaluation Criteria:
-Use lenient matching - look for conceptual alignment rather than exact matches
-Solution is considered grounded if ANY meaningful element can be reasonably derived from context
-Consider semantic similarities and related concepts
-If at least one key element aligns with context, consider it grounded
```

```
Output Guidelines:
Your response MUST contain:

<thinking>
- Identify solution elements that conceptually align with context
- Note semantic similarities and related concepts
- Explain grounding justification

<result> Score: [1 or 0]
1 = At least one meaningful element is grounded in context
0 = No elements can be reasonably derived from context

Input:
context: {context}
solution: {solution}
```

A.7 Solution Redundancy Detection Prompt

The redundancy detection prompt 7 checks if the system is repeating similar solutions. It looks for matching or very similar advice across input solutions, giving a pass (1) if all solutions are unique or fail (0) if duplicates are found.

Prompt 7: Solution Redundancy Evaluation Prompt

```
You are an expert duplicate solution identifier specialized in {domain} analysis.
Analyze the given list of {domain} solutions and determine if there are any duplicate or substantially similar solutions present.

Output Guidelines:
Your response MUST contain:

<thinking>
- List identified duplicate pairs (if any)
- Explain why they are considered duplicates
- Highlight key similarities

<result> Score: [1 or 0]
1 = No duplicates found (all solutions are unique)
0 = At least one pair of duplicate solutions detected

Input:
solutions: {solutions_str}
```

A.8 NLG Rules Evaluation Prompt

The NLG response quality evaluation prompt 8 checks three things: if they match what the user asked for, if they're safe to use, and if they're written correctly in the correct language. For each check, the LLM gives a score and explains the reason.

Prompt 8: NLG Rules Evaluation Prompt

```
You are a solution evaluator for {domain} support. Your task is to assess whether provided solutions adhere to predefined rules.

Evaluation Rules:
Solution Relevance: Solution must directly address the specific context mentioned in the query
Safety Compliance: Avoid solutions that could potentially harm users or lead to adverse outcomes
Language Correctness: Solution must be completely expressed in {response_language}, following appropriate grammar and conventions while maintaining clarity.

<thinking>
- Brief analysis notes for each rule
- Key observations about compliance
- Potential concerns or violations

<scores>
- Score for each rule: 0 (non-compliant), 1 (compliant), or -1 (not applicable)
- English reasoning for each score
- Format: <scoreN> followed by <reasonN>

Response must be structured as:
<thinking>[Analysis]</thinking>
<scores>
<score1>[0/1/-1]</score1><reason1></reason1>
<score2>[0/1/-1]</score2><reason2></reason2>
<score3>[0/1/-1]</score3><reason3></reason3>
</scores>

Input:
user_query: {query}
solution: {solution}
```

B Intent Detection Fine-Tuning

The intent detection training data is created from human-vetted utterances sampled from AutoEval-ToD approach's simulated conversations that uses an LLM-based intent detection module with prompt 1. The input to ModernBERT is structured as:

$$X = [H; \texttt{[SEP]}; U; \texttt{[SEP]}; C]$$

where H represents the chat history, U is the latest utterance, and C is the context (product details for troubleshooting domain, medical information for medical domain). This structured input ensures the model has access to all relevant information while maintaining clear boundaries between different information types. We utilize transformers (Wolf et al., 2020) library to fine-tune this with batch size of 4, max token length as 8192, and fine-tuning for 5 epochs. The troubleshooting set had 18 intents

Figure 2: Example conversation demonstrating SMART's key capabilities: (a) Initial intent detection from user query, (b) Intelligent clarification to gather missing context, (c) Enhanced retrieval based on clarified information, and (d) NLG of a deduplicated, contextually appropriate solution. This showcases SMART's ability to manage complex troubleshooting scenarios through a systematic, user-friendly approach.

(46K samples), and the medical set had 6 intents (15K samples).

C Additional Figures and Tables

Table 8 summarizes the details of the datasets and relevant statistics from the knowledge base, including the number of chunks and issues. Figure 2 showcases an example conversation demonstrating SMART approach for a customer issue.

D Human Annotation Documentation

Following Jain et al. (2025a), we implemented a rigorous human evaluation process to validate the quality and reliability of our data annotations. We recruited general experts who met specific language proficiency criteria and domain knowledge requirements. Annotators were provided with detailed guidelines and the exact instructions mentioned in the different prompts, ensuring consistency between human and LLM evaluations. For example, in the Action Detection task, human expert annotators were asked to annotate the module output using the same instructions outlined in the prompt 3. We followed the standard protocol to measure inter-annotator agreement by performing dual annotations on a sample set of 10% of the data. We observed an agreement rate of 97%, demonstrating the consistency of our annotations across all domains.

KB Statistics	Troubleshooting	Medical
Number of Chunks	2595	5196
Number of Issues	482	866

Table 8: Knowledge base (KB) statistics for Troubleshooting and Medical domains.

Think-Search-Patch: A Retrieval-Augmented Reasoning Framework for Repository-Level Code Repair

Abstract

Large language models usually suffer from multiple-file coding scenarios where strong inter-file dependencies manifest, typically demonstrated in SWE-bench. To mitigate this issue, we propose Think-Search-Patch (TSP), a retrieval-augmented reasoning framework for repository-level code repair. At the Think stage, our system breaks down a coding task and creates clear search query. Next, at the Search stage, it retrieves relevant code snippets using models like E5. At the final Patch stage, it generates standardized patches based on the key snippets. In addition the proposed framework, we enhance system reliability through a two-stage training process. At the first stage, the system undergoes supervised fine-tuning (SFT) on our TSP dataset. At the subsequent stage, we employ rejection sampling with correction to generate preference pairs for Direct Preference Optimization (DPO) training, thereby reducing errors in the intermediate phases. Experimental results demonstrate that TSP framework enhances retrieval accuracy and repair success on SWE-bench Lite, even surpassing models with a larger size in managing extensive code contexts and successfully addressing bugs spanning across multiple files. All data and code available at https://github.com/tjunlp-lab/TSP-framework.

1 Introduction

Large language models (LLMs) have demonstrated significant capabilities in code generation, achieving strong performance on single-file scenario benchmarks, such as code completion in HumanEval (Chen et al., 2021) and MBPP (Austin et al., 2021). However, code-specific LLMs, exhibit inadequate performance in multi-file scenarios, which are prevalent in real-world software development and characterized by high complexity and intricate cross-file dependencies.

The SWE-bench (Jimenez et al., 2024) accurately captures this challenge. It constructs test cases based on code snippets and issue descriptions from real open source projects, covering various repair tasks ranging from basic syntax errors to complex logical flaws. This benchmark has two main features, which collectively make it hard for models to handle multi-file repair tasks. **Task complexity**: Tasks demand multi-dimensional capabilities simultaneously, e.g. code semantic parsing, flaw localization, and precise patch generation. **Context scale**: Test samples provide an average context of hundreds of lines of code. Within such a vast context, models struggle to effectively filter out irrelevant information. Consequently, crucial code snippets relevant to the issue may be obscured by an overwhelming volume of unrelated code, thereby severely hindering accurate flaw localization.

To address the aforementioned challenges, we propose a **Think-Search-Patch (TSP)** framework. Our framework adopts a three-stage process and incorporates a two-stage training strategy, enabling it to autonomously analyze issues, identify root causes, and retrieve necessary code snippets before ultimately completing the repair. This approach mitigates the issue of context overload and enhances code repair performance at the repository level. Our framework involves the following steps: **Think stage** guides the model to decompose the problem into three sequential steps: (i) issue analysis, (ii) task decomposition, and (iii) search query construction. At this stage, semantic analysis is utilized to generate precise search queries. **Search stage** employs the E5 (Wang et al., 2022) model to search the repository, retrieving semantically relevant code snippets based on similarity metrics. **Patch stage** focuses on the retrieved key code snippets, performing code localization and code editing to generate well-formatted patch, thus completing the overall Think-Search-Patch process. The diagram of our framework is illustrated in Figure 1.

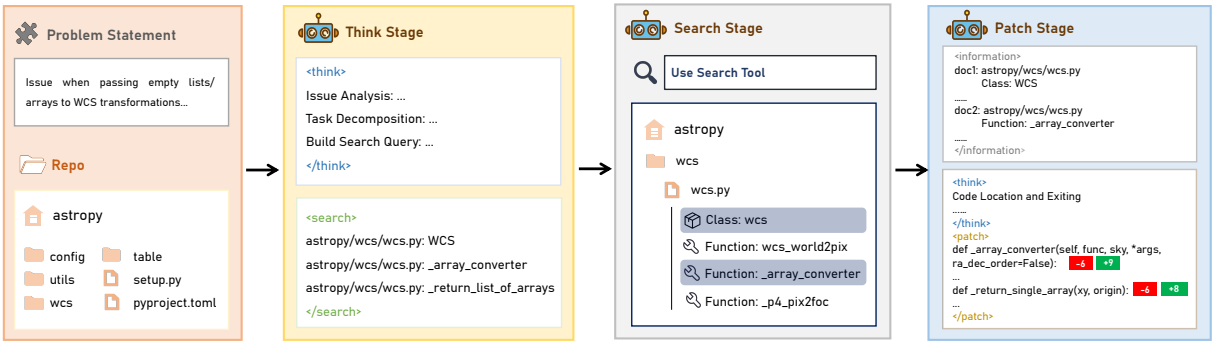

Figure 1: Overview of the framework for Think-Search-Patch.

To systematically enhance model capabilities throughout our three-stage process, we design a two-stage training strategy. The first stage focuses on process learning, where supervised fine-tuning (SFT) is performed on TSP dataset. This phase establishes fundamental capabilities in adhering to task specifications and constructing the core process. Subsequently, the second stage implements preference alignment optimization: We utilize the model trained at stage 1 to perform rollout, generating a batch of data. Then, we use GPT-4o as an LLM-judge to invoke to assess and amend the quality of these data. Corrected samples serve as positive examples, while uncorrected erroneous outputs constitute negative examples. These preference pairs then facilitate Direct Preference Optimization (Rafailov et al., 2023) training. Through this two-stage training paradigm, we trained a series of models to verify the feasibility of the TSP framework, which effectively increased the proportion of key code recall, while achieving repair success rates that markedly outperform RAG methods.

In summary, our contributions are as follows:

1. We propose the Think-Search-Patch (TSP) framework. To effectively train the reasoning process of TSP, we built the TSP dataset, comprising 60K samples specifically designed to optimize collaborative reasoning across its three stages.

2. We designed a fine-grained indexing construction strategy that retrieves code at the Class and Function levels, effectively addressing the redundancy issues associated with traditional file-level code retrieval.

3. On the SWE-bench Lite benchmark, models trained based on the TSP framework demonstrate superior performance among models of similar scale, thereby validating the effectiveness of our framework and its technical strategies in code repair tasks.

2 Related Work

Recent developments in code-specific LLMs have significantly advanced code generation capabilities (Guo et al., 2023). Closed-source models, such as GPT-4.5[1], Claude-4[2] excel in coding tasks, while open-source models, including DeepSeek-Coder (Guo et al., 2024) and Qwen-Coder (Hui et al., 2024), offer competitive performance at smaller scales. Specialized LLMs address specific engineering challenges, and many studies focus on improving program generation (Liu et al., 2024, 2023; Lin et al., 2024; Zheng et al., 2023; Yang et al., 2025b). Despite this, effectively using LLMs to address complex code generation remains a challenge. Two primary paradigms are currently harnessing the potential of LLMs: agent-based frameworks (Wang et al., 2024; Ma et al., 2024; Yang et al., 2024; Zhang and Xiong, 2025; Leng et al., 2025; Li et al., 2025), which facilitate iterative interactions with tools and environments for decision making, and pipeline-based approaches (Wei et al., 2025; Xie et al., 2025), which follow predefined sequences of steps. However, Agent-based frameworks facilitate iterative interactions with tools and environments for decision-making. This strategy incurs significant resource consumption, as it requires guiding the SWE-Agent to invoke appropriate tools, typically involving multiple rounds. The pipeline strategy, on the other hand, places greater emphasis on the inherent coding abilities, which are more dependent on the size of models. Our TSP framework belongs to the pipeline-based approach,

which emphasizes the rationality of task decomposition and the efficiency of search tool integration, enabling 7B-scale and 14B-scale models to possess certain repository-level code repair capabilities.

3 Think-Search-Patch

In this section, we elaborate our Think-Search-Patch framework and TSP dataset. Section 3.1 presents the dataset structure and index construction, while Section 3.2 details the first stage of the two-stage training approach: SFT for problem-solving. Section 3.3 then elaborates on the second stage, which enhances the problem-solving ability of the entire process through DPO.

3.1 TSP Dataset

Data structure. We extend the rigorous filtering logic of the SWE-Fixer dataset (Xie et al., 2025) to construct our TSP dataset. Our filtering strategy primarily involves removing two types of inefficient samples. The first type is issues containing non-textual information, for which we deleted problems including image links, external document links, or other content that cannot be interpreted by the model, to ensure the textual self-consistency of the issue descriptions. This is because the model cannot directly process the semantic information contained in images or links, which may lead to deviations in defect localization. The second type is issues with vague descriptions, for which we filtered out problems lacking specific defect localization or references to code entities, as vague descriptions usually cannot guide the model to locate specific code units, resulting in ineffective retrieval and repair. We adopted the practice of using the annotated reasoning chain of issue analysis, task decomposition, and code localization in the SWE-Fixer dataset as the core reasoning process. To accommodate retrieval-augmented scenarios, we embed a search module after task decomposition, utilizing Qwen-Max (Yang et al., 2025a) to generate search query and retrieve relevant code snippetss, thereby establishing the Think-Search-Patch workflow. To address the high overhead of full indexing, the target code snippets are directly extracted from annotated Oracle files, preserving SWE-Fixer's advantage in precise code localization. Furthermore, we establish a closed-loop verification system: 5% of the data is randomly sampled to build an E5 vector index that simulates real-world environments, with the top-2 recall rate quantifying search query quality, achieving up to 80% average accuracy. Through failure case analysis focusing on problem description deficiencies, this feedback optimizes the data cleaning process, ultimately forming a closed loop: 1) data cleaning, 2) search query construction, 3) Oracle extraction, 4) code localization verification, and 5) filter optimization. The pipeline fully inherits SWE-Fixer's strengths in reasoning coherence and localization precision, while enabling adaptive upgrades for real repository through the search query mechanism. All the prompt instructions used for building search query can be found in Appendix A.

Index construction. During the index construction phase of the SWE-bench framework, we address context bloat induced by file-level retrieval by proposing an Abstract Syntax Tree (AST)-based approach. As shown in Figure 2, this approach utilizes precise locator identifiers formatted as path/to/file.py:Class or path/to/file.py:Function. This methodology enables fine-grained indexing through a structured technical pipeline. Based on Python's ast module, the code file is parsed to generate an AST. By traversing the AST nodes, we extract Class and Function nodes, enriched them with metadata such as file path, name, and line number, and assigned unique identifiers to each node. Finally, the nodes are transformed into structured indexing units. Experimental results indicate that this approach reduces the average recalled context length by 78%, as shown in Table 1, effectively filtering out irrelevant code noise. Our indexes serve two key purposes: during the DPO training phase, they dynamically construct preference datasets; during the evaluation phase, they are integrated with the TSP framework to support inference and address issues.

3.2 Process Foundation Training

At Stage 1, we establish closed-loop task processing through standardized training. This phase utilizes SFT on TSP dataset. At the think phase, we base issue analysis on identifying the key requirements and objectives for solving the issue, and then

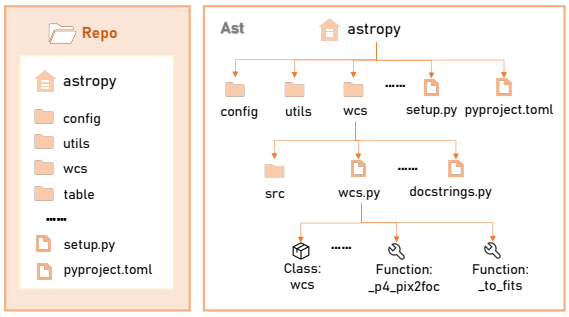

Figure 2: The construction process of the AST syntax tree.

decompose the issue into manageable subtasks. At the search phase, based on the analysis results, we generate a search query to locate the class or function in the target code snippets. At the patch phase, we utilize the retrieved results to perform code location and editing and subsequently generate a patch that conforms to the required format.

To ensure consistency with the reasoning process, we adopt a staged training strategy based on data partitioning, which is divided into the following two stages. (1) The first stage focuses on training the model's ability to generate search queries. At this stage, the model generates precise search query solely based on the issue, thus specifically cultivating its capability to map issue features to retrieval strategies. (2) emphasize training the model's ability to generate patches based on retrieved code snippets. The input for this stage consists of a combination of Issue Analysis, the retrieval process, and retrieved information, requiring the model to generate patches accordingly. This approach ensures that in real reasoning scenarios, the model is capable of integrating the retrieved results to complete closed-loop processing.

3.3 Preference Optimization Alignment

At stage 2 of preference optimization alignment training, we enhance index utilization by querying issue version information and employing an index reusability strategy for data from the same repository and version. Specifically, we first filter out data of the same version within a repository to avoid redundant index construction, thereby directly reusing existing indexes. Based on this mechanism, we sample nearly 4,000 entries and established almost 200 indexes for data from the same repository and version, thereby achieving efficient integration of the training data. Subsequently, we simulate a realistic retrieval scenario using a dynamic retrieved approach, allowing the model to generate a complete Think-Search-Patch process output for each issue. These samples contain various intermediate errors that occur naturally in the model's generation process, thus providing typical negative examples for subsequent optimization.

At the data filtering phase, an LLM-judge is introduced to conduct quality screening. Correctness is evaluated along three dimensions: **(1) search query dimension**, which assesses whether the recalled results include code snippets relevant to the issue, thereby ensuring the accuracy of search query; **(2) problem analysis logic dimension**, which requires the model to maintain logical consistency throughout the process in order to avoid haphazard fixes; **(3) code location dimension**, which enforces precise identification of files, classes, or functions, and line numbers. This allows for pinpointing of the dependency impact domain and minimizes the scope of modifications, thereby preventing interference with unrelated code areas. Ultimately, structured corrections are applied to non-compliant samples by preserving reasonable components of issue analysis, generating standardized reference outputs for the identified deficiencies, and forming revised positive sample cases.

During stage 1 optimization, we have observed a significant improvement in the model's ability to generate queries. However, practical evaluations have revealed that, despite the enhanced search query quality, the retrieved results based on Class and Function are far more concise than the file-level retrieved results. However, it remains difficult for the model to accurately identify the required code positions, resulting in suboptimal performance in the patch stage. To address this issue, we implement a targeted optimization strategy by reconstructing a dataset specifically for the patch stage. This part aims to precisely locate issue-relevant code snippets within the retrieved results and is used to reinforce the model's ability to generate accurate code locations and patches. Through data-level targeted optimization, we effectively compensate for the shortcomings in the retrieval and localization process during stage 1, thereby establishing a comprehensive TSP framework.

Based on the preference data pairs constructed using the aforementioned mechanism, we train the model using the DPO algorithm. This algorithm guides the model to learn the correct reasoning process by maximizing the conditional probability of positive examples relative to negative ones.

Specifically, during the retrieval phase, the DPO algorithm focuses on reducing the probability of generating erroneous queries, thereby enhancing query accuracy. During the patch phase, it focuses on improving the model's ability to accurately locate relevant recalled code and generate patches that address the identified issues. In this manner, the DPO algorithm effectively optimizes the model's performance in the search and patch phases, ultimately enhancing the overall capability of our framework.

4 Experiment

We conducted extensive experiments and in-depth analyses to evaluate the proposed entire framework, including evaluation results based on SWE-bench Lite, search query construction results, and the effects of our two-stage training.

4.1 Experiment Setup

In a hardware environment equipped with 16 NVIDIA H800 GPUs, to verify the effectiveness of the TSP framework, we selected multiple models, such as Qwen2.5-Coder-7B-Instruct, Qwen2.5-Coder-14B-Instruct (Hui et al., 2024), deepseek-coder-6.7b-instruct (Guo et al., 2024), Mistral-7B-Instruct-v0.3 (Jiang et al., 2023), etc., and implemented a two-stage training process. Specifically, we first conducted supervised fine-tuning (SFT) on the TSP dataset, followed by alignment with Direct Preference Optimization (DPO) using preference pairs. We employed the Verl framework (Sheng et al., 2025) for SFT training and the OpenRLHF framework (Hu et al., 2024) for DPO training. Additionally, we implemented a retrieved token loss masking mechanism. Although standard SFT and DPO typically compute loss across the entire unfolded sequence, the incorporation of externally retrieved code snippets in our TSP framework makes applying the same optimization to retrieved tokens potentially problematic, as it may induce unintended learning dynamics. To address this, we designed a specialized loss masking mechanism that explicitly excludes retrieved code snippets from policy gradient computations.

For the evaluation phase, we adopted SWE-bench Lite, a streamlined subset of the authoritative SWE-bench comprising 300 optimized representative instances. The final assessment framework employed a dual-dimensional validation mechanism. We strictly adhered to the official evaluation protocol of SWE-bench to verify whether the generated patches passed all test cases related to the issue. This standard is extremely rigorous, as it demands perfect remedying of all defects, potentially overlooking incremental improvements in partial fixes or semantic understanding. To address this, we introduced LLM-judge as a key supplementary evaluation dimension. Our LLM-judge supplements evaluation with three metrics: context relevance (accuracy of search queries), location accuracy (correctness of edit placements, including golden patch modifications), and repair effectiveness (resolution of underlying issues rather than superficial fixes).

To validate the consistency between LLM-judge and human evaluators, we selected 100 samples generated by TSP-Qwen2.5-Coder-7B from the SWE-bench Lite evaluation, invited five graduate students with backgrounds in software engineering and code repair, and used GPT-4o as the large language model evaluator. Both groups of evaluators independently scored the samples based on the three dimensions defined in the prompts—context relevance, position correctness, and core fix correctness. Detailed evaluation comparisons are provided in Appendix B. Additionally, since the TSP framework requires invoking retrieval during inference, we built indexes for each entity in the evaluation process. All prompt instructions used for scoring can be found in Appendix C.

4.2 Main Result

As shown in Table 2, the experimental results demonstrate that our Think-Search-Patch (TSP) framework exhibits significant structural paradigm advantages on SWE-bench Lite. First, during the search process, this framework, by retrieving code snippets at the class and function levels, comprehensively outperforms the traditional retrieval-augmented generation (RAG) methods that rely on file-level retrieval. In the rigorous unit tests on SWE-bench Lite, TSP-Qwen2.5-Coder-7B achieves a repair pass rate of 5.0%, and TSP-Qwen2.5-Coder-14B reaches a pass rate of 8.33%, while GPT-4 (1106) with the standard RAG process only has a pass rate of 2.67%. Moreover, compared with models of similar scale, the models trained via the TSP framework have significantly higher repair efficiency than SWE-Llama. This indicates that our finer-grained retrieval approach effectively addresses the persistent issue of long-code context interference, fully demonstrating that our finer-grained retrieval method successfully re-

Method	Model	LLM-judge score	Pass rate
RAG (Jimenez et al., 2024)	SWE-Llama-7B	27.5	1.3

Think-Search-Patch	TSP-Mistral-7B	40.5	3.33

Table 2: Performance comparison of different methods. LLM-judge score indicates model performance (0-100 scale), repair pass rate denotes task completion accuracy.

solves the challenge of long-code context interference. We also analyzed the reasons why models such as Qwen2.5-coder-7B-instruct and deepseek-coder-6.7b-instruct, which were not trained with the TSP framework, performed poorly. The main reasons are their insufficient search query generation capabilities and the lack of targeted training in the patch generation phase. This results in the models' inability to construct fine-grained retrieval queries, leading to a low recall rate of key code. In the entire pipeline, generating appropriate search queries is crucial because it directly determines whether problem-related code can be retrieved. Additionally, the absence of specialized training in the patch generation phase leads to insufficient code localization and modification capabilities.

The empirical study on the LLM-judge scoring system further reveals the core value of the two-stage training paradigm: TSP-Qwen2.5-Coder-7B achieves an overall score of 48.1, significantly surpassing Qwen2.5-Coder-7B-Instruct; TSP-Qwen2.5-Coder-14B even reaches a score of 55.6, greatly outperforming the corresponding model under RAG, and such a contrast is also reflected in the performance of other models. This structural advantage stems from a dual synergistic training mechanism: during the process foundation training phase, TSP framework models systematically establish a deep cognitive pattern for the Think-Search-Patch framework, enabling them to accurately grasp the rules of problem decomposition and the norms for generating retrieval instructions; subsequently, in the preference optimization alignment phase, through contrastive learning guided by LLM-judge corrections, the key ability — extracting problem-relevant effective content from retrieved code snippets for repair — is specifically enhanced. This result verifies the irreplaceability of the hierarchical training design in improving model performance.

Model	Search ACC

TSP-deepseek-coder-6.7b	40.1
TSP-Mistral-7B	38.6

Table 3: Search accuracy comparison across models. Metrics reflect the precision of context retrieval in respective frameworks.

These findings collectively confirm that our framework, leveraging class and function-level retrieval, addresses the contextual redundancy inherent in file-based retrieval of RAG methods, thereby enhancing the model's capability to precisely locate issue-relevant code. By decomposing the complex problems in SWE-bench into issue analysis, retrieving relevant code snippets, and performing targeted repairs, the performance of the 7B-scale and 14B-scale models can be effectively enhanced. This demonstrates that our framework rectifies the core flaws of RAG methods by eliminating redundant file-level code while establishing the previously

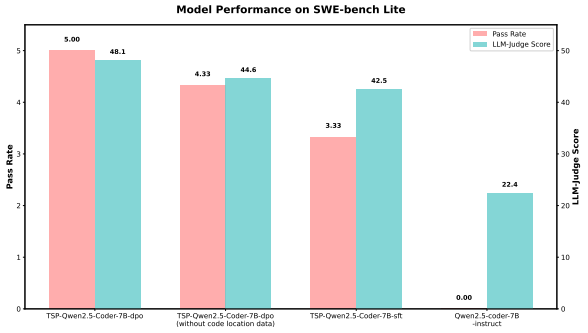

Figure 3: ablation study to validate the effectiveness of the DPO training.

missing scientific reasoning framework. A case study of our framework is included in the Appendix D.

4.3 Quality of Search Query

The quality of the generated search query plays a decisive role in the success of the task: an accurate search query can directly retrieve the code snippets related to the issue, thereby enabling model to perform comprehensive debugging on the target code snippets. To evaluate the retrieval capabilities of the models, we used the retrieved rate of key code snippets as metric to assess several models. Specifically, by extracting the function or class entity that needs modification from the golden patch, we verify whether the retrieved results encompass the relevant context code snippets for the target entity, thereby achieving an objective quantitative evaluation of the search query generation quality.

As shown in Table 3, TSP-Qwen2.5-Coder-14B demonstrates superior performance with a retrieval accuracy of 64.8%, outperforming our baseline model Qwen2.5-coder-14B-instruct (28.7% accuracy). In contrast, SWE-Llama fails completely with an accuracy of 0.0%. This failure is attributed to SWE-Llama's excessive focus on patch generation during training, which leads to severe overfitting in the retrieval phase. Conversely, our proposed two-stage training framework effectively enhances the model's ability to construct high-quality search query, thereby achieving exceptional performance in real-world retrieval tasks.

4.4 Ablation Study

We designed a rigorous ablation study to validate the effectiveness of the DPO training mechanism. The experiment evaluated performance on the SWE-bench Lite benchmark by comparing models that underwent only the first-stage SFT, completed DPO training, and those with position-enhanced data removed during the second-stage training. Key evaluation metrics included the LLM-judge score and patch pass rate.

As shown in Figure 3, by comparing the training results of Qwen2.5-coder-7B-instruct after SFT and DPO, the ablation results confirmed that the performance of our Think-Search-Patch framework was significantly enhanced through a two-stage collaborative optimization approach: TSP-Qwen2.5-Coder-7B-dpo achieved a 5% patch pass rate and an LLM-judge score of 48.1 on SWE-bench Lite, outperforming TSP-Qwen2.5-Coder-7B-sft in both evaluation metrics. This notable advantage is attributed to the alignment of DPO training with human preference data, which effectively reinforces the model's end-to-end reasoning ability from issue analysis to code modification. Further analysis showed that TSP-Qwen2.5-Coder-7B-dpo without position data systematically declines in performance, validating that the targeted construction of position-enhanced data plays a crucial role in improving the spatial localization capability of retrieved results; we believe the absence of this module directly undermines the model's precision in identifying the correct location for code modifications.

5 Conclusion

We have presented the Think-Search-Patch (TSP) framework to address strong cross-file dependencies in multi-file coding, enhancing code repair accuracy. Using a fine-grained index at the class and function levels instead of file-level retrieval reduces redundancy and improves retrieval. Our TSP-coder models are trained in two stages, SFT on the TSP dataset and DPO on correction pairs. Experimental results show that TSP-Qwen2.5-Coder-14B achieves an 8.33% patch pass rate and an LLM-judge score of 55.6 on SWE-bench Lite. This not only outperforming larger general models within the RAG framework that relies on file-level retrieval, but also demonstrates the effectiveness and practical value of our TSP framework in code repair tasks.

ments.

Limitations

Although our approach outperforms the RAG method, it still falls short compared to agent-based and pipeline methods, primarily due to the limitation in model parameter scale which restricts complex reasoning abilities and makes it difficult to handle complex, cross-document repair tasks that require hierarchical inference. Future work may draw on the dynamic decision-making mechanism of agents to enable the model to adaptively adjust the Think-Search-Patch process based on task complexity.

A Prompt for building search queries

This is the prompt we use in SWE-Fixer's reasoning dataset to call Qwen-max and construct search queries.

Search Query Construction Prompt

Based on the provided issue: {issue}, and combined with the analysis of this problem: {reasoning_process}, complete the following tasks:

<task>
1. **Reasoning for constructing search queries**: Within `<think></think>`:
   - Analyze how to reasonably construct the search query based on the provided content
   - Align with the original analysis; avoid excessive repetition

2. **Generate search query**: Within `<search></search>`:
   - Identify classes corresponding to the issue's resolution context
   - Output based on the issue and analysis as: path/file.py:Class_name or function_name. If no reliable path exists, output only the filename.
   - Output as a Python list
</task>

Final deliverables:
- Reasoning for constructing the search query in `<think></think>`
- Search query within `<search></search>`

Table 4: Search Query Construction Prompt.

B The consistency between LLM-judge and human evaluator

We used the Pearson correlation coefficient to quantify the agreement between the evaluators. The results demonstrate a high level of consistency between the LLM-judge and human evaluators.

Metric	LLM-judge Score	Human Score	Pearson Correlation Coefficient
Context Relevance (20%)	11.29	11.92	86.78%
Position Correctness (40%)	21.89	17.62	83.09%
Core Fix Correctness (40%)	14.79	10.97	78.36%
Total	48.07	40.51	83.01%

Table 5: The consistency between LLM-judge and human evaluator on SWE-bench Lite.

C Prompt of LLM-judge for scoring

We present an example of a prompt for GPT-4o as an LLM-judge. Specifically, we require GPT-4o to score from three dimensions, namely Context Relevance, Position Correctness, and Core Fix Correctness. Table 6 shows an example of a prompt in LaTeX format.

As an SWE-bench task evaluation expert, you need to evaluate the model output based on the following materials:

1. `issue`: Bug description reported by the user
2. `golden patch`: Correct code repair solution
3. `model output`: Response generated by the model (including thinking process, search query, recall information, and model patch)

Scoring Dimensions and Weights:

1. **Context Relevance (20%)**
   - Check whether the search query accurately recalls the code context related to the issue

2. **Position Correctness (40%)**
   - Determine whether the model patch includes the modification content in the golden patch

3. **Core Fix Correctness (40%)**
   - Check whether the model patch solves the core problem of the issue

Finally, put the score in <reward></reward>.

Issue: {issue}
Golden Patch: {golden_patch}
Model Output: {model_output}

Table 6: The SWE-bench Task Evaluation Prompt.

D Case Study

The repair process of the TSP framework for the `django-12453` case proceeds as follows: First, it parses the problem description (when accessing `UserAdmin` via `to_field`, the link to `PasswordResetForm` returns a 404 error) and enters the **Think** stage: here, it identifies the root cause as flawed URL generation logic for the password reset link, decomposing the task into "locating the code responsible for URL generation". Next, in the **Search** stage, leveraging fine-grained indexing at the class and function levels, it precisely retrieves the code of the `__init__` method in the `UserChangeForm` class within `django/contrib/auth/forms.py` (this method formats the `help_text` of the password field, which embeds URL concatenation logic). Finally, in the **Patch** stage, analyzing the code logic reveals that the original format string (`"../password/"`) in `help_text` causes an invalid URL path. By modifying it to `"../../{self.instance.pk}/password/"` (constructing an absolute path using the instance's primary key) and generating a diff patch, the framework completes the repair, resolving the link redirection issue under cross-file dependencies.

instant id: django-12453

problem statement: Accessing UserAdmin via to_field leads to link to PasswordResetForm being broken (404) Description (last modified by Simon Kern) Accessing the UserAdmin via another model's Admin that has a reference to User (with to_field set, e.g., to_field=üuid̈)...

<think>**Issue Analysis:** The issue at hand involves a broken link to the PasswordResetForm when accessing the UserAdmin via a to_field in Django. Specifically, the URL generated for the password reset link is incorrect, leading to a 404 error...
Task Decomposition: To resolve this issue, we need to: 1. Identify the Code Responsible for URL Generation: Locate where the password reset link is being constructed in the 'UserChangeForm' class...
Build Search query: The relevant file is identified as 'django/contrib/auth/forms.py', where the 'UserChangeForm' class resides. This class contains the '__init__' method where the 'password.help_text' is modified... </think>

<search>django/contrib/auth/forms.py:UserChangeForm </search>

<information>
```

Abstract

Automatic Speech Recognition (ASR) is a fundamental and important task in the field of speech and natural language processing. It is an inherent building block in many applications such as voice assistant, speech translation, etc. Despite the advancement of ASR technologies in recent years, it is still inevitable for modern ASR systems to have a substantial number of erroneous recognitions due to environmental noise, ambiguity, etc. Therefore, the error correction in ASR is crucial.

Motivated by this, this paper studies ASR error correction in the Chinese language, which is one of the most popular languages and enjoys a large number of users in the world. We first create a benchmark dataset named *ASR-EC* that contains a wide spectrum of ASR errors generated by industry-grade ASR systems. To the best of our knowledge, it is the first Chinese ASR error correction benchmark. Then, inspired by the recent advances in *large language models (LLMs)*, we investigate how to harness the power of LLMs to correct ASR errors. We apply LLMs to ASR error correction in three paradigms. The first paradigm is prompting, which is further categorized as zero-shot, few-shot, and multi-step. The second paradigm is finetuning, which finetunes LLMs with ASR error correction data. The third paradigm is multi-modal augmentation, which collectively utilizes the audio and ASR transcripts for error correction. Extensive experiments reveal that prompting is not effective for ASR error correction. Finetuning is effective only for a portion of LLMs. Multi-modal augmentation is the most effective method for error correction, achieving state-of-the-art performance.

1 Introduction

Automatic Speech Recognition (ASR) refers to the technology that enables computers to recognize and interpret human speech, converting it into text (Lu et al., 2025). It finds wide applications in voice assistants, speech dialogue systems, speech translations, etc. Despite significant advancements, it is still inevitable for modern ASR systems to have erroneous recognition due to environmental noise, ambiguity, etc. Thus, ASR error correction is an important problem for speech and language processing.

There are existing studies on ASR error correction. However, they mainly focus on English or other Western languages. There is a notable gap for Chinese, even though it is one of the most popular languages in the world and enjoys a large number of users. Motivated by this, in this paper, we study the ASR error correction for the Chinese language.

First, we observe that there are no existing ASR error correction datasets for Chinese. We establish a benchmark dataset for Chinese ASR error correction (Link, 2025). Based on the open-source ASR toolkit Kaldi-K1 (Povey et al., 2011) and Kaldi-K2[1][2], we construct the ASR-EC benchmark by processing audio clips from THCHS-30, AISHELL-1, AISHELL-2, and WeNetSpeech. This dataset encapsulates a broad range of decoding errors and is designed to assess LLMs' capability to correct ASR mistakes across varied utterance lengths.

Second, we investigate how to utilize LLMs (Devlin et al., 2019; Brown et al., 2020; Zhao et al., 2023) for ASR error correction in three paradigms: (1) prompting these models to act as an error correction module for existing Chinese ASR systems; (2) customizing the models to the context of the Chinese language and the ASR task with parameter-efficient fine-tuning (Hu et al., 2022); (3) through multimodal augmentation, leveraging both the audio and text modalities to enhance the LLMs' understanding of the content, providing a comprehensive basis for the LLMs to detect and correct errors.

Proceedings of the 2025 Conference on Empirical Methods in Natural Language Processing: Industry Track, pages 1567–1575
November 4-9, 2025 ©2025 Association for Computational Linguistics

Our experiments show that different strategies for applying LLMs to ASR error correction yield various degrees of effectiveness. Prompting is to correct errors by simply querying foundation models with the erroneous text. This method has proven to be ineffective and can even introduce new errors to previously correct content. This implies that, without annotated ASR error correction datasets, LLMs cannot achieve satisfactory performance even if the advanced prompting method is applied. In comparison, finetuning enables models to leverage their contextual understanding and language mastery to meaningfully refine the ASR output, correcting various decoding mistakes. Moreover, multimodal augmentation stands out as the most effective approach, significantly enhancing error correction by jointly analyzing the audio and its corresponding transcript, thereby achieving state-of-the-art performance in correcting ASR errors.

The contributions of this paper are threefold:

- We build and release a public dataset named ASR-EC for LLM-based ASR error correction. To the best of our knowledge, this is the first dataset for Chinese ASR error correction. We believe that this benchmark will pave the way for future studies on the Chinese ASR error correction.
- We undertake a comprehensive investigation on three paradigms for adapting LLMs to ASR error correction, namely *prompting*, *funetuning*, and *multi-modal*.
- We conducted an empirical study on these LLM-based paradigms for ASR error correction on our constructed benchmark. We found that multi-modal augmentation stands out as the best approach.

The discovery in this paper represents a promising direction to inject powerful LLMs into conventional ASR pipelines and significantly improve their performance. We have released our datasets and source code of this paper (Link, 2025).

The remainder of this paper is organized as follows. Section 2 presents the formal problem statement of ASR error correction. Section 3 reviews the related work of error correction. Section 4 demonstrates the construction of our proposed ASR-EC benchmark for Chinese ASR error correction. Sections 5, 6, and 7 present our investigated three approaches for LLM-based Chinese ASR error correction. Section 8 presents our empirical study. Section 9 concludes this paper.

2 Problem Statement

Let X be the space of all possible input audio signals, and Y be the space of all possible text transcriptions. An ASR system can be modeled as a function $f : X \to Y$ that maps an input audio signal $x \in X$ to a text transcription $y \in Y$.

Due to various factors, the output $\hat{y} = f(x)$ may contain errors compared to the ground truth transcription. The error correction problem can be formulated as finding a correction function $g : Y \times X \to Y$ such that the corrected transcription $y' = g(\hat{y}, x)$ minimizes the error $d(y', y)$, where d is a distance metric between the corrected transcription and the ground truth transcription.

3 Related Work

Error correction models, proposing to identify and correct inaccuracies in the text and audio, play a crucial role in Automatic Speech Recognition (ASR). Their development mirrored the advancements in Natural Language Processing (NLP).

Text Error Correction. Initially, rule-based models were predominant in error correction. These models relied on predefined rules and heuristics to correct text errors, which often limited their adaptability. The advancement of statistical models and end-to-end models marks a large leap forward (Jiang et al., 2021; Hrinchuk et al., 2020; Jiang et al., 2019; Zhao et al., 2021; Jiang et al., 2023). Instead of requiring manually defined rules, they can learn directly from data. This adaptability leads to higher accuracy and more effective error correction.

Text and Audio Error Correction. LLMs have shown considerable potential in error correction.

Firstly, for the text, Ma et al. (2023a) and Yang et al. (2023b) prompted and fine-tuned LLMs with ASR error correction data, transferring the knowledge learned by the large-scale pre-trained language model from vast textual data to error correction tasks. Ma et al. (2023b) studied the error correction performance of the most advanced Large Language Model (LLM) at present, ChatGPT. Hu et al. (2024) extended generative error correction benchmarks to noisy conditions, showcasing LLMs' dual capability in denoising and error correction.

Corpus	Source	Transcription	# Hours	# Utterances	Avg Characters
THCHS-30	Recorded speech	Manually labeled	30	13,388	33
AISHELL-1	Recorded speech	Manually labeled	200	141,597	14
AISHELL-2	Recorded speech	Manually labeled	1,000	511,123	13
WeNetSpeech	YouTube, Podcast	OCR, ASR	1,100	434,781	38
Corpus	Domains				
THCHS-30	News				
AISHELL-1	Smart home, autonomous driving, and industrial production, etc.				
AISHELL-2	Keywords, voice command, smart home, autonomous driving, industrial production, etc.				
WeNetSpeech	Audiobook, commentary, documentary, drama, interview, etc.				

Table 1: Speech Corpora Statistics

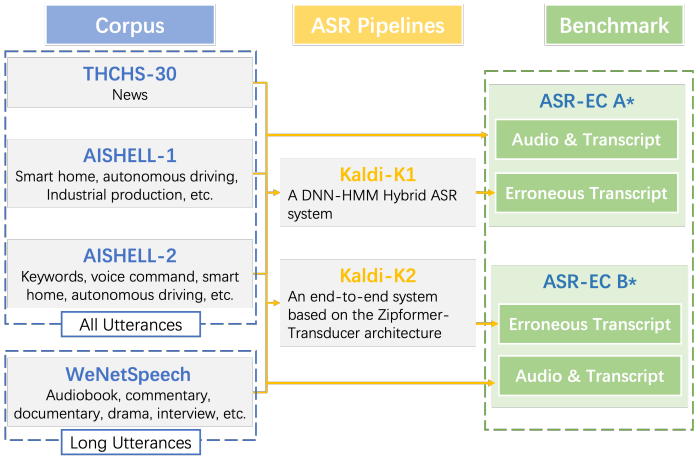

Figure 1: Pipelines for Erroneous ASR Transcripts Construction

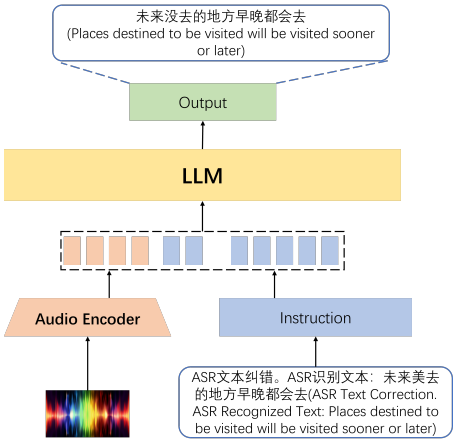

Figure 2: ASR error correction with Multi-modal model.

Secondly, for the multimodal contexts, including audio and text, the Qwen-Audio model (Chu et al., 2023) advances audio-language understanding by pre-training across various tasks and audio types, leading to a versatile model that enhances multi-turn dialogues and audio-centric interactions without needing fine-tuning. Chen et al. (2024) integrates acoustic data into the generative error correction process, enhancing the model's ability to map from N-best ASR hypotheses to accurate transcriptions.

To the best of our knowledge, there are no existing benchmarks for Chinese ASR error correction, even though Chinese is one of the most popular languages and has a large number of users in the world. Motivated by this, this paper constructs the first Chinese ASR error correction benchmark and paves the way for future research on the ASR error correction. In addition, we systematically investigate the paradigms for the LLM-based ASR error correction, i.e., prompting-based, finetuning-based, and multi-modal paradigms. Our results demonstrate that different paradigms yield various degrees of effectiveness and the multi-modal approach stands out as the best one. As far as we are concerned, our research work is the first one to study LLM-based ASR error correction and systematically study the paradigms of ASR error correction with LLMs.

4 ASR-EC Benchmark

4.1 Speech Corpora Collection

To build the ASR-EC benchmark, we curate four open-source Chinese speech corpora: THCHS-30 (Wang and Zhang, 2015), AISHELL-1 (Bu et al., 2017), AISHELL-2 (Du et al., 2018), and WeNetSpeech (Zhang et al., 2022). The characteristics of these corpora are detailed in Table 1.

Our study leverages the datasets of AISHELL-1, AISHELL-2, and THCHS-30. Notably, these three datasets contain a relatively low percentage of long utterances, and they are all one-sentence recognition tasks. In order to evaluate the error cor-

rection capabilities of LLMs on long utterances, we also select 434,781 audio clips whose transcripts contain more than 30 Chinese characters. Instead, WeNetSpeech contains both one-sentence recognition tasks and multi-sentence recognition tasks. Thus, WeNetSpeech contains a rather higher percentage of long utterances and is supposed to be harder than the other three datasets.

4.2 ASR-EC Benchmark

We adopt two well-recognized ASR pipelines, namely *Kaldi-K1* and *Kaldi-K2*, to establish the erroneous transcripts. To the best of our knowledge, they are the only two pipelines in the history of ASR systems. These two pipelines have contrasting architectures and different ASR performance. In this paper, we adopt both pipelines to create a large variety of different types of errors and different levels of difficulties in our benchmark. Kaldi-K1 (Povey et al., 2011), a DNN-HMM Hybrid ASR system, employs a multistream CNN for acoustic modeling and an n-gram language model formatted by FST structure. Kaldi-K2, an end-to-end system, is based on the Zipformer-Transducer architecture. Both of the two ASR pipelines are pre-trained on a 10000-hour Chinese speech corpus.

Based on the decoding results of Kaldi-K1 and Kaldi-K2, we establish two datasets in the ASR-EC. To reflect LLMs' performance on utterances of different lengths, we divide each dataset into two subsets: short utterances and long utterances. The average utterance length in the short utterance subset (resp. the long utterance subset) is about 13 characters (resp. about 38 characters). Table 2 reports the statistics of these datasets and subsets. To control the number of those with a CER of 0, only 10% of them are kept. Besides, in this table, we also consider three types of ASR errors, namely *substitution*, *deletion* and *insertion*. The percentages of the three types of error in the short, long and mixed utterances are also summarized in the table.

5 Prompting-based Correction

Prompting is an emerging technique for fine-tuning large language models (LLMs) in a parameter-efficient way. The prompts provide soft cues to steer the model behavior towards desired tasks, without modifying the actual parameters. We introduce two prompting methods, namely direct prompting and multi-step prompting, for conducting ASR correction using LLMs. Direct prompting encompasses both zero-shot and few-shot error correction techniques.

Zero-shot prompting. In zero-shot prompting, a prompt is presented to the model without accompanying explicit examples. The model is then anticipated to generate a response utilizing its pre-existing knowledge base. This method is suitable for quick and simple tasks.

Few-shot prompting. In few-shot prompting, we provide the model with three input-output pairs as examples, enabling it to learn from this isolated input. In each input-output pair, the input is the raw ASR translated text, which may or may not contain errors, and the output is the correct transcripts without any mistakes. This technique is beneficial for ensuring that the model's output follows a specific and consistent format.

Multi-step prompting. Given that LLMs lack context or prior knowledge about the errors in the outputs of ASR systems, correcting these errors using only direct prompting can be challenging. Multi-step prompting is a technique that breaks down a complex problem into smaller, manageable steps. LLMs process each of these steps sequentially to achieve the final objective. In particular, we employ a two-step prompting strategy, where the first step detects if the ASR output contains errors or not. After that, the second step will correct the errors if there are any errors detected in the first step. Otherwise, the second step simply outputs the ASR transcript.

6 Finetuning-based Correction

By prompting LLMs to perform ASR error correction tasks, LLMs lack a deep understanding of the task. Fine-tuning LLMs is beneficial for making them more adaptable to downstream tasks and ensuring their outputs align with expectations. Note that since full fine-tuning is time-consuming and costly, we opt for a parameter-efficient fine-tuning method. Specifically, we use the LoRA fine-tuning method, which is a breakthrough and efficient fine-tuning technique.

7 Correction based on Multimodal Augmentation

The incorporation of multimodal augmentation into ASR error correction leverages the synergy between audio and text modalities, offering a nuanced approach to identifying and correcting speech recognition errors.

			Short Utter Subset	Long Utter Subset	Whole Dataset
ASR-EC A*	Train Set	CER(%)	13.49	12.24	12.45
		#Utter	186,150	358,400	544,551
	Test Set	CER(%)	12.83	11.73	12.42
		#Utter	1,024	1,024	1,024
ASR-EC B*	Train Set	CER(%)	12.99	7.03	8.15
		#Utter	181,488	280,520	462,009
	Test Set	CER(%)	13.44	6.92	8.11
		#Utter	1,024	1,024	1,024

		Short Utter Subset	Long Utter Subset	Whole Dataset
ASR-EC A*	Substitution CER(%)	10.54	6.13	8.21
	Deletion CER(%)	2.20	3.04	2.81
	Insertion CER(%)	1.34	2.74	2.30
	Overall CER(%)	14.09	11.91	13.32
ASR-EC B*	Substitution CER(%)	9,59	2.60	5.94
	Deletion CER(%)	4.17	1.01	1.95
	Insertion CER(%)	1.57	3.46	2.50
	Overall CER(%)	15.33	7.08	10.39

Table 2: Benchmark CER Results (ASR-EC A*, and B* are respectively generated by Kaldi-K1, a DNN-HMM-Hybrid ASR system, and Kaldi-K2, an end-to-end system which is based on the Zipformer-Transducer architecture)

Multimodal augmentation employs a dynamic fusion process that integrates the complementary strengths of audio signals and textual data. This fusion enables a comprehensive understanding of content, allowing for the detection and correction of errors that may not be apparent when analyzing either modality in isolation. Once errors are identified, multimodal augmentation applies contextually informed corrections, ensuring that the final text accurately reflects the intended speech content. Figure 2 demonstrates the architecture of our multimodal augmentation approach. In the input side of the LLM, we concatenate the encoded raw audio input and the instruction which includes the error correction prompt (e.g., "ASR Text Correction, ASR Recognized Text: ") and the erroneous ASR text. The output text of LLM is the corrected text. Here's a description of how audio and text fusion is implemented in our model: **a. Feature Extraction and Embedding.** Audio Feature Extraction: The speech encoder processes the audio input to extract features such as MFCCs, spectrograms, or embeddings that capture the temporal and spectral characteristics of the speech. Text Feature Extraction: The text input is converted to be embeddings that represent the semantic and syntactic content of the text. **b. Encoding Layers.** Both the audio and text embeddings are passed through encoding layers, which are separate encoders for each modality. We adopted the encoders of Qianwen-audio in our experiment. Each modality is processed independently to capture its unique information. **c. Fusion Mechanism.** The fusion of audio and text involves combining the features extracted by the encoders from both modalities before they are fed into the next layer. We adopted concatenation to combine the features.

The multimodal LLM is trained with our proposed dataset in an end-to-end fashion. This method proves especially effective in scenarios where traditional single-modality error correction techniques may fall short.

8 Experiment

8.1 LLM Testbeds

In order to demonstrate the effectiveness of the benchmark dataset ASR-EC, we evaluate three open-source large language models that support the Chinese language: ChatGLM3 (Du et al., 2022), Qwen (Bai et al., 2023), and Baichuan2 (Yang et al., 2023a). The number of parameters of the three models are 6B, 7B and 7B, respectively.

During model inference, we set the generation configuration of Qwen (Bai et al., 2023) and Baichuan2 (Yang et al., 2023a) models to their de-

Model	No. of Parameters	Modality
ChatGLM3	6B	Text
Qwen	7B	Text
Baichuan2	7B	Text

Table 3: Information of LLMs

fault value. When using ChatGLM3 model for inference, it was observed that the default parameters would cause the model to generate repetitive text. In order to reduce the repetition of the model output, we adjusted the repetition penalty parameter to 1.05 (the default value is 1), and the rest of the parameters remain the default (Du et al., 2022). When conducting LoRA fine-tuning, we referenced the fine-tuning hyperparameters from both the official repositories of these models and some third-party repositories (Team, 2023)(Factory, Accessed in 2025-09-30.).

In this experiment, we compare our approaches with ASR baselines. For the dataset ASR-EC A^*, we compare ours with Kaldi-K1 which is the ASR model for generating the erroneous transcript in ASR-EC A^*. For the dataset ASR-EC B^*, we compare ours with Kaldi-K2 which is the ASR model for generating the erroneous transcript in ASR-EC B^*. We also compare with the state-of-the-art Chinese text error correction model called *ReLM* (Liu et al., 2024). In particular, for each erroneous transcript in ASR-EC A^* and ASR-EC B^*, we adopt *ReLM* to correct the errors and report the CER achieved.

8.2 Prompting and Finetuning

We report the evaluation results of prompting and finetuning of LLMs in Table 4. From the results, we emphasize the following key findings.

From Table 4, we observe that the prompting of LLMs had very poor performance, and their CER was significantly larger than that of ASR baselines and LoRA finetuning. Under the zero-shot and one-shot settings, LLMs tend to correct every sentence, regardless of whether the sentence has errors or not, and thus, the CER actually increased after correction by LLMs. The multi-step prompting method, which first lets the LLMs judge whether a sentence is correct and then corrects sentences labeled as incorrect, was found to mitigate the issue of over-correction in longer sentences. However, it showed no improvement for shorter sentences, likely due to the lack of contextual information necessary for LLMs to accurately complete the initial step of judging correctness. Because of the over-correction of LLMs, directly prompting the foundation models often fail to achieve good results. Specifically, the longer the sentence is corrected, the more over-correction the output has. This result also implies that LLMs can not achieve satisfactory performance without utilizing annotated ASR error correction datasets.

By fine-tuning the open-source large models, the performance of all fine-tuned LLMs showed significant improvement, as revealed in Table 4. The findings reveal that open-source LLMs possess considerable capabilities when it comes to our benchmark. Our benchmark ASR-EC provides a supervised signal regarding the ASR error and highly resolves the over-correction problem in the prompting. The Baichuan2 chat model showed the best performance after fine-tuning and demonstrated the greatest improvement compared to its performance before fine-tuning.

8.3 Multimodal Approach for LLMs

We report the results of our multimodal LLM-based approach for ASR error correction and the comparison with baselines in Table 4. Compared with ASR baselines and the prompting and finetuning of LLMs, the multimodal approach achieves significant improvement. The integration of multimodal augmentation into ASR error correction capitalizes on the synergistic relationship between audio and text modalities, presenting a sophisticated approach to identifying and rectifying speech recognition errors. By employing a dynamic fusion process, multimodal augmentation combines the complementary strengths of audio signals and textual data. This fusion facilitates a comprehensive comprehension of the content, enabling the detection and rectification of errors that may not be readily apparent when analyzing each modality independently. Once errors are detected, multimodal augmentation applies contextually informed corrections, ensuring that the final text accurately captures the intended speech content. This methodology proves particularly effective in scenarios where traditional single-modality error correction techniques may prove insufficient.

9 Conclusion

Our research demonstrates a significant advancement in integrating LLMs for enhancing Chinese

Table 4: Results of Prompting, Finetuning and Multimodal Apporach

ASR systems through Error Correction (EC). We developed a specialized ASR-EC benchmark and applied methods such as parameter-efficient finetuning and multimodal augmentation. Our experiments reveal that the multimodal approach significantly enhances model performance.

Usage of Generative AI

We utilized Generative AI to aid in refining and polishing the writing. We are fully accountable for the content and its accuracy.

Limitations

Since our benchmark and algorithm in this paper were specifically developed for Chinese ASR error correction, we would like to leave the ASR error correction task in other languages or multilingual settings as future work. Besides, in the future, we plan to further enhance our multi-modal approach with a new modal of the video.

Abstract

Large Language Models have achieved great success in tasks like sentiment analysis, machine translation, and question answering, yet their effectiveness in the multilingual financial domain remains less explored. This study explores the potential of generative LLMs for classifying financial sustainability in four diverse languages: English, Hindi, Bengali, and Telugu, representing low, medium, and high-resource language categories. We propose a novel fine-tuning approach that integrates both positive and negative rationales alongside classification labels. Unlike existing approaches, our method improves classification performance by incorporating structured bidirectional reasoning into financial decision-making. Extensive evaluations demonstrate that the proposed approach consistently outperforms prior methods across all four languages, establishing new benchmark results for multilingual financial NLP. Notably, it also enables smaller models to achieve competitive or even superior performance compared to significantly larger models fine-tuned with conventional methods, demonstrating its suitability for industry applications[1].

1 Introduction and Motivation

Recent advancements in natural language processing (NLP) have transformed domains like education (Orenstrakh et al., 2024), governance (Aoki, 2024), and finance (Li et al., 2023). The financial domain, in particular, requires accurate and timely analysis of complex, domain-specific documents for strategic decisions, risk mitigation, and regulatory compliance. Extracting insights from financial texts is essential for stakeholders, including investors, regulators, and policymakers, to assess corporate sustainability and detect emerging risks early. However, while financial markets are inherently global and multilingual, most financial NLP research has focused on high-resource languages (Zhang et al., 2024). In multilingual regions such as South Asia and other emerging markets, stakeholders relying on local financial reports often face delays and inaccuracies, leading to missed risks and suboptimal investment decisions. Addressing sustainability classification in a multilingual context ensures broader inclusion of underrepresented linguistic communities and supports more equitable decision-making across global markets.

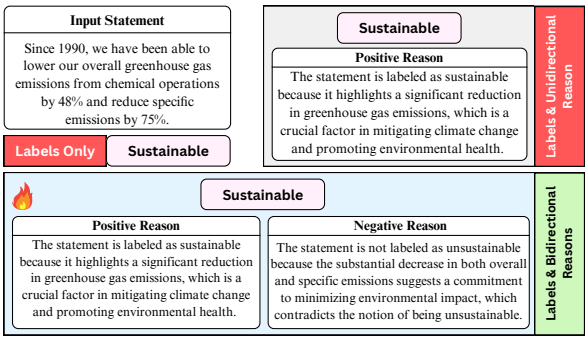

Figure 1: A high-level overview of three fine-tuning strategies: **(i)** Labels Only, **(ii)** Labels with Positive Reasoning, and **(iii)** Labels with Bidirectional Reasoning.

Previous studies have explored AI-based approaches for analyzing financial texts, with a particular focus on machine learning algorithms and large language models (LLMs) (Gerlein et al., 2016; Huang et al., 2020). More recent studies leverage LLMs for various financial applications, such as financial sentiment analysis (Araci and Genc, 2020; Rodriguez Inserte et al., 2023) and reasoning tasks (Srivastava et al., 2024). Additionally, efforts have been made to develop financial datasets for relation extraction and question answering (Jørgensen et al., 2023; Chen et al., 2024; Hamad et al., 2024). However, research on multilingual financial data, particularly for low-resource languages, remains limited. The scarcity of high-quality anno-

tated financial datasets for these languages further increases this challenge. This gap highlights the need for advanced NLP techniques to be applied to multilingual financial tasks, ensuring greater accessibility across diverse linguistic landscapes.

This study advances multilingual financial NLP by integrating low-resource languages into financial sustainability classification. Specifically, we focus on four languages: English, Hindi, Bengali, and Telugu, with Bengali and Telugu considered low-resource in computational linguistics. While (Ghosh et al., 2024) has explored financial sustainability classification for Indic languages using traditional machine learning and BERT-based approaches, their methods do not utilize the generative and reasoning strengths of modern LLMs. In contrast, we employ generative LLMs for this task. Unlike conventional fine-tuning approaches, where LLMs are trained solely with labels, we introduce reason-based fine-tuning. We explore two different reasoning-enhanced methods: *(a)* fine-tuning LLMs with sustainability labels along with a positive reason explaining why a statement is classified as sustainable or unsustainable, and *(b)* a bidirectional reasoning approach, where LLMs are fine-tuned with labels along with positive and negative reasons, as illustrated in 1. This contrastive-style reasoning framework improves classification by enabling LLMs to distinguish not only why a statement belongs to a certain category but also why it does not belong to the alternative category.

Contributions: **(1)** This study improves multilingual financial sustainability classification in low, medium, and high-resource languages, contributing to progress in the financial domain. **(2)** We propose a novel fine-tuning method that integrates bidirectional reasoning (both positive and negative) alongside labels to improve classification performance. Our approach, combined with parameter-efficient fine-tuning (PEFT), ensures strong performance while maintaining efficiency in resource-constrained environments. **(3)** Evaluations demonstrate that the proposed fine-tuning approach consistently outperforms existing methods across four languages and enables smaller models to match the performance of significantly larger models trained using a label-only approach.

2 Related Works

NLP in Multilingual Financial Data: Recent studies have introduced datasets such as MultiFin (Jørgensen et al., 2023), FAMMA (Anonymous, 2024), and FIT-ES (Zhang et al., 2024), enabling multilingual financial research. Beyond dataset creation, (Zhang et al., 2024) evaluated FinMA-ES, a model instruction-tuned on financial data, on Spanish and English text, while (Nguyen et al., 2022) assessed multilingual models across several financial tasks in three languages. Others have explored multilingual financial text summarization (Foroutan et al., 2022; Azizov et al., 2023). However, most efforts focus on high- or mid-resource languages, with low-resource languages remaining underrepresented. Our work addresses this gap by classifying financial sustainability in low-resource languages such as Bengali and Telugu.

Fine-Tuning for Financial Tasks: Supervised fine-tuning is widely used for financial text classification. (Dong and Liu, 2021) fine-tuned deep learning models for financial sentiment analysis, while (Tang et al., 2023) and (Iacovides et al., 2024) fine-tuned pretrained language models (PLMs) to enhance domain-specific performance. Beyond sentiment analysis, fine-tuning has been employed for financial sustainability classification. For example, (Ghosh et al., 2024) fine-tuned BERT-based models on the IndicFinNLP dataset for sustainability and ESG theme classification. Although these studies demonstrate the efficacy of fine-tuning for financial classification tasks, they primarily rely on label-based supervision. In contrast, our work extends fine-tuning methodologies by integrating reasoning directly into the training process.

3 Methodology

Problem Definition: Consider a dataset D consisting of financial statements $S = \{s_1, s_2, ..., s_n\}$ and corresponding labels $Y = \{y_1, y_2, ..., y_n\}$, where each statement s_i can be in any language. The objective is to classify each statement s_i into one of two categories: $y_i \in \{\text{sustainable}, \text{unsustainable}\}$. Formally, we aim to learn a mapping function:

$$\mathcal{M} : S \rightarrow y, \quad \mathcal{M}(s_i) = y_i \tag{1}$$

where $\mathcal{M}$ represents a large language model fine-tuned for financial sustainability classification. The challenge lies in ensuring accurate classification, particularly in multilingual and low-resource settings, where labeled financial data is often scarce.

Solution Overview: Existing works fine-tune large language models, denoted as $\mathcal{M}$, using only the labels Y, where the model $\mathcal{M}$ learns a direct map-

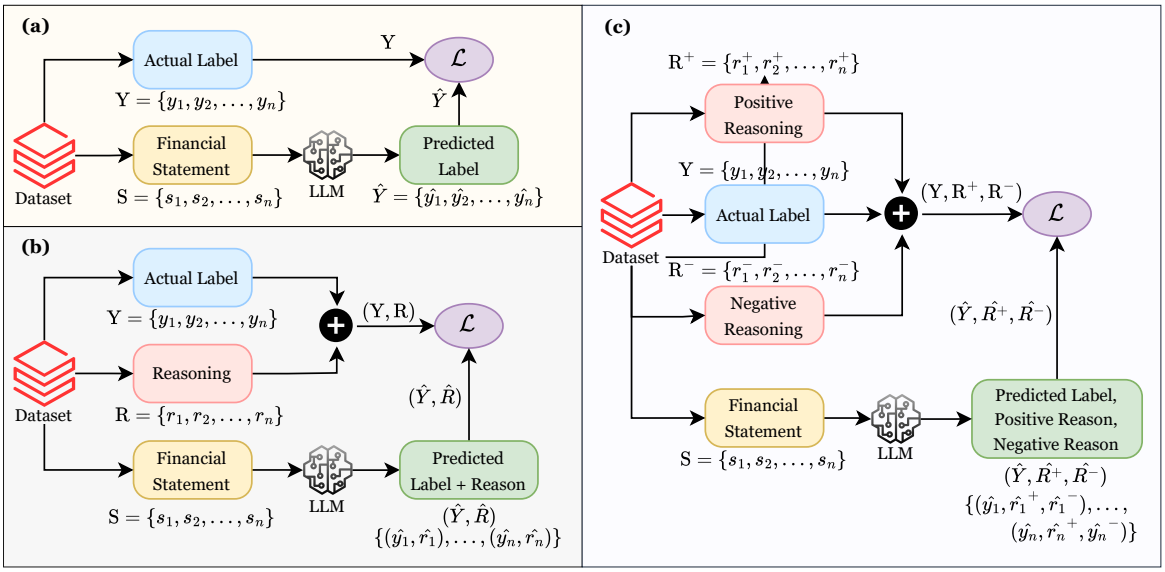

Figure 2: Overview of three fine-tuning approaches: (a) Fine-tuning using Label, (b) Fine-tuning using Label + Unidirectional Reason, and (c) Fine-tuning using Label + Bidirectional Reason (Ours). The novel third approach enhances classification performance by supervising the model's output with the classification label (Y), positive reason (R^+), and negative reason (R^-), providing a more comprehensive and context-aware training framework.

ping $\mathcal{M}(s_i) = y_i$. However, financial decision-making often requires justification. Hence, we introduce reason-based fine-tuning, particularly leveraging unidirectional and bidirectional reasoning. The first method fine-tunes LLMs with labels and their corresponding reasons $R = \{r_1, r_2, ..., r_n\}$, which justify the assigned labels: $\mathcal{M}(s_i) = (y_i, r_i)$. The second approach supervises LLMs using the label along with two reasoning components: positive reasons $R^+ = \{r_1^+, r_2^+, ..., r_n^+\}$ and negative reasons $R^- = \{r_1^-, r_2^-, ..., r_n^-\}$. Thus, the model is fine-tuned to learn $\mathcal{M}(s_i) = (y_i, r_i^+, r_i^-)$, thereby improving the model's decision-making process.
