We now measure the test set performance of the best-performing architectures from §4.1 and §4.2 in combination with the optimal transfer-learning approach from §4.3. Results are presented in Table 5 along with baseline models.

We find that RELREG and SEGENC outperform existing state-of-the-art models by a substantial margin, and that initializing the model from the

Model	Flu.	Rel.	Comp.	Fact.
BART	**4.08**	3.68	3.22	3.31
RELREG-W	3.87	3.81	3.67	**3.70**
SEGENC-W	3.93	**3.87**	**3.81**	3.63

Table 6: Human evaluation of two best-performing models from Section 4, along with a baseline BART model. Summaries were evaluates across four dimensions: fluency (**Flu.**), relevance (**Rel.**), completeness (**Comp.**), and factuality (**Fact.**).

Wikisum-fine-tuned checkpoint further improves performance, with the best model exceeding current state-of-the-art performance by a difference of 3.38 R-1, 3.72 R-2, and 3.28 R-L. Comparing the best models from each category, we find that the end-to-end approach outperforms the two-stage. Within the two-stage dual-encoder models, RELREGTT outperforms DPR on the test set despite the slightly worse performance on the validation set. We attribute this variation to the small size of the validation set, and our other findings remain consistent across validation and test sets. The single-encoder RELREG outperforms the best dual-encoder model, with RELREG-W improving upon the current state-of-the-art performance by a difference of 2.03 R-1, 3.10 R-2, and 2.18 R-L.

5 Further Analysis

In this section we conduct further analysis of the best performing models from Section 4. First, we offer additional insights into the performance of those models on the QMSum dataset through a human-based study. Next, we discuss the generalization abilities of those models by running experiments on the AQuaMuSe dataset.

5.1 Human Evaluation

To gain a better understanding of the performance of the models on the QMSum dataset, human judges were hired and asked to assess the quality of generated summaries. Summaries were evaluated across four dimensions: 1) *fluency*, measuring their grammatical quality, 2) *relevance*, assessing their relevance to the input query, 3) *completeness*, evaluating their comprehensiveness considering the input conversation and query, and 4) *factuality*, measuring their factual consistency with respect to the conversation. Scores were assigned on a Likert scale from 1 to 5 (best), where each example was evaluated by 3 judges with the final score averaged. Results are presented in Table 6.

Model	R-1	R-2	R-L
Hi-MAP	*30.34*	*14.82*	*26.86*
BART	48.74	33.96	46.02
RELREG-W	54.06	38.51	51.07
SEGENC-W	**63.62**	**51.27**	**61.37**

Table 7: AQuaMuSe test-set performance of two best-performing models from §4, along with a baseline BART model and previously reported results (in italics) for Hi-MAP (Fabbri et al., 2019a) from Kulkarni et al. (2020). Note that the version of the dataset used for previous results would have been slightly different due to variations in document selection parameters and Common Crawl indices (see Appendix).

We find that the RELREG-W and SEGENC-W models achieved comparable performance across all of the evaluated dimensions, with summaries generated by SEGENC-W rated as slightly more complete. The BART baseline was rated highest in the fluency dimension, however, it was substantially outperformed by both of the introduced models on completeness and factuality. One possible explanation for the slightly lower fluency scores for the RELREG-W and SEGENC-W models is that they are better able to retrieve content from the source, which itself may have low fluency due to its conversational nature. The results also highlight a gap between the performance of existing models and perfect scores, which shows that there is potential for improvement in future work.

5.2 Dataset Generalization

To test that the automated evaluation results generalize beyond the QMSum dataset, we trained and evaluated the best-performing models on AQuaMuSe, another high-quality dataset for QFS that includes long documents (§2.1, §3.3). Test-set performance for the best-performing two-stage and end-to-end models, along with a baseline BART model, are shown in Table 7. Results are consistent with those for the QMSum dataset (Table 5), with the best end-to-end model (SEGENC-W) outperforming the best two-stage model (RELREG-W), and both outperforming the baseline (BART) model.

6 Conclusion

In this work, we conducted an exploratory study of neural models for query-focused summarization. We studied two categories of models: two-stage and end-to-end, and presented two architectures, RELREG and SEGENC, both of which improve ROUGE performance over prior state of the art by a substantial margin. We also explored task-specific transfer learning, which further improved model performance. Besides model performance, we discussed issues of computational efficiency that practitioners may factor into their modeling choices. Finally, we conducted a human study suggesting that the summaries produced by the best-performing models are more factually correct and complete than a baseline model by a substantial margin. We hope that the analysis and modeling contributions of this paper will be a resource for future research on query-focused summarization.

7 Ethical Considerations

Dataset Biases QMSum and AQuaMuSe contain meeting transcripts and documents in English and thus mainly represent the culture of the English-speaking populace. Political or gender biases may also exist in the dataset, and models trained on these datasets may propagate these biases Additionally, the pretrained BART model carries biases from the data it was pretrained on. We did not stress test these models for biases and request that the users be aware of these potential issues in applying the models presented.

Crowdsourcing Protocols Workers were compensated \$1 per example, calibrated to equal a \$12/hour payrate. We use the following qualifications to recruit MTurk workers with good track records: HIT approval rate greater than or equal to 97%, number of HITs approved greater than or equal to 10000, and located in one of the following English native-speaking countries: Australia, Canada, New Zealand, United Kingdom, United States.

Misuse Potential and Failure Mode When properly used, the summarization models described in this paper can be time-saving. However, the current model outputs may be factually inconsistent with the input documents, and in such a case could contribute to misinformation on the internet. This issue is present among all current abstractive summarization models and is an area of active research.

Environmental Cost The experiments described in the paper primarily make use of A100 GPUs. We typically used a single GPU per experiment, and the experiments may take up to a day when repeating across random seeds. The largest backbone model used, `BART-Large`, has 400 million parameters. While our work required extensive experiments, future work and applications can draw upon our insights and need not repeat these comparisons.

8 Acknowledgements

We thank Divyansh Agarwal for his insights on existing model architectures and assistance with training DPR. We thank Semih Yavuz for providing the initial implementation of the Fusion-in-Decoder model.

A Appendix

Locator Model Parameters For MARGE experiments, we apply the original fine-tuned BERT-base checkpoint from Xu and Lapata (2021a), while for DPR, we fine-tune a BERT-base model for both query and passage encoders following Karpukhin et al. (2020).

We report results for RELREG fine-tuned from an Electra-large checkpoint (Clark et al., 2020). For a fair comparison with other metrics, we also fine-tuned RELREG from a BERT-base checkpoint. This version still outperformed DPR by about a point in R-1, R-2, and R-L, demonstrating the advantage of this locator approach beyond the chosen base model.

We apply RELREGTT fine-tuned from a distilled RoBERTa base (Liu et al., 2019) checkpoint initially fine-tuned for the task of entailment. This approach of continuing fine-tuning from an entailment checkpoint is suggested by the sentence transformers library (Reimers and Gurevych, 2019). We also experimented with fine-tuning the RELREGTT model from BERT-base and Electra-large checkpoints, but these locators did not perform better in initial experiments.

Table 8: Performance of extractor models on the validation set. The left and middle sections present the lexical overlap between utterances retrieved by extractor models and the reference summaries and summary queries, accordingly. Lexical overlap is evaluated by means of ROUGE-1 (*R-1*), ROUGE-2 (*R-2*), and ROUGE-L (*R-L*) metrics. Segments of the section focus on the lexical overlap between the highest ranked 1 (Top-1), 5 (Top-5), 15 (Top-15) utterances, and all utterances truncated to a 1024 token limit (All). The table also includes the average word counts of all extracted utterances, denoted as $\bar{x}$. The right section shows the span overlap between the utterance spans retrieved by the extractor models and those collected from human annotators by the authors of QMSum. The performance is evaluated by means of *Precision* and *Recall* scores and uses the highest ranked utterances truncated to the limit of 1024 tokens.

Summarization Model Parameters In all experiments described in this work, the LED model was initialized from the `allenai/led-large-16384` checkpoint. Two model hyperparameters, *maximal input size* and *attention window size*, were chosen through a hyperparameter search with candidate models selected based on their performance on the validation set. Best hyperparamters were found to be: `16384` maximum input size, and `1024` attention window size. LED models were trained for `10` epochs, with a batch size `1`, gradient accumulation set to `4` steps, and learning rate set to `0.000005`. The SEGENC model was initialized from the `facebook/bart-large` checkpoint. The model hyperparameters, *maximal input size* and *attention window size*, were chosen through a hyperparameter search with candidate models selected based on their performance on the validation set, with results reported in the paper. Best hyperparamters were found to be: `16384` maximum input size, and `512` attention window size. The SEGENC models were trained for `10` epochs, with a batch size of `1` and learning rate set to `0.000005`.

QMSum Details QMSum contains 1,808 query-summary pairs in total, with a train/validation/test split of 1257/272/281. It is made available through an MIT license[5], which aligns with our use for research purposes. Non-identifying names are used in place of real names.

AQuaMuse Details We experiment the V3, abstractive version of AQuaMuse, consisting of 7725 query-summary pairs, with a train/validation/test split of 5566/596/734. The original AQuaMuse paper reported results on V2 of the dataset, which contains a slightly different input document set due to variations in the semantic overlap threshold used to retrieve documents. Some input documents could not be retrieved due to differences in the Common Crawl index used; we use the cleaned, reproduced version of the C4 dataset (Raffel et al., 2020) from the Common Crawl made available by AI2[6]. We kept examples for which all input documents were found, which resulted in a dataset of 6896 examples. The natural language questions it contains are made available through an Apache 2.0 license[7], which aligns with our use for research purposes. This dataset uses publicly available entities from Wikipedia.

B Human Annotation Interface

The instructions shown to the annotators during human studies are presented in Figure 1

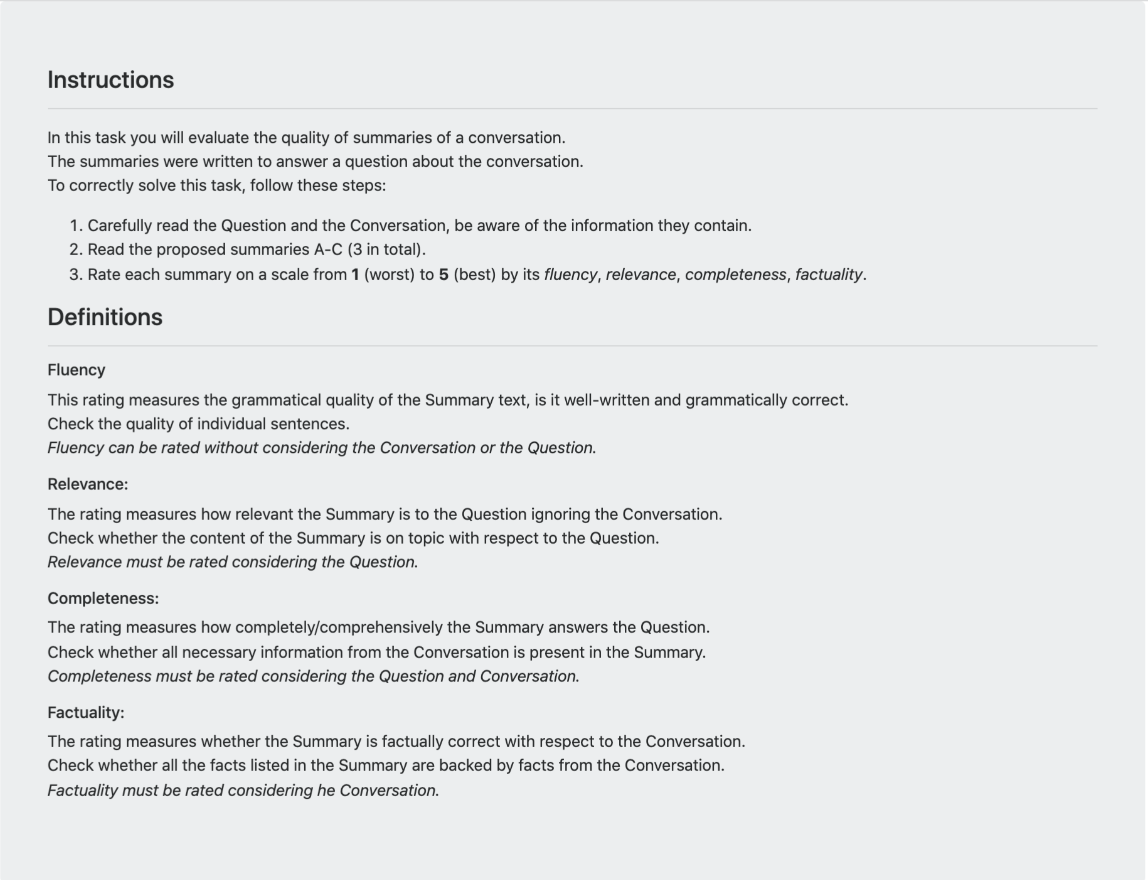
[7] `https://github.com/google-research-datasets/natural-questions/blob/master/LICENSE`



Instructions

In this task you will evaluate the quality of summaries of a conversation.
The summaries were written to answer a question about the conversation.
To correctly solve this task, follow these steps:

1. Carefully read the Question and the Conversation, be aware of the information they contain.
2. Read the proposed summaries A-C (3 in total).
3. Rate each summary on a scale from **1** (worst) to **5** (best) by its *fluency*, *relevance*, *completeness*, *factuality*.

Definitions

Fluency

This rating measures the grammatical quality of the Summary text, is it well-written and grammatically correct.
Check the quality of individual sentences.
Fluency can be rated without considering the Conversation or the Question.

Relevance:

The rating measures how relevant the Summary is to the Question ignoring the Conversation.
Check whether the content of the Summary is on topic with respect to the Question.
Relevance must be rated considering the Question.

Completeness:

The rating measures how completely/comprehensively the Summary answers the Question.
Check whether all necessary information from the Conversation is present in the Summary.
Completeness must be rated considering the Question and Conversation.

Factuality:

The rating measures whether the Summary is factually correct with respect to the Conversation.
Check whether all the facts listed in the Summary are backed by facts from the Conversation.
Factuality must be rated considering he Conversation.

BITEXTEDIT: Automatic Bitext Editing for Improved Low-Resource Machine Translation

Eleftheria Briakou[1][*] **Sida I. Wang**[2], **Luke Zettlemoyer**[2], **Marjan Ghazvininejad**[2]
[1] University of Maryland, [2] Facebook AI Research
`ebriakou@cs.umd.edu`, `{sida,lsz,ghazvini}@fb.com`

Abstract

Mined bitexts can contain imperfect translations that yield unreliable training signals for Neural Machine Translation (NMT). While filtering such pairs out is known to improve final model quality, we argue that it is suboptimal in low-resource conditions where even mined data can be limited. In our work, we propose instead, to refine the mined bitexts via automatic editing: given a sentence in a language $\mathbf{x_f}$, and a possibly imperfect translation of it $\mathbf{x_e}$, our model generates a revised version $\mathbf{x'_f}$ or $\mathbf{x'_e}$ that yields a more equivalent translation pair (i.e., $<\mathbf{x_f}, \mathbf{x'_e}>$ or $<\mathbf{x'_f}, \mathbf{x_e}>$). We use a simple editing strategy by (1) mining potentially imperfect translations for each sentence in a given bitext, (2) learning a model to reconstruct the original translations and translate, in a multi-task fashion. Experiments demonstrate that our approach successfully improves the quality of CCMatrix mined bitext for 5 low-resource language-pairs and 10 translation directions by up to 8 BLEU points, in most cases improving upon a competitive translation-based baseline.

1 Introduction

Neural Machine Translation (NMT) for low-resource languages is challenging due to the scarcity of bitexts, i.e., translated text in two languages (Koehn and Knowles, 2017). Models are often trained on heuristically aligned (Resnik, 1999; Bañón et al., 2020; Esplà et al., 2019) or automatically mined data (Schwenk et al., 2021a,b), which can be low quality (Briakou and Carpuat, 2020; Kreutzer et al., 2022). This data can include errors that range from small meaning differences in sentences that overlap in content to major differences that yield completely incorrect translations and random noise, e.g., empty sequences, text in the wrong language, non-linguistic content, among others.

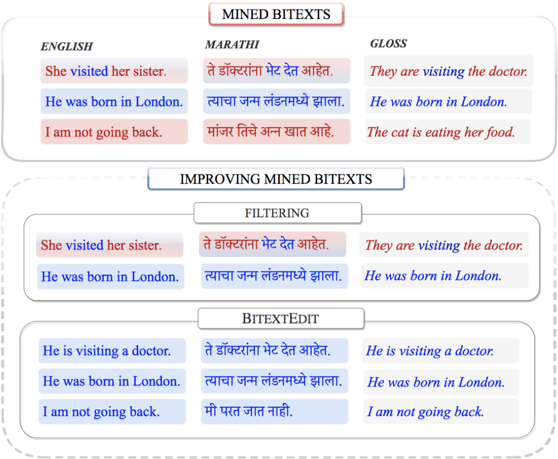

Figure 1: Noisy bitexts consist of a mixture of good-quality, imperfect, and poor-quality translations. Filtering decreases the size of training samples which is crucial for low-resource NMT. Our approach, alternatively, revises noisy bitexts via utilizing imperfect translations in a more effective way, while keeps the size of training data untouched.

Filtering out noisy samples from web-crawled bitexts is therefor standard practice for building high quality models (Koehn et al., 2018), and is particularly helpful in low-resource settings (Koehn et al., 2019, 2020). Despite the popularity of this approach, we argue it has two key limitations. First, partially correct translations provide signal that is lost if the entire example is dropped (see first sample bitext in Figure 1). Second, filtering out samples exacerbates the data scarcity problem for the long-tail of low-resource language-pairs.

In this paper, we instead aim to make use of as much of the signal from the mined bitext as possible. We propose an **editing approach to bitext quality improvement**. Our model takes as input a bitext (i.e., $(\mathbf{x_f}, \mathbf{x_e})$), and edits one of the two sentences to generate a refined version of the original (i.e., $\mathbf{x'_f}$ or $\mathbf{x'_e}$) as necessary. By framing the problem as a bitext editing (BITEXTEDIT) task, we can perform a wide range of operations from

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1469 - 1485
July 10-15, 2022

copying good-quality bitext, to *partial editing* of small meaning mismatches, and *translating* from scratch incorrect references. Following previous extrinsic evaluations of bitext quality (Koehn et al., 2019, 2020; Schwenk et al., 2021b,a), we compare NMT models trained on the original and revised versions of CCMatrix bitexts. Concretely, we report consistent improvements in translation quality for 10 low-resource NMT translation tasks: EN↔OC, IT↔OC, EN↔BE, EN↔MR, and EN↔SW, while in most cases we even improve upon a competitive translation-based baseline. Crucially, BITEXTEDIT yields from $4-8$ BLEU point improvements in the more data-scarce settings (i.e., EN-OC, IT-OC). Additionally, our quantitative and qualitative analyses indicate that BITEXTEDIT improves bitext quality in higher-resource settings with lighter editing that targets more fine-grained meaning differences.

2 Background

Bitext Mining The idea of using the web as a source of parallel texts has a long history (Resnik, 1999). Recent advances in multilingual representation learning (Artetxe and Schwenk, 2019; Liu et al., 2020) enable the curation of mined bitexts across multiple languages at scale. For instance, combining LASER (Artetxe and Schwenk, 2019) embeddings with nearest neighbor search allows for effective bitext mining from Wikipedia, i.e., WikiMatrix (Schwenk et al., 2021a) and CommonCrawl monolingual texts, i.e., CCMatrix (Schwenk et al., 2021b). While the latter approach requires parallel text supervision to train the multilingual sentence representation encoder, Tran et al. (2020) shows that it can be extended to an unsupervised framework via iterative self-supervised training.

Issues in Bitext Quality Kreutzer et al. (2022) manually audit the quality of multilingual datasets in 205 language-specific corpora that result from automatic curation pipelines, including bitexts from CCAligned (El-Kishky et al., 2020), WikiMatrix (Schwenk et al., 2021a), and ParaCrawl (Bañón et al., 2020; Esplà et al., 2019). All have systematic issues, especially for low-resource languages. The vast majority of low-resource pairs contain less than 50% valid translations. However, they do often share structural similarity and partial content. Briakou and Carpuat (2020)—in a more fine-grained annotation study—highlight that small content mismatches are even found in high resource pairs: 40% of English-French WikiMatrix sentence-pairs have *small meaning mismatches*. Our work aims at improving bitext quality via eliminating their systematic issues via editing.

Bitext Quality vs. NMT Training Khayrallah and Koehn (2018) demonstrate the often significant impact of various types of noise on NMT, via increasing the percentage of 5 types of artificially injected errors on a clean English-German corpus—mimicking frequent issues in parallel texts (i.e., copying, wrong language, non-linguistic content, short segments, empty sequences). Ott et al. (2018) also argue that data uncertainty resulting from noisy references contributes to the miscalibration of NMT models. Apart from noisy references, *small meaning mismatches* have also a measurable impact on various aspects of NMT: Briakou and Carpuat (2021) show that models trained on synthetic divergences output degenerated text more frequently and are less confident in their predictions. In contrast with prior studies that discuss how imperfect references interact with NMT training *solely* for high-resource pairs, we *primarily* focus on low-resource settings and improve NMT models by improving their training bitexts.

Bitext Quality Improvement The most standardized approach to improving bitext either discards an example or treats it as a perfect training instance (Koehn et al., 2018). Past submissions to the Parallel Corpus Filtering WMT shared task employ a diverse set of approaches covering simple pre-filtering rules based on language identifiers and sentence features (Rossenbach et al., 2018; Lu et al., 2018; Ash et al., 2018), learning to weight scoring functions based on language models, extracting features from neural translation models and lexical translation probabilities (Sánchez-Cartagena et al., 2018), combining pre-trained embeddings (Papavassiliou et al., 2018), and dual-cross entropy (Chaudhary et al., 2019). In contrast to prior work, and similar to ours, Briakou and Carpuat (2022) propose to revise imperfect translations in bitext via selectively replace them with synthetic translations generated by NMT of sufficient quality. Our work builds on top of prior work and instead of filtering out all the imperfect bitexts, we selectively edit them and keep them in the pool of training data targeting low-resource NMT.

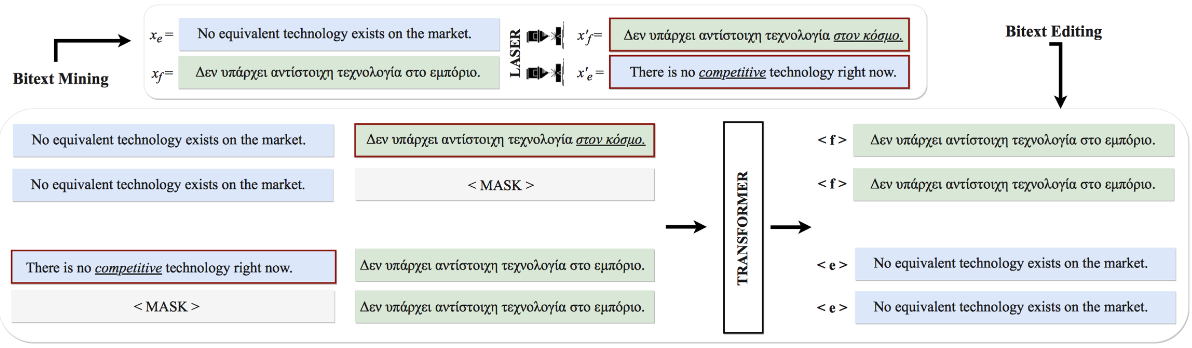

Figure 2: BITEXTEDIT training strategy: Our multi-task model is trained using synthetic supervision from mined bitexts. Starting from an original bitext (x_e, x_f), we mine imperfect translations x'_f and x'_e for each reference using LASER (Bitext Mining). A sequence-to-sequence Transformer model is trained to *translate* and *reconstruct* the original references given synthetically extracted bitexts representing imperfect translations (Bitext Editing).

3 Approach: BITEXTEDIT

We frame bitext refinement as an editing task (i.e, BITEXTEDIT) that takes two *input sentences*: a sentence $\mathbf{x_f}$ in language $\mathbf{f}$ and a sentence $\mathbf{x_e}$ in language $\mathbf{e}$, and aims at editing *one* of them (i.e., it *outputs* $\mathbf{x'_f}$ or $\mathbf{x'_e}$) with the goal of yielding a more equivalent translation pair (i.e., <$\mathbf{x_f}$, $\mathbf{x'_e}$> or <$\mathbf{x'_f}$, $\mathbf{x_e}$>). Figure 2 gives an overview of our approach while below we describe the bitext refinement model (§3.1) and the curation of data needed to train our model based on bitext mining (§3.2).

3.1 Bitext Editing

Architecture Our bitext editing model is a transformer sequence-to-sequence architecture. Each bitext ($\mathbf{x_f}$, $\mathbf{x_e}$) is encoded via adding position embeddings that are reset for each input sentence to facilitate their alignment (Conneau and Lample, 2019) and two language embeddings, initialized at random, to indicate the two languages for the editing model. The decoder generates autoregressively a refined version of $\mathbf{x_f}$ or $\mathbf{x_e}$, where the first generated token indicates which of the two input sentences is edited, as described below.

Learning During training, we optimize the multi-task loss presented in Equation 1, which has two components. The first represents a *edit-based reconstruction loss* (i.e., $\mathcal{L}_{\text{EDIT}}$) that reconstructs one of the two sentences, e.g., $\mathbf{x_f}$ started from a noised version of the original bitexts e.g., $\mathbf{x'_f}$ and $\mathbf{x_e}$. We make this loss bi-directional via adding a symmetrical loss that reconstructs $\mathbf{x_e}$ from $\mathbf{x_f}$ and $\mathbf{x'_e}$, respectively. The second component, is implemented as a bi-directional *translation loss* (i.e., $\mathcal{L}_{\text{MT}}$) via masking the inputs of the target translation directions (e.g., generate $\mathbf{x_e}$ given $\mathbf{x_f}$ and <MASK>). Finally, in both losses a language identification symbol (i.e., <f> or <e>) is used as the initial token to predict the language of the output text.

$$\mathcal{L} = \sum_{(\mathbf{x_f}, \mathbf{x_e})} \Bigg(\underbrace{\text{logp}\Big([\text{<e>}\ \mathbf{x_e}] \mid (\mathbf{x_f}, \mathbf{x'_e})\Big) + \text{logp}\Big([\text{<f>}\ \mathbf{x_f}] \mid (\mathbf{x'_f}, \mathbf{x_e})\Big)}_{\mathcal{L}_{\text{EDIT}}} + \underbrace{\text{logp}\Big([\text{<e>}\ \mathbf{x_e}] \mid (\mathbf{x_f}, \text{<MASK>})\Big) + \text{logp}\Big([\text{<f>}\ \mathbf{x_f}] \mid (\text{<MASK>}, \mathbf{x_e})\Big)}_{\mathcal{L}_{\text{MT}}} \Bigg) \tag{1}$$

Inference At test time, our model takes as input a possibly imperfect bitext and edits one of the reference translations, while first generating the language identification token. The latter is used to infer which of the two reference translations gets revised. Finally, we pair the edited output sequence with the original input that does not get revised, yielding a refined bitext.

3.2 Bitext Mining

Our model requires access to $\mathbf{x'_f}$ and $\mathbf{x'_e}$ training instances that are treated as noised versions of $\mathbf{x_f}$ and $\mathbf{x_e}$, respectively. Since our goal is to develop a model that can refine mismatches found in mined bitexts at inference time, we want our noised training instances to share similar properties with the mined ones, e.g., fluent text in the target language, possibly imperfect translations of the source text. To this direction, we take a distance-based mining approach to construct the noised samples similar to Schwenk (2018). Unlike Artetxe and Schwenk (2019) we do not use a margin score on the *normalized* cosine distance of sentence-pairs to keep the computation cost low and encourage mining of more diverse imperfect translations. Concretely, given the mined bitext $(\mathbf{x_f}, \mathbf{x_e})$ and two pools of monolingual sentences $\mathcal{F}$ and $\mathcal{E}$, in language $\mathbf{f}$ and $\mathbf{e}$, we extract $\mathbf{x'_f}$ and $\mathbf{x'_e}$ as follows:

$$\begin{aligned} \mathbf{x'_f} &= \text{argmax}_{\mathbf{z} \in \mathcal{F}} \ \cos(\text{LASER}(\mathbf{z}), \text{LASER}(\mathbf{x_e})) \\ \mathbf{x'_e} &= \text{argmax}_{\mathbf{z} \in \mathcal{E}} \ \cos(\text{LASER}(\mathbf{x_f}), \text{LASER}(\mathbf{z})) \end{aligned} \quad (2)$$

where LASER (Artetxe and Schwenk, 2019) represents a multilingual encoder used to extract sentence embeddings for each sentence, while the most similar sentence is returned based on nearest neighbor retrieval. Furthermore, this formula is extended to retrieval of top k sentences, while we also allow mining of the original CCMatrix translations. The latter happens to expose the model to good translations at training time, that should not be edited.

4 Experimental Setting

Bitexts We focus on CCMatrix data for two main reasons: a) it constitutes the only large-scale available resource for a lot of low-resource language pairs and b) recent efforts of auditing this corpus raise concerns regarding the quality of mined bitext of low-resource pairs. CCMatrix is mined using LASER embeddings following the max-strategy approach: a margin score is computed for all monolingual sentences in two languages, then the union of forward and backward candidates is build and pairs that score above a pre-defined threshold are treated as translations. Schwenk et al. (2021b) set the threshold globally for all languages at 1.06.

Our primary goal is to explore whether bitexts that are typically discarded by filtering can be refined by our model and thus benefit low-resource NMT. For this purpose, we define two pools of CCMatrix data: Pool A corresponds to CCMatrix data with LASER scores greater than 1.06, while Pool B contains bitexts with scores lower than 1.06 and greater than 1.05. The latter threshold is primarily chosen since CCMatrix bitexts is only available above this value. Editing bitexts with even smaller scores is an interesting area for future work.

Training data Our models are trained based on procedures described in §3.2, where we use Pool A to seed the generation of noised training samples $\mathbf{x'_f}$ and $\mathbf{x'_e}$. We mine k samples $\mathbf{x'_f}$ for each $\mathbf{x_e}$ and k samples $\mathbf{x'_e}$ for each $\mathbf{x_f}$, respectively. We set k to 4 and include detailed statistics in Appendix F.

Language-pairs We experiment with the following languages: English-Occitan (EN-OC), Italian-Occitan (IT-OC), English-Belarusian (EN-BE), English-Marathi (EN-MR), and English-Swahili (EN-SW). The 5 language pairs are chosen to include diverse low-resource pairs, which differ either in training data size or language similarity. Table1 summarizes the data conditions.

PAIR	SCRIPTS	Pool A	Pool B
EN-OC	Latin-Latin	0.2M	0.1M
IT-OC	Latin-Latin	0.3M	0.1M
EN-BE	Latin-Cyrillic	0.7M	1.1M
EN-MR	Latin-Devanagari	1.5M	2.1M
EN-SW	Latin-Latin	1.7M	0.9M

Table 1: Statistics of CCMatrix bitexts.

Comparisons We run several extrinsic evaluations using NMT trained on different versions of CCMatrix data. First, we train NMT models on two versions of original CCMatrix data: Pool A (Schwenk et al., 2021b) and Pool $A \cup B$. Second, we aim at revising Pool B via a) a translation-based approach that revisits the source-side of the bitexts via back-translating their target-side with a model trained on original CCMatrix, (i.e., $b(.)$) and b) via editing either the source or the target side of it using our proposed approach (i.e, $r(.)$).

Model details Our models are implemented on top of `fairseq` (Ott et al., 2019).[1] We use the same Transformer architecture as in Schwenk et al. (2021b), with embedding size 512, 4,096 transformer hidden size, 8 attention heads, 6 transformer layers, and dropout 0.4. We train with 0.2 label smoothing and Adam optimizer with a batch size of 4,000 tokens per GPU. We include more model details in Appendices D and G. We train for 100 epochs and select best checkpoint based on validation perplexity. We report single run results.

Data Preprocessing We use the standard Moses scripts (Koehn et al., 2007) for tokenization of EN, OC, IT, BE and SW and the Indic NLP library[2] for MR. For each language-pair, we learn 60K BPEs using `subword-nmt` (Sennrich et al., 2016b).[3]

Evaluation We evaluate our models on the *devtest* of `flores` (Guzmán et al., 2019). We report `spm-bleu`[4] on detokenized outputs and chrF (Popović, 2015) as our second evaluation metric.[5]

Table 2: Results on NMT tasks for models trained on different versions of CCMatrix. For each task the first column denotes spm-BLEU; the second columns (highlighted scores) give the difference of each row with the original CCMatrix. Models trained on the refined bitexts improve NMT for low-resource language-pairs.

5 Experimental Results

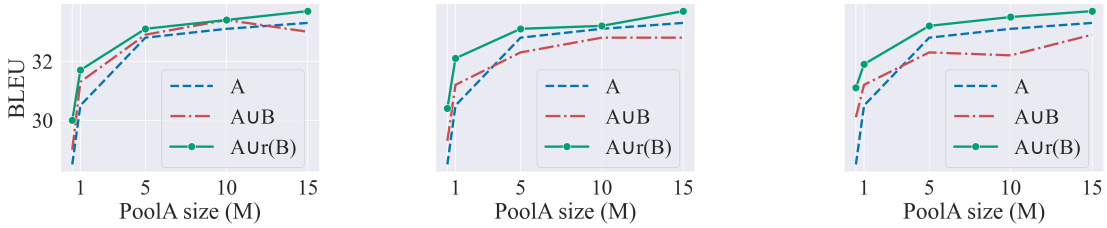
Bitext filtering revisited We first provide empirical evidence that bitext filtering might be a suboptimal solution to low-resource NMT. Table 2 shows that filtering out sentence pairs that score below the predefined threshold of 1.06 (i.e., Filtering) surprisingly hurts translation quality in almost all translation tasks (rows 2 vs. 1 and 8 vs. 7). This result is likely because the threshold was optimized for specific language-pairs, and the fact that—under low-resource regimes—increasing the amounts of *possibly imperfect* translation data might still benefit NMT. Furthermore, this experiment gives us insights on the quality of the training data our bitext editing model uses: for IT-OC, BE-EN, and EN-MR we expect Pool A to provide more noisy training signals (as BLEU scores of NMT models trained on it are $\sim$ 11), compared to EN-OC and EN-SW where the quality of the given bitext is expected to be significantly better (BLEU scores $\sim$ 18 and $\sim$ 37, respectively).

Editing Pool B Applying BITEXTEDIT to edit erroneous translations in Pool B (i.e., $A \cup r(B)$) improves the quality of NMT systems over the ones trained on the original CCMatrix corpus (rows 6 vs. 1 and 12 vs. 7). Among the language-pairs considered, the largest improvements are reported for IT-OC translation tasks (i.e., $+8.4/{+6.7}$), followed by EN-OC (i.e., $+5.5/+4.4$). The magnitude of improvements might be explained by the relatedness of the two languages which facilitates editing with simpler operations (e.g., copying instead of translating).

Our approach also brings significant improvements over the original data for distant language-pairs written in different scripts, despite being trained on more noisy data, as discussed above. For example, we see improvements $+2.0/+1.0$ for EN-BE and $+3.1/+3.7$ for EN-MR. On the other hand, improvements on EN-SW are smaller (i.e., $+0.5/+1.8$). This is expected given the high BLEU scores that the original CCMatrix data yields.

Comparison with Translation-based Baseline Since Pool B bitexts are typically filtered out from the pool of NMT training instances, one reasonable way of incorporating them in NMT training is via treating them as monolingual samples. We experiment with a translation-based model that uses back-translation—the most popular approach to employ data augmentation for NMT. Comparing NMT models trained on CCMatrix augmented with back-translated Pool B against our revised Pool B version (i.e., rows 5 vs. 6 and 11 vs. 12) shows that editing outperforms the translation-based model for $7/10$ tasks, while it yields comparable results to it for the rest 3.

Editing Pool A and Pool B Since the editing framework gives us the potential to generalize all types of operations that *might* be needed to refine bitexts, it is also important that it does not perform *overediting* (i.e., editing already good quality bitexts). For this reason, we also attempt to revise the entire CCMatrix corpus (i.e., $r(A \cup B)$), using our bitext refinement models (i.e., rows 4 and 9). To better understand the importance of performing conservative editing on good quality bitexts, we



(a) $|B| = |A|/2$ (b) $|B| = |A|$ (c) $|B| = 2|A|$

Figure 3: Translation quality (i.e., BLEU) of EN→EL NMT models trained on different amounts of Pool A and Pool B data (i.e., $|A|$ given by x-axis). Across settings, bitext refinement (i.e., $A \cup r(B)$) performs better or comparably to training on the original CCMatrix (i.e., $A \cup B$) or its filtered version (i.e., A).

also compare against the translation-based baseline (i.e, $b(A \cup B)$ in rows 3 and 9). First, we observe that our approach yields consistently significant improvements over CCMatrix with the exception of EN→SW where it performs comparably to it. Second, for most tasks the improvements are comparable to those reported when revising only Pool B, while it is consistently better than the translation-based approach. It, overall, provides a universal method that works well in every case.

6 Analysis

We now turn into analysis with a focus on understanding the broader space where BITEXTEDIT can be applied. We experiment with scaling-up bitext refinement to higher-resource settings in §6.1, we perform qualitative analysis on the edited bitexts in §6.2, and quantitative analysis on the types and intensity of edits in different corpora in §6.3.

6.1 Scaling-up BITEXTEDIT

First, we examine how models trained only on good quality data (Figure 4) behave as we vary their quantity. We experiment with English-Greek EN-EL CCMatrix bitexts and simulate various resource settings via downsampling. In *low-resource* settings (i.e., $|A| < 1$M), translation quality exhibits rapid improvements, with an increase from 100K to 500K training samples boosting BLEU, by approximately 10 points. In *medium-resource* scenarios (i.e., $1 <$M$|A| < 5$M), a proportional increase in the quantity of good quality bitexts yields smaller—yet, significant—translation quality improvements (i.e., moving from 1M to 5M bitexts yields $+2$ BLEU). Finally, in *high-resource* settings (i.e, $|A| > 5$), translation quality reaches a saturation point, with BLEU increases being small and insignificant (i.e., $\sim +0.2$) as we move from 10M to 15M training samples.

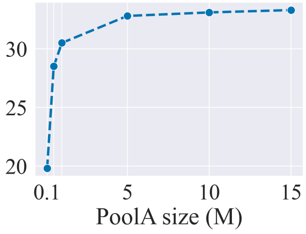


Figure 4: BLEU for EN→EL NMT trained on varying size of CCMatrix data (Pool A).

Second, we present a controlled analysis experiment on how bitext refinement impacts the translation quality of NMT systems under different resource settings (Figure 3). Starting from a high resource language-pair in CCMatrix (here, EN-EL) we sample good and poor quality bitexts (i.e, A and B, respectively) representing low- to high- data scenarios (e.g, 500K up to 15M sentence-pairs). Then, we train EN→EL NMT systems on $A \cup B$ while varying their distribution to represent three settings: (a) good quality bitexts overwhelm the training data (i.e, $|B| = |A|/2$), (b) good and poor quality bitext are equally represented (i.e, $|B| = |A|$), and (c) poor quality bitexts overwhelm the training data (i.e, $|B| = 2|A|/$). We include more details on experimental settings in Appendix B.

Across distribution conditions, adding imperfect translations (i.e., B) to the original good quality data yields improvements for low-to-medium resource settings (i.e, $|A| < 5$). This results complement the earlier observations of §5 that question the appropriateness of a filtering framework in settings where data is scarce. On the other hand, when moving to high resource scenarios, the additional signal that results from imperfect references can have either insignificant (i.e., Figure 3a) or negative impact (i.e., Figures 3b and 3c) on translation quality. The latter depends on whether the good quality data is underrepresented in the training samples.

Table 3: Examples of CCMatrix bitexts along with refined sides generated by BITEXTEDIT. → denotes the side ([EL] or [EN]) that the model edits, while highlighted segments indicate the meaning mismatches in the original CCMatrix sentence that gets edited. Greek sentences are glossed to help understanding their meaning.

Third, starting from good quality bitexts of varying sizes, we train separate bitext refinement models and edit the corresponding poor quality samples (i.e., $r(.)$) defined earlier. Across the board, NMT models that are trained on $A \cup r(B)$ yield the best translation quality results compared to both filtering and training on original CCMatrix. However, we observe that the magnitude of the improvements depends on the data settings. Concretely, bitext refinement yields significant improvements on low-to-medium resource settings (i.e., $\sim +2$ BLUE points). On the other hand, in high resource scenarios bitext refinement helps mitigate the negative impact of overwhelming poor quality instances and performs comparably to filtering. The latter suggests that our refinement strategy *improves bitexts quality across low- to high- resource settings.*

6.2 Qualitative analysis

We conduct a qualitative study to confirm that BITEXTEDIT improves the quality of CCMatrix. We include details on the annotation in Appendix C. One of the authors manually evaluates a random sample of 200 EN-EL sentence-pairs where we compare the original bitexts against the refined ones. Here, we present results on bitext refinement models that use 0.5M PoolA samples. Manual inspection on refined outputs of models trained on larger pools showed similar performance. As shown in Figure 5, our models performs edits that refine meaning mismatches found in the original CCMatrix data. While only $\sim 38\%$ of the original samples contain parallel texts that are perfect translations of each other, the revised sample contains $\sim 70\%$ perfect translations. Finally—apart from evaluating meaning differences—we also rate fluency of the edited translations. We find that our model does not suffer from major fluency issues with 84.5% of their outputs rated as *flawless* and 15.5% as *good*. Table 3 presents example outputs of our BITEXTEDIT approach for English-Greek. More examples can be found in Appendix E.

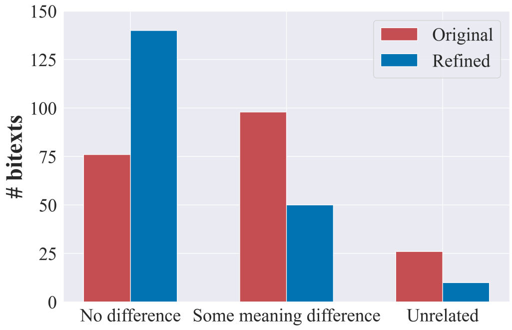

Figure 5: Number of bitexts manually rated as perfect translations (i.e., No difference), partial translations (i.e., some meaning difference), and wrong translations (i.e., unrelated) for a random sample of original vs. refined CCMatrix EN-EL data.

		C	S	D	I	C	S	D	I
CORPUS	**EDITED SENT.**	**ALL (%)**				**ALL \ COPIES (%)**			
Tatoeba	29.80%	97.47	1.88	0.29	0.34	86.38	10.16	1.56	1.88
OpenSubtitles	65.63%	90.46	5.53	1.27	2.73	74.51	14.79	3.39	7.29
ParaCrawl	88.11%	96.30	2.25	0.39	1.04	85.42	8.89	1.55	4.12

Table 4: TER statistics for bitext refinement of random samples of EN-EL OPUS bitexts. Second column gives the % of bitexts that get at least one edit operation; the last two columns present the percentage of correct (**C**), substituted (**S**), deleted (**D**), and inserted (**I**) tokens for all the bitexts (i.e., **ALL**) and the subset of bitexts that receive revisions compared to the original (i.e., **ALL**\ **COPIES**).

6.3 Quantitative analysis

Percentage of edited bitexts Table 5 presents coarse statistics on the percentage of refined bitexts that exhibit at least one edit compared to the original ones. First, we observe that the percentage of edited bitexts varies across the languages-pairs studied. This reflects the varying quality of PoolB samples in different languages and also connects to the varying magnitude of improvements we show in Table 2. The biggest improvements are given for IT-OC, where ∼ 76% of the bitexts are edited by our refinement models. On the other hand, the smallest improvements are found for EN-SW, with only ∼ 36% of its bitext being revised, probably due to the already good quality of the initial CC-Matrix sentence pairs.

Editing EN-EL OPUS corpora Broadly speaking, a good bitext refinement model should be able to rewrite bitext in a way that improves potential errors in the original references. At the same time though, it should avoid over-editing (i.e., avoid editing an already good translation-pair). We perform a quantitative analysis on EN-EL corpora from OPUS that vary in their quality and extract Translation Error Rate (TER) label (Snover et al., 2006) token-level statistics to study both the *frequency* and the *types* of edits that our bitext refinement models perform. Table 4 presents results on random samples (∼ 100K) of three popular corpora: (a) the Tatoeba corpus (Tiedemann, 2020) consisting of human translations, (b) the OpenSubtitles corpus (Lison and Tiedemann, 2016) consisting of sentence-aligned subtitles of movie series[6], and (c) the ParaCrawl corpus (Esplà et al., 2019) consisting of automatically crawled translations from translations of European Parliament Proceedings.

As expected, our model performs minimal editing on the high-quality *Tatoeba* bitexts. Concretely, only ∼ 30% of it gets revised, while as suggested by the token-level TER statistics even the revised sentence-pairs mostly consist of substituted tokens. Further manual inspection reveals that most of those tokens depict subtle spelling differences between Greek words. On the other hand, when editing the samples of automatically extracted bitexts our refinement model performs more frequent edits: it revises ∼ 65% of OpenSubtitles and ∼ 88% of ParaCrawl bitexts. Interestingly, although a greater amount of ParaCrawl texts get revised compared to OpenSubtitles, edits on the latter are more aggressive as it consists of at least 10% fewer correct (i.e., **C**) tokens than the former. A break down on the types of operations further reveals that editing OpenSubtitles requires more deletion (i.e., **D**) and insertion (i.e., **I**) operations compared to the other two. This observation connects to prior efforts on auditing OpenSubtitles that found sentence segmentation errors (i.e, added extra leading/trailing words in one side) to be a frequent type error for this corpus (Vyas et al., 2018).

PAIR	**SRC**	**TGT**	**BOTH**
EN-OC	34.06%	66.58%	67.48%
IT-OC	34.76%	41.11%	75.78%
EN-MR	58.35%	19.90%	68.07%
BE-EN	21.01%	28.06%	49.06%
EN-SW	14.52%	21.05%	35.57%

Table 5: Percentage of sentences with at least one edit operation compared to the original for: source-side (SRC), target-side (TGT), and both sides (BOTH).

7 Related Work

Automatic Post-Editing APE aims at automatically correcting the output of a black-box MT system. Recent approaches on APE (Chatterjee et al., 2019, 2020) fine-tune pre-trained multilingual models models (Lopes et al., 2019) or translation models (Yang et al., 2020) on a combination of gold-standard APE data and artificially aug-

---

[6] `http://www.opensubtitles.org/`, `https://opus.nlpl.eu/OpenSubtitles-v2018.php`

mented candidates resulting from external translations. BITEXTEDIT aims instead, at editing imperfect translations representing human generated texts in two languages, without assuming access to gold-standard training data.

Low-resource MT Haddow et al. (2021) structure the diverse set of approaches to low-resource MT to (a) efforts for increasing the amounts of available bitexts (i.e., *data collection*; Schwenk et al. (2021a,b)), (b) methods that explore how other types of data can be incorporated into MT (i.e., *data exploitation*; Baziotis et al. (2020); Zoph et al. (2016); García-Martínez et al. (2017)), and (c) advances in modeling (i.e., *model choices*; Vaswani et al. (2017)). BITEXTEDIT is an alernative *data exploitation* approach that does not require further bilingual data or other sources of supervision.

Synthetic Bitext Generating synthetic bitext has mainly been studied as a means of data augmentation for NMT through forward translation (Zhang and Zong, 2016), backtranslation (Sennrich et al., 2016a; Marie et al., 2020; Hoang et al., 2018), or round-trip translation (Ahmadnia and Dorr, 2019) of monolingual resources. Moreover, recent line of works use the predictions of forward and backward translation models to induce the creation of new versions of the parallel data: Nguyen et al. (2020) diversify the parallel data via translating both sides using multiple models and then merge them with the original to train a final NMT model; Jiao et al. (2020) employ a similar approach to rejuvenate the most inactive examples that contributes less to the model performance; Kim and Rush (2016) propose to train a student model of smaller capacity on sequence-level interpolated data generated by a teacher model of higher capacity. Using synthetic translations to augment or revise real bitexts assumes access to NMT systems of sufficient quality. Recent works propose methods to automatically revise noisy synthetic bitexts (Cheng et al., 2020; Wei et al., 2020). By contrast, our work accounts for imperfect references in *real* bitext and is tailored to low-resource settings where NMT quality is too low to provide reliable candidate translations.

Retrieve & Edit Approaches Retrieve and edit approaches have been integrated at inference time for several tasks, such as NMT (Gu et al., 2018; Zhang et al., 2018; Cao and Xiong, 2018; Hossain et al., 2020), APE (Hokamp, 2017), dialogue generation (Weston et al., 2018), among others.

8 Conclusion

We introduce an alternative approach for bitext quality improvement that we show is better suited for low-resource language pairs. Instead of filtering out imperfect translation references that result from automatic bitext mining, we instead edit them with the goal of improving their quality. Our editing models are trained using only synthetic supervision, which can be gathered at scale for any language pair that support bitext mining. Extensive quantitative analysis suggests that our approach successfully improves bitext quality for a variety of language-pairs and different resource conditions. Furthermore, extrinsic experiments on 10 low-resource NMT tasks suggest that bitext refinement constitutes a successful approach to improving NMT translation quality in low data regimes. Those findings highlight the importance of the good *quality* bitexts in scenarios where large *quantities* cannot be guaranteed and motivate future research on improving low-resource NMT further.

C Manual Annotation Details

For each bitext (i.e., original CCMatrix sample or refined sample edited by a bitext refinement model) we rate the **degree of equivalence** between the two sentences following the protocol of semantic divergences (Briakou and Carpuat, 2020). Concretely, a bitext is annotated as having *no meaning difference* if it corresponds to perfect translations, *some meaning differences* if the sentences share important content in common but differ by few tokens (e.g., small added content, or phrasal mistranslation), and *unrelated* if the sentences are only topically or structurally related. For rating **fluency** we evaluate the output sentence of the bitext refinement models in isolation on a discrete scale of 1 to 5, following Heilman et al. (2014) (Other → Incomprehensible → Somewhat Comprehensible → Comprehensible → Perfect).

D Fairseq configuration details

Table 15: Lexical characteristics of Original vs. Edited version of CCMatrix bitexts.

G Compute Infrastructure & Run time

Each experiment runs on a single machine with 8 GPUs. NMT models require less than 3.5 hours (e.g., EN-OC on $A \cup B$ requires $\sim$ 20 minutes to train). Similarly, BITEXTEDIT models require less than 13.5 hours to train (e.g., EN-OC requires $\sim$ 5 hours). All models follow the transformer architecture detailed in Appendix D with a total of 165M parameters.

H Potential Risks

Hallucination detection Our approach introduces synthetic samples (i.e., edited references that replace the originally human generated samples) that are later consumed as training instances by NMT models. One concern of using synthetic instances highlighted by recent work (Zhou et al., 2021), is the generation of hallucinations (i.e., fluent text that is not tight to the source segment). To understand whether our method potentially contributes to the issue of hallucinations, one of the authors examined a small sample of 20 outputs generated by three NMT models for EN→EL translation: 1. a model trained only on 1M of PoolA data; 2. a model trained on the concatenation of 1M PoolA and 2M PoolB data; 3. a model trained on the concatenation of 1M PooA and 2M edited PoolB data. The NMT outputs are annotated labeled as: incomprehensible, faithful, or contains hallucinations following the protocol of Zhou et al. (2021). All annotated instances are found to be faithful to the source.

Lexical Richness Synthetically generated data (e.g., machine-translated instances) are known to exhibit a decay in lexical richness when compared to human written texts (Vanmassenhove et al., 2019). To confirm that our approach does not potentially contribute to this issue, we report more detailed statistics on how the original and edited CCMatrix texts differ in terms of lexical features (i.e., #tokens, #types, and type-token ratio). As presented in Table 15 the edited text does exhibit a decrease in the type-token ratio percentage when compared to the original one.

MixQG: Neural Question Generation with Mixed Answer Types

Abstract

Asking good questions is an essential ability for both human and machine intelligence. However, existing neural question generation approaches mainly focus on short factoid type of answers. In this paper, we introduce a neural question generator, MixQG, to bridge this gap. We combine nine question answering datasets with diverse answer types, including yes/no, multiple-choice, extractive, and abstractive answers, to train a single generative model. We show with empirical results that our model outperforms existing work in both seen and unseen domains, and can generate questions with different cognitive levels when conditioned on different answer types. We run a human evaluation study to assess the quality of generated questions and find that MixQG outperforms the next best model by 10%. Our code and model checkpoints will be released and integrated with the HuggingFace library to facilitate various downstream applications.

Context: In the late 17th century, Robert Boyle proved that air is necessary for combustion. English chemist John Mayow (1641–1679) refined this work by showing that fire requires only a part of air that he called spiritus nitroaereus or just nitroaereus. In one experiment he found that placing either a mouse or a lit candle in a closed container over water caused the water to rise and replace one-fourteenth of the air's volume before extinguishing the subjects. From this he surmised that nitroaereus is consumed in both respiration and combustion.

Question: Who proved that air is necessary for combustion?
Ext. Short Answer: Robert Boyle

Question: How did John Mayow find that spiritus nitroaereus is consumed in both respiration and combustion?
Abs. Short Answer: through an experiment

Question: Does fire need air to burn?
Yes/No Answer: yes

Question: What did John Mayow discover about nitroaereus?
Ext. Long Answer: In the late 17th century … in both respiration and combustion.

Question: Why was the mouse used in the experiment?
Abs. Long Answer: The mouse was used in the experiment to test the consumption of nitroaereus during respiration.

Figure 1: Given the same context, MixQG generates diverse questions based on the target answer choice.

1 Introduction

Question generation (QG) aims to automatically create questions from a given text passage or document with or without answers. It has a wide range of applications such as improving question answering (QA) systems (Duan et al., 2017) and search engines (Han et al., 2019) through data augmentation, making chatbots more engaging (Wang et al., 2018; Laban et al., 2020), enabling automatic evaluation (Rebuffel et al., 2021) and fact verification (Pan et al., 2021), and facilitating educational applications (Chen et al., 2018).

Earlier QG approaches relied on syntactic rules that incorporated linguistic features into the QG process (Heilman and Smith, 2010; Khullar et al., 2018). Du et al. (2017) pointed out some of the limitations of such rule-based systems and formulated the task of question generation as a sequence-to-sequence learning problem. Based on this formulation, recent works rely on pre-trained Transformer-based models to generate answer-aware questions (Dong et al., 2019a; Yan et al., 2020a; Lelkes et al., 2021). However, the majority of QG research so far has been performed on the SQuAD dataset (Rajpurkar et al., 2016), and as a result, it mainly focuses on factoid short answer questions (Zhang and Bansal, 2019; Zhou et al., 2019; Su et al., 2020).

In reality, answers can come in a variety of types and forms, e.g., short/long, multiple-choice, yes-no, and extractive/abstractive answers. We hypothesize that *answer types are as important as question types*, and that different answer types have their unique QG challenges and result in questions with different cognitive levels. MixQG combines nine QA datasets with varied answer types to build a more robust and versatile QG model. We use pre-trained generative language models like T5 (Raffel et al., 2020) and BART (Lewis et al., 2019) without question-specific or domain-specific prefixes to generate the questions. Figure 1 illustrates the

above, showing MixQG-generated questions of different cognitive levels for different answer types.

The contribution of this paper is summarized as follows: 1) We train a unified QG model that achieves state-of-the-art performance in both seen and unseen domains. We release training code and model checkpoints (base, large, 3B) to facilitate various downstream QG applications [1]. 2) We show that MixQG is able to produce different cognitive level questions by controlling the answer types. We conduct a human evaluation study which confirms that MixQG leads to improvements in question quality in a practical quiz design setting.

2 Methodology

2.1 Datasets

We leverage nine commonly used QA datasets (Table 1) to train our MixQG model, including six MRQA 2019 Shared Task (Fisch et al., 2019) datasets, NarrativeQA (Kočiský et al., 2018), MCTest (Richardson et al., 2013), and BoolQ (Clark et al., 2019). These represent the majority of large-scale publicly available QA datasets. We obtain in total 560,193 training examples with different answer types and source domains. We reserve their validation set for in-domain evaluation.

In most general sense, a QA dataset comprises of <C, Q, A> tuples, where C is a context document, Q is a human-written question, and A is its corresponding answer. Following a common classification of answer types, we bucket each dataset into one of the below categories: 1) **Extractive [EX]**: the answer to the question is a substring of the context passage. 2) **Abstractive [AB]**: the answer to the question is written in free-form and is not necessarily contained within the context passage. 3) **Multiple-Choice [MC]**: question comes with multiple answers to select from, including a single correct option and several distractors. 4) **Yes-No [YN]**: the answer is a boolean response. Datasets that do not comply with the above format, such as ELI5 (Fan et al., 2019) and GooAQ (Khashabi et al., 2021), were excluded from training. We leave their exploration to future work.

We also leverage a set of datasets unseen during training to evaluate our model's generalization ability. Similar to the train datasets, these cover several text sources, domains, and answer types. Quoref (Dasigi et al., 2019) questions can have disjoint spans as answers and often require coreference resolution. DROP (Dua et al., 2019) questions require discrete reasoning over the context paragraphs. QAConv (Wu et al., 2021) uses informative conversations such as emails, channels, and panels as a knowledge source, and it includes extractive answers from multiple text spans. TweetQA (Xiong et al., 2019) uses social media as an information source and contains abstractive answers.

Note that to generate fluent questions, we need to place some restrictions on the training data we use. For example, we disregard "fill-in-the-blank" (a.k.a Cloze-style) reading comprehension datasets as their questions are implicit and thus do not aid the QG model. Similarly, we ensure that our training data does not contain unanswerable questions or multiple-choice questions that are too general (e.g., “which of the following is TRUE according to the passage?”).

---

Type	Input
EX	{answer} \n {context}
AB	{answer} \n {context}
MC	{correct_answer} \n {context}
YN	{answer} + {entities} \n {context}

Table 2: Input answer formatting.

2.2 Language Modeling

We rely on a text-to-text framework as a basis for MixQG (Training details are in Section A). When combining our training datasets, we encode all inputs and outputs into a unified plain-text format. For answer-aware question generation, the input is usually formatted in one of the two ways: (1) prepending (**-pre**) the answer before the context and separating it from the rest of the text by a special separator token or (2) highlighting (**-hl**) the answer span within the context with special highlight tokens (Chan and Fan, 2019). To maintain flexibility, we rely on prepending the answer since highlighting is only applicable to the extractive answer types. In particular, we format the inputs to our model such that the answer always precedes the context paragraph and use a "\n" separator in between, as shown in Table 2.

For MC type of data, we only take the correct answer and disregard the distractor options. For YN data, we extract entities from the question using spaCy's NER model [2] and append them to the answer. The reason for adding additional entities is to restrict the domain of questions, as given a context paragraph, there are many boolean questions whose answer would be yes or no, without further restriction. Note that no type-specific prefixes are added to the input representation, and the corresponding questions are used as output.

3 Experimental Results

3.1 Automatic Metrics

We report the commonly-used metrics applied in the QG research: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005) scores. We also report BERTScore (Zhang et al., 2020), which relies on contextual embeddings to produce the final score.

3.2 In-Domain Analysis

In Table 3, we compare baselines trained solely on the target in-domain dataset against MixQG and MixQG$_{finetuned}$. MixQG indicates our model that is joint trained on nine QA datasets with random sampling, and MixQG$_{finetuned}$ is the one further fine-tuned on the target dataset. We show results on two datasets: SQuAD and NQ. Since SQuAD is the most common benchmark for QG, we additionally compare MixQG against existing question generation models such as ProphetNet (Qi et al., 2020) and other T5 variants. The results show that MixQG outperforms an equally sized model trained directly on the target dataset. Given that question styles and dataset domains may vary across MixQG's seed datasets, additional fine-tuning on the target dataset further improves the scores. This shows that MixQG is a strong pretrained model which can be further adapted to specific use cases.

3.3 Out-of-Domain Analysis

Table 4 summarizes the evaluations on out-of-domain datasets of extractive and abstractive answer types. We observe that a dedicated model trained on the target dataset outperforms MixQG in a zero-shot setting. One potential reason is that answer and question style in different QA datasets may differ significantly. For example, answers are ambiguous pronouns in the Quoref dataset, and questions in DROP dataset are intentionally created for discrete reasoning. However, MixQG$_{finetuned}$ obtains the best overall scores after further fine-tuning on the target training set, suggesting that MixQG is a strong starting point for further fine-tuning question generation models.

3.4 Human Evaluation

Recent studies have shown that n-gram based metrics may not correlate well with human judgements Nema and Khapra (2018). The objective of human evaluation is to evaluate QG models by measuring how useful they are as a tool to aid teachers in quiz creation. We compare seven QG models and collect 3,164 human-annotated samples from 10 recruited teachers. More details are in Section B.

Quiz Design Task Given an article on the quiz topic selected from Wikipedia, teachers are asked to specify a quiz concept (a subset of the article) they want to test their students on. This is used as the target answer input for QG models. Teachers can then approve a generated question to be included on the quiz or reject it and provide a reason for rejection. The success of a QG model depends on its question approval rate.

Besides MixQG, three GPT2 baselines (Radford

Table 4: Results on unseen datasets, QAConv (Wu et al., 2021), Quoref (Dasigi et al., 2019), DROP (Dua et al., 2019), and TweetQA (Xiong et al., 2019). All models are of size base.

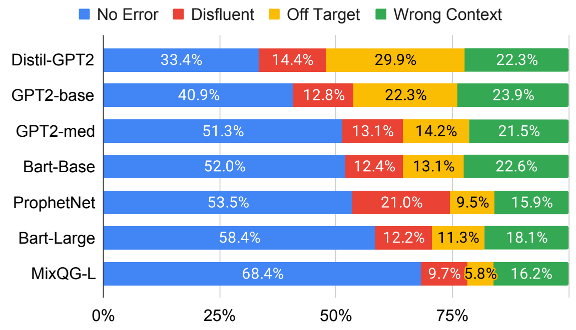

Figure 2: Human approval rate of seven QG models.

et al., 2019), two BART baselines (Lewis et al., 2019), and ProphetNet-Large finetuned on SQuAD are evaluated. In Figure 2, we see that MixQG attains a 68.4% acceptance rate, outperforming the next best model by 10%. MixQG also generates the smallest number of disfluent and off target (answer mismatch) questions - with majority of errors coming from wrong context (too general or too specific) questions. Generating questions with the right level of specificity remains a challenge and is a promising direction for future work.

3.5 Qualitative Analysis

First, we compare MixQG generated questions to the gold questions annotated in five public QA datasets (Table 5). We find that the generated questions are fluent, relevant, and reasonable to the provided answer and context, even if they differ from the gold label. This further motivates the need of human evaluation for QG research.

Second, we use the HuggingFace summarization pipeline to obtain the summary of the context, and we feed each sentence of the summary as the target answer to MixQG to obtain questions. In this way, we can test MixQG's generalization ability to abstractive answers. As shown in Figure 5, we observe that feeding in long and abstractive answers can still generate fluent and reasonable questions, suggesting that it is possible to control the question's cognitive level by its answer. We leave as future work further research into summary-based unsupervised QA-pair generation.

Lastly, in the Quiz Design study, we find there are 106 cases in which the teachers only accepted a single candidate question into the quiz. MixQG produced the accepted candidate 47 times, more than any of the other models. We provide three examples of such MixQG-only success cases as well as three instances in which the MixQG's question was not accepted in Table 6.

4 Related Work

Question generation's practical importance has lead to an increasing interest in the field. The early work in QG relied on linguistic templates and rules to produce questions from declarative sentences (Heilman and Smith, 2010; Labutov et al., 2015). With the success of neural techniques in text generation tasks, applying neural sequence-to-sequence generation models became more common (Du et al., 2017; Sun et al., 2018). More recent works leverage pre-trained transformer based networks, such as T5 (Raffel et al., 2020), BART (Lewis et al., 2019), PEGASUS (Zhang et al., 2019) and ProphetNet (Yan et al., 2020b), for question generation which have been successful in many applications (Dong et al., 2019b; Lelkes et al., 2021; Rebuffel et al., 2021; Pan et al., 2021).

However, most of the earlier work focuses on using a single QA dataset, such as SQuAD (Rajpurkar et al., 2016). While working on generation of open-ended (Cao and Wang, 2021), controllable (Cao and Wang, 2021), multi-hop (Cho et al., 2021) or cause-effect (Stasaski et al., 2021) questions has gained attention, each direction is studied in isolation as it usually requires a separate QA dataset.

Most directly related to our work is UnifiedQA (Khashabi et al., 2020), which successfully crosses format boundaries of different QA datasets to train a robust QA system. It advocates for more general and broader system designs not limited to specific dataset formats. Similar to their approach, MixQG combines multiple QA datasets and trains a single QG system in a text-to-text paradigm.

5 Conclusion

In this paper, we present MixQG, a question generation model pre-trained on a collection of QA datasets with a mix of answer types. We show through experiments that the resulting model is a strong starting point for further fine-tuning which achieves state-of-the-art results on target datasets in commonly-used similarity metrics as well as our designed human evaluation. We release our code and the model checkpoints to facilitate QG research and downstream applications.

6 Ethical Considerations

MixQG is subject to biases found in the training data of both the underlying text-to-text models and all QA datasets that we have used for pre-training. We do not collect a new dataset for question generation and instead reuse data from previously published works. As such, we rely on the published works to follow the responsible data collection practices. The model is currently English language only which limits its practical applications in the real world. We hope to make MixQG multilingual as more diverse QA datasets become available in the future. We validate the proposed model by conducting a human evaluation. We recruited 10 teachers for a study that lasted a maximum of two hours and gifted each participant a $50 gift card.

A Training Details

Training datasets are listed in Table 1. For training MixQG, we use several pre-trained text-to-text model checkpoints from the HuggingFace library (Wolf et al., 2020). We finetune them for question generation using our combined dataset described in Section 2.1. For most experiments done in this paper, we finetune on a T5-base model (Raffel et al., 2020). We also scale up the model and report results for T5-large, T5-3B, and BART-large settings (Appendix D). We train for 100,000 steps (or 22 epochs) with a learning rate of 3×10^{-5} using the AdamW (Loshchilov and Hutter, 2017) optimizer and a batch size of 32. All training was done on eight A100 NVIDIA GPUs and took approximately 35 hours.

B Quiz Design Task Details

We recruit teachers or ex-teachers from an online group forum. In total, 20 participants filled out the interest form, 14 were selected, and 10 completed the study. The participants had been teachers for at least a year and 3.6 years on average, and had taught diverse subjects such as sciences, history, literature, and IT topics, at various levels from primary school to college-level. The study was meant to last a maximum of two hours, and participants were gifted a $50 gift card upon completion.

Participants were tasked with creating between 5-7 quizzes, each with a minimum of 8 concepts, and could pick from a set list of 7 quiz topics, which we pre-selected from the list of featured Wikipedia articles[3]. We purposefully selected articles within different domains to benchmark the QGen models in diverse topical settings: two in physics (Sustainable Energy, Californium Atom), two in biology (DNA, Enzymes), two in history (Statue of Liberty, Palazzo Pitti), and one in geology (the K-T extinction). Participants were given the first 500 words

[3] `https://en.wikipedia.org/wiki/Wikipedia:Featured_articles`

of the Wikipedia page of each topic as reading material to select Quiz concepts from. User interface is shown in Figure 4. Hierarchical categorization of errors for question generation is shown in Figure 3.

C Qualitative Study Details

To understand MixQG's performance beyond automated metrics, we analyze its generated questions in Table 5. It shows several examples of questions generated by MixQG-3B on the validation sets of different datasates along with the ground-truth questions. We also generate question-answer pairs on Wikipedia articles using a pipeline approach as shown in Figure 5. First, we use a summarization model [4] to obtain the summary of the context. Then we feed each sentence of the summary as the target answer to MixQG and obtain the questions. We observe that the generated questions are grammatically fluent, relevant to the input, and answerable by the target answer paragraph. We find that feeding in longer answers to the model generates more general, higher-level questions about the source article, while short answers prompt more factoid-style questions. As a result, we are able to generate questions of varied cognitive levels from the same source document by restricting the answer part of the input.

D Scaling

Table 7 shows the performance of differently sized MixQG models on SQuAD dataset. We additionally train MixQG model based on BART-large checkpoint, referred to as MixQG$_{large}^{BART}$. As expected, the largest MixQG model (3 billion parameters) performs best among the different model size variants.

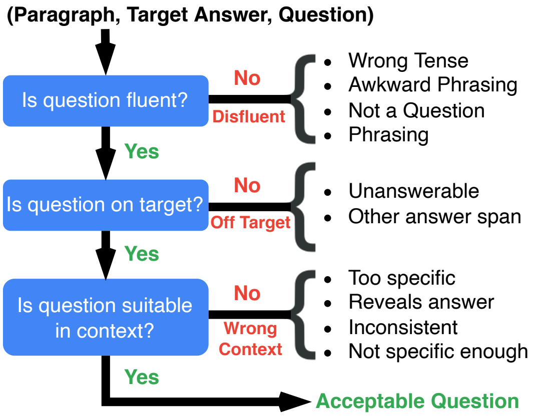

Figure 3: Hierarchical categorization of errors for question generation. Three error categories (Disfluent, Off Target, Wrong Context) each with several subtypes.

Californium

Californium is a radioactive chemical element with the symbol Cf and atomic number 98. The element was first synthesized in 1950 at the Lawrence Berkeley National Laboratory (then the University of California Radiation Laboratory), ✖ by bombarding curium with alpha particles (helium-4 ions) . It is an actinide element, the sixth transuranium element to be synthesized, and has the second-highest atomic mass of all the elements that have been produced in amounts large enough to see with the unaided eye (after einsteinium). The element was named after the university and the U.S. state of California.

Two crystalline forms exist for californium under normal pressure: one above and one below 900 °C (1,650 °F). A third form exists at high

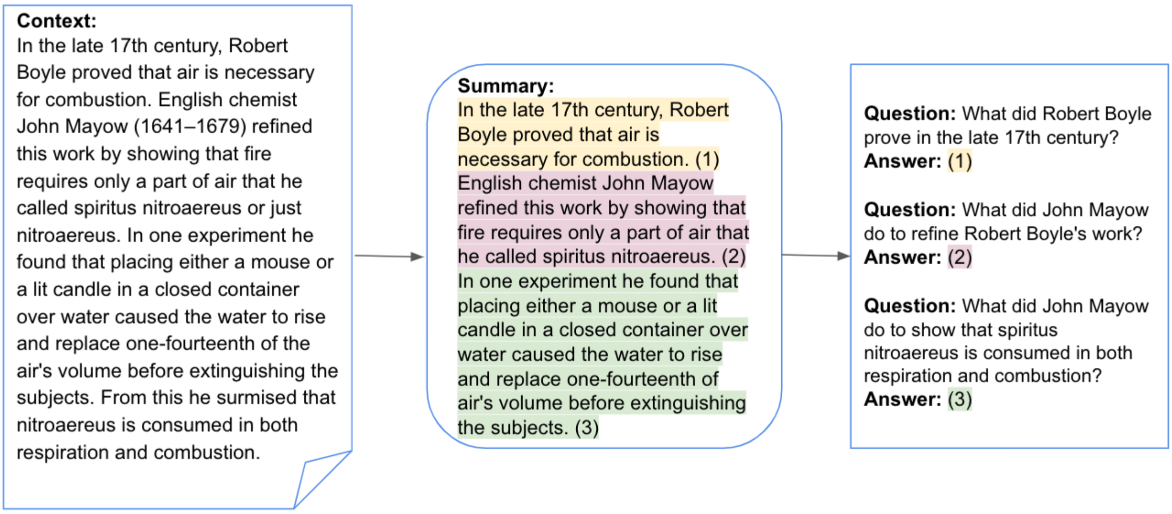
In the right column, the system gives proposes candidate questions, which can be added to the quiz, or refused with a reason.



Context:
In the late 17th century, Robert Boyle proved that air is necessary for combustion. English chemist John Mayow (1641–1679) refined this work by showing that fire requires only a part of air that he called spiritus nitroaereus or just nitroaereus. In one experiment he found that placing either a mouse or a lit candle in a closed container over water caused the water to rise and replace one-fourteenth of the air's volume before extinguishing the subjects. From this he surmised that nitroaereus is consumed in both respiration and combustion.

Summary:
In the late 17th century, Robert Boyle proved that air is necessary for combustion. (1) English chemist John Mayow refined this work by showing that fire requires only a part of air that he called spiritus nitroaereus. (2) In one experiment he found that placing either a mouse or a lit candle in a closed container over water caused the water to rise and replace one-fourteenth of air's volume before extinguishing the subjects. (3)

Question: What did Robert Boyle prove in the late 17th century?
Answer: (1)

Question: What did John Mayow do to refine Robert Boyle's work?
Answer: (2)

Question: What did John Mayow do to show that spiritus nitroaereus is consumed in both respiration and combustion?
Answer: (3)

Temporal Attention for Language Models

Guy D. Rosin and **Kira Radinsky**
Technion – Israel Institute of Technology, Haifa, Israel
`{guyrosin,kirar}@cs.technion.ac.il`

Abstract

Pretrained language models based on the transformer architecture have shown great success in NLP. Textual training data often comes from the web and is thus tagged with time-specific information, but most language models ignore this information. They are trained on the textual data alone, limiting their ability to generalize temporally. In this work, we extend the key component of the transformer architecture, i.e., the self-attention mechanism, and propose temporal attention—a time-aware self-attention mechanism. Temporal attention can be applied to any transformer model and requires the input texts to be accompanied with their relevant time points. It allows the transformer to capture this temporal information and create time-specific contextualized word representations. We leverage these representations for the task of semantic change detection; we apply our proposed mechanism to BERT and experiment on three datasets in different languages (English, German, and Latin) that also vary in time, size, and genre. Our proposed model achieves state-of-the-art results on all the datasets.

1 Introduction

Language models (LMs) are usually pretrained on corpora derived from a snapshot of the web crawled at a specific moment in time (Devlin et al., 2019; Liu et al., 2019). But our language is constantly evolving; new words are created, meanings and word usages change. For instance, the COVID-19 pandemic has caused significant changes to our language; consider the new video-related sense of "Zoom" and the new senses recently associated with the word "vaccine".

The "static" nature of existing LMs makes them unaware of time, and in particular unware of language changes that occur over time. This prevents such models from adapting to time and generalizing temporally (Röttger and Pierrehumbert, 2021; Lazaridou et al., 2021; Hombaiah et al., 2021; Dhingra et al., 2022; Agarwal and Nenkova, 2021; Loureiro et al., 2022), abilities that were shown to be important for many tasks in NLP and Information Retrieval (Kanhabua and Anand, 2016; Rosin et al., 2017; Huang and Paul, 2019; Röttger and Pierrehumbert, 2021; Savov et al., 2021). Recently, to create time-aware models, the NLP community has started to use time as a feature in training and fine-tuning language models (Dhingra et al., 2022; Rosin et al., 2022). These two studies achieve this by concatenating a time token to the text sequence before training the models. The former was concerned with temporal question answering, whereas the latter—with semantic change detection and sentence time prediction. In this work, we introduce a new methodology to create time-aware language models and experiment on the task of semantic change detection.

At the heart of the transformer architecture is the self-attention mechanism (Vaswani et al., 2017). This mechanism allows the transformer to capture the complex relationships between words by relating them to each other multiple times. An attention weight has a clear meaning: how much a particular word will be weighted when computing the next representation for the current word (Clark et al., 2019). This mechanism also enables the above-mentioned temporal models (Dhingra et al., 2022; Rosin et al., 2022) to work; by concatenating time-specific tokens to the text sequences, the self-attention mechanism would compute the relationships between them and the original tokens in the texts, effectively making the output embeddings time-aware (as the output embeddings will depend on the concatenated time tokens).

In this work, instead of changing the text sequences as in prior work, we modify the model itself and specifically the attention mechanism to make it time-aware. We propose a time-aware self-attention mechanism that is an extension of the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1498 - 1508
July 10-15, 2022

self-attention mechanism of the transformer. It considers the time the text sequences (or documents) were written when computing attention scores. As described above, self-attention captures relationships between words. We want to condition these relationships on time. By adding a time matrix as an additional input to the self-attention (along with the standard query, key, and value matrices), we condition the attention weights on the time. In other words, the adapted mechanism also considers the time when calculating the weights of each word. We refer to this adapted attention as *Temporal Attention* (Section 3.2). See Figure 1 for an illustration of our proposed mechanism.

We experiment on the task of semantic change detection — the task of identifying which words undergo semantic changes and to what extent. Semantic change detection methods are used in historical linguistics and digital humanities to study the evolution of word meaning over time and in different domains (Kutuzov et al., 2018). Most existing contextual methods detect changes by first embedding the target words in each time point and then either aggregating them to create a time-specific embedding (Martinc et al., 2020a), or computing a cluster of the embeddings for each time (Giulianelli et al., 2020; Martinc et al., 2020b; Montariol et al., 2021; Laicher et al., 2021). The embeddings or clusters are compared to estimate the degree of change between different times. We experiment with several diverse datasets in terms of time, language, size, and genre. Our empirical results show that our model outperforms state-of-the-art methods (Schlechtweg et al., 2019; Martinc et al., 2020a; Montariol et al., 2021; Rosin et al., 2022).

Our contributions are threefold: (1) We introduce a time-aware self-attention mechanism as an extension of the original mechanism of the transformer. The proposed mechanism considers the time the text sequences were written. The time is considered during the computation of attention scores, thus allowing to create time-specific contextualized word representations; (2) We conduct evaluations on the task of semantic change detection and reach state-of-the-art performance on three diverse datasets in terms of time, language, size, and genre; (3) We contribute our code and trained models to the community for further research.[1]

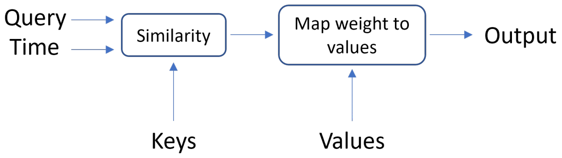

Figure 1: High-level illustration of our proposed temporal attention mechanism.

2 Related Work

2.1 Temporal Language Models

Several recent studies have explored and evaluated the generalization ability of language models to time (Röttger and Pierrehumbert, 2021; Lazaridou et al., 2021; Agarwal and Nenkova, 2021; Hofmann et al., 2021; Loureiro et al., 2022). To better handle continuously evolving web content, Hombaiah et al. (2021) performed incremental training. Dhingra et al. (2022) experimented with temporal language models for question answering. They focused on temporally-scoped facts and showed that conditioning temporal language models on the temporal context of textual data improves memorization of facts. Rosin et al. (2022) similarly concatenated time tokens to text sequences and introduced the concept of time masking (specific masking for the added time tokens). They focused on two temporal tasks: semantic change detection and sentence time prediction. Others focused on document classification by using word-level temporal embeddings (Huang and Paul, 2019) and adapting pretrained BERT models to domain and time (Röttger and Pierrehumbert, 2021). Recently, Hofmann et al. (2021) jointly modeled temporal and social information by changing the architecture of BERT and connecting embeddings of adjacent time points via a latent Gaussian process.

In this work, we create a temporal LM by adapting the transformer's self-attention mechanism to time. The model receives each text sequence along with its writing time and uses both as input to the temporal attention mechanism. As a result, the model creates time-specific contextualized word embeddings.

2.2 Semantic Change Detection

Semantic change detection is the task of identifying words that change meaning over time (Kutuzov et al., 2018; Tahmasebi et al., 2018). This task is often addressed using time-aware word representations that are learned from time-annotated corpora

---

[1] `https://github.com/guyrosin/temporal_attention`

and then compared between different time points (Jatowt and Duh, 2014; Kim et al., 2014; Kulkarni et al., 2015; Hamilton et al., 2016; Dubossarsky et al., 2019; Del Tredici et al., 2019). Gonen et al. (2020) used a simple nearest-neighbors-based approach to detect semantically-changed words. Others learned time-aware embeddings simultaneously over all time points to resolve the alignment problem, by regularization (Yao et al., 2018), modeling word usage as a function of time (Rosenfeld and Erk, 2018), Bayesian skip-gram (Bamler and Mandt, 2017), or exponential family embeddings (Rudolph and Blei, 2018).

All aforementioned methods limit the representation of each word to a single meaning, ignoring the ambiguity in language and limiting their sensitivity. Recent contextualized models (e.g., BERT (Devlin et al., 2019)) overcome this limitation by taking sentential context into account when inferring word token representations. Such models were applied to diachronic semantic change detection, where most detect changes by creating time-specific embeddings or computing a cluster of the embeddings for each time, and then comparing these embeddings or clusters to estimate the degree of change between different times (Hu et al., 2019; Martinc et al., 2020b,a; Giulianelli et al., 2020; Laicher et al., 2021; Montariol et al., 2021). Recently, Rosin et al. (2022) suggested another approach of detecting semantic change through predicting the writing time of sentences. In our work, we use language models to create time-specific word representations and compare them to detect semantic change. While the above studies used language models as is, we modify their inner workings to make them time-aware by adapting the self-attention mechanism to time.

3 Model

Our model adopts a multi-layer bidirectional transformer (Vaswani et al., 2017). It treats words in the document as input tokens and computes a representation for each token. Formally, given a sequence of n words $w_1, w_2, \ldots, w_n$, the transformer computes D-dimensional word representations $x_1, x_2, \ldots, x_n \in \mathbb{R}^D$.

3.1 Self-Attention

The self-attention mechanism is the foundation of the transformer (Vaswani et al., 2017). It relates tokens to each other based on the attention score between each pair of tokens. In practice, the attention function is computed on a set of tokens simultaneously; our input sequence is packed together into a matrix $X \in \mathbb{R}^{n \times D}$, in which each row i corresponds to a word representation x_i in the input sentence. We denote three trainable weight matrices by $W_Q, W_K, W_V \in \mathbb{R}^{D \times d_k}$. We then create three distinct representations, i.e., query, key, and value: $Q = XW_Q$, $K = XW_K$, $V = XW_V$, respectively, where $Q, K, V \in \mathbb{R}^{n \times d_k}$.

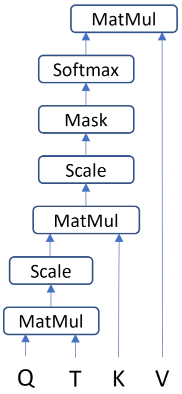

Figure 2: Illustration of our proposed temporal attention mechanism.

An attention function can be described as mapping a query and a set of key-value pairs to an output, where the query, keys, values, and outputs are all vectors. The output is computed as a weighted sum of the values, where the weight assigned to each value is determined by the dot product of the query with all the keys:

$$\mathit{Attention}(Q, K, V) = \operatorname{softmax}\left(\frac{QK^\intercal}{\sqrt{d_k}}\right) V \quad (1)$$

3.2 Temporal Attention

We now describe the temporal attention mechanism. In the temporal setting, similarly to the vocabulary of the model, our model has a vocabulary of time points. Theoretically, each token in an input sequence could have its own time point, but we simplify and assume the most common case where text sequences always refer to a single time point t.[2] Given a sequence of n words $w_1, w_2, \ldots, w_n$ and its corresponding time point t, our model computes D-dimensional time-specific word representations $x_1^t, x_2^t, \ldots, x_n^t$, where $x_i^t \in \mathbb{R}^D$. As a by-product,

---

[2] Our mechanism also supports the setting where different tokens in a sequence are associated with different time points.

we also compute D-dimensional time representations for the time points. Now, similarly to the input matrix X (Section 3.1), we define an embedding matrix $X^t \in \mathbb{R}^{n\times D}$ where each row i contains the embedding vector of x_i's time point.[3]

To incorporate time in the attention mechanism, we use an additional trainable weight matrix $W_T \in \mathbb{R}^{D\times d_k}$ and create its corresponding representation matrix $T = X^t W_T$. Note $T \in \mathbb{R}^{n\times d_k}$, i.e., its dimensions are the same as the key, query, and value matrices.

To calculate the attention scores, we multiply the query matrix by the time matrix and then multiply by its transposed matrix, to keep the dimensions intact. We then divide by the time matrix's norm, to avoid getting too large values. Formally, we define temporal attention by:

$$\begin{aligned} &\textit{TemporalAttention}(Q, K, V, T) = \\ &\text{softmax}\left(\frac{Q\frac{T^\intercal T}{\|T\|}K^\intercal}{\sqrt{d_k}}\right)V \end{aligned} \tag{2}$$

Intuitively, by multiplying the query by the time, the attention weights are now conditioned on the time, i.e., they are time-dependent.

Temporal attention can be used together with other, existing temporal language models, such as (Rosin et al., 2022; Dhingra et al., 2022). In these two models, a time-specific token is prepended to each sentence. In comparison to those methods, our approach does not require changing the input text, as it only modifies the attention mechanism of the language model. We further discuss and compare the two methods in Section 3.3.

The temporal attention mechanism requires each input text to be accompanied with a time point. There are no constraints on these time points, i.e., the mechanism is agnostic to the time granularity and the number of time points in the model.

3.3 Theoretical Analysis

We now theoretically analyze the temporal attention mechanism more deeply and compare it to existing time concatenation methods (Dhingra et al., 2022; Rosin et al., 2022). We omit the scaling factor $\sqrt{d_k}$ for readability.

We denote the row vectors of the matrices Q, K, V, and T by q_i, k_i, v_i, and t_i, respectively. The attention head computes attention weights α between all pairs of words as softmax-normalized dot products between the query and key vectors:

$$\alpha_{ij} = \text{softmax}\left(q_i k_j^\intercal\right) \tag{3}$$

where $i, j \in \{1, \dots, n\}$.

The output y_i of the attention head is a weighted sum of the value vectors:

$$y_i = \sum_{j=1}^{n} \alpha_{ij} v_j = \sum_{j=1}^{n} \text{softmax}\left(q_i k_j^\intercal\right) v_j \tag{4}$$

Baseline models, such as Rosin et al. (2022) and Dhingra et al. (2022), prepend the text sequence with a time token at index 0, resulting in:

$$y_i = \sum_{j=0}^{n} \alpha_{ij} v_j = \sum_{j=1}^{n} \alpha_{ij} v_j + \text{softmax}\left(q_0 k_0^\intercal\right) v_0 \tag{5}$$

As we can see, by concatenating the time token, we add query, key, and value vectors for that token, i.e., a time component is added to the weighted sum.

In contrast, by using temporal attention, the attention weights become:

$$\alpha_{ij} = \text{softmax}\left(q_i \frac{t_i t_j^\intercal}{\|T\|} k_j^\intercal\right) \tag{6}$$

The i-th output vector y_i is computed as:

$$y_i = \sum_{j=1}^{n} \alpha_{ij} v_j = \sum_{j=1}^{n} \text{softmax}\left(q_i \frac{t_i t_j^\intercal}{\|T\|} k_j^\intercal\right) v_j \tag{7}$$

Intuitively, we multiply by the vectors of time to scale the attention weight α_{ij} by time. We observe two main differences between our proposed mechanism and prior work:

1. The time component is more tightly integrated in temporal attention: instead of just adding a time component to the weighted sum, in temporal attention the time component is multiplied by every component in the sum.

2. Temporal attention requires learning an additional weight matrix $W_T \in \mathbb{R}^{D\times d_k}$. In prior work, each input sequence is prepended with a time token, i.e., its length n is increased by 1. As a result, the temporal attention mechanism consumes more memory (as it has additional $D \cdot d_k$ trainable parameters[4]), whereas prior

---

[3] Most tokens share the same time point, as noted above, except for special tokens such as padding and masking tokens, to which we associate unique time points.

[4] When using the standard BERT-base architecture: $D \cdot d_k = 768 \cdot 64 = 49{,}152$

work requires more time to train (as its sequences are longer). From our experiments, the overhead of both methods is negligible compared to the memory consumption and training time of BERT (see analysis in Section 6.3).

4 Semantic Change Detection

In this section, we employ our proposed temporal attention mechanism (Section 3.2) for the task of semantic change detection (Kutuzov et al., 2018; Tahmasebi et al., 2018). The ability to detect and quantify semantic changes is important to lexicography, linguistics, and is a basic component in many NLP tasks. For example, search in temporal corpora, historical sentiment analysis, and understanding historical documents. The objective of this task is to rank a set of target words according to their degree of semantic change between two time points t_1 and t_2. In this work, we follow the practice of (Martinc et al., 2020a; Rosin et al., 2022) to estimate the semantic change a word underwent and rank the target words based on these estimates.

Given a target word w, we generate time-specific representations of it and compare them to detect semantic changes. Algorithm 1 formally describes the method. We begin by sampling n sentences containing w from each time point $t \in \{t_1, t_2\}$ (line 3). For each sentence *sent*, we create a sequence embedding by running it through the temporal attention model (note the model receives as input both *sent* and t) and extracting the model's hidden layers that correspond to w (lines 5–6). We then choose the last h hidden layers and average them to get a single vector (line 7). This is the contextual word embedding of w, denoted by v. Following, the resulting embeddings are aggregated at the token level and averaged (line 10), in order to create a non-contextual time-specific representation for w for each time t, denoted by x_t. Finally, we estimate the semantic change of w by measuring the cosine distance (*cos_dist*) between two time-specific representations of the same token (line 12).

Algorithm 1: Semantic change estimation

```
Input: $w$ (target word)
Input: $t_1$ (first time point)
Input: $t_2$ (last time point)
Input: $C$ (diachronic corpus)
Input: $n$ (# of sentences to sample)
Input: $h$ (# of last hidden layers to extract)
1  for $t \in \{t_1, t_2\}$ do
2      $L_t \leftarrow \{\}$
3      $S_w \leftarrow n$ sentences sampled from
         $C(t, w)$
4      for $sent \in S_w$ do
5          $H \leftarrow TempAttModel(sent, t)$
6          $H_w \leftarrow H[w]$
7          $v \leftarrow AvgHiddenLayers(H_w, h)$
8          $L_t.insert(v)$
9      end
10     $x_t \leftarrow avg(L_t)$
11 end
12 $score = cos\_dist(x_{t_1}, x_{t_2})$
13 return $score$
```

5 Experimental Setup

5.1 Data

To train and evaluate our models, we use data from the SemEval-2020 Task 1 on Unsupervised Detection of Lexical Semantic Change (Schlechtweg et al., 2020). We use corpora provided by this task for English, German, and Latin, covering a variety of genres, times, languages, and sizes. They are all long-term: the English and German corpora span two centuries each, and the Latin corpus spans more than 2000 years. The German corpus is much larger than the other two (x7 – x10). Each corpus is genre-balanced, and split into two time points; see Table 1 for their statistics.

Each corpus is accompanied with labeled data for semantic change evaluation. We use the data from Subtask 2 of this task, where the objective is to rank a set of target words according to their degree of semantic change between t_1 and t_2. The provided data is a set of target words that are either words that changed their meaning(s) (lost or gained a sense) between the two time points, or stable words that did not change their meaning during that time. The target words are balanced for part of speech (POS) and frequency. Each target word was assigned a graded label (between 0 and 1) according to their degree of semantic change (0 means no change, 1 means total change). For the English dataset, we follow (Montariol et al., 2021) and remove POS tags from both the corpus and the evaluation set.

5.2 Baseline Methods

We use the following baseline methods:

Corpus	C1 Source	C1 Time	C1 Tokens	C2 Source	C2 Time	C2 Tokens	Target Words
SemEval-English	CCOHA	1810–1860	6.5M	CCOHA	1960–2010	6.7M	37
SemEval-Latin	LatinISE	-200–0	1.7M	LatinISE	0–2000	9.4M	40
SemEval-German	DTA	1800–1899	70.2M	BZ, ND	1946–1990	72.4M	48

Table 1: Corpora for semantic change detection. Each corpus is split into two time points, denoted by C1 and C2.

1. Schlechtweg et al. (2019) train Skip-gram with Negative Sampling (SGNS) on two time points independently and align the resulting embeddings using Orthogonal Procrustes. They compute the semantic change scores using cosine distance.

2. Gonen et al. (2020) use SGNS embeddings as well. They represent a word in a time point by its top nearest neighbors according to cosine distance. Then, they measure semantic change as the size of intersection between the nearest neighbors lists in the two time points.

3. Martinc et al. (2020a) were one of the first to use BERT for semantic change detection. They create time-specific embeddings of words by averaging token embeddings over sentences in each time point, and then compare them by calculating cosine distance.

4. Montariol et al. (2021) use BERT to create a set of contextual embeddings for each word. They cluster these embeddings and then compare the cluster distributions across time slices using various distance measures. We use their best-performing method for each dataset as reported in the paper, which uses affinity propagation for clustering word embeddings and either Wasserstein or Jensen-Shannon distance as a distance measure between clusters.

5. Rosin et al. (2022) create a time-aware BERT model by preprocessing input texts to concatenate time-specific tokens to them, and then masking these tokens while training. They introduce two methods to measure semantic change, namely temporal-cosine and time-diff. We use their best-performing method as reported in the paper, which is temporal-cosine.

6. "Scaled attention": We present several baselines which are simplified versions of our temporal attention mechanism. Intuitively, our mechanism differentiates between different time points by learning a scaling factor per each pair of time points (based on the multiplication of learned time vectors; see Section 3.2). In these baselines, we use a constant scaling factor per time point and calculate attention weights using the following formula:

$$\alpha_{ij} = \text{softmax}\left(q_i s_{ij} k_j^\intercal\right)$$

where s_{ij} is the scaling factor. This scaling method can be seen as a combination of (Martinc et al., 2020a) and our temporal attention method. We present three options for s_{ij}: (1) Linear scaling. We hypothesize that recent texts should be given more weight, and define $s_{ij} = index(t_i)$, where $index(t_i)$ is the index of the time point t_i out of all time points $t_1, \ldots, t_{n_t}$. (2) Exponential scaling: similarly to linear scaling, but using an exponent: $s_{ij} = 2^{index(t_i)}$. (3) Proportional to the number of documents: here we hypothesize that larger corpora should be given more weight, and define $s_{ij} = \frac{doc\_count(t_i)}{\sum_{k=1}^{n_t} doc\_count(t_k)}$, where $doc\_count(t_i)$ is the number of documents in t_i.

5.3 Our Method

To train our models, for each language we use a pretrained BERT (Devlin et al., 2019) model (bert-base-uncased, with 12 layers, 768 hidden dimensions, and 110M parameters) and post-pretrain it on the temporal corpus using our proposed temporal attention, as described in Section 3.2. For semantic change detection, we use the method described in Section 4. We use the Hugging Face's Transformers library[5] for our implementation.

Before training, we add any missing target words to the model's vocabulary. Since a pretrained model's vocabulary may not contain all the target words in our evaluation dataset, this is necessary to avoid the tokenizer splitting any occurrences of the target words into subwords (which we found out to reduce performance). The added words are randomly initialized.

---

5.4 Metrics

We measure semantic change detection performance by the correlation between the semantic shift index (i.e., the ground truth) and the model's semantic shift assessment for each word in the evaluation set. We follow prior work (Rosin et al., 2022) and use both Pearson's correlation coefficient r and Spearman's rank correlation coefficient ρ. The difference between them is that Spearman's ρ considers only the ranking order, while Pearson's r considers the actual predicted values. In our evaluation, we make an effort to evaluate our methods and the baselines using both correlation coefficients, to make the evaluation as comprehensive as possible. There were some cases where we could not reproduce the original authors' results; in such cases, we opted to report only the original result.

5.5 Implementation Details

Due to limited computational resources, we follow Rosin et al. (2022) and train our models with a maximum input sequence length of 128 tokens. We perform all experiments on a single NVIDIA Quadro RTX 6000 GPU. We tune the following hyperparameters for each language: for training: learning rate in $\{1\text{e-}8, 1\text{e-}7, 1\text{e-}6, 1\text{e-}5, 1\text{e-}4\}$ and number of epochs in $\{1, 2, 3, 4\}$. For inference: number of last hidden layers to use for embedding extraction $h \in \{1, 2, 4, 12\}$.

The chosen pretrained model and hyperparameters, along with the steps number and training time per language are as follows:

- For English: bert-base-uncased,[6] with 1e-9 learning rate for 2 epochs (6.3K steps, took 70 minutes); all (12) hidden layers for inference.
- For Latin: latin-bert,[7] with 1e-5 learning rate for 1 epoch (3.5K steps, took 25 minutes); last hidden layer for inference.
- For German: bert-base-german-cased,[8] with 1e-6 learning rate for 1 epoch (38.1K steps, took 10 hours); last hidden layer for inference.

6 Results

In this section, we outline the results of our empirical evaluation. In all tables throughout the section, the best result in each column is boldfaced; performance is measured using Pearson's r and Spearman's ρ correlation coefficients.

6.1 Main Result

Table 2 shows the results for semantic change detection on the SemEval datasets. Our temporal attention model outperforms all the baselines for all datasets and metrics with significant correlations ($p < 0.0005$) and large margins (7%–36%). We observe moderate to strong correlations (around 0.52–0.76) for all datasets. Even for the German dataset, on which recent BERT-based methods got relatively lower results (and were outperformed by word2vec-based methods such as Schlechtweg et al. (2019)), our model achieves strong correlations and state-of-the-art performance. In Section 6.2 and Section 6.3, we experiment with variations of our method and achieve even stronger performance on the English dataset.

Finally, looking at the three scaled attention baselines, they all perform similarly and are positioned between Martinc et al. (2020a) and our temporal attention model, as expected.

6.2 Temporal Attention with Temporal Prepend

Until now, we used temporal attention on BERT (Devlin et al., 2019) to create our model. In this section, in addition to using temporal attention, we also prepend a time token to the input sequences, as done in Rosin et al. (2022). That is, we experiment with applying temporal attention on top of their model.

Table 3 shows the results of this combined model compared to each of its components. First, prepending time tokens is inferior to the other models. When comparing our proposed temporal attention and the combined model, we observe mixed results: temporal attention alone works better for the Latin and German datasets, but for the English dataset the combination of temporal attention and prepending time tokens performs better.

6.3 Impact of BERT Model Size on Temporal Attention

Our model is based on the most commonly used pretrained BERT model, called BERT-base, which

Table 4: Results for semantic change detection for models of different sizes on SemEval-English.

contains 12 transformer layers and a hidden dimension size of 768. In this section, we train and evaluate models of different sizes, namely 'small' and 'tiny', that are based on much smaller pretrained variants of BERT: BERT-small[9] has 26% of the parameters of BERT-base, containing only 4 transformer layers while its hidden dimension is 512; BERT-tiny[10] has just 4% of the parameters of BERT-base, with 2 transformer layers and a hidden dimension of 128. We perform this evaluation only for the SemEval-English dataset, as smaller pretrained BERT models are currently publicly available only for the English language.

Table 4 shows the comparison results, where we compare the three variants of our temporal attention model, along with the two variants of Rosin et al. (2022). We also denote the number of trainable parameters for each model (see the theoretical analysis in Section 3.3). We observe a clear negative correlation between model size and performance (measured by both Pearson's r and Spearman's ρ); the smaller the model, the better the performance. While this finding may sound counterintuitive, it is in line with Rosin et al. (2022), who hypothesized that to understand time there is no need to use extremely large models, and reported higher-than-expected performance for the tiny model. In their study, that model achieved a slightly lower performance compared to their standard (base) model, but still outperformed most baselines. Overall, this is an encouraging finding; smaller models mean faster training and inference times, as well as smaller memory footprints. This lowers the bar to enter the field.

6.4 Qualitative Analysis

Figure 3 shows the Spearman correlation between the ground truth ranks and our model's ranks for the SemEval-English dataset. The correlation is moderate (0.520), and we observe a similar number of false-positive words (top-left corner) and false negatives (bottom-right corner). Interestingly, we can see that the model performs better on the more changed words (right half, rank above 19, e.g., "plane", "tip", and "head"), while there are more errors on the static words (left half, e.g., "chair-

man", "risk", and "quilt"). Most of the false positives seem to be either slang words or concerning word usages that are less likely to appear in our corpora which is mainly composed of newsletters and books (Section 5.1). For example, the verb "stab", which traditionally means to push a knife into someone, has a newer meaning of attempting to do something. The noun "word" can be used to express agreement.

7 Conclusion

In this paper, we presented a time-aware self-attention mechanism as an extension of the original mechanism of the transformer. The proposed mechanism considers the time the text sequences were written when computing attention scores, thus allowing creating time-specific contextualized word representations. We conducted evaluations on the task of semantic change detection and reached state-of-the-art performance on three diverse datasets in terms of time, language, size, and genre. In addition, we experimented with small-sized pretrained models and found they outperform larger models on this task. We conduct an experiment evaluating the marginal addition of time token prepending along with temporal attention and conclude that on all but the English dataset it hurts performance. We wish to study how to best combine the two approaches in future work. Additionally, for future work, we plan to extend this work by applying temporal attention to other tasks, such as web search and sentence time prediction, as well as experimenting with more time points and different granularities.

Efficient Few-Shot Fine-Tuning for Opinion Summarization

Arthur Bražinskas[1] **Ramesh Nallapati**[2] **Mohit Bansal**[2,3] **Markus Dreyer**[2]

Abstract

Abstractive summarization models are typically pre-trained on large amounts of generic texts, then fine-tuned on tens or hundreds of thousands of annotated samples. However, in opinion summarization, large annotated datasets of reviews paired with reference summaries are not available and would be expensive to create. This calls for fine-tuning methods robust to overfitting on small datasets. In addition, generically pre-trained models are often not accustomed to the specifics of customer reviews and, after fine-tuning, yield summaries with disfluencies and semantic mistakes. To address these problems, we utilize an efficient few-shot method based on adapters which, as we show, can easily store in-domain knowledge. Instead of fine-tuning the entire model, we add adapters and pre-train them in a task-specific way on a large corpus of unannotated customer reviews, using held-out reviews as pseudo summaries. Then, fine-tune the adapters on the small available human-annotated dataset. We show that this self-supervised adapter pre-training improves summary quality over standard fine-tuning by 2.0 and 1.3 ROUGE-L points on the Amazon and Yelp datasets, respectively. Finally, for summary personalization, we condition on aspect keyword queries, automatically created from generic datasets. In the same vein, we pre-train the adapters in a query-based manner on customer reviews and then fine-tune them on annotated datasets. This results in better-organized summary content reflected in improved coherence and fewer redundancies.

1 Introduction

Online reviews play an important role in purchasing decisions we make. They inform us about customer experiences – what aspects users like and dislike, and ultimately, whether a product or service is worth buying. Although significant progress has been made in supervised summarization in non-subjective single-document context, such as news articles (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017; Bražinskas et al., 2021b), modern deep learning methods rely on large amounts of annotated data, but these are not readily available in the review or opinion summarization domain and are expensive to produce. A key obstacle making such annotation expensive is that annotators need to consider multiple texts when writing a summary, which can be tens or even hundreds for realistic settings. Hence, most available datasets have human-written summaries for less than 100 products.

The lack of sufficiently large annotated datasets led to a variety of unsupervised abstractive models (e.g., COPYCAT (Bražinskas et al., 2020b), MEANSUM (Chu and Liu, 2019); DENOISESUM (Amplayo and Lapata, 2020)) that are trained on large collections of unannotated customer reviews. However, as the models are never exposed to actual summaries, they cannot capture their expected characteristics. This results in generated summaries mimicking the informal style of customer reviews and containing hallucinations and unimportant details. These limitations were addressed by few-shot methods learning from a handful of human-written summaries. (Bražinskas et al., 2020a; Oved and Levy, 2021). The first proposed few-shot learning model, FEWSUM (Bražinskas et al., 2020a), relies on various static features capturing differences between a customer review and a summary. While that model is more robust to overfitting, such features require manual, domain-specific engineering and can be sub-optimal for capturing correspondences between texts on the semantic level. We propose a simpler approach – ADASUM – which is based on adapters (Houlsby et al., 2019; Bapna et al., 2019). As we explain next, the adapters are pre-trained on customer reviews in a task-specific manner, and subsequently fine-tuned on gold summaries.

Adapters. We utilize a pre-trained model with powerful language understanding and generation

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1509 - 1523
July 10-15, 2022

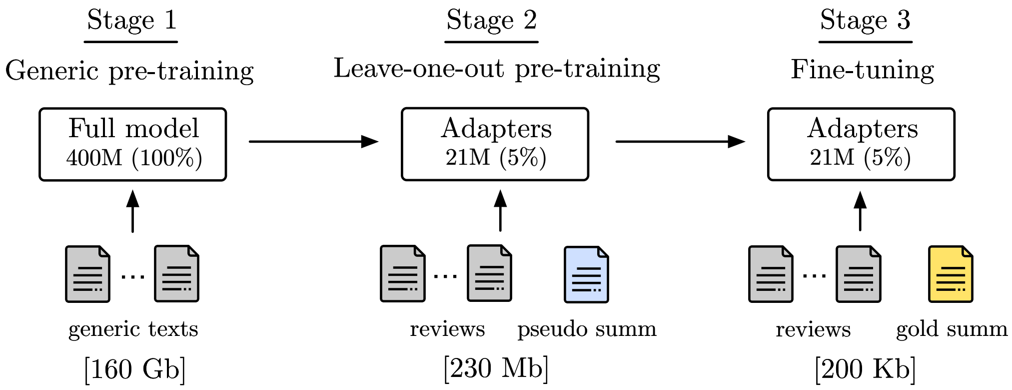

Figure 1: Illustration of the proposed approach. In Stage 1, all parameters of a large language model are pre-trained on generic texts (we use BART). In Stage 2, we pre-train adapters (5% of the full model's parameters) on customer reviews using held-out reviews as summaries. In Stage 3, we fine-tune the adapters on a handful of reviews-summary pairs.

abilities in combination with a parameter-efficient fine-tuning method – adapters. As was shown in recent studies, this method is also robust to overfitting in low-resource settings (He et al., 2021). In this way, a large pre-trained model, BART (Lewis et al., 2020), in our case, remains frozen, and only small modules (0.6% - 5% of the model parameters) are optimized. This effectively retains acquired knowledge in the pre-trained language model (PLM) without specialized training objectives as in RecAdam (Chen et al., 2020). However, available annotated data is not sufficient for learning in-domain specifics and results in summaries with subtle semantic mistakes. As explained next, we reduce these semantic mistakes by pre-training adapters on customer reviews.

Self-supervised Pre-training. Language models are pre-trained with generic objectives (e.g., single-document denoising) and rarely on in-domain data, such as customer reviews. Consequently, this makes them less attuned to in-domain specifics as these are hard to learn from a handful of summaries. This often results in subtle semantic mistakes. For instance, in Table 1, PASS (Oved and Levy, 2021) incorrectly concludes that *thin material* implies *poor quality*. To address this issue, we learn in-domain specifics from customer reviews. Concretely, we employ a self-supervised pre-training method: For any given product without a human-written summary, we predict one of the given reviews by conditioning on N other reviews with the highest lexical overlap in the *leave-one-out* fashion (Bražinskas et al., 2020b). As the standard training of PLMs is storage and memory inefficient (Mahabadi et al., 2021), we pre-train adapters only; see Stage 2 in Fig. 1. Afterwards, we fine-tune them on a small number of annotated reviews-summary pairs (< 100 pairs), see Stage 3 in Fig. 1. All in all, our method combines the general text generation and understanding abilities of the PLM with in-domain knowledge directly related to the end task.

Content Planning. Well-organized content in summaries is easier to follow and thus improves user experience. However, the lack of annotated data makes it challenging to learn a desired content structure. For example, in Table 1, FewSum's summary does not end after a concluding phrase '*Other than that, it's a great top.*' While the state-of-the-art model (PASS) addresses this issue by ranking multiple generated candidates with a specialized coherence model, we propose a simpler solution – AdaQSum – that capitalizes on *text planning* (Hua and Wang, 2019; Moryossef et al., 2019). Specifically, we allow the model to *plan ahead* by providing an intermediate summary representation in the form of a query consisting of aspect keywords. As we show, this results in more coherent text patterns with fewer redundancies. Moreover, it can be useful for personalized summaries, better reflecting user interests.

Result Highlights. We evaluate the proposed models in terms of automatic metrics and human efforts. We find that pre-training and fine-tuning of adapters leads to more than 2.0 and 1.3 ROUGE-L points improvement over fine-tuning the entire model on Amazon and Yelp datasets, respectively. We also find that our pre-trained and fine-tuned query-based model improves ROUGE-L scores by more than 2.7 and 0.9 ROUGE-L points over PASS, on Amazon and Yelp datasets, respectively, and is more preferred by humans. We further demonstrate that the query-based model (AdaQSum) substantially improves coherence and reduces redundancies in generated summaries.

FEWSUM	This tank top is well made, fits well, and is comfortable to wear. The only thing is that it runs a little small, so order a size up from what you normally wear. Other than that, it's a great top. It's well made and it looks like it will last a long time. Love it!
PASS	This is a basic tank. The photo shows it going well past the models hips. However, the material used to make it this long is thin and therefore not good quality. It is also thinner than other tanks on the market but is still comfortable to wear.
ADAQSUM	This is a basic tank top that fits well and is comfortable to wear. The color is great and the length is long enough to wear with leggings. The quality of the product is good.
REVIEWS	... This is a basic tank ... ‖ ... this tank fits like a normal tank top, not any longer ... I could wear it with leggings ... ‖ ... It is THIN and runs SMALL ... It fits tight and is NOT long like in the picture ... ‖ The tank fit very well and was comfortbale to wear. I've bought much higher quality tanks ... ‖ ... it is listed as a 'long' tank top and the photo even shows it going well past the models hips, however I'm short and the tank top is just a normal length. ‖ ... They were a lot thinner than I like ... ‖ Every women should own one in every color. Just feels quality I don't know how else to explain it ... ‖ ... They are long enough that the color peeks out from under my tops. Looks cute.

Table 1: Generated summaries for an Amazon product by baseline models (FEWSUM and PASS) and our approach (ADAQSUM). Colored words indicate aspect keywords that were part of the query. The special marker '‖' separates truncated reviews.

In summary, our contributions are as follows:

- We propose a self-supervised pre-training method to learn in-domain knowledge by adapters that alleviate catastrophic forgetting;
- We propose, to the best of our knowledge, the first aspect-based abstractive opinion summarizer learned from a few annotated samples;
- We substantially increase summary coherence using the query-based approach;
- We show that self-supervised pre-training significantly improves performance on the query-based task;
- We demonstrate state-of-the-art results on two primary benchmarks in automatic and human evaluation.[1]

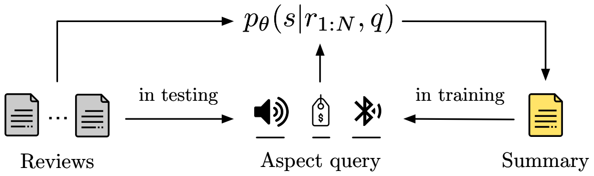

Figure 2: Illustration of the query-based summarizer that inputs reviews and a text query consisting of aspects, such as 'volume,' 'price,' and 'bluetooth.' The query is automatically created from gold summaries in training and reviews in test time.

2 Approach

2.1 Opinion Summarization Tasks

In this work, we consider two tasks of customer review summarization. The first one is *generic summarization* (Chu and Liu, 2019; Bražinskas et al., 2020a), where the aim is to produce a summary that covers overall opinions in input reviews. Formally, given N input reviews $r_{1:N}$, the task is to predict word-by-word the summary s:

$$\mathcal{L}(s, r_{1:N}; \theta) = \sum_{t=1}^{T} \log p_\theta(s^t | s^{1:t-1}, r_{1:N}).$$

In the second task, *query-based summarization*, we assume that the user provides a query q consisting of aspect keywords, such as 'bluetooth,' 'resolution,' and 'battery life.' In turn, a summarizer should generate a summary reflecting customer opinions in $r_{1:N}$ about these aspects. Formally, given a pair of input reviews and query ($r_{1:N}$, q), the task is to predict word-by-word the summary s:

$$\mathcal{L}(s, r_{1:N}, q; \theta) = \sum_{t=1}^{T} \log p_\theta(s^t | s^{1:t-1}, r_{1:N}, q).$$

Unfortunately, abstractive opinion datasets with annotated aspect queries are unavailable in the domain. To mitigate this problem, we follow Ni et al. (2019) and create queries by extracting fine-grained aspect keywords from available generic summaries. Specifically, we utilize the model proposed by Zhang et al. (2014) to build a fine-grained aspect lexicon from review datasets. Further, we use simple rules to determine which aspects appear in summaries; see an annotated summary in Table 2. At test time, we follow the intuition that a summary should reflect common opinions and create a query from K most frequent aspect keywords in input reviews. The workflow is illustrated in Fig. 2.

---

[1] Our code and associated artifacts will be publicly available at `https://github.com/amazon-research/adasum`.

2.2 Model

Our model is based on the Transformer (Vaswani et al., 2017) encoder-decoder architecture initialized with BART (Lewis et al., 2020). We adopt the same encoder as in (Raffel et al., 2020; Oved and Levy, 2021) where reviews are concatenated before encoding.[2] This allows us to capture product-level features and leverage commonalities across reviews during encoding. For query-based summarization, we concatenate a query and reviews while indicating boundaries with special markers. In this way, the encoder can contextualize aspect keywords and focus on salient review fragments reflecting these aspects.

2.3 Adapters

In training, a large pre-trained model remains frozen and only tiny neural networks called *adapters* (Houlsby et al., 2019) are optimized. These modules are injected into the transformer layers (both encoder and decoder). Formally, given the input hidden vector h, the output vector $\hat{h}$ is calculated as shown below:

$$\hat{h} = f_2(\tanh f_1(h)) + h.$$

The functions $f_1(\cdot)$ and $f_2(\cdot)$ are the down- and up- projection layers. At each transformer layer, two adapters are inserted right after the self-attention and the feed-forward layers, respectively. These modules consist of substantially fewer parameters than the language model, usually around 3% - 5%. Recent studies have shown that adapters are less prone to overfitting (He et al., 2021) and are more memory-efficient in training (Mahabadi et al., 2021). Finally, as the pre-trained model remains frozen, it retains all the prior knowledge for text understanding and generation. This effectively alleviates catastrophic forgetting (Goodfellow et al., 2013; Kemker et al., 2017) without modifying the training objective as in RECADAM (Chen et al., 2020; Yu et al., 2021). We refer to our approaches as ADASUM and ADAQSUM for generic and query-based summarization, respectively.

2.4 Self-supervised Pre-training

Language models, initially pre-trained on generic text corpora, are often not accustomed to in-domain specifics. Unsurprisingly perhaps, a wide range of product-related specifics cannot be learned from a handful of annotated summaries during fine-tuning. Consequently, this can result in subtle semantic mistakes in generated summaries. We will discuss this problem and provide examples in Sec. 5.4. Furthermore, query-based summarization is even more challenging for learning than generic summarization. To be useful in practice, the summarizer should rely on the provided query after fine-tuning. However, a handful of annotated samples might be insufficient to learn this dynamic. We will analyze this problem in Sec. 5.1. To alleviate these two problems, we leverage unannotated customer reviews to construct synthetic datasets for pre-training.

The *cover* offers durable *protection* for the MacBook, the retractable *tilt* stands offer *protection* for the *wrists*.

The *keyboard cover* can take some effort to *fit* properly, and *adjustment* to its feel may take time.

However, free and fast *shipping* make up for this one potential issue.

Table 2: Automatically annotated Amazon summary with fine-grained aspect keywords (*underlined italic*).

Synthetic In-Domain Pre-Training Dataset. From a group of product reviews, we randomly sample one review as a *pseudo summary* s and select N reviews as input ($r_{1:N}$).[3] We select N input reviews covering the content of the summary s – that have the highest ROUGE-1 F scores. Following the naming convention (Bražinskas et al., 2020b), we refer to this as *leave-one-out pre-training* (L1O). To closely resemble query-based summarization, we create aspect queries from pseudo summaries. Specifically, we leverage the aspect lexicon by matching summary keywords; in the same way as was explained in Sec. 2.1. In practice, we expect queries to have at least one aspect keyword. Therefore, we remove all pre-training pairs where the pseudo summary has no aspect keywords.

3 Experimental Setup

3.1 Data

To create synthetic datasets, we used customer reviews from Amazon (He and McAuley, 2016) and

---

[2] We experimented with the independent review encoding as in Bražinskas et al. (2020b). However, the results were slightly worse.

[3] We also experimented with selecting pseudo summaries without personal pronouns – written in the formal style (Bražinskas et al., 2020a). However, we did not observe significant improvements.

	Amazon		Yelp	
Split	Gold	Synthetic	Gold	Synthetic
Train	84	70,144 / 59,963	90	70,144 / 68,499
Valid	36	7,900 / 6,810	90	7,900 / 7,724
Test	60	-	120	-

Table 3: Source-target pair numbers for Amazon and Yelp, both gold and synthetic. Each pair has 8 source reviews. Generic and query-based pair statistics are separated by '/'.

Yelp.[4] Following Bražinskas et al. (2020a), we selected 4 categories: *Electronics*; *Clothing, Shoes and Jewelry*; *Home and Kitchen*; *Health and Personal Care*. We pre-processed the datasets by removing all reviews that are shorter than 20 words and longer than 120 words and evened the number of pairs in both datasets. Further, we used Amazon and Yelp gold summaries from (Bražinskas et al., 2020a) where each product/business has 3 references and is paired with 8 reviews. Gold and synthetic dataset statistics[5] are presented in Table 3.

3.2 Baselines

LEXRANK (Erkan and Radev, 2004) is an unsupervised extractive graph-based model that selects sentences based on graph centrality. Sentences represent nodes in a graph whose edges are weighted with tf-idf.

MEANSUM (Chu and Liu, 2019) is an unsupervised abstractive summarization model which treats a summary as a structured latent state of an autoencoder trained to reconstruct reviews of a product.

COPYCAT (Bražinskas et al., 2020b) is the state-of-the-art unsupervised abstractive summarizer with hierarchical continuous latent representations to model products and individual reviews.

FEWSUM (Bražinskas et al., 2020a) is a few-shot framework where lexical features are used to differentiate between customer reviews and summaries. In the fine-tuning phase, features leading to generation of summaries are searched.

PASS (Oved and Levy, 2021) is based on a pre-trained T5 model (Raffel et al., 2020) that is further fine-tuned on gold summaries. At inference, the model's input is perturbed to generate multiple candidates. These candidates are further ranked by a separate model based on coherence and fluency to select the best one.

We fine-tuned the full BART model (FULL) for a fair comparison, with and without the leave-one-out pre-training. We also employed a number of simple summarization baselines. First, the CLUSTROID review was computed for each group of reviews as follows. We took each review from a group and computed ROUGE-L with respect to all other reviews. The review with the highest ROUGE score was selected as the clustroid review. Second, we sampled a RANDOM review from each group to be used as the summary. And lastly, we constructed the summary by selecting the *leading sentences* (LEAD) from each review of a group.

3.3 Experimental Details

We used a standard Transformer encoder-decoder (Vaswani et al., 2017), pre-initialized with BART large (Lewis et al., 2020), consisting of 400M parameters. We used two adapter sizes – 0.6% and 5% of the full model's parameters. All input reviews were concatenated, following Raffel et al. (2020); Oved and Levy (2021). For parameter optimization, we used ADAM (Kingma and Ba, 2014), and summary generation was performed via the beam search of size 5 and with 3-gram blocking (Paulus et al., 2017). We used ROUGE-L as the stopping criterion on the end task, and perplexity (PPL) for pre-training. The learning rate for most experiments was set to 5e-5. Aspect lexicons for query-based summarization contained 2809 and 4013 fine-grained aspects for Amazon and Yelp, respectively. In pre-training and fine-tuning, we shuffled aspects to break temporal dependencies. For fine-tuning on Yelp, we also found it useful to exclude summary aspect keywords that do not appear in input reviews. This approximately matched the number of aspect keywords for Amazon and Yelp. At test time, we selected up to 6 and 5 most frequent aspects for Amazon and Yelp, respectively. All computations were performed on an 8-GPU p3.8-xlarge Amazon instance.

4 Results

4.1 Automatic Evaluation

Table 4 shows results on the Amazon and Yelp test sets for generic summarization. It shows ROUGE F1 scores (Lin, 2004) as a standard measure of informativeness[6] and perplexity (PPL) as a measure of confusion.

---

[4] `https://www.yelp.com/dataset`

[5] For the query-based setup, we removed all instances where targets had no aspects.

[6] For consistency with previous works, we used the same Python package (`https://github.com/google-research/google-research/tree/master/rouge`)

Table 4: Test set ROUGE F1 scores on gold Amazon and Yelp datasets for generic review summarization. L1O stands for leave-one-out pre-training. We also provide the total number of trainable parameters.

First of all, the results indicate the superiority of adapters over full fine-tuning and state-of-the-art few-shot models on both datasets. As was observed in He et al. (2021), adapters are less prone to overfitting, which is especially beneficial in few-shot settings. Second, we observe a significant improvement in ROUGE scores when pre-trained models are further trained using L1O. This signifies the importance of learning in-domain specifics before fine-tuning. We also observe that adapters are more effective on the Amazon dataset, which is more challenging as indicated by higher perplexity (PPL).[7] We hypothesize that the pre-trained language model (BART) is more accustomed to restaurant- than product-related texts. Moreover, larger adapters (5%) tend to overfit on the small number of annotated instances, and L1O pre-training helps substantially, as indicated both by ROUGE scores and PPL. We provide example generated summaries in the Appendix.

4.2 Human Evaluation

Coherence Improvement. As was observed in (Oved and Levy, 2021), opinion summarizers sometimes generate incoherent summaries. We hypothesized that a query should allow the model to plan ahead of time and thus generate more coherent and less redundant texts. To test the hypothesis, we compared 5% adapter-based models with and without the query; both were pre-trained via L1O. We performed human evaluation in terms of *coherence* and *non-redundancy* via Best-Worst Scaling (BWS) (Louviere and Woodworth, 1991; Louviere et al., 2015). BWS has been shown to produce more reliable results than ranking scales (Kiritchenko and Mohammad, 2016).

For each Amazon test set entry and criterion, we asked three independent workers on Amazon Mechanical Turk (AMT) to select the best and worst summary. For each criterion, a system's score is computed as the percentage of times it was selected as best, minus the percentage of times it was selected as worst (Orme, 2009). The scores range from -100 (unanimously worst) to +100 (unanimously best). For more details, please refer to Appendix 10.2.

First, the results indicate that the summaries generated by AdaQSum are substantially more preferred to AdaSum in terms of coherence and non-redundancy. Namely, +13.73 vs -30.91 and -1.96 vs -25.93 for coherence and non-redundancy, respectively. We also computed the percentage of unique n-grams in each generated summary for both datasets, as shown in Table 5. The results support that query-based summaries are less redundant. However, similar to findings in Oved and Levy (2021), we observe that more coherent summaries tend to get lower ROUGE scores. Nevertheless, our model outperforms PASS by a margin on both datasets – by 2.72 and 0.9 ROUGE-L points on Amazon and Yelp, respectively.

---

[7] Training sets are of similar sizes, i.e., 84 and 90 summaries on Amazon and Yelp, respectively

		R1	R2	RL	unique 1-gram (%)	unique 2-gram (%)

ADAQSUM (5%) + L1O	72.69	20.37	6.94

Table 7: Input fidelity on the Amazon test set, normalized by sentences.

Comparison to Baselines. To understand better how our query-based model compares to other models, we performed an additional human evaluation experiment. We used the following criteria: *coherence*, *non-redundancy*, and *fluency*. As previously, we used the Best-Worst scaling on the Amazon test set. We assigned three AMT workers to each tuple containing summaries from PASS, ADAQSUM (5%) + L1O, LEXRANK, and human annotators (GOLD).

The results in Table 6 suggest that summaries produced by our model are more fluent and non-redundant than the ones produced by PASS. In general, PASS produces more diverse and detailed summaries yet with more semantic mistakes that make them harder to understand (hence lower fluency scores). However, summaries by both systems are similarly preferred in terms of coherence. Also, we note that PASS utilizes a separately trained classifier on human-annotated summaries (Fabbri et al., 2021) to rank candidate summaries, while our approach does not.

Input Content Fidelity. As was shown in Falke et al. (2019); Tay et al. (2019), the ROUGE metric can be insensitive to hallucinations (Maynez et al., 2020). However, hallucinations can lead to user aversion, and their reduction remains an open problem in summarization. To assess the input fidelity of generated summaries, we performed a human evaluation. Specifically, we used summaries produced by the adapter models (ADASUM (5%) + L1O and ADAQSUM (5%) + L1O), FEWSUM, PASS, and human-written (GOLD). In each task (HIT), we presented both reviews and all summary sentences. We asked three workers to assess how well the content in summary sentences is supported by the reviews. The three following options were available. *Full support*: all the content is reflected in the reviews; *Partial support*: only some content is reflected in the reviews; *No support*: content is not reflected in the reviews. The results, normalized by sentences, are shown in Table 7.

First, we observe that FEWSUM hallucinates the most, potentially because it was not initialized with a pre-trained language model. Second, PASS improves input fidelity over FEWSUM yet substantially underperforms our adapter-based models. We also notice a slight decrease in input fidelity when the query is used. This is likely caused by more abstractive summaries generated by ADAQSUM, we discuss it in Sec. 5.3.

5 Analysis

5.1 Query-based Pre-training

Query-based summarizers should generate summaries reflecting all aspects in user queries to be useful in practice. We investigated how summarizers learn this task in the few-shot regime with and without pre-training. We created test-time queries from gold summaries (indicated by *) and input reviews. Further, we calculated the aspect recall (AR) score by counting aspect keywords in queries present in generated summaries. The results are shown in Table 8.

As indicated by low AR scores, without pre-training, the models miss many aspects in queries. The increase to nearly 100% in AR suggests that pre-training is crucial for the task. The same trend remains when aspect keywords from reviews are used in queries.

	R1	R2	RL	AR
FULL (100%) + Q*	40.52	10.96	25.06	59.84
FULL (100%) + L1O + Q*	42.65	11.53	26.82	96.39
ADAQSUM (5%)*	41.04	11.08	25.46	60.64
ADAQSUM (5%) + L1O*	43.84	13.41	27.31	97.19
ADAQSUM (5%)	38.58	10.10	24.19	69.14
ADAQSUM (5%) + L1O	38.53	10.52	26.06	98.78

Table 8: Amazon test set ROUGE F1 for query-based summarization. Here, * indicates that queries were created from gold summaries; AR stands for aspect recall.

	PPL↓
FULL (100%) + L1O	21.51
FULL (100%) + L1O + FT	34.87 (+13.36)
ADASUM (5%) + L1O	19.69
ADASUM (5%) + L1O + FT	**28.45 (+8.76)**

Table 9: Catastrophic forgetting evaluation on the Amazon pre-training task's validation set, before and after fine-tuning (FT).

5.2 Catastrophic Forgetting

ROUGE scores in Table 4 suggest that L1O pre-training is beneficial for the end task. However, fine-tuning on summaries can lead to the catastrophic forgetting of the acquired in-domain specifics from reviews. Because adapters have fewer parameters to optimize, we hypothesized that they might be more robust to this phenomenon.

To test the hypothesis, we evaluated two models on the pre-training L1O pairs where a review is used as a summary, before and after fine-tuning on human-written summaries. For the first model, we optimized only adapters (5%), both in pre-training and fine-tuning. And in the second case, we optimized the entire model. We used PPL to measure the model's confusion about the pre-training pseudo summaries, as shown in Table 9.

The results demonstrate that the adapter-based model better preserves information about reviews after they are fine-tuned on summaries, as indicated by lower PPL scores. Our findings are also supported by Yu et al. (2021).

5.3 Abstractiveness

Abstracting information in reviews is important for practical applications (Carenini and Cheung, 2008). To investigate how well the models abstract, we computed the number of novel n-grams in generated summaries with respect to input reviews on the Amazon test set. The results in percentages are shown in Table 10.

	2-gram	3-gram	4-gram
FEWSUM	**78.63**	**95.59**	**98.74**
PASS	70.72	86.32	93.24
ADASUM (5%) + L1O	55.47	78.24	86.78
ADAQSUM (5%) + L1O	56.27	79.18	88.48

Table 10: The abstractiveness of generated summaries in terms of novel n-grams on the Amazon test set.

First, we observe that FEWSUM tends to produce the most abstractive summaries, followed by PASS. Second, ADAQSUM has higher abstractivness than ADASUM. We also observe that abstractiveness is inversely proportional to input faithfulness in Table 7, in line with previous studies (Durmus et al., 2020; Dreyer et al., 2021).

5.4 Semantic Mistakes

When a pre-trained model (with and without adapters) is fine-tuned on a handful of annotated samples, it often results in summaries with subtle semantic mistakes; see examples in Table 11. For instance, a 5% adapter model generates a semantically contradicting fragment: *'This **dead on arrival battery** is of good quality and holds a charge well.'*.

We hypothesize that it is caused by the lack of in-domain knowledge, which we propose to learn via L1O (see Sec. 2.4). During a manual investigation, we observed that L1O pre-training substantially reduces semantic mistakes. This is also reflected in higher ROUGE scores in Table 4.

6 Related Work

Extractive opinion summarization has been an active area of research (Hu and Liu, 2004; Ganesan et al., 2010; Medhat et al., 2014; Isonuma et al., 2019; Angelidis et al., 2020). For example, a more recent extractive method of Angelidis and Lapata (2018) decouples the summarization procedure into multiple steps with separate models. Other earlier approaches (Gerani et al., 2014; Di Fabbrizio et al., 2014) relied on text planners and templates, which, however, restrict the output.

Abstractive opinion summarization is an emerging branch (Chu and Liu, 2019; Amplayo and Lapata, 2020; Bražinskas et al., 2020b, 2021a). Customer reviews were used to train unsupervised summarizers in Amplayo and Lapata (2020); Bražinskas et al. (2020b); Isonuma et al. (2021). The few-shot model FEWSUM (Bražinskas et al., 2020a) was also pre-trained on customer reviews before fine-tuning. In this work instead, we focus on pre-training adapters to avoid catastrophic forgetting

AdaSum (5%)	This Thomas the Train costume is cute and functional. The size is perfect for a toddler or 2 year old and the candy pouch is large enough to carry a lot of candy. The costume can be customized with googly eyes, pumpkin patch, spiders, bats, or train tracks to make it more suitable for a child of any age. The fit is comfortable and the **fit quality is great**. The only complaint I have is **the quality of the felt fabric**.
AdaSum (5%) + L1O	This Thomas the Train costume is very cute and the size is perfect for a 2-year-old. The hat is thin and flimsy and the face is not 3D sculpted. The candy pouch is a nice feature and it looks like it will grow with the child. Overall, it's a cute costume and will be used for Halloween next year.
AdaSum (5%)	**This dead on arrival battery is of good quality and holds a charge well**. It is easy to install and is a great value for the money. **However, it may not hold a charge as advertised due to the plastic case bulging**. Overall, this product is highly recommended.
AdaSum (5%) + L1O	This battery is a great value for the price and works great. It is a good quality battery that can be used to replace a dead battery in an alarm system. The price is great and the quality of the product is good. The shipping was fast and the customer service was excellent.

Table 11: Adapter-based models (5%) and their generated outputs with and without L1O pre-training. Semantic mistakes and disfluencies are highlighted in **bold**.

and reduce computational and memory overheads. OpinionDigest (Suhara et al., 2020) proposes to aggregate opinions in a pipeline framework. We approach the problem end-to-end and rely on aspect keywords (e.g., price) instead of opinion phrases (e.g., good location). Controllability using input fragments (e.g., entities) and meta information (e.g., coarse-grained aspects) has received recent attention in various NLP domains (Fremann and Klementiev, 2019; Liu and Chen, 2021; Narayan et al., 2021; Elsahar et al., 2021). In contrast to a related work, SelfSum (Elsahar et al., 2021), we use aspect keywords instead of generic tokens and consider a few-shot setup instead of unsupervised and a different model architecture. Also, planning was tackled in opinion summarizeration in Amplayo et al. (2021b). However, their approach is substantially less flexible, as the summary plan consists of an aspect and sentiment classes only. Query-based settings have received recent attention in the news domain (Xu and Lapata, 2020, 2021). Compared to a concurrent work on opinion summarization AceSum (Amplayo et al., 2021a), our approach does not require a trained aspect induction model, is few-shot instead of self-supervised, and benefits from a large collection of automatically created fine-grained aspects (a couple of thousands) instead of human annotated coarse-grained aspects (up to 18). Concurrently with our work, Poth et al. (2021) support our findings on the benefits of pre-training adapters for other tasks.

7 Conclusions

In this work, we improve few-shot learning for opinion summarization with adapters pre-training on customer reviews in the end task-specific manner. In this way, the model learns in-domain specifics, which reduces semantic mistakes in generated summaries. We show that our approach leads to more than 2.0 and 1.3 ROUGE-L points improvement over the entire model's fine-tuning on the Amazon and Yelp datasets, respectively. Further, we propose a simple method for few-shot query-based summarization. The queries consist of aspect keywords reflecting potential user interests. We create these queries automatically and show that pre-training is crucial for the end task, significantly improving performance. Finally, in human evaluation, we demonstrate that the query-based model generates more coherent and less redundant summaries.

Acknowledgments

We would like to thank Jonathan Pilault, Leonardo Ribeiro, Sandeep Atluri, and the Amazon AI teams for their useful feedback and discussions.

8 Ethics Statement

We used only publicly available datasets. For human evaluation, we used a publicly available service (Amazon Mechanical Turk) to hire voluntary participants, requesting native speakers of English. The participants were fairly compensated, above the minimum hourly wage in their self-identified countries of residence.

9 Limitations

In this work, we explicitly focus on multi-document abstractive opinion summarization. However, our pre-training self-supervised method and fine-tuning techniques can be applied to a broader set of multi-document summarization domains (e.g., news) and can be considered in the future work. Also, while we tested our approach only with BART, we believe that it would work with other pre-trained encoder-decoder models, like PEGASUS (Zhang et al., 2020).

10 Appendices

10.1 Human Evaluation Setup

To performed the human evaluation experiments described in Sec. 4.2, we hired workers with 98% approval rate, 1000+ HITS, Location: USA and the maximum score on a qualification test that we had designed. The test asked if the workers were native English speakers, and verified that they correctly understood the instructions of both the best-worst scaling and content support tasks. We paid the workers an approximate amount of $12 per hour.

10.2 Best-Worst Scaling Details

We performed human evaluation based on the Amazon test set using the AMT platform. We assigned 3 workers to each tuple containing summaries from different systems. We showed summaries and asked to select the best and worst one based on the criterion presented below.

1. *Fluency*: the summary sentences should be grammatically correct, easy to read and understand;
2. *Coherence*: the summary should be well structured and well organized;
3. *Non-redundancy*: there should be no unnecessary repetition in the summary.

GOLD	These transition tights are perfect for children sensitive to the tight sensation other tights have around the foot. The material is soft and durable; they stand up well to both the rough nature of children, and the washing machine. This product does tend to run slightly small, so purchasing one size up is recommended.
FEWSUM	These tights are a great value for the price. The fit is true to size and the quality of the tights is very good. They are well made and will last a long time. They do run a little on the small side, so order a size up.
PASS	These soft, breathable tights are great for transitioning from tap to ballet. They fit snugly around the body and stay in place when worn with ballet shoes. They are well made and well made, and can last longer than other tights available. The colors are beautiful and will definitely be purchasing again.
ADASUM (5%) + L1O	These tights are soft and comfortable and fit well. They are durable and will last a long time. They can be worn with sandals or flip-flops. They do run small and should be ordered one size up to avoid squishing toes. The color is beautiful and the material is soft and durable.
ADAQSUM (5%) + L1O	These tights are soft, comfortable, and durable. The **color** is beautiful and the **fit** is perfect for **tap** and ballet. They **fit** well and are durable enough to **wear** with flip-flops to class. They are recommended to order one size up if your child is chubby or slim.
REVIEW 1	These are the perfect tights for my 5-year old. The tights are very well made and have already lasted several washings (hang dry). The color is beautiful, and my daughter loves that she can wear flip-flops to class like the big girls do.
REVIEW 2	my 3 year old fit into these perfectly. I love these tights, they are great for wearing sandals to dance class and then pulling them over her toes to put ballet slippers on. They are nice and soft and the pink color is pretty. Will purchase again.
REVIEW 3	These are my daughters preferred ballet tights. They fit well and don't squish her toes as much as some others. The convertible option is nice as she can wear flip flops to the studio with her tights. I like that they appear to be fairly durable.
REVIEW 4	Bought this for my little one to use for her ballet class. She's almost 4 and this fits perfectly. Transition tights give her the ability to pull up the foot area to around the ankles so that they don't get dirty when not wearing her shoes, but fit well and stay in place when pulled over her feet and used with ballet shoes on.
REVIEW 5	Great soft fabric, runs small a though. U should consider getting one size up to avoid having your daughter, or son if he's into ballet, have little circulation. Don't get me wrong, great product and material.
REVIEW 6	I purchased these tights for my 4 year old because she has a tap class immediately followed by an acro class. Tights fit well and were easy to transition to bare feet after tap. I can't comment on how they hold up, as we only had one week of dance so far.
REVIEW 7	This is my go to tight when my daughter needs new ones. I won't buy anything else. They are super comfy and last forever! She is 7 but very slim and these will fit her for a while but the 8-12 is a better fit for longevity purposes but they only had this size left and I needed them right away.
REVIEW 8	These are great tights. If your girl is chubby on the waist i think you should order a number up. they are a strong tihgts. My daugther has it for more than 4 months and hasn't broken them. She only complains some days about the waist, just when she has had a lot of milk or food recently. she's 3 years old.

Table 12: Example summaries produced by different systems for an Amazon product. We highlight in **bold** keywords that were part of the query for ADAQSUM (5%) + L1O.

GOLD	The results with this scanner are sporadic at best- there are many problems with the software drivers and the stringent system requirements that come along with it. It does not work with the most recent versions of Windows, and the company charges for tech support calls.
FEWSUM	This is a great scanner. It is easy to use and easy to set up. The software that comes with it does not work with Windows Vista. It would be nice if it was a little more user friendly, but for the price it can't be beat.
PASS	The VuPoint Digital Scanner is very user friendly and easy to use. It can scan over 1200 35 mm negatives and about a dozen slides. It takes time and money to get the scanner to fit in the holders that come with it. The company also charges $10.00 per phone call for tech support.
ADASUM (5%) + L1O	The VuPoint Digital Scanner is easy to use and does a great job converting negatives to digital format. However, the software is not compatible with newer versions of Windows. The company ArcSoft charges $10 per phone call for tech support. Overall, this product is not recommended.
ADAQSUM (5%) + L1O	The VuPoint Digital Scanner does a great job of converting **photo** negatives to digital format. The **software** is easy to use and easy to install. However, the **image** bleaches out with too much light. A **replacement** unit is required. Overall, this product is recommended.
REVIEW 1	I recently bought this film and slide scanner to scan my grandfather's slide collection. It bleaches out the image with too much light. I tried changing the settings to improve the image quality, but had no luck. The company ArcSoft charges $10.00 per phone call for tech support. You are better off making the investment on a nicer quality scanner.
REVIEW 2	* * Not Reccommended * * Purchased as a gift in August. Opened a week ago. Spent the last week trying to get Win Xp to recognise the Vu Point scanner. Many drivers and reloads later all I have is a little black box with a red light and a message from windows that says 'USB Device Not Recognised'.
REVIEW 3	I used the VuPoint Digital Scanner to scan over 1,200 35 mm negatives and about a dozen slides and found this gadget a most user-friendly and efficient tool. I even managed to upload a few black and white negatives from 1963. I recommend the product highly.
REVIEW 4	While the software was good for Windows XP and Vista, I now have Windows 7 and would like to have software for the newer operating system. The company prefers to sell other products rather than update their software. I can't see recommending this product in today's market.
REVIEW 5	While most equipment will work with more modern versions of Windows than were available when manufactured this is not true with this scanner. Requires Windows XP means it won't work with earlier OR LATER. Its on its way back for a refund.
REVIEW 6	I found the VuPoint scanner not acceptable and I am still waiting for a replacement. My contacts with VuPoint were helpful but the equipment still did not produce acceptable images. My contact with the seller has been sporadic, at best, and a replacement unit has not been delivered.I an NOT anxious to deal with these providers again.
REVIEW 7	Product is very easy to use. Does a great job converting my slide and photo negatives to digital format. Touch-up and enhance program gave me just what I needed to clean up and enhance some of the scans, Company was great to work with!!
REVIEW 8	Its not worth the time it takes to get the negative to fit in the holders they give you. I'd much rather buy a hp flat bed scanner that lets you see the final photo image and not just an image of the negative. It takes to much time and isn't worth the money.

Abstract

Pre-training on larger datasets with ever increasing model size is now a proven recipe for increased performance across almost all NLP tasks. A notable exception is information retrieval, where additional pre-training has so far failed to produce convincing results. We show that, with the right pre-training setup, this barrier can be overcome. We demonstrate this by pre-training large bi-encoder models on 1) a recently released set of 65 million synthetically generated questions, and 2) 200 million post-comment pairs from a preexisting dataset of Reddit conversations. We evaluate on a set of information retrieval and dialogue retrieval benchmarks, showing substantial improvements over supervised baselines.

1 Introduction

As a pre-training task, language modeling and its variants (causal (Radford et al., 2018), bi-directional (Peters et al., 2018; Baevski et al., 2019), masked (Devlin et al., 2018), seq2seq (Lewis et al., 2020; Raffel et al., 2019)) have proven to be extremely versatile and shown to transfer well to most, if not all NLP tasks. Nevertheless, in-domain fine tuning remains important, as there is still a gap between the pre-training task and the downstream tasks. Numerous approaches have been proposed to fill this gap, with an additional (intermediate) pre-training stage, mostly based on multi-task learning (Raffel et al., 2019; Aghajanyan et al., 2021). It's been generally accepted that the more similar the end task is to the pre-training task, the larger the gains (e.g., NLI tasks transfer better to other NLI tasks (Phang et al., 2018), QA tasks to QA tasks (Khashabi et al., 2020), *inter alia*).

From this perspective, information retrieval (IR), which is the task of identifying the most relevant document to a given query from a large corpus of candidates, has a unique position. At the surface, IR looks similar to other NLP tasks in standard benchmarks, such as NLI or paraphrase detection. However, the need to accommodate large corpora imposes computational constraints, which leads to important practical differences. Most importantly, indexing needs to happen offline, therefore the candidate representations need to be calculated independently of the query representation. As a result, neural retrieval systems typically use a *bi-encoder* model (Figure 1), trained to minimize the similarity between the document representation and the query representation. This shallow interaction between document and query encoders makes neural IR models architecturally unique, compared to the block cross-attention transformers which are the universal choice for almost every other NLP task.

Researchers have therefore recognized the need to construct intermediate pre-training tasks that are better matched to retrieval. Lee et al. (2019) proposed the *inverse cloze task (ICT)*, which treats sentences as pseudo-queries, and matches them to the paragraph they originate from. Chang et al. (2020) combined this with *body first selection (BFS)* (selecting the first paragraph given a sentence from the same document), and *wiki link prediction*. Guu et al. (2020) pre-trained a retrieval model jointly in an end-to-end system to minimize a language modelling objective.

In each of these cases, pre-training approaches were shown to improve over their respective baselines. However, subsequent work showed that a careful fine-tuning over a vanilla BERT model can outperform all of these approaches (Karpukhin et al., 2020). The findings for model scaling are also similar to those of data scaling. Published results show only modest improvements from larger models for retrieval, and retrieval models which top the most competitive document ranking leaderboards are still based on the relatively small BERT-

base architecture.[1] This is in sharp contrast to other NLP benchmarks, where data and model scaling has been extremely successful.

We hypothesise that previously proposed pre-training tasks might be still too distant from the target task, which limits useful transfer. We therefore investigate pre-training tasks for retrieval which are as closely matched to the the target task and domain as possible. To this end, we propose using two corpora for retrieval pre-training:

- A corpus of 65 million synthetically generated question-answer pairs from Wikipedia (PAQ, Lewis et al., 2021), which we target for open domain question answering and other passage retrieval tasks.
- A corpus of 220 million post-comment pairs from Reddit, which we use for dialogue retrieval tasks.

We conduct extensive evaluations on two popular information retrieval tasks, a benchmark composed of 8 knowledge-intensive retrieval tasks, and 3 dialogue retrieval benchmarks. We find that pre-training leads to strong improvements in all cases, and also demonstrate robust generalization. We compare different pre-training tasks, investigating the effect of domain and task similarity, and find both to be important. We also experiment with models of varying sizes, with and without pre-training, showing in some cases that retrieval can indeed benefit from larger models.

2 Dense retrieval

In this section we give an overview of dense retrieval models and how they are trained.

2.1 Bi-encoder architecture

A typical dense retrieval system consists of a query encoder E_Q and a passage encoder E_P, which output a fixed d-dimensional representation for each query and passage respectively. Passages are processed offline, and their representations are indexed using a fast vector similarity search library such as FAISS (Johnson et al., 2017). At runtime, an incoming query is encoded, and the top-k closest passages to its representation in vector distance are returned using the index. Dot-product similarity is most commonly used:

$$\mathrm{sim}(q, p) = E_Q(q)^\intercal E_P(p). \tag{1}$$

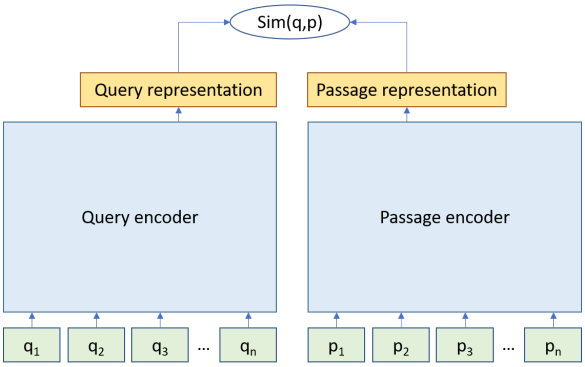

Figure 1: Bi-encoder architecture for retrieval.

The resulting *bi-encoder* architecture is pictured in Figure 1. Crucially, this formulation allows passage representations to be calculated independently from the query encoder, making efficient retrieval possible.

2.2 Training

Given a query, a relevant (positive) passage, and a list of non-relevant (negative) passages, the bi-encoder model is trained to minimize the negative log likelihood of picking the positive passage, where the probability assigned to each passage is proportional to $e^{\mathrm{sim}(q,p)}$. For efficiency reasons, positive passages are recycled as negative passages for queries they are not paired with in the batch, referred to as *in-batch* negatives. In addition, *hard* negatives have been found to be useful, which can either come from a standard retrieval system such as BM25, or an earlier iteration of the dense model (Xiong et al., 2020). We do training in two steps (which we refer to as *iterative training*). In the first step we use a single BM25 negative per query, following best practice from Karpukhin et al. (2020), and in the second step we use hard negatives obtained using the first round model. This procedure approximates the asynchronous model update, which was shown to be helpful in Xiong et al. (2020).

3 Experimental setup

3.1 Pre-training tasks

In this section, we describe the datasets we used to pre-train our retrieval models.

3.1.1 PAQ

For open-domain question answering tasks, we employ the recently-released PAQ dataset (Lewis et al., 2021). This dataset consists of 65 mil-

---

[1] https://microsoft.github.io/msmarco/

lion synthetic question-answer pairs, generated from Wikipedia passages. PAQ is generated by a pipeline of models trained on Natural Questions (NQ, Kwiatkowski et al., 2019) and TriviaQA (TQA, Joshi et al., 2017). PAQ's main distinguishing features relative to other QA-pair generation techniques are its large size, and the use of a novel *global* consistency filtering. This leads to higher quality, less ambiguous open-domain-style questions than can be achieved using standard consistency filtering with machine-comprehension models (Alberti et al., 2019).

PAQ has previously been employed as a semi-structured knowledge base of facts extracted from Wikipedia, and used as data-augmentation for closed-book question answering models (Roberts et al., 2020). However, since QA-pairs in PAQ are generated from Wikipedia passages, we can repurpose PAQ as a source of training data for a passage retrieval task. Here, given a PAQ question, the task is to retrieve the Wikipedia passage that was used to generate said question from a pool of negatives. PAQ's size makes this a suitable large-scale pre-training task and represents a close proxy of the actual downstream open-domain QA retrieval task.

3.1.2 Reddit

For dialogue tasks, we use 200 million post-comment pairs mined from Reddit. This dataset was originally extracted and made available by `pushshift.io` and shown to be useful for dialogue and chit-chat applications previously (Humeau et al., 2019; Roller et al., 2020).

3.2 Evaluation tasks

In this section, we describe our evaluation setup.

3.2.1 Passage retrieval

We evaluate on a mix of standard information retrieval and open-domain question answering benchmarks, and a suite of knowledge-intensive retrieval tasks:

MSMARCO (Nguyen et al., 2016) is a suite of benchmarks created using real user queries to the Bing search engine, with human annotated search results. We evaluate on the passage retrieval task, which is widely reported on in the IR community.

Natural Questions (NQ, Kwiatkowski et al., 2019) is a popular open-domain QA dataset, with questions originating from Google users, and answers annotated from Wikipedia.

KILT (Petroni et al., 2020) is a benchmark consisting of a diverse set of 8 knowledge-intensive tasks, including fact-checking, entity linking, relation extraction, dialogue and question answering. All tasks are grounded in Wikipedia, and we report on the passage selection metrics.

3.2.2 Retrieval for dialogue

We also evaluate on a set of dialogue retrieval benchmarks, to see how far our conclusions generalize to a different domain.

ConvAI2 is based on the PersonaChat dataset (Zhang et al., 2018), and was presented for the NeurIPS ConvAI2 competition (Dinan et al., 2019). The task involves selecting the correct next utterance in a dialogue, out of 20 candidates, given the dialogue history as well as some context about the speakers persona.

Ubuntu v2 (Lowe et al., 2015; Kummerfeld et al., 2019) is a large corpus of 1 million conversations from Ubuntu chat logs, which document users receiving support from other users regarding Ubuntu-related issues.

DSTC7 (Gunasekara et al., 2019) is a challenge set consisting of 100k samples extracted from the Ubuntu dataset described above.

3.3 Implementation

Frameworks We use the Pytorch Lightning (PL) framework (Falcon, 2019) for implementing our models. PL enables effortless scaling to hundreds of GPUs, with memory and speed optimizations such as half-precision training, and sharded gradients during distributed training. We add memory-mapped data loaders, which allow us to scale to datasets with hundreds of millions of query-passage pairs. We use pre-trained encoders provided by the Huggingface transformers library (Wolf et al., 2020).

In-batch negatives Following (Karpukhin et al., 2020) we implement in batch negatives by using the differentiable all gather primitive provided by PL. Unlike the original implementation in (Karpukhin et al., 2020) this lets us gather negatives across all nodes leading to higher training efficiency.

Validation Metrics Evaluating neural retrieval models requires embedding tens of millions of passages for indexing. This is a one-time, manageable cost for deployment systems, however for research iteration and model selection purposes, it is prohibitively expensive. One option is to use proxy-metrics such as validation cross-entropy loss, or in-batch accuracy to do model selection. Unfortunately such metrics often do not correlate well with end-to-end retrieval accuracy. As a middle-ground, we implement distributed in-memory validation using the all gather primitive. This allows us to use a fairly large proxy corpus of up to 300k passages, including up to 50 hard negative examples for each test query. We find that using mean reciprocal rank on this corpus as a model selection metric correlates well with full evaluation metrics.

Training details Pre-training on PAQ and Reddit are run for up to 10 epochs on 64 Nvidia V100 32GB GPUs, with the ADAM optimizer and triangular learning rate schedule. Learning rate and batch size vary for each model, and are presented in the appendix. We fine-tune for up to 40 epochs on the end task on 8 GPUs. For BERT and DeBERTa models, we use the [CLS] token directly as the representation, whereas for RoBERTa we add a linear projection of the same size and an additional layer normalization. BERT models use seperate encoders for query and passage, where RoBERTa and DeBERTa models use shared encoders.

Data preparation For PAQ pre-training, we mined negative examples using a publicly available DPR checkpoint[2]. For Reddit, the engineering effort to setup an index of 200M documents was too large; therefore we pre-train it without negatives. For MSMARCO and KILT, we use standard pre-processing and splits, and for NaturalQuestions we follow (Karpukhin et al., 2020). For the dialogue tasks, we use the dataset-provided negative examples when available. We concatenate all dialogue context (including persona for ConvAI2) to form the query, and truncate from the beginning if it is longer than 256 tokens.

Our code, pre-trained checkpoints, and pre-processed data files are publicly available[3].

4 Main results

In this section, we summarize our main results, before we dive into some analysis in the next section.

4.1 Passage retrieval results

Our main results for passage retrieval are presented in two tables, Table 1 for MSMARCO and NQ, and Table 2 for KILT. PAQ-based pre-training results in strong gains on almost all passage retrieval tasks. For NaturalQuestions, pre-training improves +3.2 points over our non-pretrained baseline on top-20 accuracy, without using iterative training (Figure 2). Our setup with iterative training is most similar to (Xiong et al., 2020), on which pre-training improves by *additional* 2.1 points (81.9 vs. 84.0). We advance the best published results (Qu et al., 2021) by +1.7 points on both top-20 and top-100 accuracy. We note that the main contribuition of (Qu et al., 2021) is using a large cross-encoder model to pre-filter training data - an approach which is orthogonal to pre-training and could provide additional gains. On MSMARCO, we see similar gains, improving +3.8 points over our best non-pretrained baseline.

On KILT, we advance passage retrieval SoTA on all tasks by 6.7 points of R-precision on average. This result shows that PAQ-based pre-training generalizes well across a wide variety of tasks.

4.2 Dialogue retrieval results

To further verify the matched-domain hypothesis, we conduct experiments in the dialogue retrieval domain, using Reddit chat threads as pre-training data. We see clear gains on all datasets over vanilla BERT baselines, affirming the usefulness of additional pre-training for retrieval. However, the gains are less pronounced for UbuntuV2, which has a much larger training dataset. Nevertheless, our best model (RoBERTa$_{large}$) still outperformes the previous SoTA by a comfortable margin on two tasks. For DSTC7, the results also support our conclusions, however we were not able to reproduce previous baselines on this dataset, and our numbers are generally lower.

5 Pre-training retrieval models

In this section we cover our findings regarding how to best pre-train bi-encoder models for retrieval. We compare our pre-training approach with previous approaches, and emphasize the importance of picking the right pre-training task. We discuss the effects of data and model size for pre-training retrieval models.

5.1 Picking the pre-training task

As pointed out earlier, previous attempts at pre-training dense retrieval models have largely been ineffective. In Table 4, we confirm this conclusion. We see that BFS and ICT do result in non-trivial zero-shot retrieval performance on the NQ dataset. However, after fine-tuning these gains disappear, and they do not outperform a vanilla BERT model. The performance of PAQ-pretrained retrieval is exceptionally strong even before fine-tuning. This is expected to an extent, since PAQ has been trained on NQ, and many NQ training questions might already appear verbatim in the PAQ generated questions. Nevertheless, pre-training with PAQ results in robust gains, which persist after fine-tuning. Note that both BFS and ICT were pre-trained on more data than PAQ (200 million pairs vs. 65 million). We conclude that PAQ pairs are higher quality, and better matched to the end task than previously proposed artificial pre-training tasks, resulting in better performance.

For the dialogue experiments, we compare against (Humeau et al., 2019), who also pre-trains on the same Reddit corpus, but using a cross-encoder with masked-language-modeling and next-sentence-prediction objectives *a la* BERT (Devlin et al., 2019). This allows us to compare bi-encoder pre-training, with cross-encoder pre-training on the same dataset. Looking at Table 3, we see that bi-encoder pre-training (DPR-Reddit, BERT$_{base}$) performs significantly better than cross-encoder pre-training on the ConvAI2 dataset (rows 5&8). However, the same conclusion does not hold for the larger and more domain-mismatched Ubuntu corpus. (Our RoBERTa-large bi-encoder does improve over (Humeau et al., 2019), but we don't have a corresponding cross-encoder pre-trained baseline for this model.) We conclude that transfer is somewhat fragile for dense retrieval pre-training, and is sensitive to domain and task mismatch.

5.2 Effect of data size

In Figure 2 we investigate the effect of pre-training data size on retrieval performance. We randomly downsample the PAQ pre-training dataset, and plot

	Methods	Base model	ConvAI2	DSTC7		Ubuntu v2

PAQ	78.1	81.6

Table 4: Comparison of different pre-training data, with and without fine-tuning (FT). Metric is top-20 accuracy on NaturalQuestions test set. Baseline is vanilla BERT-base model.

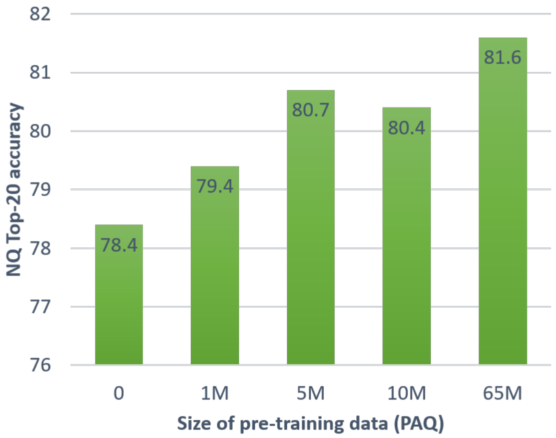

Figure 2: Effect of different sizes of PAQ data for pre-training. Results show top-20 accuracy on NQ after fine-tuning. No iterative pre-training is used.

top-20 accuracy on NQ after fine-tuning on the full NQ training set. We see that as little as 1 million pre-training examples can improve performance, with larger pre-training data resulting in more gains as expected. This suggests that expanding PAQ with even more questions could potentially be beneficial (though this could be contingent on the quality of additional generated questions).

It is interesting to note that additional MLM training is not generally helpful for retrieval on open-domain QA. RoBERTa (Liu et al., 2019) was trained on an order of magnitude more data for much longer compared to BERT, yet fine-tuning on RoBERTa results in little, if any improvement over BERT, in the absence of retrieval-specific pre-training (Table 1, rows 6&8). For dialogue retrieval, better MLM training does help, as was shown previously (Humeau et al., 2019).

5.3 Effect of model size

We experimented with pre-trained models of varying sizes, including BERT(base/large) (Devlin et al., 2019), RoBERTa(base/large) (Liu et al., 2019), and DeBERTa(xlarge-v2) (He et al., 2020). In terms of how better and larger pre-trained models interact with retrieval-specific pre-training, we get mixed results. For instance, for passage retrieval, DeBERTa-xlarge-v2 model does outperform the BERT-base baseline significantly in the fully supervised setting (Table 1, rows 6&10), yet this gain disappears after additional pre-training with PAQ (rows 11&15). The opposite is true when comparing RoBERTa vs. BERT, as we see RoBERTa performing better after intermediate pre-training, both for passage retrieval (rows 12&14) and for dialogue tasks (Table 3, rows 9&11). In contrast to the clear-cut conclusions for other NLP tasks, it is hard to conclude whether larger and better language models actually make better retrieval models.

DPR-PAQ DPR	R@20 ✓	R@20 ✗
R@20 ✓	2.5	3.2
R@20 ✗	3.3	3.1

Table 5: Mean Levenshtein distance to most similar question in PAQ, for DPR-PAQ and a DPR baseline for NQ test questions, stratified by whether the model achieves Recall@20

5.4 Effects of PAQ on Retrieval

In section 4.1, we established that pretraining on PAQ is beneficial for passage retrieval for QA. However, it is worth considering where the source of this improvement lies. Lewis et al. (2021) note that QA-pairs in PAQ have substantial overlap with the test sets of NQ — indeed, this is intentional, given their aim of preempting a large number of probable questions for use as a cache for question answering models. In fact, ∼9% of the NQ test questions appear verbatim in PAQ.

It is worth investigating then, whether the gains we observe are due to simply memorizing the relevant passages for PAQ questions which overlap with test questions, or, whether they are due to learning a more robust, generalizable model behavior.

To investigate, we compare the predictions of the DPR-PAQ retriever with an otherwise equal baseline DPR model, without PAQ-pretraining. On the subset of the NQ test set that overlaps verbatim with PAQ questions, we find that DPR-PAQ achieves 95.5% R@20, whereas the baseline achieves 94.8% These are both remarkably high scores, indicating that these verbatim questions are very easy for models to solve, regardless of pretraining. Due to the very similar performance on this subset, the difference in overall performance cannot be attributed to simply memorising verbatim-overlapping questions.

Another analysis we conduct is to check whether the questions that DPR-PAQ does well are those that *look like* the questions in PAQ. Specifically, for each test question, we find the question in PAQ that has the smallest Levenshtein distance to it[4] and record the distance value. For each retrieval model of DPR and DPR-PAQ, we split the test questions into two disjoint sets, based on whether the top 20 retrieved results of each question contain the relevant document (i.e., R@20 = 1). As shown in Table 5, questions that both retrieval models do well indeed look similar to PAQ questions, with a small mean minimum edit distance of 2.5 words. Questions where only one model performs well have higher edit distance. However, there is no big quantitative difference between DPR and DPR-PAQ, with edit distance 3.2 and 3.3 words, respectively. This suggests that the improvement of DPR-PAQ cannot be explained by simply memorizing PAQ questions. Otherwise, questions that DPR-PAQ does well should have a lower edit distance to PAQ questions.

6 Related Work

6.1 Dense retrieval

Lee et al. (2019) was first to show that dense pretrained representations can outperform BM25 for end-to-end retrieval in the context of open-domain QA. This work also proposed the ICT pre-training task for retrieval, and demonstrated its usefulness. Guu et al. (2020) improved on this work, by end-to-end pre-training of retriever and reader using a language modeling loss. It was subsequently shown (Karpukhin et al., 2020) that these sophisticated end-to-end pre-training methods are not necessary, and a fully-supervised fine-tuning of the retriever can produce superior results. The performance of fully-supervised models were improved even further in (Xiong et al., 2020) and (Qu et al., 2021) by iteratively updating negative candidates, using cross-encoder models for increasing the quality of negative candidates, and hyperparameter optimizations. Encoding each passage with multiple vectors, based on dense phrase representations, has also been proposed and shown good retrieval accuracy (Lee et al., 2021).

Pretraining for retrieval Chang et al. (2020) investigate several artificial tasks for training dense retrieval models, including ICT and BFS, showing improvements over no pre-training. However, their setting is not fully open, and they report on a smaller set of 1 million passages. These results have also been superseded by better supervised fine-tuning.

Concurrent work (Sachan et al., 2021) combined ICT pre-training with masked-salient-span pre-training, as well as an end-to-end fine-tuning

---

[4] To avoid calculating Levenshtein distance over all questions in PAQ, we use the RePAQ question retriever from Lewis et al. (2021), and calculate the minimum distance over the top 100 candidates.

using a T5-large model, obtaining results comparable or slightly better than what is presented here. The major improvements in this work are attributed to end-to-end training, which amounts to a type of distillation from the powerful T5 model into the retrieval model. It is interesting to compare this to more direct distillation methods (Izacard and Grave, 2020; Yang and Seo, 2020), which also reported similar gains. Our method also relies on a reader model indirectly, through the global filtering stage of generated questions in PAQ. However, this is different and more general than mere distillation on a supervised dataset, as it also involves data augmentation at large scale, and generalizes well to other datasets, as shown in section 4.1.

Question generation Lewis et al. (2021), used generated questions as a cache to build a fast lookup-based QA system. Using the same question bank for pre-training, we have shown that we can get additional value and generalisation from this resource. Ma et al. (2021) and Jia et al. (2021) also investigate training on generated QA pairs, but the former only considers application to domain transfer and the latter to other NLP tasks.

7 Conclusion

We have investigated domain-matched pre-training tasks for bi-encoder dense retrieval models. We found that the proposed approach is more effective than previously proposed artificial pre-training tasks. We demonstrated the generality of our conclusions, by evaluating on a large and varied set of passage retrieval and dialogue retrieval benchmarks.

Our work should be considered as a new statement in the ongoing dialogue of how to best train dense retrieval models. We believe we have addressed some important open questions, such as whether and when pre-training can be useful. However we have also raised new questions, in addition to the many which remain open. For instance, many different ways of leveraging reader models for better retrieval have been recently proposed, including end-to-end training, distillation, data filtering and data augmentation. What is the relationship between these approaches? Are they complementary? Which ones are more efficient, and more performant? We believe these questions deserve a more thorough investigation.

We have focused mostly on dense retrieval when full supervision is available, and showed that for $k = 100$ retrieval candidates, the performance is already approaching a ceiling. There is more room for improvement for smaller k. In this regime, however, re-ranking models also become feasible and separable architecture is not a strict requirement. Therefore, further improvements to retrieval will likely need to be discussed with more emphasis on the computation-accuracy trade-off. Few-shot and zero-shot retrieval will also be of increasing importance, and there are already works investigating this direction (Maillard et al., 2021; Thakur et al., 2021).

Abstract

We study open-domain question answering with *structured, unstructured* and *semi-structured* knowledge sources, including text, tables, lists and knowledge bases. Departing from prior work, we propose a unifying approach that homogenizes all sources by reducing them to text and applies the retriever-reader model which has so far been limited to text sources only. Our approach greatly improves the results on knowledge-base QA tasks by 11 points, compared to latest graph-based methods. More importantly, we demonstrate that our *unified knowledge* (`UniK-QA`[1]) model is a simple and yet effective way to combine heterogeneous sources of knowledge, advancing the state-of-the-art results on two popular question answering benchmarks, NaturalQuestions and WebQuestions, by 3.5 and 2.6 points, respectively.

1 Introduction

Answering factual questions has long been an inspirational challenge to information retrieval and artificial intelligence researchers (Voorhees and Tice, 2000; Lopez et al., 2011). In its most general form, users can ask about *any* topic and the answer may be found in *any* information source. Defined as such, the challenge of *open domain question answering* is extremely broad and complex. Though there have been successful undertakings which embrace this complexity (notably Ferrucci, 2012), most recent works make simplifying assumptions as to the source of answers, which fall largely in two categories: **structured data** and **unstructured text**.

A long line of research aims to answer user questions using a structured *knowledge base* (KB) (Berant et al., 2013; Yih et al., 2015), known as **KBQA**. Typically, a KB can be viewed as a knowledge graph consisting of entities, properties, and a predefined set of relations between them. A question can be answered, provided that it can be expressed within the language of relations and objects present in the knowledge graph. With a high-quality, carefully curated KB, answers can be extracted with fairly high precision. KBQA, however, struggles with low answer coverage due to the cost of curating an extensive KB, as well as the fact that many questions simply cannot be answered using a KB if the answers are not entities.

Figure 1: Illustration of `UniK-QA`'s workflow for unified-knowledge question answering: Heterogeneous information sources are linearized into text. A dense retriever retrieves passages from a mix of sources, which are jointly processed by the reader to produce the answer.

A second line of work targets a large collection of unstructured text (such as Wikipedia) (Chen et al., 2017) as the source of answers. Thanks to the latest advances in machine reading comprehension and text retrieval, substantial progress has been made for open-domain question answering from text (**TextQA**) in just the past couple years (Yang

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1535 - 1546
July 10-15, 2022

et al., 2019; Lee et al., 2019; Karpukhin et al., 2020; Guu et al., 2020; Izacard and Grave, 2021). On the other hand, semi-structured tables and structured KBs can be valuable knowledge sources, yet TextQA methods are restricted in taking only unstructured text as input, missing the opportunity of using these complementary sources of information to answer more questions.

When it comes to answering questions using both structured and unstructured information, a straightforward solution is combining specialized TextQA and KBQA systems. The input question is sent to multiple sub-systems, and one of them is selected to output the final answer. While this approach may take advantage of the state-of-the-art models designed for different information sources, the whole end-to-end system becomes fairly complex. It is also difficult to handle questions that require reasoning with information from multiple sources.

Having a more integrated system design that covers heterogeneous information sources has proven to be difficult. One main reason is that techniques used for KBQA and TextQA are drastically different. The former exploits the graph structure and/or semantic parsing to convert the question into a structured query, while TextQA has mostly settled on the retriever-reader architecture powered by pre-trained transformers. Recent work on multi-source QA has tried to incorporate free text into graph nodes (Sun et al., 2018; Lu et al., 2019) to make texts amenable to KBQA methods, but the performance remains unconvincing.

In this work, we propose a novel *unified knowledge representation* (`UniK-QA`) approach for open-domain question answering with heterogeneous information sources. Instead of having multiple specialized sub-systems or incorporating text into knowledge graphs, we *flatten* the structured data and apply TextQA methods. Our main motivation for doing so is to make the powerful machinary of pre-trained transformers available for structured QA. In addition, this approach opens the door to a simple and unified architecture. We can easily support semi-structured sources such as lists and tables, as well as fully structured knowledge bases. Moreover, there is no need to specially handle the schema or ontology that defines the structure of the KB, making it straightforward to support multiple KBs. Our `UniK-QA` model incorporates some 27 million passages composed of text and lists, 455,907 Wikipedia tables, and 3 billion relations from two knowledge bases (Freebase and Wikidata) in a single, unified open-domain QA model.

We first validate our approach by modeling KBQA as a pure TextQA task. We represent all relations in the KB with their textual surface form, and train a *retriever-reader* model on them as if they were text documents. This simple approach works incredibly well, improving the exact match score on the WebQSP dataset by 11% over previous state of the art. This result further justifies our choice of unifying multi-source QA under the TextQA framework as it can improve KBQA performance *per se*.

For our multi-source QA experiments, we consider lists, tables, and knowledge bases as sources of structured information, and convert each of them to text using simple heuristics. We model various combinations of structured sources with text, and evaluate on four popular open-domain QA datasets, ranging from entity-heavy KBQA benchmarks to those targeting free-form text sources. Our results indicate that our multi-source `UniK-QA` approach, unlike existing efforts on combining KBQA and TextQA, consistently improves over strong TextQA baselines in all cases. We obtain new state-of-the-art results for two datasets, advancing the published art on NaturalQuestions by 3.5 points and on WebQuestions by 2.6 points.

In addition, we consider the realistic setting in which the source of questions is not known *a priori*, as would be the case for a practical system. We train a single *multi-dataset* model on a combined dataset from several benchmarks, and show that it outperforms all single-source baselines across this diverse set of questions.

2 Background & Related Work

2.1 Knowledge-base question answering (KBQA)

A knowledge base (KB) considered in this work is a collection of facts, represented as a set of subject-predicate-object *triples*. Each triple (e_1, p, e_2) denotes a binary relationship between the subject entity e_1 and the object e_2 (e.g., places, persons, dates or numbers), as well as their relation type, or predicate p (e.g., *capital_of*, *married_to*, etc.).

Modern large-scale KBs, such as Freebase (Bollacker et al., 2008), DBPedia (Auer et al., 2007) and Wikidata (Vrandečić and Krötzsch, 2014) can contain billions of triples that describe relations between millions of entities, making them great sources of answers to open-domain questions. The prevailing approach for knowledge-base question answering (KBQA) is semantic parsing (Berant et al., 2013; Yih et al., 2015), where a natural language question is converted into a logical form that can be used to query the knowledge base. Such methods are tailored to the specific graph structure of the KB and are usually not directly applicable to other knowledge sources.

2.2 Open-domain question answering from text (TextQA)

KBQA is ultimately limited in its coverage of facts and the types of questions it can answer. On the other hand, large collections of text such as Wikipedia or CommonCrawl promise to be a richer source of knowledge for truly open domain question answering systems. This line of work (which we will refer to as TextQA) has been popularized by the TREC QA tracks (Voorhees and Tice, 2000), and has seen explosive growth with the advent of neural machine reading (MRC) (Rajpurkar et al., 2016) models. In the neural era, Chen et al. (2017) were the first to combine MRC with retrieval for end-to-end QA. Subsequent work cemented this *retriever-reader* paradigm, with improved reader models (Yang et al., 2019; Izacard and Grave, 2021) and neural retrievers (Lee et al., 2019; Guu et al., 2020; Karpukhin et al., 2020). Despite impressive advances, TextQA systems still underperform KBQA, especially on benchmarks originally created for KBs such as WebQuestions. Furthermore, they also fall short of universal coverage, due to the exclusion of other (semi-)structured information sources such as tables.

2.3 Question answering from tables

Large amounts of authoritative data such as national statistics are often available in the form of tables. While KBQA and TextQA have enjoyed increasing popularity, tables as a source of information has surprisingly escaped the attention of the community save for a few recent works.

Working with web tables can be challenging, due to the lack of formal schema, inconsistent formatting and ambiguous cell values (e.g., entity names). In contrast to relational databases and KBs, tables can at best be described as *semi-structured* information. Sun et al. (2016) considered open domain QA from web tables, however made no use of unstructured text. Some recent work investigated MRC with tables without a retrieval component (Pasupat and Liang, 2015; Yin et al., 2020; Chen et al., 2020a). In addition, Chen et al. (2021, 2020b) investigated open domain QA using tables and text. While they are in a similar direction, these works focus on complex, crowd-sourced questions requiring more specialized methods, while we target the case of simple, natural questions and investigate if popular TextQA and KBQA benchmarks can be further improved with the addition of tables.

2.4 Fusion of text and knowledge-base

As discussed, KBQA and TextQA are intuitively complementary, and several attempts have been made to merge them to get the benefits of both. An early example is (Ferrucci, 2012), which combines multiple expert systems and re-ranks them to produce the answer. More recent work attempts to enrich the KB by extracting structure from text. One way to accomplish this is using OpenIE triplets (Fader et al., 2014; Xu et al., 2016), thus staying completely within the semantic parsing paradigm. Somewhat closer to our approach are UniversalSchemas (Riedel et al., 2013; Das et al., 2017), which embed KB relations and textual relations in a common space. Yet, UniversalSchemas are also constrained to an entity-relation structure. The latest in this line are the works of (Sun et al., 2018, 2019), which augments the knowledge graph with text nodes and applies graph methods to identify candidate answers.

By retaining structure, previous work was able to take advantage of KBQA methods, but also failed to capture the full richness of TextQA. We depart radically in our approach, by foregoing all structure, and directly applying TextQA methods based on the more general *retriever-reader* architecture. We also evaluate on a more diverse benchmark set composed of natural open domain datasets, as well as those originally meant for KBQA, and demonstrate strong improvements in this truly open-domain setting. Concurrent work (Agarwal et al., 2021) proposed a similar idea for language model pretraining and also evaluated on open-domain QA. Our work differs in that (1) we have a more comprehensive treatment of sources (including tables, lists and multiple KBs) and ODQA datasets, (2) we compare against and improve on much stronger state-of-the-art baselines, and (3) we also evaluate in a more realistic multi-dataset setting with all datasets handled by a single model.

3 Modeling

3.1 `UniK-QA` architecture

We use a retriever-reader architecture, with *dense passage retriever* (DPR) (Karpukhin et al., 2020) as retriever and *fusion-in-decoder* (FiD) (Izacard and Grave, 2021) as our reader. Structured knowledge such as tables, lists and KB relations are converted to text with simple heuristics (§3.2, §3.3), and we generalize DPR to retrieve from these heterogeneous documents as well as regular text passages. Each retrieved document is concatenated with the question, then independently encoded by the reader encoder. Fusion of information happens in the decoder, which computes full attention over the entire concatenated input representations. The overall architecture is illustrated in Figure 1.

Retriever The DPR retriever consists of a dense document encoder and a question encoder, trained such that positive documents have embeddings closer to the question embedding in dot product space. We follow the original DPR implementation and hyperparameters (see §7). We further include tables, lists and KB relations in the index. The details of how these are processed into documents and merged are in the subsequent sections.

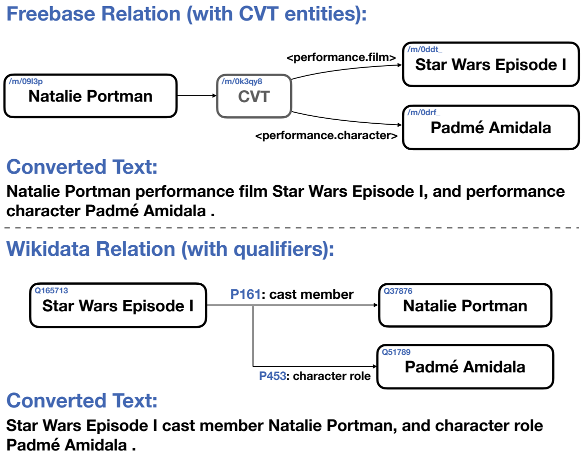
One improvement we make to the training process is iterative training, where better hard negatives are mined at each step using the model at the previous step, similar to (Xiong et al., 2021a). All models including our text-only baselines benefit from this change. We find 2 iterations sufficient.

Reader The FiD reader has demonstrated strong performance in the text-only setting and effective in fusing information from a large number of documents (Izacard and Grave, 2021). We thus find it a natural candidate for fusing knowledge from various sources. We use the FiD model with T5-large (Raffel et al., 2020), 100 context documents, and the original hyper-parameters for all experiments. See §7 for more implementation details.

3.2 Unified representations for KBs

In order to apply our retriever-reader model, we first convert KB relations into text using simple heuristics. For a relation triple $\langle subj, pred, obj\rangle$, where $subj$, $pred$ and obj are the subject, predicate and object of the relation respectively, we serialize it by concatenating the text surface forms of $subj$, $pred$ and obj.

More complex (n-ary) relations involve multiple predicates and objects, such as *Natalie Portman played the character Padmé Amidala in the movie Star Wars*, and can be expressed differently depending on the KB. In particular, Freebase uses *compound value types* (CVTs) to convert an n-ary relation into multiple standard triples, while Wikidata allows a predicate to have *qualifiers* to express additional properties (Tanon et al., 2016). In this work, we convert an n-ary relation into a single sentence by forming a comma-separated clause for each predicate (Figure 2).[2]



Natalie Portman performance film Star Wars Episode I, and performance character Padmé Amidala .

Star Wars Episode I cast member Natalie Portman, and character role Padmé Amidala .

Figure 2: Converting Freebase and Wikidata relations to text.

Besides our heuristic-based linearization of KB relations, there are alternatives such as template-based or model-based methods. Since KBs such as Freebase and Wikidata have hundreds of thousands of different types of relations, it is prohibitive to come up with templates for each relation type. On the other hand, model-based linearization achieves worse retrieval recall than our simple heuristics despite being much more expensive. In particular, we experiment with a top-ranked KB-to-text model (Li et al., 2020b) from the WebNLG 2020 challenge (Castro Ferreira et al., 2020), which is based on T5-large. Preliminary results on KBQA show that the WebNLG model achieves a 87.9% retrieval recall @100 on the dev set of WebQSP (Yih et al., 2016), while our simple heuristics performs better at 94.7%. We hence stick with our simple heuristics in all experiments.

Once converted to text, relations can be indexed and retrieved using DPR. We use existing TextQA DPR checkpoints for retrieving KB relations with-

---

[2] A side benefit of this approach is that these complex relations are now represented as a single piece of text, whereas they would normally be considered multi-hop and require more complex methods (Fu et al., 2020) if using traditional graph-based KBQA models.

out any retraining. We index individual relations to best leverage the power of DPR for retrieving the most relevant relations for a given question[3]. Unlike most existing KBQA works, our approach can also seamlessly incorporate multiple KBs by storing all relations into a joint index and retrieving from it (see §5.4).

Directly indexing billions of relations in the entire KB can bring additional engineering challenges. To avoid these, we implement retrieval of relations in two steps, where an entity linking system is used in the first step to narrow down the search to a high-recall 2-hop neighborhood of the retrieved entities for each question (We use STAGG (Yih et al., 2015) in the case of Freebase and ELQ (Li et al., 2020a) for Wikidata). We then use DPR to retrieve relations from this reduced set. As the relation representations are usually short sentences, we combine retrieved relations into passages of at most 100 tokens, after which they are fed to the FiD reader in the same way as text paragraphs.

3.3 Unified representations for lists & tables

Karpukhin et al. (2020) excludes lists and tables from their passage collection. For lists, we simply retain them as part of the text documents without special preprocessing, which improves retrieval recall in our experiments (see Table 4 in §6). We now discuss about our treatment of tables.

English Wikipedia contains more than 3 million tables ('classical' tables embedded in text as well as specialized tables like info-boxes), which are a huge source of factual knowledge by themselves and can substantially increase the coverage of open-domain QA systems. For instance, the answer to approximately a quarter of the questions in the NaturalQuestions (NQ) dataset can be found in Wikipedia tables (Kwiatkowski et al., 2019).

We start from a large subset of Wikipedia tables extracted and released as part of the NaturalQuestions dataset. We include all candidate documents which are part of the training set, extract nested tables into independent units, and filter out single-row tables as well as 'service' tables. This results in a corpus of 455,907 tables, which are used in our experiments.

As with KB relations, semi-structured content in tables need to be 'linearized' into text for the *retriever-reader* model to work. There are many ways to do such linearization (see Yin et al., 2020; Chen et al., 2020a). We tried two types of tables linearization: 'template'-like encoding used in recent literature (Chen et al., 2020a) and a simpler one which we find works the best in our experiments (see Table 4, bottom half). In particular, we concatenate cell values on the same row, separated by commas, to form the text representation, and multiple rows are then combined into longer documents delimited by newlines. As with TextQA, we divide linearized tables into 100-token chunks for indexing and retrieval. We take the first non-empty table row as the *header* and include it in every table chunk. This heuristic to select the first non-empty row as header is crucial and adds 4-6 points to top-20 passage accuracy.

Model	**Hits@1**

Table 1: Hits@1 on WebQSP dataset using Freebase. (*)EmQL uses oracle entities, hence is not directly comparable with the others.

4 KBQA as TextQA: A Motivating Experiment

In this section, we present a motivating experiment showing that our `UniK-QA` approach not only provides a natural pathway to multi-source open-domain QA, but also improves KBQA per se. In particular, we evaluate our approach on a widely-used KBQA dataset, WebQSP (Yih et al., 2016), in the single-source setting.

We use Freebase as the knowledge source, and re-use pre-computed STAGG entity linking results and 2-hop neighborhoods as provided by Sun et al. (2018) for fair comparisons. We convert KB relations in the 2-hop neighborhood into text, retrieve the most relevant ones using DPR to form 100 context passages, and feed them into the T5 FiD reader as described in Section 3.2. We use the original DPR checkpoint from Karpukhin et al. (2020) for retrieval, and train FiD using the training questions in WebQSP and the DPR-retrieved contexts with default hyperparameters (see §7). The

---

[3] Indexing at a coarser granularity (such as creating a document for each entity) also has practical challenges because certain entities (e.g., United States) may have hundreds of thousands of relations, resulting in extremely long documents.

results are shown in Table 1, where the numbers represent *Hits@1*, or the percentage of the model's top-predicted answer being a "hit" (exact match) against one of the gold-standard answers.

We see that our KBQA method outperforms previous state-of-the-art methods by a wide margin, improving exact match accuracy to 79.1%. Since we adopt the exact same KB setup and pre-processing procedure from previous work, this improvement can be attributed purely to our `UniK-QA` model. We take this result as strong evidence for our claim that powerful TextQA methods generalize well to structured data, and offer a natural new framework for unifying structured and unstructured information sources.

5 Multi-Source QA Experiments

We now present our main experiments on unified multi-source question answering.

5.1 Datasets

For our main experiments, we use the same datasets that have recently become somewhat standard for evaluating open-domain QA (Lee et al., 2019):

NaturalQuestions (NQ) (Kwiatkowski et al., 2019) consists of questions mined from real Google search queries and Wikipedia articles with answer spans annotated. While the answer spans are usually on the regular, free-form text, some span annotations are in tables.

WebQuestions (WebQ) (Berant et al., 2013) targets Freebase as the source of answers, with questions coming from Google Suggest API.

TriviaQA (Trivia) (Joshi et al., 2017) contains a set of trivia questions with answers originally scraped from the Web.

CuratedTREC (TREC) (Baudiš and Šedivý, 2015) is a collection of questions from TREC QA tracks and various Web sources, intended to benchmark open-domain QA on unstructured text.

5.2 Combinations of sources

We compare 5 variations of our model, each with a different combination of information sources. We have *Text*-only, *Tables*-only and *KB*-only variants as single-source baselines. Next, the *Text + tables* model makes use of the entire Wikipedia dump, including lists and tables. Finally we add the KBs resulting in the *Text + tables + KB* model.

The *Text + tables* model uses a unified dense index, where text passages and table chunks are jointly indexed. For the *Text + tables + KB* model, the KB relations are indexed separately. As described in §3.2, we use DPR to retrieve individual KB relations for each question, and the top-scoring KB relations are concatenated into 100-token passages to be fed to the reader. These passages are then merged with the passages retrieved from the *Text + tables* index using a fixed quota for KB relations. This quota is determined by maximizing retrieval recall on the development set (see §7.3). We also experiment with combining multiple KBs by using DPR to jointly retrieve from all relations of both KBs, which is straightforward to implement with our approach despite differences in the KB structure.

5.3 A multi-dataset model

In a realistic setting, the best knowledge source to answer a given question is unknown *a priori* to the system, but most open-domain QA datasets are collected with respect to a specific information source (e.g., Wikipedia for NQ and Freebase for WebQ). To better simulate the real-world scenario, we also experiment with a setting where we train a single model on the combination of all 4 datasets and evaluate without any input to the model as to the source of questions.[4] We refer to this as the *multi-dataset* setting. This setting was previously investigated in several works (Karpukhin et al., 2020; Maillard et al., 2021; Qi et al., 2021), but not in the multi-source context. We train multi-dataset models for all 5 variants described above. The smaller datasets, WebQ and TREC, are upsampled 5 and 8 times respectively while training.

5.4 Results

Main results are presented in Table 2. In the first set of experiments, we train a reader model independently for each dataset, as typically done in previous work. We use Freebase as knowledge base for WebQuestions as intended, and use Wikidata for all others. The multi-dataset model uses Wikidata.

The results highlight the limitation of current state-of-the-art open-domain QA models which use texts as the only information source. On WebQ, for instance, the KB-only model performs 5% better than the text-only one, and previous state of the art is also achieved by the KBQA model. Moreover,

---

[4] We normalize the questions by removing question marks and by presenting them in lowercase.

Model	NQ	WebQ	Trivia	TREC	Avg.
SoTA	51.4[1]	55.1[3]	67.6[1]	55.3[2]	57.3
Retrieval-free	28.5[4]	30.6[4]	28.7[4]	-	-

Table 2: Exact match results on the test set. SoTA numbers are from (Izacard and Grave, 2021)[1], (Iyer et al., 2021)[2] which are TextQA approaches, and (Jain, 2016)[3], which is a KBQA method. (Jain, 2016) reports another metric; however, their predictions are available from which we calculated the EM score. Retrieval-free numbers refer to closed-book results from Roberts et al. (2020)[4] with the same T5 model.

Source(s)	NQ	WebQ	Trivia	TREC
KB-only (1 KB)	27.9	55.6	35.4	32.4
KB-only (2 KBs)	30.9	56.7	41.5	36.0
All (1 KB)	54.0	**57.8**	64.1	**55.3**
All (2 KBs)	**54.9**	57.7	**65.5**	54.0

Table 3: Results for combining Freebase and Wikidata.

adding structured information sources significantly improves the performance over text-only models on *all* datasets, obtaining state-of-the-art results for NQ, WebQ and TREC. This indicates that KBs and tables contain valuable knowledge which is either absent in the unstructured texts or harder to extract from them (see also §6).

In the *multi-dataset* setting, we also observe clear improvements from combining sources, with the *Text + tables + KB* model outperforming the *Text*-only baseline by 5.4 points on average. The performance is generally lower than the per-dataset models, especially for the small datasets (WebQ and TREC), which may be due to the fact that each of these datasets was collected on a single information source and the multi-dataset model is less likely to exploit this prior knowledge.

Multiple KBs We also experiment with combining *both* Wikidata and Freebase. We see substantial improvements on all datasets in the KB-only setting over using a single KB, as well as significant gains over our best numbers for NQ and TriviaQA in the *Text+tables+KB* setting (Table 3).

6 Analysis

Having demonstrated that combining information sources does improve answer accuracy, we now provide more analysis on *how* this is achieved by inspecting both retriever and reader closely.

Retriever One natural assumption is that adding more data increases the coverage of relevant contexts that can be used to answer the input questions, thereby improving the end-to-end performance. We verify this by examining the retrieval results of different models using the NQ development set, where a context is considered relevant if it contains the correct answer string. When more knowledge sources are added, our system is able to improve retrieval *recall* (Table 4, top half), which may correlate with the end-to-end answer accuracy shown in Table 2.

Reader Although including additional information sources improves the chance of retrieving relevant contexts, it is not guaranteed that the reader can leverage those contexts and output the correct answers. For instance, reader model training may benefit from diverse sources of contexts, and the end-to-end improvement of answer accuracy may simply be attributed to a reader model that per-

Model	**R@20**	**R@100**
Text-only	80.0	85.9
w/ lists	82.7	89.6
w/ tables	83.1	91.0
w/ lists + tables	85.0	92.2
w/ lists + tables + KB	83.4	92.8
Tables-only		
simple linearization	86.3	94.3
template linearization	60.8	69.4

Table 4: Retrieval recall on the NQ dev set with different settings. Tables only results are for the NQ dev subset which has answers in tables.

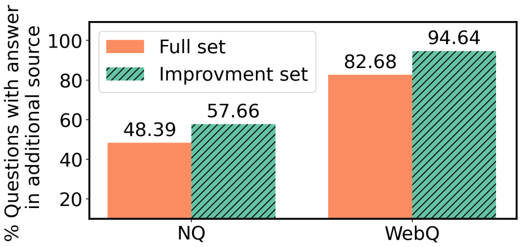

Figure 3: Percentage of questions with answers in additional sources. For NQ the additional sources are list and tables. For WebQ the additional source is KB.

forms better on contexts from regular text. Due to the nature of the FiD generative reader, however, it is non-trivial to ascertain which input context(s) contribute the answer. As a proxy, we look at the correlation between the source of *positive* contexts (those which contain a correct answer string) feeding into the reader model and the performance change in the outcome.

Suppose we are comparing two reader models M_u and M_t, where M_u uses additional sources of information compared to M_t (e.g., M_t uses text only and M_u uses text and KB). Let Q be all the questions in our development set, $Q_u \subseteq Q$ and $Q_t \subseteq Q$ the subsets of questions answered correctly by M_u and M_t, respectively. The *improvement* set $Q' = Q_u - Q_t$ is thus the questions that M_u manages to improve upon M_t. Examining the source of the positive contexts for the questions in Q' can help shed some light on how M_u performs better. For example, if more positive contexts are from KB rather than text, then the improvement is more likely due to additional information present at inference time. Figure 3 plots the percentages of positive contexts originating from the additional sources for the questions in the full development set (Q) vs those in the improvement set (Q') in two cases. The first one compares a baseline *text*-only model to a model with lists and tables added on NQ, and the second compares a *text+tables* model with *text+tables+KB* on WebQ. In both cases, answers retrieved from the additional source correlate with a better outcome.

To examine the effects of other indirect factors, such as the change of overall model quality due to the inclusion of varied sources or more training samples from the tables, we evaluate the *text + tables* model with text-only input. We find that this achieves similar performance (48.7 EM) on the NQ test set compared to a *text*-only model on the same input, suggesting that these other factors are not a major contributor and that the improved performance is primarily due to the added knowledge from structured sources.

7 Implementation Details

The code, data, and trained model checkpoints of `UniK-QA` are available at: `https://github.com/facebookresearch/UniK-QA`.

7.1 DPR Training

Our DPR model is trained on the entire Wikipedia dump, including lists and tables, as described in §3.3. Specifically, lists are treated as normal texts and included in standard text passages, while tables are converted to their own "passages" using our linearization approach. We combine all these passages from the text, lists and tables into the Wikipedia passage collection, and train DPR using the standard setup (Karpukhin et al., 2020): We use BERT-base (Devlin et al., 2019) encoders, 100-token text passages, and a single negative document per question. Negatives are mined with BM25 in the first iteration, and from the first iteration model for the second iteration. We train for 40 epochs with a linear warmup of 500 steps, batch size of 128 and learning rate 10^{-5}.

As mentioned in §3.2, we do not retrain DPR for retrieving KB relations. The public DPR checkpoint for open-domain question answering is used in our WebQSP experiment (§4), while we use our own DPR model trained on text, lists and tables for retrieving KB relations in our multi-source QA experiments (§5).

KB Quota	NQ	WebQ	TREC	Trivia
Wikipedia + Wikidata	10	30	10	10
Wikipedia + Freebase	10	40	10	20
Wikipedia + Wikidata & Freebase	10	30	10	20

Table 5: The quota of "passages" converted from KB relations in each experiment.

7.2 FiD Training

We adopt the FiD model with T5-large (Raffel et al., 2020) and 100 context documents and use the original hyper-parameters of FiD (Izacard and Grave, 2021) whenever possible. In particular, the Adam (Kingma and Ba, 2015) optimizer is used with a constant learning rate of 0.0001. The model is trained for $10k$ steps, with a batch size of 64, using 64 V100 GPUs. We did not perform any hyper-parameter search.

7.3 Merging KB and Text

As mentioned in §5.2, we tune the quota for KB relations by maximizing retrieval recall on the development set. Table 5 shows the number of KB "passages" (out of 100 total context passages) selected in our final model. The text and KB passages are interleaved in the final context passages.

For each dataset, the KB quota (which can also be interpreted as the helpfulness of the KB) is relatively stable across different choices of KBs. WebQuestions has the highest KB quota, which is expected given that it was originally collected as a KBQA dataset. Experimental results in Table 2 also confirm that using KB brings the most gains on WebQuestions.

8 Discussion

We demonstrated a powerful new approach, `UniK-QA`, for unifying structured and unstructured information sources for open-domain question answering. We adopt the simple and general *retriever-reader* framework and show not only that it works for structured sources, but improves over traditional KBQA approaches by a wide margin. By combining sources in this way, we achieved new state-of-the-art results for two popular open-domain QA benchmarks.

However, our model also has several shortcomings in its current form. As a result of flattening all sources into text, we lose some desirable features of structured knowledge bases: the ability to return *all* answers corresponding to a query, and the ability to infer multi-hop paths to answer more complex questions. In this work we have side-stepped the first issue by focusing on the exact match metric (equivalent to Hits@1), which is standard in the open-domain QA literature, but largely ignores multiple answers. We were also able to ignore the second issue, since the datasets we evaluated on, while standard, are composed mostly of simple, natural user questions which can be answered from a single piece of information.

We do believe these are important details and they can be addressed within the framework described here. For instance, outgoing edges of an entity with the same relation can easily be merged, thus encoding all answer entities into a single text representation. It is also possible to simply generate multiple answer candidates from the reader's decoder. For multi-hop question answering, there is recent work (Xiong et al., 2021b) successfully extending dense retrieval to the multi-hop setting (Yang et al., 2018; Welbl et al., 2018), which could naturally be applied within our framework. It remains to be seen how these approaches would compare to more traditional structured methods.

White-box Testing of NLP models with Mask Neuron Coverage

Arshdeep Sekhon and **Yangfeng Ji** and **Matthew B. Dwyer** and **Yanjun Qi**
University of Virginia, USA

Abstract

Recent literature has seen growing interest in using black-box strategies like CHECKLIST for testing the behavior of NLP models. Research on white-box testing has developed a number of methods for evaluating how thoroughly the internal behavior of deep models is tested, but they are not applicable to NLP models. We propose a set of white-box testing methods that are customized for transformer-based NLP models. These include MASK NEURON COVERAGE (MNCOVER) that measures how thoroughly the attention layers in models are exercised during testing. We show that MNCOVER can refine testing suites generated by CHECKLIST by substantially reduce them in size, for more than 60% on average, while retaining failing tests – thereby concentrating the fault detection power of the test suite. Further we show how MNCOVER can be used to guide CHECKLIST input generation, evaluate alternative NLP testing methods, and drive data augmentation to improve accuracy.

1 Introduction

Previous NLP methods have used black-box testing to discover errors in NLP models. For instance, Checklist(Ribeiro et al., 2020) introduces a black-box testing strategy as a new evaluation methodology for comprehensive behavioral testing of NLP models. CheckList introduced different test types, such as prediction invariance in the presence of certain perturbations.

Black-box testing approaches, like Checklist, may produce distinct test inputs that yield very similar internal behavior from an NLP model. Requiring that generated tests are distinct both from a black-box and a white-box perspective – that measures test similarity in terms of latent representations – has the potential to reduce the cost of testing without reducing its error-detection effectiveness. Researchers have explored a range of white-box coverage techniques that focus on neuron activations and demonstrated their benefit on architecturally simple feed-forward networks (Pei et al., 2017; Tian et al., 2018; Ma et al., 2018a; Dola et al., 2021). However, transformer-based NLP models incorporate more complex layer types, such as those computing self-attention, to which prior work is inapplicable.

In this paper, we propose a suite of white-box coverage metrics. We first adapt the k-multisection neuron coverage measure from (Ma et al., 2018a) to Transformer architectures. Then we design a novel MNCOVER coverage metric, tailored to NLP models. MNCOVER focuses on the neural modules that are important for NLP and designs strategies to ensure that those modules' behavior is thoroughly exercised by a test set. Our proposed coverage metric, when used to guide test generation, can cost-effectively achieve high-levels of coverage.

Figure 1 shows one example of how MNCOVER can work in concert with CheckList to produce a small and effective test set. The primary insight is that not all text sentences contain new information that will improve our confidence in a target model's behavior. In this list, multiple sentences were generated with similar syntactic and semantic structure. These sentences cause the activation of sets of attention neurons that have substantial overlap. This represents a form of redundancy in testing an NLP model. Coverage-based filtering seeks to identify when an input's activation of attention neurons is subsumed by that of prior test inputs – such inputs are filtered. In the Figure the second and third sentences are filtered out because their activation of attention neurons is identical to the first test sentence. As we show in §4 this form of filtering can substantially reduce test suite size while retaining tests that expose failures in modern NLP models, such as BERT.

The primary contributions of the paper lie in:

- Introducing MNCOVER a test coverage metric designed to address the attention-layers that

The customer service was exceptional

Figure 1: Example of our proposed MNCOVER's filtering on a set of test examples.

are characteristic of NLP models and to account for the data distribution by considering task-specific important words and combinations.

- Demonstrating through experiments on 2 NLP models (BERT, Roberta), 2 datasets (SST-2, QQP), and 24 sentence transformations that MNCOVER can substantially reduce the size of test sets generated by CheckList, by 64% on average, while improving the failure detection of the resulting tests, by 13% on average.
- Demonstrating that MNCOVER provide an effective supplementary criterion for evaluating the quality of test sets and that it can be used to generate augmented training data that improves model accuracy.

2 Background

Coverage for testing deep networks The research of Coverage testing focuses on the concept of "adequacy criterion" that defines when "enough" testing has been performed. The white-box coverage testing has been proposed by multiple recent studies to test deep neural networks (Pei et al., 2017; Ma et al., 2018a,b; Dola et al., 2021). DeepXplore (Pei et al., 2017), a white-box differential testing algorithm, introduced Neuron Coverage for DNNs to guide systematic exploration of DNN's internal logic. Let us use $\mathbf{D}$ to denote a set of test inputs (normally named as a test suite in behavior testing). The Neuron Coverage regarding $\mathbf{D}$ is defined as the ratio between the number of unique activated neurons (activated by $\mathbf{D}$) and the total number of neurons in that DNN under behavior testing. A neuron is considered to be activated if its output is higher than a threshold value (e.g., 0). Another closely related study, DeepTest (Tian et al., 2018), proposed a gray-box, neuron coverage-guided test suite generation strategy. Then, the study DeepGauge (Ma et al., 2018a) expands the neuron coverage definition by introducing the kmultisection neuron coverage criteria to produce a multi-granular set of DNN coverage metrics. For a given neuron $\mathbf{n}$, the kmultisection neuron coverage measures how thoroughly a given set of test inputs like $\mathbf{D}$ covers the range $[low_n, high_n]$. The range $[low_n, high_n]$ is divided into k equal bins (i.e., k-multisections), for $k > 0$. For D and the target neuron $\mathbf{n}$, its k-multisection neuron coverage is then defined as the ratio of the number of bins covered by D and the total number of bins, i.e., k. For an entire DNN model, the k-multisection neuron coverage is then the ratio of all the activated bins for all its neurons and the total number of bins for all neurons in the DNN.

Transformer architecture NLP is undergoing a paradigm shift with the rise of large scale Transformer models (e.g., BERT, DALL-E, GPT-3) that are trained on unprecedented data scale and are adaptable to a wide range of downstream tasks(Bommasani et al., 2021).

These models embrace the Transformer architecture (Vaswani et al., 2017) and can capture long-range pairwise or higher-order interactions between input elements. They utilize the self-attention mechanism(Vaswani et al., 2017) that enables shorter computation paths and provides parallelizable computation for learning to represent a sequential input data, like text. Transformer receives inputs in the general form of word tokens. The sequence of inputs is converted to vector embeddings that get repeatedly re-encoded via the self-attention mechanism. The self-attention can repeat for many layers, with each layer re-encoding and each layer maintaining the same sequence length. At each layer, it corresponds to the following operations to learn encoding of token at position i:

$$\alpha^{ij} = \text{softmax}\big((\mathbf{W}^q \boldsymbol{h}_i)^\top (\mathbf{W}^k \boldsymbol{h}_j)/\sqrt{d}\big) \quad (1)$$

$$\bar{\boldsymbol{h}}_i = \sum_{j=1}^{M} \alpha^{ij} \mathbf{W}^v \boldsymbol{h}_j \quad (2)$$

$$\boldsymbol{h}'_i = \sigma(\bar{\boldsymbol{h}}_i \mathbf{W}^r + \boldsymbol{b}_1)\mathbf{W}^o + \boldsymbol{b}_2. \quad (3)$$

Here $\mathbf{W}^k$ is the key weight matrix, $\mathbf{W}^q$ is the query weight matrix, $\mathbf{W}^v$ is the value weight matrix, $\mathbf{W}^r$ and $\mathbf{W}^o$ are transformation matrices, and $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$ are bias vectors.

3 Method

State-of-the-art NLP models are large-scale with millions of neurons, due to large hidden sizes and multiple layers. We propose to simplify and view these foundation models (Bommasani et al., 2021) through two levels of granularity: (1) *Word Level*: that includes the position-level embeddings at each

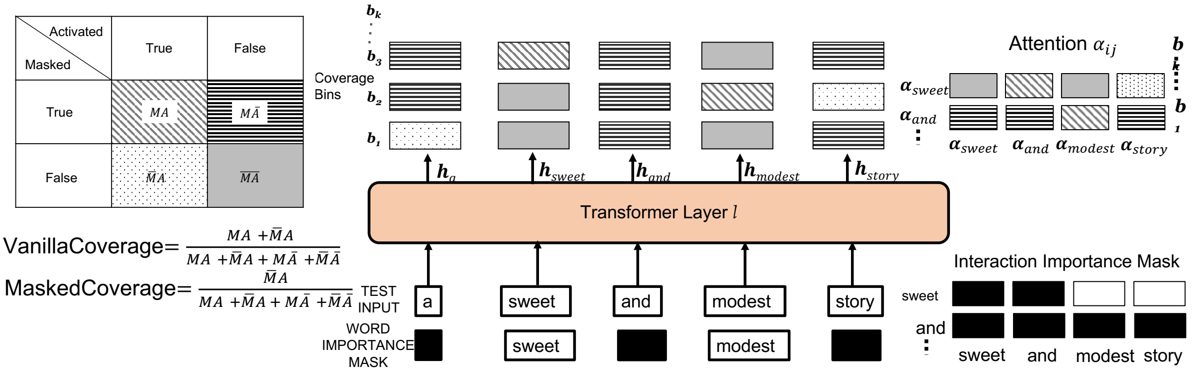

Figure 2: A visual depiction of MNCOVER for masking neurons to measure coverage.

layer and (2) *Pairwise Attention Level*: that includes the pairwise self-attention neurons between two positions at each layer. In the rest of this paper, we denote the vector embeddings at location i for layer l as $\mathbf{h'}_i^l$ and name these as the *word level neurons* at layer l. We also denote the α^{ij} at layer l and head h as α_{lk}^{ij}, and call them as the *attention level neurons* at layer l.

3.1 Extending Neuron Coverage (COVER) for Testing NLP Model

Now we use the above two layers' view we proposed, to adapt the vanilla neuron coverage concepts from the literature to NLP models. First, we introduce a basic definition: "activated neuron bins" (Ma et al., 2018b):

Definition 1 *Activated Neuron Bins (ANB): For each neuron, we partition the range of its values (obtained from training data) into B bins/sections. We define ANB for a given text input if the input's activation value from the target neuron falls into the corresponding bin range.*

Then we adapt the above definition to the NLP model setting, by using the after-mentioned two layers' view. We design two phrases: Word Neuron Bins, and Activated Word Neuron Bins in the following Definition (2).

Definition 2 *Activated Word Neuron Bins(AWB): We discretize the possible values of each neuron in $\mathbf{h}_t'^{\ell}$ (whose d-th embedding dimension is $\mathbf{h}_{dt}'^{\ell}$) into B sections. We propose a function ϕ_w who takes two arguments, as $\phi_w(h_{dt}'^{lb}, \mathbf{x})$ for a given input $\mathbf{x}$. $\phi_w(h_{dt}'^{lb}, \mathbf{x}) = 1$ if it is an activated word neuron bin (shortened as AWB), else 0 if not activated.*

Similarly, for our attention neuron at layer l, head k, word position i and position j: α_{ij}^{lk}, we introduce the definition of "attention neuron bins" and "Activated Attention Neuron Bins" in the following Definition (3).

Definition 3 *Activated Attention Neuron Bins (AAB): We discretize the possible values of neuron α_{ij}^{lk} into B sections. We denote the state of the b^{th} section of this attention neuron using $\phi_a(\alpha_{lk}^{ijb}, \mathbf{x})$. $\phi_a(\alpha_{lk}^{ijb}, \mathbf{x}) = 1$ if it is an activated attention neuron bin (denoted by AAB) by an input $\mathbf{x}$ and $\phi_a(\alpha_{lk}^{ijb}, \mathbf{x}) = 0$ if not activated.*

$$\mathbb{N}(\mathrm{AWB}(\mathbf{x})) = \sum_{ltdb} \phi_w(h_{dt}'^{lb}, \mathbf{x}) \tag{4}$$

$$\mathbb{N}(\mathrm{AAB}(\mathbf{x})) = \sum_{ijbk} \phi_a(\alpha_{lk}^{ijb}, \mathbf{x}) \tag{5}$$

The coverage, denoted by COVER, of a dataset $\mathcal{T}$ for a target model is then defined as the ratio between the number of "activated" neurons and total neurons:

$$\textsc{Cover} = \frac{\mathbb{N}(\mathrm{AWB}) + \lambda \mathbb{N}(\mathrm{AAB})}{\mathbb{N}(\mathrm{WB}) + \lambda \mathbb{N}(\mathrm{AB})} \tag{6}$$

Here, λ is a scaling factor.

Now let us assume the total number of layers be D, total number of heads H, maximum length L, total bins B and total embedding size be E. Considering the example case of the BERT(Devlin et al., 2019) model, total number of word level neurons to be measured are then $L \times E \times D = 128 \times 768 \times 13 \sim 0.1 million$. The total number of the attention level neurons is then $L \times L \times H \times D = 128 \times 128 \times 12 \times 12 \sim 2 million$.

3.2 MASK NEURON COVERAGE (MNCOVER)

However, accounting for every word and attention neuron's behavior for a large pre-trained model like BERT is difficult for two reasons: (1). If we desire to test each neuron at the output of all transformer layers in each BERT layer, we need to account for the behavior of every neuron, which for a

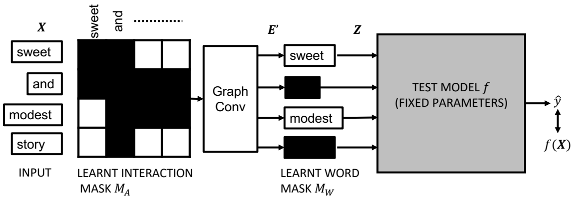

Figure 3: Learning the masks prior to testing: Globally important words and interactions are learnt by masking inputs to a target model.

large pre-trained model like BERT is in the order of millions. (2). If we test every possible neuron, we need to track many neurons that are almost irrelevant for a target task and/or model. This type of redundancy makes the behavior testing less confident and much more expensive.

To mitigate these concerns, we propose to only focus on important words and their combinations that may potentially contain 'surprising' new information for the model and hence need to be tested.

We assume we have access to a word level importance mask, denoted by $\mathbf{M}_W \in \{0,1\}^{|V|}$ and the interaction importance mask by $\mathbf{M}_A \in \{0,1\}^{|V|\times|V|}$. Each entry in $\mathbf{M}_{W w_t} \in \{0,1\}$ represents the importance of word w_t. Similarly, each entry in $\mathbf{M}_{A\mathbf{x}_i,\mathbf{x}_j} \in \{0,1\}$ represents the importance of interaction between token w_{t_i} and w_{t_j}. These masks aim for filtering out unimportant tokens (and their corresponding neurons at each layer) for measuring coverage signals. We apply the two masks at each layer to mask out unimportant attention pairs to prevent them from being counted towards coverage calculation. With the masks, the AWB and AAB are revised and we then define MASK NEURON COVERAGE (MNCOVER) accordingly:

$$\mathbb{N}(\text{Mask-AWB}(\mathbf{x})) = \sum_{ltdb} \mathbb{M}_{w\mathbf{x}_t} * \phi_w(h'^{lb}_{dt}, \mathbf{x})$$

$$\mathbb{N}(\text{Mask-AAB}(\mathbf{x})) = \sum_{ijkb} \mathbb{M}_{a\mathbf{x}_i,\mathbf{x}_j} * \phi_a(\alpha^{ijb}_{lk}, \mathbf{x})$$

$$\text{MNCOVER} = \frac{\mathbb{N}(\text{Mask-AWB}) + \lambda\mathbb{N}(\text{Mask-AAB})}{\mathbb{N}(\text{WB}) + \lambda\mathbb{N}(\text{AB})} \tag{7}$$

3.3 Learning Importance Masks

In this section, we explain our mask learning strategy that enables us to learn globally important words and their pairwise combinations for a model's prediction without modifying a target model's parameters.

We learn the two masks through a bottleneck strategy, that we call WIMASK layer. Given a target model f, we insert this mask bottleneck layer between the word embedding layer of a pretrained NLP model and the rest layers of this model. Figure 3 shows a high level overview of the mask bottleneck layer. Using our information bottleneck layer, we learn two masks : (1) a word level mask $\mathbf{M}_A$, (2) an interaction mask $\mathbf{M}_W$.

Learning Word-Pair Interaction Importance Mask: $\mathbf{M}_A$ The interaction mask aims to discover which words globally interact for a prediction task. We treat words as nodes and represent their interactions as edges in an interaction graph. We represent this unknown graph as a matrix $\mathbf{M}_A = \{\mathbf{M}_{Aij}\}_{V\times V}$. Each entry $\mathbf{M}_{A\mathbf{x}_i,\mathbf{x}_j} \in \{0,1\}$ is a binary random variable, such that $\mathbf{M}_{Aij} \sim Sigmoid(\lambda_{ij})$, follows Bernoulli distribution with parameter $Sigmoid(\lambda_{ij})$. $\mathbf{M}_{Aij}$ specifies the presence or absence of an interaction between word i and word j in the vocabulary $\mathbb{V}$. Hence, learning the word interaction graph reduces to learning the parameter matrix $\lambda = \{\lambda_{ij}\}_{V\times V}$. In Section 3.3.1, we show how λ (and therefore $\mathbf{M}_A$) is learned through a variational information bottleneck loss formulation (details in Section (A.2)).

Based on the learnt interaction mask $\mathbf{M}_A$, each word embedding $\mathbf{x}_i$ is revised using a graph based summation from its interacting neighbors' embedding $\mathbf{x}_j, j \in \mathcal{N}(i)$:

$$\mathbf{e}'_i = \mathbf{x}_i + \sigma\left(\frac{1}{|\mathcal{N}(i)|}\sum_{j\in\mathcal{N}(i)} \mathbf{x}_j\mathbf{W}\right) \tag{8}$$

$\sigma(\cdot)$ is the ReLU non-linear activation function and $\mathbf{W} \in \mathbb{R}^{H\times H}$ is a weight matrix. We denote the resulting word representation vector as $\mathbf{e}'_i$. Here $j \in \mathcal{N}(i)$, and $\mathcal{N}(i)$ denotes those neighbor nodes of $\mathbf{x}_i$ on the graph $\mathbf{M}_A$ and in $\mathbf{x}$. Eq. (8) is motivated by the design of Graph convolutional networks (GCNs) that were introduced to learn useful node representations that encode both node-level features and relationships between connected nodes (Kipf and Welling, 2016). Differently in our work, we need to learn the graph $\mathbf{M}_A$, through the λ parameter. We can compute the simultaneous update of all words in input text $\mathbf{x}$ together by concatenating all $\mathbf{e}'_i$. This gives us one matrix $\mathbf{E}' \in \mathbf{M}_W^{L\times H}$, where L is the length of input and H is the embedding dimension of $\mathbf{x}_i$.

Learning Word Importance Mask: M_W This word mask aims to learn a global attribution word mask $\mathbf{M}_W$. Aiming for better word selection, $\mathbf{M}_W$ is designed as a learnable stochastic layer with $\mathbf{M}_W \in \{0,1\}^V$. Each entry in $\mathbf{M}_W$ (e.g., $\mathbf{M}_{W_w} \in \{0,1\}$ for word w) follows a Bernoulli distribution with parameter p_w. The learning reduces to learning the parameter vector $\mathbf{p}$.

During inference, for an input text $\mathbf{x}$, we get a binary vector $\mathbf{M}_{W\mathbf{x}}$ from $\mathbf{M}_W$ that is of size L. Its i-th entry $\mathbf{M}_{W\mathbf{x}_i} \in \{0,1\}$ is a binary random variable associated with the word token at the i-th position. $\mathbf{M}_{W\mathbf{x}}$ denotes how important each word is in an input text $\mathbf{x}$. Then we use the following operation (a masking operation) to generate the final representation of the i-th word: $\mathbf{z}_i = \mathbf{M}_{W\mathbf{x}_i}\mathbf{e'}_i$. We then feed the resulting $\mathbf{Z}$ to the target model f.

3.3.1 Learning Word and Interaction Masks for a target model f:

During training, we fix the parameters of target model f and only train the WIMASK layerto get two masks.

We learn this trainable layer using the following loss objective, with the derivation of each term explained in the following section:

$$\mathcal{L}(\mathbf{x}, f(\mathbf{x}), \hat{y}) = \ell_{f(\mathbf{x}),\hat{y}} + \beta_{sparse}\ell_{sparse} + \beta_i \ell prior_{\mathbf{M}_{W\mathbf{x}}} + \beta_g \ell_{prior_{\mathbf{M}_{A\mathbf{x}}}} \quad (9)$$

First, we want to ensure that model predictions with WIMASK layer added are consistent with the original prediction $f(\mathbf{x})$. Hence, we minimize the cross entropy loss $\ell_{f(\mathbf{x}),\hat{y}}$ between $f(\mathbf{x})$ and the newly predicted output $\hat{y}$ (when with the bottleneck layer).

Then ℓ_{sparse} is the sparsity regularization on $\mathbf{M}_{A\mathbf{x}}$, $\ell prior_{\mathbf{M}_W}$ is the KL divergence between $\mathbf{M}_W$ and a random bernoulli prior. Similarly, $\ell prior_{\mathbf{M}_A}$ is the KL divergence between $\mathbf{M}_A$ and a random bernoulli prior. We provide detailed derivations in Section A.2.

4 Experiments

Our experiments are designed to answer the following questions:

1. Will a test set filtered by MNCOVER find more errors from a SOTA NLP model?
2. Does MNCOVER achieve test adequacy faster, i.e. achieve higher coverage in fewer samples?
3. Does MNCOVER help us compare existing testing benchmarks?
4. Can MNCOVER help us automatically select non-redundant samples for better augmentation?

Datasets and Models We use pretrained model BERT-base(Devlin et al., 2019) and RoBERTa-base(Liu et al., 2019) provided by (Morris et al., 2020) finetuned on SST-2 dataset and Quora Question Pair (QQP) dataset. For the QQP dataset, we use the model finetuned on the MRPC dataset. We train a word level mask ($\mathbf{M}_W$) and an interaction mask ($\mathbf{M}_A$) for each of these settings. We use a learning rate of $1e-05$, $\beta_i = 0.001$, $\beta_g = 0.001$, and $\beta_s = 0.001$ for all models.

We have provided the test accuracy of the target models and the models trained with masks in Table 5. Note that the ground truth labels here are the *predictions* from the target model f without the WIMASK layer, as our goal is to ensure fidelity of the WIMASK $+f$ to the target model f. Table 5 shows that training the WIMASK $+f$ model maintains the target model's predictions f as indicated by higher accuracies.

4.1 Experiment 1: Removing Redundant Test Inputs during Model Testing

Motivation CHECKLIST (Ribeiro et al., 2020) provides a method to generate a large number of test cases corresponding to a target template. It introduces different transformations that can be used to generate samples to check for a desired behavior/functionality. For example, to check for a model's behavior w.r.t typos in input texts, it generates examples with typos and queries the target model. CHECKLIST then compares failure rates across models for the generated examples to identify failure modes. However, it does not provide a method to quantify the number of tests that need to be generated or to determine which examples provide the most utility in terms of fault detection. Such a blind generation strategy may suffer from sampling bias and give a false notion of a model's failure modes.

Setup We evaluate MNCOVER's ability to redundant test samples out of the generated tests for a target model. The different transformations used are summarized in Column I of Table 1, Table 2, and Table 6. We measure failure rate on an initial test set of size $N = 1500$. We then filter the generated tests based on our MNCOVER coverage criteria: if adding a test example into a test suite does not lead to an increase in its coverage, it is discarded. We then measure failure rate of the new filtered test set.

Results In Table 1, we observe that MNCOVER can select more failure cases for the BERT model

Table 1: Failure Rate(%) obtained using BERT model on the original dataset D, the dataset filtered using COVER coverage (D+COVER columns) and the dataset filtered with MNCOVER coverage (D+MNCOVER columns) from the Sentiment Test Suite. We report both the max failure rate as well as the mean in the subscript across 10 thresholds of coverage. Rows are sorted regarding the failure rate difference between the dataset filtered using MNCOVER and the original dataset (column $\Delta_{D+\text{MNCOVER}}$).

across all 23 transformation on SST-2 dataset. On average, both MNCOVER and COVER can help reduce more than 60% of the test suite size, and MNCOVER achieves a slight advantage over COVER. In Table 2, when using RoBERTa model, MNCOVER based filtering wins over the original dataset in 21 of 23 cases. The average improvement of MNCOVER regarding error detection is 7.29% on RoBERTa model and 13.78% on BERT model. We include similar results on QQP dataset in Table 6.

4.2 Experiment 2: Achieving Higher Dataset Coverage with Fewer Data Points

Motivation We revisit the question: given a test generation strategy, does adding more test samples necessarily add more information? In this set of experiments, we appeal to the software engineering notion of "coverage" as a metric of test adequacy. We show that we can reach a target level of test adequacy faster, i.e. a higher coverage, hence achieving more rigorous behavior testing, with fewer test examples, by using coverage as an indicator of redundant test samples.

Setup: We use the training set as seed examples and generate samples using transformations used in the previous experiment listed in Table 1. Similar to the previous set of examples, we disregard an example if the increase in its coverage is below $threshold$. We vary these $threshold$ values $\in \{1e-04, 1e-03, 1e-02, 1e-01, 0.0\}$. Higher the $threshold$, more number of examples get filtered out.

Results: In Figure 4, we show that using our coverage guided filtering strategy, we are able to achieve coverage with a fewer number of samples than without coverage based filtering. Even with a threshold of 0.0, we are able to significantly reduce the number of samples that achieve the same coverage as the unfiltered set: we are able to achieve an average reduction across transformations (higher the better) of 71.17%, 45.94%, 28.52%, 11.33% and 2.83% for $\{0.0, 1e-04, 1e-03, 1e-02, 1e-01\}$ thresholds respectively.

4.3 Experiment 3: MNCOVER as a Metric to Evaluate Testing Benchmarks

Motivation: In this set of experiments, we utilize coverage as a test/benchmark dataset evaluation measure. Static test suites, such as the GLUE benchmark, saturate and become obsolete as models become more advanced. To mitigate the saturation of static benchmarks with model advancement, (Kiela et al., 2021) introduced Dynabench, a dynamic benchmark for Natural Language Inference(NLI). Dynabench introduced a novel human-and-model-in-the-loop dataset, consisting of three rounds that progressively increase in difficulty and complexity. This results in three sets of training, validation and test datasets, with increasing complexity testing datasets. We use MNCOVER as an additional validation measure for the datasets.

A1 + A2 + A3	0.185
A2	0.179
A3	0.181

Table 3: MNCOVER Values on the Dynabench test sets

Setup: We test the ROBERTA-Large model provided by Dynabench trained on training data from all three rounds of the benchmark. We use 10 as the number of bins and $\lambda = 1.0$.

Results: We measure coverage achieved by each of the test sets individually as well as in combination. We have summarized the results in Table 3. The test sets indeed provide more novel test inputs to the model as indicated by the increasing coverage as the test sets from each split are taken into consideration. The low values arise from a large architecture, (24-layer, 1024-hidden, 16-heads) that is potentially still unexplored with 1000 samples from each test set.

4.4 Experiment 4: Coverage Guided Augmentation

Motivation: Data augmentation refers to strategies for increasing the diversity of training examples without explicitly collecting new data. This is usually achieved by transforming training examples using a transformation. A number of automated approaches have been proposed to automatically select these transformations including like (Xie et al., 2019). Since computing MNCOVER does not require retraining, and the input selection can indicate the usefulness of a new sample, we propose to use MNCOVER to select transformed samples, in order to add them into the training set for improving test accuracy.

Setup: In this set of experiments, we focus on using coverage to guide generation of augmented samples. We propose a greedy search algorithm to coverage as guide to generate a new training set with selected augmentations. The procedure is described in Algorithm 1 and is motivated by a similar procedure from (Tian et al., 2018). This is a coverage-guided greedy search technique for efficiently finding combinations of transformations that result in higher coverage. We use transformations described in Section (A.3) and BERT model pretrained on the datasets.

We then add the coverage selected samples into the training set and retrain a target model. Using BERT model as base, Table 4 shows the test accuracy, when with or without adding the selected samples into the training set. We also show the size of the augmentation set. Our results show that using MNCOVER to guide data augmentation can improve test accuracy in both SST-2 and QQP.

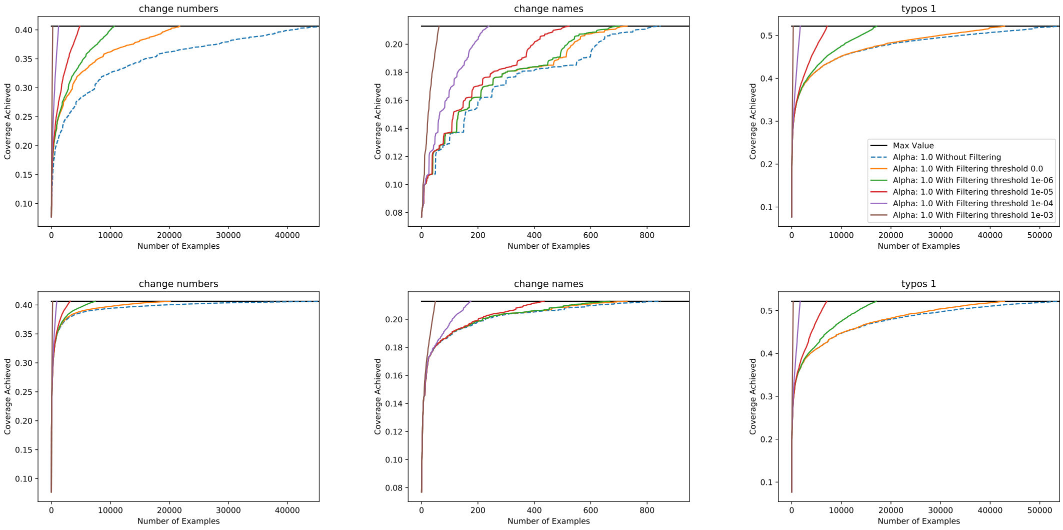

Figure 4: MNCOVER is able to achieve higher coverage with a fewer number of samples than without coverage based filtering. For this experiment we use the RoBERTa model. In the top row, we do not shuffle the examples and the bottom row with shuffling. Even with a threshold of 0.0, we are able to significantly reduce the number of samples that achieve the same coverage as the unfiltered set: we are able to achieve an average reduction (across transformations) of 28.83%, 54.06% , 71.48% , 88.67% and 97.17% for $\{0.0, 1e-04, 1e-03, 1e-02, 1e-01\}$ thresholds respectively.

Dataset	Coverage Threshold	Test Accuracy	Size of Augmented Set
SST-2	Baseline	90.22	0
	Random	90.45	6541
	MNCOVER	90.41	6541
QQP	Baseline	90.91	0
	Random	90.96	14005
	MNCOVER	91.03	14005

Table 4: The test accuracy after adding the augmented set generated using coverage guidance to the training set on SST-2 and QQP dataset.

5 Related Work

Our work connects to a few topics in the literature.

Testing for Natural Language Processing Recent literature has shown that deep learning models often exhibit unexpectedly poor behavior when deployed “in the wild". This has led to a growing interest in testing NLP models. The pioneering work in this domain is CHECKLIST (Ribeiro et al., 2020), that provides a behavioral testing template for deep NLP models. A different paradigm is proposing more thorough and extensive evaluation sets. For example, (Kiela et al., 2021) and (Koh et al., 2021) proposed new test sets reflecting distribution shifts that naturally arise in real-world language applications. On a similar line, (Belinkov and Glass, 2019; Naik et al., 2018) introduced challenge set based testing. Another line of work has focused on perturbation techniques for evaluating models, such as logical consistency (Ribeiro et al., 2019), robustness to noise (Belinkov and Bisk, 2017), name changes (Prabhakaran et al., 2019), and adversaries (Ribeiro et al., 2018).

Subset Selection Our MNCOVER can be used as a guide for filtering test inputs, and hence is a data selection approach. Previous work have looked at finding representative samples from training and/or interpretation perspectives. For example, submodular optimization from (Lin and Bilmes, 2009, 2010) provides a framework for selecting examples that minimize redundancy with each other to select representative subsets from large data sets. These methods are part of the “training the model" stage, targeting to achieve higher accuracy with fewer training samples. Moreover, Influence Functions from (Koh and Liang, 2020) provide a strategy to interpret black box models by discovering important representative training samples. The influence function can explain and attribute a model’s prediction back to its training samples. Differently, MNCOVER is a test suite evaluation approach.

6 Conclusion

This paper proposes MNCOVER to perform white-box coverage-based behavior testing on NLP models. We design MNCOVER to consider Transformer models’ properties, focusing on essential words and important word combinations. Filtering test sets using the MNCOVER helps us reduce the test suite size and improve error detection rates. We also demonstrate that MNCOVER serves as a practical criterion for evaluating the quality of test sets. It can also help generate augmented training data to improve the model’s generalization.

A Appendix

A.1 Deriving How Two Masks are Used

To learn these global masks, we update each preloaded word embedding $\mathbf{x}_i \forall i \in \{1, \ldots, L\}$ using embeddings from words that interact with $\mathbf{x}_i$ as defined by the learnt interaction matrix $\mathbf{M}_{A\mathbf{x}}$. Specifically, to get interaction-based word composition, we use the following formulation:

$$\mathbf{e}'_i = (\mathbf{e}_i + g(\mathbf{M}_{A[\mathbf{x}_i,:]}, \mathbf{E})) \tag{10}$$

Here, $\mathbf{e}'{}_i$ is the updated word embedding for token $\mathbf{x}_i$ after taking into account its interaction scores with other words in the sentence $\mathbf{E} = [\mathbf{e}_1, \ldots, \mathbf{e}_L]$. This is motivated from the message passing paradigm from (Kipf and Welling, 2016), where we treat each word in a sentence as a node in a graph. Using Equation 10, we effectively augment a word's embedding using information from words it interacts with. Note that we normalize $\mathbf{M}_{A\mathbf{x}}$, using $\mathbf{D}^{-1/2}\mathbf{M}_{A\mathbf{x}}\mathbf{D}^{-1/2}$, where $\mathbf{D}$ is the diagonal node degree matrix for $\mathbf{M}_{A\mathbf{x}}$. $g(\mathbf{M}_{A\mathbf{x}}, \mathbf{e}_{\{j\}})\ \forall j \in \{1, \ldots, L\}$ is the aggregation function. Equation 10 formulation represents words and their local sentence level neighborhoods' aggregated embeddings. Specifically, we use $g(\mathbf{M}_{A\mathbf{x}}, \mathbf{E}_\mathbf{x}) = h(\mathbf{M}_{A\mathbf{x}}\mathbf{E}_\mathbf{x})$. Here, h is a nonlinearity function, we use the ReLU non linearity. Simplifying our interaction based aggregation, if two words x_i, x_j are related in a sentence, we represent each word using $\mathbf{e}'_i = (\mathbf{e}_i + \sigma(a_{ij}(\mathbf{e}_i + \mathbf{e}_j)))$. Similarly, $\mathbf{e}'_j = (\mathbf{e}_j + \sigma(a_{ji}(\mathbf{e}_i + \mathbf{e}_j)))$. Further, to select words based on interactions, we add a word level mask $\mathbf{M}_W$ after the word embeddings, where $\mathbf{M}_W = [\mathbf{M}_{W\mathbf{x}_1}, \ldots, \mathbf{M}_{W\mathbf{x}_L}]$.

$\mathbf{z}_i = \mathbf{M}_{W\,i} * \mathbf{e}'_i$, where $\mathbf{M}_{W\,i} \in \{0, 1\}$ is a binary random variable. $\mathbf{Z} = [\mathbf{z}_1, \ldots, \mathbf{z}_L]$ represents word level embeddings input into a model for a specific input sentence after passing through the bottleneck layer.

A.2 Deriving the Loss

We introduce a bottleneck loss:

$$\ell_{IB} = max_\mathbf{Z} I(\mathbf{Z}; \mathbf{Y}) - \beta I(\mathbf{Z}; \mathbf{X}) \tag{11}$$

Given X, we assume $\mathbf{E}'$ and $\mathbf{M}_W$ are independent of each other. We write $q(\mathbf{Z}|\mathbf{X}) = q(\mathbf{M}_W|\mathbf{X})q(\mathbf{E}'|\mathbf{X})$. From Equation 10, $\mathbf{e}'{}_i = \mathbf{e}_i + \text{ReLU}(\mathbf{M}_{A\mathbf{x}}\mathbf{E}_{[1,\ldots,L]})$. $q(\mathbf{E}'|\mathbf{X})$ can be written as $q(\mathbf{M}_{A\mathbf{x}}|\mathbf{X})$.

The lower bound to be maximized is:

$$\begin{aligned}\mathcal{L} = \mathbb{E}_{q(\mathbf{Z}|\mathbf{x}^m)} log(p(\mathbf{y}^m|\mathbf{M}_W, \mathbf{M}_A, \mathbf{x}^m)) \\ -\beta_i KL(q(\mathbf{M}_W|\mathbf{x}^m)||p_{r0}(\mathbf{M}_W)) \\ -\beta_g KL(q(\mathbf{M}_A|\mathbf{x}^m)||p_{a0}(\mathbf{M}_A))\end{aligned} \tag{12}$$

We use the bernoulli distribution prior (a non informative prior) for each word-pair interaction $q_\phi[\mathbf{M}_{Ax_i,x_j}|\mathbf{x}_i, \mathbf{x}_j]$. $p_{a0}(\mathbf{M}_{Ax}) = \prod_{i=1}^L \prod_{j=1}^L p_{a0}(\mathbf{M}_{A\mathbf{x}_i,\mathbf{x}_j})$, hence $p_{a0}(\mathbf{M}_{Ax_i,x_j}) = Bernoulli(0.5)$. This leads to:

$$\begin{aligned}\beta_g KL(q(\mathbf{M}_{A\mathbf{x}}|\mathbf{x}^m)||p_{a0}(\mathbf{M}_A)) = \\ -\beta_g H_\mathbf{q}(\mathbf{M}_{A\mathbf{x}}|\mathbf{x}^m)\end{aligned} \tag{13}$$

Similarly, we use the same bernoulli distribution prior for the word mask, $p_{r0}(\mathbf{M}_W) = \prod_{i=1}^L p_{r0}(\mathbf{M}_{W\mathbf{x}_i})$, and $p_{r0}(\mathbf{M}_{W\mathbf{x}_i}) = Bernoulli(0.5)$:

$$\begin{aligned}\beta_i KL(q(\mathbf{M}_{W\mathbf{x}}|\mathbf{x}^m)||p_{a0}(\mathbf{M}_W)) = \\ -\beta_r H_\mathbf{q}(\mathbf{M}_{W\mathbf{x}}|\mathbf{x}^m)\end{aligned} \tag{14}$$

We also add a sparsity regularization on $\mathbf{M}_{A\mathbf{x}}$ to encourage learning of sparse interactions. Finally, we have the following loss function:

$$\begin{aligned}L = -(E_\mathbf{x} p(\mathbf{y}|\mathbf{x}^m, \mathbf{M}_A, \mathbf{M}_W) + \\ \beta_i H_q(\mathbf{M}_W|\mathbf{x}^m) \\ +\beta_g H_\mathbf{q}(\mathbf{M}_{A\mathbf{x}}|\mathbf{x}^m)) + \\ \beta_{sparse}||\mathbf{M}_{A\mathbf{x}}||_1\end{aligned} \tag{15}$$

As $\mathbf{M}_A$ is a binary graph sampled from a Bernoulli distribution with parameter γ, to train the learnt parameter γ, we use the Gumbel-Softmax(Jang et al., 2016) trick to differentiate through the sampling layer. To learn the word mask $\mathbf{M}_W$, we use the amortized variational inference(Rezende and Mohamed, 2015). We use a single-layer feedforward neural network as the inference network $q_{\phi(R_{x_t})|\mathbf{x}_t}$, whose parameters are optimized with the model parameters during training. We use Gumbel-Softmax for training with discrete word mask.

Abstract

Transformer models yield impressive results on many NLP and sequence modeling tasks. Remarkably, Transformers can handle long sequences, which allows them to produce long coherent outputs: entire paragraphs produced by GPT-3 or well-structured images produced by DALL-E. These large language models are impressive but also very inefficient and costly, which limits their applications and accessibility. We postulate that having an explicit hierarchical architecture is the key to Transformers that efficiently handle long sequences. To verify this claim, we first study different ways to downsample and upsample activations in Transformers so as to make them hierarchical. We use the best performing upsampling and downsampling layers to create Hourglass - a hierarchical Transformer language model. Hourglass improves upon the Transformer baseline given the same amount of computation and can yield the same results as Transformers more efficiently. In particular, Hourglass sets new state-of-the-art for Transformer models on the ImageNet32 generation task and improves language modeling efficiency on the widely studied enwik8 benchmark.

1 Introduction

Transformer models (Vaswani et al., 2017) are capable of solving many sequence modeling tasks, including classical NLP tasks (Devlin et al., 2019), summarization (Zhang et al., 2020), language modeling (Radford et al., 2019; Brown et al., 2020), code generation (Chen et al., 2021), or even music generation (Huang et al., 2018; Dhariwal et al., 2020) and image generation (Parmar et al., 2018; Chen et al., 2020; Ramesh et al., 2021). One compelling feature of Transformers is their ability to handle long contexts given as part of the input. This is particularly visible in tasks where the output depends on parts of the context that may not be close-by in the generated sequence, like in summarization, where the summary may need to refer to information scattered across the context, or in large-scale image generation, where pixels belonging to the same object may be far apart in the generation order. Transformers excel at such tasks thanks to self-attention, and they are used with longer and longer contexts.

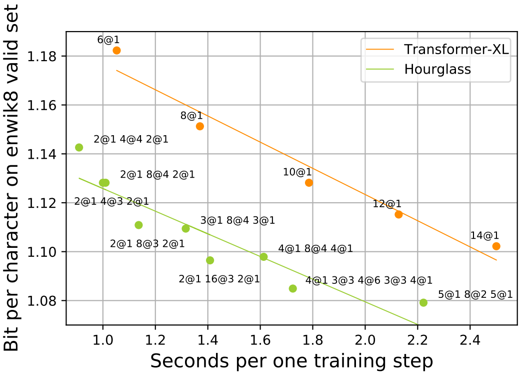

Figure 1: Bits-per-character vs. training cost for baseline (orange) and hierarchical Transformers (green). We observe significant perplexity improvements on enwik8 over the vanilla Transformer–XL baseline, see text for details.

The ability of Transformers to handle long contexts comes at a price: each self-attention layer, at least in its original form, has complexity quadratic in the length of the context. When a stack of n Transformer layers is used, both memory and time complexity is equal to $O(L^2 n)$ where L is a sequence length and n number of decoder blocks. Due to this limitation, vanilla transformers are infeasible to train on tasks with very long input sequences, for instance, on high-resolution images. This issue has been studied extensively, and a number of techniques were introduced that modify attention mechanism without changing overall transformer architecture (Child et al., 2019; Roy et al., 2020; Ren et al., 2021). These sparse attention mechanisms reduce the complexity of self-attention

but still force the model to operate on the sequence of the same length as the input.

For generative Transformer models, operating at the original scale of the input sequence is necessary, at least in the early and final layers, as the input must be processed at first and generated at the end (Section 4.3). But forcing the models to operate at this granularity throughout the layer stack has both fundamental and practical shortcomings:

- Fundamentally, we aim for the models to create high-level representations of words, entities, or even whole events – which occur at a very different granularity than single letters that the model receives on input.
- On the practical side, even layers with linear complexity can be slow and memory-intensive when processing very long sequences.

To alleviate these issues, we propose to change the Transformer architecture to first shorten the internal sequence of activations when going deeper in the layer stack and then expand it back before generation. We merge tokens into groups using a shortening operation (Section 2.1) and so reduce the overall sequence length, and then up-sample them again combining with the sequence from earlier layers (Section 2.3), The first part is analogous to the Funnel-Transformer architecture (Dai et al., 2020), and the whole architecture takes inspiration from U-Nets (Ronneberger et al., 2015). In contrast to both these architectures, the model we present is autoregressive, which is harder to ensure in hierarchical models than in vanilla Transformers.

The resulting model – which we call *Hourglass* – is an autoregressive Transformer language model that operates on shortened sequences. It yields significant performance improvements for different attention types (Fig. 6,7). We tested Hourglass with Transformer-XL (Dai et al., 2019) and Reformer (Kitaev et al., 2020) blocks on enwik8 dataset. In both cases, it is not only better in terms of perplexity, but it is faster and uses less memory during training. We also propose a regularization technique for hierarchical Transformers called *shorten factor dropout* which improves perplexity upon baselines trained with fixed shorten factor (see Section 4.1). Finally, Hourglass achieves the new state-of-the-art among Transformer models for image generation of ImageNet32 (see Tab. 3).

2 Model

Standard self-attention mechanism uses full token-level sequence representations. In the Hourglass, we bring efficiency to the model by utilizing *shortening*, which allows us to use the Transformer layers on inputs with significantly smaller lengths. A high-level overview of our proposed model architecture is shown in figures 2 and 3.

Attention type in the vanilla layers and shortened layers is a configurable parameter. By default we use relative attention defined in Transformer-XL (Dai et al., 2019). Any attention module can be used - we show significant efficiency gains when applying Hourglass also for LSH (Kitaev et al., 2020) attention (see Section 3.2 and Fig. 7).

2.1 Methods of shortening the input sequence

Shortening can be defined as any function S that accepts a tensor x of shape (l, d) and returns a tensor x' of shape $(\frac{l}{k}, d)$, where k is a hyperparameter called *shorten factor*.

A simple shortening method is 1D average pooling with stride k and pool size k, applied along the sequence dimension l. Another way of shortening is what we will further call *linear pooling* (l and d denote sequence length and d_{model}):

Algorithm 2 LinearPooling

```
$x' \leftarrow Reshape(x, (\frac{l}{k}, k \cdot d))$
$x' \leftarrow LinearProjection(x')$
```

Shortening can be also performed by attention, as was introduced in (Dai et al., 2020): $x' = S(x) + Attention(Q = S(x), K = V = x)$ where S is shortening function, originally $S = AvgPool$. Directly after this attention operation, a position-wise feed-forward with a residual is performed, so that these two layers form a Transformer block (Vaswani et al., 2017). In this work we also try $S = LinearPool$ and find it more effective on image tasks (see Tab. 8).

2.2 Shortening and autoregressive property

Information leaks Shortening interferes with the standard causal masking used in Transformer decoders. Namely, in any shortened representation by a factor of k each shortened token contributes to predicting up to the next k tokens in the finest scale, that is if e is the shortened sequence and x is the sequence on the finest scale, e_0 is not only used

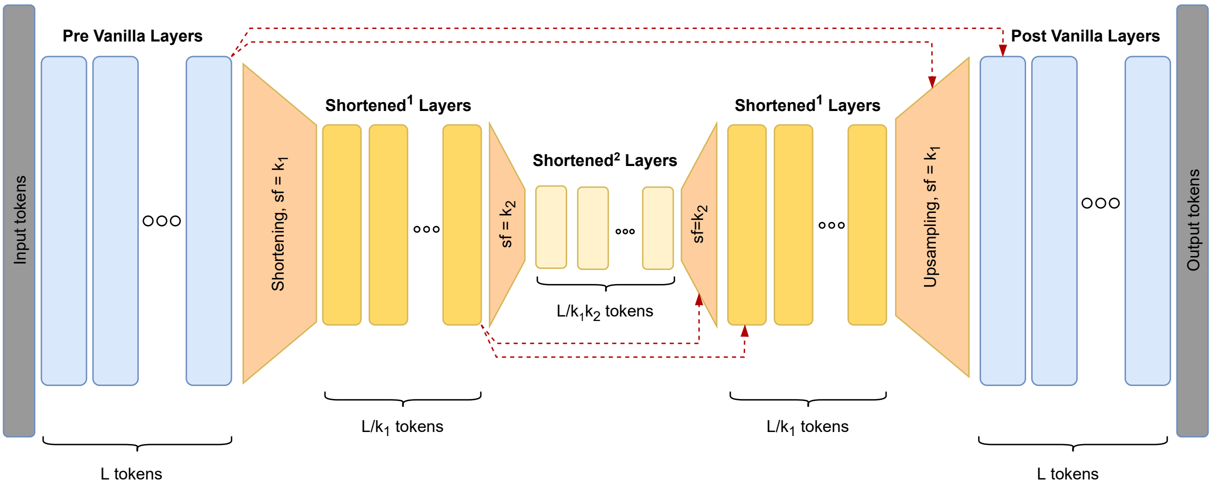

Figure 2: Hourglass - a high-level architecture overview. The arrows denote residual connections.

to generate x_0; in fact, the same embedding is used to generate tokens $x_0, ..., x_{k-1}$.

Therefore, we need to guarantee that e_0 and any other e_i cannot access information about tokens they will implicitly predict. To ensure that, we apply another shift right by $k-1$ tokens, directly before any shortening by a factor of k (Fig. 4). The shift is the smallest that does not cause an information leak (see Fig. 5 for an example of a shifting that leads to a leak). We included a more detailed analysis of this fact in the Appendix (Section A.2).

Reduced expressivity Let us consider an Hourglass model with shortening by a factor of k and no transformer blocks operating on the finest scale (that is, a model without vanilla layers).

In this situation

$$P(x) = \prod_{i=0}^{n-1} P(x_i|e_0, ..., e_{\lfloor \frac{i}{k} \rfloor}) = \prod_{i=0}^{n-1} P(x_i|x_0, ..., x_{\lfloor \frac{i}{k} \rfloor \cdot k-1})$$

because for predicting x_i we combine the processing done on shortened representations e with token-independent operations. This means token x_i is generated independently from the tokens $x_{\lfloor \frac{i}{k} \rfloor \cdot k}, ..., x_{i-1}$. This situation is detrimental to the model's capabilities, though including at least one vanilla layer solves this issue. In the Appendix we provide a detailed example illustrating this problem (Section A.1).

2.3 Upsampling methods

Upsampling is a crucial part of the Hourglass architecture since we need to convert shortened representations back to the full token-level sequence in order to perform language modeling.

A method proposed in (Dai et al., 2020) is repeating each shortened vector *shorten factor* times. This method is computationally efficient, but it does not distinguish tokens with respect to position inside the group.

Another method is *linear upsampling* which works analogously to linear pooling – it projects vectors of shape $(\frac{l}{k}, d)$ to $(\frac{l}{k}, k \cdot d)$ and then reshapes to l vectors, each of dimension d. This method is fast and allows to project shortened embeddings differently for each position in the group. This happens because the $(k \cdot d) \times d$ projection matrix can be thought of as k separate $d \times d$ matrices, one per each position.

We also investigated a method which we further call *attention upsampling*. It is similar to attention pooling (Dai et al., 2020) and to the aggregation layer from (Subramanian et al., 2020). It works as follows: $x = U(x, x') + Attention(Q = U(x, x'), K = V = x')$ where x are embeddings from just before the shortening, x' are final shortened embeddings and U is an arbitrary upsampling function. After the attention operation there is also a residual with a feed-forward layer.

Linear upsampling learns a fixed pattern that is the same for each shortened token. Attention upsampling has the advantage of being content-based – each token can extract relevant information from the shortened embeddings. We set $U(x, x') = x + LinearUpsampling(x')$ which allows to explicitly inject group-level information into the attention queries. We experimentally show that variants of attention upsampling lead to the best results for our model across different datasets (see Tab. 7).

Algorithm 1 HourglassLM

```
procedure HOURGLASS($x, [k, ...s\_factors]$)
    $x \leftarrow PreVanillaLayers(x)$
    $x' \leftarrow Shortening(ShiftRight(x, k-1), k)$

    if EMPTY($s\_factors$) then
        $x' \leftarrow ShortenedLayers(x')$
    else
        $x' \leftarrow$ HOURGLASS($x', s\_factors$)
    end if
    $x \leftarrow x + Upsampling(x, x', k)$
    $x \leftarrow PostVanillaLayers(x)$
    return $x$
```

Figure 3: The architecture starts with *pre vanilla layers* – a stack of Transformer blocks operating on the full token-level sequence. After them we insert *shortening layer* where k is the *shorten factor* parameter (Fig. 4). The sequence is shifted right before shortening to prevent information leak (Fig. 5). Then we recursively insert another Hourglass block operating on k times smaller scale. On the final level of shortening, we apply *shortened layers* – Transformer blocks operating on the smallest scale. *Upsampling layer* brings the resulting activations x' back to the original resolution. After upsampling and residual, the activations are processed by token-level *post vanilla layers*.

3 Experiments

In this section, we present experimental results of Hourglass. We start with a quick analysis of time and memory complexity of the approach (Section 3.1). Then we investigate the efficiency gains of applying Hourglass to Transformers with different attention types (Section 3.2). Finally, we use Hourglass with relative attention parametrization from Transformer-XL (Dai et al., 2019), evaluate it on three language modeling tasks, and compare the results with other models. (Sections 3.3, 3.4)

To show cross-domain generalization of our method, we train our model on one dataset related to Natural Language Processing and two from the Computer Vision field.

To ensure consistency in presenting configurations of our model, we introduce a notation describing hierarchy of our architecture: $(N_1@f_1, \ldots, N_k@f_k)$ where each entry $(N_j@f_j)$ means N_j layers shortened by factor f_j.

Our model implementation is open source.[1]

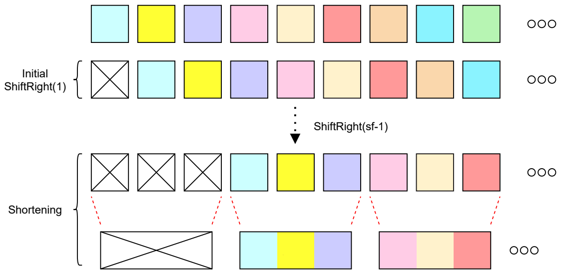

Figure 4: An overview of our shortening approach. Different colors denote token positions. Initially, we shift right by one, which is a standard step in TransformerLM. Then, just before performing shortening, we additionally shift the tokens right by *shorten factor* − 1 to preserve the autoregressive property of the model.

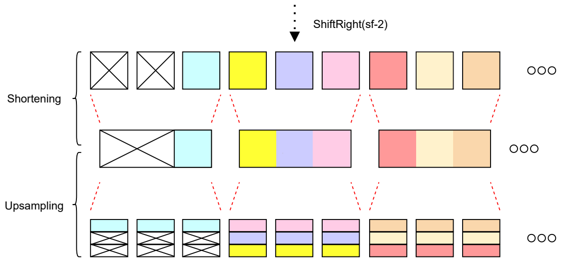

Figure 5: An example of information leak. If the shift right factor is too small, after upsampling the knowledge from the next tokens leaks to previous ones violating autoregressiveness and making decoding impossible.

3.1 Computational cost analysis

In vanilla Transformers, the number of parameters can indicate the computation required to train the model. This is not true for Hourglass – for instance, it can have 128 layers operating on a sequence shortened by 32 and still fit into the memory of a single GPU. A weak correlation between true Hourglass' computational cost and its number of parameters can be observed in Table 1.

Hourglass achieves the biggest speedup with the standard $\mathcal{O}(l^2)$ attention. In that case, a single shortening by a shorten factor k reduces the complexity to $\mathcal{O}(\frac{l^2}{k^2})$ so by a factor of k^2. For more recent linear-time attention mechanisms (Katharopoulos et al., 2020; Choromanski et al., 2021) the reduction would be smaller – but still by a factor of k. Feed-forward layers also have linear complexity so shortening reduces it by a factor of k.

In Table 1 we show an empirical efficiency comparison between Hourglass and Transformer-XL.

---

4@1 8@4 4@1	1.098	7.20	0.62	62M
2@1 16@3 2@1	**1.096**	5.89	0.71	75M
14@1 (Baseline)	1.102	9.35	0.40	48M
5@1 8@2 5@1	**1.079**	9.57	0.45	69M

Table 1: Efficiency comparison between Hourglass variants and Transformer-XL baseline on enwik8 – we report validation set perplexity (BPC), running memory (GB) and number of training steps per second (Speed). We observe significant perplexity gains over the baseline for a matching computation cost. It is also visible that for Hourglass the number of model parameters (#Param) correlates poorly with true computational cost.

3.2 Impact of Hourglass

To demonstrate the efficiency of Hourglass, we measured how computational cost decreases and perplexity improves, purely adding the technique to Transformer-XL (Dai et al., 2019) and Reformer (Kitaev et al., 2020) backbones (results depicted in Figures 6 and 7, respectively).

In both cases, models are implemented under the same codebase and the only difference between Hourglass and its corresponding baseline is the usage of shortening and upsampling layers. We show that by incorporating a single shortening of the input, we can train larger models with the same memory requirements and training speed and achieve better perplexity than baselines.

3.3 Enwik8

Enwik8 (Mahoney, 2011) is a byte-level language modeling benchmark containing the first 100M bytes of unprocessed English Wikipedia text, split into 90M train, 5M valid, and 5M test sets.

Similarly to (Dai et al., 2019) and (Beltagy et al., 2020), we evaluate our model on the test set, splitting it into overlapping sequences of size $l = 4096$ with a step size of 128 and calculate the test loss only over the last 128 tokens. With a $(4@1, 8@3, 4@1)$ hierarchy, $d_{model} = 768$, $d_{ff} = 3072$ and 8 heads, we reach **0.98** test bits-per-character.

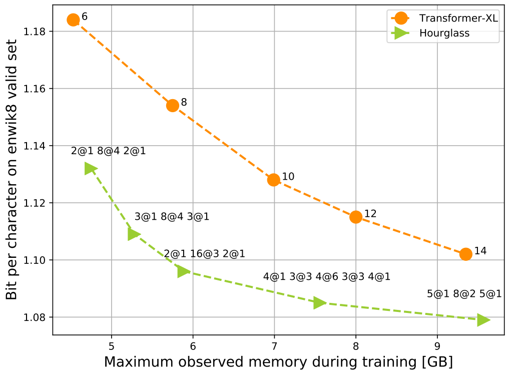

Figure 6: Comparison between Transformer-XL baseline and Hourglass on Enwik8 valid set w.r.t. maximum memory used during training. All models are trained for 200k steps with the same hyperparameters.

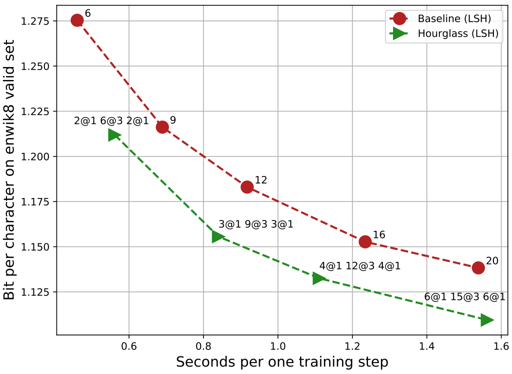

Figure 7: Comparison between Reformer baseline and Hourglass, both with LSH attention, on Enwik8 valid set w.r.t. cost of one training step in seconds.

3.4 Image Generation

We use datasets introduced in (van den Oord et al., 2016a) which are downsampled versions of the popular ImageNet. In the autoregressive image generation setup, they consist of respectively $\mathbf{32 \times 32 \times 3}$ and $\mathbf{64 \times 64 \times 3}$ tokens, corresponding to RGB channels, per image. As the only preprocessing step we flatten the images.

3.4.1 ImageNet32

For our main result the following hierarchy is used: $(3@1, 24@3, 3@1)$. We use $d_{\text{model}} = 512$, $d_{\text{ff}} = 2048$, 8 attention heads and 0.01 dropout rate. With this configuration we achieve **3.741** bits/dim, yielding the new state-of-the-art among autoregressive (Transformer-based) models on this dataset, compared to the previous state-of-the-art of 3.758 bpd by (Ho et al., 2019).

Enwik8	#Param	BPC
Transformer-XL (2019) 24L	277M	0.99
Hourglass	146M	0.98
Adaptive-Span (2019) 24L	209M	0.98
Transformer-LS (2021)	110M	0.97
Feedback Transformer (2021)	77M	0.96
Expire-Span (2021) 24L	277M	**0.95**

Table 2: **Enwik8 Results.** We report bits-per-character (BPC) on the test set and number of model parameters. Hourglass applied to Transformer-XL significantly outperforms its baseline. Our technique could be also used with other more performant attention methods which we leave for future work.

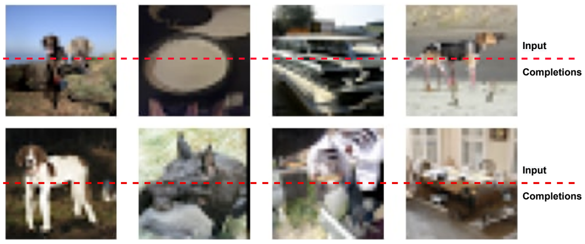

Figure 8: Examples of our model completions, where bottom half of each image was generated by our model, prompted by the upper half.

3.4.2 ImageNet64

The sequence length that our model can handle is limited mainly by the computational complexity of used attention module. We replace relative attention in vanilla layers by LSH attention (Kitaev et al., 2020), which allows us to handle **12288**-long sequences. To achieve relative attention parametrization, the LSH attention is combined with rotary positional embeddings (Su et al., 2021). In shortened layers, standard relative attention is used. For LSH attention, we set chunk length to 128 and use 2 hashes, which results in small memory complexity in our full-size layers. In this setup, we reach a score of **3.443** bpd with a $(3@1, 12@3, 3@1)$ architecture. All attention layers had $d_{model} = 768$, $d_{ff} = 3072$ and 8 heads. No dropout was used.

3.4.3 CIFAR-10

CIFAR-10 (Krizhevsky, 2009) is an image dataset consisting of 60000 images of size 32x32. We use this dataset primarily for our ablations (Section 4). Due to the relatively small number of examples compared to ImageNet, models reach convergence after 100k steps.

4 Ablations

In this section, we start by introducing a training technique called *shorten factor dropout* (Section 4.1), and then analyze Hourglass's components described above. We show that shortened layers behave similarly to full token-level layers in terms of scalability (Section 4.2). Then we study the effect of different distributions of $(pre, post)$ vanilla layers on Hourglass' accuracy (Section 4.3). We further analyze the performance of various upsampling and downsampling methods (Sections 4.4 and 4.5). Finally, we discuss different shorten factors and multi-stage shortening in Section 4.6.

DenseFlow (2021)	**3.35**

Table 3: Bits per Dimension (BPD) on downsampled imagenet. Autoregressive models are separated by a horizontal line from non-autoregressive ones. On ImageNet32, our model yields new state-of-the-art for autoregressive models.

We conduct the ablations on both text and image generation to show applicability across different domains. We report bits per character (BPC) on the enwik8 validation (dev) set evaluated without context (sequence length 2048) and bits per dim (BPD) on the CIFAR-10 test set. For the exact hyperparameter setup refer to the Appendix.

4.1 Shorten factor dropout

Different shorten factors can be used for the same model when using parameterless pooling methods. We propose a training procedure where the shorten factor is randomly sampled with uniform distribution from a predefined set in each step. We observe that such a training regime improves validation loss compared to a baseline trained with a single, fixed shorten factor. For example, a model trained with shorten factor randomly sampled from $\{2, 3\}$ performs better when evaluated with any of these shorten factors, compared to models trained with a corresponding fixed shorten factor (Tab. 4).

We hypothesise that such a technique promotes a more uniform distribution of information over the sequence of tokens. It may be essential for fixed-size pooling techniques as they do not account for variable length constituents like words. By spreading information uniformly, we prevent a situation where we lose content by shortening three information-dense tokens or lose available capacity by merging three low information ones.

Shorten factor dropout is not limited to our architecture and can be applied to any model that utilizes shortening, particularly (Dai et al., 2020).

Hierarchy	Train k	Val $k=2$	Val $k=3$
2@1 8@k 2@1	$\{2,3\}$	**1.104**	**1.116**
	2	1.116	
	3		1.124
4@1 12@k 4@1	$\{2,3\}$	**1.086**	**1.094**
	2	1.098	
	3		1.101
5@1 10@k 5@1	$\{2,3\}$	**1.082**	**1.087**
	2	1.096	
	3		1.095

Table 4: Comparison between models trained with shorten factor dropout (Train $k = \{2,3\}$, Section 4.1) and fixed shorten factor baselines on enwik8.

4.2 Scaling shortened layers

In this study, we show that layers operating on the shortened sequence contribute significantly to Hourglass's accuracy. In Table 5 we measure the impact of scaling the depth of the shortened part of the model with a fixed number of vanilla layers.

We also check if scaling laws of Transformers, described in (Kaplan et al., 2020), hold by comparing a regression line fitted to various Hourglass configurations and one fitted to Transformer-XL baseline. We observe in Figure 1 that the slopes are very similar, which indicates that the laws hold.

Number of shortened layers	enwik8	CIFAR-10
Baseline ($n=1$)	1.164	3.28
$n=4$	1.134	3.16
$n=8$	1.111	3.07
$n=16$	**1.096**	**3.03**

Table 5: Impact of increasing the number of shortened layers on perplexity. Vanilla layers: $(1,1)$ for CIFAR-10 and $(2,2)$ for enwik8, shorten factor 3 used in both.

4.3 Impact of vanilla layers

We observe a significant contribution to Hourglass' performance with increasing the number of vanilla layers. One reason is that we perform more computations as in vanilla layers we process the sequence in token-level - no shortening is applied. We also see that the distribution of vanilla layers before shortening and after shortening does impact the training (see Tab. 6), and equal distribution leads to the best perplexity.

Vanilla layers	enwik8	CIFAR-10
(0, 0)	1.460	3.429
(0, 2)	1.176	3.108
(2, 0)	1.189	3.035
(1, 1)	**1.171**	**3.012**
(2, 2)	1.128	2.966

Table 6: Impact of the distribution of vanilla layers on enwik8 (BPC) and CIFAR-10 score (BPD). We see that equal distribution of layers before and after shortening leads to better results on both datasets.

4.4 Upsampling method

In Table 7 we investigate different possibilities of choosing the upsampling method. For attention-free methods, linear upsampling performs better on images, while repeat upsampling works well for text. Attention upsampling works well regardless of the function U and has the lowest perplexity.

Upsampling method	enwik8	CIFAR-10
Repeat	1.148	3.062
Linear	1.163	3.020
$U(x,x') = x$	1.145	**2.967**
$U(x,x') = x + Linear(x')$	**1.132**	3.012

Table 7: Upsampling method ablation - baseline configurations are $(2@1, 24@4, 2@1)$ and $(1@1, 8@3, 1@1)$ for enwik8 and CIFAR-10, respectively.

4.5 Pooling method

Table 8 presents impact of pooling method on both enwik8 (BPC) and CIFAR-10 (BPD). Attention pooling reaches the lowest perplexity for both datasets. Average pooling performs well on text among attention-free methods, while linear pooling works better for images. Both of these methods perform significantly worse for the other modality. Attention pooling demonstrates small differences with respect to chosen shortening function S (Section 2.1), still preserving the preference towards linear pooling on images and average pooling on text.

Pooling method	enwik8	CIFAR-10
AvgPool	1.129	3.116
Attention, $S = AvgPool$	**1.124**	3.012
Attention, $S = LinearPool$	1.142	**2.998**
LinearPool	1.159	**2.998**

Table 8: Ablation of pooling methods. Attention pooling achieves the best perplexity on both datasets.

4.6 Shortening strategies

While the analysis above gives a clear indication of what methods to choose for shortening and upsampling, we are still left with the question of which shorten factors to use and whether to do single-stage or multi-stage shortening.

Consistently, it is beneficial to do at least one shortening and by a factor of at least 3, while keeping 2-3 vanilla layers. Beyond that, a number of different configurations can yield similar results. In Table 1 we present the different hierarchical configurations that we tested on enwik8 and plotted in Figure 1. It can be seen that configurations with similar computation costs perform similarly. The sequence length used in these experiments is 2048 – we hypothesise that more hierarchy may be beneficial with even longer sequences.

5 Related Work

Shortening in Transformers Shortening in our work is inspired by Funnel-Transformer (Dai et al., 2020). The key difference is that they train an encoder model for text classification, where our work is entirely focused on language modeling, which provides additional challenges we had to solve regarding shortening in the autoregressive setup (Section 2.2). Another difference is that they use repeat upsampling method while we use attention. There are also a few works related to character-level modeling which use shortening, namely (Clark et al., 2021) and (Tay et al., 2021). However, the authors of these works focused mainly on shortening sequence in encoder part of the transformer, whereas we focused on applying shortening in decoder.

The idea of shortening is also discussed in (Subramanian et al., 2020). However, proposed architectures either focus on downsampling or upsampling, while Hourglass is a U-Net-like architecture and is symmetric in these terms. Their models use transformer layers on the finest scales when postprocessing final representations. We do these also, in the beginning, to preprocess tokens on the finest scale, and we have found it essential to the score (Section 4.3). Our attention upsampling method is similar to their *aggregation layer* in the bottom-up model, however we use one upsampling for each scale change while they combine different scales to create one global upsampling.

Relative positional encoding Our work is primarily built on the backbone of Transformer-XL (Dai et al., 2019) - we use the same relative attention parametrization. Instead of the segment-level recurrence mechanism, we use shortening to make our model more efficient and feasible to train on longer sequences. Another relative attention parametrization is RoFormer (Su et al., 2021) where rotary positional embeddings are introduced. We find this work particularly relevant because the method is compatible with any attention type, including efficient attention, and can be combined with our model (Section 3.4.2).

Sparse Attention A well-known approach addressing the memory bottleneck is utilizing sparsity patterns in the attention matrix - Routing (Roy et al., 2020) and Sparse Transformer (Child et al., 2019) are examples of such methods. Our solution is different in the sense that it uses full attention - just with shortened sequence length. Combiner (Ren et al., 2021) makes a step further and provides full attention capabilities with similar computational complexity to Routing and Sparse transformers by leveraging structured factorization. This work, similarly to papers mentioned above on efficient transformers, concentrates on speeding up the attention component, while the most important feature of the Hourglass architecture is that it can use any attention module as a drop-in.

Image generation on downsampled ImageNet VDM (Kingma et al., 2021) and DenseFlow (Grcić et al., 2021) are recently proposed state-of-the-art methods for density estimation on this dataset. The difference between these methods and Transformer-based methods (Parmar et al., 2018; Ho et al., 2019) including this work is that the former, unlike Transformers, are non-autoregressive.

6 Conclusion

In this paper, we show how hierarchy can improve the efficiency of Transformers in a language modeling setup. Our proposed architecture, Hourglass, significantly outperforms the baseline both in terms of perplexity reached at a given computation cost (Figure 1) and empirical metrics like running memory (Figure 6). Hourglass achieves state-of-the-art results among autoregressive models on the ImageNet32 generation task and competitive results on other image generation and language modeling tasks.

Hourglass can be used with any attention type, which opens many directions for future research related to Transformers capable of processing longer sequences. Another line of future work might be related to advances in the shortening mechanism itself, for example, involving a dynamic pooling operation that could explicitly handle the problem of fixed-size groups in multi-stage shortening. We also leave open the problem of choosing the best hierarchy for a task. We conjecture that experiments with much longer contexts will provide better guidance for this choice and will benefit even more from the Hourglass architecture.

7 Acknowledgments

Some experiments were performed using the Entropy cluster funded by NVIDIA, Intel, the Polish National Science Center grant UMO-2017/26/E/ST6/00622, and ERC Starting Grant TOTAL. The work of Henryk Michalewski was supported by the Polish National Science Center grant UMO-2018/29/B/ST6/02959. The authors would like to thank Marek Cygan and Kamil Wilczek for their help with cluster setup, and Grzegorz Grudziński, Dawid Jamka and Sebastian Jaszczur for helpful discussions. This article describes a Team Programming Project completed at the University of Warsaw in the academic year 20/21. We are grateful to Janusz Jabłonowski, the head of Team Programming Projects, for his support and open-mindedness.

A Autoregressive shortening

In Section 2.2 we address two problems of shortening in an autoregressive setup: information leaks and reduced expressivity. Here we study these issues in more detail.

A.1 Motivation behind using vanilla layers

At first sight, it may be tempting to create hierarchical models that directly shorten the input to maximize the efficiency gains. In this section, we explain why vanilla layers are crucial for modeling at least some sequences, especially due to autoregressivity.

Consider a sequence modeling task where the input is a random sequence with repeats, such as `A#AC#CD#DB#B`. The sequence consists of chunks `L#L` where `L` is a random uniform letter and `#` is a special symbol. A vanilla Transformer language model can achieve 66% sequence accuracy on this task – it cannot predict the token at the beginning of the chunk, but it can predict the last token of the chunk by simply copying the token at 2 positions earlier, which is possible using a vanilla self-attention layer.

It is however not easy to learn this task in a shortening setup when there are no vanilla layers operating on the finest scale – this is the situation defined in *Reduced expressivity* subsection of Section 2.2. Assume shorten factor is $k = 3$ and the input is `A#AB#BC#C`. To avoid information leak, we shift the input sequence right by 1, and then by $k-1 = 2$ directly before shortening. Then the sequence is `000A#AB#B`. Our shortened embeddings are as follows: $e_0 = S(emb_0, emb_0, emb_0), e_1 = S(emb_A, emb_\#, emb_A)$ where emb is input embedding matrix and S is a shortening function.

Shortened embeddings Shifted input embeddings	`[000]` `0A#`	`[A#A]` `AB#`	`[B#B]` `BC#`
Target sequence	`A#A`	`B#B`	`C#C`
Positions	`123`	`456`	`789`

Table 9: Example input sequence which is difficult to model without vanilla layers. The model can use only input embeddings shifted by one from the residual and shortened embeddings (shorten factor is 3) to predict the target sequence. Note that it is impossible to predict tokens at positions divisible by 3 using only that information.

Because no vanilla layers are used, for prediction we can use only shortened embeddings and input token embeddings shifted right by 1 from the residual connection. Note that to predict the `A` token at position 3 we can use only embedding of $emb_\#$ and e_0 - both of these contain no information so we are unable to predict this token better than randomly (see Table 9). An analogous situation occurs for prediction of any tokens at positions divisible by 3, which makes the model unable to achieve more than 50% accuracy when the task has vocabulary size of at least 2.

This issue can be solved by adding at least one vanilla layer to the model, so that it can attend within the neighborhood of k previous tokens. For this particular problem, it is sufficient to use local attention with context size k in vanilla layers which is significantly more efficient than full attention.

A.2 Information leaks – analysis

A.2.1 Definition of autoregressive model

Formally, given a target sequence, $x = x_1, ..., x_n$, an autoregressive model (e.g. transformer decoder) models the sequence as $P(x) = \prod_{i=1}^{n} P(x_i | x_1, ..., x_{i-1})$ and

$$\forall_i P(x_i | x_1, ..., x_n) = P(x_i | x_1, ..., x_{i-1})$$

namely x_i token depends only on previous tokens, never on itself nor next ones.

A.2.2 Definition of information leak

We say that a leak was caused by function $F_n \colon A^n \longrightarrow A^n$ transforming sequence of input tokens $(x_1, x_2, ..., x_n)$ into another sequence $(u_1, ..., u_n) = F((x_1, ..., x_n))$ when $\exists_{i<j<n} P(x_i | x_1, ..., x_{i-1}, x_j) \neq P(x_i | x_1, ..., x_{i-1})$, namely there exists $j \geq i$ that token x_i depends on x_j which violates the autoregressive property.

A.2.3 Model representation

Let $R_k \colon A^n \longrightarrow A^n$ be a shift right function which reindexes tokens by shifting each of them right by k positions:

$$R_k((x_1, x_2, ...x_n)) = (\underbrace{0, ..., 0}_{k}, x_1, ..., x_{n-k})$$

$S_k : A^* \longrightarrow A^*$ shortening function with factor k which takes on input $x_1, ..., x_n$ sequence and returns $s_1, ..., s_m$ where $m = \frac{n}{k}$, U_k upsampling function which works in similar way but upsamples $U_k((u_1, ..., u_m)) = u_1, ..., u_n$.

Between them there is also applied D decoder function, $D = D_1 \circ \cdots \circ D_l$, where each D_i is a function representing decoder block. Due to causal attention masking in the decoder block, there is no risk of information leak caused by function D.

A.2.4 Leak description

Because of mentioned attention mask, we will omit the flow of information between tokens caused by the influence of attention mechanism because this mask keeps the autoregressive property.

Now, let $(x_1, ..., x_n)$ be an input sequence and $(u_1, ..., u_n) = U(D(S_k(T_s((x_1, ..., x_n))))) = F$. In order to preserve autoregressive property, it is obligatory that no leak occurs.

We will show that shift by any value $0 < s < k - 1$ where k is the shorten factor will cause a leak.

To start with, consider input sequence $(x_1, ..., x_n)$ and perform operation F. $R_s((x_1, ..., x_n)) = (\underbrace{0, ..., 0}_{s}, x_1, ..., x_{n-s}) = r$. Assuming that n is divisible by s, we have $S_k(r) = (v_1, ..., v_{\frac{n}{k}}) = v$ where each v_i consists of information obtained in $(r_{(i-1)\cdot k+1}, ..., r_{ik})$. Now let see that operation D preserves autoregressive property, let $d = D(t)$. Now, $U(d) = (u_1, ..., u_n)$ and each u_i depends on $d_{\lfloor \frac{i-1}{k} \rfloor +1}$.

Now consider $s \leq k - 2$ and let $(u_1, ..., u_n) = F((x_1, ..., x_n))$ will be a result of our Transformer part. Let take u_1 which depends on d_1 and d_1 depends on $(r_1, ..., r_k) = (0, ..., 0, x_1, ..., x_{k-s})$. For that reason d_1 depends on $x_1, x_2, ..., x_{k-s}$, so we have

$$P(x_1|x_{k-s}) \neq P(x_1)$$

which violates the autoregressive property.

B Experimental setup

B.1 Common parameters

Here we list common hyperparameters used for all experiments mentioned in the paper. We use Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 1\mathrm{e}{-9}$. Weight decay and gradient clipping is not used.

In terms of model details, we decided to use a Pre-Norm architecture and FastGelu activation in feed-forward layers.

B.2 Enwik8

We use $d_{model} = 512$, $d_{ff} = 2048$ and 8 attention heads. Models in ablation study are trained for 200k steps with cosine learning rate schedule, setting cycle length for 200k steps and linear warmup of 4000 steps.

For the main result achieving **0.98** bpc with $4@1, 8@3, 4@1$ hierarchy, we set $d_{model} = 768$, $d_{ff} = 3072$ and $n_{heads} = 8$ which results in 146M parameters. It is trained for a total number of 350k steps with one cycle of cosine schedule. Linear warmup of 20k steps is used.

At the beginning of our work on this paper, we have performed grid search over following hyperparameters for enwik8:

- batch size: $\{8, 16, 32\}$, finally chosen 8
- dropout: $\{0.05, 0.1, 0.15, 0.20\}$, finally chosen 0.15
- learning rate: $\{1\mathrm{e}{-4}, 2\mathrm{e}{-4}, 3\mathrm{e}{-4}, 4\mathrm{e}{-4}, 5\mathrm{e}{-4}\}$, finally chosen $4\mathrm{e}{-4}$

All next experiments were conducted using these parameters without additional searching.

B.3 Downsampled ImageNet - common parameters

For ImageNet32 and ImageNet64 experiments we use inverse square root learning rate decay from (Vaswani et al., 2017), setting warmup steps to 8000 in both experiments. Total batch size is 64.

B.4 ImageNet32

In this dataset, we operate on input sequence length of 3072. We use $d_{\text{model}} = 512$, $d_{\text{ff}} = 2048$, 8 attention heads and 0.01 dropout rate. We perform 400k training steps with linear warmup and inverse square root decay and then we train for additional 70k steps with cosine learning rate decay, starting from the learning rate from the previous schedule at 400k and decreasing it to 0 at 470k steps.

B.5 ImageNet64

As an input we receive a sequence of 12288 tokens representing $64 \times 64 \times 3$ images. We set $d_{\text{model}} = 768$, $d_{\text{ff}} = 3072$, 8 attention heads and dropout equal to 0. We perform 300k steps with linear warmup and inverse square root decay.

B.6 CIFAR-10

All the ablation studies are run for 100k training steps, unless otherwise specified. Input sequence has length 3072 and model parameters are as follows: $d_{\text{model}} = 512$, $d_{\text{ff}} = 2048$, 8 attention heads and dropout equal to 0. Total batch size is 8. Cosine learning rate decay with linear warmup of 5000 steps and 100k cycle length is used.

C Environment setup

C.1 Hardware

Experiments are conducted on several setups.

- Ablation Study and short training sessions were computed on nodes consisting of 4x *Titan V* with 12GB memory each, 64GB RAM, *Intel Xeon E5-2660 v4* CPU
- longer trainings were completed on 8x *RTX 2080 Ti* with 11GB memory each, 128GB RAM and *Intel Xeon E5-2660 v4* CPU.
- Few longest trainings were conducted on 8×8 TPUv3 units, each with 16GB memory.

C.2 Software

All experiments were performed on Linux operating system using Trax library version 1.3.9 along with all its dependencies from this particular release date. Additionally, to run shorten factor dropout experiments we modified the Transformer-XL codebase in PyTorch.

D Reproducibility

To ensure the reproducibility of this work and to support open science principles, we made our code publicly available at `github.com/google/trax`. In this repository, we also provide Google Colab notebooks where the evaluation of our main Enwik8 and ImageNet32/64 results can be reproduced.[2][3]

D.1 Randomness

Seeds in all experiments were chosen randomly, however each experiment contains history which allows retrieving all randomly set parameters for reproductions.

For each ablation described in the ablation study section, we rerun the baseline 3 times to calculate standard deviation. All other experiments are run only once due to costs and since the variance we noticed was minimal.

D.2 Experiment representation

Each experiment is represented by a configuration file that unambiguously determines the whole setup – all hyperparameters and training details like specific optimizers, data preprocessing functions, or batch size per device.

Abstract

Internet memes have emerged as an increasingly popular means of communication on the Web. Although typically intended to elicit humour, they have been increasingly used to spread hatred, trolling, and cyberbullying, as well as to target specific individuals, communities, or society on political, socio-cultural, and psychological grounds. While previous work has focused on detecting harmful, hateful, and offensive memes, identifying whom they attack remains a challenging and under-explored area. Here we aim to bridge this gap. In particular, we create a dataset where we annotate each meme with its victim(s) such as the name of the targeted person(s), organization(s), and community(ies). We then propose `DISARM` (Detecting vIctimS targeted by hARmful Memes), a framework that uses named entity recognition and person identification to detect all entities a meme is referring to, and then, incorporates a novel contextualized multimodal deep neural network to classify whether the meme intends to harm these entities. We perform several systematic experiments on three test setups, corresponding to entities that are (a) all seen while training, (b) not seen as a harmful target on training, and (c) not seen at all on training. The evaluation results show that `DISARM` significantly outperforms ten unimodal and multimodal systems. Finally, we show that `DISARM` is interpretable and comparatively more generalizable and that it can reduce the relative error rate for harmful target identification by up to 9 points absolute over several strong multimodal rivals.

1 Introduction

Social media offer the freedom and the means to express deeply ingrained sentiments, which can be done using diverse and multimodal content such as memes. Besides being popularly used to express benign humour, Internet memes have also been misused to incite extreme reactions, hatred, and to spread disinformation on a massive scale.

(a) Harmful reference **(b)** Harmless reference

Figure 1: (a) A meme that targets Justin Trudeau in a *harmful* way, with a communal angle. (b) A *non-harmful* mention of Justin Trudeau, as a benign humor.

Numerous recent efforts have attempted to characterize harmfulness (Pramanick et al., 2021b), hate speech (Kiela et al., 2020), and offensiveness (Suryawanshi et al., 2020) within memes. Most of these efforts have been directed towards detecting malicious influence within memes, but there has been little work on identifying *whom the memes target*. Besides detecting whether a meme is harmful, it is often important to know whether the meme contains an entity that is particularly targeted in a harmful way. This is the task we are addressing here: detecting the entities that a meme targets in a harmful way.

Harmful targeting in memes is often done using satire, sarcasm, or humour in an explicit or an implicit way, aiming at attacking an individual, an organization, a community, or society in general. For example, Fig. 1a depicts Justin Trudeau, the Prime Minister of Canada, as *communally biased against* Canadians, while favoring alleged *killings by* Muslims, whereas Fig. 1b shows an arguably benign meme of the same person expressing subtle humour. Essentially, the meme in Fig. 1a *harmfully* targets *Justin Trudeau* directly, while causing indirect harm to *Canadians* and to *Muslims* as well. Note that in many cases interpreting memes and their harmful intent requires some additional background knowledge for the meme to be understood properly.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1572 - 1588
July 10-15, 2022

Hence, an automated system for detecting the entities targeted by harmful memes faces two major challenges: (*i*) insufficient *background context*, (*ii*) complexity posed by the *implicit* harm, and (*iii*) keyword *bias* in a supervised setting.

To address these challenges, here we aim to address the task of harmful target detection in memes by formulating it as an open-ended task, where a meme can target an entity not seen on training. An end-to-end solution requires (*i*) identifying the entities referred to in the meme, and (*ii*) deciding whether each of these entities is being targeted in a harmful way. To address these two tasks, we perform systematic contextualization of the multimodal information presented within the meme by first performing intra-modal fusion between an external knowledge-based *contextualized-entity* and the *textually-embedded harmfulness* in the meme, which is followed by cross-modal fusion of the contextualized textual and visual modalities using low-rank bi-linear pooling, resulting in an enriched multimodal representation. We evaluate our model using three-level stress-testing to better assess its generalizability to unseen targets.

We create a dataset, and we propose an experimental setup and a model to address the aforementioned requirements, making the following contributions:[1]:

1. We introduce the novel task of detecting the entities targeted by harmful memes.
2. We create a new dataset for this new task, Ext-Harm-P, by extending Harm-P (Pramanick et al., 2021b) via re-annotating each harmful meme with the entity it targets.
3. We propose `DISARM`, a novel multimodal neural architecture that uses an expressive contextualized representation for detecting harmful targeting in memes.
4. We empirically showcase that `DISARM` outperforms ten unimodal and multimodal models by several points absolute in terms of macro-F1 scores in three different evaluation setups.
5. Finally, we discuss `DISARM`'s generalizability and interpretability.

2 Related Work

Misconduct on Social Media. The rise in misconduct on social media is a prominent research topic. Some forms of online misconduct include rumours (Zhou et al., 2019), fake news (Aldwairi and Alwahedi, 2018; Shu et al., 2017; Nguyen et al., 2020), misinformation (Ribeiro et al., 2021; Shaar et al., 2022), disinformation (Alam et al., 2021; Hardalov et al., 2022), hate speech (MacAvaney et al., 2019; Zhang and Luo, 2019; Zampieri et al., 2020), trolling (Cook et al., 2018), and cyber-bullying (Kowalski et al., 2014; Kim et al., 2021). Some notable work in this direction includes stance (Graells-Garrido et al., 2020) and rumour veracity prediction, in a multi-task learning framework (Kumar and Carley, 2019), wherein the authors proposed a Tree LSTM for characterizing online conversations. Wu and Liu (2018) explored user and social network representations for classifying a message as genuine vs. fake. Cheng et al. (2017) studied user's mood along with the online contextual discourse and demonstrated that it helps for trolling behaviour prediction on top of user's behavioural history. Relia et al. (2019) studied the synergy between discrimination based on race, ethnicity, and national origin in the physical and in the virtual space.

Studies Focusing on Memes. Recent efforts have shown interest in incorporating additional contextual information for meme analysis. Shang et al. (2021a) proposed knowledge-enriched graph neural networks that use common-sense knowledge for offensive memes detection. Pramanick et al. (2021a) focused on detecting COVID-19-related harmful memes and highlighted the challenge posed by the inherent biases within the existing multimodal systems. Pramanick et al. (2021b) released another dataset focusing on US Politics and proposed a multimodal framework for harmful meme detection. The Hateful Memes detection challenge by Facebook (Kiela et al., 2020) introduced the task of classifying a meme as hateful vs. non-hateful. Different approaches such as feature augmentation, attention mechanism, and multimodal loss re-weighting were attempted (Das et al., 2020; Sandulescu, 2020; Zhou et al., 2021; Lippe et al., 2020) as part of this task. Oriol et al. (2019) studied hateful memes by highlighting the importance of visual cues such as structural template, graphic modality, causal depiction, etc.

Test	612	316	296
Total	4,446	1,594	2,852

Table 1: Summary of Ext-Harm-P, with overall and category-wise # of samples.

Web-entity detection along with fair face classification (Karkkainen and Joo, 2021) and semi-supervised learning-based classification (Zhong, 2020) were also used for the hateful meme classification task. Other noteworthy research includes using implicit models, e.g., topic modelling and multimodal cues, for detecting offensive analogy (Shang et al., 2021b) and hateful discrimination (Mittos et al., 2020) in memes. Wang et al. (2021) argued that online attention can be garnered immensely via fauxtography, which could eventually evolve towards turning into memes that potentially go viral. To support research on these topics, several datasets for offensiveness, hate speech, and harmfulness detection have been created (Suryawanshi et al., 2020; Kiela et al., 2020; Pramanick et al., 2021a,b; Gomez et al., 2020; Dimitrov et al., 2021; Sharma et al., 2022).

Most of the above studies attempted to address classification tasks in a constrained setting. However, to the best of our knowledge, none of them targeted the task of detecting the specific entities that are being targeted. Here, we aim to bridge this gap with focus on detecting the specific entities targeted by a given harmful meme.

3 Dataset

The Harm-P dataset (Pramanick et al., 2021b) consists of 3,552 memes about US politics. Each meme is annotated with its harmful label and the social entity that it targets. The targeted entities are coarsely classified into four social groups: individual, organization, community, and the general public. While these coarse classes provide an abstract view of the targets, identifying the *specific* targeted person, organization, or community in a fine-grained fashion is also crucial, and this is our focus here. All the memes in this dataset broadly pertain to *US Politics domain*, and they target well-known personalities or organizations. To this end, we manually re-annotated the memes in this dataset with the specific people, organizations, and communities that they target.

Candidates:
bill clinton,
hillary clinton,
white house,
donald trump,
democrat
Harmful:
bill clinton,
hillary clinton,
democrat
Not-harmful:
white house,
donald trump

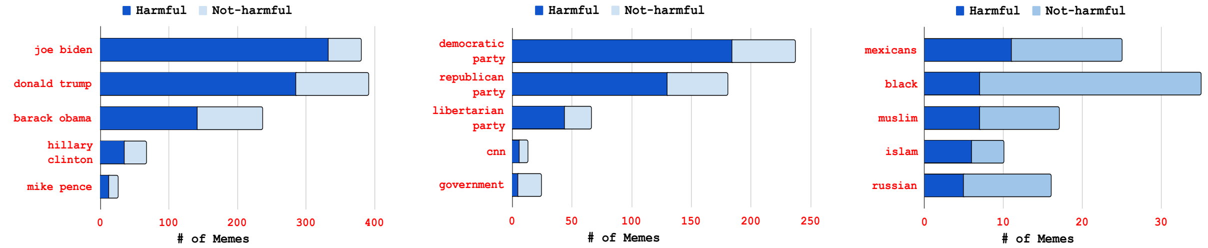
Figure 2: Example meme, along with the candidate entities, harmful targets, and non-harmful references.

Extending Harm-P (Ext-Harm-P). Towards generalizability, we extend Harm-P by redesigning the existing data splits as shown in Table 1. We call the resulting dataset Ext-Harm-P. It contains a total of 4,446 examples including 1,594 harmful and 2,852 non-harmful; both categories have references to a number of entities. For training, we use the *harmful* memes provided as part of the original dataset (Pramanick et al., 2021b), which we re-annotate for the fine-grained entities that are being targeted harmfully as positive samples (*harmful* targets). This is matched with twice as many negative samples (*not-harmful* targets). For negative targets, we use the top-2 entities from the original entity lexicon, which are not labeled for harmfulness and have the highest lexical similarity with the meme text (Ferreira et al., 2016). This at least ensures lexical similarity with the entities referenced within a meme, thereby facilitating a confounding effect (Kiela et al., 2020) as well. For the test set, *all* the entities are first extracted automatically using named entity recognition (NER) and person identification (PID)[2]. This is followed by manual annotation of the test set.

Dataset Annotation Process Since assessing the harmfulness of memes is a highly subjective task, our annotators were requested to follow four key steps when annotating each meme, aiming to ensure label consistency. The example in Fig. 2 demonstrates the steps taken while annotating: we first identify the candidate entities, and then we decide whether a given entity is targeted in a harmful way. We asked our annotators to do the following (additional details about the annotation process are given in Appendix D):

---

[2] NER using SpaCy & PID using `http://github.com/ageitgey/face_recognition.`



(a) Individual **(b)** Organization **(c)** Community

Figure 3: Comparison plots for the top-5 *harmfully referenced* entities, for their harmful/non-harmful referencing in our dataset.

1. Understand the meme and its background context.
2. List all the valid *candidate* entities that are referenced in the meme. For the example on Fig. 2, the valid entities are *Bill Clinton, Hillary Clinton, White House, Donald Trump*, and *Democrat*.
3. Assign the relevant entities as *harmful*. For the example on Fig. 2, *Bill Clinton, Hillary Clinton*, and *Democrat* are targeted in the meme for influencing the appointment of their kin on government positions.
4. Finally, assign *harmless* references to entities under the non-harmful category. In the example on Fig. 2, *Donald Trump* and *White House* would be annotated as *non-harmful*.

We had three annotators and a consolidator. The inter-annotator agreement before consolidation had a Fleiss Kappa of 0.48 (moderate agreement), and after consolidation it increased to 0.64 (substantial agreement).

Analyzing Harmful Targeting in Memes. The memes in Ext-Harm-P are about *US Politics*, and thus they prominently feature entities such as *Joe Biden* and *Donald Trump*, both harmfully and harmlessly. The ratio between these types of referencing varies across *individuals*, *organizations*, and *communities*. We can see in Fig. 3 that the top-5 harmfully referenced *individuals* and *organizations* are observed to be subjected to a more relative harm (normalized by the number of occurrences of these entities in memes). However, the stacked plots for the top-5 harmfully targeted communities *Mexicans, Black, Muslim, Islam*, and *Russian* in Fig. 3c show relatively less harm targeting these communities.

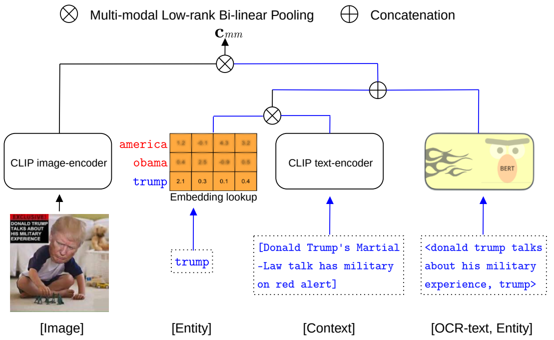


Figure 4: The architecture of our proposed approach DISARM. Here, $\mathbf{c}_{mm}$ is the multimodal representation used for the final classification.

4 Proposed Approach

Our proposed model DISARM, as depicted in Fig. 4, is based on a fusion of the textual and the visual modalities, explicitly enriched via contextualised representations by leveraging CLIP (Radford et al., 2021). We chose CLIP as a preferred encoder module for contextualization, due to its impressive zero-shot multimodal embedding capabilities. At first, valid entities are extracted automatically, as part of the process of creating training/validation sets. Then, for each meme, we first obtain the *contextualized-entity* (CE) representation by fusing the CLIP-encoded context and the entity representation. CE is then fused with BERT-based (Devlin et al., 2019) *embedded-harmfulness* (EH) encoding fine-tuned on the OCR-extracted text and entities as inputs. We call the resulting fusion output a *contextualized-text* (CT) representation. CT is then fused with the *contextualized-image* (CI) representation, obtained using the CLIP encoder for the image. We, henceforth, refer to the resulting enriched representation as the *contextualized multimodal* (CMM) representation. We modify the multimodal low-rank bi-linear pooling (Kim et al., 2017) to fuse the input representation into a joint space.

This approach, as can be seen in the subsequent sections below, not only can capture complex cross-modal interactions, but it also provides an efficient fusion mechanism towards obtaining a context-enriched representation. Finally, we use this representation to train a classifier for our task. We describe each module in detail below.

Low-rank Bi-linear Pooling (LRBP). We begin by revisiting *low-rank bi-linear pooling* to set the necessary background. Due to the many parameters in bi-linear models, Pirsiavash et al. (2009) suggested a low-rank bi-linear (LRB) approach to reduce the rank of the weight matrix $\mathbf{W}_i$. Consequently, the number of parameters and hence the complexity, are reduced. The weight matrix $\mathbf{W}_i$ is re-written as $\mathbf{W}_i = \mathbf{U}_i\mathbf{V}_i^T$, where $\mathbf{U}_i \in \mathbb{R}^{N \times d}$ and $\mathbf{V}_i \in \mathbb{R}^{M \times d}$, effectively putting an upper bound of $\min(N, M)$ on the value of d. Therefore, the low-rank bi-linear models can be expressed as follows:

$$f_i = \mathbf{x}^T\mathbf{W}_i\mathbf{y} = \mathbf{x}^T\mathbf{U}_i\mathbf{V}_i^T\mathbf{y} = \mathbb{1}^T(\mathbf{U}_i^T\mathbf{x} \circ \mathbf{V}_i^T\mathbf{y}) \quad (1)$$

where $\mathbb{1} \in \mathbb{R}^d$ is a column vector of ones, and $\circ$ is Hadamard product. f_i in Equation (1) can be further re-written to obtain $\mathbf{f}$ as follows:

$$\mathbf{f} \quad = \quad \mathbf{P}^T(\mathbf{U}^T\mathbf{x} \circ \mathbf{V}^T\mathbf{y}) + \mathbf{b} \qquad (2)$$

where $\mathbf{f} \in \{f_i\}$, $\mathbf{P} \in \mathbb{R}^{d \times c}$, $\mathbf{b} \in \mathbb{R}^c$, d is an output, and c is an LRB hyper-parameter.

We further introduce a non-linear activation formulation for LRBP, following Kim et al. (2017), who argued that non-linearity both before and after the Hadamard product complicates the gradient computation. This addition to Equation (2) can be represented as follows:

$$\mathbf{f} \quad = \quad \mathbf{P}^T\tanh(\mathbf{U}^T\mathbf{x} \circ \mathbf{V}^T\mathbf{y}) + \mathbf{b} \qquad (3)$$

We slightly modify the multimodal low-rank bi-linear pooling (MMLRBP). Instead of directly projecting the input $\mathbf{x} \in \mathbb{R}^N$ and $\mathbf{y} \in \mathbb{R}^M$ into a lower dimension d, we first project the input modalities in a joint space N. We then perform LRBP as expressed in Equation 3, by using jointly embedded representations $\mathbf{x}_{mm} \in \mathbb{R}^{N \times d}$ and $\mathbf{y}_{mm} \in \mathbb{R}^{N \times d}$ to obtain a multimodal fused representation $\mathbf{f}_{mm}$, as expressed below:

$$\mathbf{f}_{mm} \quad = \quad \mathbf{P}^T\tanh(\mathbf{U}^T\mathbf{x}_{mm} \circ \mathbf{V}^T\mathbf{y}_{mm}) \quad (4)$$

Structured Context. Towards modelling auxiliary knowledge, we curate *contexts* for the memes in Ext-Harm-P. First, we use the meme text as a search query[3] to retrieve relevant contexts, using the title and the first paragraph of the resulting top document as a *context*, which we call con.

Contextualized-entity Representation (CE). Towards modelling the context-enriched entity, we first obtain the embedding of the input entity ent. Since we have a finite set of entities referenced in the memes in our training dataset, we perform a lookup in the embedding matrix from $\mathbb{R}^{V \times H}$ to obtain the corresponding entity embedding $\mathbf{ent} \in \mathbb{R}^H$, with $H = 300$ being the embedding dimension and V the vocabulary size. We train the embedding matrix from *scratch* as part of the overall training of our model. We project the obtained entity representation $\mathbf{ent}$ into a 512-dimensional space, which we call $\mathbf{e}$. To augment a given entity with relevant contextual information, we fuse it with a contextual representation $\mathbf{c} \in \mathbb{R}^{512}$ obtained by encoding the associated context (con) using CLIP. We perform this fusion using our adaptation of the multimodal low-rank bi-linear pooling as defined by Equation (4). This yields the following contextualized-entity (CE) representation $\mathbf{c}_{ent}$:

$$\mathbf{c}_{ent} \quad = \quad \mathbf{P}_1^T\tanh(\mathbf{U}_1^T\mathbf{e} \circ \mathbf{V}_1^T\mathbf{c}) + \mathbf{b} \qquad (5)$$

where $\mathbf{c}_{ent} \in \mathbb{R}^{512}$, $\mathbf{P}_1 \in \mathbb{R}^{256 \times 512}$, $\mathbf{b} \in \mathbb{R}^{512}$, $\mathbf{U}_1 \in \mathbb{R}^{512 \times 256}$, and $\mathbf{V}_1 \in \mathbb{R}^{512 \times 256}$.

Contextualized-Text (CT) Representation. Once we obtain the contextualized-entity embedding $\mathbf{c}_{ent}$, we concatenate it with the BERT encoding for the combined representation of the OCR-extracted text and the entity ($\mathbf{o}_{ent} \in \mathbb{R}^{768}$). We call this encoding an *embedded-harmfulness* (EH) representation. The concatenated representation from $\mathbb{R}^{1280}$ is then projected non-linearly into a lower dimension using a dense layer of size 512. We call the resulting vector $\mathbf{c}_{txt}$ a *contextualized-text* (CT) representation:

$$\mathbf{c}_{txt} \quad = \quad \mathbf{W}_i[\mathbf{o}_{ent}, \mathbf{c}_{ent}] + b_i \qquad (6)$$

where $\mathbf{W} \in \mathbb{R}^{1280 \times 512}$.

---

[3] `https://pypi.org/project/googlesearch-python/`

Contextualized Multimodal (CMM) Representation. Once we obtain the contextualized-text representation $\mathbf{c}_{txt} \in \mathbb{R}^{512}$, we again perform multimodal low-rank bi-linear pooling using Equation (4) to fuse it with the contextualized-image representation $\mathbf{c}_{img} \in \mathbb{R}^{512}$, obtained using the CLIP image-encoder. The operation is expressed as follows:

$$\mathbf{c}_{mm} = \mathbf{P}_2^T \tanh(\mathbf{U}_2^T \mathbf{c}_{txt} \circ \mathbf{V}_2^T \mathbf{c}_{img}) \quad (7)$$

where $\mathbf{c}_{mm} \in \mathbb{R}^{512}$, $\mathbf{P}_2 \in \mathbb{R}^{256\times512}$, $\mathbf{U}_2 \in \mathbb{R}^{512\times256}$, and $\mathbf{V}_2 \in \mathbb{R}^{512\times256}$.

Notably, we learn two different projection matrices $\mathbf{P}_1$ and $\mathbf{P}_2$, for the two fusion operations performed as part of Equations (5) and (7), respectively, since the fused representations at the respective steps are obtained using different modality-specific interactions.

Classification Head. Towards modelling the binary classification for a given meme and a corresponding entity as either harmful or non-harmful, we use a shallow multi-layer perceptron with a single dense layer of size 256, which represents a condensed representation for classification. We finally map this layer to a single dimension output via a sigmoid activation. We use binary cross-entropy for the back-propagated loss.

5 Experiments

We experiment with various unimodal (image/text-only) and multimodal models, including such pre-trained on multimodal datasets such as MS COCO (Lin et al., 2014) and CC (Sharma et al., 2018). We train `DISARM` and all unimodal baselines using PyTorch, while for the multimodal baselines, we use the MMF framework.[4] [5]

5.1 Evaluation Measures

For evaluation, we use commonly used macro-average versions of accuracy, precision, recall, and F1 score. For example, we discuss the harmful class recall, which is relevant for our study as it characterizes the model's performance at detecting *harmfully* targeting memes. All results we report are averaged over five independent runs.

Evaluation Strategy. With the aim of having a realistic setting, we pose our evaluation strategy as an open-class one. We train all systems using under-sampling of the entities that were not targeted in a harmful way: using all positive (harmful) examples and twice as many negative (non-harmful) ones. We then perform an open-class testing, for all referenced entities (some possibly unseen on training) per meme, effectively making the evaluation more realistic. To this end, we formulate three testing scenarios as follows, with their Harmful (H) and Non-harmful (N) counts:

1. **Test set A (316H, 296N)**: All examples in this dataset are about entities that were *seen* during training.
2. **Test set B (27H, 94N)**: The examples in this set are about entities that were *not seen* as *harmful* during training.
3. **Test set C (16H, 76N)**: All examples are about entities that were completely *unseen* during training.

Baseline Models. Our baselines include both unimodal and multimodal models as follows:

– *Unimodal Systems*: ▶ **VGG16, VIT:** For the unimodal (image-only) systems, we use two well-known models: VGG16 (Simonyan and Zisserman, 2015) and VIT (Vision Transformers) that emulate a Transformer-based application jointly over textual tokens and image patches (Dosovitskiy et al., 2021). ▶ **GRU, XLNet:** For the unimodal (text-only) systems, we use GRU (Cho et al., 2014), which adaptively captures temporal dependencies, and XLNet (Yang et al., 2019), which implements a generalized auto-regressive pre-training strategy.

– *Multimodal Systems*: ▶ **MMF Transformer:** This is a multimodal Transformer model that uses visual and language tokens with self-attention.[6] ▶ **MMBT:** Multimodal Bitransformer (Kiela et al., 2019) captures the intra-modal and the inter-modal dynamics. ▶ **ViLBERT CC:** Vision and Language BERT (Lu et al., 2019), pre-trained on CC (Sharma et al., 2018), is a strong model with task-agnostic joint representation. ▶ **Visual BERT COCO:** Visual BERT (Li et al., 2019), pre-trained on the MS COCO dataset (Lin et al., 2014).

Table 3: Performance comparison of unimodal and multimodal models vs. DISARM (and its variants) on Test Set C.

Experimental Results. We compare the performance of several unimodal and multimodal systems (pre-trained or trained from scratch) vs. DISARM and its variants. All systems are evaluated using the 3-way testing strategy described above. We then perform ablation studies on representations that use the *contextualized-entity*, its fusion with *embedded-harmfulness* resulting into *contextualized-text*, and the final fusion with *contextualized-image* yielding the *contextualized-multimodal* modules of DISARM (see Appendix B for a detailed ablation study).[7] This is followed by interpretability analysis. Finally, we discuss the limitations of DISARM by performing error analysis (details in Appendix C).

All Entities Seen During Training: In our unimodal text-only baseline experiments, the GRU-based system yields a relatively lower *harmful* recall of 0.74 compared to XLNet's 0.82, but a better overall F1 score of 0.75 vs. 0.67 for XLNet, as shown in Table 2. The lower *harmful* precision of 0.65 and the *not-harmful* recall of 0.52 contribute to the lower F1 score for XLNet.

Among the image-only unimodal systems, VGG performs better with a *non-harmful* recall of 0.81, but its poor performance for detecting harmful memes yields a lower *harmful* recall of 0.68. At the same time, VIT has a relatively better *harmful* recall of 0.74. Overall, the unimodal results (see Table 2) indicate the efficacy of self-attention over convolution for images and RNN (GRU) sequence modeling for text.

Multimodally pre-trained models such as VisualBERT and ViLBERT yield moderate F1 scores of 0.70 and 0.68, and *harmful* recall of 0.78 and 0.77, respectively (see Table 2). Fresh training facilitates more meaningful results in favour of *non-harmful* precision of 0.78 for both models, and *harmful* recall of 0.84 and 0.82 for VisualBERT and ViLBERT, respectively. Overall, ViLBERT yields the most balanced performance of 0.75 in terms of F1 score. It can be inferred from these results (see Table 2) that multimodal pre-training leverages domain relevance.

We can see in Table 2 that multimodal low-rank bi-linear pooling distinctly enhances the performance in terms of F1 score. The improvements can be attributed to the fusion of the CE and EH representations, respectively, with CI, instead of a simple concatenation. This is more prominent for CE with an F1 score of 0.78, which shows the importance of modeling the background context. Finally, DISARM yields a balanced F1 score of 0.78, with a reasonable precision of 0.74 for *non-harmful* category, and the best recall of 0.86 for the *harmful* category.

All Entities Unseen as Harmful Targets During Training: With Test Set B, the evaluation is slightly more challenging in terms of the entities to be assessed, as these were never seen at training time as *harmful*.

---

[7] We use the abbreviations CE, CT, CI, CMM, EH, and MMLRBP for the *contextualized* representations of the entity, the text, the image, the multimodal representation, the embedded-harmfulness, and the multimodal low-rank bilinear pooling, respectively.

(a) L-AT **(b)** MM-AT-CLIP **(c)** V-AT-`DISARM` **(d)** V-AT-ViLBERT

Target Candidate→`democratic party`

Context→Politics tears families apart during bruising political season, when many Americans drop friends and family members who have different political views.

Figure 5: Comparison of the attention-maps for `DISARM` [(a), (b) & (c)] and ViLBERT [(d)] using BertViz and Grad-CAM.

Unimodal systems perform poorly on the *harmful* class, with the exception of XLNet (see Table 2), where the *harmful* class recall as 0.56. For the multimodal baselines, systems pre-trained using COCO (VisualBERT) and CC (ViLBERT) yield a moderate recall of 0.64 and 0.71 for the *harmful* class in contrast to what we saw for Test Set A in Table 2. This could be due to additional common-sense reasoning helping such systems, on a test set that is more open-ended compared to Test Set A. Their non-pre-trained versions along with the MM Transformer and MMBT achieve better F1 scores, but with low *harmful* recall.

Multimodal fusion using MMLRBP improves the *harmful* class recall for CE to 0.52, but yields lower values of 0.37 for EH fusion with CI (see Table 2). This reconfirms the utility of the context. In comparison, `DISARM` yields a balanced F1 score of 0.65 with the best precision of 0.83 and 0.38, along with decent recall of 0.79 and 0.69 for *non-harmful* and *harmful* memes, respectively.

All Entities Unseen During Training: The results decline in this scenario (similarly to Test Set B), except for the *harmful* class recall of 0.62 for XLNet, as shown in Table 3. In the current scenario (Test Set C), none of the entities being assessed at testing is seen during the training phase. For multimodal baselines, we see a similar trend for VisualBERT (COCO) and ViLBERT (CC), with the *harmful* class recall of 0.72 for ViLBERT (CC) being significantly better than the 0.12 for VisualBERT (COCO). This again emphasizes the need for the affinity between the pre-training dataset and the downstream task at hand. In general, the precision for the *harmful* class is very low.

We observe (see Table 3) sizable boost for the *harmful* class recall for MMLRBP-based multimodal fusion of CI with CE (0.69%), against a decrease with EH (0.31%). In comparison, `DISARM` yields a low, yet the best *harmful* precision of 0.36, and a moderate recall of 0.70 (see Table 3). Moreover, besides yielding reasonable precision and recall of 0.86 and 0.76 for the *non-harmful* class, `DISARM` achieves better average precision, recall, and F1 scores of 0.61, 0.73, and 0.64, respectively.

Generalizability of DISARM. The generalizability of `DISARM` follows from its characteristic modelling and context-based fusion. `DISARM` demonstrates an ability to detect harmful targeting for a diverse set of entities. Specifically, the three-way testing setup inherently captures the efficacy with which `DISARM` can detect *unseen* harmful targets. The prediction for entities *completely* unseen on training yields better results (see Tables 2 and 3), and suggests possibly induced bias in the former scenario. Moreover, it is a direct consequence of the fact that we were able to incorporate only a limited set of the 246 potential targets. Overall, we argue that `DISARM` generalizes well for unseen entities with 0.65 and 0.64 macro-F1 scores, as compared to ViLBERT's 0.58 and MMBT's 0.51, for Test Sets B and C, respectively.

Comparative Diagnosis. Despite the marginally better *harmful* recall for ViLBERT (CC) on Test Set B (see Table 2) and Test Set C (see Table 3), the overall balanced performance of `DISARM` appears to be reasonably justified based on the comparative interpretability analysis between the attention maps for the two systems.

Fig. 5 shows the attention maps for an example meme. It depicts a meme that is *correctly* predicted to *harmfully* target the *Democratic Party* by DISARM and incorrectly by ViLBERT. As visualised in Fig. 5a, the harmfully-inclined word *killing* effectively attends not only to *baby*, but also to *Democrats* and *racist*. The relevance is depicted via different color schemes and intensities, respectively. Interestingly, *killing* also attends to the *Democratic Party*, both as part of the OCR-extracted text and the target-candidate, jointly encoded by BERT. The multimodal attention leveraged by DISARM is depicted (via the CLIP encoder) in Fig. 5b, demonstrating the utility of contextualised attention over the *male* figure that represents an attack on the *Democratic Party*. Also, DISARM has a relatively focused field of vision, as shown in Fig. 5c, as compared to a relatively scattered one for ViLBERT (see Fig. 5d). This suggest a better multimodal modelling capacity for DISARM as compared to ViLBERT.

6 Conclusion and Future Work

We introduced the novel task of detecting the targeted entities within harmful memes and we highlighted the inherent challenges involved. Towards addressing this open-ended task, we extended Harm-P with target entities for each harmful meme. We then proposed a novel multimodal deep neural framework, called DISARM, which uses an adaptation of multimodal low-rank bi-linear pooling-based fusion strategy at different levels of representation abstraction. We showed that DISARM outperforms various uni/multi-modal baselines in three different scenarios by 4%, 7%, and 13% increments in terms of macro-F1 score, respectively. Moreover, DISARM achieved a relative error rate reduction of 9% over the best baseline. We further emphasized the utility of different components of DISARM through ablation studies. We also elaborated on the generalizability of DISARM, thus confirming its modelling superiority over ViLBERT via interpretability analysis. We finally analysed the shortcomings in DISARM that lead to incorrect harmful target predictions.

In the present work, we made an attempt to elicit some inherent challenges pertaining to the task at hand: augmenting the relevant context, effectively fusing multiple modalities, and pre-training. Yet, we also leave a lot of space for future research for this novel task formulation.

Ethics and Broader Impact

Reproducibility. We present detailed hyper-parameter configurations in Appendix A and Table 4. The source code, and the dataset Ext-Harm-P are available at `https://github.com/LCS2-IIITD/DISARM`

User Privacy. The information depicted/used does not include any personal information. Copyright aspects are attributed to the dataset source.

Annotation. The annotation was conducted by NLP experts or linguists in India, who were fairly treated and were duly compensated. We conducted several discussion sessions to make sure all annotators could understand the distinction between harmful vs. non-harmful referencing.

Biases. Any biases found in the dataset are unintentional, and we do not intend to cause harm to any group or individual. We acknowledge that detecting harmfulness can be subjective, and thus it is inevitable that there would be biases in our gold-labelled data or in the label distribution. This is addressed by working on a dataset that is created using general keywords about US Politics, and also by following a well-defined schema, which sets explicit definitions for annotation.

Misuse Potential. Our dataset can be potentially used for ill-intended purposes, such as biased targeting of individuals/communities/organizations, etc. that may or may not be related to demographics and other information within the text. Intervention with human moderation would be required to ensure that this does not occur.

Intended Use. We make use of the existing dataset in our work in line with the intended usage prescribed by its creators and solely for research purposes. This applies in its entirety to its further usage as well. We commit to releasing our dataset aiming to encourage research in studying harmful targeting in memes on the web. We distribute the dataset for research purposes only, without a license for commercial use. We believe that it represents a useful resource when used appropriately.

Environmental Impact. Finally, large-scale models require a lot of computations, which contribute to global warming (Strubell et al., 2019). However, in our case, we do not train such models from scratch; rather, we fine-tune them on a relatively small dataset.

Acknowledgments

The work was partially supported by a Wipro research grant, Ramanujan Fellowship, the Infosys Centre for AI, IIIT Delhi, and ihub-Anubhuti-iiitd Foundation, set up under the NM-ICPS scheme of the Department of Science and Technology, India. It is also part of the Tanbih mega-project, developed at the Qatar Computing Research Institute, HBKU, which aims to limit the impact of "fake news," propaganda, and media bias by making users aware of what they are reading, thus promoting media literacy and critical thinking.

Appendix

A Implementation Details and Hyper-parameter Values

We trained all our models using PyTorch on NVIDIA Tesla V100 GPU, with 32 GB dedicated memory, CUDA-11.2 and cuDNN-8.1.1 installed. For the unimodal models, we imported all the pre-trained weights from the `TORCHVISION.MODELS`[8], a sub-package of the PyTorch framework. We initialized the remaining weights randomly using a zero-mean Gaussian distribution with a standard deviation of 0.02. We train `DISARM` in a setup considering only *harmful* class data from Harm-P (Pramanick et al., 2021b). We extended it by manually annotating for *harmful* targets, followed by including *non-harmful* examples using automated entity extraction (textual and visual) strategies for training/validation splits and manual annotation (for both harmful and non-harmful) for the test split.

When training our models and exploring various values for the different model hyper-parameters, we experimented with using the Adam optimizer (Kingma and Ba, 2015) with a learning rate of $1e^{-4}$, a weight decay of $1e^{-5}$, and a Binary Cross-Entropy (BCE) loss as the objective function. We extensively fine-tuned our experimental setups based upon different architectural requirements to select the best hyper-parameter values. We also used early stopping for saving the best intermediate checkpoints. Table 4 gives more detail about the hyper-parameters we used for training. On average, it took approximately 2.5 hours to train a multi-modal neural model.

B Ablation Study

In this section, we present some ablation studies for sub-modules of `DISARM` based on CE, EH, CT, and CI, examined in isolation and in combinations, and finally for `DISARM` using CMM.

B.1 Test Set A

As observed in the comparisons made with the other baseline systems for the Test Set A in Table 2, the overall range of the F1 scores is relatively higher with the lowest value being 0.66 for XLNet (text-only) model. The results for unimodal systems, as can be observed in Table 5, is satisfactory with values of 0.74, 0.73, and 0.77 for CE EH, and CI unimodal systems, respectively. For multimodal systems, we can observe distinct lead for the MMLRBP-based fusion strategy, for both CE and EH systems over the concatenation-based approach, except for EH's recall drop by 7%. Finally `DISARM` yields the best overall F1 score of 0.78.

B.2 Test Set B

With *context* not having any harmfulness cues for a given meme when considered in isolation, the unimodal CE module performs the worst with 0.48 F1 score, and 0.07 recall for the *harmful* class, in the open-ended setting of Test Set B. In contrast, EH yields an impressive F1 score of 0.55, and a *harmful* recall of 0.41. This relative gain of 7% in terms of F1 score could be due to the presence of explicit harmfulness cues. The complementary effect of considering contextual information can be inferred from the joint modeling of CE and EH, to obtained CT, that enhances the F1 score and the *harmful* recall by 2% and 3%, respectively (see Table 5). Unimodal assessment of CI performs moderately with an F1 score of 0.51, but with a poor *harmful* recall of 0.15. MMLRBP, towards joint-modeling of CE and CI yields a significant boost in the *harmful* recall to 0.52 (see Table 5). On the other hand, MMLRBP-based fusion of EH and CI yields 0.54 F1 score, which is 1% below that for the unimodal EH system. This emphasizes the importance of accurately modeling the embedded harmfulness, besides *augmenting* with additional context. A complementary impact of CE, EH, and CI is observed for `DISARM` with a balanced F1 score of 0.6 and a competitive *harmful* recall value of 0.69.

Table 5: Ablation results for DISARM and its variants for Test Sets A, B, and C.

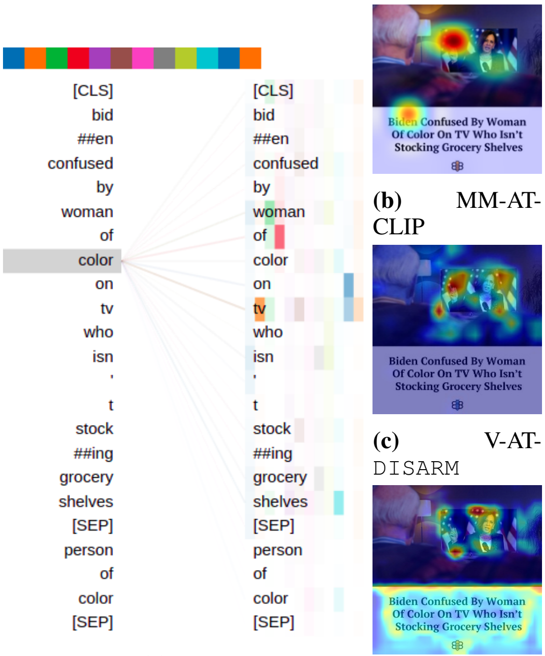
B.3 Test Set C

As observed in the previous scenario, the unimodal models for CE yield a low F1 score of 0.48 and the worst *harmful* recall value of 0.06. Much better performance is observed for unimodal setups including EH, and its joint modelling with CE with improved F1 scores of 0.56 and 0.58, respectively, along with the *harmful* recall score of 0.56 and 0.57, respectively. CI based unimodal evaluation again yields a moderate F1 score of 0.53 (see Table 5), along with a poor *harmful* recall of 0.19, which shows its inadequacy to model harmful targeting on its own. For multimodal setups, the joint modelling of CE and CI benefits from MMLRBP based fusion, yielding a gain of 7% and 13% in terms of F1 score and *harmful* recall, respectively. This confirms the importance of contextual multimodal semantic alignment. Correspondingly, joint multimodal modelling of EH and CI regresses the unimodal affinity within the EH. Finally, DISARM outperforms all other systems in this category with the best F1 score of 0.64, with a decent *harmful* recall score of 0.7.

The experimental results here are for comparison and analysis of the optimal set of design and baseline choices. We should note that we performed extensive experiments as part of our preliminary investigation, with different contextual modelling strategies, attention mechanisms, modelling choices, etc., to reach a conclusive architectural configuration that show promise for addressing the task of target detection in harmful memes.

C Error Analysis

It is evident from the results shown in Tables 2 and 3 that DISARM still has shortcomings. Examples like the one shown in Fig. 6 are seemingly *harmless*, both textually and visually, but imply serious *harm* to a *person of color* in an implicit way.



(a) L-AT

(b) MM-AT-CLIP

(c) V-AT-DISARM

(d) V-AT-ViLBERT

Target Candidate→`person of color`

Context→`During the evening of the VP debates, Joe Biden settled down on his soft couch with a glass of warm milk to watch this.`

Figure 6: Comparison of attention maps for miclassification between DISARM [(a), (b) & (c)] and ViLBERT [(d)] using BertViz and Grad-CAM.

This kind of complexity can be challenging to model without providing additional context about the meme like *people of colour face racial discrimination all over the world*. This is also analogous to a fundamental challenge associated with detecting implicit hate (MacAvaney et al., 2019). In this particular example, despite modelling contextual information explicitly in DISARM, it misclassifies this meme anyway.

(a) Harmful analogy **(b)** Sensitive visuals **(c)** Political grounds **(d)** Religious grounds **(e)** International threat

Figure 7: Examples of memes depicting different types (a)–(e) of *harmful* targeting.

Even though the context obtained for this meme pertains to its content (see Fig. 6), it does not relate to *global racial prejudice*, which is key to ascertaining it as a harmfully targeting meme. Moreover, besides context, visuals and the message embedded within the meme do not convey definite harm when considered in isolation. This error can be inferred clearly from the embedded-harmfulness, contextualised-visuals, and the visuals being attended by `DISARM` as depicted in Fig. 6a, Fig. 6b, and Fig. 6c, respectively. On the other hand, as shown in the visual attention plot for ViLBERT in Fig. 6d, the field of view that is being attended encompasses the visuals of *Kamala Harris*, who is the *person of colour* that i sbeing primarily targeted by the meme. Besides the distinct attention on the primary target-candidate within the meme, ViLBERT could have leveraged the pre-training it received from Conceptual Captions (CC) (Sharma et al., 2018), a dataset known for its diverse coverage of complex textual descriptions. This essentially highlights the importance of making use of multimodal pre-training using the dataset that is not as generic as MS COCO (Lin et al., 2014), but facilitates modelling of the complex real-world multimodal information, especially for tasks related to memes.

D Annotation Guidelines

Before discussing some details about the annotation process, revisiting the definition of *harmful* memes would set the pretext towards consideration of *harmful* targeting and *non-harmful* referencing. According to Pramanick et al. (2021b), a harm can be expressed as an abuse, an offence, a disrespect, an insult, or an insinuation of a targeted entity or any socio-cultural or political ideology, belief, principle, or doctrine associated with that entity. The harm can also be in the form of a more subtle attack such as mocking or ridiculing a person or an idea.

Another common understanding[9,10,11] about the harmful content is that it could be anything online that causes distress. It is an extremely subjective phenomenon, wherein what maybe be harmful to some might not be considered an issue by others. This makes it significantly challenging to characterize and hence to study it via the computational lens.

Based on a survey of 52 participants, Scheuerman et al. (2021) defines online harm to be any violating content that results in any (or a combination) of the following four categories: (*i*) physical harm, (*ii*) emotional harm, (*iii*) relational harm, and (*iv*) financial harm. With this in mind, we define two types of referencing that we have investigated in our work within the context of internet memes: (*i*) *harmful* and (*ii*) *non-harmful*.

D.1 Reference Types

Harmful. The understanding about harmful referencing (*targeting*) in memes, can be sourced back to the definition of harmful memes by Pramanick et al. (2021b), wherein a social entity is subjected to some form of ill-treatment such as mental abuse, psycho-physiological injury, proprietary damage, emotional disturbance, or public image damage, based on their background (bias, social background, educational background, etc.) by a meme author.

Not-harmful. Non-harmful referencing in memes is any benign mention (or depiction) of a social entity via humour, limerick, harmless pun or any content that does not cause distress. Any reference that is *not* harmful falls under this category.

Table 6: The top-5 most frequently referenced entities in each harmfulness class and their target categories. The total frequency for each word is shown in parentheses.

D.2 Characteristics of Harmful Targeting

There are several factors that collectively facilitate the characterisation of *harmful* targeting in memes. Here are some:

1. A prominent way of harmfully targeting an entity in a meme is by leveraging sarcastically harmful analogies, framed via either textual or visual instruments (see Fig. 7a).
2. There could be multiple entities being harmfully targeted within a meme as depicted in Fig. 2. Hence, annotators were asked to provide all such targets as harmful, with no exceptions.
3. A harmful targeting within a meme could have visual depictions that are either gory, violent, graphically sensitive, or pornographic (see Fig. 7b).
4. Any meme that insinuates an entity on either social, political, professional, religious grounds, can cause harm (see Fig. 7c and 7d).
5. Any meme that implies an explicit/implicit threat to an individual, a community, a national or an international entity is harmful (see Fig. 7d and 7e).
6. Whenever there is any ambiguity regarding the harmfulness of any reference being made, we requested the annotators to proceed following the best of their understanding.

E Ext-Harm-P Characteristics

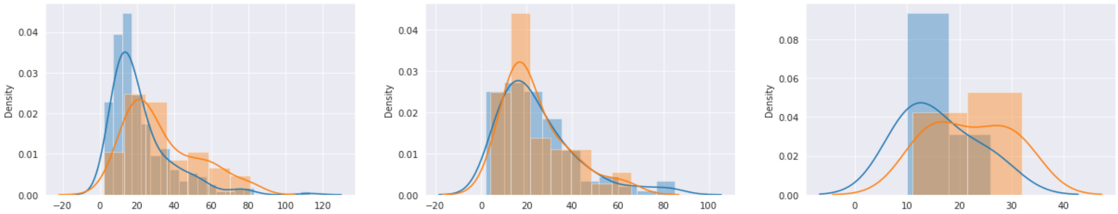
Below, we perform some analysis of the lexical content of the length of the meme text.

E.1 Lexical Analysis

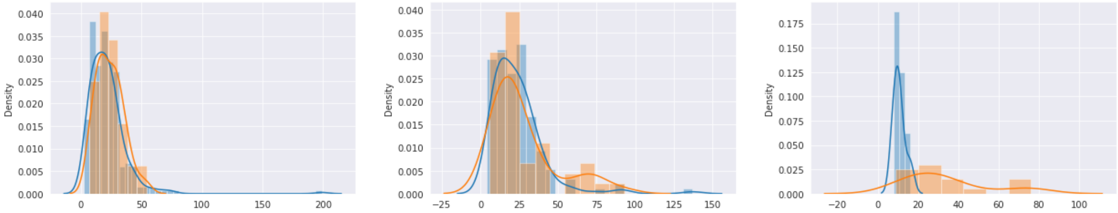
Interestingly, a significant number of memes are disseminated making references to popular *individuals* such as *Joe Biden, Donald Trump, etc.*, as can be observed for individual sub-categories (for both harmful and non-harmful memes) in Table 6.

We can see in Table 6 that for *harmful–organization*, the top-5 harmfully targeted organizations include the top-2 leading political organizations in the USA (the *Democratic Party* and the *Republican Party*), which are of significant political relevance, followed by the *Libertarian Party*, a media outlet (*CNN*), and finally the generic *government*. At the same time, non-harmfully referenced organizations includes the *Biden camp* and the *Trump administration*, which are mostly leveraged for harmfully targeting (or otherwise) the associated public figure. Finally, communities such as *Mexicans, Black, Muslim, Islam*, and *Russian* are often immensely prejudiced against online, and thus also in our meme dataset. At the same time, non-harmfully targeted communities such as the *Trump supporters* and the *African Americans* are not targeted as often as the aforementioned ones, as we can see in Table 6.

The above analysis of the lexical content of the memes in our datasets largely emphasizes the inherent bias that multimodal content such as memes can exhibit, which in turn can have direct influence on the efficacy of machine/deep learning-based systems for detecting the entities targeted by harmful memes. The reasons for this bias are mostly linked to societal behaviour at the organic level, and the limitations posed by current techniques to process such data. The mutual exclusion for harmful vs. non-harmful categories for community shows the inherent bias that could pose a challenge, even for the best multi-modal deep neural systems. The high pervasiveness of a few prominent keywords could effectively lead to increasing bias towards them for specific cases. At the same time, the significant overlap observed in Table 6 for the enlisted entities, between harmful and not-harmful individuals, highlights the need for sophisticated multi-modal systems that can effectively reason towards making a complex decision like detecting harmful targeting within memes, rather than exploit the biases towards certain entities in the training data.



(a) Trump **(b)** Republican Party **(c)** Mexican



(d) Biden **(e)** Democratic Party **(f)** Black

Figure 8: Distributions of the OCR's length for the memes of top-5 harmful references: harmful (Blue) and non-harmful (Orange). The depiction is for Individual: (a) and (d); Organization: (b) and (e); and Community: (c) and (f).

E.2 Meme-Message Length Analysis

Most of the *harmful* memes are observed to be created using texts of length 16–18 (see Fig. 8). At the same time, *not-harmful* meme-text lengths have a relatively higher standard deviation, possibly due to the diversity of *non-harmful* messages. *Trump* and the *Republic Party* have meme-text length distributions similar to the *non-harmful* category: skewing left, but gradually decreasing towards the right. This suggests a varying content generation pattern amongst meme creators (see Fig. 8). The meme-text length distribution for *Biden* closely approximates a normal distribution with a low standard deviation. Both categories would pre-dominantly entail creating memes with shorter text lengths, possibly due to the popularity of *Biden* amongst humorous content creators. A similar trend could be seen for the *Democratic Party* as well, where most of the instances fall within the 50–75 meme-text length range. The overall harmful and non-harmful meme-text length distribution is observed to be fairly distributed across different meme-text lengths for *Mexican*. At the same time, the amount of harm intended towards the *Black* community is observed to be significantly higher, as compared to moderately distributed *non-harmful* memes depicted by the corresponding meme-text length distribution in Fig. 8.

KD-VLP: Improving End-to-End Vision-and-Language Pretraining with Object Knowledge Distillation

Abstract

Self-supervised vision-and-language pretraining (VLP) aims to learn transferable multi-modal representations from large-scale image-text data and to achieve strong performances on a broad scope of vision-language tasks after finetuning. Previous mainstream VLP approaches typically adopt a two-step strategy relying on external object detectors to encode images in a multi-modal Transformer framework, which suffer from restrictive object concept space, limited image context and inefficient computation. In this paper, we propose an object-aware end-to-end VLP framework, which directly feeds image grid features from CNNs into the Transformer and learns the multi-modal representations jointly. More importantly, we propose to perform object knowledge distillation to facilitate learning cross-modal alignment at different semantic levels. To achieve that, we design two novel pretext tasks by taking object features and their semantic labels from external detectors as supervision: 1.) ***Object-guided masked vision modeling*** task focuses on enforcing object-aware representation learning in the multi-modal Transformer; 2.) ***Phrase-region alignment*** task aims to improve cross-modal alignment by utilizing the similarities between noun phrases and object labels in the linguistic space. Extensive experiments on a wide range of vision-language tasks demonstrate the efficacy of our proposed framework, and we achieve competitive or superior performances over the existing pretraining strategies.

1 Introduction

With the success of BERT (Devlin et al., 2018) in language modeling, self-supervised Vision-and-Language Pretraining (VLP) has attracted much interest from AI community, which aims to learn generalizable multi-modal representations from large-scale image-text data. Combined with a pretrain-then-transfer strategy, it shows great potential in tackling vision and language reasoning tasks, such as image-text retrieval, visual question answering (VQA) and visual entailment (Antol et al., 2015; Lee et al., 2018; Xie et al., 2019; Liu et al., 2021, 2020). A critical step in such representation learning is to jointly model linguistic entities and visual semantic concepts (e.g., attributes, objects, and relations), as well as their alignment. However, this is particularly challenging due to large discrepancy in visual and language representations (pixels vs words) and lack of entity-level cross-modal correspondence in supervision.

To tackle those challenges, most existing approaches (Li et al., 2021; Gan et al., 2020; Chen et al., 2020; Lu et al., 2019) adopt a two-step pretraining strategy that firstly utilizes off-the-shelf detectors to parse images into a set of object tokens, and then builds a multi-layer Transformer to learn visual and language embeddings jointly. In order to facilitate the multi-modal learning, those networks are typically trained via a set of carefully designed BERT-like objectives (e.g. Image-Text Matching). Despite its promising performance, the two-step strategy suffers from several limitations: 1) limited visual object concepts as the external detectors are trained on a predefined set of object categories; 2) lack of context cues outside of the object regions, which are crucial for complex reasoning tasks; 3) sub-optimal visual representation due to stage-wise training; and 4) computational inefficiency caused by additional detection modules. To overcome those limitations, recent works attempt to learn a joint visual-linguistic representations in an end-to-end manner (Huang et al., 2021, 2020; Xu et al., 2021; Kim et al., 2021). These methods directly take dense visual features from image grids as inputs to a multi-modal Transformer network, and hence do not rely on external object detectors in both pretraining and finetuning stages. Such model design significantly simplifies overall network architecture and allows deeper integration

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1589 - 1600
July 10-15, 2022

between visual and language features. However, using grid-level features makes it difficult to capture object-level visual concepts, which often results in less expressive multi-modal representations and inferior performances in downstream tasks.

In this work, we propose a novel object-aware end-to-end (E2E) VLP approach that inherits the strengths of both types of pretraining strategies mentioned above. Our core idea, which we name KD-VLP, is to incorporate visual object concepts in the E2E multi-modal learning, which is instantiated by performing **K**nowledge **D**istillation from semantic objects (e.g., from the off-the-shelf detectors) during the pretraining stage. This allows the network to better capture object representations and hence facilitates learning the alignment of linguistic entities and visual concepts. To achieve this, we introduce two novel pretext tasks to perform object knowledge distillation based on a CNN+Transformer architecture: an object-based masked vision modeling task for enforcing object-aware feature embeddings, and a phrase-region alignment task for building correspondence between object regions and language entities.

Specifically, we adopt a typical CNN backbone+multi-modal Transformer model for the pretraining. Given an image-text pair, the visual backbone firstly computes a set of visual features on the image grid. Then a multi-layer Transformer takes the visual features and the corresponding text tokens as input to generate their multi-modal embeddings. Based on those embeddings, a set of task-specific heads compute the corresponding objectives to train the entire network in an end-to-end fashion. Here, in addition to the commonly-used image-text matching and masked language modeling objectives, we develop two object-aware pretext tasks. The first task, *object-guided masked vision modeling* (OMVM), aims to reconstruct the RoI features and semantic label of each object (from an external detector) using the surrounding visual context and text description. To facilitate cross-modal alignment, we also develop a knowledge-guided masking strategy, which samples object candidates for reconstruction according to the similarity scores between the noun phrases in the corresponding text and their semantic labels. The second task, *phrase-region alignment* (PRA), aims to further improve cross-modal alignment by matching the above-mentioned phrase-label similarity scores of each phrase with the cross-modal similarity scores between the noun phrase embeddings and object region embeddings. After pretraining, we then transfer the learned multi-modal representations to different downstream vision-language tasks.

We perform pretraining on two widely-used indomain datasets: MSCOCO Caption (Lin et al., 2014) and Visual Genome (Krishna et al., 2016), and validate the learned multi-modal representations on five well-known visual-language tasks: Visual Question Answering (VQA), Image-text retrieval, Nature Language Visual Reasoning (NLVR^2), Visual Entailment (VE) and Visual Commonsense Reasoning (VCR). Empirical results show that our method outperforms the state-of-the-art end-to-end approaches by a sizeable margin. To better understand our method, we also provide a detailed ablation study and visualization.

The contributions of our work are three-fold:

- We propose a novel end-to-end pretraining strategy, capable of better encoding visual object concepts and facilitating multi-modal representation learning.
- We design an object-guided masked vision model task for distilling knowledge from external object detectors, and a phrase-region alignment task to facilitate learning better phrase-region correspondence.
- Compared with existing methods, we achieve competitive or superior performances without using external detection outputs during finetuning stage and model test.

2 Related Work

The existing self-supervised VLP approaches can be largely categorized into two groups: the two-step pretraining and the end-to-end pretraining, depending on whether they rely on visual object embeddings as input for the Transformer.

Two-step Pretraining firstly employ an off-the-shelf object detector to convert an image into a set of object embeddings, and then feed them into a Transformer jointly with text embeddings to generate their multi-modal representations. Hence their visual feature networks are not optimized during both pretraining & finetuning stage. Most of these methods, such as LXMERT (Tan and Bansal, 2019),ViLBert (Lu et al., 2019), VL-Bert (Su et al., 2020), Unicoder-VL (Li et al., 2020a) and

UNITER (Chen et al., 2020), adopt BERT-like objectives to train their networks, which include Masked Language Modeling (MLM), Masked Vision Modeling (MVM) and Image-Text Matching (ITM). In addition, VILLA (Gan et al., 2020) develops an advanced adversarial pretraining and finetuning strategy to improve generalization ability. OSCAR (Li et al., 2020b) and VINVL (Zhang et al., 2021) introduce object labels to bridge different modalities and revisit the importance of visual features. Ernie-ViL (Yu et al., 2020) exploits structured knowledge in the text and constructs scene graph prediction tasks to learn joint representations. UNIMO (Li et al., 2021) proposes a unified model to leverage large-scale free text corpus, image collections, and image-text pairs simultaneously through a contrastive learning task. Despite their strong performances, those methods are limited by the object detector and neglect visual cues outside of object regions, often leading to mistakes in downstream tasks.

End-to-End (E2E) Pretraining directly feed dense features on image grids from a visual backbone network into a Transformer network along with text tokens. As such, both the visual and Transformer networks are optimized jointly in an end-to-end manner in the pretraining & finetuning stage. Pixel-Bert and SOHO (Huang et al., 2021, 2020) pioneer the use of the E2E pretraining architecture and propose a novel visual-dictionary masked vision modeling task. E2E-VLP (Xu et al., 2021) presents a pretraining framework supervised with additional object detection and image captioning tasks to enhance visual semantics learning. It is worth noting that their object detection pretext task requires millions of bounding boxes annotation, unable to generalize to large-scale image-text corpus. ViLT (Kim et al., 2021) is the first to unify vision and language with a pure Transformer network, which has a simpler structure and enjoys faster inference. However, compared to the two-step methods, they are typically less expressive in terms of object-level concepts and thus suffer from weaker performances on challenging visual reasoning tasks. Our method is in line with the E2E pretraining framework. The key difference is that we propose to facilitate learning object-aware multi-modal representations by performing object semantic knowledge distillation.

3 Our Approach

3.1 Problem Definition and Overview

The goal of self-supervised VLP is to learn a generic and transferable visual-linguistic representation from a large amount of image-text data, which can achieve strong generalization performances in downstream vision-language tasks. To this end, the pretraining framework typically develops a variety of carefully-designed cross-modal pretext tasks (e.g. MLM, ITM) to train a deep network that encodes the multi-modal representation. Formally, we denote the image-text corpus for training as $\mathcal{X} = \{(I^i, D^i)\}_{i=1}^{|\mathcal{X}|}$ where I represents the image and D is the corresponding language description. In general, we construct a pretraining network consisting of a representation network module $\mathcal{M}_\theta$ and a set of task-specific network heads $\{\Phi_{\theta_s}\}_{s=1}^{S}$ where s indicates the pretext tasks. The overall pretraining objective is defined as follows,

$$\min_{\theta,\theta_1,\ldots\theta_S} \mathbb{E}_{(I,D)\sim\mathcal{X}}[\textstyle\sum_s L_s(Y_s, \Phi_{\theta_s} \circ \mathcal{M}_\theta(I, D)] \qquad (1)$$

where Y_s and L_s are task-specific ground-truth label and loss function respectively, and $\circ$ is a network compound operator. After pretraining, we remove all the task-specific heads and apply the representation network $\mathcal{M}_{\theta^*}$ with the learned parameters θ^* to the downstream tasks, followed by task-specific fine-tuning.

In this work, we aim to design an E2E pretraining strategy for the VLP problem. To this end, we adopt a modular representation network, which takes image grid features from a CNN-based visual network and the corresponding text embeddings into a multi-modal Transformer (Huang et al., 2020, 2021). Our goal is to learn the visual network and the Transformer jointly, and yet to effectively encode object-level visual concepts in the multi-modal representations. This enables us to capture rich cross-modal alignment between linguistic entities and visual semantic concepts for the downstream tasks, and meanwhile to enjoy the benefits of an efficient E2E network design without relying on detectors during fine-tuning and inference.

To achieve this, we propose a set of cross-modal pretext tasks that perform object knowledge distillation from external detectors in both semantic and feature space. Specifically, in addition to the image-text matching (ITM) and masked language modeling (MLM) tasks, we introduce two novel pretext tasks, Object-Guided Masked Vision Modeling

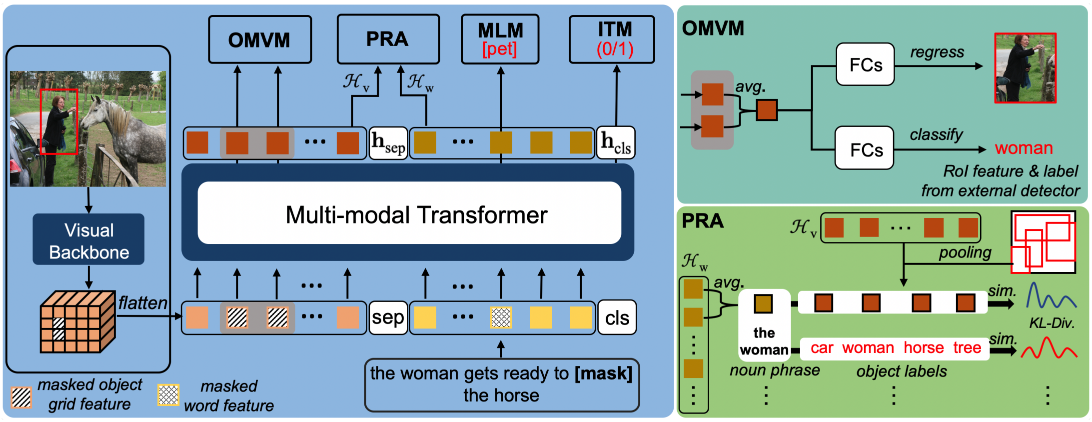

Figure 1: **Overview:** The model contains a Visual Backbone for preparing image embeddings and a Transformer for vision & language fusion. The entire framework is supervised by two novel proposed pretext tasks: Object-guided Masked Vision Modeling (OMVM), Phrase-Region Alignment (PRA) as well as two standard tasks: Masked Language Modeling (MLM) and Image-Text Matching (ITM).

(OMVM) and Phrase-Region Alignment (PRA), which take the object RoI feature embeddings and semantic labels from external detectors as supervision. The OMVM task masks out the object regions and forces the network to predict the corresponding external RoI feature embeddings and object labels while the PRA task exploits object labels to encourage the alignment between visual objects and language entities. Fig.1 illustrates an overview of our framework. Below we will first present the details of model architecture in Sec.3.2, followed by our design of pretext tasks in Sec.3.3.

3.2 Model Architecture

Given an image-text pair, our model firstly computes the image embeddings and linguistic embeddings respectively, and then concatenates them into a sequence of tokens with two additional tokens **[sep]** and **[cls]** as inputs to a Transformer for generating multi-modal contextualized embeddings.

Visual Embedding We adopt a CNN backbone to extract image features $\mathcal{V} = \{\mathbf{v}_i\}_{i=1}^{L}$ for each image I where L is the size of feature grids and $\mathbf{v}_i \in \mathcal{R}^{d_v}$ is a feature vector with dimension d_v. In addition, each feature is further concatenated with its 2-D sine position embedding (Carion et al., 2020). Following SOHO, we use a ResNet-101(He et al., 2016) as the visual backbone, followed by additional 1x1 Conv and 2x2 strides Max-pooling to reduce the memory footprint.

Linguistic Embedding For the language D, we first tokenize the sentence into a sequence of word tokens using WordPiece (Wu et al., 2016), then encode them into word embeddings $\mathcal{W} = \{\mathbf{w}_j\}_{j=1}^{T}$ where $\mathbf{w}_j \in \mathcal{R}^{d_w}$ is the feature vector. Similarly, an index position (Devlin et al., 2018) embedding is supplemented to each word embedding.

Multi-modal Transformer After obtaining image and linguistic embeddings, we assemble them into a sequence of tokens $\{\mathcal{V}, [\mathbf{sep}], \mathcal{W}, [\mathbf{cls}]\}$, and adopt a multi-layer Transformer to compute their representations encoded by the final-layer states $\{\mathcal{H}_{\mathcal{V}}, \mathbf{h}_{\mathbf{sep}}, \mathcal{H}_{\mathcal{W}}, \mathbf{h}_{\mathbf{cls}}\}$ where $\mathcal{H}_{\mathcal{V}} = \{\mathbf{h}_{\mathbf{v}_i}\}_{i=1}^{L}$ and $\mathcal{H}_{\mathcal{W}} = \{\mathbf{h}_{\mathbf{w}_j}\}_{j=1}^{T}$ represent the states for visual and language part respectively. Finally, those representations are sent into each pretext task head to compute the supervision signals.

3.3 Pretext Tasks

We now describe our cross-modal pretext tasks for the E2E pretraining, aiming to learn more effective multi-modal representations. Below we will first introduce objects-aware pretext tasks that take external object features and semantic labels as supervision, followed by the standard MLM and ITM.

Specifically, for each image, we first generate a set of object proposals from an off-the-shelf detector, denoted as $\{(o_n, c_n, \mathbf{f}_n)\}_{n=1}^{N}$ where $o_n \in \mathcal{R}^4$ is box location, c_n indicates object category, and $\mathbf{f}_n \in \mathcal{R}^{d_o}$ is object RoI features with dimension $\mathcal{R}^{d_o}$. For ease of notation, we also introduce a binary mask[1] on the feature map for each object o_n and denote its flattened version as $\mathbf{m}_n \in \mathcal{R}^L$. For the corresponding text, we extract a set of noun phrases $\mathcal{P} = \{p_z\}_{z=1}^{|\mathcal{P}|}$ with an external language tool[2] and calculate the similarity $\alpha_{z,n}$ between each

---

[1] We give an illustration in Suppl.

[2] https://spacy.io/

noun phrase p_z and the object category c_n in the linguistic space:

$$\alpha_{z,n} = \mathrm{Cos}(E_{ext}(p_z), E_{ext}(c_n)), \tag{2}$$

where $\mathrm{Cos}(\cdot,\cdot)$ indicates cosine distance function and E_{ext} represents an off-the-shelf language embedding (e.g. BERT). Using them as supervision, we design two novel pretext tasks to distill object-level knowledge below.

Object-guided Masked Vision Modeling (OMVM) The first task aims to learn more explicit object concepts in the E2E pretraining. Specifically, we sample an object each time and mask out its features in the Transformer input, and enforce the network to generate external object RoI features and semantic labels. To learn better cross-modal alignment, we propose a knowledge-guided masking strategy, which samples noun phrase-related object regions to mask based on the (normalized) similarity score $\alpha_{z,n}$. The selected object region is denoted with its binary mask, category and RoI features, as $(\mathbf{m}^*, c^*, \mathbf{f}^*)$.

We design two learning objectives, Masked Region Classification (MRC) and Masked Region Feature Regression (MRFR) as below

$$\begin{aligned}\mathcal{L}_{\mathrm{OMVM}} =& \mathbb{E}_{(I,D)\sim\mathcal{X}} L_{\mathrm{MRC}}(c^*, \mathcal{V}_{\backslash\mathbf{m}^*}, \mathcal{W}) \\ &+ L_{\mathrm{MRFR}}(\mathbf{f}^*, \mathcal{V}_{\backslash\mathbf{m}^*}, \mathcal{W})\end{aligned} \tag{3}$$

To calculate the losses L_{MRC} and L_{MRFR}, we first compute the object representation $\mathbf{h}_{\mathbf{m}^*}$ for the masked region at the final layer, which is average-pooled over $\mathcal{H}_{\mathcal{V}}$ based on its binary mask $\mathbf{m}^*$. For MRC, a multi-layer FC network Φ_{MRC} is adopted to predict its object category. Thus, L_{MRC}= $\mathrm{CE}(\Phi_{\mathrm{MRC}}(\mathbf{h}_{\mathbf{m}^*}), c^*)$ is the standard cross-entropy loss. In addition, we take another FC network Φ_{MRFR} to learn the object concept in feature space directly by minimizing the L2 distance, $L_{\mathrm{MRFR}} = ||\Phi_{\mathrm{MRFR}}(\mathbf{h}_{\mathbf{m}^*}) - \mathbf{f}^*)||_2^2$.

Phrase Region Alignment (PRA) The second task, PRA, mainly focuses on learning cross-modal alignment at object-level, which aims to pull positive phrase-region pairs closer and push negative pairs away. Here we utilize the similarity $\alpha_{z,n}$ between the noun phrase and object category in the linguistic space as a guidance.

Concretely, we first compute the object representation $\mathbf{h}_{\mathbf{m}_n}$ for each proposal and the phrase representation $\mathbf{h}_{p_z}$, both of which are obtained from the final layer states of the Transformer. Specifically, $\mathbf{h}_{\mathbf{m}_n}$ is average-pooled over $\mathcal{H}_{\mathcal{V}}$ based on binary mask $\mathbf{m}_n$ while $\mathbf{h}_{p_z} = \frac{1}{|p_z|}\sum_{j\in p_z}\mathbf{h}_{\mathbf{w}_j}$ represents average states of word tokens within p_z. We define the cross-modal similarity as $\hat{\alpha}_{z,n} = \mathrm{Cos}(\mathbf{h}_{p_z}, \mathbf{h}_{\mathbf{m}_n})$.

The task PRA minimizes the KL-divergence between the cross-modal similarities $\hat{\alpha}_z = \{\mathrm{Softmax}(\hat{\alpha}_{z,n})\}_{n=1}^N$ and the phrase-label similarities $\alpha_z = \{\mathrm{Softmax}(\alpha_{z,n})\}_{n=1}^N$ as below:

$$L_{\mathrm{PRA}} = \frac{1}{|\mathcal{P}|}\sum_z D_{KL}(\hat{\alpha}_z||\alpha_z) \tag{4}$$

Finally, denoting the mask set $\mathcal{M} = \{\mathbf{m}_n\}_{n=1}^N$, we have the overall PRA loss function as follows:

$$\mathcal{L}_{\mathrm{PRA}} = \mathbb{E}_{(I,D)\sim\mathcal{X}} L_{\mathrm{PRA}}(\{\alpha_{z,n}\}_{z,n=1}^{|\mathcal{P}|,N}, \mathcal{M}, \mathcal{P}, \mathcal{V}, \mathcal{W}) \tag{5}$$

Masked Language Modeling (MLM) We take the same masking strategy (15% *prob.* to mask) as in BERT (Devlin et al., 2018) to randomly mask out the input word tokens. Here, MLM aims to predict the original word index in vocabulary space for each masked token based on the whole image and its surrounding language context via the Transformer. Hence a cross-entropy loss is adopted:

$$\mathcal{L}_{\mathrm{MLM}} = -\mathbb{E}_{(I,D)\sim\mathcal{X}} \log P(\mathbf{w}_j|\mathcal{V}, \mathcal{W}_{\backslash j}) \tag{6}$$

Image-Text Matching (ITM) In ITM, the multi-layer Transformer is trained to distinguish whether the input image-text pairs are semantically matched based on the final layer **[cls]** token representation $\mathbf{h_{cls}}$. To construct the training samples, we randomly replace the text for each image-text pair with another text from dataset with a probability of 0.5. Thus, the output label can be defined as $y \in \{0, 1\}$ where $y = 1$ indicates matched pair. The training objective for the ITM task is to minimize binary cross-entropy loss:

$$\mathcal{L}_{\mathrm{ITM}} = -\mathbb{E}_{(I,D)\sim\mathcal{X}} \log P(y|\mathcal{V}, \mathcal{W}) \tag{7}$$

4 Experiments

4.1 Experiment Setup

Pretraining Corpus: Following the E2E pretraining strategy (Huang et al., 2021, 2020; Xu et al., 2021), we take indomain datasets: MSCOCO (Lin et al., 2014) and VG (Krishna et al., 2016) as pretraining datasets since it is widely used in literature. In total, two datasets comprise about 200K images and 5.6M image-text pairs, where each image is associated with multiple captions.

Table 1: Evaluation results on the multi-modal downstream tasks. **Indomain** denotes MSCOCO and Visual Genome corpus while **outdomain** stands for Conceptual Caption and SBU corpus. **Text corpus** includes BookWiki and OpenWebText while **image corpus** contains OpenImages and unlabeled COCO. AT means using adversarial training during both pretraining and finetuning stages. Blue number denotes experiments with additional text premise input. - denotes the result is not available

Implementation Details: We follow BERT to tokenize caption into word tokens by using WordPiece, and resize the image into (800, 1333) as prior works. For model architecture, a widely-used ResNet101 for visual encoding and 12-layer Transformer for multi-modal fusion are adopted for a fair comparison. Both networks are initialized with ImageNet and BERT pretrained parameters. Besides, following the majority of two-step methods, we apply the widely-used object detector BUTD (Anderson et al., 2018) to generate object proposals as well as their RoI embeddings as our supervision.

For model learning, we optimize the entire network by using SGD for CNNs with a learning rate of 1e-2 and AdamW for Transformer with a learning rate of 1e-4, as suggested in SOHO. The training iterations are up to 100K with batch-size 512 in each. The learning rate decays 10 times at 20K, 40K respectively. All experiments are conducted on 16 NVIDIA V100 GPUs with mixed-precision training to reduce memory cost about 7 days.

4.2 Downstream Tasks

As in prior works, we evaluate our approach by finetuning it over a set of well-established VL understanding tasks, including image-text retrieval, visual entailment (VE), natural language visual reasoning (NLVR^2), VQA, and VCR. During finetuning, we compound a specific learnable head with the pretrained visual backbone and Transformer, then finetune the entire network with downstream task-specific loss in an E2E fashion. In this work, we mainly compare performance with SOHO, Pixel-Bert, E2E-VLP, and ViLT since they are the E2E pretraining as ours. Besides, several representative two-step pretraining approaches are also selected to compare without loss of generality. Next, we will depict results analysis for each task and leave finetuning experiment setups in Suppl.

Image-Text Retrieval aims retrieval an image when give a specific caption, or vice versa. As in Tab.1&2, we achieve superior performances in all evaluation settings on both datasets, especially outperforming SOHO by 5.65% and 4.90% R@1 in Flickr30k-IR/-TR, 1.71% and 3.52% R@1 in MSCOCO-IR/-TR 1K test set as well as 6.04% and 7.88% in the 5K test set. It is worthing noting that we outperform the two-step pretraining SOTA approach UNIMO by a moderate margin, despite that they use additional outdomain datasets, text corpus, image collections, and adversarial training.

Visual Entailment (VE) predicts whether an image semantically entails the text and requires

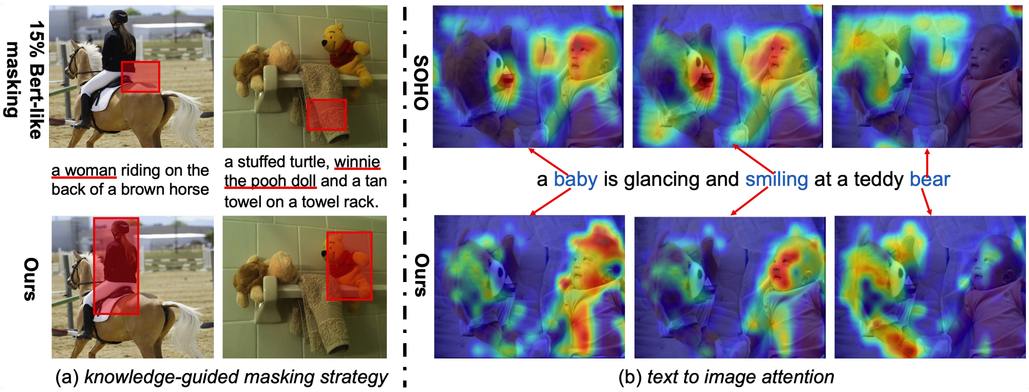
-	ITM+MLM+RandomMVM	58.18 / 87.12 / 94.68	73.60 / 94.80 / 97.50	73.99 / 74.58	64.02 / 64.68	66.90 / 66.05
-	ITM+MLM+OMVM	60.32 / 88.65 / 95.15	74.83 / 94.34 / 97.74	74.54 / 75.12	66.23 / 66.76	67.95 / 68.21
KD-VLP (ours)	ITM+MLM+OMVM+PRA	61.10 / 89.40 / 95.50	76.70 / 95.00 / 98.00	74.62 / 75.22	66.71 / 67.59	68.19 / 68.43



(a) *knowledge-guided masking strategy*

(b) *text to image attention*

Figure 2: (a) demonstrates the comparison of different masking vision strategies where the first row presents the 15% Bert-like masking strategy adopted by all previous works and the second row shows our knowledge-guided masking strategy. Red masks denotes the masked regions. (b) demonstrates a comparison of word-to-image attention maps. The bright region denotes higher attention scores between word and visual tokens.

fine-grained reasoning ability in a model. In Tab.1, we achieve we achieve 78.21% accuracy in val set and 77.87% in test set. It is worth noting that SOHO takes additional text premise as input, which leads to large improvements. For a fair comparison, we also implement that setting and outperform SOHO by a sizeable margin.

NLVR^2 aims to determine whether a natural caption is true about a pair of photographs, which is full of semantic diversity, compositionality challenges. We outperform SOHO, Pixel-bert, ViLT and E2E-VLP by a clear margin as in Tab.1, and performs comparably with two-step pretraining.

VQA requires requires a richer multi-modal understanding to solve the free-form and open-ended questions. In Tab.1, the results present a clear improvement compared with E2E pretraining methods while surprisingly outperform the strong two-step pretraining methods by a slight margin.

VCR requires higher-order cognition and commonsense reasoning about the world. We achieve superior accuracy, specifically 76.70%/78.63%/60.53% in three different problem setting. It is worth noting that we set up the first end-to-end benchmark for the challenging VCR task without relying on detection during inference. Besides, we outputform VL-BERT and OSCAR by a clear margin and work comparably with VILLA, which adopts advanced adversarial training and more outdomain corpus.

Overall, our approach outperforms the previous E2E pretraining by a sizeable margin, which indicates the superiority of our object-aware E2E multimodal representation. In addition, we also performs better or comparably with previous state-of-the-art two-step pretrainig, like UNIMO, VILLA, Ernie-ViL, which even adopt more outdomain corpos, sophisticated adversarial training.

4.3 Ablation Study & Visualization Analysis

In this section, we validate the effectiveness of each pretext task and provide qualitative visualization analysis. To save experimental cost, we adopt a light-weighted ResNet-18 and 3-layer Transformer network to conduct the ablation study.

Baseline: The baseline takes standard ITM and MLM to train the entire model. In Tab.3, it still achieves decent results over various VL tasks.

Object-guided masked vision modeling: As in Tab.3, compared with baseline, OMVM presents a clearly consistent improvement over all downstream tasks. It suggests that OMVM can enhance the end-to-end multi-modal representations with explicit object concepts learning. In addition, the knowledge-guided masking strategy further helps establish cross-modal correspondence.

To further investigate the OMVM task, we randomly mask a box region with 15% probability

rather than sampling a region based on the normalized similarity score $\alpha_{z,n}$, denoted as RandomMVM. The other pretraining details are the same as in OMVM. We observe a significant performance drop over all downstream tasks, especially in image-text retrieval and NLVR^2. It indicates that simple RandomMVM will result in inefficient multi-modal representation learning because there is a high probability that the selected region has no relationship with the associated description.

In addition, we also explore the similar masked feature regression task as in UNITER by randomly masking out the image grid features as in BERT and then requiring the Transformer to reconstruct its original features rather than the external object RoI embeddings, denoted as StandardMVM. The results show that such StandardMVM fails to facilitate multi-modal representation learning in the E2E framework.

Phrase-region alignment: The OMVM above mainly focuses on instance-level knowledge distillation by absorbing external object RoI features and semantic labels. Different from that, PRA aims to establish positive object-phrase correspondence while suppressing the negative ones under the guidance of similarities between noun phrases and object labels in linguistic space. As in Tab. 3, we significantly improve 0.78% R@1 of MSCOCO-TR and 1.87% in MSCOCO-IR. In addition, PRA shows slight improvements for more challenging fine-grained reasoning tasks, like VE, NLVR^2, and VQA. The results indicate that PRA is beneficial to multi-modal representation learning.

Visualization analysis: In Fig.2(a), our knowledge-guided masking strategy always masks out the phrase-related image regions, which can facilitate multi-modal learning. On the contrary, previous works, like SOHO, VILLA ..., mask out background regions or part of the object region with a high probability, which have no relationship with the corresponding description and result in inefficient cross-modal alignment. Fig.2(b) demonstrates the word-to-image attention maps. Compared to SOHO, our method can attend more accurately to image regions for the corresponding word. Surprisingly, even the word "smiling" can locate the baby's face correctly, which suggests that our approach not only learns better noun-region alignment but also helps establish high-order correspondence, like actions. (see Suppl. for more visualization.)

Influence of object detector: We adopt the default BUTD detector in a typical 2-step pretraining method for a largely fair comparison. To investigate the influence of object detectors, we also conduct pretraining with objects knowledge extracted from FRCNN-RN101 pretrained on COCO. In Tab.4, we observe a performance drop compared with the model pretrained with BUTD, which suggests large object knowledge space will facilitate multimodal pretraining. Besides, although with COCO detector, we still outperform SOHO by a clear margin, indicating the superiority of object knowledge in E2E pretraining framework.

Contribution of each pretext task: In Tab.5, we show the individual contributions of our proposed tasks. MRC, MRFR, PRA pretext tasks all help facilitate multi-modal representation learning and improve the performance compared with the baseline model as a result.

Impact of object knowledge distillation in different model sizes: We take SOHO as a strong baseline and compare it at different model sizes (ResNet18 + 3-layer Transformer, ResNet101 + 12-layer Transformer) to investigate the impact of object knowledge distillation. Fig.3 demonstrates the performance gains over some representative vision-language tasks. It shows that object concepts learning always helps multi-modal representation learning no matter what model size it is. In

VE and text-retrieval, the larger model even improves significantly than the light-weighted model and shows more capacities to learn external object semantics knowledge.

5 Conclusion

In this paper, we have proposed a novel self-supervised VLP method that promotes learning object-aware multi-modal representations in an end-to-end framework. Our key idea is to perform object knowledge distillation in both semantic and feature space from external detectors in the pre-training stage. In particular, we develop an object-guided masked vision modeling task for distilling external object knowledge, and a phrase-region alignment task for learning better alignment of linguistic entities and visual concepts. Compared with prior works, we achieve competitive or superior performance without relying on sophisticated object detectors during model finetuning and test in downstream tasks.

Appendix

In this supplementary material, we firstly discuss the limitations of work, then give the detailed dataset statistics of pretraining and each downstream task, and depict more advanced implementation details of the pretraining. In addition, we also demonstrate how to generate a binary mask for each object proposal, followed by detailed experimental setups and finetuning strategies of downstream tasks. Besides, we also discuss the influence of image size during pretraining stge. Finally, we provide more qualitative visualization results for better understanding.

A Limitations

In this paper, we only pretrain our proposed KD-VLP framework on indomain datasets, including MSCOCO and Visual Genome caption datasets. In the future, we need to scale up our model pretrained on more noisy web image-text pairs to make it to learn more general knowledge.

B Experiments

B.1 Dataset Statistics

As shown in Tab.6 we summarize the dataset statistics of pretraining and each downstream task, including the number of image-text pairs and number of images for each dataset split. It is worth mentioning that we select the MSCOCO & Visual Genome image-text data as our pretraining datasets since they are typical indomain datasets for many downstream tasks and are widely adopted by prior works.

Table 6: Dataset statistics of pretraining and downstream tasks. The number in brackets indicates the number of images

task	data sources	training	val	test
pretraining	MSCOCO Visual Genome	5.1M(207K)	131K(7.1K)	-
VCR	MovieClips LSMDC	213K(80K)	26.5K(9.9K)	25.2K(9.5K)
Image-text Matching	Flickr30k	145K(29K)	5K(1K)	5K(1K)
	MSCOCO	567K(113.2K)	25K(5K)	25K(5K)
Visual Entailemnt	Flickr30k SNLI	52.9K(29.7K)	17.8K(1K)	17.9K(1K)
VQA	MSCOCO Abstract Scenes	443.8(82.8K)	214.4K(40.5K)	447.8K(81.4K)
NLVR^2	Flickr30k	529.5K(29.8K)	17.9K(1K)	17.9(1K)

B.2 More Pretraining Details

In pretraining stage, we also adopt gradient accumulation[3] and gradient checkpointing[4] techniques to further reduce the GPU memory footprint and increase the batch-size. In our experiments, the gradient accumulation step size is set as 4.

B.3 Binary mask for each proposal

As shown in Fig.4, we generate a binary mask of the same size of feature map for each proposal

---

[3] https://nvidia.github.io/apex/advanced.html

[4] https://pytorch.org/docs/stable/checkpoint.html

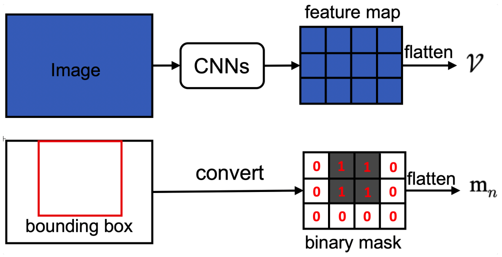

Figure 4: Illustration of generating binary mask for each proposal.

where locations within the bounding box fill 1 and others fill 0.

B.4 Detailed experiment setup for each downstream task

Image-Text Retrieval: The image-text retrieval typically includes two sub-tasks: image-retrieval (**IR**) aims to retrieval an image when given a specific caption and text-retrieval (**TR**) is on the contrary. We perform experiments on both Flickr30k (Plummer et al., 2015) and MSCOCO dataset. As in UNITER, we construct a mini-batch for each GPU of a matched image-text pair, t-1 negative images, and t-1 negative texts where t is set as 32. Besides, we take a fully-connected network on top of $\mathbf{h}_{\text{cls}}$ and adopt the binary cross-entropy loss as supervision signal. The finetuning iterations are up to 10K by following linear decay scheduling with initial lr 7e-5 for Transformer, 1e-4 for CNNs. Top-K (R@K, $K \in \{1, 5, 10\}$) recall is the evaluation metric.

Visual Entailment (VE): VE task aims to predict whether an image semantically entails the text and requires fine-grained reasoning ability in a model. VE dataset is built upon SNLI (Bowman et al., 2015) and Flickr30k. Each image-text pair is assigned with one of three classes: *entailment, neutral, contradiction*. As in UNITER, we formulate it as 3-way classification problem based on $\mathbf{h_{cls}}$. The batch size is 32 per GPU while other finetuning strategies are the same.

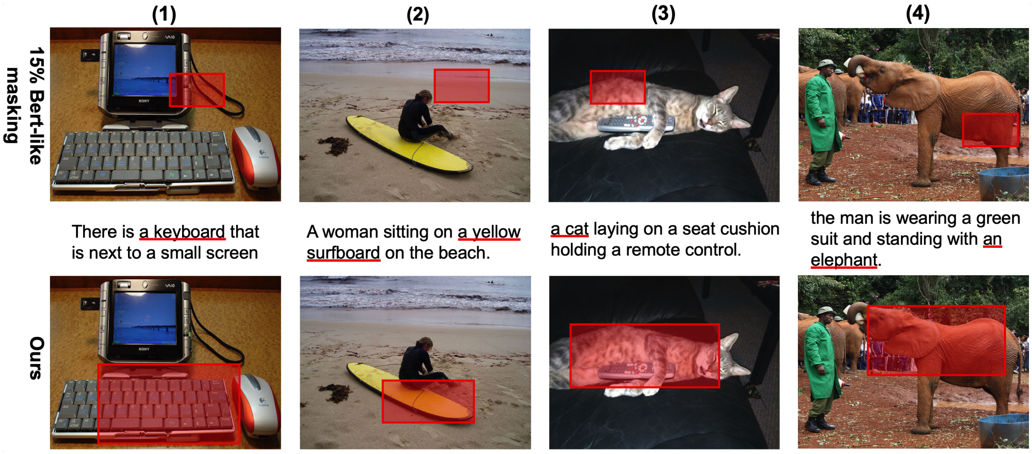
Natural Language Visual Reasoning (NLVR^2): NLVR^2 aims to determine whether a natural caption is true about a pair of photographs, which is full of semantic diversity, compositionality challenges. We follow UNITER to construct two image-text pairs for each sample and concatenate their $\mathbf{h_{cls}}$ features to infer *true* or *false*. All finetuning strategies are the same as before except for a batch size 12 per GPU.

Visual Question Answering (VQA): VQA requires a richer multi-modal understanding to solve the free-form and open-ended questions. VQA dataset contains 204K images from MSCOCO, 614K free-from nature language question and around 6M answers. It is typically formulated as a 3192-way classification problem and supervised by binary cross-entropy loss as in UNITER. The batch size here is 32 per GPU while other finetuning strategies are kept the same.

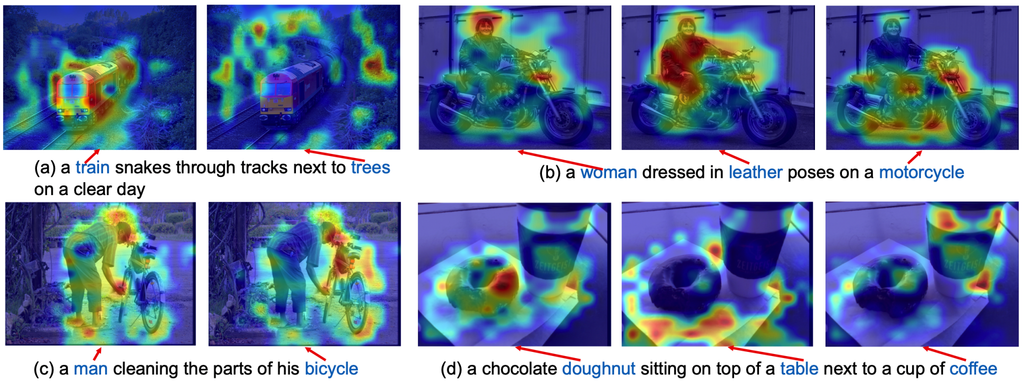
Visual Commonsense Reasoning (VCR): Given a question for an image, VCR needs to 1.) correctly answer (Q→A); 2.) provide a rationale justifying its answer (QA→R); 3.) reason both of them (Q→AR), which requires higher-order cognition and commonsense reasoning about the world. Following UNITER, we introduce a second-stage pretraining over the VCR dataset due to severe difference in dataset distribution compared to indomain image-text corpus. In addition, we also utilize a similar person grounding (Park et al., 2020) pretext task to tightly align the person tags in text and their visual locations. During finetuning stage, we concatenate each question along with each possible answer to form four kinds of text inputs, and feed each of them into Transformer network with corresponding image embeddings. Finally, a binary cross-entropy loss is adopted to supervise each pair. Since VCR questions explicitly reference objects at specific locations, we implement coreferencing between text and image by replacing referenced entities in the questions with their corresponding box locations. In the second stage pretraining for VCR, we reduce the learning rate to a constant 5e-05 and trained for an additional 9K steps. Due to longer sequence lengths in the VCR dataset, a training batch-size of 224 is used. We also use a step size of 2 for gradient accumulation. After pretraining, we finetuned on the VCR task for 10K steps with a learning rate of 1e-04 for both the Transformer and the CNNs. Linear warmup of the learning rate is applied for 1000 steps, followed by a linear decay ending at a total of 10K steps.

B.5 Influence of image size

We adopt larger image size mainly for fair comparisons with most 2-step pretraining methods, PixelBert and E2E-VLP as all of them use the size (800, 1333). To investigate this, we pretrain our method with size (600,1000) and report the results



(a) Knowledge-guided masking strategy. Red mask denotes the masked region in an image



(b) Text-to-image attention maps. The bright region denotes higher attention scores between word tokens and image regions.

Table 7: Performance comparison of different image size

Models	Image Size	NVLR-dev	VQA-test dev
SOHO	(600,1000)	64.62	66.69
KD-VLP(ours)	(600,1000)	66.52	68.04
KD-VLP(ours)	(800,1333)	66.71	68.19

in Tab.7. We can see that our method has a mild performance drop, but still outperforms SOHO by a decent margin.

B.6 More Visualizations

As in Fig.5a, we observe that our knowledge-guided masking strategy masks out the image regions, which are highly related to the corresponding sentences. This design can force Transformer to infer object features and semantic labels based on the surrounding visual context and its language descriptions. On the contrary, SOHO randomly masks out either background regions (Fig.5a(1) & Fig.5a(2)) or local object parts (Fig.5a(3) & Fig.5a(4)), which are not related to the corresponding sentences with a high probability and result in inefficient multi-modal representation learning.

As shown in Fig.5b, it shows that our object-aware end-to-end multi-modal representations can accurately establish the correspondence between word tokens and visual tokens, which demonstrates the superiority of our approach.

Dependency Position Encoding for Relation Extraction

Qiushi Guo, Xin Wang, Dehong Gao[*]

{qiushi.gqs,lucas.wangx,dehong.gdh}@alibaba-inc.com

Abstract

Leveraging the dependency tree of the input sentence is able to improve the model performance for relation extraction. A challenging issue is how to remove confusions from the tree. Efforts have been made to utilize the dependency connections between words to selectively emphasize target-relevant information. However, these approaches are limited in focusing on exploiting dependency types. In this paper, we propose dependency position encoding (DPE), an efficient way of incorporating both dependency connections and dependency types into the self-attention mechanism to distinguish the importance of different word dependencies for the task. In contrast to previous studies that process input sentence and dependency information in separate streams, DPE can be seamlessly incorporated into the Transformer and makes it possible to use an one-stream scheme to extract relations between entity pairs. Extensive experiments show that models with our DPE significantly outperform the previous methods on SemEval 2010 Task 8, KBP37, and TACRED.

1 Introduction

Relation extraction (RE) has been a long standing goal in natural language processing (NLP) and plays a crucial role in supporting many downstream task (Trisedya et al., 2019; Sun et al., 2019; Xu et al., 2016; Wang and Cardie, 2012). Nowadays, methods with powerful encoders (*e.g.* Transformer) have achieved promising success in RE (Baldini Soares et al., 2019; Tian et al., 2021; Yu et al., 2020; Guo et al., 2019; Mandya et al., 2020) due to their effectiveness in capturing contextual information. In addition, previous studies (Miwa and Bansal, 2016; Zhang et al., 2018; Sun et al., 2020; Chen et al., 2021) try to utilize the extra syntactic knowledge (*e.g.* word dependency) to further improve the ability to encode relations between entity pairs and have demonstrated its benefit in many methods. Nevertheless, intensively leveraging dependency information is not able to always improve the model performance, due to the confusions introduced by the noise in the dependency tree. Efforts have been made to utilize the separate module to selectively emphasize target-relevant dependency connections between words, with little attention paid to dependency types. We argue that dependency types associated with the dependency connections are able to help the relation extraction task and try to find a direct way to infuse them into the model.

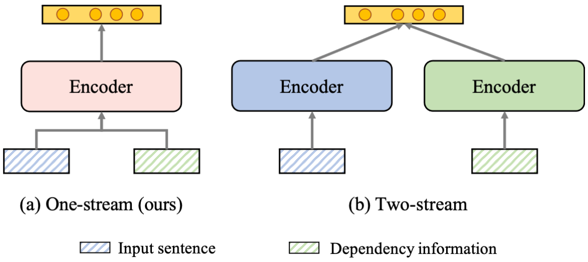

Figure 1: We introduce an one-stream scheme for relation extraction. By modeling the dependency information as a labeled and fully-connected graph, we extend self-attention to consider words dependencies and seamlessly incorporate them into Transformer-based encoder.

In this paper, we present dependency position encoding (DPE), an efficient way of incorporating dependency information into the self-attention mechanism of the Transformer to distinguish the importance of different word dependencies for relation extraction. Specially, we first encode dependency information obtained from an off-the-shelf dependency parser and map it into embeddings, then assign different weights to different labeled dependency connections between any two words through attention calculation. Different from previous studies that process input sentence and dependency tree in separate streams, our DPE can be seamlessly incorporated into the encoder and makes it possible

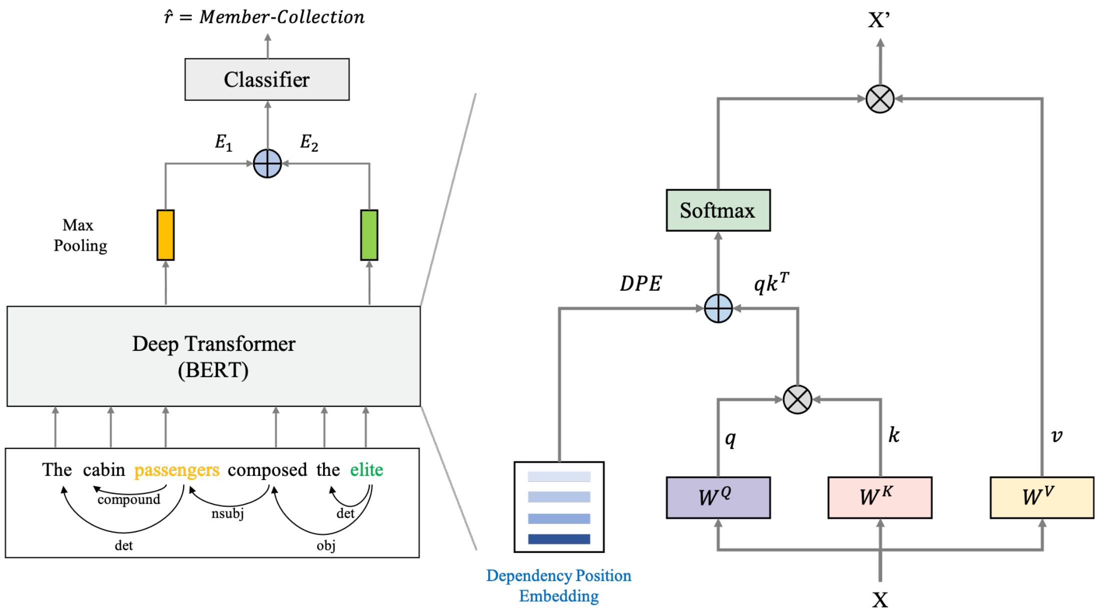

Figure 2: Relation extraction with dependency position embedding. The left side shows the overall architecture, while on the right side, we illustrate the detail of extending the self-attention to consider word dependencies.

to introduce an one-stream scheme for relation extraction. We conduct experiments on three English benchmark datasets (i.e., SemEval 2010 Task 8, KBP37 and TACRED) where the results demonstrate the effectiveness of our method.

2 Background and Motivation

BERT (Devlin et al., 2019) is a pre-trained language model which has Transformer-based model architecture and is widely used as sentence encoder in RE methods (Baldini Soares et al., 2019; Wu and He, 2019; Tian et al., 2021). The self-attention mechanism in Transformer does not explicitly model relative or absolute position information. To this end, Transformer (Vaswani et al., 2017) adopts explicit absolute sinusoidal positional encodings added into input embeddings. Absolution positions can be more naturally encoded as relative positional encodings (RPE) as follows:

$$\begin{aligned} Attn(x_i) &= \sum_{j=1}^{n} \alpha_{ij}(W^V x_j + a_{ij}^V) \\ \alpha_{ij} &= \frac{exp\ e_{ij}}{\sum_{k=1}^{n} exp\ e_{ik}} \\ e_{ij} &= \frac{x_i W^Q (x_j W^K + a_{ij}^K)^T}{\sqrt{d_k}} \end{aligned} \quad (1)$$

where $a_{ij} \in \mathbb{R}^{d_k}$ denotes edge distances between x_i and x_j when seeing input elements as labeled, directed, fully-connected graph (Shaw et al., 2018). Inspired by RPE, we argue that dependency types associated with the dependency connections among words also can be regarded as dependency graphs, which contain highly useful information for RE. We propose dependency positional encoding (DPE) and use it as an extension of self-attention to consider the dependency information between words. Different from previous studies (Guo et al., 2019; Zhang et al., 2018) that treat the dependency connections among words equally, DPE is able to distinguish the importance of different labeled connections through self-attention calculation.

3 Methodology

Following the previous studies, we perform RE as a classification task. Specifically, given an input sentence $x = (x_1, ..., x_n)$ with $E1$ and $E2$ denoting two entities in it, we predict the relation $\hat{r}$ between entities as fowllows:

$$\hat{r} = \underset{r \epsilon R}{arg\,max}\ p(r|DPE(x, \tau_x)) \quad (2)$$

where R is the set of entity relation types and τ_x is the dependency tree obtained from an off-the-shelf toolkit. The overall architecture of our method is illustrated in Figure 2 and we impose the dependency information into the model through DPE.

3.1 Dependency Position Encoding

Dependency tree τ_x indicates type-aware connections between input elements. We firstly repre-

sent dependency types in $\mathcal{T}_x$ by a type matrix $T = (t_{i,j})_{n \times n}$, where $t_{i,j}$ is the dependency type (*e.g.* nusbj) associated with the directed dependency connection between x_i and x_j. We then map each $t_{i,j}$ to its embedding $e_{i,j}$. For each Transformer layer, we operate self-attention calculation as follows:

$$Att(x) = Softmax(\frac{QK^T + DPE}{\sqrt{d_k}}) \cdot V$$

$$Q = W^Q x, K = W^K x, V = W^V x \qquad (3)$$

where W^Q, W^K, and W^V are weight matrices to generate Q, K, and V via linear transformations on x; DPE denotes the type embedding $e_{i,j}$. DPE can be seamlessly incorporated to the Transformer framework and and infuse word dependencies into the model in an one-stream manner.

3.2 Relation Extraction with DPE

We first encode the input sentence into hidden vectors by BERT (Devlin et al., 2019) with DPE, where h_i denotes the hidden vector for x_i. Then, we apply the max pooling to the output hidden vector of each word in the entity to obtain the entity representation h_{E_k} by

$$h_{E_k} = MaxPooling(h_i | x_i \epsilon E_k) \qquad (4)$$

Next, we concatenate the representation of the two entities and pass the resulting vector through a fully connected layer to obtain the final prediction $\hat{r}$, as follows:

$$\hat{r} = W \cdot (h_{E_1} + h_{E_2}) + b \qquad (5)$$

4 Experiments

4.1 Experimental Settings

Datasets. We conduct experiments of relation extraction on three English benchmark datasets: SemEval 2010 Task 8 (SemEval)[*] (Hendrickx et al., 2019), KBP37 (Zhang and Wang, 2015) and TACRED[†] (Zhang et al., 2017). For fair comparison, we use their official train/dev/test split[‡]. Following previous studies (Hendrickx et al., 2019; Wang et al., 2016; Baldini Soares et al., 2019; Yu et al., 2020), we report the macro-averaged F_1 scores on SemEval and the micro-averaged F_1 scores on KBP37 and TACRED.

Dependency Information Construction. We employ Standard CoreNLP Toolkits (SCT) [§] to obtain the dependency tree $\mathcal{T}_x$ for each input sentence x. Motivated by previous studies (Xu et al., 2015; Zhang et al., 2018), we use two groups of dependency connections which are filtered out through particular pruning strategies: (1) *full connections*

Model	Order	SemEval	KBP37	TACRED
Baseline	-	89.2	67.5	67.4
DPE (Full)	1st	89.6	67.8	67.7
	2nd	89.8	67.9	67.8
	3rd	89.9	68.3	68.3
DPE (Part)	1st	89.9	68.5	68.4
DPE (Both)	1st	**90.2**	**68.7**	**68.5**
	2nd	89.9	68.4	68.2
	3rd	89.6	67.9	67.8

Table 4: Ablation study of different dependency information.

include all dependencies that directly connect to the heads of two entities; (2) *part connections* are obtained from the shortest dependency path (SDP) between entities.

Implementation Details. We use the uncased version of BERT (Devlin et al., 2019) (we utilize 24 layers of multi-head attentions with 1024-dimensional hidden vectors for BERT-large) with DPE and insert four special tokens (*i.e.*, "<*e1*>", "</*e1*>", "<*e2*>", and "</*e2*>") into the input sentence to mark the boundary of the two entities (Baldini Soares et al., 2019). We randomly initialize all trainable parameters and the dependency type embeddings. We utilize Adam optimizer with the initial learning rate of 3e-5 and the batch size of 64 to train the model.

4.2 Main Results

In table 1, we compare the the F_1 scores of different models on the test set of SemEval (Hendrickx et al., 2019). As can be seen, our model consistently outperforms other methods and achieves the best F_1 score. To further demonstrate the advantage of DPE, we also conduct experiments on the KBP37 and TACRED datasets. Table 2 and Table 3 show that our method also achieves strong performance on these two benchmark datasets. Above results illustrate the great generalizability of DPE in condensing the useful dependency information for relation extraction.

4.3 Analysis

The Effect of Dependency Information. We study the performance of our proposed model with different combinations and different orders of word dependencies. As we can see in Table 4, models with DPE under all settings outperform the BERT-large baseline on all datasets. We find that DPE models with part connections (*i.e.*, DPE (Part)) surpass the ones with full connections (*i.e.*, DPE (Full)) under the same setting since using the dependency information in an intensive way may introduce noise. Besides, we obtain the best performance when using two types of word dependencies (*i.e.*, DPE (Both)). Furthermore, we observe that DPE (Full) models obtain better results when using higher order dependencies while the trend is on the opposite for the DPE (Both) ones. One possible reason is that leveraging higher order dependencies makes it possible to capture more useful contextual information between two entities for DPE (Full) and introduces confusions when DPE (Both) encodes most essential word dependencies.

Model	Position	SemEval	KBP37	TACRED
Baseline	-	89.2	67.5	67.4
DPE (Full)	1-12	89.4	67.7	67.5
	13-24	89.5	67.6	67.6
	1-24	**89.6**	**67.8**	**67.7**
DPE (Part)	1-12	89.8	68.2	68.1
	13-24	89.7	68.3	68.2
	1-24	**89.9**	**68.5**	**68.4**
DPE (Both)	1-12	89.6	68.5	68.2
	13-24	89.8	68.3	68.3
	1-24	**90.2**	**68.7**	**68.5**

Table 5: Ablation study of different plugin positions.

The Plugin Positions of DPE. We also experiment by varying the position of the DPE in the model. Table 5 presents the ablations for variable positions based on the BERT-large. For fair comparison, we use the model on first-order word dependencies used in the above analysis. We denote the first BERT layer by index 1 and $i - j$ as the plugin positions of DPE which start from i and end at j. We achieve the best performance when each layer in the BERT-large equipped with DPE across all combinations of dependency information, which demonstrates the effectiveness of our method.

5 Conclusion

In this paper, we propose dependency position encoding (DPE) and use it as an extension of self-attention to consider dependency information. Different from previous studies, DPE is able to seamlessly incorporated into the Transformer and makes it possible to use an one-stream scheme to extract illuminating word dependencies for relation extraction. Experimental results on several public datasets illustrate the effectiveness of our approach.

Abstract

Multimodal named entity recognition and relation extraction (MNER and MRE) is a fundamental and crucial branch in information extraction. However, existing approaches for MNER and MRE usually suffer from error sensitivity when irrelevant object images incorporated in texts. To deal with these issues, we propose a novel **H**ierarchical **V**isual **P**refix fusion **Ne**T**w**ork (**HVPNeT**) for visual-enhanced entity and relation extraction, aiming to achieve more effective and robust performance. Specifically, we regard visual representation as pluggable visual prefix to guide the textual representation for error insensitive forecasting decision. We further propose a dynamic gated aggregation strategy to achieve hierarchical multi-scaled visual features as visual prefix for fusion. Extensive experiments on three benchmark datasets demonstrate the effectiveness of our method, and achieve state-of-the-art performance[1].

1 Introduction

Named entity recognition (NER) and relation extraction (RE) are important tasks in information extraction and knowledge base population, due to its research significance in natural language processing (NLP) and wide applications (Hosseini, 2019; Zhang et al., 2020; Qin et al., 2021; Zhang et al., 2021c). Currently, with the rapid development of multimodal learning, multimodal NER (MNER) and Multimodal RE (MRE) methods (Moon et al., 2018; Zheng et al., 2021) have been proposed to enhance linguistic representations with the aid of visual clues from images. It significantly extends the text-based models by taking images as additional inputs, since the visual contexts help to resolve ambiguous multi-sense words.

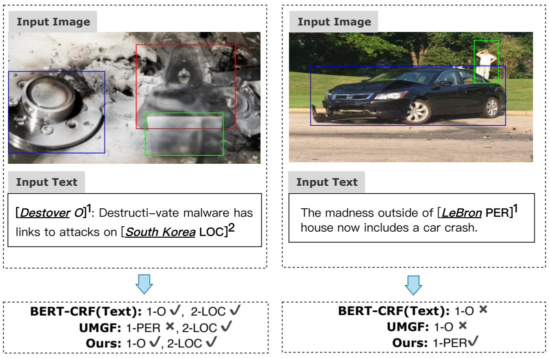

Figure 1: Motivation for robust and effective hierarchical modality fusion.

The essence of MNER and MRE tasks is how to learn great visual features and how to incorporate it into textual representation for enhancing NER and RE. Early methods (Zhang et al., 2018; Moon et al., 2018) study how to incorporate the feature of whole image into the textual representation. Yu et al. (2020); Zhang et al. (2021a); Zheng et al. (2021) further validate that object-level visual fusion is more specific and important for MNER and MRE. Recently, RpBERT (Sun et al., 2021) propose to train a classifier of whether the "Image adds to the tweet meaning" before MNER tasks. However, they heavily rely on pre-training on large extra annotated corpus of image-text relevance and only focus on the whole image with ignoring the bias of relevant object-level visual fusion. In practice, irrelevant objects may directly exert negative effects on the text inference. Meanwhile, it is not trivial to acquire absolutely relevant object-level visual information to enhance the text. Thus, an effective method should be derived to learn better visual representation and alleviate error sensitivity of irrelevant object images for social media NER and RE tasks.

Considering images often appear before the text in a web document, we argue that images can be regarded as the prefix for their textual descriptions,

which is inspired by prompt learning (Gao et al., 2021; Li and Liang, 2021; Liang et al., 2022; Zhang et al., 2021d) in the language model. Specifically, given a image-text pair, we prepend object-level image feature sequence of length V_i (visual prefix) to the text sequence at each self-attention layer of BERT (Devlin et al., 2019). Note that the visual prefix is a pluggable operation and don't require any annotation on relevance. Therefore, visual prefix can not only introduce object-level visual signals, but also further reduce the impact on the architecture representing text. Intuitively, visual prefix regarded as a prompt for text may helps alleviate the error sensitivity of irrelevant object images.

While Convolution Neural Networks (CNNs) contain the multi-scale information with pyramidal feature hierarchy (Ren et al., 2015) from low to high levels. And BERT encodes a rich hierarchy of linguistic information (Jawahar et al., 2019) from the bottom to the top. Inspired by Lin et al. (2017); Liu et al. (2018) that objects of different sizes can have appropriate feature representations at the corresponding scales, we propose to make each layer of BERT aware of hierarchical multi-scale visual features to make a more enlightened and comprehensive forecasting decision.

To this end, we propose a novel **H**ierarchical **V**isual **P**refix fusion **NeT**work (**HVPNeT**) for visual-enhanced entity and relation extraction. Specifically, inspired by SimVLM (Wang et al., 2021), we propose visual prefix-guided fusion mechanism involving **concatenate** object-level visual representation as the prefix of each self-attention layer in BERT, which is a more soft and robust attention module for visual enhanced NER and RE. We further design a dynamic gate for each layer to generate image-dependent paths, so that a variety of aggregated hierarchical multi-scaled visual features can be considered as visual prefix for enhancing NER and RE. Overall, we summerize the major contributions of our paper as follows:

- We present a hierarchical visual prefix fusion network towards MNER and MRE, incorporating hierarchical multi-scaled visual features through visual prefix-based attention mechanism at each self-attention layer of BERT to generate effective and robust textual representation for reducing error sensitivity.

- We utilize the exploitation of dynamic gates to fully leverage the hierarchical visual features. Thus, textual representation of each layer in Transformer can be aware of corresponding hierarchical visual features adaptively. To the best of our knowledge, this paper is the first work to leverage hierarchical pyramidal visual features for multimodal learning.

- We evaluate our method on MNER and MRE tasks. Our experimental results on three benchmark datasets validate the effectiveness and superiority of our HVPNeT

2 Related work

Multimodal Entity and Relation Extraction As the crucial components of information extraction, named entity recognition (NER) and relation extraction (RE) have attracted much attention in the research community (Liu et al., 2019; Zhang et al., 2021b; Liu et al., 2021; Chen et al., 2021b,a). Previous studies typically focus on textual modality and standard text. As multimodal data become increasingly popular on social media platforms, early research focusing on textual modality and standard text is limited. Recently, several studies have focused on the MNER and MRE task, aiming to utilize the associate images to recognize the named entities and their relation better.

In the early stages, Zhang et al. (2018),Lu et al. (2018), (Moon et al., 2018) and Arshad et al. (2019) propose to encode the text through RNN and the whole image through CNN, then designing implicit interaction to model information between two modalities to explore multimodal NER tasks. Recently, Yu et al. (2020); Zhang et al. (2021a) propose to leverage regional image features to represent objects in the image to exploit fine-grained semantic correspondences based on Transformer and visual backbones.

While most of the current methods ignore the error sensitivity, one exception is that Sun et al. (2021), which proposes to learn a text-image relation classifier to enhance multimodal BERT to reduce the interference from irrelevant images while requiring extensive annotation for the irrelevance of image-text pairs.

Pre-trained Multimodal Representation The pre-trained multimodal BERT has recently achieved significant improvements in many multimodal tasks (e.g., visual question answering). We summarize and compare The existing visual-linguistic BERT models can be divided into two aspects as follows: 1) **Architecture**. The single-stream structures consist of Unicoder-VL (Li et al., 2020), VisualBERT (Li et al., 2019), VL-BERT (Su et al., 2020), and UNITER (Chen et al., 2020b), where the text tokens and images are combined into a sequence and fed into BERT to learn contextual embeddings. The two-streams structures, LXMERT (Tan and Bansal, 2019) and ViLBERT (Lu et al., 2019), separately process the visual and language into two streams with interacting through cross-modality or co-attentional transformer layers. 2) **Pretraining tasks**. The pretraining tasks of multimodal visual-language model mainly consist of masked language modeling (MLM), masked region classification (MRC), and image-text matching (ITM). However, most of previous models are pre-trained on the datasets of image captioning (Sharma et al., 2018; Chen et al., 2015) or visual question answering where multi-modal interactions are required. Applying current visual-language models to the MNER and MRE task may not result in a good performance, since **MNER and MRE mainly focus on leveraging visual information to enhance the text rather than conducting prediction on the image side**.

3 Methodology

As illustrated in Figure 2, we present a novel hierarchical prefix fusion network for multi-modal entity and relation extraction. Note that our method can also be applied to other visual-enhanced tasks towards text.

3.1 Collection of Pyramidal Visual Feature

On the one hand, the image associated with a sentence maintains several visual objects related to the entities in the sentence, further providing more semantic knowledge to assist information extraction. On the other hand, the global image features may express abstract concepts, which play the role of a weak learning signal. Thus, we collect multiple visual clues for multimodal entity and relation extraction, which involves taking the regional image as the vital information and the global images as the supplement.

Given an image, we follow (Zhang et al., 2021a) to adopt the visual grounding toolkit (Yang et al., 2019) for extracting local visual objects with top m salience. Then, we rescale the global image and object image to 224×224 pixels as the **global image** $\mathcal{I}$ and **visual objects** $\mathcal{O} = \{o_1, o_2, ..., o_m,\}$.

In the area of CV, the feature fusion method that leveraging features from different blocks of pre-trained models (Wang et al., 2019; Kim et al., 2018; Lin et al., 2017) is widely applied for improving model performance. Inspired by such practices, we take the first step to focus on the application of pyramid features in the area of multi-modality. We propose to fuse hierarchical image features into each Transformer layer; thus, leveraging a feature pyramid is essential. Typically, given an image, we encode it with a backbone model and generate a list of **pyramidal feature maps** $\{F_1, F_2, F_3, \ldots, F_c\}$ with different scales, then map them with $M_\theta(\cdot)$ as follows:

$$V_c = \mathit{Conv}_{1\times1}(F_c), \tag{1}$$

$$V_i = \mathit{Conv}_{1\times1}(\mathit{Pool}(F_i)),\ i = 1, 2, \dot{c} - 1, \tag{2}$$

where i denotes the i-th block of the backbone model, c denotes the number of blocks in the visual backbone model (here is 4 for ResNet), *Pool* represents the pooling operation, where the features are aggregated to the same spatial sizes. The 1×1 convolutional layer is leveraged to map the pyramidal visual features to match the embedding size of the Transformer.

3.2 Dynamic Gated Aggregation

Although objects of different sizes can have appropriate feature representations at the corresponding scales, it is not trivial to decide which block in the visual backbone is assigned visual prefix for each layer in Transformer. To address this challenge, we propose constructing the densely connected routing space, where hierarchical multi-scaled visual features are connected with each transformer layer.

3.2.1 Dynamic Gate Module

We conduct routine processes through a dynamic gate module, which can be viewed as a procedure of path decision. The motivation of the dynamic gate is to predict a normalized vector, which represents how much to execute the visual feature of each block. In the dynamic gate, $g_i^{(l)} \in [0, 1]$ denotes the path probability from the i-th block of visual backbone to the l-th layer of Transformer. It is calculated as $g^{(l)} = \mathbb{G}^{(l)}(V) \in \mathbb{R}^c$, where $\mathbb{G}^{(l)}(\cdot)$ denotes the gating function according to the l-th layer in Transformer, c represents the numbers of the block in backbone. We first produces the logits $\alpha_i^{(l)}$ of the gate signals:

$$\alpha^{(l)} = f(W_l(\frac{1}{c}\sum_{i=1}^{c} P(V_i))), \tag{3}$$

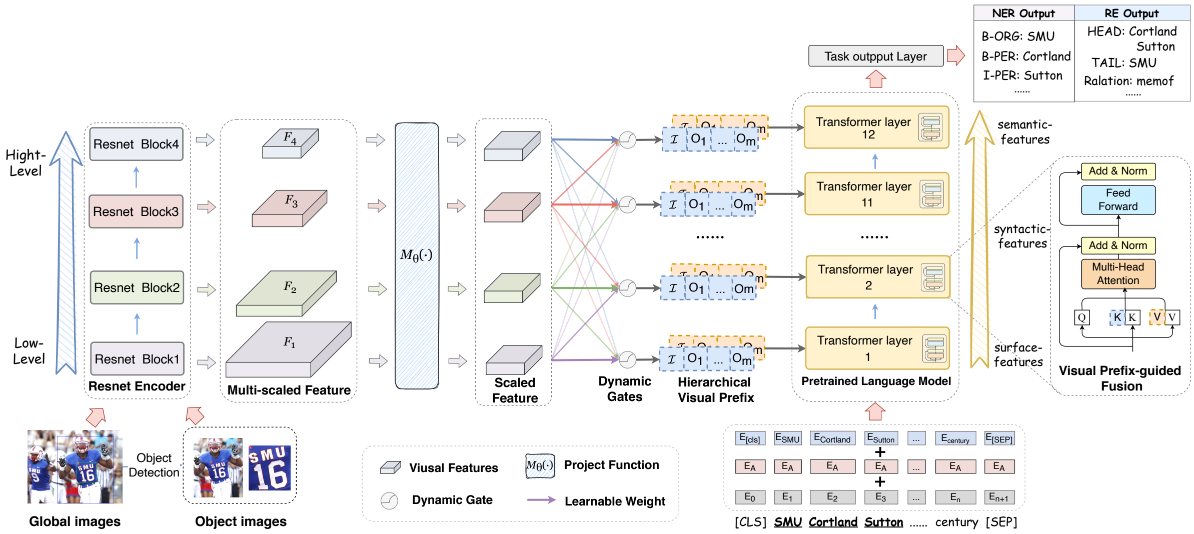

Figure 2: The overall architecture of our hierarchical visual prefix for multimodal entity and relation extraction.

where $f(\cdot)$ denotes the activate function Leaky_ReLU, P represents the global average pooling layer. We first squeeze the input features V_i with a shape of (d_i, h_i, w) from the i-th bloc by an average pooling operation. Then we add the features from multiple blocks to generate the average vectors. We further reduce the feature dimension by c with the MLP layer W_l and consider a soft gate via generating continuous values as path probabilities. Afterward, we generate the probability vector $g^{(l)}$ for the l-th layer of Transformer as follows:

$$g^{(l)} = Softmax(\alpha^{(l)}) \tag{4}$$

3.2.2 Aggregated Hierarchical Feature

Based on the above dynamic gate $g^{(l)}$, we can derive the final aggregated hierarchical visual feature V_{gated} to match the l-th layer in Transformer, as:

$$V_{gated}^{(l)} = g^{(l)} V^{(l)}. \tag{5}$$

Formally, the final visual features $\tilde{V}_{gated}^{(l)}$ corresponding to the l-th layer of Transformer is obtained by the following concatnation operation,

$$\tilde{V}_{gated}^{(l)} = [V_{gated}^{(l,I)}; V_{gated}^{(l,o_1)}; \ldots; V_{gated}^{(l,o_m)}], \tag{6}$$

which will be adopted to enhance layer-level representations of textual modality through visual prefix-based attention.

3.3 Visual Prefix-guided Fusion

We regard hierarchical multi-scaled image feature as visual prefix, and prepend the sequence of visual prefix to the text sequence at each self-attention layer of BERT(Devlin et al., 2019) In particular, given an input sequence $X = \{x_1, x_2, ..., x_n\}$, the contextual representations $\boldsymbol{H}^{l-1} \in \mathbb{R}^{n \times d}$ is first projected into the query/key/value vector:

$$\boldsymbol{Q}^l = \boldsymbol{H}^{l-1}\boldsymbol{W}_l^Q, \boldsymbol{K}^l = \boldsymbol{H}^{l-1}\boldsymbol{W}_l^K, \boldsymbol{V}^l = \boldsymbol{H}^{l-1}\boldsymbol{W}_l^V. \tag{7}$$

As for aggregated hierarchical visual features $\tilde{V}_{gated}^{(l)}$, we use a set of linear transformations $W_l^\phi \in \mathbb{R}^{d \times 2 \times d}$ for l-th layer to project them into the same embedding space[2] of textual representation in self-attention module. Besides, we define the operation of visual prompt $\phi_k^l, \phi_v^l \in \mathbb{R}^{hw(m+1) \times d}$ as:

$$\{\phi_k^l, \phi_v^l\} = \tilde{V}_{gated}^{(l)} W_l^\phi, \tag{8}$$

where $hw(m+1)$ represents the length of the visual sequences, m denotes the number of visual objects detected by the object detection algorithm. Formally, the visual prefix-based attention are calculated as follows:

$$Prefix\_Attention^l = softmax\left(\frac{\boldsymbol{Q}^l[\boldsymbol{\phi}_k^l; \boldsymbol{K}^l]^T}{\sqrt{d}}\right)[\boldsymbol{\phi}_v^l; \boldsymbol{V}^l]. \tag{9}$$

Remark 1 *We regard hierarchical multi-scaled visual features as visual prefix at each fusion layer and sequentially conduct multi-modal attention to update all textual states. In this way, the final textual states encode both the context and the cross-modal semantic information simultaneously. which*

---

[2] Remarkably, the key and value in the self-attention module contain the different information in two types of semantic space, here 2 means that we apply two sets of transformation parameters to project aggregated visual features to match the state update process, respectively.

is beneficial to reduce error sensitivity for irrelevant object elements.

3.4 Classifier

Based on above description, we get the final representation of BERT, $H^L = U(X, \tilde{V}^{(l)}_{gated})$, where $U(\cdot)$ denotes the operation of visual prefix-based attention. Finally, we conduct different classifier layers for NER and RE, respectively.

Named Entity Recognition. Following (Moon et al., 2018; Yu et al., 2020), we also adopt the CRF decoder to perform the NER task. Formally, we feed the final hidden vectors $\boldsymbol{H}^L =$ of BERT to the CRF model. For a sequence of tags $y = \{y_1, \ldots, y_n\}$, the probability of the label sequence y and the objective of NER are defined as follows (Lample et al., 2016a):

$$\begin{aligned} p(y|H^L) &= \frac{\prod_{i=1}^{n} S_i(y_{i-1}, y_i, H^L)}{\sum_{y' \in Y} \prod_{i=1}^{n} S_i(y'_{i-1}, y'_i, H^L)}, \\ \mathcal{L}_{ner} &= -\sum_{i=1}^{M} log(p(y^{(i)}|U(X^{(i)}, \tilde{V}_{gated}))). \end{aligned} \tag{10}$$

where Y represents the pre-defined label set with the BIO tagging schema, and $S(\cdot)$ represents potential functions. Details can be referred in (Lample et al., 2016a).

Relation Extraction. An RE dataset can be denoted as $\mathcal{D}_{re} = \{(X^{(i)}, r^{(i)})\}_{i=1}^{M}$, the goal of RE is to predict the relation $r \in \mathcal{Y}$ between subject entity and object entity. Specifically, a `[CLS]` head is utilized to compute the probability distribution over the class set $\mathcal{Y}$ with the softmax function $p(r|X) = \texttt{Softmax}(\mathbf{W}\mathbf{H^L}_{\texttt{[CLS]}})$, and the parameters of $\mathcal{L}$ and $\mathbf{W}$ are fine-tuned by minimizing the cross-entropy loss over $p(r|X)$ on the entire $\mathcal{X}$ as follows:

$$\mathcal{L}_{re} = -\sum_{i=1}^{M} log(p(r^{(i)}|U(X^{(i)}, \tilde{V}_{gated}))). \tag{11}$$

4 Experiments

In the following section, we conduct experiments to evaluate our method on two multimodal information extraction tasks, MNER and MRE. Specifically, we adopt ResNet50 (He et al., 2016) as visual backbone and BERT-base (Devlin et al., 2019) as textual encoder. Results on three datasets demonstrate that our HVPNeT outperforms a number of unimodal and multimodal approaches.

4.1 Datasets

We select three datasets for our experiments: Twitter-2015 (Zhang et al., 2018) and Twitter-2017 (Lu et al., 2018) for MNER, MNRE (Zheng et al., 2021) for MRE. Statistical details of datasets and experimental details are provided in Appendix A, B.

4.2 Compared Baselines

We compare our HVPNeT with several baseline models for a comprehensive comparison to demonstrate the superiority of our HVPNeT. Our comparison mainly focuses on three groups of models: the text-based models, previous SOTA MNER and MRE models, and the variants of our models.

Text-based models: we first consider a group of representative text-based models: 1) *CNN-BiLSTM-CRF* (Ma and Hovy, 2016), 2) *HBiLSTM-CRF* (Lample et al., 2016b) and 3) *BERT-CRF* for NER. The following models are specific for RE: 4) *PCNN* (Zeng et al., 2015); 5) *MTB* (Soares et al., 2019) is an RE-oriented pretraining model based on BERT.

Previous SOTA models: besides, we further consider another group of previous SOTA multi-modal approaches for MNER and MRE: 1) *AdapCoAtt-BERT-CRF* (Zhang et al., 2018); 2) *OCSGA* (Wu et al., 2020); 3) *UMT* (Yu et al., 2020); 4) *UMGF* (Zhang et al., 2021a), the newest SOTA for MNER, which proposes a unified multi-modal graph fusion approach for MNER. 5) *BERT+SG* is proposed in Zheng et al. (2021) for MRE, which concatenate the textual representation from BERT with visual features generated with scene graph (SG) tool (Tang et al., 2020). 6) *MEGA* (Zheng et al., 2021), the newest SOTA for MRE, which develops a dual graph for multi-modal alignment to capture this correlation between entities and objects for better performance. 7) *VisualBERT*(Li et al., 2019), different from the above SOTA methods mainly based on co-attention, VisualBERT is a single-stream structure, which is a strong baseline for comparison. And the results of VisualBERT listed in our paper are referred from Chen et al. (2020a)

Variants of Our Model: we set the ablation experiments to explore the effectiveness of our design. We conduct on the same parameter settings of HVPNeT for each variant model for a fair comparison.

Modality	Methods	*Twitter-2015*			*Twitter-2017*			*MNRE*

Table 1: Performance comparison of different competitive baseline approaches for NER and RE. Since the original results of UMT, UMGF and MEGA only involve single extraction task, we reproduce their public code for more comprehensive comparision.

HVPNeT-Flat: This is another variant of our model without the pyramid structure. Here we assign the visual features with the output of the 4-th block of ResNet and then map the visual features to each layer corresponding to BERT to conduct image-text fusion.

HVPNeT-1T3: As ResNet and BERT have four blocks and 12 layers, respectively thus, it is intuitive to directly map visual features in one block to the three layers in BERT. We denote this variant as *HVPNeT-1T3* to compare with our final version with hierarchical visual features.

HVPNeT-OnlyObj: Visual objects are considered as fine-grained image representations. We conduct ablation by only adopting the object-level features in this model to validate the effect of the object features.

4.3 Overall Performance Comparison

4.3.1 Main Results

The experimental results of HVPNeT and all baselines on three testing sets are presented in Table 1. From the experimental results, we can observe that:

Firstly, we can find that incorporating the visual features is generally helpful for NER and RE tasks by comparing the SOTA multimodal approaches with their corresponding text-based baselines. Despite previous multimodal approaches can generally achieve better performance, the enormous improvement of F1 score for NER is only about 2.0% (compare UMGF with BERT-CRF), which for RE is about 5.55% (compare MEGA with MTB). This observation reveals that the performance improvement of images on text-based NER tasks is relatively limited compared with RE tasks.

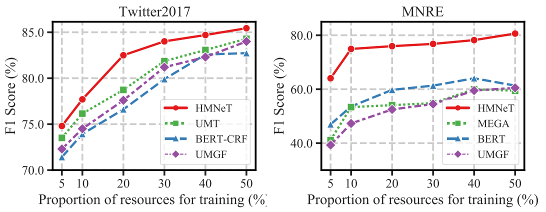

Figure 3: Performances on low-resource setting on MNER and MRE task.

Secondly, our method is superior to the newest SOTA models UMGF and MEGA, which improves 1.36%, and 15.44% F1 scores for Twitter-2017, and MNRE datasets, respectively. It is worth noting that most of previous multimodal methods ignore the error sensitivity of irrelevant object-level images, while our method regard hierarchical visual prefix as a prompt for text. This results indicate that our method can effectively alleviate the error sensitivity irrelevant object images, which is a more robust method for visual enhanced NER and RE.

Finally, we also compare with VisualBERT, which is a pre-trained multimodal BERT with a single-stream structure. We notice that even as the pre-trained multimodal model, VisualBERT leaves much to be desired in MNER and MRE tasks, which performs worse than UMGF and MEGA, let alone our methods. We hold that VisualBERT is truly dissatisfactory since the datasets and pre-training process are less relevant to information extraction tasks.

	Relevant Image-text Pair	Weak Relevant Image-text Pair	Irrelevant Image-text Pair
	Taylor Hill holding Jun 's GQ japan lol.	Cold front over Blyde River Canyon in Limpopo Province, South Africa.	President Bush when he sees the lights of America.
Text-Images Attention of HVPNeT			
Gold Relations:	per/per/couple	loc/loc/contain	per/loc/place_of_residence
BERT:	per / per /couple ✗	misc / misc /part_of ✗	per / loc /place_of_residence ✔
VisualBERT:	per / per /peer ✔	misc / misc /part_of ✗	misc / loc /held_on ✗
MEGA:	per / per /peer ✔	per / per /peer ✗	misc / loc /held_on ✗
HVPNeT(Ours):	per / per /peer ✔	loc / loc /contain ✔	per / loc /place_of_residence ✔

Table 2: The first row shows the split of the relevance of image-text pairs, and the several middle rows indicate representative samples together with their entity-object attention in the test set of MNRE datasets (The y-axis represents the textual entites, and the x-axis denotes the visual objects with length of flattened 4 patches), and the bottom four rows show predicted relation of different approaches on these test samples.

Methods	*Twitter-2017 → MNRE*	*MNRE → Twitter-2017*
UMGF	63.85 → 62.90 ↓ (0.95)	85.51 → 84.35 ↓ (1.16)
HVPNeT	81.85 → 82.50 ↑ (0.75)	86.87 → 87.13 ↑ (0.26)

Table 3: Performance comparison of HVPNeT and UMGF in cross-task scenario.

4.3.2 Low-resource Scenario

We further conduct experiments in low-resource settings by randomly sampling 5% to 50% from the original training set to form a low-resource training set. Figure 3 shows the performance of our method in a low-resource scenario compared with several baselines. By analyzing this results, we can observe: 1) UMT and MEGA consistently outperform the compared baselines in the low-resource scenario; the improvement indicates that incorporating the visual features is still helpful for NER and RE tasks in low-resource scenarios. 2) Moreover, it can be observed that the performance of HVPNeT still outperforms the other baselines. It further proves the effectiveness and data-efficiency of our proposed method.

4.3.3 Cross-task Scenario

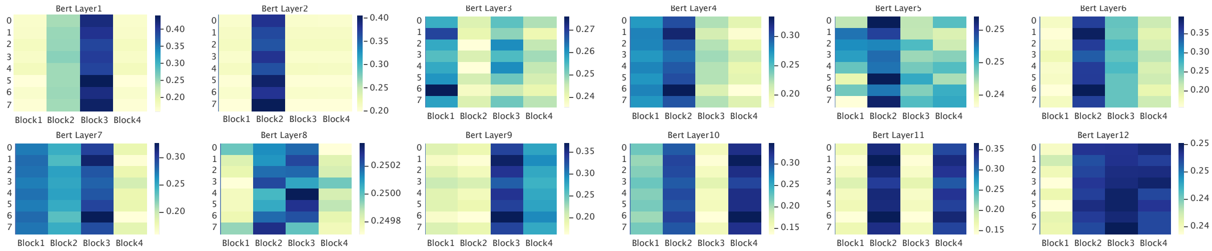
Table 3 shows performance comparison of HVPNeT and UMGF in a cross-task scenario for versatility analysis. For the first part, Twitter2017 → MNRE denotes that the trained model on Twitter-2017 is further used to train and test on MNRE. For the second part, MNRE → Twitter-2017 represents that the trained model on Twitter-2017 is used to further train and test on Twitter-2017. From this Table, we can observe that our HVPNeT significantly outperforms UMGF by a more considerable margin. Note that our method can achieve further improvement in a cross-task scenario, while UMGF performs worse than previous results on the corresponding dataset. This justifies that our HVPNeT is robust to automatically reduce the interference of visual information of irrelevant pictures; thus, more image-text data may facilitate learning better parameters for modality fusion. Besides, it is also interesting to extend our work to multi-task learning or multi-modal pre-training and we leave these for future works.

4.4 Detailed Model Analysis

Ablation Study. In this part, we conduct extensive experiments with the variants of our model to further analyze the effectiveness of our model. We illustrate the results of the variant set in Table 1 . We can observe that:

(1) ***Visual Prefix-guided Fusion.*** The core module of our HVPNeT is visual prefix-guided fusion, which is a pluggable operation. Therefore, ablating visual prefix-guided fusion is equivalent to a purely bert-based baseline model. As shown in Table 1, HVPNeT achieve significant improvements over purely bert-based baseline model, revealing the effectiveness of pluggable visual prefix-guided fusion.

(2) ***Hierarchical Visual Features.*** To validate the impact of our proposed hierarchical visual features, we carry out experiments by introducing two variants: 1) HVPNeT-Flat, crudely assign single visual feature for each layer of BERT; and 2) HVPNeT-1T3, intuitively leveraging visual fea-



Bert Layer1 Bert Layer2 Bert Layer3 Bert Layer4 Bert Layer5 Bert Layer6
Bert Layer7 Bert Layer8 Bert Layer9 Bert Layer10 Bert Layer11 Bert Layer12

Figure 4: Visualization of dynamic gate learned on MNER task. Each subgraph denotes one layer in BERT, and the ordinate and abscissa respectively represent the instance id in a batch and the block id of ResNet.

tures from low-level to high-level blocks. We observe that HVPNeT with hierarchical visual features achieves the best performance consistently compared with the other variants. Although the HVPNeT-1T3 performs slightly lower than the version of dynamic gate, it still outperforms the crude variant HVPNeT-Flat. It reveals that the dynamic gate can automatically learn appropriate weights for multi-scaled visual representations, enabling the model to learn good visual guidance for multimodal entity and relation extraction.

(3) ***Visual Clues Term.*** As recent SOTA models such as UMT, UMGF, and MEGA all adopt visual objects to enhance textual representation, we conduct experiments by ablating global images to explore the impact of the visual clues. As expected, we find that HVPNeT-OnlyObj performs slightly worse than HVPNeT, which is consistent with the observation of previous works. This can be attributed to that abstract clues maybe not be associated with the text in information extraction tasks. In other words, this empirical finding demonstrates the flexibility of our methods to infuse visual clues with different granularity.

Case Analysis for Error Sensitivity To validate the effectiveness and robustness of our method, we conduct case analysis for image-text relevance as indicated in Table 2. We notice that VisualBERT, MEGA, and our method can recognize the relation for the relevant image-text pair. We can further find that the attention between relevant entities and objects is significant. While in the situation that image represents the abstract semantic that is weak relevant to the text, only our method success in prediction due to HVPNeT captures the more hierarchical features. It should be noted that another two multimodal baselines fail in irrelevant image-text pairs while text-based BERT and ours still predict correctly. These observations reveal that our model regards visual prefix as a prompt for text may helps learn more robust multimodal representation, which is essential for the noise of uncorrelated object images.

Gate Visualization We argue that dynamic gated aggregation for hierarchical visual representation is another key component of HVPNeT achieving the superior performance. Specifically, the dynamic gated aggregation can adaptively assign different modality integration paths for different input images, thus, incorporating visual guidance with hierarchical multi-scaled information. To this end, we randomly sample eight images in a batch and visualize their gate vectors learned by HVPNeT according to 12 layers of BERT in Figure 4. Note that optimized gate vectors follow the trend of matching low-level textual semantics with low-level visual semantics and matching high-level textual semantics with high-level visual semantics. Meanwhile, the modality fusion obtained by dynamic gate learning may provide some valuable insights for efficient visual-language approaches in the future.

5 Conclusion and Future Work

In this paper, we propose a novel hierarchical visual prefix fusion neTwork (HVPNeT) for visual-enhanced entity and relation extraction. To be specific, we present visual prefix-guided fusion by concatenating object-level visual representation as the prefix of each self-attention layer in BERT, which is a more soft and robust attention module for visual enhanced NER and RE. We further design leveraging hierarchical multi-scaled visual representation as visual guidance for fusion. Intuitively, ***Good Visual Guidance Make A Better Extractor***, and extensive experimental and results on three benchmarks have demonstrated the effectiveness and robustness of our proposed method. Meanwhile, our method also face the limitation that they don't suitable for mulimodal tasks in visual side, such as visual grounding.

In the future, we plan to 1) explore more applications of hierarchical visual prefix in multimodal representation learning, making it more flexible and extensible; 2) try to apply the reverse version of our approach to boost visual representation with text for CV; 3) extend our approach to multitask multimodal pre-training.

6 Acknowledgments

We want to express gratitude to the anonymous reviewers for their hard work and kind comments. A Detailed Statistics of Dataset

Dataset	Train	Dev	Test	Avg length (characters)
Twitter-2015	4,000	1,000	3,257	95
Twitter-2017	4,290	1,432	1,459	64

Table 4: Size of the datasets in numbers of tweets.

Dataset	# Sent.	# Ent.	# Rel.	# Img.
TACRED	53,791	152,527	41	-
MNRE	9,201	30,970	23	9,201

Table 5: Comparison of MNRE with existing sentence-level Relation Extraction dataset TACRED (Sent.: sentence, Ent.: entity, Rel.: relation,Img.: image.

B Experimental Details

This section details the training procedures and hyperparameters for each of the datasets. We use the BERT-base-uncased model from hugging face library[3]. We follow UMGF (Zhang et al., 2021a) to revise some wrong annotations in the Twitter-2015 dataset. Considering the instability of the few-shot learning, we run each experiment 5 times on the random seed [1, 49, 1234, 2021, 4321] and report the averaged performance. We utilize Pytorch to conduct experiments with 1 Nvidia 3090 GPUs. All optimizations are performed with the AdamW optimizer with a linear warmup of learning rate over the first 10% of gradient updates to a maximum value, then linear decay over the remainder of the training. And weight decay on all non-bias parameters is set to 0.01. We set the number of image objects m to 3. We describe the details of the training hyper-parameters in the following sections.

B.1 Standard Supervised Setting

In the MNER task, we fix the batch size as 8 and search for the learning rates in varied intervals [1e-5, 3e-5]. We train the model for 30 epochs and do evaluation after the 16th epoch. In the MRE task, we fix the batch size as 32 and learning rates as 1e-5. We train the model for 12 epochs and do evaluation after the 8th epoch. In the two tasks, we all choices the model performing the best on the validation set and evaluate it on the test set.

B.2 Low-Resource Setting

For different instances per class, we sample five times on the random seed [1, 2, 49, 4321, 1234] and report the averaged performance. For all models, we fix the batch size as 8 and search for the learning rates in varied intervals [3e-5, 5e-5]. We train the model for 30 epochs and do evaluation after the 16th epoch. We choose the model performing the best on the validation set and evaluate it on the test set.

B.3 Cross-Task Setting

In the MNER task and RE task, we all use ResNet and BERT-base as the backbone, we transfer the same parameters except the classifier layer and CRF layer when we do cross-task. In further training, we fix the batch size as 8 and search for the learning rates in varied intervals [1e-5, 3e-5]. We train the model for12 epochs and do evaluation after the 8th epoch. We choose the model performing the best on the validation set and evaluate it on the test set.

The Role of Context in Detecting Previously Fact-Checked Claims

Abstract

Recent years have seen the proliferation of disinformation and fake news online. Traditional approaches to mitigate these issues is to use manual or automatic fact-checking. Recently, another approach has emerged: checking whether the input claim has previously been fact-checked, which can be done automatically, and thus fast, while also offering credibility and explainability, thanks to the human fact-checking and explanations in the associated fact-checking article. Here, we focus on claims made in a political debate and we study the impact of modeling the context of the claim: both on the source side, i.e., in the debate, as well as on the target side, i.e., in the fact-checking explanation document. We do this by modeling the local context, the global context, as well as by means of co-reference resolution, and multi-hop reasoning over the sentences of the document describing the fact-checked claim. The experimental results show that each of these represents a valuable information source, but that modeling the source-side context is most important, and can yield 10+ points of absolute improvement over a state-of-the-art model.

1 Introduction

The fight against dis/mis-information has become an urgent social and political matter. Online media have been widely used not only for social good, but also to mislead entire communities. Many fact-checking organizations, such as FactCheck.org,[1] Snopes,[2] PolitiFact,[3] and FullFact,[4] as well as some broader international initiatives such as the *Credibility Coalition*[5] and *Eufactcheck*,[6] have emerged to address the problem (Stencel, 2019).

There have also been efforts to develop automatic systems to detect such content (Vo and Lee, 2018; Shu et al., 2017; Thorne and Vlachos, 2018; Li et al., 2016; Lazer et al., 2018; Vosoughi et al., 2018a; Nguyen et al., 2020), including the development of datasets (Augenstein et al., 2019), systems (Chernyavskiy et al., 2021b), and evaluation campaigns (Barrón-Cedeño et al., 2020; Nakov et al., 2021b,c; Shaar et al., 2021a; Nakov et al., 2022b).

An important issue with automatic systems is that journalists and fact-checkers often question their credibility for reasons such as (perceived) insufficient accuracy given the state of present technology, but also due to the lack of explanation about how the system has made its decision. On the other hand, manual fact-checking is time-consuming and does not scale. Yet, time is precious: it has been reported in the literature that *fake news* travels faster than real news (Vosoughi et al., 2018b), and that 50% of the spread of some very viral false claims has happened within the first ten minutes after they got published (Zaman et al., 2014). Such findings show the importance of real-time fake news detection, which can enable a timely intervention.

As both manual and automatic systems have their limitations, there have been proposals for human-in-the-loop settings, aiming to bring the best of both worlds. In order to enable such an approach, one question that arises is how to facilitate fact-checkers and journalists with automated systems (Nakov et al., 2021a). An immediate problem is to know whether a given input claim has been previously fact-checked by a reputable fact-checking organization. This would give the journalist a credible reference and could save her significant amount of time, as manually fact-checking a single non-trivial claim may take from 1-2 days to 1-2 weeks. While earlier studies have suggested that such a mechanism should be part of an end-to-end automated system, there has been limited work in this direction (Shaar et al., 2020a; Vo and Lee, 2020).

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1619 - 1631

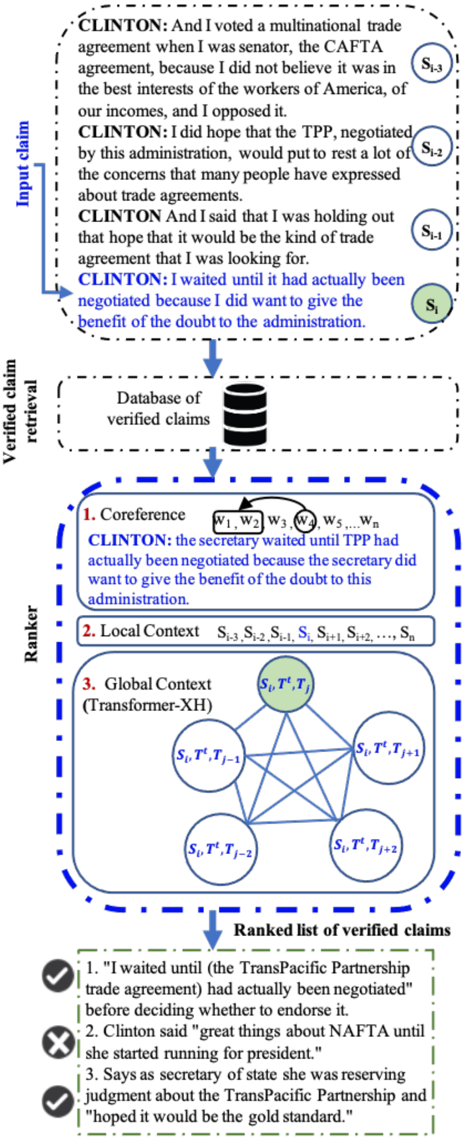

Figure 1: A pipeline of retrieving and ranking previously fact-checked claims. S_i is the claim (source), T^t is the title of the target, T_j is a sentence from the target.

At the time of COVID-19, there are a number of false claims and conspiracy theories spreading online, e.g., about Bill Gates and his chips in the COVID-19 vaccine, about garlic water as a cure, etc. Many such claims have already been debunked, but this does not stop them, as they keep being repeated, potentially in a slightly different form but with the same meaning. Thus, it is important to recognize such variations quickly, and possibly to post a reply in social media with a link to a fact-checking article. Similarly, in a scenario where a politician is being interviewed or is taking part in a debate, a quick check against a collection of previously fact-checked claims would make it possible to put him/her on the spot in real time.

However, the problem in a real-time scenario is that, unlike written text, interviews, debates, and speeches are more spontaneous, and the claims that are being made are often not clearly formulated in a single sentence. This is illustrated in Figure 1, where we can see a fragment from a Democratic debate as part of the 2016 US Presidential election, where Hillary Clinton said: "*I waited until it had actually been negotiated because I did want to give the benefit of the doubt to the administration.*" Understanding this claim requires pronominal co-reference resolution (e.g., what does *it* refer to, is it *CAFTA* or is it *TPP*, as both are mentioned in the previous sentences?), more general co-reference (e.g., that the administration being discussed is the *Obama* administration), as well as general understanding of the conversation so far, and possibly general world knowledge about US politics at the time of the debate (e.g., that Hillary Clinton was Secretary of State when TPP was being discussed).

Moreover, previous research has shown that it is beneficial to match the input claim not only against the canonical verified claim that fact-checkers worked with, but against the entire article that they wrote explaining why the claim was ultimately judged to be true/false (Shaar et al., 2020a; Vo and Lee, 2020). This is because, in the fact-checking article, the claim is likely to be paraphrased in different ways, and there could also be background information and related terms, which can facilitate claim matching, and thus improve recall. This means that we need to make use of the global contextual information contained within the full text of the fact-checking article or at least the sentences next to the claim, i.e., the local context. Similarly, for the FEVER fact-checking task, which asks to fact-check against Wikipedia, it has been shown that multi-hop reasoning (Transformer-XH) over the sentences of the target article can help (Zhao et al., 2019), an observation that was further confirmed in the context of fact-checking political claims (Ostrowski et al., 2021). Transformer-XH uses a novel attention mechanism that naturally "hops" across the connected text sequences in addition to attending over tokens within each sequence. As claims and reasoning about them are manifested across documents, this hop-based attention mechanism constructs global contextualized representation to provide better joint multi-evidence reasoning. In the present work, we rely on Transformer-XH to extract and use global contextual information.

Based on the above considerations, we propose a framework that focuses on modeling co-reference, local context (representation from neighboring sentences; see Section 4.2.2), and global context (representation from Transformer-XH; see Section 4.2.3), both on the source and on the target side, while also using multi-hop reasoning over the target side.

Our contributions can be summarized as follows:

- We perform careful manual analysis to understand what makes detecting previously fact-checked claims a hard problem, and we categorize the claims by type. We release these annotations to enable further research.
- Unlike previous work, we focus on modeling the context both on the source side and on the target side, both locally and globally, using co-reference resolution and reasoning with Transformer-XH, which yields sizable improvements over state-of-the-art models of over ten MAP points absolute.
- We propose a realistic and challenging, time-sensitive and document-aware, data split compared to previous work, which we also release.[7]

The rest of the paper is organized as follows. Section 2 provides a brief overview of previous work. Section 3 introduces the dataset development process. Section 4 presents the experiments. Section 5 discusses the evaluation results. Finally, Section 6 concludes with lessons learned and points to possible directions for future work.

2 Related Work

Below, we describe three relevant lines of research: on detecting previously fact-checked claims, on semantic matching and ranking, and on context modeling for factuality.

2.1 Previously Fact-Checked Claims

While there is a surge in research on automatic fact-checking, fully automatic systems suffer from credibility issues, e.g., in the eyes of journalists, and manual checking is still the norm. Thus, it is important to reduce that manual effort by detecting when a claim has already been fact-checked.

A recent survey has identified the task of detecting previously fact-checked claims as one of the most important ways in which automation can assist human fact-checkers (Nakov et al., 2021a). The task was recognized as an important element of the typical sequence of fact-checking steps (Vlachos and Riedel, 2014): (*i*) extracting statements that are to be fact-checked, (*ii*) constructing appropriate questions, (*iii*) obtaining the pieces of evidence from relevant sources, and (*iv*) reaching a verdict using that evidence. Hassan et al. (2017) also mentioned the task as an important component of their end-to-end fact-checking pipeline, but did not evaluate it as a component on its own right.

Recently, Shaar et al. (2020a) gave a formulation of the task of detecting previously fact-checked claims, and proposed a learning-to-rank approach combining BM25 retrieval with BERT-based semantic matching. They further developed two specialized datasets: (a) on political debates and speeches, using fact-checked claims from PolitiFact, and (b) on tweets, using claims from Snopes.

The CLEF 2020-2022 CheckThat! lab (Barrón-Cedeño et al., 2020; Hasanain et al., 2020; Shaar et al., 2020b; Nakov et al., 2021b,c; Shaar et al., 2021b; Nakov et al., 2022b,c,d) extended these datasets with additional data in English and Arabic, adding more data each year. The best systems (Pritzkau, 2021; Mihaylova et al., 2021; Chernyavskiy et al., 2021a) used a combination of BM25 retrieval, semantic similarity using sentence embeddings (Reimers and Gurevych, 2019), and reranking. Bouziane et al. (2020) further used external data from fact-checking datasets (Wang, 2017; Thorne et al., 2018; Wadden et al., 2020).

Chernyavskiy et al. (2022) fine-tuning BERT using batch-softmax contrastive loss as an alternative to mean squared error and triplet loss, and demonstrated sizable performance gains for a number of sentence scoring tasks, including detecting previously fact-checked claims.

Another recent work by Sheng et al. (2021) highlighted the importance of using lexical, semantic, and pattern-based information and proposed a reranker based on memory-enhanced transformers for claim matching.

Vo and Lee (2020) proposed a multi-modal text+image neural ranking model for detecting previously fact-checked claims about images.

However, none of the above work modeled the context of the input claim, which is our focus here.

---

[7] `https://github.com/firojalam/Detecting-Previously-Fact-Checked-Claims.git`

2.2 Semantic Matching and Ranking

Here, we focus on the textual formulation of the problem, as defined by Shaar et al. (2020a): given an input claim, we want to detect potentially matching previously fact-checked claims and to rank them accordingly. A related research area is semantic matching and ranking, as matching some *InputClaim–VerClaim* pairs might require sentence embeddings, natural language inference, and coreference resolution. An example of such a difficult pair is shown in Table 1, line 607. Recent relevant work has used neural approaches. Nie et al. (2019) proposed a semantic matching method that combines document retrieval, sentence selection, and claim verification neural models to extract claims and to verify them. Thorne et al. (2018) proposed a simple model, where pieces of evidence are concatenated together and then fed into a Natural Language Inference (NLI) model. Yoneda et al. (2018) used a four-stage approach that combines document and sentence retrieval with NLI. Hanselowski et al. (2018) used a BiLSTM-based enhanced sequential inference model (Chen et al., 2017) to rank candidate facts and to classify a new claim based on the selected facts. Several studies used model combination (i.e., document retrieval, sentence retrieval, and NLI to classify the retrieved sentences) with joint learning (Yoneda et al., 2018; Hidey and Diab, 2018; Luken et al., 2018).

2.3 Context Modeling for Factuality

Previous work has shown that modeling the context can help for predicting the check-worthiness of claims in political debates, e.g., the interaction between the debaters, and the reaction of the moderator and of the public to what was said (Gencheva et al., 2017; Atanasova et al., 2019b; Vasileva et al., 2019). The CLEF 2018-2022 CheckThat! lab had a shared task on this (Atanasova et al., 2018, 2019a; Shaar et al., 2020b, 2021c; Nakov et al., 2022a).

The CLEF-2018 CheckThat! lab featured a shared task on fact-checking a claim in the context of a political debate (Barrón-Cedeño et al., 2018; Nakov et al., 2018), and SemEval-2019 had a shared task on fact-checking in community question answering forums (Mihaylova et al., 2019).

Liu et al. (2020) proposed a kernel graph attention network to model evidence as a context for fact verification. Similarly, Zhou et al. (2019) used a fully connected evidence graph with multi-evidence information sources for fact verification.

Zhong et al. (2020) used different pre-trained Transformer models and a graph-based approach, i.e., graph convolutional network and graph attention network, for fact verification. Zhao et al. (2019) introduced extra hop attention to incorporate contextual information, while maintaining the Transformer capabilities, thus making it possible to learn a global representation of the different pieces of evidence and to jointly reason over the evidence graph. One of the limitations of their approach was the need for human-labeled evidence in relation to the input claims in existing fact-verification datasets. Ostrowski et al. (2021) developing a dataset of annotated pieces of evidence associated with input claims and used multihop attention to make a prediction about the factuality of a claim.

Unlike the above work, here we target a different task: detecting previously fact-checked claims as opposed to check-worthiness prediction or fact-checking a claim. Moreover, while the above work was limited to the target context, here we also model the source context, which turns out to be much more important.

3 Dataset

Here, we focus on the problem of detecting previously fact-checked claims, using the task formulation and an adaptation of data from (Shaar et al., 2020a). They had two datasets: one on matching tweets against Snopes claims, and another one on matching claims in the context of a political debate to PolitiFact claims. Here, we focus on the latter,[8] and we perform a close analysis of the claims and what makes them easy/hard to match.

We experimented with their PolitiFact dataset, which targets claims related to US politics. After a US political debate, speech, or interview, fact-checking journalists from PolitiFact would select few claims made in the event and would verify them either from scratch or by linking them to a previously fact-checked claim. Each fact-checked claim has an associated article stating its degree of factuality along with an explanation of how the fact-checkers arrived at their verdict. The dataset has two parts: (*i*) verified claims {normalized *VerClaim*, article *title*, and article *text*}, (*ii*) transcripts of the political events (e.g., debates). Shaar et al. (2020a) annotated the data by linking sentences from the transcript (*InputClaim*) to one or more verified claims (out of 16,636 claims in PolitiFact).

---

[8] `github.com/sshaar/That-is-a-Known-Lie`

Line No.	**Type**	**Input Claim**		**Verified Claim**
255	*clean*	D. Trump:	*Hillary Clinton wanted the wall.*	Says Hillary Clinton “wanted the wall.”
695	*part-of*	C. Wallas:	*And since then, as we all know, nine women have come forward and have said that you either groped them or kissed them without their consent.*	The stories from women saying he groped or forced himself on them “largely have been debunked.”
			⋮	
699	*part-of*	D. Trump:	*Well, first of all, those stories have been largely debunked.*	The stories from women saying he groped or forced himself on them “largely have been debunked.”
688	*clean-hard*	D. Trump:	*She gave us ISIS as sure as you are sitting there.*	Hillary Clinton invented ISIS with her stupid policies. She is responsible for ISIS.
605		D. Trump:	*Now she wants to sign TransPacific Partnership.*	
			⋮	
607	*context-dep*	D. Trump:	*She lied when she said she didn’t call it the gold standard in one of the debates.*	Says Hillary Clinton called the TransPacific Partnership “the gold standard. You called it the gold standard of trade deals. You said its the finest deal youve ever seen.”

Table 1: Fragment from the 3rd US Presidential debate in 2016 showing the *verified claims* chosen by PolitiFact and the fine-grained category of the pair. Most input sentences have no *verified claim*, e.g., see line 605.

To further analyze the dataset, we looked at the *InputClaim–VerClaim* pairs, and we manually categorized them into one of the following categories:

1. ***clean*** **:** A *clean* pair is a self-contained *InputClaim* with a *VerClaim* that directly verifies it (see line 255 in Table 1 as an example).
2. ***clean-hard*****:** A *clean-hard* pair is a self-contained *InputClaim* with a *VerClaim* that indirectly verifies it (see line 688 in Table 1).
3. ***part-of*****:** A *part-of* pair’s *InputClaim* is not self-contained and requires the addition of other sentences from the transcript to fully form a single claim.
4. ***context-dep*****:** A *context-dep* pair is similar to *clean* and *clean-hard*, but the *InputClaim* is not self-contained and needs co-reference.

The above categories include all types of pairs we have seen. Moreover, since the dataset is constructed from speeches, debates, and interviews, the structure of the *InputClaim–VerClaim* pairs differs. For example, in debates, we see more *part-of* examples, as there are multiple question–answer claim pairs, as well as back-and-forth arguments splitting the claims into multiple sentences.

The annotations were performed by three annotators who are experts in fact-checking (and co-authors of this paper), using the above definitions for the categories. We consolidated their annotations using majority voting, and they had a consolidation discussion for cases with no majority. The Fleiss Kappa inter-annotator agreement was 0.5, which corresponds to moderate agreement, which is reasonable for such a complex annotation task.

Table 1 shows examples of *InputClaim–VerClaim* pairs that illustrate the four categories. We can see that the task goes beyond simple textual similarity and natural language inference, as the examples in lines 607 and 695–699 show. Moreover, matching *context-dep* pairs (lines 605–607) requires understanding the *InputClaim*’s local context, while matching *clean-hard* pairs (line 688) requires analysis of the overall global context of the *VerClaim*.

Finally, we should note while annotating the data into the above four categories, we found out that a small number of *InputClaim–VerClaim* pairs in (Shaar et al., 2020a) were false matches (which happened, as they did the matching automatically, without manually double-checking every single example). We removed these pairs, and thus our reported number of pairs is slightly lower than theirs.

InputClaim–VerClaim pairs	695	
– *clean*	291	42%
– *clean-hard*	210	30%
– *part-of*	68	10%
– *context-dep*	126	18%
Total # of verified claims (to match against)	16,636	

Table 2: **Statistics about our dataset:** total number of *InputClaim–VerClaim* pairs and of *VerClaims* in PolitiFact to match an *InputClaim* against.

Split	**MAP**
Debate-Level – Chrono	**0.429**
Debate-Level – Semi-chrono	0.539
Debate-Level – Random	0.590
Sentence-Level – Random (Shaar et al., 2020a)	0.602

Table 3: MAP scores of the reranker models when using four different splits representing different scenarios. We use *Debate-Level – Chrono* for our experiments.

Table 2 shows statistics about the distribution of the four categories of claims in our dataset. We can see that *clean* and *clean-hard* are the most frequent categories, while *part-of* is the least frequent one.

We further observed that Shaar et al. (2020a) dealt with each *InputClaim* independently, i.e., at the sentence level. This is problematic because for *part-of* claims we could end up splitting them and putting them in different sets: one in training, and one in testing. Moreover, splitting the dataset in this way means that the examples for a given topic can split between training and test, and thus information can leak, e.g., a claim can be repeated. Therefore, we considered new splits for the data:

- *Debate-Level Chrono*: We split the data chronologically. We use the first 50 debates for training, and the last 20 for testing. Specifically, we have 554 pairs for training, and 141 pairs for testing. This is a more realistic scenario, where we would only have access to earlier debates, and we can use them to make decisions about claims made in future debates. The complexity of this setting is also reflected in the MAP score as shown in Table 3. We see that this score is lower than the best model in previous work (last row). This is because this setting is complex as we use a model trained on debates and speeches from 2012-2018, and we test on debates from 2019. Across those different time frames, different politicians discuss different topics.

- *Debate-Level Semi-Chrono*: We split the data per year, e.g., for year 2018, we divide the transcripts into train and test with 80/20 splits, and then we train and evaluate using the same reranking model. In Table 3, we can see an improvement with this setting compared to the *Debate-Level Chrono* setting. This might be because the same politicians discuss the same/similar issues throughout the same year.

- *Debate-Level Random*: We randomly choose 80% of the debates for training and the remaining ones for testing. This is a comparatively easier setting as the data is randomly distributed in training and testing. This is also reflected in the results in Table 3. The reason could be that politicians repeat themselves a lot, especially in two consecutive political events, and the random split can lead to having two similar debates/speeches in two splits.

- *Sentence Level Random*: This is the setting in (Shaar et al., 2020a), where *sentences* from the debates are randomly divided into train and test in a proportion of 80:20. This is the most unrealistic split.

In our experiments, we chose to use the most realistic, but also the hardest setup: *Debate-Level Chrono*. As a result, our MAP score, when experimenting with the state-of-the-art model of (Shaar et al., 2020a), decreases from 0.602 to 0.429.

4 Experimental Setup

Below, we first introduce the experimental setup for our baseline, and then we describe our proposed model that takes the context of the input claim into account, both on the source and on the target side.

4.1 Baseline

From our analysis of the dataset (described in Section 3), we conclude that (*i*) we need to resolve the references in the *InputClaim*, (*ii*) to capture the local context of the *InputClaim*, and (*iii*) to encapsulate the global context of the *VerClaim*.

For our baseline, we use the setup of the state-of-the-art model of Shaar et al. (2020a). We use the claim as a query against the full text of the documents using BM25. We then train a reranker on the top-100 BM25 results using rankSVM (Herbrich et al., 1999) with an RBF kernel.

The reranker uses nine similarity measures that compare the *InputClaim* to the *VerClaim*, as well as the respective reciprocal ranks. In particular, we compute the BM25 score for *InputClaim* vs. *VerClaim*, *title*, *text*, *VerClaim+title+text*. We also compute the cosine using sentence-BERT embeddings for *InputClaim* vs. *VerClaim*, *title*, and the top-4 sentences from *text*. Using these scores, we create a vector representation of the *InputClaim*–*VerClaim* pair with dimensionality $\mathbb{R}^{18}$. We then scale the vectors of all *InputClaim*–*VerClaim* pairs in $[-1; 1]$ and we train a rankSVM with default values of the hyper-parameters: $KernelDegree = 3$, $\gamma = 1/num\_features$, and $\epsilon = 0.001$.

4.2 Proposed Model

As shown in Figure 1, our model uses co-reference resolution on the source and on the target side, the local context (i.e., the neighboring sentences), and the global context (using Transformer-XH) as discussed below. It is still a pairwise reranker, but with a richer context representation.

4.2.1 Co-reference Resolution

We manually inspected the training transcripts and the associated verified claims, and we realized that there were many co-reference dependencies, resolving which could potentially help to obtain more representative textual and contextual similarity scores. As for the verified claims, we noticed that not all *VerClaim*s were self-contained, and that some understanding of the context was needed[9] of the article's *text* that explains the verdict provided by the PolitiFact journalists. Therefore, our hypothesis was that resolving such co-references could improve the downstream matching scores.

For the same reason, we also performed co-reference resolution on the PolitiFact articles when they were used to compute the BM25 scores.

We experimented with various co-reference resolution tools including **NeuralCoref**,[10] **e2e-coref**,[11] and **SpanBERT**,[12] and we found that **NeuralCoref** was best on the input transcripts, while **e2e-coref** was best on the articles about the target *VerClaim*s. Hence, in the rest of our experiments below, we show results using **NeuralCoref** for the source side, and using **e2e-coref** for the target side.

We resolved the co-reference in the *InputClaim* by performing co-reference resolution on the entire input transcript (as was suggested in the literature); we will refer to this as ***src-coref***. As for the verified claims, we aimed to resolve the co-references both in the *VerClaim* and in the *text* of the PolitiFact articles. We also aimed to ensure that the dependencies from the *text* can be used for the *VerClaim*. Therefore, we concatenated both the text and *VerClaim* (in the same order), and we applied the co-reference model on the concatenated text. We chose this order of concatenation because the published *text* reserves the last paragraph to rephrase the *VerClaim* and to provide a summary of the justification; hence, there is a higher probability to resolve the co-references correctly.

4.2.2 Local Context

Resolving the pronominal co-references allows us to obtain the correct objects and the names the *InputClaim* refers to. However, in the process of analyzing the dataset, we noticed that different *VerClaim*s, although having similar structure, could talk about different things, depending on the article text and also on the surrounding context. Therefore, it is important to understand the context of an *InputClaim*. In particular, we achieve this by performing a feature-level concatenation of the neighboring sentences in the transcript, i.e., we take the eighteen features ($\mathbb{R}^{18}$, as discussed in Section 4.1 above) for the neighboring sentences, and we concatenate them to the similarity score for the *InputClaim*. We then use the resulting representation as a feature vector to be fed into our reranker. For example, if we take three sentences before the *InputClaim* and one sentence after it, we denote this as ***FC***(3, 1).

Let S_i be our *InputClaim*, which is the i'th sentence in the transcript. We compute the similarity measures and the reciprocal rank (as described in Section 4.1) to obtain the vector representation $S_{i,v}$ for S_i. With $k = 3$ previous and $l = 1$ following neighbouring sentences our final feature vector is

$$FC(k=3, l=1) = S_{i-3,v} \mathbin{+\!\!\!+} S_{i-2,v} \mathbin{+\!\!\!+} S_{i-1,v} \mathbin{+\!\!\!+} S_{i,v} \mathbin{+\!\!\!+} S_{i+1,v} \quad (1)$$

where $\mathbin{+\!\!\!+}$ represents concatenation.

Note that after the concatenation, the resulting dimensionality of the feature vector for ***FC(3, 1)*** is $18 \times (3 + 1 + 1) = 90$.

---

Table 4: MAP scores of the reranker models on the test set using the *Debate-Level Chrono* split.

4.2.3 Global Context

The similarity scores that leverage the local context in the textual content of the *InputClaim* and the *VerClaim* are obtained using (*i*) BM25, and (*ii*) the cosine similarity between the Sentence-BERT embeddings of the *InputClaim* vs. the top-4 sentences of the *VerClaim*. This might miss relevant information further away from the *InputClaim* in the input document and further away from the *VerClaim* in the document accompanying the *VerClaim*. We refer to such scattered information as the **global context**. To capture it, we use Transformer-XH (Zhao et al., 2019), which is pretrained on the FEVER (Fact Extraction and VERification) dataset to predict whether a given input claim is supported/refuted by a set of target sentences (from Wikipedia), represented as a graph, or there is no enough information. We used the model from (Zhao et al., 2019). For a given *InputClaim*, we generate a graph for each of the top-100 *VerClaim*s retrieved using BM25 and the normalized claim, the *title*, and the top-3 sentences from the *text* as nodes. Using the ***Transformer-XH*** model on the graph, we obtain three additional scores that correspond to the posterior probability that *VerClaim* supports or refutes the *InputClaim*, or there is no enough information.

4.3 Hyper-Parameter Values

For the baseline, we use the best values of the hyper-parameters as found in (Shaar et al., 2020a). For our context-aware models, we select the values of the hyper-parameters by splitting the training dataset into train-train (debates from 2012-2017) and train-dev (debates from 2018), then we train on the former, and we test on the latter.

4.4 Evaluation Measures

As we have a ranking task, we use mean average precision (MAP) for evaluation. It is a suitable measure as some *InputClaim*s are paired with more than one *VerClaim*. This is why we opted for not using mean reciprocal rank (MRR), which would only pay attention to the highest-ranked match.

5 Results

Below, we described the results for our source-side and target-side context modeling experiments.

5.1 Source-Side Experiments

For the source side experiments, we used co-reference resolution on transcripts and variations of the local context by varying k and l in Eq. 1.

When we inspected the transcripts, we found that co-references tended to be resolved by a few sentences before the *InputClaim*; therefore, we tried ***FC***(1, 1), ***FC***(3, 1), ***FC***(3, 3), and ***FC***(5, 1). We obtained the best results on cross-validation using ***FC***(3, 1), which we use below. As shown in Table 4, the local context (line 2) improves over the baseline (line 1) by eight MAP points absolute.

We experimented using co-reference resolution with **NeuralCoref**. This yielded a sizable improvement over the baseline as shown in line 3 in Table 4, especially for *part-of* and *context-dep* pairs, as they have many co-references, which can make it hard for the model the understand the *InputClaim*. After combining the two methods, i.e., *src-coref* and ***FC***(3,1) (see line 4), we achieved the highest MAP score of 0.532. We always see an improvement for the *clean* category as the resolved *InputClaim* can match the article text better.

5.2 Target-Side Experiments

For the target-side experiments, we tried using co-reference resolution (on the source and on the target side) for the *VerClaim* and the fact-checking article, as well as modeling the global context with *Transformer-XH*. Compared to the baseline, we see on line 5 of Table 4 a sizable improvement from 0.365 to 0.441 MAP points for *clean-hard*.

This is expected as the pair does not exhibit much semantic similarity, and we need to build our own understanding of the *text* of the *VerClaim* in order to capture the contextual similarity in the pair. We also experimented with co-reference resolution on the *VerClaim* and the *text* of the *VerClaim* and also see some improvement. Combining *tgt-coref* and *Transformer-XH* (line 7) improved the performance over *tgt-coref* alone, but it is worse than *Transformer-XH* alone. The combination outperforms other target-side experiments for *clean*.

5.3 Source-Side & Target-Side Experiments

Eventually, we experimented with modeling the context both on the source and on the target side. Line 8 in Table 4 shows the evaluation results when we use co-reference resolution both on the source and on the target side. We can see that this yields a higher overall MAP score of 0.487, compared to using source-side (MAP of 0.479; line 3) or target-side context only (MAP of 0.443; line 6). Moreover, co-reference resolution on both sides helps for *clean-hard* and *part-of* (compared to using co-reference on one side only) as they require better local and global context, respectively.

We further tried putting it all together, and the result is shown in line 9.[13] While this yielded better results for *clean*, it was slightly worse compared to the source-side context modeling combination in line 4. This is probably due to the source-side context models being generally stronger than the target-side ones (compare lines 2–3 to lines 5–6).

We can conclude that modeling the context on the source side is much more important than on the target side. This is expected for political debates, which are conversational in nature. In contrast, the target side is a well-written journalistic article, where sentences are much more self-contained. Thus, features from the source side (i.e., from the debate) are more useful as can be seen in Table 4.

5.4 Discussion

As mentioned above, our baseline is a reimplementation of the best system of Shaar et al. (2020a), and our context modeling extensions add additional components on top of it. Note, however, that our experimental results are not directly comparable to their published ones, as we use a more realistic and also a much harder setup, where the data is split by entire debates and also chronologically, following the *Debate-Level Chrono* data split, as we discussed in Section 3, i.e., training on the data from 2012 to 2018 and testing on 2019 (while they split all debates into sentences and randomly distribute them to training/testing). However, we do have comparison to their approach, as we ran their model on our data split, which is our baseline, as shown on line 1 of Table 4.

6 Conclusion and Future Work

We have presented our work on the important but under-studied problem of detecting previously fact-checked claims in political debates and speeches. We studied the impact of modeling the context: both on the source side, i.e., in the debate, as well as on the target side, i.e., in the fact-checking document that explains how human fact-checkers have arrived at their decision about the factuality of the claim. In particular, we modeled the local context, the global context, and we further used co-reference resolution and multi-hop reasoning over the target text using Transformer-XH. The experimental results have shown that each of these components represents a valuable information source, but modeling the source-side context is more important, and can yield 10+ points of absolute improvement over a context-free state-of-the-art baseline.

In future work, we want to try other multi-hop reasoning frameworks for context modeling. We also plan to experiment with other kinds of conversations, e.g., in community forums and in social media, including for other languages.

Acknowledgments

This research is part of the Tanbih mega-project, developed at the Qatar Computing Research Institute, HBKU, which aims to limit the impact of "fake news," propaganda, and media bias by making users aware of what they are reading, thus promoting media literacy and critical thinking.

---

[13] Note that in this result we did not use target-side co-reference, as adding it yielded somewhat worse results. It seems to interact badly with Transformer-XH, which can also be seen by comparing lines 5 and 7.

Ethics and Broader Impact

Biases We note that there might be some biases in the data we use, as well as in some manual judgments for claim matching. There could be also biases in the data selection and the fact-checking process of the human fact-checkers, which are beyond our control. Finally, there are known biases in the large-scale pre-trained transformer models that we experiment with.

Intended Use and Misuse Potential Our models can make it possible to put politicians on the spot in real time, e.g., during an interview or a political debate, by providing journalists with tools to do trustable fact-checking in real time. They can also save a lot of time to fact-checkers for unnecessary double-checking something that was already fact-checked. However, these models could also be misused by malicious actors. We, therefore, ask researchers to exercise caution.

Environmental Impact We would also like to warn that the use of large-scale Transformers requires a lot of computations and the use of GPUs/TPUs for training, which contributes to global warming (Strubell et al., 2019). This is a bit less of an issue in our case, as we do not train such models from scratch; rather, we fine-tune them on relatively small datasets. Moreover, running on a CPU for inference, once the model has been fine-tuned, is perfectly feasible, and CPUs contribute much less to global warming.

Abstract

Pre-trained language models have shown great success in multiple downstream tasks. However, they are computationally expensive to fine-tune. Thus, transfer learning with adapter modules has been introduced to alleviate this problem, helping to extract knowledge of the downstream tasks. Adapterfusion models are an example of the transformers-with-adapter-modules, which merge multiple adapters to incorporate knowledge from different tasks. However, merging multiple adapters will inevitably cause redundancies, increasing the training and inference time massively. Therefore, in this paper, we propose an approach to identify the influence of each adapter module and a novel way to prune adapters based on the prestigious Lottery Ticket Hypothesis. Experiments on GLUE datasets show that the pruned Adapterfusion model with our scheme can achieve state-of-the-art results, reducing sizes significantly while keeping performance intact.

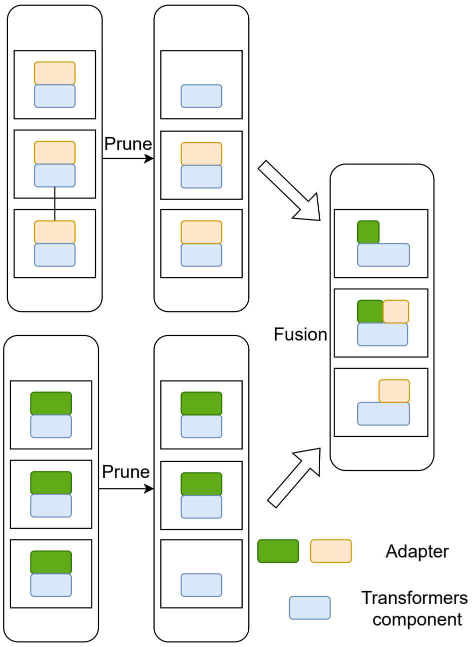

Figure 1: Pruning Adapterfusion. Adapters from different tasks are combined into Adapterfusion after pruning with proposed method separately.

1 Introduction

Transfer learning with transformer-based pre-trained language model has become a go-to method for solving multiple NLP tasks (Vaswani et al., 2017). The language models are pre-trained on large amounts of unlabeled text data with methods such as masked language modeling (e.g. BERT (Devlin et al., 2019a), Roberta (Liu et al., 2019), and XLNet (Yang et al., 2019)]). Despite the state-of-the-art performance for most natural language understanding tasks, they are notoriously deep requiring millions or even billions of parameters to gain great results (Kaplan et al., 2020). For different tasks, models needs to be fine-tuned entirely, which is computationally expensive and requires large storage.

Therefore, adapter modules (Houlsby et al., 2019) are introduced to tackle this issue. It's an alternative way of transfer learning that achieves comparable performance to full fine-tuning on most NLP tasks, without the need of fine-tuning the whole model for a downstream task. Adapter is a small residual neural network inserted in each layer of the transformer. During training, only the parameters in adapters are fine-tuned, while the rest of the parameters are frozen. This approach can reduce the number of parameters needed to be trained at the training phase and enable parameter sharing among tasks. Moreover, recent studies have revealed that the adapter is capable of extracting knowledge from the target task (Rücklé et al., 2020b; Pfeiffer et al., 2020), so research attempts have also been made to fuse multiple adapters across multiple tasks to incorporate different aspects of knowledge (e.g. Adapterfusion (Pfeiffer et al., 2021), K-adapter Wang et al. (2021)). How-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1632 - 1646
July 10-15, 2022

ever, the fusing of adapters in these models can inevitably cause a lot of redundancies. So, Rücklé et al. (2020a) have recently proposed AdapterDrop which aims to drop the redundant adapters. They tried to remove adapters from lower transformer layers during training and inferences, resulting in faster training and inference speed with some performance cost. However, the utilization of each adapter has not been fully analysed yet and how to introduce new pruning strategies remains to be explored.

To address these deficits, in this paper, we propose an approach to model the utilization of different adapters in the transformer layer, and a novel way to prune adapters in the model while keeping the loss of the performance to be negligible. The contributions are summarized as follows:

- We propose a new indicator LIA (Layer Influence Of Adapter) to quantify the utilization of adapters at each layer and identify the most influential adapters in the model.
- We introduce a novel way for pruning adapter modules, inspired by the prestigious Lottery Ticket Hypothesis (Frankle and Carbin, 2019), which states that dense, randomly-initialized, feed-forward networks contain subnetworks (winning tickets) that can have test accuracy comparable to the original network in a similar number of iterations when trained in isolation.
- We have evaluated the proposed approach on the GLUE datasets. For the performance and LIAs of the pruned adapters in the latest state-of-the-art Adapterfusion model, we can remove more than half of the adapters and reduce computation of the Adapterfusion model by nearly 40% with little performance loss.

2 Adapterfusion pruning

Adapterfusion model (Pfeiffer et al., 2021) is to merge multiple adapters from different tasks. And inference time of the model increases drastically after the fusion. However, not all the adapter modules in the model are utilized in the downstream task. We prune adapter modules from model to improve inference speed. Our proposed pruning strategy to remove redundant adapters from Adapterfusion model will be two-stage. First, we prune single task adapters before the fusion using Lottery Ticket Hypothesis (Frankle and Carbin, 2019). We then fuse the less utilized adapters after training the model. The whole framework is presented in Figure 1. To identify the roles of adapters, we firstly define a new indicator LIA (Layer Influence Of Adapter) for the adapter module to measure its utilization in each layer.

2.1 Pruning single task adapter with Lottery Ticket Hypothesis

Since not all adapters in the model are created equal, removing some of the adapters does not compromise the performance too much. We will prune the single task adapter before the Adapterfusion.

Inspired by Lottery Ticket Hypothesis (Frankle and Carbin, 2019), we prune the adapter iteratively to find the sub-network (winning ticket) that can reach the same accuracy when trained in isolation. After every pruning, we reinitialize the weights of the adapter to the initial values when the first iteration starts .

We explore to find the winning ticket in adapters by training and pruning them iteratively. Since the importance of adapters is different in each layer, we are performing the pruning globally. We train the transformer model with adapters as $f(x; \theta_0; \alpha)$ with initial parameter in adapters $\theta = \theta_0 \sim D_\theta$ and transformer parameter $\alpha = \alpha \sim D_\alpha$. Then the winning ticket can be found by the following steps:

1. Randomly initialize adapter parameters in the model $f(x; \theta_0; \alpha)$.
2. Train the adapters for j iterations, arriving at parameters θ_j.
3. Prune $p\%$ of the adapters in θ_j.
4. Reset the remaining parameters in adapters to θ_0, and go back step 2 to train the model $f(x; \theta_0; \alpha)$ if it is not a winning ticket yet.

We prune adapters based on their sum of weights. Here we do not use LIA yet because it only represents the influence of adapter at each layer and it can not distinguish the influence between layers.

Let $\theta_{t,l}$ be the weights of the adapter at layer l at iteration t and $a_{i,j}$ denote the parameters in $\theta_{t,l}$. The importance of an adapter of size N with input size of H is $\sum_{i,j}^{N,H} |a_{i,j}|$. Adapters are then sorted by the sum of weights in the descending order as well, and the $p\%$ smallest adapters in list R are removed from the model. And the remaining adapters step back to their initial weights for the re-training. The whole procedure is elaborated in Algorithm 1. See Appendix B for more details.

Algorithm 1: Sort the importance of adapter layers

```
Result: a list of tuple containing values of
        importance and the number of
        layers
$R$ is an empty list;
The size of adapter is $N$ ;
Input size of adapter is $H$ ;
Weights of adapter at iteration $t$ as $\theta_t$;
for layer $l$ in $\theta_t$ do
    if layer $l$ not pruned then
        Value of importance
          $Imp_l = \sum_{i,j=0}^{N,H} |a_{i,j}|$ ;
        Append tuple $(Imp_l, l)$ to list $R$ ;
    end
end
Sort list $R$ with $Imp$
```

2.2 Layer influence of Adapter

To identify the usage of adapter module, we propose a new indicator LIA(Layer influence of Adapter).

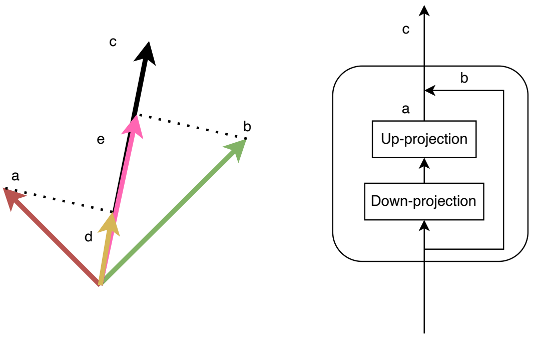

Figure 2: Layer influence of Adapter.

In a adapter module, let $\vec{a}$ denote the output of adapter up projection module, $\vec{b}$ be the residual connection of the adapter, and $\vec{c}$ be the output of the adapter. See Figure2 for more detail. Their connection can be modeled as equation 1:

$$\vec{a} + \vec{b} = \vec{c} \tag{1}$$

Let $\vec{d}$ denote the projection of $\vec{a}$ on $\vec{c}$, $\vec{e}$ be the projection of $\vec{b}$. Therefore $\vec{c}$ is the combination of $\vec{d}$ and $\vec{e}$.

Since the activation of adapters varies between different inputs and different layers, it's difficult to see the influence of adapter in each layer based on the activation. So we use the projection vector $\vec{d}$ to represent $\vec{a}$ influence and normalize it by the length of $\vec{c}$. We name this quantity as Layer Influence Of Adapter (LIA), which is defined as:

$$LIA_{\vec{a}} = \frac{|\vec{a}| \times \cos\theta}{|\vec{c}|} = \frac{\vec{a} \cdot \vec{c}}{|\vec{c}|^2} \tag{2}$$

With LIA, we can model the importance of adapters and streamline the model accordingly. We compare the LIAs of adapter before and after the pruning.

In Adapterfusion model, adapters are fused with a adapterfusion layer which is a self-attention layer. It calculate the attention of adapters and use the weighted sum of adapters as the output. Their connection can be modeled as equation 3:

$$\vec{c} = \vec{b} + \sum_{i=1}^{n} W_i * \vec{a}_i \tag{3}$$

We use $W_i * \vec{a}_i$ to calculate the LIA of each adapter. We compare LIA between different adapters to show whether the adapters are fully utilized, and identify which adapter is more useful for certain layer.

3 Experimental studies

In this section, we examine the influence of the single task adapter under different downstream tasks, and present the results of our proposed pruning scheme evaluated on the prestigious GLUE datasets (Wang et al., 2018).

3.1 Experimental settings

We use the public BERT-Based uncased model which has 12 layers and a total of 110M parameters as our base model. And we apply the similar approach in (Devlin et al., 2019b) to perform a text classification task. In each input sequence, the first token is a classification token. Its embedding is then fed into a linear layer to make a prediction. In the training of Adapterfusion, a new linear layer is initialized for classification and Adapterfusion model is inserted in each transformer layer.

In the experiment of pruning single task adapters, we set the adapter size to 128 because engineering practices (Bengio et al., 2005) suggest that overparameterized networks are easier to train. We use Adam optimizer to train the single task adapter model and perform hyperparameter search using TPE algorithm (Bergstra et al., 2011). We run 30 trials on learning rate settings in $\{1 \times 10^{-4}, 5 \times 10^{-4}, 1 \times 10^{-3}\}$, and number of epochs in $\{3, 4, 5\}$. We select the best settings for pruning experiments. We prune 20% of the adapters from the model at each pruning iteration, and use an early-stopping strategy with patience of 3 to speed up training, and we use the minimum validation loss for early-stopping criterion.

In the experiment of pruning Adapterfusion model, we set the learning rate to 5×10^{-5} and use AdamW optimizer as suggested by Pfeiffer et al. (2021). We run each task with 4 epochs and set the batch size to 32, and each model for each task with five different random seeds.

We have evaluated the single adapter with pruning, and Adapterfusion on GLUE datasets (Wang et al., 2018), which contain eight sentence or sentence-pair language understanding tasks.[1] And we treat MNLI $_{\text{mm}}$, MNLI $_{\text{m}}$ equally. We have reported the test results of the single task adapter through the GLUE submission website.[2]

3.2 LIAs in single task adapter

In order to analyse the influence of single task adapter at each layer, we run a test on the standard adapters and analyse the utilization of each of them.

In the evaluation step, we store the residual output and the output of each adapter to calculate the LIAs at each step. We then average LIAs of each adapter across the datasets. And we run the test from tasks with small datasets to large datasets, whose results are shown in Figure 3.

We have found that as the size of dataset gets bigger, LIAs of adapters also become larger, implying that the size of target task dataset affects the influence of the adapters. After training on larger datasets, adapters learn more and extract more knowledge, and thus become more essential for the whole model. This could explain why in Adapterfusion (Pfeiffer et al., 2021), using adapters from large datasets can help improve the performance of the task with small datasets.

For adapters in large dataset task (QQP[3], QNLI(Rajpurkar et al., 2016), MNLI(Williams et al., 2018)), most of them have large LIAs, suggesting they are already concise and there are no many redundant parameters in them.

3.3 Pruning single task adapter

We insert adapters of size 128 into each layer of transformers in the BERT-Based model. For different text classification task, we put a task-specific classifier at the end of the model. Only the parameters in the adapters and task-specific classifier are fine-tuned, and the rest of the parameters in the model are untouched.

We iteratively prune the parameters in the adapter by 20% per iteration. We perform 11 iterations for layer pruning since there will be less than one adapter left after the 11-th iteration.

Results on GLUE test sets are presented in Table 1. We select the best result in all iterations of pruning. The best model is chosen by metrics of the corresponding task. And we evaluate the result on GLUE testing sever. We can see there is a 0.2 percentage performance gap between the full fine-tuning model and the adapter model, and there is a small performance gap between the adapter model and the pruned adapter model. Therefore, we preserve most of the essential adapters while pruning the redundant ones.

We evaluate the adapter model on GLUE development datasets after each iteration of pruning and obtain the average score of three runs, see Figure 5. We discover that there is no major performance loss before the number of adapters drops below 9 (40%). By contrast, AdapterDrop model (Rücklé et al., 2020a) removed the first 5 layers of adapters and preserve most of the performance with about 60% of the adapters left. We thus can prune adapters 20% further than their work. The speed comparison between the two models is shown in Table 2. We discover that our model is faster than AdapterDrop in most tasks.

We further analyse how the adapters are distributed when there is only nine adapters left, see Figure 6. Interestingly, we can see that most of the adapters close to the output layer are pruned. These layers are removed but no harm is done to the performance, and we think that maybe the last few layers are just a redundant extension of classification layer.

We also find that there are more adapters after feed-forward layers than self-attention layers, implying that adapters after feed-forward layers are more valuable. Similar phenomena can be found in the experiments of ALBERT (Lan et al., 2020),

---

where most of the performance drop appears to come from sharing the feed-forward layer parameters, while sharing the attention layer parameters results in no performance loss.

Since different tasks require different number of adapters, in the following experiments, we use the best adapter model of all iterations of pruning in each task.

After using layer pruning with Lottery Ticket Hypothesis, the average influence of each adapter increases as shown in Figure 4. In most tasks, the LIAs increase after the pruning, which means the redundant part of the adapters are removed. And we can see a significant LIA boost, mostly in tasks of small datasets, especially in MRPC. However, in larger dataset task like MNLI, pruning the adapters causes a small decrease in LIAs, implying that most of the adapters for large datasets are playing an important role for the task. In summary, we have greatly increased the utilization of each adapter after pruning, because we deleted most of the less essential layers, and the model is thus streamlined to perform better.

3.4 Merging pruned adapters to Adapterfusion

In this experiment, we fuse eight single task adapters to construct the Adapterfusion model. An extra self-attention layer is inserted in each layer of the model to fuse the results of multiple adapters. Only the parameters in these newly inserted self-attention layers are fine-tuned, and the rest of the parameters (including adapters) remains unchanged.

We run our test on the same eight tasks of GLUE datasets as in the previous experiment. We compare the fusion of full-size adapters and the pruned adapters with 5 runs each. We use the best adapter model of all iterations of pruning for the fusion. Then, we calculate the mean and variance of each task, whose results are in Table 3. It shows that there is not much difference between the pruned Adapterfusion model and the full-size Adapterfusion model. And there is even a mild improvement of performance using the pruned one. Therefore, it justifies that the proposed pruning of adapters is very effective and we can obtain a small and dense version of the general Adapterfusion model for GLUE datasets.

	AF	AF w. LTH
CoLA	55.16 ±1.1	**55.96** ±2.3
SST-2	91.67±0.7	**91.87**±0.4
MRPC	91.46 ±1.6	**92.16** ±1.5
STSB	**89.83**±0.33	89.27±0.64
QQP	86.74±0.39	**86.88**±0.22
MNLI	83.13±0.42	**83.16**±0.18
QNLI	**90.84**±0.21	90.73±0.33
RTE	**75.90**±3.43	73.00±6.68

Table 3: Development score of Adapterfusion and Adapterfusion pruned with Lottery Ticket Hypothesis (LTH). CoLA is evaluated using Matthew's Correlation. STS-B is evaluated using Spearman's correlation coefficient. MRPC and QQP are evaluated using F1 score. The rest of the tasks are evaluated by accuracy.

The original Adapterfusion model has 192 adapters ($8tasks \times 12layer \times 2adapter/layer$), while after pruning the redundant adapters from the model, it only has 89, with more than half of the adapters removed. For layers left without adapters, there isn't a self-attention layer insertion for fusion, resulting in the reduction of depth as well.

We also have measured the total number of floating point operations (FLOPs) for each task in the evaluation process. We average the FLOPs across different tasks, as shown in Table 4 and Table 5. And it reveals that after pruning, we reduce the computation by about 40%, which is a very significant improvement for the inference speed.

To better analyse the training and inference speed, we use the basic fine-tuning model as the base model and calculate the relative speed of dif-

	Num of adapter	FLOPs (10^9)	Steps/sec
AF	192	554.8	9.86
AF-LTH	**89**	**332.8**	**13.86**

Table 4: FLOPs of the standard Adapterfusion and pruned Adapterfusion

	AF	AF-LTH	Saved (%)
RTE	1157.9	703.1	39.23%
MRPC	934.9	565.6	39.50%
STSB	805.9	487.4	39.52%
COLA	221.3	133.6	39.62%
SST2	513.2	310.1	39.57%
QNLI	248.4	150.3	39.49%
QQP	356.1	215.3	39.53%
MNLI	432.2	261.4	39.51%

Table 5: Floating points (10^9) operation of standard Adapterfusion and pruned Adapterfusion in each tasks

ferent models including single task adapter model, Adapterfusion model and pruned Adapterfusion model. We use one NVIDIA RTX 3090 with a batch size of 16 to test the models and results are shown in Table 6. We can see that fusing 8 adapters slow down the model both in training and inference. However, using pruning the model can reduce the effect of slowing down to a certain level.

	Adapter	AF	AF-LTH
Train	0.93	0.52	0.79
Eval	0.63	0.12	0.18

Table 6: The average relative training speed and inference speed of Adapter, Adapterfusion and pruned Adapterfusion

Moreover, we analyse the LIAs of each adapter for different target tasks. LIAs of the original Adapterfusion and the pruned Adapterfusion are shown in 3D heat map in Figure 7[4], where X-axis represents eight different target tasks for the model, y-axis is the source of each fused adapters, z-axis denotes the adapters in different layers ranging from 1 to 24, the odd number layers in z-axis represent the adapter modules inserted after attention layers, and the even number layers in z-axis are the ones inserted after the output layer.

Figure 7(a) shows the LIAs of the original Adapterfusion model. We discover that there are a number of adapters not utilized in the original Adapterfusion model and most of the essential adapters are at the back of the cube which are the adapters trained on large datasets. As the layers get deeper, more adapters in the model are utilized. Figure 7(b) shows the LIAs of the pruned Adapterfusion model. Compared to the original Adapterfusion model, the pruned Adapterfusion model has much fewer adapters. Furthermore, most of the adapter modules have larger LIA values, which implies that most of the adapters become more important for the task.

Then, we average the LIAs of adapters in Adapterfusion across 12 layers and 5 test runs, as shown in Figure 8. We find that for the original Adapterfusion model, most of the adapters' LIAs are zeros, which means that most of them are not used in the model. And most of the tasks use the adapters trained in QQP and MNLI, both of which are tasks with large datasets. Moreover, with a larger dataset, the model will utilize more of the adapters trained from the same task.

By comparing the original Adapterfusion and the pruned Adapterfusion model, we have seen that more of the adapters are utilized after the pruning. And there are fewer zeros of LIAs in the pruned Adapterfusion model, suggesting that remaining adapters after pruning have become much more influential on average and the model are using more adapters from different tasks.

4 Related work

Pre-trained language model Language models pre-trained on large corpora are widely used in multiple NLP tasks to improve performance. However, these models are often very large. Recently, Transformer-based (Vaswani et al., 2017) models have become the most popular pre-trained language models. There are plenty of model variants, such as BERT (Devlin et al., 2019a), GPT-3 (Brown et al., 2020), XLNET (Yang et al., 2019), and Roberta (Liu et al., 2019), etc. Transformer models are huge models, ranging from 110M parameters in BERT-Base to trillions (Fedus et al., 2021; Lepikhin et al., 2020) in the largest, best-performing models. Due to the resource constraints in GPU/TPU memory and computational power, it is difficult to run a large model. So Lan et al. (2020) propose an approach to reduce the amount of training parameters by sharing weights among all transformer layers. The model named ALBERT can lower the usage of memory and speed up the training process of BERT. By contrast, ALBERT reduces the amount of parameters needed to be trained, while adapters introduce new parameters and deepen the model.

Figure 8: LIAs of Adapterfusion w/o pruning

Adapters and fine-tuning Since fine-tuning approaches have proven to have better performance than feature-based approaches (Peters et al., 2019), researchers often prefer fine-tuning approaches to feature-based ones. Most of the state-of-the-art results of NLP tasks are achieved by fine-tuning a complex pre-trained model. Fine-tuning does not require a task-specific design beforehand, which is more general across tasks than feature-based ones. However, every time a model is fine-tuned on a new task, a new set of parameters are created and trained, leading to pretty low degree of parameter sharing among tasks.

Adapter model is a lightweight fine-tuning approach introduced by Houlsby et al. (2019). They insert a small set of newly initialized neural networks named adapters in each layer of the transformers. At training step, only parameters of adapters will be updated and the parameters in the pre-trained language model will be unchanged. Therefore it reduces the number of parameters to be trained in the training phase and enables efficient parameter sharing between tasks by combining many task-specific or language-specific adapters.

Merging and pruning adapters Adapters have achieved great results in multi-task (Pfeiffer et al., 2021), cross-lingual transfer learning (Pfeiffer et al., 2020) and infusing knowledge (Wang et al., 2021). Adapters are capable of extracting knowledge from different tasks that can be applied to fuse knowledge they learned from different tasks (Rücklé et al., 2020b; Pfeiffer et al., 2020; Wang et al., 2021). There are plenty of ways to merge multiple adapters, including stacking (Pfeiffer et al., 2020), fusing and concatenating adapters (Pfeiffer et al., 2021). However, adapters are still far from being concise, and merging multiple adapters from different tasks will introduce redundancies and slow down the inference speed of the model. Therefore, Rücklé et al. (2020a) have firstly introduced a way to remove adapters from lower transformer layers. By removing the first few layers of the adapters, it effectively speeds up the training and inference of the adapter models.

Neural networks are easily overparameterized and carry plenty of redundancies. To tackle this problem, distillation (Ba and Caruana, 2014; Hinton et al., 2015) and pruning (LeCun et al., 1990; Han et al., 2015) are introduced to streamline the model while perserving good performance. And there are several research directions in this field. For pruning before training, MobileNets (Howard et al., 2017) is designed for image-recognition networks. For pruning after training, LeCun et al. (1990) use the second derivatives to truncate the neural networks. For pruning during training, Bellec et al. (2018) reinitialize weights near zeros with random number after training the model. Moreover, we can prune models based on activations (Hu et al., 2016), filters (Li et al., 2017; Molchanov et al., 2017) or channels (He et al., 2017).

The most influential theory recently for pruning comes from Frankle and Carbin (2019), in which they prove that a dense neural network contains subnetworks (winning ticket) that can have the same performance as the original network when trained isolated. Their experiments reveal that not only the structure of the pruned networks matters but also the initial weights of these networks can affect the performance of the model. They also find that a subnetwork extracted from pruning learns faster than the original model and even reaches higher test accuracy. Our pruning approach is inspired by this theory and can prune the original Adapterfusion model to a much more concise one.

5 Conclusion and future work

In this paper, we propose a new approach to model the utilization of the adapters at each layer by defining a new indicator LIA (Layer Influence Of Adapter) with which we can identify the most influential adapters. Moreover, we introduce a novel way of pruning adapter modules inspired by the prestigious Lottery Ticket Hypothesis. The proposed pruning strategy has been extensively evaluated on the GLUE datasets, whose results show that we can prune adapters up to 40% of its original size while keeping the performance intact. We further examine the performance and LIAs of the pruned adapters in the latest state-of-the-art Adapterfusion model, and we can remove more than half of the adapters and reduce computation of the Adapterfusion model by nearly 40% with little performance loss.

This work can be further extended in many ways. For instance, iterative pruning is time-consuming. Running 10 iterations of pruning also means training the model for almost 10 times. We can try to find the redundant adapters before and after the training by introducing new elaborate measurements.

A Detail Results: AdapterFusion model LIA

We calculate the LIA of each adapters in the Adapterfusion model. In order to have a better insight of the model, we gradually remove adapters with small LIA from the 3D heatmap, see Figure 9. In standard adapters modules, we discover that there are a number of adapters not utilized in the original Aadapterfusion model and most of the essential adapters are at the back of the cube which are the adapters trained on large datasets. In pruned Adapterfusion model, most of the adapters are essential and most of the adapters become more important for the task.

Figure 10 and Figure 11 shows the LIAs of each adapters in Adapterfusion model in each tasks which is cross-section of the cube. We find that in tasks with small datasets, the model uses adapters from different tasks, while in tasks with large datasets, the model mainly uses the adapter trained from the same task (e.g. QNLI, QQP and MNLI). However, after pruning the Adaterfusion model, it uses adapters trained on different tasks even when the target task is the one with a large dataset.

B Detail of Pruning Adapters

The single task adapter model contains 24 adapter modules. There are 12 layer of transformers block in Bert-base. Each layer with 2 adapter modules. We prune 20% of the adapters for each iteration of pruning.

For a better understanding of the pruning algorithm 1. We summarized the proposed pruning strategy and demonstrate the inner structure of adapter in Figure 12.

Abstract

Knowledge-based authentication is crucial for task-oriented spoken dialogue systems that offer personalised and privacy-focused services. Such systems should be able to *enrol* (E), *verify* (V), and *identify* (I) new and recurring users based on their personal information, e.g. postcode, name, and date of birth. In this work, we formalise the three authentication tasks and their evaluation protocols, and we present *EVI*, a challenging spoken multilingual dataset with 5,506 dialogues in English, Polish, and French. Our proposed models set the first competitive benchmarks, explore the challenges of multilingual natural language processing of spoken dialogue, and set directions for future research.

1 Introduction

Computer systems need to be able to identify and verify their users before granting access to personalised services and confidential information (Braz and Robert, 2006; O'Gorman, 2003). In particular, **identification (I)** is the process of specifying the identity of a person, i.e. answer the question: *"who are you?"*. On the other hand, **verification (V)** (aka authentication) is the process of confirming the assertion about a claimed identity, i.e. answer *"are you who you claim you are?"* (Jain et al., 2004). In both processes, the system compares information given by the user with information held by the system; thus they presume **enrolment (E)**, that is, the process of registering the identity information of a new user into the system (Jain et al., 2004).

Task-oriented dialogue systems that offer personalised and privacy-focused services (e.g. set up utilities, track a parcel, or access a bank account) should be able to enrol, identify, and verify new and recurring users, without interrupting their natural conversational interface. Different types of authentication factors may be used (Smith, 2001; O'Gorman, 2003): i) knowledge-based ("*what you know*"), rely on a secret *password* or personal information, e.g. full name, date of birth, mother's maiden name, etc.; ii) possession-based ("*what you have*"), rely on possession of a physical *token*, e.g. a smart card, a metal key, etc.; and iii) inherence-based ("*who you are*"), typically rely on *biometric* properties, e.g., a voiceprint, fingerprint, eye scan, or signature (Variani et al., 2014). Most businesses use knowledge-based authentication in their call centres to identify customers over the phone (Hrabí, 2020; Amein, 2020; Morgen, 2012; Petersen, 2019). As conversational AI is increasingly being used to automate call centres, we seek to enable task-oriented spoken dialogue systems with EVI functionalities.

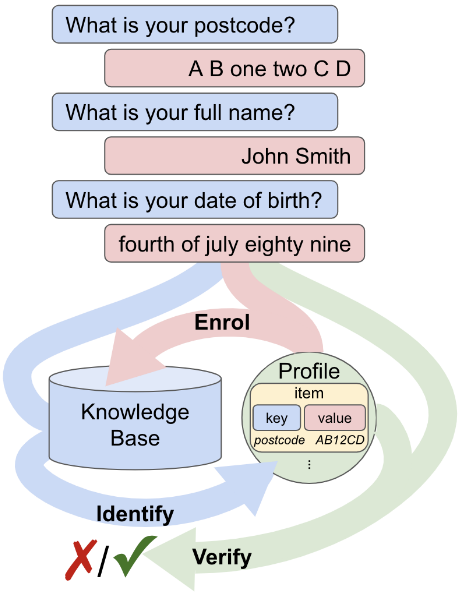

Figure 1: Knowledge-based EVI for task-oriented spoken dialogue systems: enrolment (E) creates a new user profile to store in a KB; identification (I) retrieves a pre-enrolled profile for a user; and verification (V) asserts whether the user matches a claimed profile.

The core **contributions** of this paper are:

1. We motivate and formalise knowledge-based enrolment, verification, and identification as **novel tasks** for task-oriented spoken dialogue systems (Section 2).

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1647 - 1659
July 10-15, 2022 ©2022 Association for Computational Linguistics

2. We collect and publish a **novel conversational dataset** with 5,506 dialogues that can be used to develop and evaluate EVI-oriented spoken dialogue systems in 3 languages (British English, Polish, and French; Section 3). The multilingual aspect of the dataset allows us to also study language-specific variations in data and performance, reaching beyond monolingual, English-only setups.
3. We define baseline models and suitable evaluation protocols (Section 4) for the new tasks. Finally, we evaluate **benchmarks** on the new dataset, explore the unique challenges of these tasks, and set directions for future research (Section 5).

The code and dataset is available online at: https://github.com/PolyAI-LDN/evi-paper.

2 The EVI Dialogue Tasks

Preliminaries. For all tasks, we assume that the dialogue system can interact with a *Knowledge Base (KB)* of stored profiles, $P_{KB} = \{p_1, p_2, ...\}$. Each *profile*, p, is a structured record of a real-world entity (e.g. a user, product, etc.) that comprises one or more *items*, i.e. key-value pairs (e.g. postcode, name, date of birth, etc.). The user and system take alternate turns, t, that make up a multi-turn *dialogue*, $T_{dialogue} = \{t_{1,system}, t_{1,user}, t_{2,system}, t_{2,user}, \dots\}$.

Enrolment Task. The goal of enrolment is to create and store a profile that represents the identity of a *new user* and that can be used to identify or verify the same user in the future. For dialogue-based enrolment, the system must be able to extract all required item key-value pairs from the dialogue to construct a new profile to store in the KB (cf. Fig. 1):

$$p_{new} = \text{enrol}(T_{dialogue}) \tag{1}$$

Verification Task. The goal of verification is to decide whether a user who claims an identity is *genuine* or an *impostor*. For dialogue-based, knowledge-based verification, the system must be able to compare information stored in the KB about the claimed identity with information provided by the user in the dialogue to produce a verification *score* that quantifies the degree of the match (cf. Fig. 1):

$$s_{profile} = \text{verify}(p_{claimed}, T_{dialogue}) \in [0,1], \tag{2}$$

where $s = 1$ signifies a genuine verification attempt, and $s = 0$ denotes an impostor verification attempt. The system designer can apply a threshold, θ, to obtain a crisp verification outcome and control the system's trade-off between security and usability (see later Subsections 4.3 and 4.5).

Identification Task. The goal of identification is to determine the identity of an unknown user from a KB of pre-enrolled user profiles. For dialogue-based, knowledge-base identification, the system must be able to query the KB with the information provided by the user in the dialogue to retrieve a ranked list of the best matching profiles (cf. Fig. 1):

$$p_1, p_2, \dots = \text{identify}(P_{KB}, T_{dialogue}) \tag{3}$$

The list might be empty if no qualifying profiles (i.e. above a score threshold) could be retrieved.

3 A Multilingual Spoken Dialogue Dataset

We set out to build a novel, first of its kind, human-to-machine conversational dataset that can be used to develop and evaluate task-oriented spoken dialogue systems that support the functionality of the knowledge-based EVI tasks. The dataset is multilingual and covers 3 locales: British English (en-GB), French (fr-FR), and Polish (pl-PL).[1]

3.1 Generating the Profiles Knowledge Base

For each locale, we populate a KB to be shared across EVI tasks. We randomly generated locale-dependent profiles using the *faker* tool.[2] Each profile in the KB consists of its generated item key-value pairs for *postcode*, *full name*, and *date of birth* (cf. Fig. 1). These three different slots are popular in industrial authentication procedures. Because in the real world people might share the same name, postcode, or date of birth by coincidence, we allow duplicate values in our generated data, e.g. for each locale our KB contains 10,000 unique profiles, but only 2,000 unique postcodes. Table 1 shows the size of the generated KB.

3.2 Collecting the Dialogue Data

We developed a **spoken dialogue system** to collect the postcode, full name, and date of birth of a user over the phone. The system operates under a deterministic policy with static retries for each collection step. We use the same sequence of dialogue acts

---

[1] The choice of these languages was motivated by the popularity, the phonetic richness and a large enough base of high-quality crowdworkers.

[2] https://faker.readthedocs.io/; it is a python package that can generate fake but reasonable data (names, addresses, phone numbers, etc.) for bootstrapping databases.

for all EVI tasks, and vary the scripted prompts (see Subsection 3.3) to elicit more diverse responses:

Q1: What is your postcode?
Q2: Please tell me your postcode.
Q3: I heard [A B 1]. Please tell me your postcode.
Q4: What is your full name?
Q5: Please tell me your first and last name.
Q6: Please spell your full name.
Q7: What is your date of birth?
Q8: Please tell me your date of birth.
Q9: I heard [the 1st of January]. Please tell me your date of birth.

For other locales, see Appendix A. For each locale, we enlisted cohorts of speakers on the *Prolific Academic* (www.prolific.co) crowdsourcing platform. We displayed a random profile from the KB for each speaker to impersonate, e.g.:

Postcode: *AB1 2CD*
Full Name: *John Smith*
Date of Birth: *4/7/1989*

Kod Pocztowy: *12-345*
Imię i Nazwisko: *Anna Krupa*
Data urodzenia: *1/1/2000*

Then, we directed speakers to call a phone number to interact with our spoken dialogue system. To ensure quality, the crowdsourced speakers had to complete all turns of the static policy to receive their payment code.[3] Additionally, we filtered out all dialogues for which text-to-speech detected silence for all turns of a single item or for more than half of the turns of the dialogue.

For each turn, the EVI conversational dataset contains: the unique identifier of the impersonated profile from the KB; a unique speaker identifier; the raw audio data; the n-best list of transcriptions (see Appendix B); and any variation in the prompts (see Subsection 3.3). Table 1 shows the size of our dialogue dataset for all locales, which contains 5,506 dialogues in total.

3.3 Diversifying Speaker Behaviours

To elicit mode diverse behaviours from the speakers, and thus increase the generality and richness of our dataset, we exploited two psychological phenomena: priming and entrainment.

Priming is the psychological effect wherein exposure to a stimulus (*prime*) unconsciously influences the response to a later stimulus (*target*). Priming also affects linguistic decision making, e.g. exposure to a lexical item or syntactic structure reinforces reuse of the same pattern in the future (Reitter et al., 2006, 2010). Likewise, *entrainment* is the phenomenon wherein conversational interlocutors adopt each other's linguistic patterns. Entrainment can be observed at multiple levels, e.g. lexical (Brennan and Clark, 1996), syntactic (Reitter and Moore, 2007), stylistic (Niederhoffer and Pennebaker, 2002), phonetic (Pardo, 2006), and prosodic (Coulston et al., 2002). The Interactive Alignment Model (Pickering and Garrod, 2004) proposes that conversational interlocutors automatically prime each other at multiple levels, causing their speech to converge.[4]

Diversifying Spoken Dates. Our primes to diversify the speakers' lexical choice for dates were the formats that we used to lexicalise and display the dates of birth to the crowdsourced speakers. We used either of two formats at equal proportions:

(*a*) **month=name**: *1 January|stycznia|janvier 2000*
(*b*) **month=number**: *1/1/2000*

The Sankey diagram[5] in Figure 2 (top) shows that 92% of English speakers primed with the *month=name* format echoed this pattern in Q_7, and only 10% of those switched to say the month's number in follow-up turns (similar results for pl-PL and fr-FR; see Appendix C for their Sankey diagrams). On the other hand, only 54% of English speakers (cf. 26% for pl-PL, 36% for fr-FR; Appendix C) primed with the *month=number* format echoed that pattern in Q_7, and 77% of those switched to say the month's name later. Overall, the *month=name* format (more lexical) had a stronger priming effect than the *month=number* format (more symbolic), and speakers say the month's name (more verbose) increasingly after reprompts (Q_8 and Q_9).

Diversifying Spoken Spellings. Our primes to diversify the speakers' spelling choices were the agent reprompts in the Q_3 that read back partial spellings of postcodes to the speaker. We used either of two strategies at equal proportion:

(*a*) **spell=naive**: *A B one two C D*
(*b*) **spell=nato**:[6] *Alfa Bravo one two Charlie Delta*

---

[3] The workers were not aware that the system was scripted, yielding the natural behaviour of irritated customers.

[4] Alternatively, Communication Accommodation Theory (Giles et al., 1991) proposes that more strategic decisions drive convergence (or divergence).

[5] Sankey diagrams visualise the flow or route of communication (or other quantity) within a system to help locate the most important contributions to a flow. The width of the links between nodes is proportional to the flow rate between them.

		Locale		
	counts (unique)	en-GB	pl-PL	fr-FR
KB	#profiles	10,000	10,000	10,000
	#postcodes	2,000	2,000	2,000
	#names(first)	364	153	216
	#names(last)	500	3,455	400
	#names(full)	9,412	9,923	9,433
	#DoBs	8,884	8,862	8,862
Dialogues	#dialogues	1,407	1,991	2,108
	#turns	12,663	17,919	18,972
	#speakers	1,081	803	521
	#profiles	886	961	1,464

Table 1: Size of the created EVI Knowledge Bases and the collected Conversational Dataset.

These strategies acted as primes that *entrained* the speaker concerning their spelling strategy.

Figure 2 (bottom) shows that only 1% of en-GB speakers spontaneously used NATO spelling before/without encountering the *spell=nato* strategy in Q_3. Conversely, using the *spell=nato* strategy entrained 52% of speakers to adopt that strategy in their response to Q_3. Entrainment weakens over time: only 28% of entrained speakers remained entrained by Q_6. Postcodes do not contain letters in the pl-PL and fr-FR locales, so both spelling strategies are equivalent. Only 0.5% of pl-PL and 0.1% of fr-FR speakers spontaneously used complex spelling strategies (listed in Appendix D).

In conclusion, we validated that priming and entrainment are effective tools to subtly guide speaker behaviour towards desired patterns. It is by varying those primes that we could increase the variability of speaker behaviours in our dataset.

4 EVI-oriented Spoken Dialogue Systems

This section presents the components of task-oriented spoken dialogue systems for EVI tasks and provides benchmark implementations for the upcoming experiments (see Sections 5.1, 5.2, and 5.3)

4.1 Components of EVI Dialogue Systems

Automatic Speech Recognition (ASR). When collecting the EVI dataset, we used Google's locale-specific speech-to-text[7] in streaming mode to derive n-best transcriptions and to implement quality control (see Subsection 3.2). Consequently, this is the ASR used in all experiments. The length of the n-best lists was on average 4.85, 2.60, and 8.65 for English, Polish, and French, respectively (see Appendix B) and was capped at a maximum of 20 items.

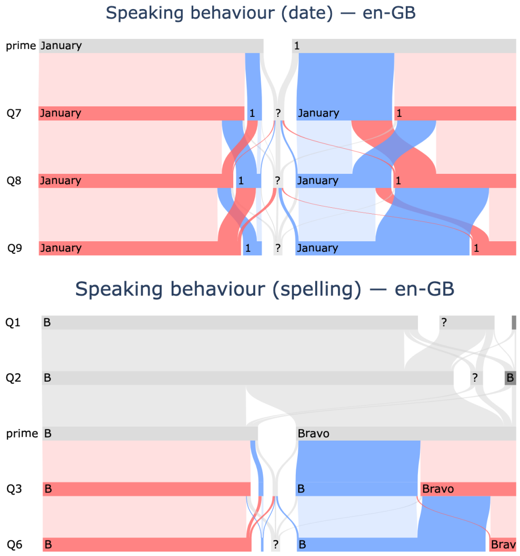

Figure 2: Sankey diagrams that visualise priming and entrainment of speaker behaviour for dates (*top*) and spelling (*bottom*) for the British English locale. Transitions in the direction of priming in red; against, in blue.

Natural Language Understanding (NLU). For each item, we use an appropriate resource to extract values from the whole ASR n-best list into an NLU results n-best list. In our experiments, we first preprocess to normalise numbers ('one'→'1') and letter spellings ('Bravo|[B for B.*]'→'B'), and then extract values for postcodes using locale-dependent regular expressions ('A(A)9(A) 9AA' for en-GB; '99999' for pl-PL and fr-FR); for names, the lists of names from the US Census[8] and other sources (Remy, 2021); and for dates, the *dateparser* package.[9] Using these resources, we define two NLU models for value extraction: the `cautious` model requires whole-string match, whereas the `seeking` model searches for (potentially overlapping) substring matches.

Top-Level Policy. All EVI tasks share a common sequence of *dialogue acts* (DAs): the agent asks (`request` DA) the user to input the value (`inform` DA) of each profile item successively, with a limited number of re-prompts per item. In the experiments, the order of items is: postcode,

---

[6] The NATO phonetic alphabet substitutes a word for each letter to be easily understood in voice communications; https://www.nato.int/cps/en/natohq/declassified_136216.htm

[8] https://www.census.gov/topics/population/genealogy/data/1990_census/1990_census_namefiles.html

[9] https://dateparser.readthedocs.io/ it is a python package that can parse localised dates in any string format

full name, and date of birth, with up to 3 attempts per item (fixed at the time of dataset collection; see Subsection 3.2).

Task-Level Dialogue Management. Each of the three tasks requires task-specific *dialogue state tracking* (DST) and *dialogue policy*. The DST model tracks and updates the system's state and belief about the values of items and the candidate profiles, whereas dialogue policy selects the following system action (e.g. re-prompt user, proceed to next item, terminate task) and interacts with the profiles KB. We define the task-specific DST models and policies in more detail in Subsections 4.2, 4.3, and 4.4.

Integration with the Profiles KB. For enrolment, the system needs write access to the KB to store the extracted profile; for identification, the system needs read access to the KB to retrieve candidate profiles via a dynamic sequence of queries; and for verification, the claimed profile in the KB is previously made available from an upstream identification process (cf. Fig. 1). In the experiments, we do not explicitly model KB integration for enrolment (write-only access) and verification (downstream of identification); for identification, we model a read-only KB integration that supports querying *by postcode* (exact match) and an `oracle` that always includes the postcode of the correct profile in the query, regardless of the NLU results.

Natural Language Generation (NLG). When collecting the dataset, we used *scripted* prompts (Subsection 3.2) translated for each locale (Appendix A).

Text-to-Speech (TTS). We used Google's[10] locale-specific TTS when collecting the EVI dataset.

4.2 Enrolment Models and Policies

Enrolment DST and Model. We track the value of each item, which is initially *undefined*. After each user input for an item, we may use the NLU n-best results to update its value. When the enrolment policy terminates, the enrolment model straightforwardly builds the new profile from the tracked items. In the experiments, we update an item's value with its latest *top-1* result of the NLU (if not empty).

Enrolment Policy. The task-level policy determines when to proceed to the next item, and decides when to terminate enrolment. The policy (re)prompts the user about an item until either the DST returns a well-defined value or the top-level policy reaches the limit for attempts (3; see Subsection 4.1). After exhausting all items, the policy terminates and writes the new profile into the KB.

4.3 Verification Models and Policies

Verification DST and Model. We track a verification score for each item s_{item} as follows (cf. Eq. 2):

$$s_{item} = \textbf{score}(\mathrm{item}(p_{claimed}), \mathrm{item}(T_{dialogue})) \in [0,1], \qquad (4)$$

The scores are initially undefined, and we track their maximum evaluation after each user input. For the experiments, we define the following scoring models: the `random` model samples from the $[0,1]$ uniform distribution; the `exact` model returns 1 if the value from the claimed profile exactly matches any NLU n-best result, else, 0 (*undefined* for no NLU results); and the `fuzzy` model returns the best *fuzzy match* score between the value from the claimed profile and all NLU n-best results (*undefined* for no NLU results). We implement this as the normalised Levenshtein edit distance using the Wagner–Fischer algorithm (Wagner and Fischer, 1974). Finally, we evaluate a logical expression under *fuzzy logic* to combine all item-level scores (Eq. 4) into a profile-level score as follows (see Eq. 2):

$$\begin{gathered} s_{profile} = s_{postcode} \text{ AND } s_{dob} \text{ AND} \\ (s_{name\_full} \text{ OR} (s_{name\_first} \text{ AND } s_{name\_last})) \end{gathered} \qquad (5)$$

Fuzzy logic (Zadeh, 1996) is a many-valued logic wherein truth values are real numbers in $[0,1]$ that represent degrees of truthfulness and reasons using fuzzy logic operators (analogous to Boolean logic's AND, OR, and NOT). In the experiments, we choose the standard fuzzy logic operators (Zadeh, 1996):

$$\begin{gathered} \textbf{Boolean} \longleftrightarrow \textbf{Fuzzy} \\ \mathrm{AND}(x,y) \longleftrightarrow \min(x,y) \\ \mathrm{OR}(x,y) \longleftrightarrow \max(x,y) \\ \mathrm{NOT}(x) \longleftrightarrow 1-x \end{gathered} \qquad (6)$$

Verification Policy. The task-level policy determines when to proceed to the next item, and decides when to terminate the verification process. The policy (re)prompts the user about an item until either the DST returns a well-defined score (Eq. 4) or the top-level policy reaches the limit for attempts (again, 3). The policy terminates either after exhausting all items or when it meets an *early termination* criterion: a low upper bound on the profile score (i.e. Eq. 5 with *undefined* $\equiv 1$ is below the verification threshold, θ) guarantees a negative verification outcome. Upon termination, the policy returns the profile-level verification score (Eq. 5 with *undefined* $\equiv 0$).

---

Table 2: Results for enrolment task: Precision (P), Recall (R), F1 score, and average number of turns (L) for exact match of the whole profile and each of its items (postcode, full name, and date of birth (DoB)).

4.4 Identification Models and Policies

Identification DST and Model. We track the NLU n-best results from all turns and the candidate profiles retrieved from the KB. Our identification process is an *anytime* algorithm (Zilberstein, 1996) that ranks the thus-far retrieved profiles by a score (Eq. 5), excluding profiles below an identification threshold, θ. Following the literature on *fuzzy retrieval* (Zadrożny and Nowacka, 2009), instead of the standard fuzzy operators (Eq. 6), we use `p-norm` fuzzy operators (Salton et al., 1983):[11]

$$\begin{aligned}\mathrm{AND}^p(s_1,\ldots,s_n) &= 1-\left(\frac{1}{n}\sum_{i=1}^{n}|1-s_i|^p\right)^{1/p} \\ \mathrm{OR}^p(s_1,\ldots,s_n) &= \left(\frac{1}{n}\sum_{i=1}^{n}|s_i|^p\right)^{1/p}\end{aligned} \tag{7}$$

In the experiments, we approximate Eq. 7 by the *infinity-one* linear combination (Smith, 1990):

$$\begin{aligned}\mathrm{OR}_\alpha &= \alpha\mathrm{OR}^\infty + (1-\alpha)\mathrm{OR}^1 \\ &= \alpha\max + (1-\alpha)\mathrm{mean} \\ \mathrm{AND}_\alpha &= \alpha\mathrm{AND}^\infty + (1-\alpha)\mathrm{AND}^1 \\ &= \alpha\min + (1-\alpha)\mathrm{mean}\end{aligned} \tag{8}$$

Note that $\mathrm{AND}_1 = \mathrm{AND}^\infty = \min$ and $\mathrm{OR}_1 = \mathrm{OR}^\infty = \max$ are the standard fuzzy operators (Eq. 6). Finally, an identification `oracle` always retrieves the correct profile if it is among the tracked candidates (i.e. retrieved from the KB).

	Turns (Subsection 3.2)	Postcode P%	Postcode R%	Postcode F1%	Name P%	Name R%	Name F1%	DoB P%	DoB R%	DoB F1%

	multi (Q_{1-9})	77.62	**72.09**	**74.75**	44.21	**44.00**	**44.10**	90.81	**86.81**	**88.76**

Table 3: Results for single- vs multi-turn value extraction with `cautious` NLU: Precision (P), Recall (R), F1 score per item (postcode, full name, and date of birth).

Identification Policy. The task-level policy queries the KB to retrieve candidate profiles (see Subsection 4.1), determines when to proceed to the next item, and decides when to terminate the identification process. The policy queries the KB with the NLU n-best results, and sends the retrieved profiles to the DST. Similarly to verification, the policy (re)prompts the user about an item until either the DST returns a well-defined score (Eq. 4) or the top-level policy reaches the limit for attempts (again, 3). The policy terminates after having exhausted all items, or when the anytime result of identification is an empty list and the KB cannot be queried by any upcoming item. Upon termination, the policy returns the ranked list of identified profiles.

4.5 Evaluating the EVI Tasks

Evaluating Enrolment. Suitable evaluation metrics come from the area of information extraction: *precision* (P), *recall* (R), and *F1* score, at the profile level or per item.[12]

Evaluating Verification. The relevant literature describes two basic metrics (El-Abed et al., 2012): *False Rejection Rate* (FRR) is the proportion of genuine users that the system incorrectly rejects as impostors; conversely, *False Acceptance Rate* (FAR) is the proportion of impostors that the system incorrectly accepts as genuine. Lower FRR indicates more usable systems, and lower FAR, more secure, e.g. FRR = 1% at FAR = 1/10 000 means that 1% of genuine users will fail verification at the security level that falsely accepts 1 impostor per 10,000 impostor attempts. *Equal Error Rate*

---

[11] The expression is based on the L^p-norm, $||x||_p := \left(\sum_{i=1}^{n}|x_i|^p\right)^{1/p}$, and is related to the generalised (aka power or Hölder) means (Bullen, 2013).

[12] Enrolment outputs (new profiles) are stored in the KB and fed into I&V downstream tasks (Fig. 1); evaluating interactions among tasks is outside the scope of this paper.

Table 4: Results of verification task: Equal Error Rate (EER), False Rejection Rate (FRR) @FAR = 1/10,000, and average number of turns (L; in parentheses: with early termination @FAR = 1/10,000).

(EER) is the error rate when FAR = FRR; it is a popular evaluation metric when a security level is not a priori specified. Finally, the *Detection Error Trade-off* (DET) graph plots FRR (y-axis) against FAR (x-axis) for varying values of the verification threshold (θ) to visualise usability across a range of security levels (Martin et al., 1997).

Evaluating Identification. We rely on the *identification rate at rank r* (IR@r) (El-Abed et al., 2012): the proportion of identification transactions by pre-enrolled users in which the correct profile is among the top-r retrieved by the system. It is equivalent to the familiar *recall at rank* metric from information retrieval (Manning et al., 2008).

5 Experiments and Results

This section evaluates benchmarks and empirically explores the unique challenges of each EVI task.

Experimental Setup. For all experiments, we deterministically simulate ground truths and user inputs from our EVI KB and dataset, respectively (see Subections 3.1 and 3.2). The implementations of ASR, top-level policy, NLG, and TTS were set at the time of data collection and are common for all EVI tasks (see Subsection 4.1). Subsection 4.5 describes the evaluation metrics for each task.

5.1 Enrolment Experiments

We evaluate the enrolment policy with `cautious` or `seeking` NLU (see Subsection 4.1).

Results. Table 2 shows the impact of NLU on enrolment task accuracy (i.e. precision, recall, F1), for the whole profile and per item, and the average dialogue length. For whole profiles and almost all items, `cautious` NLU, which is more conservative and extracts fewer values, yields better accuracy than `seeking` NLU, which is more liberal and over-extracts values. Notably, extraction of French names and English postcodes (alphanumeric) was less accurate than for other locales (digit-only postcodes).

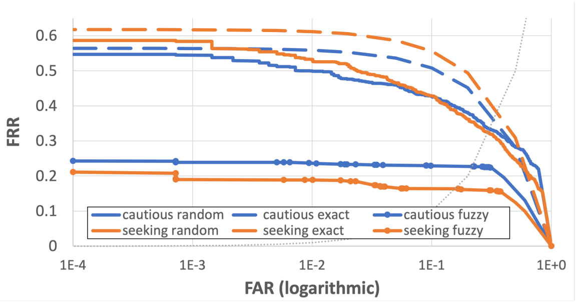

Figure 3: Detection Error Trade-off (DET) curves for the en-GB locale. A curve that is closer to the bottom of the plot corresponds to better verification performance.

Further Analysis. Table 3 shows per item the accuracy (i.e. precision, recall, F1) of single- and multi-turn value extraction with the `cautious` model. Consistently, recall with multi-turn extraction is higher than single-turn recall of any individual turn. Conversely, individual single-turns yield the highest precisions. Across locales, the relevant precisions of turns is retained for postcodes ($Q_3 > Q_2 > Q_1$) and names ($Q_4 > Q_5 > Q_6$) (cf. Section 3.2). In particular, extraction of name spellings (Q_6) is distinctly poor; this barely affects multi-turn performance, because, on average, the system collects names before Q_6 (Table 2).

5.2 Verification Experiments

We evaluate the verification policy with `cautious` or `seeking` NLU and `random`, `exact`, or `fuzzy` verification (Subsection 4.3) on the EVI dataset and KB (Section 3), from which we sample genuine and impostor profiles at a 1 : 1 ratio.

Results. Table 4 shows the impact of NLU and verification models on the equal error rate (EER), the FRR at the FAR = 1/10 000 security level and length. Consistently, `seeking` NLU with `fuzzy` verification yields the best EER and FRR. Interestingly, `exact` verification fails to improve reliably over the `random` baseline. Finally, early termination shortens verification length by 25-30%.

Further Analysis. Figure 3 shows the DET curves for the en-GB locale and all models. `Exact` verification produces single points on the y-axis, which we linearly interpolate to produce its DET curve. Again, `seeking` NLU with `fuzzy` verification yields the best usability-security trade-off (lowest-lying curve) for the whole range of security levels in the graph. The same holds for the DET curves of the pl-PL and fr-FR (shown in Appendix E).

5.3 Identification Experiments

We evaluate the identification policy with `cautious` or `seeking` NLU (Subsection 4.1), and no (`none`), `exact`, `fuzzy`, or `oracle` (upper bound) identification (Subsection 4.4). We vary the α parameter of the infinity-one `p-norm` (Eq. 7).

Results. Table 5 shows the impact of NLU and identification models on identification rate at rank 1 and identification length. Without an explicit identification model (`none`) the agent cannot differentiate among multiple retrieved profiles and accuracy is very low. Consistently, `seeking` NLU, `fuzzy` models, and $\alpha = 0.5$ perform better than `cautious` NLU, `exact` matching, and $\alpha = 1$ (i.e. the standard fuzzy operators), respectively. These effects are orthogonal: `seeking` NLU with `fuzzy` model and $\alpha = 0.5$ produces the best accuracy, almost on par with the `oracle`.

Further Analysis. Most identification errors ($> 98\%$) were caused by low recall: the correct target profile was not included in those returned by querying the KB with the NLU results, which is reminiscent of the *unlinkable entity* (NIL) problem from entity linking (Ling et al., 2015; Hoffart et al., 2014; McNamee and Dang, 2009). Table 6 shows the upper bounds using a `KB oracle` (Subsection 4.1), and corroborates the results of Table 5. The best combination (`seeking` NLU, `fuzzy` model and $\alpha = 0.5$) can achieve almost perfect performance as an upper bound.

5.4 Directions for Further Research

Our findings highlight the most promising directions for further improvements. In particular, for enrolment: high-precision NLU and multi-turn belief tracking; for verification: high-recall NLU and fuzzy matching; and for identification: high-recall NLU, fuzzy retrieval, and boosting the recall of querying the KB. All tasks can benefit from better multilingual NLU, and our dataset includes audios to encourage improvements in ASR.

6 Related Work

Authentication Tasks. Our EVI tasks seek to automate the process of knowledge-based authentication (Braz and Robert, 2006; O'Gorman, 2003) in a voice communication context (O'Gorman et al., 2006a,b; O'gorman et al., 2005) using task-oriented spoken dialogue systems. We define and evaluate the tasks analogously to automated systems for biometric authentication (signatures, Yeung et al., 2004; fingerprints, Maio et al., 2002; faces, Phillips et al., 2003; irides, Phillips et al., 2008; and voice, Doddington et al., 2000).

Dialogues, NLP, and Logic. Our EVI benchmarks focus on speech recognition and spoken language understanding of names (Kaplan, 2020; Pappu and Rudnicky, 2014), dates (Price et al., 2021), and spellings (Vertanen and Kristensson, 2012; Filisko and Seneff, 2004; Chung et al., 2003). Furthermore, enrolment is a particular case of the slot-filling dialogue task (Young, 2002; Bellegarda, 2014); and identification is related to information retrieval and shares challenges with entity linking (Ling et al., 2015; Hoffart et al., 2014; McNamee and

Dang, 2009). We extend fuzzy logic methods from information retrieval (Radecki, 1979; Zadrożny and Nowacka, 2009; Salton et al., 1983) and from multi-modal verification (Lau et al., 2004; Conti et al., 2007; Azzini et al., 2007) to the context of spoken dialogues.

Dialogue Datasets. Research in dialogue systems is driven by competitions (Kim et al., 2019; Gunasekara et al., 2020) and challenge datasets, which may be human-to-human (Schrading et al., 2015; Lowe et al., 2015; Ritter et al., 2010), machine-to-machine (Shah et al., 2018), or human-to-machine (H2M) conversations; about single (Coope et al., 2020; Wen et al., 2017; Hemphill et al., 1990) or multiple domains (Rastogi et al., 2020; Zhu et al., 2020; Zang et al., 2020; Budzianowski et al., 2018; El Asri et al., 2017); in one or several languages (Xu et al., 2020; Li et al., 2021); and with written or spoken data (Lugosch et al., 2019; Li et al., 2018; Hemphill et al., 1990). Our EVI dataset is a spoken-language, multi-lingual, single-domain, human-to-machine challenge dataset for multiple tasks, which were not covered by any dialogue dataset from prior work.

7 Conclusion

We introduced novel spoken-dialogue tasks (knowledge-based enrolment, verification, and identification), the EVI multi-lingual spoken-dialogue dataset with 5,506 dialogues, and benchmark models, evaluations, and upper-performance bounds that leave ample margins for future improvements.

Limitations. During data collection, our policy (fixed-length with reprompts for all items) might have caused artefacts in speaker behaviour (e.g. frustration, chuckling, simplification for later items). Additionally, speaker behaviour of crowd-sourced speakers who impersonate a fake profile will be qualitatively different to presenting one's own personal information (e.g. a young female speaker might be asked to impersonate an older male profile); however, ethical and privacy concerns preclude the publication of a dataset with real data. Finally, our current evaluation considers each downstream task in isolation, although in practice they form a sequence (enrolment, identification, and then verification) that may propagate errors.

Future Work. We invite the community to work on the novel EVI tasks and challenge dataset, which pose a variety of unresolved technical challenges: speech recognition, multi-turn spoken language understanding, fuzzy matching and retrieval, etc.

Acknowledgements

We are grateful to our colleagues at PolyAI for our many fruitful discussions. We also thank the anonymous reviewers for their helpful suggestions.

Ethical Considerations

PolyAI is ISO27k-certified and fully GDPR-compliant. Before data collection, we informed the crowd-sourced human workers that their voluntary participation will allow us to collect, store, publish, and use their fully-anonymous data for research purposes. During data collection, we did not ask workers for their own personal information (e.g. name, postcode); instead, we provided fictional (but realistic looking) profiles for them to impersonate. We instructed workers on how to hide their caller id, we did not store any inbound phone numbers, and we use fully anonymised identifiers in our dataset. Finally, we offered a fair compensation (around the average hourly wage in the UK, pro-rata) to all workers from all locales.

A Appendix

This appendix presents the scripted NLG prompts (see Subsection 3.2 and Subsection 4.1). For the British English locale (en-GB), see Subsection 3.2. All scripted prompts for the Polish locale (pl-PL):

Q1: Podaj proszę swój kod pocztowy.
Q2: Podaj go proszę jeszcze raz.
Q3: Usłyszałam [1 2 3]. Podaj go jeszcze raz.
Q4: Podaj teraz swoje imię i nazwisko?
Q5: Podaj proszę swoję imię oraz nazwisko.
Q6: Przepraszam, możesz przeliterować swoje imię i nazwisko?
Q7: Jaka jest Twoja pełna data urodzenia?
Q8: Podaj proszę datę urodzenia jeszcze raz.
Q9: Usłyszałam [1 stycznia]. Podaj datę urodzenia jeszcze raz.

All scripted prompts for the French locale(fr-FR):

Q1: Quel est votre code postal?
Q2: Veuillez répéter votre code postal?.
Q3: J'ai entendu [1 2 3]. Veuillez répéter votre code postal.
Q4: Pourrais-je avoir votre nom et prénom?
Q5: Pourrais-je avoir à nouveau votre nom et prénom
Q6: Veuillez épeler votre nom complet?
Q7: Quel est votre date de naissance?
Q8: Pourrais-je avoir votre date de naissance.
Q9: J'ai entendu [le 1er janvier]. Pourriez-vous répéter votre date de naissance.

B Appendix

This appendix presents statistics of the ASR transcriptions (see Subsections 3.2 and 4.1). In particular, the table shows the average length of the n-best lists returned by the ASR per turn and for each locale.

	Locale		
Turn	**en-GB**	**pl-PL**	**fr-FR**
1	2.36	2.31	6.48
2	2.57	2.87	7.90
3	2.87	3.61	9.67
4	7.41	2.65	13.79
5	7.27	2.68	14.21
6	3.86	4.40	14.36
7	6.03	1.59	3.91
8	6.26	1.73	4.08
9	4.99	1.56	3.42
all	4.85	2.60	8.65

Table 7: Average length of the ASR n-best lists in the EVI dataset. The maximum length is 20.

C Appendix

This appendix presents Sankey diagrams for priming and speaker behaviour of dates (see Subsection 3.3). Transitions in the direction of priming in red; against, in blue. For the British English locale (en-GB), see Subsection 3.3 and Fig. 2.

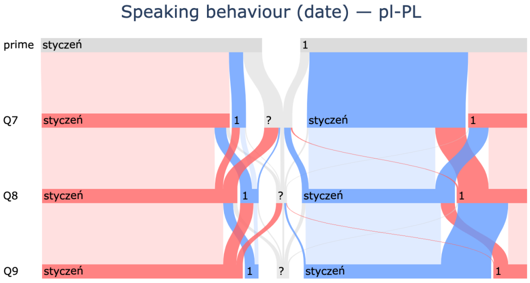

Figure 4: Polish locale (pl-PL): 85% of speakers primed with *month=name* echoed this pattern in Q_7, and only 10% of those switched later; 26% primed with *month=number* echoed and 71% later switched.

D Appendix

This appendix presents the target names and top-1 ASR transcriptions for all responses that employed

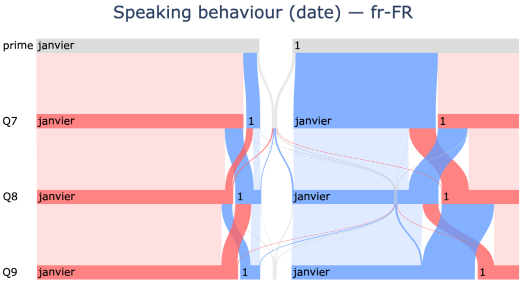

Figure 5: French locale (fr-FR): 92% of speakers primed with *month=name* echoed this pattern in Q_7, and only 9% of those switched later; 36% primed with *month=number* echoed and 67% later switched.

complex spelling strategies. For the British English locale (en-GB), consult the raw data (too many examples to list exhaustively). All 10 names with complex spelling transcriptions for the Polish locale (pl-PL):

Post-Training Dialogue Summarization using Pseudo-Paraphrasing

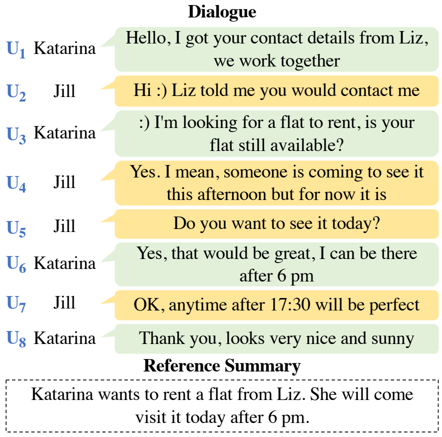
Abstract

Previous dialogue summarization techniques adapt large language models pretrained on the narrative text by injecting dialogue-specific features into the models. These features either require additional knowledge to recognize or make the resulting models harder to tune. To bridge the format gap between dialogues and narrative summaries in dialogue summarization tasks, we propose to post-train pretrained language models (PLMs) to rephrase from dialogue to narratives. After that, the model is fine-tuned for dialogue summarization as usual. Comprehensive experiments show that our approach significantly improves vanilla PLMs on dialogue summarization and outperforms other SOTA models by the summary quality and implementation costs.[1]

1 Introduction

Dialogue summarization is a specialized summarization task that takes a series of utterances from multiple speakers in the first person as input, and outputs fluent and concise summaries in third persons as shown in Figure 1. Different from previous monologue inputs such as news (Narayan et al., 2018) and scientific publications (Cohan et al., 2018), dialogues are always less well-organized. They usually contain complicated reference relations, inconsecutive inter-utterance dependencies, informal expressions, and so on, making dialogue summarization a more challenging task.

The most obvious characteristic of this task is the difference in the format and language styles between dialogue and its narrative summary. Liu, Shi and Chen (2021b) mentioned that coreference resolution models trained on general narrative text underperforms by about 10% on dialogue corpus, demonstrating the inherent gap between dialogue and narrative text. As a result, popular PLMs such as BART (Lewis et al., 2020) and PEGASUS (Zhang et al., 2020a) which excel on news summarization perform mediocrely on dialogue summarization.



Dialogue

U_1	Katarina	Hello, I got your contact details from Liz, we work together
U_2	Jill	Hi :) Liz told me you would contact me
U_3	Katarina	:) I'm looking for a flat to rent, is your flat still available?
U_4	Jill	Yes. I mean, someone is coming to see it this afternoon but for now it is
U_5	Jill	Do you want to see it today?
U_6	Katarina	Yes, that would be great, I can be there after 6 pm
U_7	Jill	OK, anytime after 17:30 will be perfect
U_8	Katarina	Thank you, looks very nice and sunny

Reference Summary

Katarina wants to rent a flat from Liz. She will come visit it today after 6 pm.

Figure 1: An example from SAMSum dataset.

To narrow this gap, previous work on dialogue summarization mainly resort to injecting dialogue features into PLMs to enhance dialogue understanding. These features include dialogue acts (Goo and Chen, 2018), topic transitions (Chen and Yang, 2020), coreference relations (Liu et al., 2021b), discourse graphs (Chen and Yang, 2021), etc, leading to the rule-based conversion from dialogues to plain text (Ganesh and Dingliwal, 2019). However, they suffer from three weaknesses. First, collecting or extracting these features becomes an additional step in the summarization pipeline, complicating the inference procedure at runtime. Second, oracle feature labels are hard to collect and errors can propagate from wrong labels to poor summaries. Third, additional layers or more encoders are required to incorporate features into PLMs, increasing the GPU memory footprint both during training and inference.

A more natural way to bridge this gap is to give the model more dialogue-narrative pairs to train on.

---

[*] The corresponding author.

[1] Our code and results are publicly available at `https://github.com/JiaQiSJTU/DialSent-PGG`.

Due to the scarcity of dialogue summarization data, one approach (Zhu et al., 2020) is to convert other text summarization pairs into dialogue to summary pairs via some template, but such work requires additional data [2].

In this paper, we propose an alternative approach that doesn't use any more data than the original dialogue summarization dataset. We convert each existing data pair into many "**pseudo-paraphrase**" pairs between a dialogue and a narrative sentence. Then we post-train a pre-trained seq2seq language model using a **prefix-guided generation** (PGG) task on the augmented paraphrase dataset. After that, the post-trained model is further fine-tuned as usual for dialogue summarization. To this end, no human efforts on crafting complicated rules or hyper-parameter tuning, or additional memory costs, as well as additional training data, is required. In sum, our contributions are:

- We propose a novel and effective post-training process to close the format and linguistic style gap between dialogues and narrative texts (§ 2).
- PGG with pseudo-paraphrase pairs requires no extra training data or labeling tools for features extractions (§ 3.2).
- Extensive experiments show that the proposed approach compares favorably with current SOTA models using less human efforts and computational costs (§ 3.3).

2 Approach

The training of a dialogue summarization model is divided two stages: post-training and fine-tuning. The model can be any seq-to-seq PLMs and it remains unchanged except for the parameters which are updated stage by stage. We will elaborate on the post-training stage in the rest of this section.

2.1 Pseudo-paraphrase Dataset Construction

We construct rephrasing datasets from the dialogue summarization dataset itself. The original dialogue summarization dataset (**DSum**) is made up of dialogue-summary (D-S) pairs. Each dialogue D is a sequence of utterances and can be concatenated into a whole sequence:

$$D = \{U_1, U_2, ..., U_T\} = \{x_1, \ldots, x_n\} \qquad (1)$$

Each turn U_t is in the form of [r_t: u_t], where r is a speaker and u is the actual utterance.

Our goal is to create more dialogue to narration kind of paraphrasing pairs. The most intuitive approach is to divide S into sentences, and pair each sentence to D. We call such pairs "pseudo-paraphrases" because the output sentence (which we call p) isn't exactly the paraphrase of the whole input, but rather part of the input.

However, doing this poses two challenges: 1) S is a coherent piece of text, and its sentences may depend on each other, so a single sentence p out of it may not stand by itself; 2) one D will be paired with several different p, and it is hard for the model to distinguish the meaning of these pairs.

Datasets	**Input**	**Output**
DSum	$U_{1\sim8}$	Katarina wants to rent a flat from Liz. She will come visit it today after 6 pm.
DialSent	$U_{1\sim8}$	*Katarina wants* to rent a flat from Liz.
	$U_{1\sim8}$	*Katarina will come* visit it today after 6 pm.

Table 1: Example pseudo-paraphrase pairs generated from the example in Figure 1. One pair in DSum becomes two pairs in DialSent. The prefix tokens determined by linguistic features, NOUN and ROOT, are underlined and italic respectively.

To solve 1) we apply coreference resolution[3] on S and convert every personal pronoun in it to the full reference first, before splitting the summary S into sentences. Sentence with fewer than 3 words (e.g., "Ally agree") are discarded since it carries too little information. The set of data pairs thus created is called (**DialSent**). An example is in Table 1.

To tackle 2), one obvious thought is to further split D into sets of sentences in which each set corresponds to a sentence p in the summary. However, our extensive experiments (see Appendix C) showed that none of the straight-forward heuristics work well to establish such alignments. This is mainly due to the fact that dialogue utterances are highly dependent. Thus, splitting operations are not optimal. Instead of changing D, we decide to use the pseudo-paraphrases directly but introduce a prefix-guided generation task to guide the model learning to extract relevant information from D.

2.2 Prefix-guided Generation Task

Summarization for dialogues focuses on analyzing "who-did-what" storylines (Chen and Yang, 2021) and the beginning of each summary sentence are

---

[2] More related work is in Appendix A.

[3] We use `https://spacy.io/`.

usually different speakers or the same speaker doing different things. As a result, using the prefix made up of "who" or "who-did" can help to select the related information from dialogues or plan the content to be generated.

In other words, we take the inspiration from content planning (Narayan et al., 2021; Wu et al., 2021). When training, the first few tokens of p are provided as prefix to the decoder. This prefix serves as an information selection hint to the model so it is easier to learn why that particular p should be generated. The losses are calculated between the generated tokens and reference tokens after the prefix as shown in Figure 2.

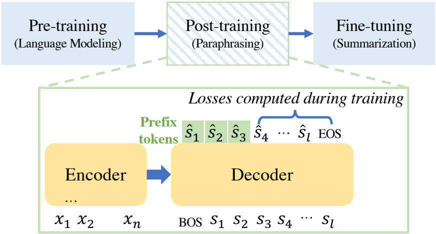


Figure 2: A illustration of our approach. BOS and EOS stand for begin and end of the sequence.

Let $p = \{s_1, \ldots, s_l\}$. Our prefix-guided training task is a vanilla auto-regressive generation task minimizing the negative log-likelihood of p:

$$L = -\frac{1}{l-a}\sum_{t=a}^{l} \log P(s_t|s_{<t}, H^d) \qquad (2)$$

where a is the number of prefix tokens. H^d is the output hidden vectors of the encoder with input D.

There are various ways to determine the prefix length a. We can take a fixed length, a random length or a prefix up to a certain linguistic feature such as NOUN, VERB or ROOT. The exact linguistic feature to use is a dataset-dependent hyperparameter and can be tuned by the validation set. Examples of prefix tokens is marked in Table 1.

3 Evaluation

We first present the experimental setups, then conduct an ablation study to determine the proper prefix in PGG training, before our main results. More implementation details are in Appendix B.

3.1 Experimental Setup

We implement our experiments on **SAMSum** (Gliwa et al., 2019) and **DialSumm** (Chen et al., 2021), whose statistics are listed in Table 2.

Datasets	**Variation**	**Train/Val/Test**	**IW**	**OW**	**CR**
SAMSum	DSum	14,731/818/819	124.10	23.44	0.25
	DialSent	29,757/1,654	149.93	11.93	0.13
DialSumm	DSum	12,460/500/500	187.52	31.02	0.18
	DialSent	22,407/840	214.00	17.78	0.10

Table 2: Statistics of dialogue summarization datasets. IW, OW and CR represent the number of input words, the number of output words and compression ratio (OW/IW) respectively.

We compare our method with these baselines. **Lead-3** and **Longest-3** are simple rule-based baselines that extract the first or the longest 3 utterances in a dialogue as the summary respectively. **PGN** (See et al., 2017), **Fast-Abs** (Chen and Bansal, 2018), and **PEGASUS** (Zhang et al., 2020a) are well-known models for text summarization. **BART** (Lewis et al., 2020) is a general PLM and performs well after fine-tuning. **CODS** (Wu et al., 2021), **Multi-view** (Chen and Yang, 2020) and **DialoBART** (Feng et al., 2021b) are the SOTA models designed for dialogue summarization.

We evaluate both automatically and by human. For **automatic evaluation**, we use Rouge-1, 2, and L (Lin, 2004) F1-scores [4]. Following Feng et al. (2021b), we adopt the same Rouge evaluation tool and compute between reference summaries and generated summaries. For DialSumm, we use maximum rouge scores among references for each sample. For **human evaluation**, we three proficient English speakers to evaluate 100 random samples from SAMSum. Each original dialogue and its reference summary are shown with generated summaries in a random order simultaneously. Showing summaries from different approaches together helps humans do comparisons between them. Following Chen and Yang (2020) and Liu et al. (2021b), each summary is scored on the scale of $[2, 0, -2]$, where 2 means concise and informative, 0 means acceptable with minor errors, and -2 means unacceptable. The final scores are averaged among annotators. We also ask human annotators to label the error types in the summary. We consider the following 4 error types: **Miss**ing important contents, **Red**undant content, **Cor**eference mismatches, and **Rea**soning error. Rea and Cor concentrate on comparisons to the dialogue, and the rest two focus on comparisons to the reference. We determine the error for each case by majority voting, and count the errors of each model.

DialSent-PGG	**54.73**	**30.47**	**53.46**

Table 3: Ablations on DialSent with PGG task.

3.2 Ablations Study

We conduct ablations to verify the effectiveness of post-training on DialSent with PGG, including post-training on DSum with PGG task (DSum-PGG), DSum with vanilla generation task (DSum-VG), and DialSent with vanilla generation task (DialSent-VG) in Table 3. The results of DSum-VG drop, indicating that fine-tuning for BART on DSum with early-stop is enough. Post-training with the same data and task leads to overfitting. DialSent-PGG performs best for two reasons. Compared with DialSent-VG, the prefix solves one-to-many mappings between a dialogue and summary sentences, so that the same dialogue can lead to different generations. On the other hand, the prefix can manipulate the selection within a short sentence but is not strong enough to direct content in multiple sentences. Thus, DialSent-PGG learns more cross-format paraphrasing ability and performs better.

Models	Rouge-1	Rouge-2	Rouge-L
SAMSum			
w/o	52.16	27.79	49.41
const	51.71	27.34	49.25

random	53.82	29.88	52.43
Ling-Root	**54.73**	**30.47**	**53.46**

Table 4: Ablations on prefix designs for PGG.

We try several choices of prefix length: (1) **W/O**: without any prefix. (2) **Const**: Constant length set to 2 and 3 for SAMSum and DialSumm respectively, since a person's name is 1.69 ± 0.69 tokens long on average [5]. (3) **Random**: set by uniform sampling from a range of numbers. We set the range to $1 \sim 3$ and $2 \sim 4$ for the two datasets respectively. (4) **Ling**: using the validation set, we determined that Noun and Root are the best choice for the two datasets, respectively. In this way, the number of prefix tokens for SAMSum and DialSum are 1.90 ± 1.10 and 3.55 ± 1.24.

In Table 4, Ling performs the best among these variants. The actual linguistic feature to use may vary from dataset to dataset though. The remaining experiments will be conducted using PGG-Ling.

3.3 Comparison to SOTA Models

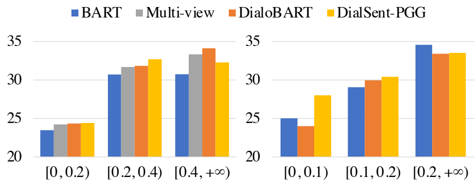
Automatic Evaluation: Our model DialSent-PGG performs competitively against other models on SAMSum and significantly better than the peers on DialSumm. It improves 1.5 on Rouge scores over BART for both datasets, while DialoBART achieves less gains on DialSumm. Based on Table 1, DialSumm is a more difficult dataset with lower compression ratios. Our model performs better on samples with lower CR, i.e. more compressed samples, as shown in Figure 3, thus differences between DialSent-PGG and DialoBART are more obvious on DialSumm. A simple case study is shown in Table 6. Multi-view faces the repetition problem as it takes the dialogue as input twice with two encoders. DialoBART has reasoning errors because it regards "William" as a keyword. DialSent-PGG instead generates a concise and correct summary. More cases are in Appendix D.

Human Evaluation: The overall human scores on BART, Multi-view, DialoBART and DialSent-PGG are 0.35, 0.40, 0.43 and 0.55 respectively. The Fleiss Kappa among three annotators is 0.39 [6].

---

[5] DialSumm normalizes speaker names into "#Person1#" resulting in more tokens.

[6] Fleiss Kappa between 0.4 and 0.6 is considered moderate.



(a) **SAMSum** (b) **DialSumm**

Figure 3: Comparison for models on samples with different CR. X-axis represents the ranges for CR(%). Y-axis is the Rouge-2 F1(%).

Dialogue	William: are you still angry? Emilia: YES William: :(
Multi-view	Emilia is still angry *and still angry*.
DialoBART	*William and* Emilia are still angry.
DialSent-PGG	Emilia is still angry.

Table 6: A case from SAMSum. *Errors* are in italic.

The latter three models all improve BART, with DialSent-PGG topping the ranks.

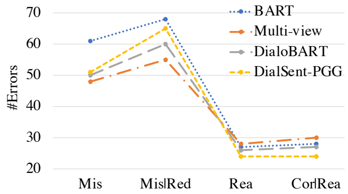


Figure 4: Error analysis on SAMSum.

For error analysis, the Fleiss Kappa for Mis, Red, Cor and Rea are 0.55, 0.10, 0.26, 0.42 respectively. The agreement on Red is lower because identifying unimportant information is hard. The agreement on Cor is fair due to undistinguishable errors. For example, mismatching of a person and an event among multiple utterances can be either a Cor or a Rea. Besides, Red always leads to Mis. So, we divide the error types into two groups and merge them with "OR" logical operation within each group. The Fleiss Kappa for Mis|Red and Cor|Rea are 0.45 and 0.46. We show error types with the agreement larger than 0.40 in Figure 4.

Multi-view performs better on content selection and DialSent-PGG performs better on reasoning and coreference understanding, while DialoBART lies in between. Fewer errors on Rea and Cor|Rea reflect that our approach successfully narrows the understanding gap. Because references are not the only good summary, high missing content doesn't mean that the generated summary is unacceptable. As a result, the model with fewer Cor|Rea errors receives higher overall score.

Implementation Costs: We compare the implementation costs between our approach and two state-of-the-art models, i.e. Multi-view and DialoBART, in Table 7. Although explicitly injecting features for dialogue understanding is effective, labels for these features are hard to collect and implementation costs for these approaches on a new dataset are high. Multi-view and DialoBART proposed doing labeling automatically with unsupervised algorithms or language models. However, these labeling approaches bring extra hyper-parameters which are different between datasets and need to be found by trial and error. If we use the same keywords extraction ratio, similarity threshold and topic segmentation ratio from SAMSum directly, the results on DialSumm are only 50.61/26.67/49.06 (Rouge-1/2/L). We searched for the best combination of hyper-parameters following their paper and did 14 trials, while applying our approach on DialSumm only need 4 trials.

On the other hand, injecting features increases the requirement of GPU memory. With the same training parameters(max tokens=1024, batch size=1, gradient checkpointing=False), Multi-view with double-encoder design encounters an out-of-memory error on RTX 2080Ti with 11G GPU memory. DialoBART occupies around 10.36G since it lengthens the dialogue with additional annotations. DialSent-PGG only occupies 9.87G during post-training for recording the length of the prefix, and 9.65G during fine-tuning which is the same as vanilla BART. In a word, our approach costs less for implementation.

Models	**Mem**	**#HP**	**#Tri**	**#St**
Multi-view	OOM	5	-	-
DialoBART	10.36G	3	14	38.61k
DialSent-PGG	9.87G/9.65G	1	4	19.32k

Table 7: The upper-bound of GPU memory footprint (Mem), newly introduced hyper-parameter counts (#HP), the number of trails (#Tri) and total training steps (#St) for implementing different models.

4 Conclusion

We propose to post-train dialogue summarization models to enhance their cross-format rephrase ability by prefix-guided generation training on dialogue-sentence pseudo-paraphrases, and get promising results. Creating self-supervised tasks for cross-format post-training and incorporating compatible features for downstream fine-tuning are plausible future directions.

A Related Work

Dialogue summarization and pretrained language models are discussed as follows.

Dialogue Summarization: A growing number of works have been proposed for dialogue summarization in recent years. In this work, we mainly refer to the chat summarization defined in (Feng et al., 2021a). Previous works widely explore dialogue features explicitly and input them as known labels to enhance the dialogue understanding ability of summarization models. Features, including dialogue acts (Goo and Chen, 2018), topic transitions (Chen and Yang, 2020), discourse dependencies (Chen and Yang, 2021), coreference relations (Liu et al., 2021b), argument graphs (Fabbri et al., 2021), semantic structures or slots (Lei et al., 2021; Zhao et al., 2021), etc. are carefully designed and collected by transferring tools pre-trained on other corpus or unsupervised methods with multiple hyper-parameters. These work also modify the basic transformer-based models with additional encoders (Chen and Yang, 2020) or attention layers (Chen and Yang, 2021; Liu et al., 2021b; Lei et al., 2021; Zhao et al., 2021) to utilize the injected features. Liu et al. (2021a) propose a contrastive learning approach for dialogue summarization with multiple training objectives. They also introduce a number of hyper-parameters for contrastive dataset construction and balancing among those objectives.

Pretrained Language Models: Previous pretrained seq-to-seq models can be divided into two categories by training data formats. One is models pretrained on narrative text, such as BART (Lewis et al., 2020), PEGASUS (Zhang et al., 2020a), and T5 (Raffel et al., 2020). They use training data from Wikipedia, BookCorpus (Zhu et al., 2015) and C4 (Raffel et al., 2020). These models show great potentials for tasks such as translation and story ending generation. The other is models pretrained on dialogue, such as DialoGPT (Zhang et al., 2020b) and PLATO (Bao et al., 2020). Their training data are general-domain dialogues, such as Reddit (Henderson et al., 2019) and Twitter (Cho et al., 2014). These models work for dialogue response selection and generation tasks. All of the above models are trained to exploit language features within the same data format, with pre-training tasks such as masked token/sentence prediction and utterance permutation. Pretraining with cross-format data hasn't been researched so far. As a first step, we focus on narrowing the gap by learning to rephrase unidirectionally from dialogue to narratives.

B Implementation Details

We use BART[7] as our basic language model. For both post-training and fine-tuning, the speakers and utterances of each dialogue are concatenated into a single sequence and truncated to the first 1024 tokens. The learning rate is set to $3e{-}5$ with weight decay equaling 0.01. The number of warmup steps is 500 and dropout is 0.1. The model is tested on the corresponding validation set after each training epoch and the early-stop is activated if there is no improvement in the Rouge-2 F1 score. The early-stop and maximum training epochs are set to 3 and 10. During inference, i.e., validation and testing, the beam size is set to 4 with length penalty equaling 1.0 and no-repeat-n-gram size equaling 3. The minimum and maximum lengths are set to the corresponding lengths of the reference summaries based on statistics of each dataset, allowing for free-length text generation. Besides, for the inference on the validation set during the post-training stage, we also set the first 3 tokens as the known prefix. This constant number enables a fair comparison of performances on validation sets under different experimental settings. All of our experiments are done on an RTX 2080Ti with 11G GPU memory. We run experiments three times and show the best results following (Feng et al., 2021b).

C Other Types of Paraphrase Datasets

To make the input and output carry the same amount of information, one way is to fix D as input and convert utterances into indirect speech as the output. Ganesh and Dingliwal (2019) restructured dialogue into text with complicated rules which are not released and difficult to transfer among datasets under different scenarios. Thus, we only use simple rules to convert all of the utterances into [r_t says,“u_t”] and concatenated as the output. We call this dataset as **DialIndirect**.

Another way is fixing S as output and removing the redundant utterances in D to get the rephrasing input. We take advantage of the idea of oracle extraction for news summarization (Zhou et al., 2018) and regard the combination of dialogue utterances with the highest Rouge scores computed with S as the input. Considering that utterances are

DialSent	22,407/840	214.00	17.78	0.10

Table 9: Statistics of constructed datasets. IW and OW refer to the number of words in the input and output of corresponding dataset. DSum and DialSent are in-list for easier comparison.

highly dependent, we modify the original extraction algorithm by extracting all of the utterances lying between the extracted ones, different from the window-sized snippet selection in (Liu et al., 2021a). Datasets with or without this modification are called **ExtSum** and **ExtSumM** respectively.

A summary S is divided into sentences to construct more rephrase pairs. Similar extraction operations can be done between D and p, and we get **ExtSent** and **ExtSentM** datasets.

An example of the paraphrase pair generated from the dialogue-summary pair in Figure 1 is shown in Table 8. The statistics of post-training datasets derived from SAMSum and DialSumm are shown in Table 9. We compare the performances between different rephrasing approaches with these datasets of our two-stage approach with the fine-tuning-only BART. The results are in Table 10.

Models	Rouge-1	Rouge-2	Rouge-L
SAMSum			
BART	52.06	27.45	48.89
DialIndirect	53.08	28.51	**50.25**
ExtSum	53.20	28.26	49.80
ExtSumM	52.20	27.91	49.74
EntSent	51.82	27.43	49.19

ExtSumM	52.29	27.72	50.09
EntSent	51.41	27.81	49.65
ExtSentM	52.46	28.86	51.36
DSum	53.27	28.64	51.69
DialSent	**54.73**	**30.47**	**53.46**

Table 10: Comparisons among different post-training approaches and fine-tuning-only BART baseline on dialogue summarization.

DialIndirect performs incredibly well on SAMSum. However, if we use the converted dialogue as input and directly fine-tune the original BART, the results are only 50.91/28.51/50.25 for Rouge-1/2/L. It shows that when accompanied with the post-training stage, the model can learn relationships between speakers and utterances, and boundaries of utterances better than a direct transformation of dialogue inputs. This rule-based transformation falls on DialSumm compared with BART baseline. More complicated rules may lead to better results, but such labored work is not what we are after.

The extraction-based methods fall behind the others. The modification to the algorithm tends to bring more noises than useful information to the input as the results drop mostly. Besides, splitting the summary into sentences doesn't improve the results here. In a word, such hard extractions hurt the intricate discourse and coreference relations among utterances and are not suitable for cross-format data construction.

DialSent with PGG task outperforms other methods and BART consistently across datasets, while DSum with PGG performs almost the same as BART. If we use DialSent data to augment the original DSum during fine-tuning, the results on SAMSum are 44.61/22.81/44.15 for Rouge-1/2/L respectively showing that the data in both datasets is not compatible. Thus, our approach is different from data augmentation. Overall, post-training with cross-format rephrasing intuition does help with dialogue summarization,

D Case Studies

We show more cases as follows.

Dialogue	**Kate**: Hey, do you know if our medical insurance covers hospital costs? **Greg**: Hm, it depends **Mel**: What happened dear? **Kate**: I broke my arm and they're sending me to the hospital :/ **Greg**: Call Linda or ask someone at the reception, they should be able to tell you what kind of package you have **Kate**: thnx
Reference	**Kate** broke her arm and she's going to the hospital. She'd like to know whether her medical insurance covers hospital costs. **Greg** suggests her to call **Linda** or ask someone at the reception about it.
BART	**Kate** broke her arm and they're sending her to the hospital. **Greg** doesn't know if their medical insurance covers hospital costs. **(53.33/37.93/53.19)**
Multi-view	**Kate** broke her arm and they're sending her to the hospital. ***Greg*** *will call* ***Linda*** *or ask someone* at the reception to find out if their insurance covers hospital costs.**(67.64/51.52/56.15)**
DialoBART	**Kate** broke her arm and they're sending her to the hospital . **Greg** advises her to call **Linda** or ask someone at the reception .**(65.57/50.85/67.62)**
DialSent-PGG	**Kate** broke her arm and they're sending her to the hospital. **Greg** advises her to call **Linda** or ask someone at the reception if their insurance covers hospital costs. **(71.64/55.38/62.39)**

Table 11: A case from SAMSum. **Names** are in bold and *unfaithful contents* are in italic. Rouge-1/2/L scores(%) are in parentheses.

The case in Table 11 is a dialogue happened between three speakers from SAMSum. The labeled dialogues, which are directly extracted from Multi-view's and DialoBART's released datasets are shown in Table 12. "|" label for Multi-view refers to the topic transitions and stage transitions for the same dialogue respectively. We can see that topic segments by Multi-view BART are reasonable. However, such linear segmentation is not quite suitable for this dialogue since the first and third topics are the same. "|" in DialoBART just refers to the end of each utterance. DialoBART failed to label any topic transitions or redundant utterances.

Compared to the reference summary, the summary generated by BART lost the information about Greg's suggestion, and DialoBART lost the information about "medical insurance" even though it recognized "medical insurance" as a keyword. Multi-view did incorrect reasoning on who will call Linda. Our model generated a more condensed summary covering the same key points as the reference with the original dialogue as input.

Another case from DialSumm between two speakers is in Table 13. BART recognized "him" in the second utterance as "#Person1#" incorrectly. DialoBART regarded the man as "#Person1#'s friends" which isn't mentioned in the original dialogue. Our model, DialSent-PGG generates a more accurate summary.

Multi-view Topic	Kate: Hey, do you know if our medical insurance covers hospital costs? Greg: Hm, it depends | Mel: What happened dear? Kate: I broke my arm and they're sending me to the hospital :/ | Greg: Call Linda or ask someone at the reception, they should be able to tell you what kind of package you have Kate: thnx |
Multi-view Stage	| Kate: Hey, do you know if our medical insurance covers hospital costs? Greg: Hm, it depends Mel: What happened dear? | Kate: I broke my arm and they're sending me to the hospital :/ | Greg: Call Linda or ask someone at the reception, they should be able to tell you what kind of package you have Kate: thnx
DialoBART	Kate : Hey , do you know if our medical insurance covers hospital costs ? | Greg : Hm , it depends | Mel : What happened dear ? | Kate : I broke my arm and they're sending me to the hospital | Greg : Call Linda or ask someone at the reception , they should be able to tell you what kind of package you have | Kate : thnx #KEY# Mel Kate Greg Hey do you know if our medical insurance covers hospital costs happened dear Linda reception package

Table 12: Modified inputs by Multi-view and DialoBART.

Dialogue	**#Person1#**: Like a cat on hot bricks, as you might say. I don ' t believe you are listening at all. **#Person2#**: Sorry, I just worried about him. You know, he should be here an hour ago. **#Person1#**: Don ' t worry him, he has been grown up and I think he can take himself very well. **#Person2#**: But he still does not come back. **#Person1#**: Maybe he is on the way home now.
Reference-1	**#Person2#** is worried about one man, and **#Person1#** thinks that that man might be on the way home now.
Reference-2	**#Person2#** is worried about a man, but **#Person1#** thinks it would be fine.
Reference-3	**#Person2#** is worried about a man but **#Person1#** is not.
BART	***#Person2#*** *is worried about* ***#Person1#*** because he hasn't come back from work. **(43.48/28.57/50.01)**
DialoBART	**#Person2#** is worried about ***#Person1#*** *'s friend* who hasn't come back. **(45.45/30.00/51.87)**
DialSent-PGG	**#Person2#** is worried about a boy who hasn't come back.**(47.62/42.11/53.90)**

Abstract

Sarcasm employs ambivalence, where one says something positive but actually means negative, and vice versa. The essence of sarcasm, which is also a sufficient and necessary condition, is the conflict between literal and implied sentiments expressed in one sentence. However, it is difficult to recognize such sentiment conflict because the sentiments are mixed or even implicit. As a result, the recognition of sophisticated and obscure sentiment brings in a great challenge to sarcasm detection. In this paper, we propose a Dual-Channel Framework by modeling both literal and implied sentiments separately. Based on this dual-channel framework, we design the Dual-Channel Network (DC-Net) to recognize sentiment conflict. Experiments on political debates (*i.e.,* IAC-V1 and IAC-V2) and Twitter datasets show that our proposed DC-Net achieves state-of-the-art performance on sarcasm recognition. Our code is released to support research[1].

1 Introduction

Sarcasm is a complicated linguistic phenomenon. Intuitively, it means that one says something positive on surface form, while he/she actually expresses negative, vice versa (Liu, 2012; Merrison, 2008). Take the sentence "*Final exam is the best gift on my birthday*" as an example, the literal sentiment on surface is *positive*, which is reflected by the explicit sentiment words, *i.e.,* "*best gift*". However, the factual part of the text (*i.e.,* "*final exam happens on birthday*") implies that the sentiment expressed is *negative*. This example suggests that it is the sentiment conflict that causes sarcasm linguistically.

However, modeling this linguistic nature of sarcasm is a great challenge due to the difficulty of digging sentiment conflict between the literal and the implied meanings. We know that non-sarcastic texts do not contain implied meaning, so the literal sentiment is consistent with the actual sentiment. But for sarcastic text, there is more than one meaning that coexists in one sentence. The literal meaning and the implied meaning are reflected in different sub-sentences. Even more challenging, sentiments behind the two meanings are mixed or even implicit.

Many existing studies adopt generic classification models for sarcasm recognition (Lou et al., 2021; Ghosh and Veale, 2016). However, these methods directly model the entire sentence without considering the contradictory meanings behind sarcastic texts. There are also studies using contrast patterns (*e.g.,* phrase pair and word pair) as indicators to detect sarcasm, which is approaching the linguistic essence of sarcasm. Riloff et al. (2013); Joshi et al. (2015) detect contrast or incongruity patterns, *i.e.,* the co-occurrence of positive sentiment phrases and negative situational phrases. Tay et al. (2018); Xiong et al. (2019) use attention mechanism to measure the sentiment conflict between word pairs in sarcastic texts. However, these methods emphasize too much on the explicit sentiment conflict on surface form (*i.e.,* word/phrase level), which mainly reflect the literal meaning. As a result, the factual text is underestimated, which expresses the implied sentiment.

Dual-Channel Framework. In this paper, we propose a dual-channel framework to model the lit-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1670 - 1680
July 10-15, 2022

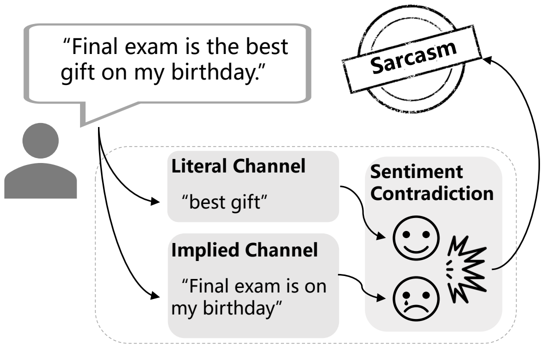

Figure 1: The Dual-Channel Framework for sarcasm recognition.

eral sentiment and the implied sentiment simultaneously. This allows us to leverage the conflict between the two channels in a comprehensive way. Figure 1 depicts the proposed dual-channel framework. In this framework, literal channel and implied channel are used to detect the surface and the hidden meanings separately. Once sentiment conflict is detected, we could determine the existence of sarcasm. The design of our dual-channel framework balances the effect of literal and implied inputs and avoids focusing too much on either one channel while ignoring the other. Our framework covers existing sarcasm patterns, and could be further enhanced to detect more sentiment conflict patterns.

Based on this framework, we develop the Dual-Channel Network (DC-Net) to detect sarcasm. DC-Net contains four modules: decomposer, literal channel, implied channel, and analyzer. In general, sentiment words directly reflect the surface sentiment, while the text without sentiment words reflects the implied sentiment. Hence, we split the sentiment words of input text to literal channel, and the remaining words to implied channel by decomposer. Then we use the literal channel to model surface meaning, and the implied channel to model hidden meaning. Lastly, we use analyzer to recognize the conflict. Experiments on three benchmark datasets (*i.e.,*, IAC-V1, IAC-V2 and Tweets) show that our proposed DC-Net model achieves state-of-the-art performance.

The main contributions of this paper are twofold. First, to the best of our knowledge, the dual-channel framework is the first attempt to explicitly separate literal meaning and implied meaning to recognize sarcasm by detecting sentiment conflict. Second, experiments conducted on benchmark datasets (*i.e.,* IAC-V1/V2 and Tweets) show that DC-Net achieves state-of-the-art performance.

2 Related Work

Prior methods of sarcasm recognition can be divided into traditional models and neural models. There are also methods considering context information, *e.g.,* posting history (Hazarika et al., 2018; Zhang et al., 2016), and user profile (Poria et al., 2016; Kolchinski and Potts, 2018). However, such context may not be always available.

2.1 Traditional Models

Most traditional approaches adopt machine learning methods such as SVM with manually crafted rules or feature engineering. The features include sentiment lexicons (González-Ibáñez et al., 2011; Patra et al., 2016), pragmatic features (*i.e.,* emoticons (González-Ibánez et al., 2011), capitalization, punctuations (Joshi et al., 2015)), and pattern-based features (Riloff et al., 2013) *et al.*. Hee et al. (2018b) utilize common sense to assist sarcasm detection on Twitter. Accordingly, the accuracy of sarcasm recognition highly depends on the quality of features.

Rewriting key parts of a sentence manually is an expensive but effective method. Ghosh et al. (2015) believe that sarcasm involves a figurative meaning which is usually the opposite of literal meaning. They reframe sarcasm recognition as a literal/sarcastic word sense disambiguation problem. Then they paraphrase sarcastic texts manually to obtain target words that cause sarcastic disambiguation. This work is novel but heavily relies on manual paraphrasing and labeling of datasets to find target words. Moreover, target words are mostly limited to sentiment words. As a result, the model is dominated by these explicit sentiment words and ignores the implied channel.

2.2 Neural Models

Ghosh and Veale (2016) propose a model composed of CNN, LSTM and DNN to detect sarcasm. As attention mechanism has led to improvements in various NLP tasks, Tay et al. (2018); Xiong et al. (2019) use attention to capture the relationship of word pairs along with an LSTM to model the entire sentence. Lou et al. (2021) design a GCN-based model combining SenticNet (Cambria et al., 2020), dependency tree and LSTM with GCN (Kipf and Welling, 2017) together, which achieves promising performance. Similar to previous studies, to better understand sarcasm, many approaches are able to utilize external information such as emoji expressions (Felbo et al., 2017), affective knowledge (Babanejad et al., 2020) and commonsense (Li et al., 2021). Joshi et al. (2017) provide a more comprehensive survey. Moreover, there have been many systems developed for a shared task (Ghosh et al., 2020). These models are rarely designed to reflect the essential features of the sarcasm phenomenon.

3 Dual-Channel Network (DC-Net)

The architecture of the proposed DC-Net is shown in Figure 2. It consists of four modules: *decomposer*, *literal channel*, *implied channel*, and *analyzer*. Given an input text, we use the decomposer to split it into two sub-sentences corresponding to the two channels. Then we use these two channels to derive literal and implied representations independently. Lastly, the analyzer predicts whether the text is sarcastic or not by detecting sentiment conflict.

3.1 Decomposer

The decomposer module is designed to split input text to the literal and implied channels. From numerous sarcastic corpora, we observe that sarcastic texts often contain evident sentiment words. More specifically, the literal channel itself is to reflect the intuitive sentiment. So it is reasonable to use sentiment lexicons as direct keywords. The remaining text expresses the implied sentiment. For example, sentiment words of input text (*e.g.,* "best gift") represent *positive*, while the remaining part (*e.g.,* "Final exam is on my birthday") implies the *negative* sentiment. Shown in Table 1, proportion of texts that contain sentiment words ranges from 88% to 96% in three datasets. Hence, using sentiment words to split input well serves the purpose.

Considering a text $W_T = \{w_1, w_2, \ldots, w_N\}$ with N words, we decompose it into two pieces: the sentiment words W_L, and the remaining text W_D (see Figure 2). W_L is fed to the literal channel, and W_D to the implied channel. In this process, we use the sentiment lexicon released in Wilson et al. (2005) to pick up sentiment words. If no sentiment words are matched from the given text, the original text is used as the literal channel's input, which is the same as the implied channel. Note that in quite a few texts, sentiment words are adjectives or adverbs, deleting them from sentences has no much impact on the overall semantics. Although the text is not normative as expected after decomposing, we do not fill in the full text with placeholders.

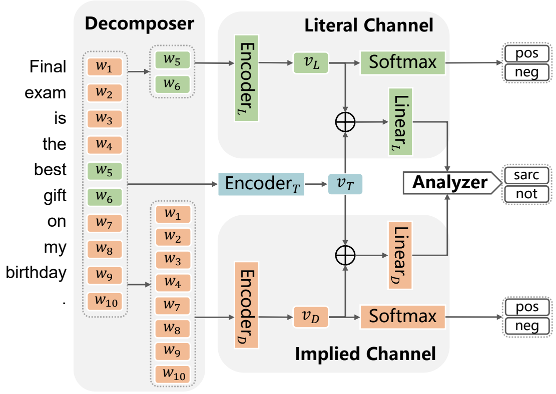

Figure 2: The architecture of the DC-Net.

3.2 Literal Channel

The literal channel includes an encoder, two linear layers, and a softmax classifier. Encoder$_L$ is used to encode the literal text W_L. Then we can get the literal representation v_L through

$$v_L = \text{Encoder}_L(W_L). \tag{1}$$

Next, we use a softmax layer to compute the literal sentiment distribution based on the literal representation v_L.

$$\mathcal{P}_l = \text{softmax}(W_r v_L + b_r), \tag{2}$$

where, W_r and b_r are parameters of the linear layer.

Considering the semantic complexity of sarcastic texts, a single representation of sentiment words may lose context information. So we adopt another Encoder$_T$ to encode the original text W_T and obtain the representation of the entire text v_T through

$$v_T = \text{Encoder}_T(W_T). \tag{3}$$

Last, we concatenate the literal state v_L and the entire text's state v_T, followed by a linear layer and ReLU activation function to reduce dimension. Briefly, the final representation $v_L^{'}$ of the literal channel could be formulated as:

$$v_L^{'} = \text{ReLU}(W_l[v_L; v_T] + b_l), \tag{4}$$

where W_l and b_l are parameters of the second linear layer.

3.3 Implied Channel

In the implied channel, we also adopt an Encoder with the same structure but different parameters to encode the implied input text W_D, and the representation of the implied channel is formulated as:

$$v_D = \text{Encoder}_D(W_D). \tag{5}$$

Similarly, we use softmax to calculate the implied sentiment distribution based on the implied hidden state v_D:

$$\mathcal{P}_d = \text{softmax}(W_z v_D + b_z), \tag{6}$$

where W_z and b_z are parameters.

Again, we concatenate the implied hidden state v_D with the entire text's hidden state v_T, followed by a linear layer and an activation layer ReLU. The final representation $v_D^{'}$ of the implied channel is formulated as:

$$v_D' = \text{ReLU}(W_d[v_D; v_T] + b_d), \tag{7}$$

where W_d and b_d are parameters.

Note that the structures of the two channels are symmetrical. However, the two encoders in the two channels do not share parameters, and their inputs are different. Since both channels are not specific to particular encoders, the dual-channel framework is able to adapt to mainstream encoders, *e.g.,* LSTM (Hochreiter and Schmidhuber, 1997), CNN (Kim, 2014), Recursive Neural Network (Socher et al., 2011), BERT (Devlin et al., 2019) *et al.*. In DC-Net, we adopt Bi-LSTM as encoders for both channels.

3.4 Analyzer

The analyzer is designed to measure the conflict between the literal and the implied channels. We concatenate the literal representation $v_L^{'}$ and the implied representation $v_D^{'}$ and feed the result to a softmax layer. Other analyzers such as subtraction or cosine similarity also fit our design.

$$\mathcal{P}_s = \text{softmax}(W_p([v_L^{'}, v_D^{'}]) + b_p), \tag{8}$$

where W_p and b_p are parameters.

Although sarcasm has a strong correlation to literal sentiment and implied sentiment, we do not have gold labels for both sentiments. Hence, requesting the model to directly output sentiments on both channels may confuse the model. For this reason, we develop the objective function of sarcasm classification by adding objectives of the literal and implied channels.

3.5 Training Objective

The training objective of the proposed DC-Net model considers three aspects. One is to minimize the cross-entropy loss of the sarcasm probability distribution. The other two are to minimize the cross-entropy losses of the literal and that of the implied sentiment probability distributions respectively.

Sarcasm Objective. The sarcasm objective is to ensure the basic ability of detection. Hence, we use cross-entropy loss of sarcasm classification. The objective J_s is formulated as:

$$J_s(\theta) = \sum \text{cross-entropy}(y_s, \mathcal{P}_s), \tag{9}$$

where $\mathcal{P}_s$ denotes the sarcasm probability distribution of the text. The groundtruth of the sarcasm label is y_s.

Literal Sentiment Objective. Due to the expensive manual annotations, we use sentiment words for approximate labeling, which is widely used in Eisenstein (2017); Taboada et al. (2011); Hu and Liu (2004). In our implementation, we determine the literal sentiment label based on the number of words with positive sentiment and the words with negative sentiment in input text. For sarcastic texts, if the number of positive words is greater than that of negative words, the literal sentiment label is positive and the implied sentiment label is negative, and vice versa. For non-sarcastic texts, both the literal sentiment label and the implied sentiment label are the same, determined by the number of positive/negative sentiment words.

The literal sentiment classification objective is then formulated as:

$$J_l(\theta) = \sum \text{cross-entropy}(y_l, \mathcal{P}_l), \tag{10}$$

where $\mathcal{P}_l$ is the literal sentiment probability distribution. The label generated by the labeling processing of the literal sentiment is y_l.

Implied Sentiment Objective. We observe that literal sentiment and implied sentiment of sarcastic texts are often opposite. Using the implied labels based on the automatic labeling processing, we calculate the implied sentiment classification objective by

$$J_d(\theta) = \sum \text{cross-entropy}(y_d, \mathcal{P}_d), \tag{11}$$

where $\mathcal{P}_d$ denotes the implied sentiment probability distribution. The label generated by the labeling processing of the implied sentiment is y_d.

Considering these three objectives, we obtain the final objective function L by adding them together:

$$L(\theta) = \lambda_1 J_s(\theta) + \lambda_2 J_l(\theta) + \lambda_3 J_d(\theta), \quad (12)$$

where θ is the parameter set of the model. λ_1, λ_2 and λ_3 are used to leverage the contributions of the three objectives.

4 Experiment

4.1 Datasets and Implementation Details

We conduct experiments on three benchmark datasets: IAC-V1, IAC-V2, and Tweets. These datasets do not contain context information such as historical tweet posts and user profiles. All of them have been widely used in evaluating sarcasm detection.

- **IAC-V1** is collected from online political debates forum[2]. It is the subset of the Internet Argument Corpus (Lukin and Walker, 2013). The written language of IACs is English. Each instance, typically a sentence, is annotated with sarcasm label, either "sarcasm" or "non-sarcasm". Compared to tweets, texts of IAC are much longer and more normative.

- **IAC-V2** (Oraby et al., 2016) contains more data than IAV-V1 (the two versions have a few overlaps). IAC-V2 divides sarcasm into three sub-types, (*i.e.,* general sarcasm, hyperbole, and rhetorical questions). We use the largest subset (general sarcasm) in our experiments.

- **Tweets** dataset written in English is proposed in SemEval 2018 Task 3 Subtask A (Hee et al., 2018a). Each instance (*i.e.,* a sentence) is labeled sarcastic or non-sarcastic. There are three variations of the text in this dataset: (i) original texts, (ii) texts with hashtags removed, and (iii) texts with hashtags and emoji expressions removed. Hashtags like "#not", "#sarcasm", and "#irony", are originally obtained from users. The hashtags are also used as prior knowledge for collecting sarcastic posts. In our experiments, we used the version without hashtags.

Table 1: Statistics of datasets. Avg ℓ denotes the average length of texts in the number of tokens. s ratio is the proportion of texts that contain sentiment words.

Dataset	Train	Valid	Test	Avg ℓ	s ratio
IAC-V1[3]	1,596	80	320	68	91%
IAC-V2[4]	5,216	262	1,042	43	96%
Tweets[5]	3,634	200	784	14	88%

Table 1 reports the statistics. We observe that more than 88% of the texts contain sentiment word(s). Hence, it is reasonable to decompose the original text into sentiment words and non-sentiment words, as inputs to the literal channel and implied channel, respectively. The number of instances in the three datasets is between $1k$ and $6k$. All three datasets are class-balanced. The ratio of sarcastic instances and non-sarcastic instances is nearly 1:1. Due to the small size, the split of train/valid/test is important to avoid overfitting. For Tweets dataset, we follow the official train/test split. Then we randomly select 5% from training as valid sub-dataset. There is no official train/valid/test split for the two IAC datasets, so we split IAC datasets following the same ratio of Tweets. The baselines papers do not provide the split (or not conduct experiments on IAC datasets). So we cannot directly adopt the results of baselines reported in their original papers. Hence, we re-implement all baseline models on IAC-V1 and IAC-V2 datasets.

There are another three datasets for sarcasm detection. Riloff et al. (2013) and Ptáček et al. (2014) propose another two datasets based on Tweets, but they only provide tweet IDs. Due to modified authorization status, lots of tweets are unavailable or deleted. For this reason, we could not experiment on these two Tweet datasets. Khodak et al. (2018) build a large self-annotated dataset from the Reddit forum platform. This dataset contains rich context information including posts, comments, responses, and authors. Since our work focuses on text-based sarcasm recognition, we do not use this dataset.

Implementation Details. We use 300-dimensional Glove (Pennington et al., 2014) embeddings to initialize word vectors. There is a checkpoint every 16 mini-batch, and the batch size is 32. For Tweets dataset, the dropout on embeddings is set to 0, while for IAC datasets it is set to 0.5. Adam (Kingma and Ba, 2015) is used to optimize

our model. The parameters β_1 and β_2 of Adam are set to 0.9 and 0.999. The learning rates for model parameters except word vectors are 1e-3, and 1e-4 for word vectors. Our model is implemented with Pytorch[6] (version 1.7.0).

On IAC datasets, all of the loss contributions $\lambda_1, \lambda_2, \lambda_3$ of our DC-Net model are set to 1. On Tweets, they are set to 1, 1e-4, and 3e-1, respectively. The hyperparameters are searched over the validation sub-dataset.

4.2 Compared Methods

We evaluate our model against the following baselines:

UCDCC (Ghosh and Veale, 2018) is a siamese LSTM model exploiting Glove word embedding features. The method designs a lot of rules to preprocess Twitter data. It achieves the best performance on SemEval 2018 Task 3 Subtask A.

THU-NGN (Wu et al., 2018) consists of densely connected LSTMs based on word embeddings, sentiment features, and syntactic features. It ranks second on SemEval 2018 Task 3 Subtask A.

Bi-LSTM (Hochreiter and Schmidhuber, 1997) is a variant of RNN, which could learn long-term dependencies and bidirectional information.

AT-LSTM (Wang et al., 2016) is an LSTM model followed by a neural attention mechanism. It could attend the important part of the input.

CNN-LSTM-DNN (Ghosh and Veale, 2016) is a combination of CNN, LSTM, and DNN. It stacks two layers of convolution and two LSTM layers, then passes the output to a DNN for prediction.

MIARN (Tay et al., 2018) learns the intra-sentence relationships of word pairs and the sequential relationships of a given text.

ADGCN (Lou et al., 2021) is a GCN-based method with sentic graph and dependency graph[7]. The initial input of GCN is the hidden state of Bi-LSTM.

4.3 Main Experiment Results

Table 2 shows that our DC-Net achieves the best macro $F1$ results across all datasets. On Tweets dataset, DC-Net achieves about 3.5% improvement in $F1$ score than the best baseline. On IAC-V2 dataset, our model outperforms the second-best by 1.2% in $F1$. Surprisingly, compared with the basic encoder model Bi-LSTM, our DC-Net boosts the performance up to 5% and 3% respectively on Tweets and IAC-V2, demonstrating the effectiveness of our dual-channel design. For Tweets dataset, the average length of texts is 14 words, which leads to a lack of information for sarcasm recognition. Nevertheless, our DC-Net improve 3.5% on $F1$ compared with the previous state-of-the-art ADGCN.

Interestingly, UCDCC achieves the best precision of 78.8% and accuracy of 79.7% on Tweets dataset. Besides, THU-NGN gets the best recall at 80.1% on Tweets. This is because UCDCC designs targeted rules to preprocess the input text and it achieves the best performance on SemEval 2018 Task 3 Subtask A. Rules could improve precision effectively, but they are hard to take recall into account at the same time. So the $F1$ is not good enough. The last place performance of UCDCC on IAC-V1/V2 also supports this point. These designed rules are hard to fit missing instances and other domains. Similarly, THU-NGN uses linguistic knowledge such as sentiment and syntactic, so it

[7] We employ spaCy toolkit to derive dependency tree.

Table 3: The precision, recall, and macro $F1$ of models including BERT, DC-Net with BERT as Encoder, and DC-Net with Bi-LSTM as Encoder.

Model	Tweets			
	Pre.	Rec.	F1	Acc.
BERT	69.1	67.6	68.1	71.6
DC-Net (w/ BERT)	70.2	70.7	70.4	71.3
DC-Net (w/ Bi-LSTM)	**76.4**	**77.5**	**76.3**	**76.7**

achieves the highest recall on Tweets but it cannot perform equally well on other datasets. That is, rules have limitations in handling this task.

The previous state-of-the-art ADGCN achieves second-best on IAC-V2 and Tweets. However, on IAC-V1 dataset, ADGCN performs not as well as the result reported in their paper. IAC-V1 dataset is relatively small so the train/valid/test split has a significant impact. Our experiments also show that MIARN's performance is not as good as expected. This indicates that the basic utilization of word pair correlation is not enough to improve the performance of sarcasm detection. Bi-LSTM, AT-LSTM, and CNN-LSTM-DNN methods are all based on LSTM. Thus the performances of these models on Tweets and IAC-V1 are close.

4.4 Comparison with BERT

BERT has contributed to significant improvements on various NLP tasks. To do a comprehensive comparison, we apply the dual-channel framework to BERT (Devlin et al., 2019) model by using BERT as the encoder. The new model with BERT is named DC-Net (w/ BERT). Table 3 reports the experimental results.

As expected, the DC-Net (w/ BERT) model achieves significant improvement compared with the basic BERT. This result shows that our dual-channel framework is adaptable and effective. Interestingly, we observe that BERT-based methods perform not well enough compared with its huge improvement on other NLP tasks. This can be attributed to the fact that the corpus of pre-trained BERT contains more deterministic data (*e.g.,* only one meaning without sentiment conflict). However, sarcasm is a niche linguistic phenomenon. The poor performance of BERT further reinforces that sarcasm recognition is a difficult task. It tells us that applying well-performed classification methods directly is difficult to achieve desirable performance.

Table 4: Ablation study on Tweets dataset. J_s denotes using sarcasm loss only. J_s+J_d means using sarcasm and implied loss. J_s+J_l means using sarcasm and literal loss. J_s+J_l+J_d denotes using sarcasm, literal, and implied loss.

Objective	Tweets			
	Pre.	Rec.	F1	Acc.
J_s	74.6	75.4	74.8	75.4
J_s+J_d	74.2	75.2	74.0	74.4
J_s+J_l	73.0	74.0	72.8	73.1
J_s+J_l+J_d	**76.4**	**77.5**	**76.3**	**76.7**

4.5 Ablation Study

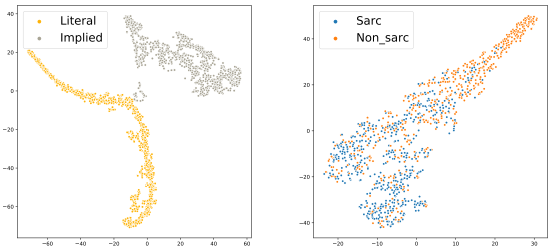
Recall that the model training (see Section 3) contains three objectives: sarcasm recognition, literal sentiment classification, and implied sentiment classification. To study the effect of the three objectives, we conduct ablation study on Tweets dataset.

Table 4 lists the result of ablation study. As expected, the model with both literal and implied losses performs the best. Interestingly, the model using sarcasm recognition loss with single channel loss (*i.e.,* literal and implied) performs worse than the model using only sarcasm recognition loss. This is because adding literal and implied sentiment classification objectives interferes with the judgment of the model. By adding both literal and implied sentiment classification losses, the model's performance improves 1.5 points in $F1$ score. This is very important because it reveals that the dual channels are effective. There is no effect or the opposite effect when single channel is applied alone. However, once dual-channel is used, the performance improves largely. It reveals that the dual channels complement each other. Conflict detection could recognize sarcasm when both of them are considered.

4.6 Effectiveness of DC-Net by Visualization

To verify the rationality and effectiveness of our proposed DC-Net, we adopt t-SNE (Van der Maaten and Hinton, 2008) to visualize high-dimensional vector representations based on the test sub-dataset of IAC-V2 (with largest data).

To figure out the effect of each channel, we visualize the representations of the literal channel and the implied channel. Figure 3(a) shows the visualization of literal representation $v_L^{'}$ and implied representation $v_D^{'}$. Recall that the decomposer module splits the original text into sentiment words and the



(a) Literal and implied reps. of each channel

(b) Sarc. and non-sarc. reps. in analyzer module

Figure 3: Results of t-SNE visualization

remaining. We observe that there is a clear separation between literal and implied representations from Figure 3(a). This strongly indicates that our dual-channel framework is capable of effectively separating the representations of the two channels.

To get into the essence of sarcastic and non-sarcastic texts, we visualize the sarcastic and non-sarcastic representations. Figure 3(b) shows the sarcastic and non-sarcastic representations in the analyzer module. We observe that non-sarcastic texts focus on the upper right corner, while sarcastic texts scatter on the lower left corner. It reveals that the sarcasm patterns are complex and changeable. Nevertheless, the dividing line between the two is relatively clear. To this end, explicitly separating the literal and implied channels is necessary and effective. Further, DC-Net makes a distinct difference between sarcastic and non-sarcastic representations, which greatly promotes the performance of the dual-channel framework. We also plot the sarcastic representation and non-sarcastic representation of each channel respectively, which show the same trend as Figure 3(b). So they are not detailed here.

4.7 Flexibility of Dual-Channel Framework

Flexibility of encoder. The dual-channel framework is flexible and generic, and can be realized by plugging in existing sarcasm recognition models, *e.g.,* MIARN, or classification models, *e.g.,* AT-LSTM, Bi-LSTM, and BERT. Therefore, we use these methods as the encoder to examine the flexibility of our proposed framework. The changing range on macro $F1$ from original baseline models to dual-channel models is shown in Table 5.

As expected, the performance of baseline models has different degrees of improvement on all datasets after applying dual-channel framework. For relatively simple models such as MIARN and Bi-LSTM, the improvement could be up to 4.8%. Interestingly, for complex models like BERT, the improvement is up to 2.3%. As we mentioned earlier, the basic BERT performs not good enough because sarcasm is a niche language phenomenon and the training dataset of BERT contains few sarcasm texts. After applying the dual-channel framework to BERT, the performance for sarcasm recognition improves a lot. These indicate that our designed framework is able to fit various encoders with a significant improvement.

Table 5: The macro $F1$ changes from basic models to dual-channel based models.

Basic Model	Changing Range on F1		
	IAC-V1	IAC-V2	Tweets
AT-LSTM	↑ 0.4	↑ 1.1	↑ 1.5
BERT	↑ 0.4	↑ 1.7	↑ 2.3
MIARN	↑ 1.1	↑ 2.8	↑ 4.8
Bi-LSTM	↑ 1.8	↑ 2.4	↑ 4.6

Table 6: Comparisons of different analyzer methods.

Analyzer	F1		
	IAC-V1	IAC-V2	Tweets
Subtraction	65.1	80.7	75.2
Concatenation	**66.4**	**82.1**	**76.3**

Flexibility of analyzer. The analyzer module is used to measure the difference between the literal channel and the implied channel. As we described in Section 3.4, other analyzer methods such as concatenation and subtraction could be applicable. To this end, we compare different analyzer methods. Table 6 shows the results. We observe that concatenation performs better than subtraction on all datasets. It is because concatenation holds more useful information and DC-Net could compare the difference between the two input representations. However, subtraction only outputs the margin between the two representations. It loses the original values which also contain useful information.

5 Conclusion

In this study, we argue that the essential characteristic of sarcastic text is the conflict between literal and implied sentiments in the same sentence. To this end, we propose a dual-channel framework to recognize sarcasm by decomposing the input text into the literal channel and the implied channel. Based on this framework, we develop DC-Net. DC-Net is capable of exploiting the literal sentiment by encoding the sentiment words of input text, and exploiting the implied sentiment by encoding the remaining text. Experiments show that the proposed DC-Net achieves state-of-the-art performance.

6 Limitation

Sarcasm as a complex linguistic phenomenon has various patterns, *e.g., text with word/phrase pair sentiment conflict*. Nevertheless, sentiment conflicts are common in sarcasm texts. In this paper, we make the very first attempt to recognize sarcasm by detecting sentiment conflict. More importantly, our proposed dual-channel framework could be further developed to detect more sentiment conflict patterns. For now, we use sentiment words as a static decomposer. This intuitive method can cover common sarcasm patterns but not all. Therefore, how to minimize the dependence on sentiment words is an important research direction.

Another limitation is that we assume that sentiment polarity is decided by the sentiment lexicon approximately in the analyzer module. While the assumption is widely accepted, there is still a gap between approximate label and groundtruth. In the current design, we adopt a soft weighting mechanism to detect sentiment conflict between the two channels. We expect that the model could output the opposite sentiment labels directly, which is a more effective way to express conflict.

Abstract

Entity Linking (EL) maps an entity mention in a natural language sentence to an entity in a knowledge base (KB). The Zero-shot Entity Linking (ZEL) extends the scope of EL to unseen entities at the test time without requiring new labeled data. BLINK (Wu et al., 2020) (BERT-based) is one of the SOTA models for ZEL. Interestingly, we discovered that BLINK exhibits diminishing returns, i.e., it reaches 98% of its performance with just 1% of the training data and the remaining 99% of the data yields only a marginal increase of 2% in the performance. While this extra 2% gain makes a huge difference for downstream tasks, training BLINK on large amounts of data is very resource-intensive and impractical. In this paper, we propose a *neuro-symbolic, multi-task learning* approach to bridge this gap. Our approach boosts the BLINK's performance with much less data by exploiting an auxiliary information about *entity types*. Specifically, we train our model on two tasks simultaneously - *entity linking (primary task)* and *hierarchical entity type prediction (auxiliary task)*. The auxiliary task exploits the hierarchical structure of entity types. Our approach achieves superior performance on ZEL task with significantly less training data. On four different benchmark datasets, we show that our approach achieves significantly higher performance than SOTA models when they are trained with just 0.01%, 0.1%, or 1% of the original training data. Our code is available at `https://github.com/IBM/NeSLET`.

1 Introduction

Entity linking is a fundamental task in the field of Natural Language Processing (NLP) and plays an important role in numerous applications including Knowledge Base (KB) question answering, document understanding, dialogue systems, etc. Consider the sentence – "*She noticed a* **Jaguar** *speeding on the highway.*" In this sentence, the phrase **Jaguar** is called as *entity mention* and the task of mapping this mention to a real world entity from a given KB, e.g. Wikipedia, Wikidata, DBpedia, etc., is called as *entity linking (EL)*[1]. For Wikipedia KB, above mention of **Jaguar** should be mapped to **Jaguar car** and not to **Jaguar cat**.

Majority of the prior works on EL focus only on *in-domain* linking (Jiang et al., 2021; Orr et al., 2021; Yamada et al., 2016; Chisholm and Hachey, 2015) where, gold entities (ground truth entities) of the test examples are seen during training. In other words, they assume both KB and entity set are static. However, KBs evolve over time with addition of new entities and relations (Morsey et al., 2012) because they are inherently incomplete and facts change over time. This brings in a more useful and challenging scenario of *zero-shot* linking where the gold entity of test examples is unseen during training. This task is known as *zero-shot entity linking (ZEL)*[2] and has gained attention in recent times (Wu et al., 2020; Logeswaran et al., 2019; Vyas and Ballesteros, 2021; Onoe and Durrett, 2020; Gupta et al., 2017). A BERT-based model, called BLINK (Wu et al., 2020), is a state-of-the-art (SOTA) solution for the ZEL task. Recently, a BART-based model, called GENRE (Cao et al., 2021), was proposed and is claimed to outperform BLINK. While experimenting with BLINK, we observed an interesting phenomenon: *BLINK exhibits diminishing returns*. As shown in Figure 1, BLINK attains 98% of its performance with just 1% of training data and further increase in the training data from 1% to 100% yields an additional gain of just 2% in the performance. But note that

---

[*] Equal contribution

[1] In literature, this task is also called as Entity Disambiguation (ED) and the combined task of mention detection plus ED is called as EL. In this paper, we assume entity mentions are given to us.

[2] In practice, a small percentage of test entities do get seen during training time while working with large benchmark datasets. We call this phenomenon as *leakage*. In the computer vision field, the very same phenomenon of *leakage* is called as *Generalized Zero-Shot Learning (GZSL)* (*Jiang et al., 2019*).

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1681 - 1697
July 10-15, 2022 ©2022 Association for Computational Linguistics

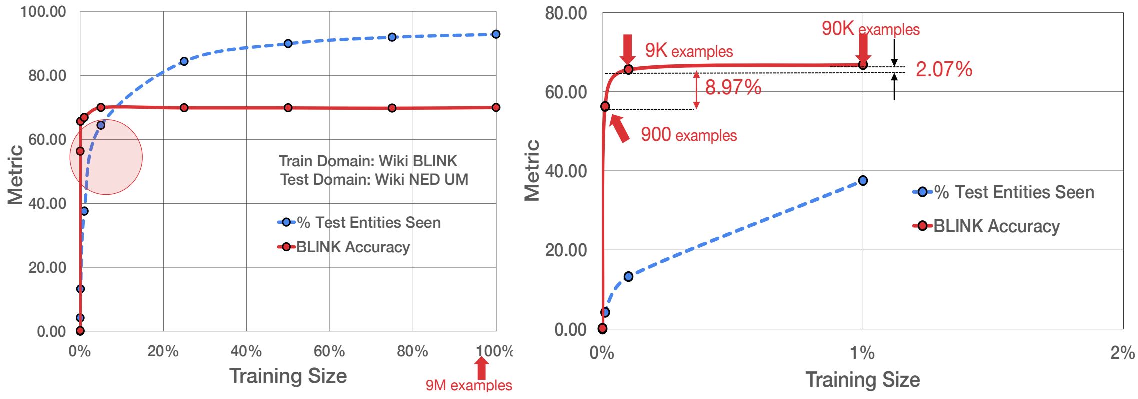

Figure 1: Figure on the right is a zoomed version of the figure on the left. The solid curve denotes diminishing returns for linking accuracy of BLINK's bi-encoder on the target domain as we increase the source domain's training data size. The dotted curve denotes the % of test entities leaking into training. A 10-fold increase in the training data (from 900 to $9K$ examples) yields a performance gain of less than 10%. A further 10-fold increase (from $9K$ to $90K$) merely yields a boost of 2.07%. As source domain training data increases, the leakage increases and problem drifts from ZEL to EL setting.

even a slight increase in entity linking performance has been shown to improve downstream tasks such as question answering significantly (Kapanipathi et al., 2021). However, training BLINK on a such a large volume of data just to offer a marginal gain of 2% is quite impractical due to heavy investment required in terms of data, time, and hardware. As per a tweet[3] from an author of the BLINK, its training took about a week's time on 8-GPUs for $9M$ examples. Based on the above observation, this paper aims to beat BLINK performance[4] while utilizing only 1% of training data.

To achieve above goal, we design a novel neuro-symbolic approach that combines an easily available *symbolic information*, called *entity types hierarchy*, with the BLINK model to reduce training data requirement without compromising ZEL performance. For example, most of the KBs would tag the entity *Mercedes-Benz* as `Company` or `Organization`. Type information can help disambiguate *Mercedes-Benz* even if it was unseen during training because mentions of similar-typed entities, say *Jaguar*, would have been seen. Our experiments empirically verify the above hypothesis. Previous works (Gupta et al., 2017; Raiman and Raiman, 2018; Onoe and Durrett, 2020) have also demonstrated performance gains by using entity types. However, their primary focus was on improving the performance, not on reducing the training data requirement, as they were not based on large language models. Even after utilizing type information, their performance is substantially lower than systems based on large language models such as BLINK and GENRE.

Furthermore, to the best of our knowledge, all of the existing systems that exploit entity types for entity linking task ignore the hierarchical structure of types. We hypothesize that exploiting the hierarchical structure of types can aid in the task of entity linking, especially when training with less data. A common strategy while training models with less training data is to apply a strong prior (arising from domain knowledge) on the parameters. The type hierarchy can be used as a prior and encoded into the model directly so that the model will not have to learn it from the very limited training data. We encode such a prior via ensuring the logical consistency (imposed by the hierarchy) of predicted entity types – *if a type is predicted, then its parent must also be predicted*. For this, we have developed a novel *neuro-symbolic* technique inspired from Gödel and Łukasiewicz norms (Klement et al., 2000).

The following are the contributions of this paper:

- We show BLINK exhibits diminishing returns (Fig. 1).
- By utilizing *diminishing returns behavior of BLINK*, we propose a solution, called *Neuro-symbolic entity Linking using Entities Type (NeSLET)*, for the zero shot entity linking problem in low training data regimes. NeSLET is a novel combination of techniques from a diverse set of fields namely multi-task learning, fuzzy

---

[3] https://twitter.com/riedelcastro/status/1256283045855969286

[4] In our experiments BLINK consistently outperforms GENRE by a significant margin in low data regimes.

logic, and hierarchical multi-label classification. NeSLET is trained on two tasks simultaneously - entity linking (primary task) and hierarchical entity type prediction (auxiliary task).

- We are the first ones to show that accounting for hierarchical structure of entity types improves entity linking as compared to treating it flat.
- For the scenarios where a ZEL model is given to us in the form of just black-box, we have proposed a neuro-symbolic inference algorithm that explicitly uses types just at inference time to improve the performance of given black-box.
- Our experiments on four benchmark datasets show that NeSLET beats both SOTA baselines (BLINK and GENRE) in multiple low-data regimes.

2 Related Works

Entity Linking (EL): Recently, the models (Wu et al., 2020; Cao et al., 2021) based on large language models such as BERT (Devlin et al., 2019) and BART (Lewis et al., 2020) have achieved SOTA results for the EL task. Table 1 slices the EL literature based on the flavor of underlying neural model (BERT or non-BERT) and variants of the EL task. Here, end-to-end EL means solving both mention detection and entity disambiguation tasks at the same time. BERT-based models require large training data and hence leads to poor generalizability in the case of cross-domain EL (aka ZEL) when training data is less. This motivated us to use auxiliary information about entity types. As shown in Table 1, previous works have used entity types to help the EL task. However, to the best of our knowledge, none of these approaches are designed to work in a low-data regime. Moreover, these approaches do not leverage intrinsic hierarchical structure of types and instead work with a flat hierarchy. Logeswaran et al. (2019) proposed an interesting dataset for ZEL based on the community portal (https://www.fandom.com). We, however, do not work with this dataset and related approaches (Tang et al., 2021) as it lacks entity type information.

Fine-grained Entity Typing (FET): FET (Ling and Weld, 2012; Gillick et al., 2014) is the task of assigning types from a semantic hierarchy to the entity mentions in text. FET is a *hierarchical multi-label classification (HMLC)* task and our auxiliary task is also an FET task. The popular datasets for FET, such as AIDA, BBN (Weischedel and Brunstein, 2005), OntoNotes (Gillick et al., 2014), FIGER (Ling and Weld, 2012), etc., come with shallow hierarchies (2 to 3 levels deep) compared to our DBpedia type hierarchy (7 levels deep). Ultra-Fine entity typing dataset (Choi et al., 2018) comes with around $10k$ types, but the types are not arranged in a hierarchy. There are also independent studies on the abstract HMLC problem (Giunchiglia and Lukasiewicz, 2020; Srivastava et al., 2020) without tying it to any application. The latest work on HMLC (Giunchiglia and Lukasiewicz, 2020) uses a loss function that is similar to our Gödel and Łukasiewicz t-norms (Klement et al., 2000).

Multi-task Learning (MTL): An MTL framework (Caruana, 1995) is often used to improve the performance on the primary task by learning a shared representation between the primary and one or more closely related auxiliary tasks. Learning a joint representation between related tasks helps in preventing over-fitting (Maurer, 2006), even when the amount of training data is less for each task. In our case, the primary task is *entity linking* and the auxiliary task is *entity type prediction*.

3 Problem Definition

The ZEL task is akin to a cross-domain classification task where entities play the role of classes. It has two distinct characteristics - (i) number of classes (in both source and target domain) could be in the order of millions, e.g., Wikipedia has more than 5 million entities, (ii) classes are not merely labels but have rich features in the form of short textual descriptions. Formally, in a ZEL task, we are given an entity set $\mathcal{E}_S$, called *seen* (aka *train*) entities. Each entity $e \in \mathcal{E}_S$ is seen during training in the form of a linked gold entity for some training mention m. We are also given another entity set $\mathcal{E}_U$, called *unseen* (aka *test*) entities, where $\mathcal{E}_S \cap \mathcal{E}_U = \emptyset$[5]. The element-level structure of these entity sets is as follows: $\mathcal{E}_S = \{(e_i, d_i)\}_{i=1}^{K}$ and $\mathcal{E}_U = \{(e_i, d_i)\}_{i=(K+1)}^{L}$, where e_i is the unique title of the entity and d_i is a short textual description of the entity. The train, validation, and test sets look as follows. $\mathcal{D}_{train}^{zel} = \{(m_i, e_i) \mid e_i \in \mathcal{E}_S\}_{i=1}^{N}$; $\mathcal{D}_{val}^{zel} = \{(m_j, e_j) \mid e_j \in \mathcal{E}_S\}_{j=1}^{V}$; $\mathcal{D}_{test}^{zel} = \{(m_k, e_k) \mid e_k \in \mathcal{E}_U\}_{k=1}^{M}$. In these datasets, the

---

[5] In an ideal ZEL task, for each of the test example, the corresponding linked gold entity comes from the set $\mathcal{E}_U$. However, in practice, for a small fraction of test examples, we have their linked gold entities coming from the set $\mathcal{E}_S$.

	with types	Jiang et al.	**This Paper**	

Table 1: Slicing the space of prior art on EL.

first part m_i (and m_j, m_k) corresponds to the input text string along with the entity mention substring marked. The second part e_i (and e_j, e_k) corresponds to the gold entity that must be linked to this mention. A standard practice is to represent m_i as the following tuple - *(left context, mention, right context)*. For the sentence *"She noticed a* **Jaguar** *speeding on the highway"*, we have $m_i =$ (*She noticed a*, *Jaguar*, *speeding on the highway*) and $e_i =$ `Jaguar_Cars` .

A typical model for ZEL task is a scoring function $f_{zel} : \mathcal{M} \times \mathcal{E} \mapsto \mathbb{R}$, here $\mathcal{E} = \mathcal{E}_S \cup \mathcal{E}_U$. For any given mention $m \in \mathcal{M}$, it induces a score for each entity $e \in \mathcal{E}$. The ZEL model uses these induced scores $f_{zel}(m, e)$ to rank all the entities and highest-scoring entity is predicted as the final answer. The performance of a ZEL model is measured via Hits@k for $k \geq 1$. Hits@k measures if the gold entity appears within the top-k elements. For $k = 1$, it is called *accuracy*.

3.1 Entity Type Prediction - Auxiliary Task

We use *entity type prediction (ETP)* as an auxiliary task. The goal behind ETP is to link an entity mention to one or more type classes from a given *entity type set* $\mathcal{T} = \{t_j\}_{j=1}^{|\mathcal{T}|}$. for e.g., in sentence *"She noticed a* **Jaguar** *speeding on the highway"*, the mention *Jaguar* is classified into *Organization* and *Company* classes as per DBpedia's (Lehmann et al., 2015) type classes hierarchy. Training data for such a task is given in the form of $\mathcal{D}_{train}^{type} = \{(m_i, \mathbf{t}_i)\}_{i=1}^{N}$ where $\mathbf{t}_i = [t_{ij}]_{j=1}^{|\mathcal{T}|}$ is a binary vector of size $|\mathcal{T}|$ where t_{ij} equals 1 if $t_j \in \mathcal{T}$ is a valid type for the corresponding gold entity e_i, and 0 otherwise. A typical model for the entity type prediction is given by $f_{type} : \mathcal{M} \times \mathcal{T} \mapsto [0, 1]$. For any given mention $m \in \mathcal{M}$, it induces a probability score for each type class $t_j \in \mathcal{T}$. That is, $p(t_j|m) = f_{type}(m, t_j)$, $\forall t_j \in \mathcal{T}$. The performance of the ETP task is measured via F_1 score computed over predicted type set and gold type set. We make a simplifying assumption that size of gold type set is known to us; this helps us avoid hassle of setting a threshold.

4 NeSLET

As mentioned earlier, NeSLET is an MTL-based neuro-symbolic approach where we use ETP as an auxiliary task and jointly learn it with the primary task of EL. Both the primary and auxiliary tasks are classification tasks for a given mention m except that: (i) the corresponding classes are different – entities for the primary task and types for the auxiliary task, and (ii) auxiliary task is a HMLC task. In our modeling, we make a simplified assumption that the probability of entity e being the gold entity of a mention m is conditionally independent of the probability of any type t_j being the valid type of the gold entity. In other words, $p(e, \mathbf{t} \mid m) = p(e \mid m) \cdot \prod_{j=1}^{|\mathcal{T}|} p(t_j \mid m)$, $\forall e, \mathbf{t}, m$.

Neural Model for $p(e \mid m)$: We use following models for $p(e \mid m)$ where, V_m and V_e are the vector representations of mention m and entity e, respectively.

$$p(e \mid m) = f_{zel}(m, e) = \frac{\exp(V_m^\top \cdot V_e)}{\sum_{e' \in \mathcal{E}} \exp(V_m^\top \cdot V_{e'})} \quad (1)$$

As shown in Figure 3, we use BERT to obtain vector representation for both mention m and the entity e (as described in Wu et al. (2020)). Parameters of these BERT models are denoted by θ_m and θ_e, respectively. Thus, we can say $V_m =$ mention-bert(m, θ_m) and $V_e =$ entity-bert(e, θ_e).

Neuro-symbolic Model for $p(t_j \mid m)$: In practice, KB's organize entity types in the form of a logical hierarchy as shown in Figure 2. In such a hierarchy, if we traverse along a path from leaf node to the root, e.g. *cat* → *mammal* → *animal*, the corresponding types become coarse grained. To ensure this logical consistency property of the type hierarchy, we require that our proposed model satisfies the following *path monotonicity* property.

[Path Monotonicity Property]: Let t_k be the parent node of t_j in the given type hierarchy. For any mention m, we must ensure that type probabilities predicted by our model satisfy the following monotonicity condition: $0 \leq p(t_j \mid m) \leq p(t_k \mid m) \leq 1$. We ensure this by exploiting Gödel or Łukasiewicz t-norm (Klement et al., 2000) used in the field of *fuzzy logic* (Klir and Yuan, 1995). As per these t-norms, if t_j is an internal node in the hierarchy then we compute its probability purely in a symbolic fashion by using the probabilities assigned to its children nodes. We use logical `OR` formula (given below) of the *Gödel* (equation 2a) or *Łukasiewicz* (equation 2b) t-norm for this purpose. $\mathcal{C}_{t_j}$ in these formulas denotes the set of children nodes for t_j.

$$p(t_j|m) = \begin{cases} \max_{t_k \in \mathcal{C}_{t_j}} \; p(t_k|m) & \text{(2a)} \\ \min\left\{1, \sum_{t_k \in \mathcal{C}_{t_j}} p(t_k|m)\right\} & \text{(2b)} \end{cases}$$

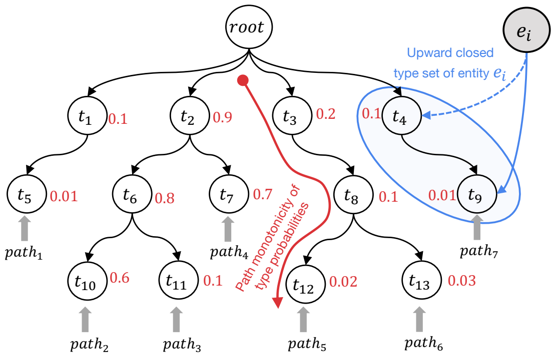

Figure 2: An illustration of type hierarchy and issue of path consistency during training.

For above model to work, we still need to address the issue of computing type probability for each leaf node t_j in the hierarchy. We achieve this via a neural model where we obtain vector representations V_{t_j} for each leaf node by using a *type network*. The *type network* comprises an initial embedding vector for each type class and an optional linear layer followed by non-linearity. The parameters of this type network are denoted by θ_t and hence, we have $V_{t_j} = \text{type-network}(t_j, \theta_t)$. Type probability of each leaf node is computed using:

$$p(t_j \mid m) = f_{type}(m, t_j) = \frac{1}{1 + \exp(-V_m^\top \cdot V_{t_j})} \quad (3)$$

Because of equations (4) and (3), we call this model as *neuro-symbolic*. While training the above model, we need to prepare our data so as to ensure a property called *upward closure of entity types*.

[Upward Closure of Entity Types]: If t_j is given to be a type of an entity e_i in a training example then all the nodes on the path from t_j till root must also be considered as its valid types. For e.g., suppose $\{t_9\}$ is given as a valid type for entity e_i as shown in Figure 2. Then, we must augment its type set by adding all the ancestor nodes of $\{t_9\}$. This results in $\{t_4, t_9\}$ as the upward closed type set for e_i.

Model Training: For training our model parameters θ_m, θ_e, and θ_t; we define loss ℓ_{zel} for the primary task and ℓ_{type} for the auxiliary task.

$$\ell_{zel}(\theta_m, \theta_e) = -\sum\nolimits_{(m_i, e_i) \in \mathcal{D}^{zel}_{train}} \log p(e_i|m_i)$$

$$\ell_{type}(\theta_m, \theta_t) = -\sum_{(m_i, e_i) \in \mathcal{D}^{zel}_{train}} \sum_{t_j \in \mathcal{T}} \mathbb{1}_{e_i}(t_j) \log p(t_j|m_i) + (1 - \mathbb{1}_{e_i}(t_j)) \log(1 - p(t_j|m_i))$$

where, $\mathbb{1}_{e_i}(t_j)$ is an indicator variable capturing whether t_j is a valid type of entity e_i or not. The loss function ℓ_{zel} is similar to the bi-encoder loss function used in BLINK (Wu et al., 2020). The combined loss for the two tasks is given by

$$\ell_{mtl}(\theta_m, \theta_e, \theta_t) = \ell_{zel}(\theta_m, \theta_e) + \alpha \; \ell_{type}(\theta_m, \theta_t)$$

where α is a hyperparameter.

Thus, learning of NeSLET involves solving the following optimization problem.

$$\theta_m^*, \theta_e^*, \theta_t^* = \underset{(\theta_m, \theta_e, \theta_t)}{\arg\min} \; \ell_{mtl}(\theta_m, \theta_e, \theta_t) \quad (4)$$

Observe, the parameter θ_m is common across both the tasks' loss terms. Due to this, both these tasks get tied together during training and the ETP task *induces a bias* in the hypothesis selection for the EL task. If there are multiple equally good EL hypotheses (i.e. model parameters θ_m and θ_e), the inductive bias forces model to pick an hypothesis that does well on the ETP task. Such inductive bias helps in better generalization for the EL task across new domain even when trained with the less data. We train EL and ETP tasks jointly using *hard parameter sharing* (Sun et al., 2020; Ruder, 2017) strategy. In this strategy, we train $\theta_m, \theta_e, \theta_t$ simultaneously. The backpropagation scheme for this scenario is depicted in Figure 3.

Inference: Given a mention m, the trained EL model is used to predict entities in a ranked order.

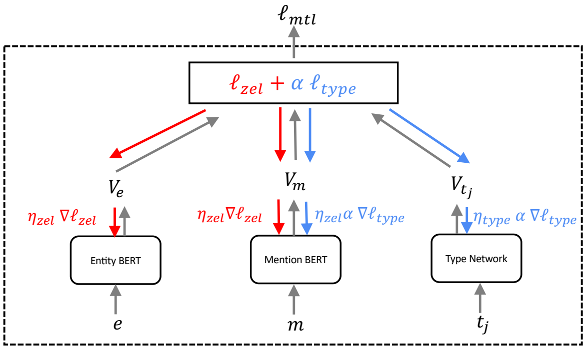

Figure 3: Training strategy with hard parameter sharing.

5 Experiments

Datasets and Type Hierarchy: Table 2 summarizes various benchmark datasets used in our experiments. We use *Wiki BLINK* (Wu et al., 2020) and *Wiki FGET* (Onoe and Durrett, 2020) as two different datasets for the training domain. Each of these datasets are based on Wikipedia. For the test domain, we use two benchmark datasets – *WikilinksNED UM* (NED for short) (Onoe, 2020; Onoe and Durrett, 2020) and *CoNLL-YAGO* (CoNLL for short) (Hoffart et al., 2011; Max Planck Institute for Informatics, 2013). For the Wiki FGET dataset, we have two variants available – one for each of the test domains. These two variants were prepared by the authors so as to ensure a good amount of entity types being covered between train and test domains where entity types were taken from Wikipedia categories. For each entity across all datasets, we use DBpedia (Lehmann et al., 2015) to get the entity types. DBpedia ontology (dbp, 2020) contains 769 types including root type *owl:Thing*. These types are arranged in a tree structure having 7 levels and 611 leaves.

Domain	Dataset	# Examples			# Unique Entities		
		Train	Val.	Test	Train	Val.	Test
Train	Wiki BLINK	9M	10K	–	1.49M	8.7K	–
	Wiki FGET (NED)	5.6M	3K	–	1.3M	2.8K	–
	Wiki FGET (CoNLL)	6M	5K	–	1.14M	4.5K	–
Test	NED	–	10K	10K	–	2.3K	2.5K
	CoNLL	–	4791	4485	–	1.6K	1.5K

Table 2: Datasets summary. For train (test) domain datasets, we have specified a dash (–) in its test (train) column as that set is never used. For the last row, the splits are as per Onoe and Durrett (2020).

Implementation Details: We used the BLINK source code from (Wu, 2020) as the base model and implemented NeSLET on top of it. The hyperparameters that we used closely follow BLINK. For both the mention and entity BERT models, we use the *bert-base-uncased* model. We use a batch size of 128, maximum context length of 64 (32 tokens on each side of the mention), and the maximum entity description length is set to 128. The learning rates are $\eta_{zel} = 10^{-5}$ and $\eta_{type} = 10^{-3}$. We use ADAM (Kingma and Ba, 2015) to optimize the objective. For BLINK and NeSLET models, we train each of them in two stages – first with *in-batch negative* entities, followed by *hard-negative* (Gillick et al., 2019) entities. We obtained the hard-negatives similar to Wu et al. (2020) by finding the top-10 predicted entities for each training example. These hard negatives are combined with the random in-batch negatives during training. We do not perform *hard negative mining* for the types because we use all the negatives types while computing ℓ_{type}. In both these stages, the number of training epochs is 30 for 0.01% and 0.1% data splits, and 4 for the 1% data splits. The best model is selected based on the source domain validation set accuracy which is computed after each epoch. We initialize the NeSLET model with the weights obtained by training BLINK on the corresponding training data splits ($0.01\%, 0.1\%$ and 1%). We use BERT to compute the initial embedding for types based on their names. The type loss weight, α, for each iteration is obtained using: $\alpha = \frac{2}{1+e^{-\gamma p}} - 1$ where, γ is set to 10 and $p \in [0, 1]$ is the training progress. In the NeSLET model, we use a weighted sum (learnt) of the CLS vectors from layer #5 to #11 of the mention BERT as the *mention representation* for the purpose of type prediction.

Computing Infrastructure: We trained our models on a single machine having 2 × 20 core POWER9 processors, 6×Nvidia Volta V100 GPUs with 32GB memory, and 512GB system RAM. A single training epoch for the NeSLET model on a train set of 900 samples takes 2 to 3 minutes.

Results: Table 3 summarizes our experimental results, where we have compared performance of NeSLET with two baselines – BLINK and GENRE (Cao et al., 2021). For training and inference of GENRE, we use the hyperparameters reported in (Cao et al., 2021) (more details given in Section B.4 of the appendix). The performance

Domain		Training Data %	Method						
Train	Test		GENRE	BLINK	NeSLET-G	NeSLET-L	NeSLET-F	Gain	Hierarchy Gain

Table 3: Performance of NeSLET compared to GENRE and BLINK on target domain's test set. NeSLET-G, NeSLET-L, and NeSLET-F correspond to the variants of NeSLET that use Gödel (G), Łukasiewicz (L) norms to exploit the type hierarchy, or, assume that the types are Flat (F) i.e, no hierarchy. The Gain column denotes the performance gain (in %) obtained by the best of NeSLET-G and NeSLET-L and NeSLET-F relative to the best of GENRE and BLINK. The Hierarchy Gain column denotes the performance gain (in %) obtained using the hierarchical structure of entity types and is calculated as the best of NeSLET-G and NeSLET-L relative to NeSLET-F.

numbers for NeSLET in Table 3 were reported using the models (hyperparameter configurations) that resulted in the best performance on the source domain's validation set. In all of our experiments, BLINK performed better than GENRE in low training data regimes. The detailed performance numbers for validation and test sets across tuning ranges of various hyperparameters are captured in Tables 16, 17, and 18 of the appendix. These tables also capture the performance on the auxiliary task. Table 10 of the appendix shows the performance saturation trend for BLINK beyond 1% training data. We have captured the statistics related to leakage of entities and mentions in Tables 6, 7, and 8 of the appendix.

Domain		Method	
Train	Test	BLINK (100%)	NeSLET (1%)
Wiki BLINK	NED	**71.7**	70.0
	CoNLL	71.5	**75.2**
Wiki FGET	NED	67.7	**69.2**
	CoNLL	74.4	**75.1**

Table 4: Comparing the accuracy of BLINK trained on 100% data and NeSLET trained on 1% data.

Insights: In Table 3, we see that NeSLET outperforms the baselines in all twelve training and test domain combinations (2 training datasets x 2 test sets x 3 training data percentages). These results validate our claim that learning entity linking and entity type prediction in a multi-task learning fashion leads to improved performance on entity linking in low training data regimes. This characteristic is beneficial for real-world applications, where acquiring training data is quite expensive. From Table 3, we can see that the variants of NeSLET that exploit the type hierarchy using Gödel and Łukasiewicz norms (NeSLET-G and NeSLET-L) outperform NeSLET-F (which ignores the type hierarchy) in nine out of the twelve experiments. It shows that exploiting type hierarchy boosts the entity linking accuracy most times. The experiments in Table 3 also suggest that one fuzzy logic operator need not perform the best on all domains. The choice of these operators can be considered as a hyperparameter. In Table 4, we compare the accuracy of BLINK trained on 100% data with NeSLET trained on 1% data. For the purpose of this study, we consider the version of NeSLET (Gödel, Łukasiewicz or Flat) that achieves the highest accuracy on the given combination of train and test datasets. NeSLET trained on 1% data outperforms BLINK trained on 100% data in three out of the four experiments. NeSLET not only manages to recover the accuracy that BLINK loses due to the reduction in training data size, but also goes beyond. The positive transfer of knowledge from the auxiliary task of entity type prediction to the primary task of entity linking enables NeSLET to outperform the baselines in low data regimes.

6 What if ZEL Model is a Black-Box?

Note that NeSLET model exploits entity type information only at the time of training a ZEL model (BLINK in this case). However, what if the ZEL model is available only as a black-box? For such a scenario, which is quite plausible in practice, it is not possible to train NeSLET like models that exploit entity types. To address this, we propose a neuro-symbolic inference Algorithm 1 that leverages entity type information only at inference time and thereby improves the performance of the given black-box ZEL model. Algorithm 1 assumes access to two black-box models - one for ZEL task and other for entity types prediction. Both of these models may be trained on separate datasets and made available as pre-trained black-box models. Algorithm 1 uses the types model to re-rank entities outputted by the ZEL model.

Algorithm 1: Type-based Inference

```
For a given $m_{test}$, pick a set $\mathcal{S}$ of top-$k$
    entities from $\mathcal{E}$ using the *zel* score
    $S_{zel}(e \mid m_{test}) = p(e \mid m_{test};\ \theta_m^{zel^*}, \theta_e^*)$;
For each entity $e \in \mathcal{S}$, compute *type based*
    ranking score by $S_{type}(e \mid m_{test}) =$
    $\sum_{t_j \in \mathcal{T}} \mathbb{1}_e(t_j) \cdot p(t_j \mid m_{test};\ \theta_m^{type^*}, \theta_t^*)$;
For each entity $e \in \mathcal{S}$, compute a *total*
    ranking score given by
    $S_{total} = (\beta_{zel} \cdot S_{zel}) + (\beta_{type} \cdot S_{type}) +$
    $(\beta_{both} \cdot S_{zel} \cdot S_{type})$ where,
    $0 \le \beta_{zel}, \beta_{type}, \beta_{both}$ are weights of
    different terms and act as hyperparameters;
Output the entity with highest joint score.
```

When $\beta_{zel} = 1, \beta_{type} = \beta_{both} = 0$, Algorithm 1 gets simplified to the inference strategy of the ZEL model. The inference strategy of Algorithm 1 runs into a problem if types are arranged in a hierarchy. Consider two entities e_1 and e_2. After type augmentation, suppose valid type sets of e_1 and e_2 are given by the paths $root \rightarrow t_2 \rightarrow t_6$ and $root \rightarrow t_2 \rightarrow t_6 \rightarrow t_{10}$, respectively, in type hierarchy of Figure 2. In this case, the *type-based* score $S_{type}(\cdot)$ will always score e_2 higher than e_1. Thus, it has a bias in terms of preferring the entities having deeper penetration in the hierarchy. If we modify the formula $S_{type}(\cdot)$ and divide it by the *path length* then also it will be problematic as it will now favor shallow paths. To mitigate this bias, we suggest following revision in this formula: $\tilde{S}_{type}(e \mid m_{test}) = \sum_{path_j} p(path_j \mid m_{test}) \cdot p(path_j \mid e)$ where, sum is taken over all the *paths from root till leaves* in the type hierarchy (see Figure 2). For each such path, $p(path_j \mid m_{test})$ denotes predicted probability for mention's type being the leaf node on that path. The entity's path probability $p(path_j \mid e)$ depends on whether $path_j$ contains any valid type of e. Details of computing $p(path_j \mid e)$ are given in Section B.6 of the appendix.

Hierarchy Pruning: Computation of $p(path_j \mid e)$ involves estimating prior probability $p(t_b|t_a)$ of an entity having finer type t_b given it has a coarse type t_a (parent of t_b). If t_b is too fine-grained, we do not have enough data to reliably estimate $p(t_b|t_a)$. To mitigate such data sparsity issues, we consider only top-k levels of the hierarchy from the root and restrict all the calculations on these types (see Figure 2). Our experiments show strong evidence that pruning improves the performance.

Results: Table 5 shows the performance gain obtained by using type-based inference on top of the NeSLET-L model (treated as black-box). There are two hyperparameters in Algorithm 1 – top-k entities return by ZEL model, and pruning level of the type hierarchy. The values and tuning ranges of these hyperparameters are given in Table 9 of the appendix. The detailed performance numbers are given in Tables 16, 17, and 18 of the appendix. Anecdotal examples given in Tables 11 and 12 show how our inference scheme pushes the gold entity to Rank-1 which otherwise lies at Rank-2 in ZEL model's prediction. Also, in few cases, our type-based inference pushes down the correct prediction from Rank-1 position. Two such examples are given in Tables 13 and 14 of appendix.

Domain		Method

	CoNLL	75.06	**75.39**

Table 5: Accuracy boost for ZEL black-box model (NeSLET-L trained on 1% data) when applied type inference (NeSLET-LT).

7 Conclusions

We have developed a multi-task approach called NeSLET wherein one can leverage the auxiliary domain knowledge about entity types so as to improve the performance on zero-shot entity linking task, beyond what SOTA methods such as BLINK and GENRE offer, in an extremely low training data regime. We believe, this research opens up an avenue for such deep learning based methods to be tried in real applications where training examples are very less. The future directions include exploring other architectures and learning schemes to train our hard parameter sharing model. Design of newer auxiliary tasks based on self-supervision is another potential direction.

8 Ethical Considerations

Any ZEL technique, like ours, that advances the SOTA with less training data is a boon for applications such as KB question answering, document understanding, dialogue systems, etc. Our solution, however, comes with its own limitations and risks as follows. 1) Our assumption of entity types coming from the same hierarchy for both train and test domains is not always true in practice. Moreover, if there is no entity type information available in the first place, then our approach can not even be used. 2) The sensitivity of our predictions with respect to mild perturbation in input text could be a risk factor while deploying it in real-life applications. It warrants a rigorous study that we leave as future work.

We use publicly available datasets for training and testing our models. The Wiki BLINK and CoNLL-YAGO datasets are available under the MIT and CC-BY-3.0 licenses respectively. For the other datasets mentioned in Table 2, we obtained permissions from the authors (Onoe and Durrett, 2020) as the license was not explicitly mentioned on their Github. All of these datasets were constructed using publicly available sources such as Wikipedia for the purpose of developing entity linking systems and they are being used as intended. We believe these datasets do not contain any information that is offensive or uniquely identifies any individual.

Acknowledgments

We would like to thank the entire team from the IBM Research AI Hardware Center and the Center for Computational Innovation at Rensselaer Polytechnic Institute for computational resources on the AiMOS Supercomputer. We conducted most of our experiments on the AiMOS computing platform. We would also like to acknowledge IBM Cognitive Computing Cluster (CCC) for providing resources to carry out various experiments.

A Leakage Analysis for Entity and Mention

Tables 6, 7, and 8 show the percentage of test examples in our benchmark datasets whose gold entities (e), mentions (m), entity and mention pairs (e, m) were seen during training, respectively.

B Experiments

B.1 Type-based Inference Hyperparameters

Table 9 shows hyperparameters and their tuning ranges related to our proposed type-based inference Algorithm 1. Initially, we tuned these hyperparameters on the source domain's validation set, but that did not result in any performance gain. The reason could be a significant difference in the source and target domain's data distributions. To explore further, we tuned these hyperparameters on the target domain's validation set and obtained a boost in entity linking performance. Improving the type-based inference algorithm to obtain gains by tuning on the source domain alone is a direction of future work.

B.2 BLINK Accuracy

Table 10 shows BLINK's bi-encoder accuracy with varying level of training set size. This serves as a key baseline for our results.

B.3 Anecdotal Examples

Tables 11 and 12 show anecdotal examples where, NeSLET model predicts the gold entity at Rank-2 but, our proposed type-based inference corrects the prediction of NeSLET by promoting it to Rank-1 during inference time. Tables 13 and 14, on the other hand, show anecdotal examples where type-based inference makes the prediction of the ZEL model incorrect. However, at an aggregate level, our type-based inference overall improves ZEL performance. Here the type model comes from NeSLETwith the Łukasiewicz norm.

B.4 GENRE Experiment Details

GENRE (Cao et al., 2021) is a SOTA entity linking system based on BART (Lewis et al., 2020). Given an input mention m to GENRE, it autoregressively generates an entity name e. We initialized BART weights with pre-trained BART from (Lewis et al., 2020) and fine-tuned it on *Wiki BLINK* (Wu et al., 2020) and *Wiki FGET* (Onoe and Durrett, 2020) datasets for different training data splits ($0.01\%, 0.1\%$ and 1%). We used the hyperparameters reported in (Cao et al., 2021) and the training script available at `https://github.com/facebookresearch/GENRE` for training GENRE. For different training data splits, we used different numbers of training update steps as reported in Table 15. We selected the model using test domain's validation set. For inference, we used the same hyperparameters as used by (Cao et al., 2021) for the entity disambiguation task. We have constructed a trie (Cormen et al., 2009) using BLINK's $5.9M$ entities set to perform constrained decoding at the inference time.

B.5 Comparison of NeSLET vs. BLINK

Tables 16, 17, and 18 show detailed comparison of NeSLET with BLINK when both are trained with 0.01%, 0.1%, and 1% of training data splits. The ETP F_1 is the performance of the auxiliary ETP task. Different rows capture variations in train/test domain datasets as well as key hyperparameters for NeSLET. 'Flat' loss means treating the type hierarchy as flat. Column $\boldsymbol{\beta}$ corresponds to the values for $(\beta_{zel}, \beta_{type}, \beta_{both})$. The NeSLET accuracy when inferred w/o types corresponds to the case $\beta_{zel} = 1, \beta_{type} = \beta_{both} = 0$. For each row, the NeSLET performance w/ types is taken for the combination of 'Tree Level', 'top-k', and $\boldsymbol{\beta}$ that resulted in the best NeSLET performance on test domain's validation set.

B.6 Entity Path Probability $p(path_j \mid e)$

The entity's path probability $p(path_j \mid e)$ is computed as follows.

1. $p(path_j \mid e) \leftarrow 0$ if leaf node of $path_j$ is not reachable from any valid type of e. For example, in Figure 2), we would be having $p(path_j \mid e_i) = 0, \; \forall j = 1 \rightarrow 6$.

2. $p(path_j \mid e) \leftarrow 0$ if leaf node of $path_j$ is reachable from some valid type (say t_k) of e but a direct child of t_k not lying on the $path_j$ is also a valid type for e. For e.g., in Figure 2, imagine node t_4 having one more child called t_{14} and the corresponding path being $path_8$. Then, we would be having $p(path_8 \mid e_i) = 0$.

3. For each of the remaining $path_j$, let t_k be the deepest node which is also a valid type of e. Traverse the lower portion of $path_j$ starting from node t_k all the way up to leaf node and multiply *conditional probabilities* of the edges on the way to get $p(path_j \mid e)$ as follows: $p(path_j \mid e) = \prod_{(b,a) \in path_j, b \text{ is descendant of } t_k} p(t_b \mid t_a)$. We approximate the conditional probabilities $p(t_b \mid t_a)$ with prior probabilities from the given dataset about entities and the corresponding type set.

GRAPHCACHE: Message Passing as Caching for Sentence-Level Relation Extraction

Abstract

Entity types and **textual context** are essential properties for sentence-level relation extraction (RE). Existing work only encodes these properties within individual instances, which limits the performance of RE given the insufficient features in a single sentence. In contrast, we model these properties from the whole dataset and use the dataset-level information to enrich the semantics of every instance. We propose the GRAPHCACHE (**Graph Neural Network as Caching**) module, that propagates the features across sentences to learn better representations for RE. GRAPHCACHE aggregates the features from sentences in the whole dataset to learn **global** representations of properties, and use them to augment the **local** features within individual sentences. The global property features act as dataset-level prior knowledge for RE, and a complement to the sentence-level features. Inspired by the classical caching technique in computer systems, we develop GRAPHCACHE to update the property representations in an online manner. Overall, GRAPHCACHE yields significant effectiveness gains on RE and enables efficient message passing across all sentences in the dataset.

1 Introduction

Sentence-level relation extraction (RE) aims at identifying the relationship between two entities mentioned in a sentence. RE is crucial to the structural perception of human language, and also benefits many NLP applications such as automated knowledge base construction (Distiawan et al., 2019), event understanding (Wang et al., 2020a), discourse understanding (Yu et al., 2020), and question answering (Zhao et al., 2020). The modern tools of choice for RE are the large-scale pretrained language models (PLMs) that are used to encode individual sentences, therefore obtaining the sentence-level representations (Liu et al., 2019; Joshi et al., 2020; Yamada et al., 2020).

Existing work considers **entity types** and **textual context** as essential **properties** for RE (Peng et al., 2020; Peters et al., 2019; Zhou and Chen, 2021). Nonetheless, most existing RE models only capture these properties *locally* within individual instances, while not *globally* modeling them from the whole dataset. Given the insufficient features of a single sentence, it is beneficial to model these properties from the whole dataset and use them to enrich the semantics of individual instances.

To overcome the aforementioned limitation, we propose to mine the entity and contextual information beyond individual instances so as to further improve the relation representations. Particularly, we first construct a heterogeneous graph to connect the instances sharing common properties for RE. This graph includes the sentences and *property caches*. Each cache represents a property of entity types or contextual topics. We connect every sentence to the corresponding property caches (see Fig. 1), and perform message passing over edges based on a graph neural network (GNN). In this way, the property caches aggregate the features from connected sentences, which will act as a complement to the sentence-level features and provide prior knowledge when identifying relations.

The constructed graph connecting sentences has the same scale as the whole dataset, which leads to high computational complexity of the GNN. To address this issue, our idea is to view the message passing of GNNs as data loading in computer systems, adapting the classical caching techniques to efficiently mining the property information from all sentences. We encapsulate this computational idea in a new GNN module, called GRAPHCACHE (**Graph Neural Network as Caching**), that uses an online updating strategy to refresh the property caches' representations. In addition, we design an attention-based global-local fusion module to augment the sentence-level representations using the property caches with adaptive weights.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1698 - 1708
July 10-15, 2022 ©2022 Association for Computational Linguistics

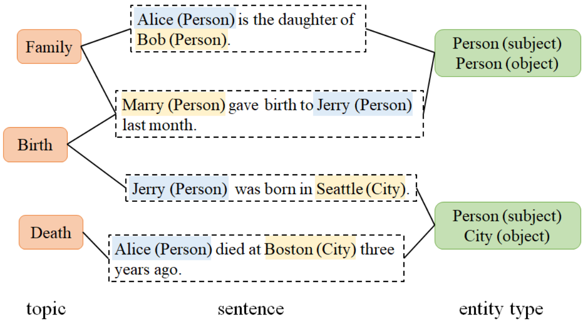

Figure 1: We construct a heterogeneous graph to connect the sentences sharing common properties for RE. We consider two kinds of properties: contextual topics and entity types.

GRAPHCACHE can be incorporated into popular RE models to improve their effectiveness without increasing their time complexity, as analyzed in theory (§3.2). As far as we know, ours is the first work to propagate the features across instances to enrich the semantics for sentence-level RE. We evaluate GRAPHCACHE on three public RE benchmarks including TACRED (Zhang et al., 2017), SemEval-2010 task 8 (Hendrickx et al., 2019), and TACREV (Alt et al., 2020a). Empirical results show that GRAPHCACHE consistently improves the effectiveness of popular RE models by a significant margin and propagates features between all sentences in an efficient manner.

2 Related Work

Sentence-Level Relation Extraction. Early research efforts (Zeng et al., 2014; Wang et al., 2016; Zhang et al., 2017) train RE models from scratch based on lexicon-level features. Recent work has shifted to fine-tuning pretrained language models (PLMs; Devlin et al. 2019; Liu et al. 2019) resulting in better performance. For example, BERT-MTB (Baldini Soares et al., 2019) continually fine-tunes the PLM with a matching-the-blanks objective that decides whether two sentences share the same entity. SpanBERT (Joshi et al., 2020) pre-trains a masked language model on random contiguous spans to learn span-boundaries and predict the entire masked span. LUKE (Yamada et al., 2020) extends the PLM's vocabulary with entities from Wikipedia and proposes an entity-aware self-attention mechanism. K-Adapter (Wang et al., 2020b) fixes the parameters of the PLM and uses feature adapters to infuse factual and linguistic knowledge. Despite their effectiveness, most existing work on sentence-level RE exploits the entity information and context within only an individual instance, while we propose to globally capture the semantic information from the whole dataset to augment the relation representations. Our model can be flexibly plugged into existing RE models and improve their effectiveness without increasing the time complexity.

Graph Neural Networks for Natural Language Processing. Due to the large body of work on applying GNNs to NLP, we refer readers to a recent survey (Wu et al., 2021) for a general review. GNNs have been explored in several NLP tasks such as semantic role labeling (Marcheggiani and Titov, 2017), machine translation (Bastings et al., 2017), and text classification (Henaff et al., 2015; Defferrard et al., 2016; Kipf and Welling, 2016; Peng et al., 2018; Yao et al., 2019). GNNs have also been widely adopted in various variants of relation extraction on the sentence level, (Zhang et al., 2018; Zhu et al., 2019; Guo et al., 2019a), the document level (Sahu et al., 2019; Christopoulou et al., 2019; Nan et al., 2020; Zeng et al., 2020), and the dialogue level (Xue et al., 2021). However, on the sentence-level relation extraction, most existing work (Zhang et al., 2018; Guo et al., 2019b; Wu et al., 2019) uses the graph neural networks to encode the relation representations from individual instances instead of operating the message passing between instances. In contrast, we build a heterogeneous graph to connect the instances that share the properties for RE, and design the caching updater to efficiently perform the message passing between instances.

3 Methodology

Task Definition. Sentence-level relation extraction (RE) aims to identify the relation between a pair of entities in a sentence. In this task, each instance is composed of a sentence, the subject and object entities, and entity types. For example, in the sentence *'Mary gave birth to Jerry at the age of 21.'*[1], *'Mary'* and *'Jerry'* are the entities, the entity types are both *person*, and the ground-truth relation between *'Jerry'* and *'Mary'* is *parent*.

We propose GRAPHCACHE (Graph Neural Networks as Caching) as a message passing methodology to model the dataset-level property repre-

---

[1] We use underline and wavy line to denote subject and object respectively by default.

sentations and use them to enrich every instance's semantics. GRAPHCACHE creates a graph representation where sentences with shared property information are connected with property caches. GRAPHCACHE first models the global semantic information by aggregating the features from the whole dataset, and then fuses the global and local features to augment the relational representations for every sentence.

We analogize the message passing in GNNs to caching in computer systems. Caching is about loading data from high volume disks to low volume caches, so as to accelerate data loading. Analogously, when GNNs perform the message passing between sentences through a smaller number of bridge nodes, we can think of the massive sentences in the dataset as the disk data, and the properties, which aggregates the features from sentences, as caches. GRAPHCACHE can be flexibly plugged into existing RE models. As far as we know, ours is the first work to propagate the features between instances to enrich the semantics for RE. GRAPHCACHE takes an existing RE model as the backbone, e.g., BERT, and takes the sentence-level representations given by the backbone as the inputs of message passing.

A GRAPHCACHE module consists of three key components: (i) *A graph construction technique* builds a few property caches. Each cache represents a property for RE: entity type or contextual topic. We connect each sentence to its corresponding properties, so that every property aggregates the features from its neighbor sentences. (ii) *Caching message passing* aggregates the sentence-level representations to model the properties' representations in an online manner. (iii) *Global-local fusion* fuses the global property representations and local sentence-level ones to augment the relation representations. Next, we will discuss the three main components in more detail.

3.1 Graph Construction for Sentence-level Relation Extraction

We build a large and heterogeneous graph to connect the sentences sharing the properties: **entity types** and **textual context**, which are essential for RE (Peng et al., 2020; Peters et al., 2019; Zhou and Chen, 2021). The heterogeneous graph is defined as $G = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ is the set of nodes, and $\mathcal{E}$ is the set of edges. $\mathcal{V} = \mathcal{V}_S \cup \mathcal{V}_P$, where $\mathcal{V}_S$ is the set of sentences, and $\mathcal{V}_P = \mathcal{V}_C \cup \mathcal{V}_E$ is the property caches. Here $\mathcal{V}_C$ is the set of latent topics (Zeng et al., 2018) mined from the latent topics from the text corpus using LDA (Blei et al., 2003), which has been found effective in modeling useful contextual patterns (Jelodar et al., 2019). Each topic is represented by a probability distribution over the words, and we assign each sentence to the top P topics with the largest probabilities. $\mathcal{V}_E$ is the set of entity types, where every cache represents the types of an entity pair. The entity types are also crucial for predicting relations (Peng et al., 2020; Zhou and Chen, 2021). An edge $(p, s) \in \mathcal{E}$ exists if the sentence $s \in \mathcal{V}_S$ has the property $p \in \mathcal{V}_P$.

We will implement a GNN on this graph. Specifically, to incorporate the global property information into relation extraction, the property caches aggregates the features from the connected neighboring sentences. This step enables property caches to globally model the properties from the whole dataset. We then use the global property representations from the caches to enrich every sentence's semantics. In this way, the property caches act as prior knowledge when identifying relations and provide each sentence with more representative features.

3.2 Caching Message Passing

We take an existing RE model as the backbone, e.g., BERT (Devlin et al., 2019), which produces the sentence-level representation as $\mathbf{h}_s$. Next, we deploy a two-layer GNN on our heterogeneous graph for message passing across sentences. Specifically, the first GNN layer aggregates the sentence-level representations to property caches at the tth training step:

$$\begin{aligned} \bar{\mathbf{h}}_p(t) &= \mathrm{MEAN}\left(\{\mathbf{h}_s(t), s \in \mathcal{N}(p)\}\right), \\ \mathbf{h}_p(t) &= \mathrm{FFN}\left(\bar{\mathbf{h}}_p(t)\right), \end{aligned} \tag{1}$$

where $p \in \mathcal{V}_P$ is a property, $s \in \mathcal{N}(p)$ is a sentence having property p, $\mathrm{MEAN}(\cdot)$ is the mean aggregator (Hamilton et al., 2017), and $\mathrm{FFN}(\cdot)$ is the feed-forward network. $\mathrm{FFN}(\cdot)$ can be a linear layer in SGC (Wu et al., 2019), a linear layer followed by a nonlinear activation function in GraphSAGE (Hamilton et al., 2017), or a multi-layer perception in GIN (Xu et al., 2018), etc. We follow SGC (Wu et al., 2019) to implement $\mathrm{FFN}(\cdot)$ by default. For each property p, this layer aggregates the sentence-level representations $\mathbf{h}_s(t)$ from $s \in \mathcal{N}(p)$ to obtain a global property embedding $\mathbf{h}_p(t)$. In this way, the generalized context of each

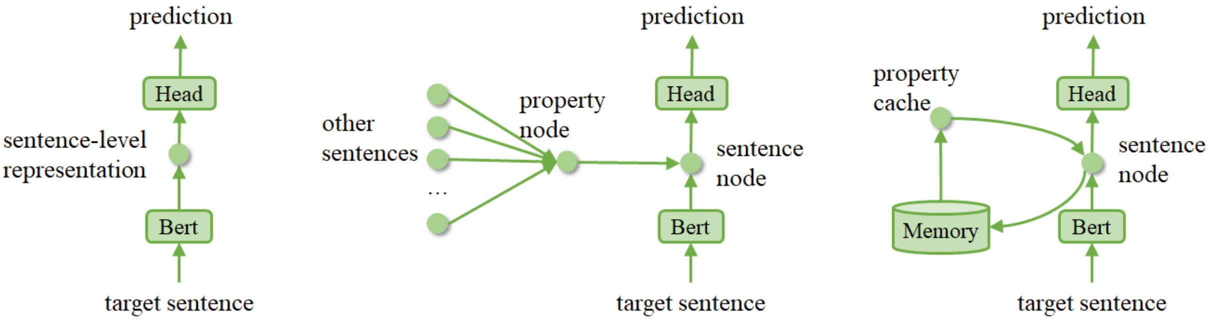

Figure 2: (left) Existing models encode individual instances for RE. (middle) In standard GNNs (Kipf and Welling, 2016), we predict for an instance by aggregating the features from many other sentences in the dataset, leading to high time complexity. (right) Our GRAPHCACHE implements a caching updater (see Eq. 2) to update the properties' representations in an online manner, which significantly reduces the time complexity.

Algorithm 1 GRAPHCACHE for Relation Extraction

Input: The number of training steps T, the dataset $\mathcal{D} = \{se_s, r_s | s = 1, 2, \ldots, N\}$, where se_s, r_s are the sentence and relation of the sth instance, our graph G defined in §3.1, and the batch size B.
Output: The model's trained parameters.

```
Initialize the model's parameters as random values, and initialize the values of memory $\mathcal{M}$ and property caches $\hat{\mathbf{h}}_p(t)$ as zero.
for $t \leftarrow 1$ to $T$ do
    Sample a batch $\mathcal{B}(t)$ from $\mathcal{D}$.
    for $s$ in $\mathcal{B}(t)$ do
        $\mathbf{h}_s(t) \leftarrow \text{Backbone}(se_s)$
    end for
    for $p$ in $\mathcal{V}_p$ do
        Update $\hat{\mathbf{h}}_p(t)$ as Eq. 2.
        $\mathbf{h}_p(t) \leftarrow \text{FFN}(\hat{\mathbf{h}}_p(t))$ as Eq. 1.
    end for
    for $s$ in $\mathcal{B}(t)$ do
        Update $\hat{r}_s(t)$ as Eq. 7.
        $\mathcal{M}[s] \leftarrow \mathbf{h}_s(t)$.
    end for
    Back-propagate to update the parameters by minimizing the cross entropy loss between $\hat{r}_s(t)$ and $r_i$ of instances in $\mathcal{B}$.
end for
```

property is captured from the whole dataset, which is further used to enhance the relation representations for each sentence in the second GNN layer. We describe the details of the second GNN layer in §3.3.

Recall our heterogeneous graph for RE defined in §3.1. At each training step, classical GNNs perform message passing across edges between the sentences and properties. In this case, the time complexity of the first GNN layer at each training step is $|\mathcal{E}|$. Note that $|\mathcal{E}|$ is larger than $|V_s|$, which is the number of sentences in the dataset. This leads to poor scalability of GNN, since $|V_s|$ is large in practice.

To address this efficiency issue, we propose Caching GNN for RE in Alg. 1. Our GRAPHCACHE implements a memory dictionary $\mathcal{M}$ to store the sentence-level representations from the backbone. To keep consistency with the updating parameters during training, we deploy a caching updater to refresh the properties' representations at each training step:

$$\begin{aligned}&\hat{\mathbf{h}}_p(t)\\ =&\text{Updater}(\hat{\mathbf{h}}_p(t-1), \{\mathbf{h}_s(t), s \in \mathcal{B}(t)\})\\ =&\hat{\mathbf{h}}_p(t-1) + \sum_{s \in \mathcal{N}(p) \cap \mathcal{B}(t)} \frac{\mathbf{h}_s(t) - \mathcal{M}[s]}{|\mathcal{N}(p)|},\end{aligned} \tag{2}$$

where $\mathcal{B}(t)$ denotes the batch at the tth training step. By doing so, GRAPHCACHE greatly reduces the time complexity from $|\mathcal{E}|$ to $|\mathcal{B}(t)|$ at each training step by using Updater to obtain the property caches' representations $\hat{\mathbf{h}}_p(t)$.

Our caching updater is much more efficient than the classical message passing of GNNs, since $|\mathcal{B}(t)| \ll |V_s| < |\mathcal{E}|$ generally holds in practice. When we aggregate the sentence-level representations from $\mathcal{M}$, we provide the following proposition to show that our cache updater is as effective as the first GNN layer in Eq. 1.

Proposition 1. *At the tth training step, denote the property caches' representations in the first GNN layer (see Eq. 1) as $\bar{\mathbf{h}}_p(t)$, and those returned by* *our updater in Eq. 2 as* $\hat{\mathbf{h}}_p(t)$. *There is* $\hat{\mathbf{h}}_p(t) = \bar{\mathbf{h}}_p(t)$ *for* $\forall p \in \mathcal{V}_P, t > 0$.

Proof. When $t > 1$, if $\hat{\mathbf{h}}_p(t-1) = \bar{\mathbf{h}}_p(t-1)$, we have:

$$\hat{\mathbf{h}}_p(t)$$

$$=\text{Updater}(\hat{\mathbf{h}}_p(t-1), \{\mathbf{h}_s(t), s \in \mathcal{B}(t)\}) \tag{3}$$

$$=\hat{\mathbf{h}}_p(t-1) + \sum_{s \in \mathcal{N}(p) \cap \mathcal{B}(t)} \frac{\mathbf{h}_s(t) - \mathcal{M}[s]}{|\mathcal{N}(p)|}$$

$$= \sum_{s \in \mathcal{N}(p)} \frac{\mathcal{M}[s]}{|\mathcal{N}(p)|} + \sum_{s \in \mathcal{N}(p) \cap \mathcal{B}(t)} \frac{\mathbf{h}_s(t) - \mathcal{M}[s]}{|\mathcal{N}(p)|} \tag{4}$$

$$= \sum_{s \in \mathcal{N}(p) \setminus \mathcal{B}(t)} \frac{\mathcal{M}[s]}{|\mathcal{N}(p)|} + \sum_{s \in \mathcal{N}(p) \cap \mathcal{B}(t)} \frac{\mathbf{h}_s(t)}{|\mathcal{N}(p)|} \tag{5}$$

$$=\bar{\mathbf{h}}_p(t). \tag{6}$$

Besides, because $\hat{\mathbf{h}}_p(0) = \bar{\mathbf{h}}_p(0)$ for $\forall p \in \mathcal{V}_P$ holds as initialized in Alg. Alg. 1, we have $\hat{\mathbf{h}}_p(t) = \bar{\mathbf{h}}_p(t)$ for $\forall p \in \mathcal{V}_P, t > 0$. □

3.3 Global-Local Fusion

In the second GNN layer, we propagate the properties' representations from the property cache to their neighboring sentences in the batch. Since a sentence s may have more than one latent topic $|\mathcal{V}_C \cap \mathcal{N}(i)| > 1$, we utilize the attention mechanism to enable the target sentence to attend to different topics with adaptive weights.

$$\mathbf{h}_s^{topic}(t) = \text{Attention}(\mathbf{h}_s(t), \{\mathbf{h}_p(t), p \in \mathcal{V}_C\}),$$

where we follow (Vaswani et al., 2017) to implement Attention. The output $\mathbf{h}_s^{topic}(t)$ is the topic embedding fused for sentence s. In this way, a sentence can be trained to attend to more relevant topics with higher weights.

Next, we have the entity type embedding of sentence s as $\mathbf{h}_s^{entity}(t) = \mathbf{h}_p(t), p \in \mathcal{V}_E \cap \mathcal{N}(s)$, where $p \in \mathcal{V}_E \cap \mathcal{N}(s)$ is the entity type node connected to sentence s. $\mathbf{h}_s^{topic}(t)$ and $\mathbf{h}_s^{entity}(t)$ are the global representations of the properties related to sentence s, while $\mathbf{h}_s$ is the local representation of sentence s. We fuse the global and local representations to enrich the semantics of sentence s through a sentence-wise head:

$$\hat{r}_i(t) = \text{Head}\left(\mathbf{h}_s(t) \| \mathbf{h}_s^{topic}(t) \| \mathbf{h}_s^{entity}(t)\right), \tag{7}$$

where $\|$ denotes concatenation. GRAPHCACHE makes sentence-wise relation predictions $\hat{r}_i(t)$ using a sentence-wise Head, implemented as a multilayer perception (MLP), analogous to a PointNet (Qi et al., 2017). Since GRAPHCACHE predicts a relation label for each sentence, it can be trained by standard task-specific classification losses, e.g., cross-entropy (Mannor et al., 2005). During inference, we take $\hat{r}_i(t)$ after convergence as the output for RE.

Dataset	#Train	#Dev	#Test	#Classes
TACRED	68,124	22,631	15,509	42
SemEval	6,507	1,493	2,717	19
TACREV	68,124	22,631	15,509	42

Table 1: Statistics of datasets.

4 Experiments

In this section, we evaluate the effectiveness of our GRAPHCACHE method when incorporated into various RE models. We compare our methods against a variety of strong baselines on the task of sentence-level RE. We closely follow the experimental setting of the previous work (Zhang et al., 2017; Zhou and Chen, 2021; Zhang et al., 2018) to ensure a fair comparison, as detailed below.

4.1 Experimental Settings

Datasets. We use the standard sentence-level RE datasets: TACRED (Zhang et al., 2017), SemEval-2010 Task 8 (Hendrickx et al., 2019), and TACREV (Alt et al., 2020b) for evaluation. TACRED contains over 106k mention pairs drawn from the yearly TAC KBP challenge. SemEval does not provide entity type annotations, for which we only construct the topic caches for message passing. Alt et al. (2020b) relabeled the development and test sets of TACRED to build TACREV. The statistics of these datasets are shown in Tab. 1. We follow (Zhang et al., 2017) to use F1-micro as the evaluation metric.

Compared Methods. We compare GRAPHCACHE with the following state-of-the-art RE models: (1) **PA-LSTM** (Zhang et al., 2017) extends the bi-directional LSTM by incorporating positional information to the attention mechanism. (2) **GCN** (Zhang et al., 2018) uses a graph convolutional network to gather relevant contextual information along syntactic dependency paths. (3)

Method	TACRED	SemEval	TACREV
PA-LSTM (Zhang et al., 2017)	65.1	82.1	73.3
GCN (Zhang et al., 2018)	64.0	80.7	71.9
C-GCN (Zhang et al., 2018)	66.4	84.2	74.6
C-SGC (Wu et al., 2019)	67.0	84.8	75.1
SpanBERT (Joshi et al., 2020)	70.8	86.1	78.0
RECENT (Lyu and Chen, 2021)	75.2	85.8	83.0
IRE$_{\text{BERT}}$ (Zhou and Chen, 2021)	72.9	86.4	81.3
LUKE (Yamada et al., 2020)	72.7	87.8	80.6
LUKE + GraphCache (ours)	74.8	**89.1**	81.5
IRE$_{\text{RoBERTa}}$ (Zhou and Chen, 2021)	74.6	87.5	83.2
IRE$_{\text{RoBERTa}}$ + GraphCache (ours)	**75.5**	88.2	**84.2**

Table 2: F1 scores (%) of Relation Extraction on the test set of TACRED, SemEval, and TACREV. The best results in each column are highlighted in **bold** font.

C-GCN (Zhang et al., 2018) combines GCN and LSTM, leading to improved performance than each method alone. (4) **C-SGC** (Wu et al., 2019) simplifies GCN by removing the nonlinear layers and achieves higher effectiveness. (5) **SpanBERT** (Joshi et al., 2020) extends BERT by introducing a new pretraining objective of continuous span prediction. (6) **RECENT** (Lyu and Chen, 2021) restricts the candidate relations based on the entity types. (7) **LUKE** (Yamada et al., 2020) pretrains the language model on both large text corpora and knowledge graphs and further proposes an entity-aware self-attention mechanism. (8) **IRE** (Zhou and Chen, 2021) proposes an improved entity representation technique in data preprocessing, which enables RoBERTa to achieve state-of-the-art performance on RE.

Model Configuration. For the hyper-parameters of the considered baseline methods, e.g., the batch size, the number of hidden units, the optimizer, and the learning rate, we set them as those in the original papers. For LDA used in GraphCache, we set the number of topics K as 50, and the number of top relevant topics for every sentence P as 2. For all experiments, we report the median F-1 scores of five runs of training using different random seeds.

4.2 Overall Performance

We incorporate the GraphCache framework with LUKE and IRE$_{\text{RoBERTa}}$, and report the results in Tab. 2. Our GraphCache method improves LUKE by 2.9% on TACREV, 1.5% on SemEval, and 1.1% on TACREV in the F1 score. For IRE$_{\text{RoBERTa}}$, GraphCache leads to the improvement of 1.2% on TACRED, 0.8% on SemEval, 1.2% on Re-TACRED. As a result, our GraphCache achieves substantial improvements for LUKE and IRE$_{\text{RoBERTa}}$ and enables them to outperform the baseline methods.

Method	Complexity	Time	F1 (%)
IRE$_{\text{RoBERTa}}$ (Zhou and Chen, 2021)	$\mathcal{O}(B)$	7492s	74.6
IRE$_{\text{RoBERTa}}$ + GNN	$\mathcal{O}(N)$	N.A.	N.A.
IRE$_{\text{RoBERTa}}$ + GraphCache (ours)	$\mathcal{O}(B)$	7681s	**75.5**

Table 3: Training time, the time complexity per training step, and F1 scores of IRE$_{\text{RoBERTa}}$ with our proposed message passing implemented as GNN and GraphCache on TACRED. The training time of IRE$_{\text{RoBERTa}}$ with the classical GNN is unavailable due to the our-of-memory error. B and N are the batch and dataset sizes respectively.

Note that LUKE and IRE$_{\text{RoBERTa}}$ are both based on large pre-trained models, which have sufficiently large learning capacity to encode the individual instances. In this case, our GraphCache still improves their effectiveness by a large margin, which validates the benefits of modeling the properties: entity types and contextual topics, globally from the whole dataset. This is due to the use of the global property representations that enrich the semantics of each instance, which effectively act as prior knowledge that helps identify the relations and complements the sentence-level features.

4.3 Efficiency and Effectiveness of GraphCache

As analyzed in §3.2, GraphCache enhances the backbone RE models without increasing their time complexity. In the experiments, we analyze the efficiency and effectiveness of GraphCache on the TACRED dataset, following the experimental setting of RE in §4.2.

The methods we evaluate include IRE$_{\text{RoBERTa}}$, IRE$_{\text{RoBERTa}}$ implemented with classical GNN for message passing, and IRE$_{\text{RoBERTa}}$ with our GraphCache. Tab. 3 reports the performance, where 'Time' is the training time until convergence using a Linux Server with an Intel(R) Xeon(R) E5-1650 v4 @ 3.60GHz CPU and a GeForce GTX 2080 GPU.

We notice that, compared with the classical message passing of GNN, our GraphCache method significantly reduces the time complexity per training step. As a result, our GraphCache method takes significantly less training time than the classical GNN method, and exhibits similar efficiency to the original IRE$_{\text{RoBERTa}}$ without message pass-

Method	TACRED	TACREV
LUKE (Yamada et al., 2020)	76.5	82.9
LUKE + GRAPHCACHE (ours)	78.9	85.6
IRE$_{\text{RoBERTa}}$ (Zhou and Chen, 2021)	78.7	86.9
IRE$_{\text{RoBERTa}}$ + GRAPHCACHE (ours)	**80.1**	**88.2**

Table 4: Test F1 scores (%) of Relation Extraction on the filtered test sets (see §4.4), i.e., the instances containing unseen entities.

Technique	F1 (%)	Δ	Cumu Δ
LUKE (Yamada et al., 2020)	72.7	0	0
+ Entity Types	73.4	+0.7	+0.7
+ Contextual Topics	74.8	**+1.4**	**+2.1**

Table 5: Effects of different properties in our heterogeneous graph on the RE of TACRED.

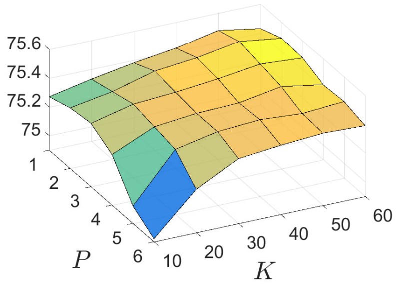

Figure 3: The F1 scores (% in z-axis) of IRE$_{\text{RoBERTa}}$ with GRAPHCACHE on relation extraction on TACRED with different hyper-parameters P and K.

ing between sentences. The running time and F1 of IRE$_{\text{RoBERTa}}$ with GNN is unavailable due to the out-of-memory error. This agrees with the theoretical analysis in §3.2. N and B denote the data and batch sizes respectively. IRE$_{\text{RoBERTa}}$'s time complexity is $\mathcal{O}(B)$, which is the same as the original RoBERTa, while the time complexity of RoBERTa with GNN is $\mathcal{O}(N)$, being significantly higher than our GRAPHCACHE. In practice, N is generally large, and $N \gg B$, e.g., $|\mathcal{E}| > 1 \times 10^5$ and $B < 100$ holds for TACRED and state-of-the-art models.

In terms of effectiveness, our GRAPHCACHE leads to substantial improvements for RoBERTa. Our GRAPHCACHE enriches the input features for RE on every sentence by utilizing the dataset-level information beyond the individual sentences. GRAPHCACHE implements the attention module to incorporate the global property features from different topic caches with adaptive weights, which capture the most relevant information for the target relation. The improvements in effectiveness are rooted in the message passing mechanism between sentences, which mines the property information beyond individual instances and acts as a complementary to the sentence-level semantics. Our GRAPHCACHE method resolves the efficiency issues of message passing based on the caching mechanism, which updates the properties' representations in an online manner.

4.4 Analysis on Unseen Entities

Some previous work (Zhang et al., 2018; Joshi et al., 2020) suggests that RE models may not generalize well to unseen entities. To evaluate whether the RE models can generalize to unseen entities, existing work designs a filtered evaluation setting (Zhou and Chen, 2021). This setting removes all testing instances containing entities from the training set of TACRED and TACREV, which results in filtered test sets of 4,599 instances on TACRED and TACREV. These filtered test sets only contain instances with unseen entities during training.

We present the experimental results on the filtered test sets in Tab. 4. Our GRAPHCACHE still achieves consistently substantial improvements for LUKE and IRE$_{\text{RoBERTa}}$ on the TACRED and TACREV datasets. Specifically, our GRAPHCACHE improves the F1 scores of LUKE by 3.1% on TACRED, 3.3% on TACREV, and improves IRE$_{\text{RoBERTa}}$ by 1.8% on TACRED, 1.5% on TACREV. Taking a closer look, we observe that the improvements given by GRAPHCACHE on the filtered test sets are generally larger than those on the original test sets. The reason is that our GRAPHCACHE mines global information from the whole dataset and uses it as the prior knowledge for RE, which is not influenced by the entity names in individual sentences. When the entity names are new to the RE models, the semantic information is relatively scarce and our mined global information plays a more important role to augment the sentence-level representations.

4.5 Ablation Study

We investigate the contributions of properties that we consider for constructing the heterogeneous graph. We apply different kinds of properties sequentially with our GRAPHCACHE on the LUKE model. The results are presented in Tab. 5. Our entity type nodes improve the effectiveness of LUKE by modeling the entity information globally on the

dataset level to enrich the semantics of every sentence. This finding is consistent with Peng et al. (2020), suggesting that the entity information can provide richer information to improve RE. Furthermore, the contextual topics lead to more significant improvements than the entity types, since the contextual information is fundamental for identifying the relations.

Finally, we analyze the sensitivity of GraphCache to the hyper-parameters K, P, where K is the number of topics and P is the number of relevant topics assigned to an instance. The result is visualized in Fig. 3. We vary K among $\{10, 20, 30, 40, 50, 60\}$ and P among $\{1, 2, 3, 4, 5, 6\}$. The performance of $\text{IRE}_{\text{RoBERTa}}$ with GraphCache is relatively smooth when parameters are within certain ranges. However, extremely small values of K and large P result in poor performances. Too small K cannot effectively model the complex contextual topics in the large text corpus, while too large P induces irrelevant or noisy features for every instance. Moreover, only a poorly set hyper-parameter does not lead to significant performance degradation, which demonstrates that our GraphCache framework is able to effectively mine the beneficial properties at the dataset level and use them to enhance the relation representations for RE.

4.6 Case Study

We conduct a case study to investigate the effects of our GraphCache. Tab. 6 gives a qualitative comparison example between LUKE and the LUKE with our GraphCache on the relation extraction dataset TACRED. The result shows that the global property information that we mine from the whole dataset can guide the RE systems to make correct predictions. For example, in the first row, we model the global entity type information of the subject as the *person* and the object as the *date* from the whole dataset. This type information acts as the prior knowledge that prevents the model from making the wrong relation prediction of 'founded' between the entities '*Quentin Fabris*' and '*1947*' (date). Similarly, in the final row, our GraphCache filters out the incorrect relation '*schools_attend*', since we model the entity type information from the whole dataset and thus enable the model to be aware that this relation cannot hold for the subject type as '*organization*'.

In addition, in the second row, the sentence '*According to the suspect, Gonzalez was strangled and buried the day after the video was made, Rosas said.*' attends to the topic of keywords '[strangle, die, after, when, injury, day, hospital, police, murder, later]' in our heterogeneous graph, which enriches the semantics of the sentence with the context related to the death and time. This helps the model to make the correct relation prediction '*date_of_death*'.

5 Conclusion

In this paper, we study the efficient message passing to enhance the relation extraction models. We propose a novel method named GRAPHCACHE, which provides efficient message passing between instances in the whole dataset. GRAPHCACHE is a model-agnostic technique that can be incorporated into popular relation extraction models to enhance their effectiveness without increasing their time complexity. In our work, we present a simple yet effective implementation of GRAPHCACHE, which models two universal and essential properties for relation extraction: entity information and textual context. Our experimental results show that GRAPHCACHE, with our heterogeneous graph, yields significant gains for the sentence-level relation extraction in an efficient manner.

Revisiting Generative Commonsense Reasoning: A Pre-Ordering Approach

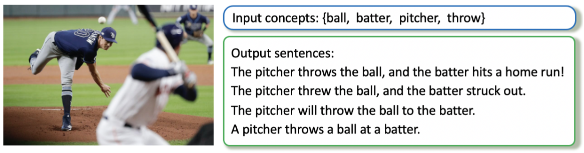
Abstract

Pre-trained models (PTMs) have lead to great improvements in natural language generation (NLG). However, it is still unclear how much commonsense knowledge they possess. With the goal of evaluating commonsense knowledge of NLG models, recent work has proposed the problem of generative commonsense reasoning, e.g., to compose a logical sentence given a set of unordered concepts. Existing approaches to this problem hypothesize that PTMs lack sufficient parametric knowledge for this task, which can be overcome by introducing external knowledge or task-specific pre-training objectives. Different from this trend, we argue that PTM's *inherent* ability for generative commonsense reasoning is underestimated due to the order-agnostic property of its input. In particular, we hypothesize that the order of the input concepts can affect the PTM's ability to utilize its commonsense knowledge. To this end, we propose a pre-ordering approach to elaborately manipulate the order of the given concepts before generation. Experiments show that our approach can outperform the more sophisticated models that have access to a lot of external data and resources.

1 Introduction

Pre-trained models (PTMs), such as BART (Lewis et al., 2020) and T5 (Raffel et al., 2020), have achieved significant progress in many natural language generation tasks. However, their ability to reason with common sense while generating text is questionable. To push research in this direction, Lin et al. (2020) proposed the task of generative commonsense reasoning (GCR), where the goal is to compose a fluent and rational sentence from a set of concepts. Figure 1 shows an example of this problem. To achieve this goal, the model must do commonsense reasoning to build connections between the given concepts and produce a logically sound sentence (e.g., it is the *pitcher* who throws the ball to the *batter* rather than the other way).



Input concepts: {ball, batter, pitcher, throw}

Output sentences:
The pitcher throws the ball, and the batter hits a home run!
The pitcher threw the ball, and the batter struck out.
The pitcher will throw the ball to the batter.
A pitcher throws a ball at a batter.

Figure 1: Example of the GCR task.

Prior works hypothesize that the vanilla PTMs are not capable of solving this challenging task (Liu et al., 2021; Fan et al., 2020; Zhou et al., 2021) partly because their self-supervised objectives do not explicitly capture the relational commonsense knowledge (Zhou et al., 2021). These works enhance the PTMs' performance by explicitly introducing knowledge during fine-tuning or implicitly teaching the model during further pre-training. However, we observe that in some cases, even without external knowledge, PTMs can create reasonable output for this task, indicating that PTMs may already have the commonsense reasoning ability to some degree. Therefore the challenge turns out to be how to make it easier for PTMs to fully utilize the inherent commonsense knowledge.

One potential solution of this challenge is to make the order of input concepts more natural and aligned with commonsense. For example, in Figure 1, taking {*pitcher*, *throw*, *ball*, *batter*} as the input is better than {*batter*, *throw*, *ball*, *pitcher*}, since the order of concepts in the former input is more close to that in the outputs. Models that are not pre-trained, such as LSTM and GRU, prefer a pre-ordering of input tokens to align them with the (expected) output (Vinyals et al., 2016; Bisazza and Federico, 2016). For PTMs, recent works (Kale and Rastogi, 2020; Ribeiro et al., 2021; Hoyle et al., 2021) show that they can achieve reasonable performance on graph-to-text tasks without pre-ordering. However, the impact of pre-ordering on PTMs, in general, is not well analyzed.

In this work, we revisit PTMs' ability of generative commonsense reasoning *without access to ex-*

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1709 - 1718
July 10-15, 2022

ternal knowledge or task-specific pre-training. We choose BART and T5, two state-of-the-art PTMs, as our underlying models. To analyze the utility of pre-ordering the concepts on models' performance, we introduce **Planned-BART** and **Planned-T5** to manipulate the input concept order before generation, which helps to make the order of input concepts more natural (more close to the order of concepts in the output sentence). We experimentally show that via pre-ordering, Planned-BART and Planned-T5 exceed the more sophisticated models that have access to external knowledge or training data. It indicates that PTM's inherent ability for generative commonsense reasoning was underestimated while a simple pre-ordering step can help PTMs better use this ability.

2 Related Works

2.1 Generative Commonsense Reasoning

There are two major approaches to enhance the vanilla PTM's ability of commonsense reasoning on generation. The first approach is to introduce explicit knowledge from external sources such as ConceptNet (Liu et al., 2021) and retrieved prototypes (Fan et al., 2020; Wang et al., 2021), which can facilitate GSR by either building connections between related concepts or providing adjunct words for the input. The second approach is to explicitly teach models to reason over the concepts via new pre-training objectives (Zhou et al., 2021). Different from these works, we examine PTMs' inherent ability of GSR without the help of external knowledge or task-specific pre-training.

2.2 Sequence Pre-Ordering

Previous works have shown that the pre-ordering of input sequence can improve the task of graph-to-text generation (Moryossef et al., 2019; Zhao et al., 2020), but they use non-pre-trained LSTM and the pre-ordering methods rely on rich structural information from the input. We instead focus on PTMs and non-structural input. For PTMs, Hessel and Schofield (2021) and Sinha et al. (2021) show that PTMs are resilient to shuffling the order of input tokens on the tasks of natural language understanding, but they didn't study the generation problem. Hoyle et al. (2021) show that a suitable pre-ordering can improve the generation quality. However, they didn't provide a general pre-ordering method for the problem of keywords-to-text generation.

3 Generative Commonsense Reasoning

3.1 Task Formalization

Given a set of lemmatized tokens representing concepts $\mathcal{X} = \{x_1, \cdots, x_m\}$, where each x_i can be a noun or a verb, the goal is to generate a fluent and grammatically correct English sentence $\mathbf{y} = \{y_1, \cdots, y_n\}$ such that it contains all of the concepts in $\mathcal{X}$. The task does not require x_i to have the same morphological form as it appears in $\mathbf{y}$. Figure 1 shows an example of the task. Note that $\mathcal{X}$ is an unordered set of concepts. We refer to a permutation of $\mathcal{X}$ as a *Plan* of the concept set. For a given output sentence $\mathbf{y}$, we re-order $\mathcal{X}$ to make the concepts have the same order as those in $\mathbf{y}$ and call it as the *Skeleton* of $\mathbf{y}$. Note that skeletons are associated with the outputs while plans are determined before generation. We refer to the plans which are identical to the references' skeletons as *Oracle Plans*.

We use BART and T5, two state-of-the-art PTMs, as the underlying generation models. Both models are based on the Transformer architecture (Vaswani et al., 2017). Similar to other sequence-to-sequence models, they receive $\mathbf{x} = \{x_1, \cdots, x_m\}$ as input, and model the probability of the output sequence $\mathbf{y} = \{y_1, \cdots, y_n\}$ as:

$$p(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\theta}) = \prod_{t=1}^{|\mathbf{y}|} p\left(y_t \mid y_{1:t-1}, \mathbf{x}; \boldsymbol{\theta}\right). \quad (1)$$

3.2 Planned Model

To fine-tune PTMs on this task, previous works regard the input as an unordered set and use its random linearization as the input in both training and inference phases. Although it is trained in an order-agnostic setting, PTMs are naturally position-sensitive models because the same input words in different permutations have different positional representations.

Leveraging this property, we introduce Planned-BART and Planned-T5 to make both models aware of the input order by regarding the input as an ordered sequence. To order the input concepts properly, in the training phase, we re-order the concepts according to the corresponding oracle plan. That is, we force the order of concepts in both input and output sequences to be identical during training, which can better help the model utilize its inherent commonsense reasoning capabilities. In the inference phase, the oracle plans of concepts are unavailable.

Model \ Metrics	ROUGE-2/L		BLEU-3/4		METEOR	CIDEr	SPICE	Coverage
BART (Lin et al., 2020)	22.23	41.98	36.3	26.3	30.9	13.92	30.6	97.35
EKI-BART (Fan et al., 2020)	24.36	45.42	42.9	32.1	32.0	16.80	32.5	-
KG-BART (Liu et al., 2021)	23.38	44.54	42.1	30.9	32.4	16.83	32.7	98.68
Planned-BART (Ours)	24.97	46.13	44.8	34.1	32.9	17.47	33.1	98.99
T5 (Lin et al., 2020)	22.01	42.97	39.0	28.6	30.1	14.96	31.6	95.29
CALM (Zhou et al., 2021)	-	-	-	29.5	31.9	15.61	33.2	-
RE-T5 (Wang et al., 2021)	-	-	-	-	-	-	34.3	-
Planned-T5 (Ours)	24.07	46.11	44.6	33.7	32.8	17.60	34.0	98.60
Human Performance	48.88	63.79	48.2	44.9	36.2	43.53	63.5	99.31

Table 1: Automatic evaluation of generation quality. We compare our methods with pre-train- or knowledge-enhanced baselines. Our best model outperforms previous models on all automatic measures. The only exception is RE-T5, which uses both external knowledge and pre-training (with 7 times larger training data).

We instead obtain the plan using a *Planner*. Leveraging the power of PTMs, the planner is a vanilla BART or T5 model, which is fine-tuned on unordered (randomly linearized) input and produces a sentence as output. The skeleton of the planner's output forms the plan for planned models.

4 Experiments

4.1 Dataset and Evaluation

We conduct experiments [1] on the COMMONGEN dataset (Lin et al., 2020), which contains 35k concepts-sentence pairs for training/validation/test. To build concepts-reference pairs, COMMONGEN first collects frequently co-occurring concepts from image captions. Each concept-set contains three to five concepts. The references in the training set are original captions while those in the validation and test sets are collected by crowd-sourcing.

The quality of the generated text is evaluated through several automatic metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), and SPICE (Anderson et al., 2016). We also report Coverage (Lin et al., 2020), which is the average percentage of input concepts that are present in the output sentences.

4.2 Results

We compare the performance of our pre-ordered method with the unordered BART and T5, as well as two knowledge-enhanced BART models: EKI-BART and KG-BART, and two T5 models enhanced by further pre-training: CALM and RE-T5. Table 1 lists the results of automatic measures. The training details can be found in Appendix A.

Our Planned-BART and Planned-T5 models outperform vanilla BART and T5 models, demonstrating that pre-ordering the input helps PTMs in effectively leveraging their inherent commonsense knowledge. Our models also outperform three out of four baselines that use external knowledge or pre-training objectives. The only exception is RE-T5, which is further pre-trained.This indicates that PTMs inherently contain a lot of commonsense knowledge that needs to be first utilized before bringing in information from external sources.

To further explore the potential of the pre-ordering method, we conduct another experiment to investigate the impact of concept orders on generation quality. Given a test concept set, we feed all of its permutations to either BART or Planned-BART to generate sentences. We then rank the sentences according to their probabilities in Equation 1 and pick the most probable sentence as the final output. We refer to the methods using this strategy as BART $_{\text{Rank}}$ and Planned-BART $_{\text{Rank}}$, respectively. Note that the ranking method is computationally inefficient. In this work, we only use these models to provide an estimate of the upper bound on the performance of the pre-ordering method.

As shown in Table 2, the performance of Planned-BART is close to its ranking variant. This demonstrates the effectiveness of our planning strategy – it helps Planned-BART achieve a performance comparable to the upper bound at a much lower computational overhead. We also observe that Planned-BART $_{\text{Rank}}$ achieves better scores than BART $_{\text{Rank}}$. This is because Planned-BART is trained on oracle plans, which helps it in better utilizing its inherent commonsense knowledge.

4.3 Human Evaluation

We randomly select 100 test instances and evaluate the generation quality of a system according

---

[1] Code is available at `https://github.com/zhaochaocs/Planned-PTM`

Model \ Metrics	R-2	B-4	M	C	S
Planned-BART	24.97	34.1	32.9	17.47	33.1
BART $_{\text{Rank}}$	24.31	33.0	33.0	17.39	33.2
Planned-BART $_{\text{Rank}}$	25.04	35.0	33.3	17.89	33.6

Table 2: Evaluation of Planned-BART and ranking models on ROUGE-2, BLEU-4, METEOR, CIDEr, and SPICE.

Model \ Metrics	Ration	Fluency	Succinct
BART	-0.38	-0.33	-0.56
BART $_{\text{Rank}}$	-0.10	0.04	-0.13
Planned-BART	-0.29	-0.19	-0.17

Table 3: Results of human evaluation on rationality, fluency, and succinctness. We report the pair-wise scores between Planned-BART $_{\text{Rank}}$ (the best model) with three other models. Negative scores indicates worse performance compared with Planned-BART $_{\text{Rank}}$.

to Rationality, Fluency, and Succinctness as in Liu et al. (2021). We conduct a pairwise comparison between Planned-BART $_{\text{Rank}}$ (the best model) with our three other methods.For each test instance, we obtain the output sentences from two different models, and then ask three workers on Amazon Mechanical Turk to compare the two sentences according to the three measures listed above. More details can be found in Appendix B.

Table 3 lists the results, where negative scores indicate worse performance compared with Planned-BART $_{\text{Rank}}$. The original BART performs the worst on all measures, while Planned-BART achieves closer quality to BART $_{\text{Rank}}$ and Planned-BART $_{\text{Rank}}$. These results are consistent with those of automatic evaluations and support our claim that Planned-BART can be a reasonable trade-off between performance and efficiency.

5 Analysis

In this section, we analyze the impact of input permutation on the model and the generated sentences.

5.1 Permutation Invariance

We first examine how the output changes when the original BART (which we refer to as Unordered-BART for clarity) and Planned-BART receive all possible permutations of concepts as input. We compare the skeleton of Planned-BART's outputs with the input plans and find that the output skeleton is consistent with the order of input concept in 94% of the cases, which is as expected.

In contrast, for Unordered-BART, we find that for 61% of the permutations, it can organize the concepts in one particular order irrespective of the input order. More details are provided in Appendix C. This observation suggests that Unordered-BART is permutation-invariant to the input to some degree. However, it is difficult for the model to be entirely insensitive to the input permutation, which explains the performance difference between BART and BART $_{\text{Rank}}$: a ranking strategy helps select a more suitable permutation of input and can therefore improve the generation quality.

5.2 Impact of Permutation on Encoding

The observations in Section 5.1 prompt a question about how Unordered-BART and Planned-BART have different behaviors when receiving input permutation. Here, we explore this question by studying the impact of input permutation on the model encoder, especially the global attention distributions and the local attention strength between certain word pairs.

One possible reason for the permutation invariance of Unordered-BART is that although different input plans have different positional embeddings and may affect hidden states of the lower layers, the encoder can build stable association among tokens at the higher layers, alleviating the disturbance from positional embeddings. For example, the model may know that people should "ride a bike on trail" even when the concept order is {ride, trail, bike}. We measure the word association inside the encoder using the strength of attention weights between concepts.

To verify our assumption, we calculate (i) the Jensen–Shannon divergence (JSD) of the encoder attention distributions w.r.t. all possible permutations of the input, and (ii) the variance of encoder hidden states w.r.t. the input permutations. Figure 2 shows the layer-wise JSD and variance averaged over the test set. For comparison, we also include the results from a randomly-initialized BART and the pre-trained BART (without fine-tuning).

From Figure 2 we observe that the attention distributions of Planned-BART have high JS divergence at each layer, and have a similar trend compared with that of Pre-trained BART. It indicates that attention distributions of these two models are affected by the input permutation, which is expected since their input is well ordered during pre-training or fine-tuning. As a result, the variances of hidden states on both models increase with a growth in layer depth. In contrast, the JS

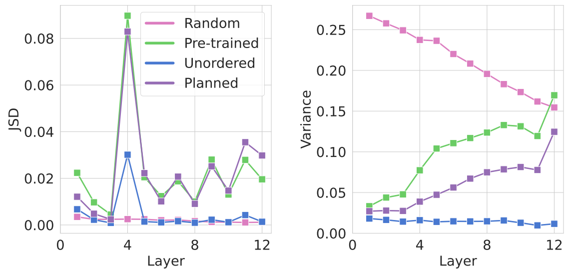


Figure 2: Left: JS divergence of encoder attention distributions w.r.t. the input permutations. Right: the variance of encoder hidden states w.r.t. input permutations.

divergence of attention in Unordered-BART gets close to 0 starting from layer 2 and becomes similar to that of the randomly initialized model. It indicates that the encoder can assign stable attention distributions to the input despite the difference in permutation. Because of this, the variances of hidden states on these two models decrease as the layer goes deeper. It partially explains the permutation invariance of Unordered-BART. We also noticed a substantial negative correlation between the variance of the encoder output and the percentage of the mode sentence (Spearman's $\rho = -0.435$), which supports our explanation.

In addition to the analysis of global attention distribution, we also investigate local attention patterns, i.e., whether the attention weights between concept tokens can reflect their commonsense relations. More details are listed in Appendix D. We find that compared with a randomly-initialized BART, the pre-trained BART is better at tracking commonsense relations of concepts despite input permutation, and fine-tuning can further strengthen this capability. We also find that the model heavily relies on the tracking ability when generating texts. It demonstrates that BART has the commonsense reasoning ability to some degree, and it is reasonable to leverage the output of Unordered-BART to obtain the plan for planned-BART.

5.3 Impact of Permutation on Decoding

In this section, we discuss how the input permutation can affect the quality of decoding output. Particularly, we show that reasonable planning can create less repetitive and more diverse output.

First, we find that the unordered models suffer from the repetition of content in the output. For example, in 34.2% of test cases, there is at least one concept that appears more than once in the output of the unordered BART. However, this percentage decreased to 3.2% for the output of Planned-BART. It is because the decoder of Planned-BART can assign attention weights monotonically to the input, and reduce the repetition caused by re-attending the previous concepts. In Appendix E, we provide a visualization of how the input order can impact the attention weights during decoding.

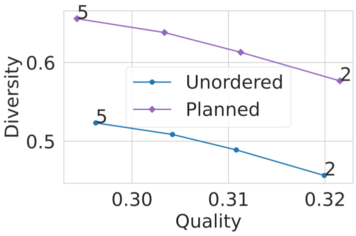

Figure 3: The quality-diversity plot of Unordered-BART $_{\text{Rank}}$ and Planned-BART $_{\text{Rank}}$.

Second, the order consistency between inputs and outputs in Planned-BART also allows us to have more control over output skeletons by adjusting the input concept order. Different orders can help the encoder to capture diverse commonsense relations between concepts and create diverse outputs. While unnatural diversity may hurt generation quality, we use SPICE as the measure for quality and BLEU-based discrepancy (Shu et al., 2019) for diversity, and evaluate the performance of Unordered-BART $_{\text{Rank}}$ and Planned-BART $_{\text{Rank}}$ by selecting the top 2 to 5 candidates as outputs. Figure 3 shows the quality-diversity plot of two models. It indicates that with little degradation of generation quality, Planned-BART can create more diverse output than Unordered-BART. We show an example in Appendix F.

6 Conclusion

In this work, we revisit the PTM's inherent ability of generative commonsense reasoning. We use BART and T5 as underlying generators and propose their planned variants to manipulate the order of the given concepts before generation. Experiments on COMMONGEN dataset demonstrate that this simple pre-ordering approach can outperform the previous pre-trained or knowledge-enhanced models. Besides that, planned models can leverage the pre-ordered concepts to create more succinct and diverse sentences. In conclusion, our work suggests that PTM's inherent ability for generative commonsense reasoning is underestimated due to the unordered input, and the pre-ordering step can help PTMs to improve the generation quality.

A Training Details

The BART and T5 models are implemented using the Transformers library (Wolf et al., 2020). We fine-tune each model on the training data of COMMONGEN with Adam (Kingma and Ba, 2015). We set the learning rate as 2e-5 and adopt early stopping based on the loss of development set. The batch size of training is 64.

B Human Evaluation Details

We randomly select 100 test instances that had 5 concepts as input, since they are more challenging than those with fewer concepts. The three measures we used are 1) Rationality: whether or not the sentence is in accordance with commonsense; 2) Fluency: whether or not the sentence is fluent and has no grammatical errors; and 3) Succinctness: whether or not the sentence contains redundant words or repeated information.

The pairwise scores of those measures are calculated as follows. When comparing a certain approach to Planned-BART $_{\text{Rank}}$, we report the percentage of instances that were judged to be better/worse/same than those of Planned-BART $_{\text{Rank}}$, yielding a score ranging from -1 (unanimously worse) to 1 (unanimously better). For example, when evaluating the rationality scores, Unordered-BART $_{\text{Vanilla}}$ performs better/worse/same than Planned-BART $_{\text{Rank}}$ for 27%/65%/8% of the instances, yielding a pairwise score as 0.27-0.65=-0.38.

C Permutation Invariance

To figure out to what extent Unordered-BART is permutation-invariant, we conduct the following analysis. For each test instance, we feed all different input permutations to the Unordered-BART to obtain the corresponding output sentences. We measure the invariance of the outputs by computing the percentage of the most frequent output. If the concept order does not affect the output, all different permutations will lead to identical outputs and the percentage will be 100%. If half of the permutations obtain the same outputs, the percentage will be 50%. We measure the input invariance at the following two levels.

Sentence-level invariance For various permutations of a specific concept-set, if the percentage of the most frequent sentence is greater than an invariance threshold α, we regard the model as input-invariant to that instance at the sentence level.

Skeleton-level invariance The sentence-level invariance requires the output sentences to be identical, which is strict and does not consider minor lexical differences (e.g., the difference in function words or modifiers). Therefore, we also report the skeleton-level invariance by measuring the percentage of the most frequent skeleton (mode skeleton). It reflects whether or not the model output will follow a certain order under different permutations, which is a more forgivable invariance measure compared to its sentence-level counterpart.

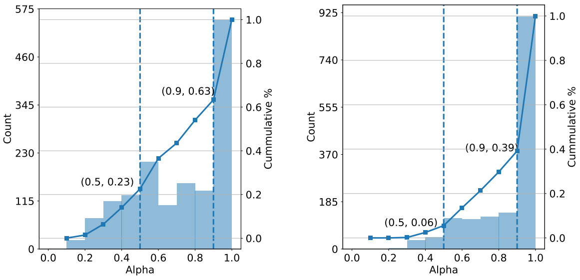

Figure 4: The histogram of COMMONGEN test set w.r.t. the percentage of most frequent sentences (left) and skeletons (right), respectively. We also show the cumulative distribution in blue lines. When $\alpha = 0.9$, 37% and 61% of the test instances are invariant at the sentence and skeleton-level, respectively.

Figure 4 shows the distribution of COMMONGEN test set w.r.t. the percentage of most frequent sentences (left) and skeletons (right). When setting $\alpha = 0.9$, 37% of the test instances are invariant at the sentence level, and 61% are invariant at the skeleton level. This indicates that for 61% of the permutations, Unordered-BART can organize the concepts in one particular order irrespective of the input order.

Relation	**Head**	**UAS**	I_{lh}
v-dobj-n	10-7	83.97	13
v-prep-adp-pobj-n	10-7	82.61	13
n-nsubj-v	11-12	87.62	3
n-prep-adp-pobj-n	10-8	60.55	15
v-advcl-v	4-11	85.37	4
v-conj-v	10-1	83.07	2
n-nsubj-v-dobj-n	6-16	62.34	40
v-xcomp-v	8-15	91.32	19
n-conj-n	10-0	88.75	56
n-comp-n	1-8	83.31	24

Table 4: The functional heads for each relation, as well as the corresponding UAS and importance rank.

D Analysis of Local Attention

In addition to the analysis of global attention distribution, we also investigate local attention patterns, i.e., the attention weights between concept tokens. Previous works show that some attention heads can reflect certain aspects of syntactic and semantic relations between words (Clark et al., 2019; Htut et al., 2019). We want to investigate if the heads can track commonsense relations between concepts.

For this purpose, we first build gold relations between the concepts that capture commonsense knowledge. One option is to utilize ConceptNet relations between concepts (Lin et al., 2020). However, these relations connect only two concepts at a time disregarding the context information from other concepts. Consider {throw, catch, dog, frisbee} as an example. “Dog” may be “caught” but this relation is less plausible in this case because of the existence of “frisbee”. When considering this context, humans provide references such as “The dog catches the frisbee when the boy throws it.”

Another option is to use the dependency relations between words in the reference sentences, which can capture the commonly occurring relations between concepts while incorporating the context. For example, the relation “catch$\xrightarrow{\text{dobj}}$frisbee” captures the commonsense that frisbee is often caught, Similar ideas are also adopted in Zhang et al. (2020). In particular, we extract the one-hop and two-hop dependency relations of all concept pairs from the references, and only keep the relations that appear in two or more references.

For attention probing, we use attention weights between input tokens to reflect the strength of their associations. Given two concepts c_i and $c_{j,j>i}$, we regard them as strongly associated under the attention head (l, h) if the attention weight $\alpha_{ij}^{l,k}$ is the highest among the scores from all the other concepts $c_{k\setminus\{i,j\}}$ to c_j.

Model	Output	Skeleton
Unordered-BART	A crowd of people watch and dance to the music.	crowd watch dance music
Planned-BART	A crowd of people are dancing to music while others watch.	crowd dance music watch
	A man plays music and watches the crowd dance.	music watch crowd dance
	A group of people dance to music as a crowd watches.	dance music crowd watch
	A man watches a crowd of people dancing to music.	watch crowd dance music
Human	The crowd likes to watch her dance to the music.	crowd watch dance music
	The crowd watched the dance, and listed to the music.	crowd watch dance music
	I watched as the crowd dance to the music.	watch crowd dance music
	A person dancing to the music as a crowd of people watch.	dance music crowd watch

Table 5: Sample texts generated by Unordered-BART, Planned-BART, and humans for the concept set {dance, music, crowd, watch}. The diversity of Planned-BART is more close to human generation.

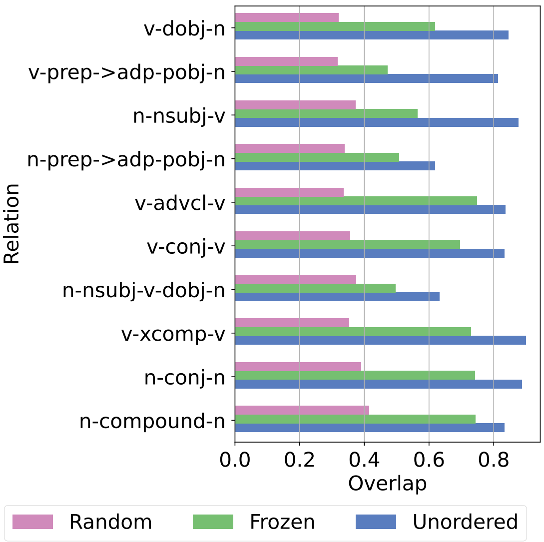

Figure 5: UAS of commonsense relations from three BART models via attention probing. The performance of fine-tuned Unordered-BART > pre-trained Frozen-BART > randomly-initialized BART among all of the relations.

We choose the 10 most common dependency relations from the test set and report the Unlabeled Attachment Score (UAS) of attention probing in Figure 5. We also list the UAS of a randomly initialized BART and a pre-trained BART without fine-tuning for comparison.

Results in Figure 5 show that for some frequent and simple relations such as "v-dobj-n" and "n-nsubj-v", there is at least one attention head that tends to track them regardless of the differences in the permutation orders. For example, attention head "Layer-10 Head-7" tracks the "v-dobj-n" relation with a UAS of 83.9%. The comparison among the three models shows that the pre-trained BART already exceeds the randomly initialized model in tracking commonsense relations between words, and fine-tuning further strengthens those relations.

Figure 6: The cross-attention matrix of two permutations of the same concept-set produced by Unordered-BART. It's difficult for Unordered-BART to learn the optimal order of attention.

To demonstrate that these functional heads are important for generation, we use the expected sensitivity (Michel et al., 2019) of the model to each head to evaluate the head importance as

$$I_{lh} = \mathbb{E}_{x\sim X}\left|\frac{\partial\mathcal{L}(x)}{\partial\xi_{lh}}\right| \tag{2}$$

where $\mathcal{L}(x)$ is the loss of generation and ξ_{lh} is the mask variable for head $l-h$ with values in $\{0,1\}$. The general idea is that the value change of important heads can have a larger impact on the model loss. Results are shown in Table 4. For most relations, the corresponding functional heads also have a high rank of importance. This consistency indicates that the model heavily relies on these heads when generating texts, and further demonstrates that the finetuned BART can capture the commonsense between concepts for generation.

E Impact on Repetition

The repetition of the unordered BART is caused by the order-agnostic property of its input. Since the input concepts are unordered, the decoder cannot pay attention to the input in a monotonic way (from left to right) during decoding, which may mislead the decoder to attend to the concepts that have been previously generated. For example, on the left of Figure 6, the decoder attends to “tea” and “glass” twice during decoding, which achieves the local coherence but causes the global repetition issue and unnatural text. However, when modifying the input in another order, as shown in the right of Figure 6, the repetitive and unnatural expressions disappear. It indicates that the BART decoder has difficulty ordering the input globally, and providing a well-ordered plan as input can alleviate this issue. On the contrary, in Planned-BART, the decoder can assign attention weights monotonically to the input, and therefore reduce the repetition caused by re-attending the previous concepts.

F Impact on Diversity

Table 5 provides an example with the outputs created by both models and humans. Unordered-BART can create only one output due to the permutation invariance. Also, the object of *watch* is missing in its output. On the other hand, similar to the human-written output, the output of Planned-BART is more natural and diverse.

Identifying and Mitigating Spurious Correlations for Improving Robustness in NLP Models

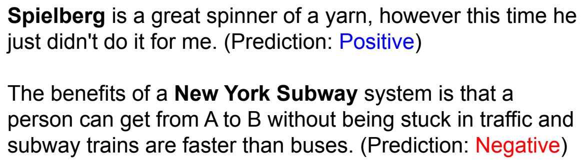
Abstract

Recently, NLP models have achieved remarkable progress across a variety of tasks; however, they have also been criticized for being not robust. Many robustness problems can be attributed to models exploiting *spurious correlations*, or *shortcuts* between the training data and the task labels. Most existing work identifies a limited set of task-specific shortcuts via human priors or error analyses, which requires extensive expertise and efforts. In this paper, we aim to automatically identify such spurious correlations in NLP models at scale. We first leverage existing interpretability methods to extract tokens that significantly affect model's decision process from the input text. We then distinguish "genuine" tokens and "spurious" tokens by analyzing model predictions across multiple corpora and further verify them through knowledge-aware perturbations. We show that our proposed method can effectively and efficiently identify a scalable set of "shortcuts", and mitigating these leads to more robust models in multiple applications.

1 Introduction

Despite great progress has been made over improved accuracy, deep learning models are known to be brittle to out-of-domain data (Hendrycks et al., 2020; Wang et al., 2019), adversarial attacks (McCoy et al., 2019; Jia and Liang, 2017; Jin et al., 2020), partly due to sometimes the models have exploited *spurious correlations* in the existing training data (Tu et al., 2020; Sagawa et al., 2020). In Figure 1, we show an example of a sentiment classification model making spurious correlations over the phrases "*Spielberg*" and "*New York Subway*" due to their high co-occurrences with positive and negative labels respectively in the training data.



Spielberg is a great spinner of a yarn, however this time he just didn't do it for me. (Prediction: Positive)

The benefits of a **New York Subway** system is that a person can get from A to B without being stuck in traffic and subway trains are faster than buses. (Prediction: Negative)

Figure 1: Examples of spurious correlations in sentiment classification task. A sentiment classification model takes *Spielberg* and *New York Subway* as shortcuts and makes wrong predictions.

Most existing work quantifies spurious correlations in NLP models via a set of pre-defined patterns based on human priors and error analyses over the models, e.g., syntactic heuristics for Natural Language Inference (McCoy et al., 2019), synonym substitutions (Alzantot et al., 2018), or adding adversarial sentences for QA (Jia and Liang, 2017). More recent work on testing models' behaviour using CheckList (Ribeiro et al., 2020) also used a pre-defined series of test types, e.g., adding negation, temporal change, and switching locations/person names. However, for safe deployment of NLP models in the real world, in addition to pre-defining a small or limited set of patterns which the model could be vulnerable to, it is also important to proactively *discover* and *identify* models' unrobust regions automatically and comprehensively.

In this work, we introduce a framework to automatically identify spurious correlations exploited by the model, sometimes also denoted as "shortcuts" in prior work (Geirhos et al., 2020; Minderer et al., 2020)[1], at a large scale. Our proposed framework differs from existing literature with a focus more on automatic shortcut identification, instead of pre-defining a limited set of shortcuts or learning from human annotations (Table 1). Our framework works as follows: given a task and a trained model, we first utilize interpretability methods, e.g., attention scores (Clark et al., 2019b; Kovaleva et al., 2019) and integrated gradient (Sundararajan et al., 2017) which are commonly used for interpreting model's decisions, to automatically extract tokens that the model deems as important for task label

---

[1] Throughout the paper we use spurious correlations and shortcuts interchangeably.

Table 1: Comparison of our work and other related literature.

prediction. We then introduce two extra steps to further categorize the extracted tokens to be "genuine" or "spurious". We utilize a *cross-dataset* analysis to identify tokens that are more likely to be "shortcut". The intuition is that if we have data from multiple domains for the same task, then "genuine" tokens are more likely to remain useful to labels across domains, while "spurious" tokens would be less useful. Our last step further applies a *knowledge-aware perturbation* to check how stable the model's prediction is by perturbing the extracted tokens to their semantically similar neighbors. The intuition is that a model's prediction is more likely to change when a "spurious" token is replaced by its semantically similar variations. To mitigate these identified "shortcuts", we propose a simple yet effective *targeted* mitigation approach to prevent the model from using those "shortcuts" and show that the resulting model can be more robust. Our code and data have been made publicly.[2] Our contributions are as follows:

- We introduce a framework to automatically identify shortcuts in NLP models at scale. It first extracts important tokens using interpretability methods, then we propose *cross-dataset analysis* and *knowledge-aware perturbation* to distinguish spurious correlations from genuine ones.
- We perform experiments over several benchmark datasets and NLP tasks including sentiment classification and occupation classification, and show that our framework is able to identify more subtle and diverse spurious correlations. We present results showing the identified shortcuts can be utilized to improve robustness in multiple applications, including better accuracy over challenging datasets, better adaptation across multiple domains, and better fairness implications over certain tasks.

2 Related Work

Interpretability There has been a lot of work on better interpreting models' decision process, e.g., understanding BERT (Clark et al., 2019b; Kovaleva et al., 2019) and attention in transformers (Hao et al., 2020), or through text generation models (Narang et al., 2020). In this paper we utilize the attention scores as a generic way to understand what features a model relies on for making its predictions. Other common model interpretation techniques (Sundararajan et al., 2017; Ribeiro et al., 2016), or more recent work on hierarchical attentions (Chen et al., 2020) and contrastive explanations (Jacovi et al., 2021), can be used as well. In Pruthi et al. (2020), the authors found that attention scores can be manipulated to deceive human decision makers. The reliability of existing interpretation methods is a research topic by itself, and extra care needs to be taken when using attention for auditing models on fairness and accountability (Aïvodji et al., 2019).

Robustness and Bias An increasing body of work has been conducted on understanding robustness in deep neural networks, particularly, how models sometimes might exploit spurious correlations (Tu et al., 2020; Sagawa et al., 2020) and take shortcuts (Geirhos et al., 2020), leading to vulnerability in generalization to out-of-distribution data or adversarial examples in various NLP tasks such as NLI (McCoy et al., 2019), Question-Answering (Jia and Liang, 2017), and Neural Machine Translation (Niu et al., 2020). Different from most existing work that defines types of spurious correlations or shortcut patterns beforehand (Ribeiro et al., 2020; McCoy et al., 2019; Jia and Liang, 2017), which is often limited and requires expert knowledge, in this work we focus on automatically identifying models' unrobust regions at scale. Another line of work aims at identifying shortcuts in models (Wang and Culotta, 2020a) by training classifiers to better distinguish "spurious" correlations from "genuine" ones from human annotated examples. In contrast, we propose a cross-dataset approach and a knowledge-aware perturbation approach to automate this identification process with less human intervention in-between.

---

[2] https://github.com/tianlu-wang/Identifying-and-Mitigating-Spurious-Correlations-for-Improving-Robustness-in-NLP-Models

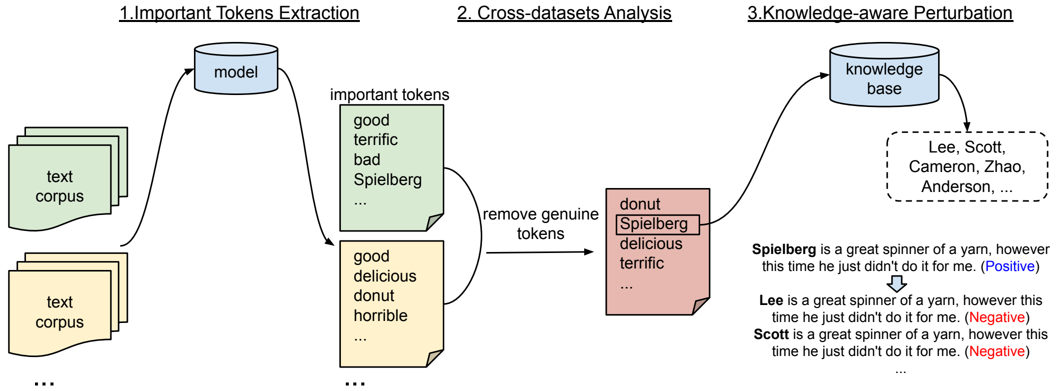

Figure 2: Our proposed pipeline to identify spurious correlations at scale. In the first step, we extract important tokens from input text. In the second step, we analyze extracted tokens from various datasets to identify likely "spurious" tokens. Finally, we further validate the output from the second step through knowledge-aware perturbation.

Mitigation Multiple approaches have been proposed to mitigate shortcut learning and data biases (Clark et al., 2020; Bras et al., 2020; Zhou and Bansal, 2020; Minderer et al., 2020), through data augmentation (Jin et al., 2020; Alzantot et al., 2018), domain adaptation (Blitzer et al., 2006, 2007), and multi-task learning (Tu et al., 2020). Du et al. (2021) proposes to mitigate shortcuts by suppressing model's prediction on examples with a large shortcut degree. Recent study has also shown removing spurious correlations can sometimes hurt model's accuracy (Khani and Liang, 2021). Orthogonal to existing works, we propose to first identify unrobust correlations in an NLP model and then propose a *targeted* mitigation to encourage the model to rely less on those unrobust correlations.

3 Framework for Identifying Shortcuts

In this section, we introduce our framework to identify spurious correlations in NLP models. Our overall framework consists of first identifying tokens important for models' decision process, followed by a cross-dataset analysis and a knowledge-aware perturbation step to identify spurious correlations.

3.1 Identify Tokens Key to Model's Decision

The first step of the framework aims to identify the top-K most important tokens that affect model's decision making process. We look at the importance at the token-level.[3] In general, depending on how the tokens are being used in model's decision process, they can be roughly divided into three categories: "genuine", "spurious", and others (e.g., tokens that are not useful for a model's prediction). *Genuine* tokens are tokens that causally affect a task's label (Srivastava et al., 2020; Wang and Culotta, 2020b), and thus the correlations between those tokens and the labels are what we expect the model to capture and to more heavily rely on. On the other hand, *spurious* tokens, or *shortcuts* as commonly denoted in prior work (Geirhos et al., 2020; Minderer et al., 2020), are features that correlate with task labels but are not genuine, and thus might fail to transfer to challenging test conditions (Geirhos et al., 2020) or out-of-distribution data; spurious tokens do not causally affect task labels (Srivastava et al., 2020; Wang and Culotta, 2020b).

In this step, we will extract both genuine tokens and shortcut tokens because they are both likely to affect a model's prediction. We rely on interpretability techniques to collect information on whether a certain input token is important to model's decision making. In this paper, we use the attention score in BERT-based models as an explanation of model predictions (Clark et al., 2019b; Kovaleva et al., 2019), due to its simplicity and fast computation. Recent work (Jiaao et al., 2021) also reveals that attention scores outperform other explanation techniques in regularizing redundant information. Other techniques (Ribeiro et al., 2016; Sundararajan et al., 2017; Chen et al., 2020; Jacovi et al., 2021) can also be used in this step. As an example, given a sentence "*Spielberg is a good director.*", assuming "*good*" is a genuine token and "*Spielberg*" is a shortcut token, we expect that in a BERT-based sentiment classification model, the attention scores for "*good*" and "*Spielberg*" are

---

[3] In this paper, we mostly focus on unigrams. Our method can also be easily extended to multi-gram, text span or other type of features by summing the attention scores over spans. For a vocabulary of wordpieces as used in BERT, we concatenate wordpieces with a prefix of "##" to form unigrams and sum the attention scores.

Algorithm 1: Important Token Extraction.

```
Input  : Sentiment classification model: $f$
         Text corpus: $\mathcal{D}$
// Obtain attention scores for tokens in each
   input sentence $s_i \in \mathcal{D}$:
for $i = 1$ to $n$ do
    $p_i^{pos}, p_i^{neg}, \{a_i^1, a_i^2, ..., a_i^m\} = f(s_i)$;
    for $j = 1$ to $m$ do
        if $p_i^{pos} > p_i^{neg}$: $\tilde{a}_i^j = a_i^j \cdot p_i^{pos}$;
        else: $\tilde{a}_i^j = -a_i^j \cdot p_i^{neg}$;
    end
end
// Use $\{\tilde{a}_i^j\}$ to compute an importance score
   for each token $t$ in the vocabulary $\mathcal{V}$:
$Importance = dict()$
for $i = 1$ to $n$ do
    for $j = 1$ to $m$ do
        $Importance[t_i^j]$.append($\tilde{a}_i^j$);
    end
end
// Normalize the importance score and
   penalize low-frequency tokens:
for $t$ in $\mathcal{V}$ do
    $\bar{a}_t = average(Importance[t])$;
    $I_t = \bar{a}_t / \Sigma_{t \in \mathcal{V}} \bar{a}_t$;
    $I'_t = \log(I_t)$;
    $\hat{I}_t = I'_t - \lambda / \log(1 + frequency[t])$;
end
Output : A list of tokens sorted according to
         their importance scores:
         $\{t_1, t_2, ..., t_{|\mathcal{V}|}\}$,
         where $\hat{I}_{t_i} \geq \hat{I}_{t_2} \geq ... \geq \hat{I}_{t_{|\mathcal{V}|}}$
```

higher and thus will be extracted as important tokens. On the other hand, for "*is*", "*a*" and "*director*" the attention scores would be lower as they are relatively less useful to the model decision.

We now describe this step using sentiment classification task as an example (more details can be found in Algorithm 1). Let f be a well trained sentiment classification model. Given a corpus $\mathcal{D}$, for each input sentence s_i, $i = 1, \ldots, n$ for a total of n sentences in the corpus, we apply f on it to obtain the output probability p_i^{pos} and p_i^{neg} for positive and negative label respectively. We then extract attention scores $\{a_i^1, a_i^2, \ldots, a_i^m\}$ for tokens $\{t_i^1, t_i^2, \ldots, t_i^m\}$ in sentence s_i, where m is the length of the sentence. In BERT-based classification models, the embedding of [CLS] token in the final layer is fed to a classification layer. We thus extract the attention scores of each token t used for computing the embedding of the [CLS] token and average them across different heads. If $p_i^{pos} > p_i^{neg}$, we obtain the updated attention score $\tilde{a}_i^j = a_i^j * p_i^{pos}$, otherwise $\tilde{a}_i^j = -a_i^j * p_i^{neg}$. For each token t in the vocabulary $\mathcal{V}$, we compute the average attention score: $\bar{a}_t = \frac{1}{mn} \cdot \Sigma_{i=1}^{n} \Sigma_{j=1}^{m} [\tilde{a}_i^j \cdot \mathbb{1}(t_i^j = t)]$, where we aggregate the attention scores $\tilde{a}_i^j$ for token t, across all n sentences in the corpus. We then normalize the attention scores across the vocabulary to obtain the importance score for each token t: $I_t = \bar{a}_t / \Sigma_{t \in \mathcal{V}} \bar{a}_t$. This can lead to very small I_t for certain tokens, thus we take the log of all importance scores to avoid underflow, $I'_t = \log(I_t)$.

So far, we have computed the importance score for each token. However, we observe that some tokens appearing only very a few times could accidentally have very high importance scores. Thus, we propose to penalize the tokens with low frequencies: $\hat{I}_t = I'_t - \lambda / \log(1 + c_t)$, where c_t is the frequency of token t and λ is a temperature parameter to adjust the degree that we want to penalize over the frequency.

3.2 Cross-Dataset Stability Analysis

As mentioned before, the tokens that are important to a model's prediction could be either genuine or spurious, thus in this step, we want to categorize the extracted tokens into these two categories and maintain a list of tokens that are more likely to be "spurious".

In many real-world NLP tasks, if we have access to datasets from different sources or domains, then we can perform a *cross-dataset* analysis to more effectively identify "spurious" tokens. The reasoning is that "spurious" tokens tend to be important for a model's decision making on one dataset but are less likely to transfer or generalize to other datasets, e.g. "*Spielberg*" could be an important token for movie reviews but is not likely to be useful on other review datasets (e.g., for restaurants or hotels). On the other hand, genuine tokens are more likely to be important across multiple datasets, for example, tokens like "*good*", "*bad*", "*great*", "*terrible*" should remain useful across various sentiment classification datasets. Thus, in this step, we try to distinguish "genuine" tokens from "spurious" tokens from the top extracted important tokens after the first step. Our idea is to compare tokens' im-

Shortcut token: **bread**
Original: I bought this in the hopes it would keep **bread** I made fresh. However, after a few times of usings the I found out that moister w still getting in bread would become stale or moldy ...(Neg)
Perturbed: I bought this in the hopes it would keep **loaf** I made fresh. However, after a few times of usings the I found out that moister w still getting in bread would become stale or moldy ... (Pos)

Shortcut token: **iPhone**
Original: I lost my original TV remote, and found this one thinking it was the same one. ... Now this one is merely a back up. Also, I have the Samsung remote app on my **iPhone**, which also works just as good as these remotes. (Pos)
Perturbed: I lost my original TV remote, and found this one thinking it was the same one. ... Now this one is merely a back up. Also, I have the Samsung remote app on my **ipod**, which also works just as good as these remotes. (Neg)

Table 2: Examples of shortcut tokens with significant performance drop during knowledge-aware perturbation.

portance ranking and find the ones that have very different ranks across datasets.

To this end, we conduct a cross-dataset stability analysis. Specifically, we apply the same model f on two datasets A and B, and obtain two importance ranking lists. Since importance scores may have different ranges on the two datasets, we normalize all importance scores to adjust the value to be in the range of $[0, 1]$:

$$\tilde{I}_t^A = \frac{\hat{I}_t^A - \min(\{\hat{I}_t^A | t \in \mathcal{V}\})}{\max(\{\hat{I}_t^A | t \in \mathcal{V}\}) - \min(\{\hat{I}_t^A | t \in \mathcal{V}\})}$$

$$\tilde{I}_t^B = \frac{\hat{I}_t^B - \min(\{\hat{I}_t^B | t \in \mathcal{V}\})}{\max(\{\hat{I}_t^B | t \in \mathcal{V}\}) - \min(\{\hat{I}_t^B | t \in \mathcal{V}\})}$$

where $\tilde{I}_t^A$ and $\tilde{I}_t^B$ are normalized importance scores on dataset A and B respectively. We then subtract $\tilde{I}_t^B$ from $\tilde{I}_t^A$ and re-rank all tokens according to their differences. Tokens with largest differences are the ones with high importance scores in dataset A but low importance scores in dataset B, thus they are more likely to be "shortcut" tokens in dataset A. Similarly, we can also extract tokens with largest differences from dataset B by subtract $\tilde{I}_t^A$ from $\tilde{I}_t^B$.

3.3 Knowledge-aware Perturbation

The cross-dataset analysis is an efficient way to remove important tokens that are "genuine" across multiple datasets, after which we can obtain a list with tokens that are more likely to be "spurious". However, on this list, domain-specific genuine tokens can still be ranked very high, e.g., "*ambitious*" from a movie review dataset and "*delicious*" from a restaurant review dataset. This is because domain-specific genuine tokens have similar characteristics as shortcuts, they are effective for a model's decision making on a certain dataset but could appear very rarely (and thus could be deemed as not important) on another dataset. Hence, in this section, we further propose a slightly more expensive and a more fine-grained approach to verify whether a token is indeed "spurious", through *knowledge-aware perturbation*.

For each potential shortcut token, we extract N synonyms by leveraging the word embeddings curated for synonym extraction (Mrkšić et al., 2016), plus WordNet (Miller, 1995) and DBpedia (Auer et al., 2007). More specifically, for each top token t in the list generated by the previous step, we first search counter-fitting word vectors to find synonyms with cosine similarity larger than a threshold[4] τ. Additionally we search in WordNet and DBpedia to obtain a maximum of N synonyms for each token t. Then we extract a subset S_t from $\mathcal{D}$, which consists of sentences containing t. We perturb all sentences in S_t by replacing t with its synonyms. The resulted perturbed set S_t' is N times of the original set S_t. We apply model f on S_t and S_t' and obtain accuracy acc_t and acc_t'. Since we only perturb S_t with t's synonyms, the semantic meaning of perturbed sentences should stay close to the original sentences. Thus, if t is a genuine token, acc_t' is expected to be close to acc_t. On the other hand, if t is a shortcut, model prediction can be different even the semantic meaning of the sentence does not change a lot (see examples in Table 2). Thus, we assume tokens with larger differences between acc_t and acc_t' are more likely to be shortcuts and tokens with smaller differences are more likely to be domain specific "genuine" words. From the potential shortcut token list computed in Sec 3.2, we remove tokens with performance difference smaller than δ to further filter domain specific "geniue" tokens .

3.4 Mitigation via Identified Shortcuts

In this section, we describe how the identified shortcuts can be further utilized to improve robustness in NLP models. More specifically, we propose *targeted* approaches to mitigate the identified

---

[4] We set it as 0.5 following the set up in (Jin et al., 2020).

Dataset	Top **important** tokens extracted from each dataset
SST-2	terrific, impeccable, exhilarating, refreshingly, irresistible, heartfelt, thought-provoking, ...
Yelp	Awesome, Definitely, is, Excellent, Very, Great, Good, Best, attentive, worth, definitely, Highly, ...
Amazon Kitchen	utensils, thermometer, Cuisinart, Definitely, Pyrex, Bought, utensil, Arrived, Recommend, ...
Dataset	Top **shortcuts** extracted from each dataset (verified by human annotators)
SST-2	recycled, seal, sitcom, longest, fallen, qualities, rises, impact, translate, emphasizes, ...
Yelp	ambiance, tastes, bartenders, patio, burgers, staff, watering, donuts, cannot, pancakes, regulars, ...
Amazon Kitchen	utensils, Cuisinart, Rachael, Pyrex, utensil, Breville, Zojirushi, Corelle, Oxo, dehumidifier, ...

Table 3: Top *important* tokens and top *shortcut* tokens identified by our proposed framework and further verified by human annotators. Many shortcuts reflect the characteristics of the datasets, e.g. "captures" from a movie review dataset, "burgers" from a restaurant review dataset and brand names from an Amazon kitchen review dataset.

		Prec.	Impor.	Prec.	Impor.	Prec.	Impor.
SST-2	1	0.00	-	0.05	0.97	0.02	0.96
	2	0.10	0.95	0.05	0.94	0.04	0.93
	3	0.40	0.90	0.35	0.87	0.32	0.85
Yelp	1	0.10	0.96	0.05	0.95	0.18	0.95
	2	0.40	0.89	0.25	0.89	0.30	0.88
	3	0.60	0.89	0.50	0.87	0.56	0.87
Amazon Kitchen	1	0.70	0.98	0.80	0.96	0.78	0.95
	2	1.00	0.97	1.00	0.95	1.00	0.95
	3	1.00	0.97	1.00	0.95	1.00	0.95

Table 4: We report the precision as well as the averaged importance score $\tilde{I}$ of identified "shortcuts" after each step based on our framework. The identified "shortcut" is a true shortcut or not is verified by 3 independent human annotators (Amazon Turkers). We can see that the precision increases after each step in our framework, demonstrating the utility of cross-dataset analysis (step 2) and knowledge-aware perturbation (step 3).

shortcuts including three variants: (1) a *training-time* mitigation approach: we mask out the identified shortcuts during training time and re-train the model; (2) an *inference-time* mitigation approach: we mask out the identified shortcuts during inference time only, in this way we save the extra cost of re-training a model; (3) we combine both approach (1) and (2). In the experiment section, we will demonstrate the effect of each approach over a set of benchmark datasets. We found that by masking out shortcuts in datasets, models generalize better to challenging datasets, out-of-distribution data, and also become more fair.

4 Experiments

4.1 Tasks and Datasets

Task 1: Sentiment classification. For the task of sentiment classification, we use several datasets in our experiments. To find shortcuts in Stanford Sentiment Treebank (SST-2) (Socher et al., 2013) dataset, we first train a model on SST-2 training set which consists of $67,349$ sentences. We then evaluate the model on SST-2 training set[5] and Yelp (Asghar, 2016) test set and obtain attention scores. For cross-dataset analysis, we compare the important tokens extracted from SST-2 and Yelp. Similarly, we train another model on $80,000$ amazon kitchen reviews (He and McAuley, 2016), and apply it on the kitchen review dev set and the amazon electronics dev set, both having $10,000$ reviews.

Task 2: Occupation classification. Following Pruthi et al. (2020), we use the biographies (De-Arteaga et al., 2019) to predict whether the occupation is a surgeon or physician (non-surgeon). The training data consists of $17,629$ biographies and the dev set contains $2,519$ samples.

Models. We use the attention scores over BERT (Devlin et al., 2019) based classification models as they have achieved the state-of-art performance. Note that our proposed framework can also be easily extended to models with different architectures. BERT-based models have the advantage that we can directly use the attention scores as explanations of model decisions. For models with other architectures, we can use explanation techniques such as LIME (Ribeiro et al., 2016) or Path Integrated Gradient approaches (Sundararajan et al., 2017) to provide explanations.

---

[5] We use training set of SST-2 because the test set has a very limited number of examples.

Evaluation. Evaluating identified shortcuts in machine learning or deep leaning based models can be difficult. We do not have ground-truth labels for the shortcuts identified through our framework, and whether a token is a shortcut or not can be subjective even with human annotators, and it can further depend on the context. Faced with these challenges, we carefully designed a task and adopted Amazon Mechanical Turk for evaluation. We post the identified shortcuts after each step in our framework, along with several sample sentences containing the token, as additional context, to the human annotator. We ask the question "does the word determine the sentiment in the sentence" and ask the annotator to provide a "yes"/"no" answer[6] to the question based on the answer that holds true for the majority of the provided sentences (we also experimented with adding an option of "unsure" but found most annotators do not choose that option). Each identified shortcut is verified by 3 annotators.

4.2 Experimental Results

We summarized the top important tokens after each step in our framework (Table 3). We also report the precision score (the percentage of tokens) out of the top 50 tokens identified as true shortcuts by human annotators in Table 4.

Across all datasets, we see that the precision score increases after each step, which demonstrates that our proposed framework can consistently improve shortcut identification more precisely. Specifically, after the first step, the precision score of shortcuts is low[7] because most of the top extracted tokens are important tokens only (thus many of them are genuine). After the second step (cross-dataset analysis) and the third step (knowledge-aware perturbation), we see a significant increase of the shortcuts among the top-K extracted tokens. Table 2 shows examples of perturbing shortcut tokens leading to model predictions changes.

Agreement analysis over annotations. Since this annotation task is non-trivial and sometimes subjective, we further compute the intraclass correlation score (Bartko, 1966) for the Amazon Mechanical Turk annotations. Our collected annotations reaches an intraclass correlation score of 0.72, showing a good agreement among annotators. Another agreement we analyze is showing annotators 5 sample sentences compared to showing them all sentences, to avoid sample bias. We ask annotators to annotate a batch of 25 tokens with all sentences containing the corresponding token shown to them. The agreement reaches 84.0%, indicating that showing 5 sample sentences does not significantly affect annotator's decision on the target token. More details of Amazon Mechanical Turk interface can be found in the Appendix.

4.3 A Case Study: Occupation Classification

Pruthi et al. (2020) derived an occupation dataset to study the gender bias in NLP classification tasks. The task is framed as a binary classification task to distinguish between "surgeons" and "physicians". These two occupations are chosen because they share similar words in their biographies and a majority of surgeons are male. The dataset is further tuned – downsample minority classes (female surgeons and male physicians) by a factor of ten to encourage the model to rely on gendered words to make predictions. Pruthi et al. (2020) also provides a pre-specified list of impermissible tokens [8] that a robust model should assign low attention scores to. We instead treat this list of tokens as shortcuts and analyze the efficacy of our proposed framework on identifying these tokens. These impermissible tokens can be regarded as shortcuts because they only reflect the gender of the person, thus by definition should not affect the decision of a occupation classification model. Table 6 presents the result on identifying the list of impermissible tokens. Among the top ten tokens selected by our method, 6 of them are shortcuts. Furthermore, 9 out of 12 impermissible tokens are captured in the top 50 tokens selected by our method. This further demonstrates that our method can effectively find shortcuts in this occupation classification task, in a more automated way compared to existing approaches that rely on pre-defined lists.

4.4 Mitigating Shortcuts

We also study mitigating shortcuts by masking out the identified shortcuts. Specifically, we use shortcut tokens identified by human annotators and mask them out in training set and re-train the model (Train RM), during test time directly (Test

---

[6] In the instruction, we further specify "select yes" if the highlighted word is a determining factor for the sentiment label, and we provide a few example sentences along with their shortcuts as references. The exact template is shown in the Appendix.

[7] Some cells have "-" importance score due to no shortcut is identified by human annotators in the top-K identified tokens.

RM), and both (Train & Test RM) as described in Sec 3.4. We evaluate these three approaches in multiple settings: 1) domain generalization; 2) challenging datasets; 3) gender bias. As shown in Table 5, masking out shortcuts, especially in training data, can improve model's generalization to out-of-distribution data. Note in this setting, different from existing domain transfer work (Pan and Yang, 2010), we do not assume access to labeled data in the target domain during training, instead we use our proposed approach to identify potential shortcuts that can generalize to unseen target domains. As a result, we also observe model's performance improvement on challenging datasets (Table 7). Table 8 demonstrates that mitigating shortcuts helps to reduce the performance gap (Δ) between male and female groups, resulting in a fairer model. Note the original performance might degrade slightly due to models learning different but more robust feature representations, consistent with findings in existing work (Tsipras et al., 2019).

Ablation Study We conduct an ablation study of changing the hyper-parameter λ in the first step of extracting important tokens. As shown in Table 9, our method is not very sensitive to the choice of λ. In Table 10, we show that Attention scores and Integrated Gradient can both serve as a reasonable method for extracting important tokens in our first step, suggesting the flexibility of our framework.

5 Conclusion

In this paper, we aim to improve NLP models' robustness via identifying spurious correlations automatically at scale, and encouraging the model to rely less on those identified shortcuts. We perform experiments and human studies over several benchmark datasets and NLP tasks to show a scalable set of shortcuts can be efficiently identified through our framework. Note that we use existing interpretability approaches as a proxy to better understand how a model reaches its prediction, but as pointed out by prior work, the interpretability methods might not be accurate enough to reflect how a model works (or sometimes they could even deceive human decision makers). We acknowledge this as a limitation, and urge future research to dig deeper and develop better automated methods with less human intervention or expert knowledge in improving models' robustness.

Instructions

Please select "Yes" or "No" based on your answer to the question "if the highlighted word determines the sentiment of the provided sentence?".
Select yes if the highlighted word is a determining factor when assigning a sentiment label to the provided sentence.
For each word, we provided several samples sentences for reference, you should select Yes or no based on the answer that holds true for most of the sentences.
Examples:
(1) I am very **happy** today.
"happy" is crucial to the sentiment of the sentence and thus you should select "yes"
(2) I am very happy **today**
"today" does not affect the sentiment of the sentence and thus you should select "no"
(3) This **Walmart** store is good.

Word: Dyson

Sample sentences:
(1) Glad I purchased this replacement battery. When the battery is fully charged it seems to allow me to use my handheld **Dyson** far longer than I was able with the original battery. I've already purchased a second for another I keep in my garage to use in the car.
(2) Some of these reviews are silly. If you are expecting something akin to a **Dyson**, Kirby or Oreck, you are going to be horribly disappointed.With that said, I wasn't expecting to get a professional quality vacuum. I was expecting to get a solid inexpensive lightweight quick picker-upper and that is exactly what I got. I'm very happy with it and would buy another if needed.
(3) Probably not a good idea to rely on this review, as I've had an ongoing love affair with **Dyson** for several years, ever since the first time I used the vacuum that showed me the dust, hair, and dirt that I was removing from my floors.Given that, these are nice additions to the device.
(4) Although the attachment conversion pieces or whatever you call it doesn't fit what I wanted it for, which was to use my old **Dyson** animal (DC17) attachments with my **Dyson** DC23. Floor attachment is great and really picks up hair nicely....I'm still searching for a conversion piece that will do what I need.
(5) I love my **Dyson**, and we have a lot of hard floors, this goes all the way under our king size bed, I use it

Abstract

Commonsense reasoning in natural language is a desired ability of artificial intelligent systems. For solving complex commonsense reasoning tasks, a typical solution is to enhance pre-trained language models (PTMs) with a knowledge-aware graph neural network (GNN) encoder that models a commonsense knowledge graph (CSKG). Despite the effectiveness, these approaches are built on heavy architectures, and can't clearly explain how external knowledge resources improve the reasoning capacity of PTMs. Considering this issue, we conduct a deep empirical analysis, and find that it is indeed *relation features* from CSKGs (but not *node features*) that mainly contribute to the performance improvement of PTMs. Based on this finding, we design a simple MLP-based knowledge encoder that utilizes statistical relation paths as features. Extensive experiments conducted on five benchmarks demonstrate the effectiveness of our approach, which also largely reduces the parameters for encoding CSKGs. Our codes and data are publicly available at `https://github.com/RUCAIBox/SAFE`.

1 Introduction

In the era of artificial intelligence, it is desirable that intelligent systems can be empowered by the capacity of commonsense reasoning in natural language. For this purpose, a surge of commonsense reasoning tasks and datasets are proposed to evaluate and improve such an ability of NLP models, *e.g.,* CommonsenseQA (Talmor et al., 2019) and SocialIQA (Sap et al., 2019b). Although large-scale pre-trained models (PTMs) (Devlin et al., 2019; Liu et al., 2019) have surpassed human performance in a number of NLP benchmarks, it is still hard for PTMs to accurately capture and understand commonsense knowledge for accomplishing complex reasoning tasks (Talmor et al., 2021).

In order to enhance the reasoning capacity, commonsense knowledge graphs (CSKGs) (*e.g.,* ConceptNet (Speer et al., 2017) and ATOMIC (Sap et al., 2019a)) have been adopted for injecting external commonsense knowledge into PTMs. By conducting entity linking to CSKGs, existing methods (Yasunaga et al., 2021; Feng et al., 2020a) aim to capture the structured knowledge semantics via knowledge graph (KG) encoders (*e.g.,* graph neural network (GNN) (Velickovic et al., 2018; Kipf and Welling, 2017)), and then integrate the KG encoders for improving the commonsense reasoning capacity of PTMs (Yasunaga et al., 2021).

Despite the effectiveness, these approaches are built on highly complicated network architectures (involving both PTMs and GNNs). Thus, it is difficult to explain how and why external commonsense knowledge improves the commonsense reasoning capacity of PTMs. Besides, existing CSKGs (Mehrabi et al., 2021; Nguyen et al., 2021) are mostly crowdsourced from massive selected resources (*e.g.,* books, encyclopedias, and scraped web corpus), containing a wide variety of content. Without a clear understanding of how these external resources should be utilized, it is likely to incorporate irrelevant concepts or even knowledge biases (Mehrabi et al., 2021; Nguyen et al., 2021) into PTMs, which might hurt the reasoning performance. Indeed, some researchers have noted this issue and questioned whether existing GNN-based modules are over-complicated for commonsense reasoning (Wang et al., 2021a). Furthermore, they find that even a simple graph neural counter can outperform existing GNN modules on CommonsenseQA and OpenBookQA benchmarks.

However, existing studies can't well answer the fundamental questions about knowledge utilization for commonsense reasoning: How do external knowledge resources enhance the commonsense reasoning capacity of PTMs? What is necessarily required from external knowledge resources

for PTMs? Since the simplified knowledge-aware GNN has already yielded performance improvement on the CommonsenseQA (Wang et al., 2021a), we speculate that there might be a simpler solution if we could identify the essential knowledge for commonsense reasoning.

Focusing on this issue, we think about designing the solution by further simplifying the KG encoder. Based on our empirical analysis, we observe a surprising result that it is indeed *relation features* from CSKGs, but not *node features*, that are the key to the task of commonsense reasoning (See more details in Section 3). According to this finding, we propose a rather simple approach to leveraging external knowledge resources for enhancing the commonsense reasoning capacity of PTMs. Instead of using a heavy GNN architecture, we design a lightweight KG encoder fully based on the multi-layer perceptron (MLP), which utilizes **S**tatistical relation p**A**th from CSKGs as **FE**atures, namely **SAFE**. We find that semantic relation paths can provide useful knowledge evidences for PTMs, which is the key information for helping commonsense reasoning. By conducting extensive experiments on five benchmark datasets, our approach achieves superior or competitive performance compared with state-of-the-art methods, especially when training data is limited. Besides the performance improvement, our approach largely reduces the parameters for encoding CSKGs (fewer than 1% trainable parameters compared to GNN-based KG encoders (Yasunaga et al., 2021)).

Our main contributions can be summarized as follows: (1) We empirically find that relation features from CSKGs are the key to the task of commonsense reasoning; (2) We design a simple MLP-based architecture with relation paths as features for enhancing the commonsense reasoning capacity of PTMs; (3) Extensive experiments conducted on five benchmark datasets demonstrate the effectiveness of our proposed approach, which also largely reduces the parameters of the KG encoder.

2 Task Description

According to pioneer works (Talmor et al., 2019; Mihaylov et al., 2018), the commonsense reasoning task can be generally described as a multi-choice question answering problem: given a natural language question q and a set of n choices $\{c_1, \cdots, c_n\}$ as the answer candidates, the goal is to select the most proper choice $c^\star$ from these candidates to answer the question based on necessary commonsense knowledge.

To explicitly capture commonsense knowledge, external commonsense knowledge graphs (CSKGs) have often been utilized in this task, *e.g.,* ConceptNet (Speer et al., 2017). A CSKG can be formally described as a multi-relational graph $\mathcal{G} = (\mathcal{V}, \mathcal{R}, \mathcal{E})$, where $\mathcal{V}$ is the set of all concept (or entity) nodes (*e.g., hair* and *water*), $\mathcal{R}$ is the set of relation types (*e.g., relatedto* and *atlocation*), and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{R} \times \mathcal{V}$ is the set of relational links that connect two concept nodes in $\mathcal{V}$.

Following prior studies (Lin et al., 2019), we solve the commonsense reasoning task in a *knowledge-aware* setting, where a CSKG $\mathcal{G}$ is available as input. We first link the mentioned concepts from the question and the answer candidates to the CSKG, so that we can leverage the rich semantic knowledge from the CSKG for commonsense reasoning. Based on the linked concepts in the question and each answer candidate, we further extract their neighbouring nodes from $\mathcal{G}$ and the relational links that connect them, to compose a subgraph $\mathcal{G}^{q,c_i}$ for characterizing the commonsense knowledge about the question q and the answer candidate c_i.

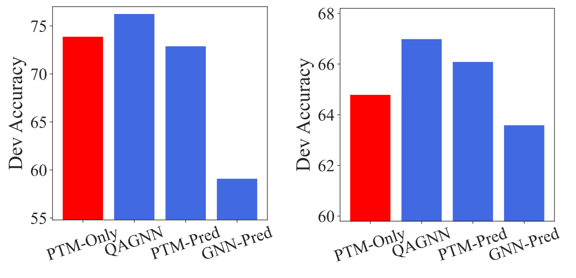
3 Empirical Analysis on the Commonsense KG Encoder

In this section, we conduct an empirical study to investigate how the external KG encoder helps PTMs with commonsense reasoning.

3.1 Analysis Setup

To conduct the analysis experiments, we select QA-GNN (Yasunaga et al., 2021), a representative approach that integrates PTM with GNN for the commonsense QA task, as the studied model. We adopt the CommonsenseQA (Talmor et al., 2019) and OpenBookQA (Mihaylov et al., 2018), two of the most widely used commonsense reasoning benchmarks, for evaluation, with the same data split setting in (Lin et al., 2019).

We perform two analysis experiments: one examines the effect of the commonsense KG encoder, and the other one examines the effect of different features in the commonsense KG encoder. To be specific, the two experiments focus on two key questions about commonsense reasoning: (1) what is the effect of the commonsense KG encoder on PTMs? (2) what is the key information within the



(a) CommonsenQA (b) OpenBookQA

Figure 1: Performance comparison on CommonsenseQA and OpenBookQA (Dev accuracy).

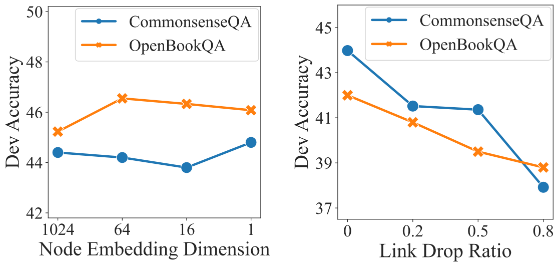


Figure 2: Performance examination for KG encoder on CommonsenseQA and OpenBookQA (Dev accuracy).

commonsense KG encoder?

3.2 Results and Findings

Next, we conduct the experiments and present our findings of commonsense reasoning.

Effect of Commonsense KG Encoder. Since existing studies have widely utilized a GNN module to encode the commonsense knowledge, we examine its contribution to the improvement of reasoning performance. We consider comparing three variants of QA-GNN: (A) *PTM-Only* that directly removes the GNN module and degenerates into a pure PTM, (B) *PTM-Pred* that trains the PTM and GNN simultaneously but only makes the prediction with the PTM module, and (C) *GNN-Pred* that trains the PTM and GNN simultaneously but only makes the prediction with the GNN module.

The comparison results are shown in Figure 1. As we can see, using the predictions solely based on the GNN module (*i.e.,* GNN-Pred) can only answer a relatively minor proportion of the questions (no more than 60% in CommonsenseQA). As a comparison, when trained independently (*i.e.,* PTM-Only) or jointly with the GNN module (*i.e.,* PTM-Pred), the PTM module can answer a large proportion of the questions (at least 70% in CommonsenseQA). Furthermore, the incorporation of the GNN encoder is useful to improve the performance of PTMs (PTM-Only *v.s.* QAGNN). These results show that:

- In the joint PTM-GNN approach, PTM contributes the most to the commonsense reasoning task, which is the key to the reasoning performance.
- Commonsense KG encoder is incapable of performing effective reasoning independently, but can enhance PTM as the auxiliary role.

Effect of Node/Relation Features from KG. The major aim of the KG encoder is to characterize the commonsense knowledge and provide necessary knowledge evidence for enhancing the reasoning capacity of PTMs. Generally, a CSKG consists of concept nodes and relational links. To identify the key knowledge information that is necessarily needed, we now examine the effect of node and relation features from CSKG. To eliminate the effect of PTM module, we remove it and compare the performance of only KG encoder under two experiment settings: (A) reducing the dimension of node embeddings to d (PCA (Jolliffe, 1986) is applied to select d most informative dimensions), and (B) randomly removing p percent of relational links in the KG subgraph for a question-candidate pair.

As shown in Figure 2, we surprisingly find that even after reducing the dimension of node embeddings to 1, the performance of the GNN encoder can be still improved. These results show that node features are not the key information utilized by the GNN encoder. In contrast, removing a considerable proportion of links significantly reduces the performance. From these observations, we can conclude that: The relation features from the CSKG are indeed the key knowledge information that is actually needed by the KG encoder.

4 Approach

The former sections show that the role of the KG encoder on CSKGs is to mainly complement PTMs in the task of commonsense reasoning. Instead of node features, relations features are the key to the KG encoder for improving PTMs. Based on these findings, we develop a simple commonsense KG encoder based on the statistical relation features from CSKGs, namely **SAFE**. Figure 3 presents the overview of our model.

4.1 Capturing High-Order Relation Semantics

Since relation features are shown useful to improve the performance of commonsense reasoning, we consider extracting relation features for better capturing the knowledge semantics from the CSKG. Inspired by KG reasoning studies (Lin et al., 2018; Feng et al., 2020b), we construct multi-hop relation paths that connect question nodes with answer candidate nodes on the CSKG to capture the higher-order semantic relatedness among them.

Formally, given the commonsense subgraph $\mathcal{G}^{q,c_i}$ for the question q and the answer candidate c_i, we first extract a set of relation paths within k hops that connect a question concept node $v_q \in \mathcal{V}_q$ and an answer concept node $v_{c_i} \in \mathcal{V}_{c_i}$, denoted as $\mathcal{P}^{q,c_i}$. Specifically, a path $p \in \mathcal{P}^{q,c_i}$ can be represented as a sequence of nodes and relations as $p = \{v_1, r_1, \cdots, r_{k-1}, v_k\}$. Based on the empirical findings in Section 3, we consider a simplified representation for relation paths that removes node IDs but only keeps the relations on a path. To keep the role of each node, we replace a node ID by a three-valued type, indicating this node belongs to a *question node* (0), *answer node* (1) or *others* (2). In this way, a path p can be represented by $p = \{t_{v_1}, r_1, t_{v_2}, r_2, \cdots, r_{k-1}, t_{v_k}\}$, where t_v is the role type of node v. Since we remove explicit node IDs, our model can concentrate on more essential relation features.

Based on the above method, for a question q and an answer candidate c_i, we extract all the simplified relation paths and count their frequencies among all the paths. We use $\mathcal{F}^{q,c_i} = \{\langle p_j, f_j \rangle\}$ to denote all the paths for the question q and the answer candidate c_i, where each entry consists of the j-th path p_j and its frequency f_j. Unlike prior approaches (*e.g.,* QA-GNN), we use such very simple features of relation paths from CSKGs to improve the reasoning capacity of PTMs.

4.2 A MLP-based KG encoder

Our KG encoder is built on a full MLP architecture based on simplified relation path features, consisting of a path encoder and a feature aggregator.

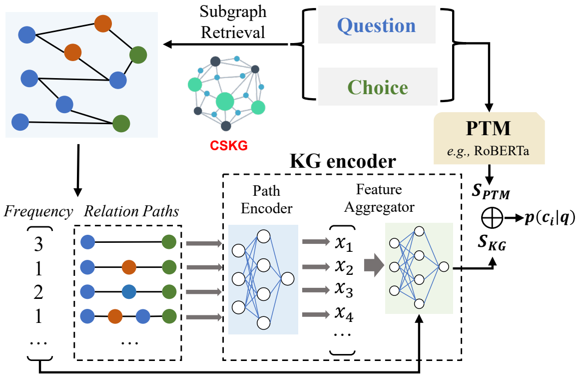

Figure 3: The illustration of our approach. We adopt an all-MLP KG encoder to model the extracted relation features from CSKG to enhance the PTM.

Path Encoder. The path encoder is a two-layer MLP that encodes a relation path into a scalar feature value. As shown in Section 4.1, we can obtain the path feature set $\mathcal{F}^{q,c_i} = \{\langle p_j, f_j \rangle\}$ for the question q and the answer candidate c_i. Different from general KGs, CSKGs usually contain much fewer types of relations (*e.g.,* 36 relations in ConceptNet), we adopt one-hot representations of these types to represent these relations. For node type (from *question*, *candidate* or *others*), we also adopt the similar representations. Then, we concatenate these one-hot vectors to compose the sparse representation of a relation path p in order, denoted as $\mathbf{v}_p$. Subsequently, the sparse path representation is encoded by a two-layer MLP (*i.e.,* the path encoder) to produce the corresponding scalar feature value x_p:

$$x_p = \text{MLP}_2(\text{MLP}_1(\mathbf{v}_p)), \qquad (1)$$

where x_p reflects the importance of such a relation path for commonsense reasoning.

Feature Aggregator. Based on the above path encoder, we can generate the scalar feature values for all the relation paths in the feature set $\mathcal{F}^{q,c_i} = \{\langle p_j, f_j \rangle\}$. The feature aggregator aims to aggregate these feature values to produce the confidence score of the answer candidate *w.r.t.* the question, from the KG perspective. Concretely, we sum the different feature values of relation paths weighted by their frequencies as follows:

$$x_{q,c_i} = \sum_{\langle p_j, f_j \rangle \in \mathcal{F}^{q,c_i}} x_{p_j} \cdot f_j, \qquad (2)$$

where x_{p_j} is the mapping feature value of path p_j and f_j is the frequency of path p_j. Here, x_{q,c_i} aims to capture the overall confidence score based on the subgraph $\mathcal{G}^{q,c_i}$ given the question and the answer candidate. However, since the weighted sum is likely to cause extreme values (*i.e.,* too large or too small), we add an extra two-layer MLP for scaling:

$$S_{KG}(q, c_i) = \text{MLP}_4(\text{MLP}_3(x_{q,c_i})), \qquad (3)$$

where S_{KG} is the prediction score indicating the confidence level that candidate c_i is the right answer to question q from the perspective of KG.

4.3 Integrating KG Encoder with PTM

In this part, we integrate the above KG encoder with the PTM for commonsense reasoning.

The PTM Encoder. Following existing works (Yasunaga et al., 2021), we utilize a PTM as the backbone of commonsense reasoning. Given a question q and an answer candidate c_i, we concatenate their text to compose the input of the PTM. After encoding by the multiple Transformer layers, we select the output of the `[CLS]` token in the last layer as the contextual representation of the question-candidate pair, denoted by $\mathbf{h}_{cls}$. Then, we feed $\mathbf{h}_{cls}$ into a MLP layer to produce a scalar output S_{PTM},

$$\mathbf{h}_{cls} = \text{PTM}(q, c_i), \tag{4}$$

$$S_{PTM}(q, c_i) = \text{MLP}(\mathbf{h}_{cls}), \tag{5}$$

which is the plausibility score of the answer candidate from the perspective of PTM.

Combining the Prediction Scores. We then derive the prediction score of each answer candidate for a question by leveraging both the PTM and KG encoder based on either textual or structured semantics. For each question-candidate pair (q, c_i), we combine the prediction scores of the two modules as:

$$S(q, c_i) = S_{PTM}(q, c_i) + S_{KG}(q, c_i), \tag{6}$$

where $S_{PTM}(q, c_i)$ (Eq. 5) and $S_{KG}(q, c_i)$ (Eq. 3) are the prediction scores of PTM and KG encoder, respectively. Given a set of answer candidates $\{c_1, ..., c_n\}$, we further normalize $S(q, c_i)$ into a conditional probability $\text{Pr}(c_i|q)$ via the softmax operation over the n candidates.

During the training stage, we optimize the parameters of the whole model (including both the PTM and KG encoder) with the cross entropy loss between the predictions and the ground-truth answer (based on the probability distribution $\{\text{Pr}(c_i|q)\}_{i=1}^{n}$). During inference, we first compute the probability score $\text{Pr}(c_i|q)$ for each answer candidate, and then select the highest one as the predicted answer.

4.4 Comparison with Existing KG Encoders

For the task of commonsense reasoning, it has become a common approach by integrating PTM with an external KG encoder based on CSKGs. The major difference among these methods (including our approach) lies in the design of the KG encoder. Next, we compare these variants for the KG encoder.

	RGCN	MHGRN	QAGNN	SAFE
Node emb.	√	√	√	×
Relation	√	√	√	√
GNN	√	√	√	×
MLP-based	×	×	×	√
# Params	365K	547K	2845K	4.7k

Table 1: Comparisons of different KG encoders for commonsense reasoning. Instead of using node embeddings and GNN structure, we adopt relation paths as the input features and incorporate a full MLP architecture.

We summarize the comparison between our KG encoder and representative KG encoders in Table 1. We can see that, our approach no longer lies in the node embeddings and the structure of GNNs. Instead, we mainly utilize relation paths as the features of the KG encoder, which is built on a simple MLP-based architecture. Therefore, the number of the model parameters involved in our KG encoder is much smaller than those of existing KG encoders. As will be shown in Section 5, our KG encoder yields better or at least comparable performance compared with existing GNN-based encoders, based on the same configuration for PTMs.

Specifically, our approach can largely reduce the computational costs for encoding the CSKG. For our approach, we need to extract the relation paths from question nodes to all the answer candidate nodes on the CSKG, and it can be efficiently fulfilled via a k-hop constrained Depth-First Search (Tarjan, 1972), which can be pre-computed in offline processing. When the relation paths have been extracted, it is efficient to encode these paths with our MLP architecture. Such a process can be easily paralleled or accelerated by optimized matrix multiplication. In contrast, existing GNN-based encoders rely on iterative propagation and aggregation on the entire subgraph, which takes a much larger computational time cost.

5 Experiment

5.1 Experimental Setup

In this part, we introduce the experimental setup.

Evaluation Tasks. We conduct experiments on five commonsense reasoning tasks, shown in Table 2.

Task	Train	Dev	Test
CommonsenQA	9,741	1,221	1,140
OpenBookQA	4,957	500	500
SocialIQA	33,410	1,954	-
PIQA	16,113	1,838	-
CoPA	-	500	500

Table 2: Statistics of the datasets. "-" denotes the unused or not available dataset split in our experiments.

- **CommonsenseQA** (Talmor et al., 2019) is a 5-way multiple-choice QA dataset. It is created based on ConceptNet (Speer et al., 2017).
- **OpenBookQA** (Mihaylov et al., 2018) is a 4-way multiple-choice QA dataset about elementary science questions to evaluate the science commonsense knowledge.
- **SocialIQA** (Sap et al., 2019b) is a 3-way multiple-choice QA dataset to evaluate the understanding of social commonsense knowledge.
- **PIQA** (Bisk et al., 2020) is a binary-choice QA dataset about physical commonsense.
- **CoPA** (Roemmele et al., 2011) is a commonsense inference dataset, to select the most plausible alternative with the causal relation to the premise.

Data Preprocessing. For CommonsenseQA and OpenBookQA, we use their original train/dev/test split settings. Since the test set of CommonsenseQA is not available, we follow previous work (Lin et al., 2019) that extracts 1,241 examples from the original training set as the test set. Besides, the test sets of SocialIQA and PIQA are not available. Therefore, we report the experimental results on their development sets for a fair comparison (Shwartz et al., 2020). For CoPA that only provides development and test sets, we follow Niu et al. (2021) to train models on the development set and evaluate the performance on the test set. For commonsense KG, we adopt *ConceptNet* (Speer et al., 2017), a general-domain and task-agnostic CSKG, as our external knowledge source $\mathcal{G}$ for all the above models and tasks. For each question-candidate pair (q, c_i), we follow previous works (Lin et al., 2019; Feng et al., 2020a) to retrieve and construct the subgraph $\mathcal{G}^{q,c_i}$ from the CSKG $\mathcal{G}$.

Baseline Methods. We compare our model with the following six baseline methods, including a fine-tuned PTM and five PTM+GNN models:

- **Fine-tuned PTM** directly fine-tunes a PTM without using any CSKG. We use RoBERTa-large (Liu et al., 2019) for all tasks. Additionally, we also use BERT-large (Devlin et al., 2019) and AristoRoBERTa (Clark et al., 2020a) for OpenBookQA to evaluate the generality of our KG-encoder.
- **PTM+GNN models** integrate PTM with additional GNN-based KG encoders. Based on the same PTM (the above baseline), we consider five variants with different KG encoders: (1) *Relation Network* (RN) (Santoro et al., 2017) using a relational reasoning structure over the CSKG; (2) *GcoAttn* (Lin et al., 2019) using a graph concept attention model to aggregate entity information from the CSKG; (3) *RGCN* (Schlichtkrull et al., 2018) extending the GCN with relation-specific weights; (4) *MHGRN* (Feng et al., 2020a) using a GNN architecture reasoning over the CSKG that unifies both GNNs and path-based models; (5) *QA-GNN* (Yasunaga et al., 2021) using a GAT to perform jointly reasoning over the CSKG.

For all these methods, we adopt the same architecture and configuration for the PTM, so that we can examine the effect of different KG encoders.

5.2 Implementation Details

We implement all PTMs based on HuggingFace Transformers (Wolf et al., 2020). For all the baselines, we keep the common hyper-parameters as identical as possible and set their special hyper-parameters following the suggestions from the original papers. In our approach, we extract the relation paths with no more than 2 hops between the concept nodes from the question and the answer candidate. We tune the hidden dimension of MLPs from the path encoder in {32, 64, 100}, and the batch size in {32, 48, 60, 120}. The parameters of the model are optimized by RAdam (Liu et al., 2020), and the learning rate of the PTM and the KG encoder is also tuned in {$1e$-4, $1e$-5, $2e$-5} and {$1e$-3, $1e$-2}, respectively. To accelerate the training process, we don't incorporate Dropout regularization in our model. All the above hyper-parameters are tuned on the development set.

5.3 Results Analysis

Following previous works (Yasunaga et al., 2021; Wang et al., 2021a), we take the results on CommonsenseQA and OpenBookQA as the main experiments to compare different methods. In order to test their robustness to data sparsity, we examine the performance under five different proportions of training data, *i.e.,*

Methods	CommonsenseQA						OpenBookQA					
	5%	10%	20%	50%	80%	100%	5%	10%	20%	50%	80%	100%

$\{5\%, 10\%, 20\%, 50\%, 80\%, 100\%\}$.

CommonsenseQA and OpenBookQA. The results of different methods on CommonsenseQA and OpenBookQA are presented in Table 3.

Comparing the results under the full-data setting (*i.e.,* 100% training data), we can see that all the PTM+GNN methods perform better than vanilla PTM (*i.e.,* RoBERTa-large). It indicates that the KG encoder on the CSKG is able to incorporate useful knowledge information to improve PTMs on commonsense reasoning tasks. Additionally, among all the PTM+GNN baselines, QA-GNN performs the best. The major reason is that QA-GNN uses the PTM to estimate the importance of KG nodes and connects the QA context and the CSKG to form a joint graph, which is helpful to improve the reasoning ability on the CSKG. Finally, our method consistently outperforms all the baselines. Our approach incorporates a lightweight MLP architecture as the KG encoder with relation paths as features. It reduces the parameter redundancy of the KG encoder and focuses on the most essential features for reasoning, *i.e.,* semantic relation paths. Such an approach is effective to enhance the commonsense reasoning capacity of PTMs.

Comparing the results under different sparsity ratios of training data, we can see that the performance substantially drops when the size of training data is reduced. While, our method performs consistently better than all baselines. It is because that our KG encoder consists of significantly fewer parameters than those of the baselines, which reduces the risk of overfitting and endows our approach with better robustness in data scarcity scenarios.

Other Commonsense Reasoning Datasets. To further verify the effectiveness of our method, we also compare the results of different methods on other commonsense reasoning datasets. These datasets are from different domains or different tasks. These results are shown in Table 4. Similarly, our approach also achieves the best performance in most cases. It indicates that our approach is generally effective for various commonsense reasoning datasets or tasks, by outperforming competitive but complicated baselines. Among all the datasets, our approach improves the performance of the PTM on CoPA dataset by a large margin. The reason is that CoPA is a small dataset with only 500 training

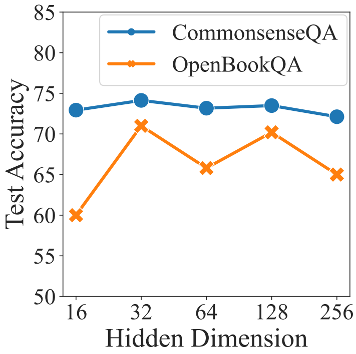

Figure 4: Analysis of different hidden dimension size of our SAFE model.

examples. Baselines with heavy architectures are easy to overfit on it. In contrast, our KG encoder is lightweight, which is more capable of resisting the overfitting issue.

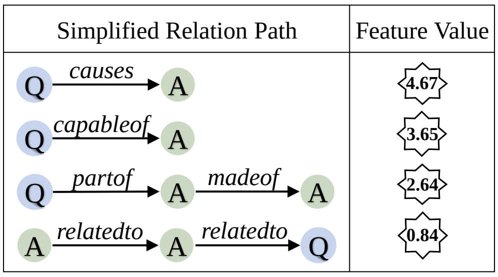
5.4 Evaluation with Other PTMs

The major contribution of our approach lies in the lightweight KG encoder, which can be also used to enhance the commonsense reasoning capacity of various PTMs. To validate it, we examine the performance of our KG encoder when integrated with two other PTMs, *i.e.,* BERT-large and AristoRoBERTa, on OpenBookQA dataset.

As shown in Table 5, the BERT-large and AristoRoBERTa enhanced by our KG encoder perform better than original PTMs. Especially, our KG encoder can improve the performance of AristoRoBERTa by a large margin (with 8.73% improvement). These results show that our KG encoder is a general method to improve PTMs for commonsense reasoning. In contrast, when adapting other KG encoders to these two PTMs, the performance decreases in most cases. It is mainly because these KG encoders have complicated architectures, which may not be easily adapted to other PTMs.

5.5 Hyper-parameters Analysis

For hyper-parameter analysis, we study the hidden dimension size of the MLP in the path encoder. Concretely, we evaluate our model with varying values of the hidden dimension size on CommonsenseQA and OpenBookQA datasets using RoBERTa-large model. The results are shown in Figure 4. We can see that with the increase of the hidden dimension size, the performance improves at first and then drops to some extent. The possible reason lies in two aspects. On the one hand, a too small hidden dimension size makes the path encoder hard to represent sufficient information from relation paths for commonsense reasoning. On the other hand, a larger hidden dimension size enlarges the parameter number of our KG encoder, which increases the risk of overfitting that may cause performance degradation.



Simplified Relation Path	Feature Value
Q $\xrightarrow{causes}$ A	4.67
Q $\xrightarrow{capableof}$ A	3.65
Q $\xrightarrow{partof}$ A $\xrightarrow{madeof}$ A	2.64
A $\xrightarrow{relatedto}$ A $\xrightarrow{relatedto}$ Q	0.84

Figure 5: The generated feature values of relation path examples by the path encoder. **Q** and **A** denote the concept nodes from the question and the answer candidate, respectively.

5.6 Case Study

We propose a rather simple KG encoder to effectively utilize the relation features from the CSKG, which first computes the feature values of the relation paths and then aggregates these values as the confidence score of the question and choice from the perspective of KG. In this way, we can generate a table in advance that maps each type of relation path into its feature value that reflects its contribution to the confidence score. Based on this table, it is convenient to directly judge the importance of the relation path and quickly assess the confidence about if the choice is the answer to the question from the perspective of KG. Figure 5 shows some path-value examples on CommonsenseQA dataset. As we can see, the path with a higher value indeed provide more persuasive evidence (*e.g., causes* and *capableof*) that indicates the choice is more likely to be the answer to the question. In contrast, the path with a lower value usually represents an ambiguous relationship (*e.g., relatedto*), which contributes less to the judge of whether the choice is the answer.

6 Related Work

We review the related studies in two aspects, *i.e.,* commonsense reasoning and KG-enhanced pre-trained models.

Commonsense Reasoning. Commonsense reasoning tasks aim to evaluate the understanding of commonsense knowledge (Davis and Marcus, 2015), *e.g.,* physical commonsense (Zellers et al., 2019), which are mostly formulated as a multi-choice QA problem. Early studies either rely on explicit text features (Clark et al., 2016) to capture the relations between the question and answer candidates, or adopt neural networks (*e.g.,* DNN or LSTM) (Yu et al., 2014; Chen et al., 2017) to model the implicit correlation features. Recently, pre-trained models (PTM) (Devlin et al., 2019; Liu et al., 2019) have achieved remarkable performance on commonsense reasoning tasks. Furthermore, a surge of works incorporate external knowledge resources to further improve the reasoning performance. Among them, CSKG (*e.g.,* ConceptNet (Speer et al., 2017)) has been widely studied, and existing works mainly adopt graph neural networks to learn useful commonsense knowledge from the CSKG to enhance PTMs. Based on these works, we systemically study what is necessarily needed from CSKGs for improving PTMs. Our analysis leads to an important finding that relation features mainly contribute to the performance improvement, and we design a lightweight MLP architecture to simplify the KG encoder.

KG-Enhanced Pre-trained Models. Recently, a series of works focus on enhancing PTMs with external KGs to improve the performance on factual knowledge understanding (Sun et al., 2020; Wang et al., 2021b) and knowledge reasoning tasks (Talmor et al., 2019; Zhang et al., 2019; He et al., 2020). These works inject the structured knowledge from the external KG into PTMs in either pre-training or fine-tuning stage. The first class of works mainly focus on devising knowledge-aware pre-training tasks (Wang et al., 2021b; Zhang et al., 2019) to improve the understanding of entities or triples from the KG, *e.g.,* knowledge completion (Wang et al., 2021b) and denoising entity auto-encoder (Zhang et al., 2019). Another class of works adopt task-specific KG encoders to enhance PTMs during fine-tuning, *e.g.,* path-based relation network (Feng et al., 2020a) and GNN (Yasunaga et al., 2021). Different from them, we aim to directly enhance PTMs with a KG encoder on the downstream commonsense reasoning tasks, and design a rather simple yet effective KG encoder.

7 Conclusion

In this work, we study how the external commonsense knowledge graphs (CSKGs) are utilized to improve the reasoning capacity of pre-trained models (PTMs). Our work makes an important contribution to understanding and enhancing the commonsense reasoning capacity of PTMs. Our results show that relation paths from the CSKG are the key to performance improvement. Based on this finding, we design a rather simple MLP-based KG encoder with relation paths from the CSKG as features, which can be generally integrated with various PTMs for commonsense reasoning tasks. Such a lightweight KG encoder has significantly fewer than 1% trainable parameters compared to previous GNN-based KG encoders. Experimental results on five commonsense reasoning datasets demonstrate the effectiveness of our approach.

In future work, we will study how to effectively leverage the commonsense knowledge from large-scale unstructured data to improve PTMs. We will also try to apply our approach to other knowledge-intensive tasks, *e.g.,* knowledge graph completion and knowledge graph based question answering (Lan et al., 2021).

8 Ethical Consideration

This work primarily investigates how external commonsense knowledge graphs (CSKGs) enhance the commonsense reasoning capacity of pre-trained models (PTMs) and proposes a simple but effective KG encoder on CSKGs to enhance PTMs. A potential problem derives from using PTMs and CSKGs in our approach. PTMs have been shown to capture certain biases from the data that have been pre-trained on (Bender et al., 2021). And existing works (Mehrabi et al., 2021) have found that CSKGs are likely to contain biased concepts derived from human annotations. However, a comprehensive analysis of such biases is outside of the scope of this work. It is a compelling direction to investigate to what extent the combination of CSKGs and PTMs can help mitigate such biases. An alternative consideration is to consider filtering biased concepts in the process of subgraph extraction from the CSKG. By devising proper rules, it is promising to reduce the influence of biased concepts on our approach.

Abstract

Complaining is a speech act that expresses a negative inconsistency between reality and human expectations. While prior studies mostly focus on identifying the existence or the type of complaints, in this work, we present the first study in computational linguistics of measuring the *intensity* of complaints from text. Analyzing complaints from such a perspective is particularly useful, as complaints of certain degrees may cause severe consequences for companies or organizations. We create the first Chinese dataset containing 3,103 posts about complaints from Weibo, a popular Chinese social media platform. These posts are then annotated with complaints intensity scores using Best-Worst Scaling (BWS) method. We show that complaints intensity can be accurately estimated by computational models with the best mean square error achieving 0.11. Furthermore, we conduct a comprehensive linguistic analysis around complaints, including the connections between complaints and sentiment, and a cross-lingual comparison for complaints expressions used by Chinese and English speakers. We finally show that our complaints intensity scores can be incorporated for better estimating the popularity of posts on social media.[1]

1 Introduction

Complaining is caused by the gap between reality and people's expectations (Olshtain and Weinbach, 1985). Brown et al. (1987) state that the purpose of complaining is not to confirm that the two parties have reached an agreement but to face-threatening acts. People use complaints to express their concerns or dissatisfaction based on the severity and urgency of situations.

Researchers from linguistics and psychology have long pointed out that people may shape their complaints to varying degrees (Olshtain and Weinbach, 1985; Jenkins and Cangemi, 1979; Trosborg, 2011). Leech (2016) classifies complaints as conflicting speech acts. Mild complaints can reach the purpose of venting emotions to promote mental health, but serious complaints can lead to hatred and even bullying behaviors (Iyiola and Ibidunni, 2013). In computational linguistics, prior studies primarily focus on building automatic classification models for identifying the existence of complaints (Preotiuc-Pietro et al., 2019). Most recently, Jin and Aletras (2021) provided a dataset annotated with different severity levels of complaints based on the theory of pragmatics, including four distinct categories "no explicit reproach", "disapproval", "accusation" and "blame".

Among these studies, we note one missing piece is to measure the *intensity* of complaints. To illustrate this point, consider two sentences from the newest annotated dataset from Jin and Aletras (2021): *can i complain to you about the coffee i just received ?* and *virgin media as usual full of lies lies lies ! ! !*. Although these two complaints may have the same type "accusation", it is clear that they are different regarding the degree of complaints. As another example, *totally not cool.* and *please reply my dm asap ! ! !* are both classified as "disapproval". However, the latter makes a stronger complaint. Analyzing different complaints levels can also be beneficial. Companies need to regularly monitor the feedback from users, as certain complaints may significantly impact the reputation of their products. Organizations or governments need to monitor people's biggest complaints to understand their urgent needs.

In this work, we analyze the intensity of complaints on social media. To the best of our knowledge, it is the first computational linguistics study that tries to automatically capture the complaints intensity from text. We present the first Chinese complaints intensity dataset, consisting of 3,103 posts

---

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1742 - 1754
July 10-15, 2022

from Weibo. We then show that the complaints intensity can be measured from text by building computational models. We further demonstrate the necessity and importance of understanding complaints intensity. This includes a detailed analysis that distinguishes the differences between our complaint intensity scores and original sentiment scores. As a pilot study for complaints in Chinese, we also perform a cross-lingual analysis to understand the differences in the complaint expressions used in Chinese and English. We have some interesting empirical findings. For example, we observe that English speakers tend to use more ironic expressions than Chinese speakers. Finally, we show how our annotated corpus can help predict the popularity of posts on social media.

2 Data

In this section, we present the first Chinese dataset that is annotated towards the intensity of the complaints reflected from text.

2.1 Data Collection

We collect data from Weibo,[2] a famous social media platform in China that is similar to Twitter. As posts about complaints only account for a minority of the total posts on Weibo, in this work we consider education domain – an area that is the primary focus for most families in China, which generally raises hot debates and complaints about current education policies. We selected a set of keywords related to complaints, including 抱怨 (*complaint*), 不公平 (*unfair*), and 举报 (*report*). We then randomly sampled 5 hashtags around these keywords and collected Weibo posts from these hashtags. We collected a total of 4,490 Weibo posts from August 2020 to May 2021.

Pre-processing. We notice that the hashtag on Weibo is usually a sentence (in "#...#" format), rather than a phrase like its Twitter counterparts. To ensure a certain amount of content generated by users, we filtered out posts with less than 10 words and more than 200 words (without hashtags). For each post, we removed the name of the author, location tags, and URLs. We also converted emoticon into text format. Finally, 3,103 Weibo posts remain for annotation. Table 1 shows the breakdown statistics in our corpus.

Hashtag	**Num.**
#代表建议让学生在校内完成家庭作业# (*#The representative suggested that students should complete their homework on campus#*)	762
#江苏明确教师不得用手机布置作业# (*#Jiangsu Province makes it clear that teachers are not allowed to use mobile phones to assign homework#*)	534
#院士不建议普通孩子学奥数# (*#Academician does not recommend ordinary children to learn Mathematical Olympiad#*)	627
#西安外国语大学封闭管理# (*#Close management of Xi'an International Studies University#*)	598
#人大法硕复试30余人成绩0分# (*#More than 30 people scored 0 in the postgraduate examination of law at Renmin University#*)	582
Total	3,103

Table 1: Hashtags and number of collected Weibo posts in our annotated corpus.

2.2 Data Annotation

Complaints Levels. Our goal is to measure the intensity of complaints from text. We adopt the definition from Jenkins and Cangemi (1979), which quantifies the complaints into five levels, as shown in Table 2. Higher levels indicate stronger complaints.

Level	**Description**
1	a little anxiety and disgust
2	deliberately expressing anxiety
3	actively looking for ways to solve anxiety
4	frustrated behavior
5	depression, fear, and despair

Table 2: Guideline used in annotation process for distinguishing different levels of complaints, adopted from Jenkins and Cangemi (1979).

In pilot studies, we test the feasibility of using these levels as the annotation guideline for the annotators, along with the potential mismatches between Chinese and English speakers. We observe that annotators are able to make comparison between complaints of different degrees. As discussed later, our annotations also achieve high agreement between annotators.

Best-Worst Scaling (BWS). In this work, we annotate the complaint intensity using Best-Worst Scaling, proposed by Louviere and Woodworth (1991). We choose this method as it can produce more stable and fined-grained scores than directly scoring (Kiritchenko and Mohammad, 2017). We note similar methods have been applied to various tasks, including measuring offensiveness (Hada et al., 2021) and intimacy (Pei and Jurgens, 2020) in the computational linguistic literature.

In BWS annotation, annotators are provided with

---

[2] `www.weibo.com`

4-tuples randomly generated that meet certain criteria.[3] Annotators are then asked to select the strongest complaint item and the weakest complaint item within each 4-tuple. In practice, we randomly generated $2n$ distinct 4-tuples, with n being the number of posts. This amount of tuples is considered to be sufficient for getting reliable scores from annotation (Kiritchenko and Mohammad, 2017). We assign the complaint intensity score for each post by using the percentage of strongest cases minus the weakest cases, ranging from -1 to 1.

Annotation Quality. To ensure the quality of our annotations, we manually annotated 100 posts and asked all annotators to annotate them beforehand. We removed annotators whose accuracy is less than 70% on these golden annotations. To get highly reliable results, we got each tuple annotated by 3 annotators. In total, we received more than 14,000 annotations from 15 annotators.

We follow the literature (Kiritchenko and Mohammad, 2017) and measure the quality of annotations by using score-to-half reliability (SHR). SHR score is calculated by randomly splitting all the tuples into two halves and then computing the correlation between these two groups. We repeat the above process 100 times. The average SHR score is 0.91, which indicates strong reliability.

2.3 Data Analysis

We first analyze the distribution for the annotated complaint intensity scores in our corpus. As shown in Figure 1 (Left), we observe a normal distribution for the number of posts across different complaint scores, with most of the posts having intensity of complaints within -0.2 and 0.2.

We also observe that the length of complaint posts (intensity>0) is longer than that of non-compliant posts (intensity<0) in Figure 1 (Right). By examining our data, we observe it is because stronger complaints contain more details with more aspects. For example, in bin 5 of Table A1 (in Appendix A), the target of complaint changes from 学校 (*school*) to dissatisfaction with 图书馆 (*library*) and even accuses the behavior of 门卫 (*security guard*). This is the halo effect in psychology: if something leaves a wrong impression, everything related to it becomes terrible. On the contrary, we observe that most non-complaining posts contain only plain expressions, and people will not describe too much after expressing their opinions on the matter.

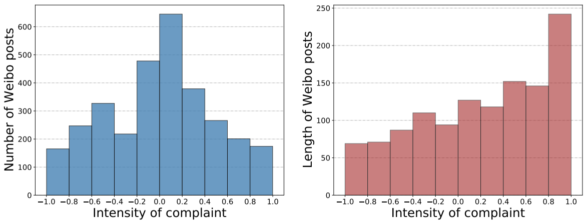

Figure 1: Distribution for the number and length of posts over complaints intensity in our corpus.

3 Predicting the Intensity of Complaints

In Section 2, we have a dataset annotated with the intensity of complaints from -1 to 1. We now build computational models for predicting the intensity of complaints of a given post.

3.1 Models

Support Vector Regression (SVR). We use support vector regression as our first baseline model. We experiment with two different input sentence representations: bag of {2,3,4}-gram features and 300-dimensional GloVe embeddings (Pennington et al., 2014). Results in Table 4 use an RBF (Radial Basis Function) kernel. We observe similar results using other kernels in practice (e.g., linear kernel).

Bidirectional LSTM. We also experiment with a bidirectional Long Short-Term-Memory (Bi LSTM) model. The LSTM and the average pooling layer concatenation are passed through a linear layer with a tanh activation, producing a score between -1 and 1. We use two sets of embedding for input layers: Glove (Pennington et al., 2014) and BERT for embedding (Li et al., 2020). The attention mechanism is also considered. Other hyperparameters for the models are a batch size of 64, a learning rate of 1e-3, 13 epochs with early stopping, and a dropout of 0.5 to avoid overfitting.

Pre-trained Models. We finally experiment with pre-trained models, including BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and ERNIE (Zhang et al., 2019). For all pretrained models, we add a linear layer as a regression layer to the model. We then fine-tune these models using a mean square error loss objective. We set the batch size to be 16 and learning rate to be 2e-5. The model is trained for 3 epochs. All hyperparameters are selected using a held-out dev set.

---

[3] Requirements are: (1) no two 4-tuples are the same; (2) no two posts within a 4-tuple are identical; (3) each post appears approximately in the same number of 4-tuples; (4) each pair of posts appears approximately in the same number of 4-tuples.

Bin	Weibo posts	Scores
1	以前在没有手机的年代，孩子们都是自己记作业。我觉得有助于形成自我管理能力 (*In the era when there were no mobile phones, children kept their homework by themselves. I think it helps to form self-management ability.*)	-1
2	最好的解决办法就是没有家庭作业，对老师对家长都好 (*The best solution is to have no homework, which is good for teachers and parents.*	-0.56
3	现在的学生作业为啥都得用手机做? (*Why do students have to use mobile phones to do their homework now?*)	+0.12
4	我是真的觉得用手机交作业很烦 (*I find it really annoying to hand in homework with my mobile phone.*)	+0.4
5	气死了！食堂涨价，超市关门，就没人管理嘛? (*Mad! The price of the canteen increases, and the supermarket closes, no one manages it?*)	+1

Table 3: Sample posts with complaints intensity scores. We divide our scoring scale (from -1 to 1) into 5 bins of size 0.4 (i.e., bin 1 refers to scores ranging from -1.0 to -0.6, bin 2 from -0.6 to -0.2, etc.). More examples are provided in Table A1 in Appendix A.

3.2 Experiments

We evaluate the model performances for our complaint intensity prediction task in two settings: (1) mix hashtag, where we combine Weibo posts from different hashtags together, and (2) cross hashtag, where the posts for train, dev and test sets are separately from different hashtags. We use Pearson's correlation and MSE (Mean Square Error) as metrics for all our experiments.

Mix Hashtag. We combine Weibo posts from different hashtags together and then split them into 80% for training, 10% for validation, and 10% for test. Results are shown in Table 4. We observe that RoBERTa outperforms all other models and reaches Pearson up to 0.79, followed by the LSTM model. The SVR model has the worst performance.

Cross Hashtag. We choose four of total five collected hashtags as the train and development set, and hold out the rest one for test. We report the average value after five experimental runs in Table 4. We observe under cross hashtag setting, models get comparable performances to mix hashtag setting. It indicates models seem to learn common linguistic cues between different hashtags.

Models	Mix Hashtag		Cross Hashtag	
	r	MSE	r	MSE
SVR ({2,3,4}-gram)	0.36	0.46	0.35	0.46
SVR (GloVe)	0.49	0.36	0.47	0.38
LSTM (GloVe)	0.69	0.24	0.65	0.27
LSTM Attn (Glove)	0.72	0.22	0.70	0.25
LSTM (BERTembed)	0.76	0.15	0.75	0.16
ERNIE	0.76	0.14	0.76	0.14
BERT	0.77	0.20	0.75	0.23
RoBERTa	0.79	0.11	0.78	0.11

Table 4: Pearson's r and Mean Square Error (MSE) on two datasets for predicting the intensity of complaints.

3.3 Error Analysis

We perform an error analysis to shed light on the limitations of our best-performing model. A prediction is defined to be wrong when the difference between ground truth and the predicted score is greater than 0.5. We randomly sample 100 errors and manually inspect them. All errors are divided into three categories: 43% of errors are because of irony expression in complaints, 29% are due to implicit expressions, and 28% are due to the insufficient and vague expressions.

Ironic Expressions. We observe that most errors happen when the posts contain ironic expressions. Users use positive words such as "perfect" or "great" to express dissatisfaction, which are misleading models to ignore the implicit complaints. A typical example is as follows: 食堂的涨价消息比封校政策来的快, 这学校真好 (*The news of price increase in the cafeteria is coming faster than the school closure policy. This school's management is really good*).[4]

Implicit Expressions. The model struggles with complaints expressed in more subtle ways. These complaints do not contain any prominent negative words, but through other means like strike a chord or entrust. In the following example, the user hopes that managers can personally experience the status quo to understand the user's dissatisfaction. Therefore, predicting them correctly requires more contextual understanding: 真的非常极其的希望校领导也能来感受一下封校的生活 (*I really hope that school leaders can also come and experience the life of the closed school*).

---

[4] During COVID-19 pandemic, Chinese universities restrict students from going outside and limit their activities within campus. It thus causes students' complaints.

Vague Expressions. We observe that the model is likely to be confused by vague or incomplete expressions in the posts. Consider the following example: 赶上这破事，如果教育真的公平不如直接取消复试吧 (*Encountered this shit. If the education is really fair, it is better to cancel the exam*). The hypothetical relationship using 如果 (*if*) is an expression of uncertainty (Wei et al., 2018) and there are no prominent emotional words in the text. Thus, our model fails to understand the speaker's intention well.

4 Complaints as an Emotion

From Table 3, we notice stronger complaints seem to be associated with negative emotion words. Prior studies also point out that complaints can be treated as an influential emotional dimension (Iyiola and Ibidunni, 2013). Then a natural question to ask is whether existing sentiment models have already been able to predict complaints intensity scores and our annotation efforts are actually not needed?

In this section, we demonstrate the necessity of building corpus annotated with complaints intensity, by showing the model trained on standard sentiment datasets fails to do well in our complaints intensity prediction task. We also show that analyzing complaints can be a useful complement for sentiment analysis.

4.1 Differences between Complaints and Sentiment

In sentiment analysis, models normally output a score between 0 and 1, indicating how likely a post is to express negative emotion. Here we make the assumption that the most negative emotion may lead to the strongest complaint. We first examine if these probability scores from sentiment models can be used as intensity scores for measuring complaints intensity.

Setup. To ensure a fair comparison, we select a newly developed dataset on COVID-19, collected also from Weibo using hashtags related to COVID-19 by Lyu et al. (2020). The dataset contains 21,174 posts with fine-grained emotion annotations.[5]

In our experiments, we follow the same steps in Section 2.1 to pre-process this dataset. As our pre-processing steps result in a category imbalance issue, we merge categories with similar emotions. Specifically, we merge labels "fear", "anger", "disgust", and "sadness" into "negative" category and merge labels "gratitude", "surprise", and "optimism" into the "positive" category. Finally, we have 8,783 posts in the negative category and 8,336 posts in the positive category.

We use BERT to train a sentiment model using the above COVID-19 data. We also sample 80% of our corpus for developing our BERT-based complaints model. The performances of both models are compared on the left 20% annotated posts. During evaluation, the sentiment scale from 0 to 1 is linearly mapped to our complaints intensity interval from -1 to 1.

Results. Results are shown in Table 5. We observe that using the probability scores from sentiment models shows decent performance on our complaints intensity prediction task. It indicates a clear connection between complaints and emotions. We also observe that models trained on our annotated corpus outperform sentiment model, demonstrating the necessity of building such corpus for complaints intensity estimation.

Model	**Pearson's r**	**MSE**
Complaint	0.76	0.20
Sentiment	0.71	0.24

Table 5: Performances of sentiment model and complaint model for complaints intensity prediction task.

Valence and Arousal. We also quantitatively studied the correlation between complaints and sentiment through Valence-Arousal. Valence can be positive or negative and corresponds to the standard dimension of sentiment analysis; Arousal, which can be low or high and express the degree (Vorakitphan et al., 2020). We use the VA score annotated by Xu et al. (2021), which contains 11,310 simplified Chinese words. The valence and arousal ratings include scores -3 to +3 for valence rating and scores 0 to 4 for arousal rating.

We identify sets of words in the Valence-Arousal lexicon that have high valence scores (>2), low valence scores (<-2), high arousal scores (>3), and low arousal scores (<2). A similar approach is used in Hada et al. (2021). We average the scores of tokens from the above four dimensions in each post and calculate the correlation with our complaints intensity. Results in Table 6 show low valence and high arousal are more correlated with complaints intensity compared to the other two dimensions.

---

[5] To the best of our knowledge, there does not exist a Chinese Weibo dataset annotated with continuous sentiment intensity. We note some datasets with discrete sentiment levels, like Douban movie short comments dataset (Ma et al., 2011).

Dimension	Pearson's r
High valence	0.02
Low valence	0.31
High arousal	0.18
Low arousal	0.05

Table 6: Pearson's correlation between the complaints intensity scores and emotion dimensions.

4.2 Complaints Help Sentiment Analysis

We now show that analyzing complaints could be helpful for the binary sentiment analysis task.

Models. We still use the COVID-19 dataset discussed in Section 4.1 for the binary sentiment classification task. We experiment with the SVM and BiLSTM-Attention models. The complaints score is added as an additional feature input to the model.

Results. Table 7 shows the results of the models on the sentiment classification task. Overall, we observe that the models with the complaint feature perform better than the original model. It demonstrates that a simple add-on can boost the prediction accuracy of sentiment classification for non-neural and traditional neural models. We also provide the performance of BERT for reference in Table 7.

Models	P	R	F1
SVM	0.51	0.49	0.50
+ complaint	0.53	0.50	0.51
BiLSTM-Att	0.72	0.70	0.71
+ complaint	0.74	0.71	0.72
BERT	0.79	0.76	0.77

Table 7: Results for binary sentiment prediction. F1 score of models with complaint feature is significantly better than the original model (p-value < 0.01, t-test).

4.3 Case Study

We are interested in what types of tokens sentiment model and complaint model try to capture. We thus take the BiLSTM-Attention model trained for sentiment classification task in Section 4.2 and our complaints model for comparison. We visualize the attention weights extracted from the above two models for the following example: 准备这么久的考试推迟真是绝了呵呵 (*After preparing for so long, the exam is now postponed. It's absolutely speechless. Hmm. How interesting.*). We observe that sentiment model assigns high attention weights for tokens 绝了 (*speechless*) and 呵呵 (*Hmm. How interesting.*), both expressing emotions. However, our complaint model puts high weights on tokens 推迟 (*postponed*) and 考试 (*exam*). These are tokens that reflect the reasons for complaining. These differences again demonstrate the need for building a specific dataset for complaints intensity.

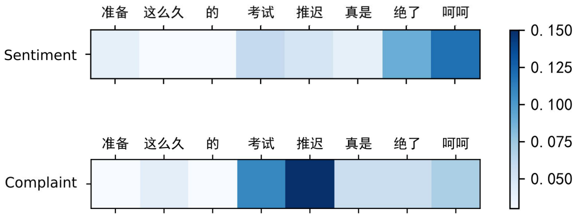

Figure 2: Attention weights for the sample sentences in sentiment model and our complaint model.

5 Cross-lingual Analysis

Our newly collected complaints intensity dataset is written in Chinese, while current existing datasets (Preotiuc-Pietro et al., 2019; Jin and Aletras, 2021) contain English tweets. It provides us an opportunity to understand the linguistic differences for complaints made by Chinese and English speakers on social media.

Our cross-lingual analysis is performed in the following way. First, we evenly sample 200 complaint tweets released in Jin and Aletras (2021) from their defined four categories. Similarly, we divide our annotated data with intensity greater than 0 (as complaint posts) into 4 bins for sampling. We ask 5 in-house annotators to mark and then use majority voting to decide if a post makes a direct or indirect complaint, along with the strategy used to make complaints.

Direct and Indirect Complaints. According to Boxer (2010), the speech of complaint can be divided into direct and indirect complaints. In social media, direct complaints are addressed to a complainee who is held responsible for the complaint action, and the addressee is fully or partially responsible for this behavior. Here is an example for a direct complaint: 学校的管理怎么这么不人性化? (*Why is the management of the school so inhumane?*) While indirect complaints refer that the recipient is not primarily responsible for perceived complaints and is more about the evaluation of the target or event, such as: 这样做让我们的压力很大,真无语 (*This puts us under a lot of pressure, so speechless*).

We compare the percentages of direct and indirect complaints for two languages based on our annotations. Results show that indirect expressions are more likely to be used in Chinese posts (80%

are indirect complaints). On the contrary, 91% of English tweets make complaints in a direct way. This finding seems to be consistent with the study of Deng et al. (2019), which demonstrates that Chinese people tend to use indirect expressions.

Strategy. In pragmatics, strategy is an appropriate countermeasure adopted to achieve the purpose of language communication. House and Kasper (1981) conducted a comparative study of English and German complaints from the direct degree and emotional markers. Anna (2008) discussed the choice of Chinese and English complaining strategies and proposed an explicit-implicit strategy. Implicit complaints are very subtle and even use metaphors to express complaints about the target, which requires more semantic information to capture. In contrast, explicit complaints can be further divided into types of with-redress and without-redress. With-redress is the strategy of request for repair; without-redress usually contains complaint targets or objects, which can be easily identified by recognizing an obvious complaint word or phrase.

Table 8 shows that strategy varies across languages. We find that the Chinese are more inclined to without-redress strategy, while the most frequent strategy used by Americans is with-redress strategies. It provides some empirical support for findings in Anna (2008).

Strategy	Chinese	English
Implicit	65%	12%
With-redress	13%	78%
Without-redress	22%	10%

Table 8: Percentages of strategies across languages.

Irony. Irony implies the opposite of the literal meaning. Dealing with non-literal means is a challenging task. On Twitter, Reyes et al. (2012) used specific hashtags as gold labels to detect irony in a supervised learning setting, such as *#irony* and *#sarcasm*. Attardo (2013) observed that native speakers are usually able to process the meaning of sarcasm automatically, but the ability of second language learners to infer meaning from context varies greatly. In Section 3.3, we observe irony counts for the majority of errors made by our model.

We analyze the number of complaints using irony. To detect ironic expressions, we separately use the Chinese irony dataset of Tang and Chen (2014) and the English dataset of Van Hee et al. (2018) to train the Bi-LSTM model. Results showed that 10% of Chinese data contained irony, and 26% of English data contained irony. It shows that English speakers use ironic expressions more often compared to Chinese speakers. Further, we conduct part-of-speech analysis on these ironic expressions. Table 9 shows that Chinese irony has the highest proportion of nouns, followed by verbs; while in English irony, verbs are the most, followed by nouns. In addition, there are more adjectives and adverbs in English than in Chinese.

Part of Speech	Chinese	English
Nouns	31.2%	27.9%
Verbs	21.8%	35.2%
Adjectives	3.1%	10.7%
Adverbs	9.9%	11.9%

Table 9: Percentages for POS tags across languages.

Limitations. We note a few limitations for our cross-lingual analysis. One limitation is domain mismatch. Our Chinese posts are collected from education domain, while English posts are collected from domains including food or online service. People may exhibit different behaviors when making complaints. We also note that the sample size for making comparisons is rather small, due to budget issues for experts annotations. In future work, we will perform a large-scale comparison by using the data collected from the same domains and utilizing crowdsourcing annotations.

6 Predicting Post Popularity

Finally, we demonstrate that complaint intensity scores from our computational models can help estimate the post popularity on social media. We envision incorporating these scores into existing social media monitoring systems to improve their prediction accuracy.

Task. Predicting the popularity of content on social media has been extensively studied in literature (Szabo and Huberman, 2010; Hong et al., 2011; Bao et al., 2013; Carta et al., 2020). Our task is to predict the popularity of a Weibo post. Specifically, given the popularity prediction $p(t_{i-1})$ at time t_{i-1}, we wish to predict the popularity $p(t_i)$ at next time step t_i. The popularity $p(t)$ is measured by the number of blog posts under the topic at time t.

Methods. We follow Szabo and Huberman (2010) and consider the following baseline that only uses early prevalence for prediction:

$$\ln \widehat{p}(t_i) = \alpha_1 \ln p(t_{i-1}) + \alpha_2,$$

where α_1 and α_2 are learnable coefficients. It is justified as a strong baseline in Bao et al. (2013) that a strong correlation exists between logarithmically transformed popularity and early popularity.[6]

The popularity of posts on social media can be measured by multiple dimensions (Bao et al., 2013). To show the effectiveness of our complaint scores, we add in the complaint intensity as a new term to estimate the final logarithmic popularity:

$$\ln \widehat{p}(t_i) = \beta_1 \ln p(t_{i-1}) + \underbrace{\beta_2 d_c(t_{i-1})}_{\text{complaints density}} + \beta_3,$$

where $d_c(t_{i-1})$ is the complaints density at time t_{i-1}, calculated by the ratio between the sum of the complaint intensity of blog posts per unit time to the number of all blog posts. β_1, β_2 and β_3 are learnable new coefficients from data.

Setup. We collected a new set of 4,973 posts under 8 hashtags on Weibo from March 2021 to November 2021, which are shown in Table A2 (in Appendix B). We pre-process these posts using the same steps in Section 2.1. Within each hashtag, 80% of the posts are used for training, and the left 20% are used for testing. We set the time step to be two hours. RMSE (root mean square error) and MAE (mean absolute error) are used to evaluate predicted results.

Results. We first examine the relationship between complaints density and post popularity as a sanity check. Results show a strong positive correlation with an upper cluster slope of 0.95.

We report our post popularity prediction results in Table 10. We observe our method that combines complaint density outperforms the baseline method. In Figure 3 we also show the comparison between our predictions and real values for a specific hashtag: #巨人教育宣布倒闭# (*#JuRen Education Group announces its bankruptcy#*). We observe that adding complaints scores help better estimate the post popularity, especially in the early stages. It is probably because complaints are likely to draw users' attention to engage in discussions and hence boost the popularity of events.

Method	**RMSE**	**MAE**
Baseline	0.41 ± 0.01	0.35 ± 0.01
+ complaints density	0.35 ± 0.02	0.33 ± 0.01

Table 10: RMSE and MAE for popularity prediction.

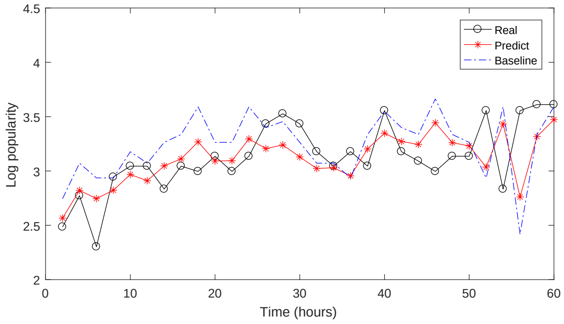

Figure 3: Comparison between actual post popularity and our predictions for hashtag *#JuRen Education Group announces its bankruptcy#*. RMSE = 0.32, MAE = 0.30.

7 Related Work

There have been various studies for complaints in linguistics, economics, and public opinion research. In Olshtain and Weinbach (1985), complaints are defined as what happened does not meet people's expectations, making people dissatisfied and blaming others. Kolodinsky (1995) explained the characteristics of consumers' complaining behavior from an economic point of view. Liu and Yen (2016) analyzed complaints about public transportation. Complaints on social media have also drawn great attention in recent years. Andreassen and Streukens (2013) focused on the study of the difference between social media complaints and traditional complaints, and argue that social media complaints are a unique way for consumers to express dissatisfaction. Balaji et al. (2015) studied the causes of complaints and found most of the complaints occur after a double deviation caused by dissatisfaction with the last solution. Motivated by these, in this paper, we collect complaints from Weibo, a widely used social media application.

In the area of linguistic studies on computational sociology, Meinl and Ebba (2010) studied the complaints act sequence in eBay reviews through 200 annotated English and German reviews. Ganesan and Zhou (2016) collected 2,500 reviews from Yelp and Walmart about commodity, then manually categorized them into 5 categories: negative only, complaint, positive only, raise, and irrelevant. Preotiuc-Pietro et al. (2019) focused on binary classification between complaints and non-complaints in various domains, such as food, car, online service, e-commerce. Jin and Aletras (2021) categorized complaints into 4 categories: no explicit reproach, disapproval, accusation, and blame. In this work,

---

[6] Bao et al. (2013) further proposed to use link density and diffusion depth for popularity prediction. Above methods were tested on WISE 2012 challenge dataset. We tried our best but are not able to have access to this dataset. In our own collected dataset, we do not have link or diffusion information.

we present the first study of estimating the intensity of complaints from text.

Our work is also related to prior work on emotion detection and sentiment intensity estimation (Mohammad and Bravo-Marquez, 2017; Cortis et al., 2017). Kiritchenko and Mohammad (2017) created a Twitter dataset annotated with sentiment intensity. We have discussed the connections between complaints and sentiment in detail in Section 4.

8 Conclusion

In this paper, we present the first study of measuring the intensity of complaints from text. We build a corpus of 3,103 Chinese Weibo posts about complaints, annotated with complaints intensity scores using Best-Worst Scaling method. We then demonstrate that our corpus supports the development of automatic computational models for accurate complaints intensity predictions. Furthermore, we study the connections between complaints and sentiment, and perform a cross-lingual comparison for complaints expressions between Chinese and English. We finally show that our complaints intensity scores help better estimate the posts popularity on social media.

Ethical Concerns

In this paper, we collect a complaint dataset from Weibo. The tools we use to collect posts comply with Weibo's terms of service. We will follow Weibo's policy for content redistribution to release our annotated corpus. Specifically, we will not release any user information or demographic data, including the authors' names, ages, and origins.

We recruited part-time research assistants for our annotation task. Annotators were warned that the complaint posts might contain offensive or upsetting content. Annotators were shown only anonymized posts and agreed not to make attempts to de-anonymize them. We did not collect any personal data from the annotators before, after, or during the annotation task. Moreover, we pay them 15.7 USD/hour and at most 14 hours per week.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable feedback. This work was partially supported by a grant from the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No. PolyU/25200821) and CCF-Baidu Open Fund (No. 2021PP15002000).

A More Sample Posts

We provide more sample posts in Table A1 from our dataset grouped according to the 5 bins defined in Table 3.

Bin	Weibo posts	Scores
1	突然感觉农业大学做的还不错 (*Suddenly I feel that the Agricultural University is doing pretty well.*)	-1.00
1	校内完成作业挺好的，回家可以做自己喜欢的事 (*It's good to finish homework in school, you can do what you like when you go home.*)	-0.80
2	为了疫情防控而封闭管理其实是没有问题的。但是既然实行这项制度，就要真正把好关，校外人员不能随意进出学校 (*In fact, there is no problem with closed management for the prevention and control of the epidemic. However, since this system is implemented, it is necessary to truly ensure that people outside the school cannot enter and leave the school at will.*)	-0.50
2	让学生在校内写完作业这不怎么可能实现吧？对家长来说确实挺好的，因为很多题都不会，也没办法辅导。 (*Isn't it possible for students to finish their homework in school? It's really good for parents, because many problems parents don't know how to solve them, and they can't help students.*)	-0.33
3	从来没有人去教家长要如何做一个合格的学生家长 (*No one has ever taught parents how to be a qualified student parent.)*	-0.15
3	这不太好吧，所谓家庭作业不是在家完成么，在校内完成的不是校内作业或者课堂作业吗，真是这样那干脆不要布置家庭作业罢了 (*This is not so good. Isn't the so-called homework done at home? Isn't it done in school or classwork? If it's true, then just don't assign homework.*)	+0.17
4	老师也是人他们虽然是服务行业但也需要自己的生活吧小学作业也没有那么多根本不用老师熬夜去批那初中毕业学年和高中呢作业量多难度大一个老师交两三个班一百多号人学生写完作业都要十点多了难道还让老师在学校通宵批完没有效率出现错误又说是老师不负责? (*Teachers are also humans. Although they are in the service industry, they also need their own lives. There are not so many primary school homework. There is no need for teachers to stay up late to correct them. The middle and high school homework is a lot and difficult. One teacher teaches two or three classes. For many students, it's more than ten o'clock when the students finish their homework. Could it be that the teacher is allowed to finish the correction at school overnight? This is not efficient. If there is a mistake, the teacher will be accused of being irresponsible.*)	+0.40
4	为什么都是0分啊？是作弊被抓到了吗？还是怎么样？还是根本就没来考试啊？浪费这机会，有那机会给我多好，我想上还上不了呢 (*Why are their scores all 0 points? Was it caught for cheating? Or what? Or didn't you come to the exam at all? The two of them wasted this opportunity, how good it is for me to have that opportunity, I want to go to school but I don't have the opportunity.*)	+0.57
5	学校偏僻，所以西安这些学校的职工都是从隔壁村子随便找的？隔壁西电，门卫满嘴官话实际怠惰工作，保洁在图书馆大声唠嗑，合着招职工没有限制应聘即上岗?西外职工都敢拖行女生了，原来职工素质低不是我校特例啊西安高校，你有事吗？ (*Due to **the school**'s remoteness, the employees of these schools in Xi'an are all looking for them from the neighboring village? At the Xidian University next door, **the guards** are lazy, and **the cleaners** babble loudly in the library. Is it possible to recruit staff to take up jobs without restrictions? The school's **security guards** are very rude to girls. It turns out that the low quality of staff is not a special case of our school. The problems in Xi'an colleges and universities are severe.*)	+0.92
5	现在的学校，真恶心，老师们拿的有工资啊，双休寒暑假，还美其名曰：家校共育这本来没错，但，能不能不要让家长充当老师的角色？？？？作业，回家写可以，家长还要拍照、打卡、发视频交作业，还要批改作业，这都是老师的工作好吗？？这部分工作家长做了，老师在干啥？这部分工作的工资，学校给家长发了吗？？没有啊！！那就请老师们，完成你们份内的工作！！别说什么辛苦之类的，拿着那份工资与待遇，就要干好那份工作在其位不谋其职！！！！ (*The current school is really disgusting. The teachers are paid, and they have two winter vacations and summer vacations. They also have a good name: family-school co-education is not wrong. But can we not let parents act as teachers? ? ? ? Homework can be written at home. Parents have to take photos, check in, send videos to hand in homework, and also correct homework. This is the teacher's job. If the parents do this part of the work, then what does the teacher do? Has the school sent the salary for this part of the work to the parents? ? No! ! Then please teachers, finish your job! ! Not to mention that the work is very hard. With the salary and benefits, you must do the job well. Don't be irresponsible in this position! ! ! !*)	+1.00

Detecting Narrative Elements in Informational Text

Effi Levi[1], Guy Mor[2], Tamir Sheafer[2,3], Shaul R. Shenhav[2]

Abstract

Automatic extraction of narrative elements from text, combining narrative theories with computational models, has been receiving increasing attention over the last few years. Previous works have utilized the oral narrative theory by Labov and Waletzky to identify various narrative elements in personal stories texts. Instead, we direct our focus to informational texts, specifically news stories.

We introduce NEAT (Narrative Elements AnnoTation) – a novel NLP task for detecting narrative elements in raw text. For this purpose, we designed a new multi-label narrative annotation scheme, better suited for informational text (e.g. news media), by adapting elements from the narrative theory of Labov and Waletzky (`Complication` and `Resolution`) and adding a new narrative element of our own (`Success`). We then used this scheme to annotate a new dataset of 2,209 sentences, compiled from 46 news articles from various category domains[1]. We trained a number of supervised models in several different setups over the annotated dataset to identify the different narrative elements, achieving an average F_1 score of up to 0.77. The results demonstrate the holistic nature of our annotation scheme as well as its robustness to domain category.

1 Introduction

Automatic extraction of narrative elements from texts is a multidisciplinary field of research, combining narrative theories with computational models, which has been receiving increasing attention over the last few years. Examples include modeling narrative structures for story generation (Gervás et al., 2006), using unsupervised methods to detect narrative event chains (Chambers and Jurafsky, 2008) and detecting content zones (Baiamonte et al., 2016) in news articles, using semantic features to detect *narreme* boundaries in fictitious prose (Delmonte and Marchesini, 2017), identifying turning points in movie plots (Papalampidi et al., 2019) and using temporal word embeddings to analyze the evolution of characters in the context of a narrative plot (Volpetti et al., 2020).

A recent and more specific line of work focuses on using the theory laid out by Labov and Waletzky (1967) and later refined by Labov (2013) to characterize narrative elements in personal experience texts. Swanson et al. (2014) relied on Labov and Waletzky (1967) to annotate a corpus of 50 personal stories from weblogs posts, and tested several models over hand-crafted features to classify clauses into three narrative clause types: *orientation*, *evaluation* and *action*. Ouyang and McKeown (2014) constructed a corpus from 20 oral narratives of personal experience collected by Labov (2013), and utilized logistic regression over hand-crafted features to detect instances of *complicating actions*. More recently, Li et al. (2017) utilized a combination of ideas from Labov and Waletzky (1967) and Freytag (1894) to annotate a collection of short stories, and Saldias and Roy (2020) used convolutional neural networks (CNNs) to classify clauses from spoken personal texts into the same three narrative clause types as Swanson et al. (2014).

While these works concentrated their effort on narrative analysis of personal experience texts, we direct our focus to detecting narrative patterns in informational texts, such as news stories. The social impact of news stories distributed by the media and their role in creating and shaping of public opinion incentivized our efforts to adapt narrative analysis approaches to this domain. To the best of our knowledge, this is the first attempt to automatically detect narrative elements based on Labov and Waletzky (1967) and later works by Labov (1972, 2013) in news articles.

In this work, we introduce NEAT (Narrative Ele-

---

[1] `https://github.com/efle/NEAT`

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1755 - 1765

ments AnnoTation) – a novel NLP task for detecting narrative elements in raw text. For this purpose, we adapted two elements from the narrative theory presented in Labov and Waletzky (1967); Labov (1972, 2013), namely `Complication` and `Resolution`, while adding a new narrative element, `Success`, to create a new multi-label narrative annotation scheme. This scheme was designed with two main objectives in mind. First, capturing elements oriented towards discourse structure, rather than semantic content. Second, possessing the flexibility required to capture narrative characteristics within a wide variety of text types, specifically informational text (as opposed to personal experience), and not only literary and well-structured stories. We used this scheme to annotate a newly-constructed dataset of 2,209 sentences, compiled from 46 English news articles; each sentence was tagged with a subset of the three narrative elements (or, in some cases, none of them), thus defining a novel multi-label classification task.

We explored two different approaches towards solving our new task: splitting into three unrelated binary classification tasks (`Complication`, `Resolution` and `Success`), and jointly learning the three narrative categories as a multi-label classification task. We experimented with three supervised models, each based on fine-tuning a different pre-trained language model: BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019) and DistilBERT (Sanh et al., 2020), achieving an average F_1 score of up to 0.77. An analysis of the results indicates that our narrative categories are strongly connected and form a coherent narrative scheme which is more than just the sum of its parts. Additional experimentation with cross-domain classification demonstrates the task's robustness to domain category, suggesting that our annotation scheme is more grounded in discourse characteristics rather than semantic context.

The remainder of this paper is organized as follows: Section 2 gives a theoretical background and describes the adjustments we have made to the scheme in Labov (2013) in order to adapt it to informational text. Section 3 provides a complete description of the dataset and of the processes and methodologies which were used to construct and annotate it, along with a short analysis and some examples for annotated sentences. Section 4 describes the experiments conducted on the dataset, and Section 5 provides an analysis and a discussion of the results. Finally, Section 6 contains a summary of our contributions as well as several potential directions for future work.

2 Narrative Analysis

2.1 Background

Ever since the emergence of formalism and structuralistic literary criticism (Propp, 1968) and throughout the development of narratology (Genette, 1980; Fludernik, 2009; Chatman, 1978; Rimmon-Kenan, 2003), narrative structure has been the focus of extensive theoretical and empirical research. While most of these studies were conducted in the context of literary analysis, the interest in narrative structures has made inroads into social sciences (Shenhav, 2015). The classical work by Labov and Waletzky (1967) on oral narratives, as well as later works (Labov, 1972, 2013), signify this stream of research by providing a schema for an overall structure of narratives, according to which a narrative construction encompasses the following building blocks (Labov, 1972, 2013): *abstract* (what is the narrative about), *orientation* (information on the time, the place, the persons and the behavior involved), *complicating action* (or simply complication; the forward progression of narrative clauses), *evaluation* (establishing the narrative's "point"), *resolution* (what finally happened), and *coda* (bringing the time of reference back to the present time of narration). These building blocks provide useful and influential guidelines for oral narratives analysis.

2.2 Adaptation

Despite the substantial influence of Labov and Waletzky (1967) and Labov (2013), scholars in the field of communication have noticed that this overall structure does not necessarily comply with the form of informational text, such as news stories (Thornborrow and Fitzgerald, 2004; Van Dijk, 1988), and consequently proposed modified narrative structures (Thornborrow and Fitzgerald, 2004). Unlike well-tailored narrative texts, such as personal experience texts, narrativity in informational text is somewhat more challenging as it does not necessarily follow conventional or predefined genre-related structures. This requires a flexible coding scheme, unconstrained by a specific type of text. Instead, it should be open to a wide range of text types (such as informational text), and allow the presence of micro stories, encompassing

	Complication	Resolution	Success
# Sentences	1,092	541	312
Proportion in Dataset	49%	24%	14%

Table 1: Overview of the NEAT dataset. Note that the categories are not mutually exclusive, due to the multi-labeled nature of the annotation scheme.

any combination of all narrative categories even at the sentence level. We set to accomplish that via two objectives: first, formalizing narrative categories which are oriented towards discourse structure, rather than semantic context. Second, defining our task as a multi-labeled one, to allow the flexibility required to capture sentence-level narrative characteristics. A special consideration was given to the variety of contents, forms and writing styles typical for media texts. For example, we required a coding scheme that would fit laconic or problem-driven short reports (too short for full-fledged "Labovian" narrative style), as well as complicated texts with multiple story-lines moving from one story to another. We addressed this challenge by focusing on two of Labov's six elements - *complicating action* and *resolution*, considered to be the most fundamental and relevant for informational text analysis (Labov, 2013). There are several reasons for our focus on these particular elements: first, it goes in line with the understanding that worth-telling stories usually consist of protagonists facing and resolving problematic experiences (Eggins and Slade, 2005). Moreover, these elements resonate with what is considered by Entman (2004) to be the most important Framing Functions - problem definition and remedy.

In order to adapt the original *complicating action* and *resolution* categories to informational content, we designed our annotation scheme as follows. *Complicating action* – hence, `Complication` – was defined in our narrative scheme as an event, series of events or situation, that point at problems or tensions. `Resolution` refers to the way the story is resolved or to the release of the tension. An improvement from – or a manner of coping with – an existing or a hypothetical situation was also considered to be a `Resolution`. This choice was made in order to follow the often tentative or speculative notion of future resolutions in news stories (Thornborrow and Fitzgerald, 2004; Bell, 1991). We have therefore included in this category any temporary or partial resolutions. The transitional characteristic of the `Resolution` motivated us to add a new category defined as `Success`. Unlike `Resolution`, which refers, implicitly or explicitly, to a prior situation, this category was designed to capture any description or indication of an achievement or a desirable outcome.

3 The Dataset

3.1 Pilot Study

We started by conducting a pilot study, for the purpose of formalizing an annotation scheme and training our annotators. For this study, sample sentences were gathered from print news articles, published between 1995 and 2017 and collected via *Lexis-Nexis*. These were used to refine the annotation scheme described in Section 2.2, as well as perform extensive training for our annotators.

Following the conclusion of the pilot study, we used the sentences which were collected and manually annotated during the pilot to train a multi-label classifier, later used to provide labeled candidates for the annotators during the annotation stage of the NEAT dataset, in order to optimize annotation rate and accuracy. The pilot samples were then discarded.

3.2 News Articles

The news articles for the dataset were sampled from leading news websites in the English language, all published between 2017 and 2020. The result is a corpus of 2,209 sentences taken from 46 news articles, with an average of 48 sentences per article ($\sigma^2 = 39.44$), and an average of 20.2 tokens per sentence ($\sigma^2 = 11.2$). The articles are semantically diverse, as they were sampled from a wide array of domain categories.

3.3 Preprocessing

The news articles' content was extracted using diffbot. The texts were scraped and split into sentences using the Punkt unsupervised sentence segmenter (Kiss and Strunk, 2006). Remaining segmentation errors were manually corrected.

3.4 Annotation

3.4.1 Guidelines

Following the pilot study (Section 3.1), a code book containing annotation guidelines was produced. For each of the three categories in the annotation scheme – `Complication`, `Resolution` and `Success` – the guidelines provide:

- A general explanation of the category
- A list of well-defined criteria for identifying the category
- Select examples of sentences labeled with the category

3.4.2 Process

We employed a three-annotator setup for annotating the collected sentences. First, the pilot stage model (Section 3.1) was used to produce annotation suggestions for each of the sentences in the corpus. Each sentence was then separately annotated by two trained annotators according to the guidelines described in Section 3.4.1. Each annotator had the choice to either accept the suggested annotation or to change it by adding or removing any of the suggested labels. Disagreements were later decided by a third expert annotator. Table 2 reports inter-coder reliability scores for each of the three categories, averaged across pairs of annotators: pairwise percent agreement (PPA), and Cohen's Kappa coefficient, accounting for chance agreement (Artstein and Poesio, 2008). Article-level domain categories (Table 3) were initially assigned according to the news section from which the articles were taken, and later verified by two annotators.

	PPA (avg.)	κ (avg.)
Complication	89.6%	0.79
Resolution	87.5%	0.65
Success	92.8%	0.7

Table 2: Inter-coder reliability: average pairwise percent agreement (PPA) & average Cohen's Kappa (κ)

3.5 Analysis

Narrative categories vary significantly in their prevalence in the corpus; their respective proportions in the dataset are given in Table 1. The categories are unevenly distributed: `Complication` is significantly more frequent than `Resolution` and `Success`. This was to be expected, considering the known biases of "newsworthiness" towards problems, crises and scandals (Esser et al., 2016), and due to the fact that in news media, resolutions often follow reported complications.

Interestingly, the distribution over narrative categories varies significantly between the different category domains (see Table 3). Most domains contain many more `Complications` than `Resolutions` or `Successes`, which is consistent with the distribution in the complete dataset (Table 1); the "Crime" domain is an extreme example, with a very small number of `Resolutions` and no `Successes` at all. However, some domains exhibit a completely different distribution. For example, the "Travel" and the "Science & Technology" domains possess a relatively uniform distribution over the three narrative categories. The "Sports" domain contains a similar number of `Complications` and `Successes`, with a smaller number of `Resolutions`.

Table 4 reports pairwise Pearson correlations between the categories. The `Complication` and `Resolution` categories are completely uncorrelated ($r = 0.016$). A minor negative correlation was found between `Complication` and `Success` ($r = -0.234$), and a minor positive one was found between `Resolution` and `Success` ($r = 0.228$). These minor correlations – in our opinion – indicate that the `Success` category does indeed bring added value to our narrative scheme.

All the possible combinations of narrative categories appear in the dataset; Table 5 summarizes the occurrences of each of the possible category combinations. Examples of sentences annotated with various category combinations are given in Appendix A. There is, however, a significant variability to the frequency in which different combinations occur in the dataset. For example, the `Complication-Resolution` combination, designating a typical narrative tension-relief pattern (Shenhav, 2015), is by far the most frequent one with 226 sentences. `Complication-Success`, on the other hand, is a very rare combination with only 15 sentences, embodying a far less trivial or common logic, where a success is accompanied by an unresolved problem.

The fact that the dataset is assembled from full coherent news articles allows the analysis of a range of micro and macro stories in narrative texts. For example, an article in the dataset concerning

Domain Category	# Sentences	Complication	Resolution	Success
Economy & Job Market	221	99	71	25
Politics	860	514	220	89
Health	66	38	13	10
Travel	200	47	46	42
Arts & Culture	345	166	63	49
Crime	28	25	3	0
Accidents & Disasters	12	9	4	2
Welfare	47	30	11	1
Sports	115	51	21	47
Science & Technology	223	53	60	40
Immigration	92	60	29	7

Table 3: Domain category distribution in the NEAT dataset

	Comp.	Res.	Suc.
Comp.	1		
Res.	0.016	1	
Suc.	-0.234	0.228	1

Table 4: Inter-category Pearson correlations

Combination	# Sentences
Complication & Resolution	226
Complication & Success	15
Resolution & Success	103
All Three Categories	49

Table 5: Narrative category co-occurrences in the NEAT dataset

the coronavirus outbreak in South Korea[2] opens with a one-sentence summary, tagged with both `Complication` and `Resolution`:

> "South Korea's top public health official hopes that the country has already gone through the worst of the novel coronavirus outbreak that has infected thousands inside the country." (`Complication`, `Resolution`)

This problem-solution (in this case, hopeful solution) plot structure reappears in the article, this time detailed over a series of sentences:

> "More than 7,300 coronavirus infections have been confirmed throughout South Korea, killing more than 50." (`Complication`)
>
> "It is one of the largest outbreaks outside mainland China, where the deadly virus was first identified." (`Complication`)
>
> "However, the number of new daily infections in South Korea has declined in recent days." (`Complication`, `Resolution`)
>
> "... while he believes the aggregate number of infections is high, he is confident in the job South Korea did to combat the virus' spread and would advise other governments..." (`Complication`, `Resolution`)
>
> "The South Korean government has been among the most ambitious when it comes to providing the public with free and easy testing options." (`Success`)

The sequence starts with two sentences tagged with `Complication`, followed by two sentences tagged with `Complication` and `Resolution`, and concludes with a sentence tagged with `Success`, demonstrating a more gradual transition from problem through solution to success.

4 Experiments

4.1 Dataset Partition

We randomly divided the dataset into article-wise mutually-exclusive train, validation and test sets (details in Table 6), while keeping the distribution over the three narrative categories in each of the sets as similar as possible to the one in the complete dataset. The train set was used to train a supervised model for the task; the validation set was used to select the best model configuration during the training phase by tuning the model's hyper-parameters (see Section 4.3 for details), and the test set was used to evaluate the chosen model and produce the results reported in Section 5.

	# Sentences (Articles)	Ratio
Train	1,767 (37)	80%
Validation	222 (5)	10%
Test	220 (4)	10%

Table 6: Train, validation & test set statistics

4.2 Task Definition

We explored two different approaches for solving the task: (1) addressing each of the three narrative categories as a separate classification task, and (2) treating the task as multi-label classification with three labels (one for each narrative category).

4.2.1 Separate Classification Tasks

In this approach, we defined a separate binary classification task for each of the narrative categories: `Complication`, `Resolution` and `Success`. For each such task, we trained a dedicated supervised model (further details given in Section 4.3), specifically optimized for the learned category. However, any potential information stemming from inter-correlations between the different categories was ignored, effectively treating them as three unrelated tagging schemes.

4.2.2 Multi-Label Classification

Here, the task was treated as a three-way multi-label classification problem (each sentence may contain any combination of the three narrative categories), thus taking advantage of inter-correlations between the three narrative categories to better learn them as part of a coherent narrative scheme. We trained and optimized a single multi-label model to jointly predict the three categories (further details given in Section 4.3).

4.3 System Architecture

We employed the method of fine-tuning a pre-trained language model for our task. In each experimental setup, we chose a pre-trained language model as a backbone, applied a multilayer perceptron (MLP) classifier on top of it, and fine-tuned the entire model over the train set.

4.3.1 Backbone

We experimented with three state-of-the-art transformer-based language models as the backbone for our inference model, using pre-trained weights from the *transformers* python package (Wolf et al., 2019).

BERT. Following common practice, we first utilized the base-sized BERT (Devlin et al., 2018) as the backbone model.

RoBERTa. This BERT variant was developed by training the original BERT model with altered design choices and training techniques, and has been recently shown to produce better results on various NLP tasks (Liu et al., 2019). We used the base-sized RoBERTa as the backbone model.

DistilBERT. A recent body of work has focused on developing "lighter" transformer-based language models which allow for faster fine-tuning for downstream NLP tasks (Sanh et al., 2020; Lan et al., 2020). In order to assess robustness to a decrease in the model's size, we also experimented with DistilBERT (Sanh et al., 2020), which follows the same basic architecture as BERT but consists of 66M parameters (as opposed to 110M in BERT), as the backbone model.

4.3.2 Classifier

In order to fine-tune the backbone language model, we appended a multilayer perceptron (MLP) over the output of the language model. The MLP consisted of one hidden layer (increasing the number of hidden layers produced no improvement in performance), the size of which was optimized as a hyper-parameter. In the case of a single binary classification task (Section 4.2.1), the output layer consisted of a single sigmoid output, while in the case of a multi-labeled task, it consisted of three sigmoid outputs, one for each narrative category.

4.3.3 Training Procedure

All models were optimized using the AdamW algorithm (Loshchilov and Hutter, 2017) and the binary cross entropy loss function. Positive weighting was used in order to compensate for class imbalance (evident in Table 1). Hyper-parameters – batch size, learning rate and MLP hidden layer size – were chosen via a standard grid search (see Appendix B for more details). For each configuration of task definition, backbone model and hyper-parameters, the model was evaluated over the validation set after every epoch of training, and the best-performing checkpoint was tested on the test set to produce the results reported in Section 5.

4.4 Cross-Domain Classification

Given the semantic diversity in the dataset, as well as the variability in distribution over the narrative categories between the various domains (Table 3),

		Complication			Resolution			Success			Average		
Task	Backbone	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1
Separate	BERT	0.89	0.87	0.88	0.67	0.40	0.50	0.33	0.72	0.45	0.63	0.66	0.61
Separate	RoBERTa	**0.92**	0.85	0.88	0.69	0.56	0.62	**0.83**	0.56	0.67	**0.81**	0.66	0.72
Separate	DistilBERT	0.87	0.84	0.85	0.69	0.40	0.51	0.53	0.44	0.48	0.70	0.56	0.61
M.Label	BERT	0.88	0.89	0.88	0.72	0.60	0.65	0.53	0.50	0.51	0.71	0.66	0.68
M.Label	RoBERTa	0.90	**0.90**	**0.90**	**0.76**	**0.67**	**0.71**	0.64	**0.78**	**0.70**	0.77	**0.78**	**0.77**
M.Label	DistilBERT	0.86	0.87	0.86	0.73	0.53	0.61	0.75	0.50	0.60	0.77	0.63	0.69

Table 7: Test set precision (P), recall (R) and F_1 scores, for every combination of task definition (a separate task for each narrative category / a multi-labeled task) and backbone model. See Sections 4.2 and 4.3.1 for details.

we wished to assess the domain category's effect on learning our narrative scheme. For this purpose, we experimented with a cross-domain classification setup. For each of the eleven category domains, we concatenated the sentences from all other domains into a train set, which was then used to train a classification model. The training process was done using the configuration of the best-performing model from the previous stage (described in Sections 4.1–4.3), including task definition, backbone model and hyper-parameters (i.e. no hyper-parameter tuning was performed in this setup). The trained model was then evaluated on the test set.

5 Results & Discussion

Results are reported in Table 7. For each task definition and choice of backbone model, we report the precision, recall and F_1 score for each of the three narrative categories, as well as their average, over the test set.

First, we observe that addressing the task as a multi-labeled one proved to be a better strategy than learning each narrative category separately. This is evident across backbone models as well as across narrative categories; for each backbone model, the multi-label model produced a higher F_1 score for each and every one of the narrative categories. This is a clear indication that these categories are substantially connected as they constitute intertwining elements in an underlying story. Therefore, the three categories form a coherent narrative scheme that is more than just the sum of its parts.

Interestingly, while this effect is relatively small for `Complication` (F_1 increased by 0.00–0.02), it is much more prominent for `Resolution` (F_1 increased by 0.09–0.15) and `Success` (F_1 increased by 0.03–0.12), meaning that incorporating all three categories into one coherent scheme contributes mostly to learning the `Resolution` and `Success` categories. This suggests that perhaps the narrative properties of the `Complication` category make it more independent and self-contained than the other two categories. `Resolution` and `Success`, on the other hand, are more relative in nature, and seem to be anchored, implicitly or explicitly, by a prior situation or condition.

Among the three narrative categories, `Complication` gained the highest F_1 scores by all the models, ranging between 0.85 and 0.90. The models were less successful predicting `Resolution`, with F_1 scores ranging between 0.50 and 0.71, and `Success`, with F_1 scores ranging between 0.45 and 0.70. This is consistent with the proportion of instances belonging to each category in the dataset (see Table 1), which may provide a possible explanation for this observation. However, the fact that positive weighting was used in the training process (Section 4.3.3) to counter class imbalance, motivates us to search for another explanation. Defined by Labov and Waletzky (1967)'s overall structure of narratives as "the main body of narrative clause", `Complication` may just be an easier narrative category to learn.

Comparing different backbone models, the DistilBERT-based model performed similarly to the BERT-based one – an average F_1 score of 0.61 for both in the separate-task setting, and 0.69 compared to 0.68 in the multi-label setting – suggesting that the task is fairly robust to a decrease in the backbone model's size. However, RoBERTa significantly outperformed the other two language models as the backbone in both settings – an average F_1 score of 0.71 compared to 0.61 in the separate-task setting, and an average F_1 score of 0.77 compared to 0.68 and 0.69 in the multi-label setting. We also note that the difference in performance between `Complication` and the other two categories is less extreme in the RoBERTa-based models compared to the other backbone models.

	Complication			**Resolution**			**Success**			**Average**		
Domain Category	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1
Accidents & Disasters	1.00	0.89	0.94	1.00	0.50	0.67	1.00	0.50	0.67	1.00	0.63	0.76

Sports	0.87	0.65	0.74	0.53	0.76	0.63	0.84	0.81	0.83	0.75	0.74	0.73
Travel	0.89	0.87	0.88	0.66	0.89	0.76	0.69	0.83	0.75	0.75	0.87	0.80
Welfare	1.00	0.97	0.98	0.80	0.73	0.76	0.33	1.00	0.50	0.71	0.90	0.75
Average	**0.90**	**0.86**	**0.87**	**0.71**	**0.74**	**0.71**	**0.65**	**0.78**	**0.68**	**0.76**	**0.79**	**0.76**

Table 8: Precision (P), recall (R) and F_1 scores for cross-domain classification. See Section 4.4 for details.

5.1 Cross-Domain Classification

The best-performing configuration (a multi-label classifier based on the RoBERTa language model) was used to perform the cross-domain classification experiment. As stated in Section 4.4, hyperparameters were fixed to the values obtained in the train-validation-test setup. Results are presented in Table 8. Averaged over domain categories, they are virtually identical to the results obtained on the test set (reported in Table 7), with a precision, recall and F_1 score of 0.76, 0.79 and 0.76 compared to 0.77, 0.78 and 0.77 (respectively). In our opinion, this demonstrated invariance to domain category is a strong indication that our narrative elements are more grounded in discourse characteristics rather than in the semantic field.

6 Conclusion

We introduced NEAT (Narrative Elements AnnoTation) - a novel NLP task for detecting narrative elements in raw text. For this purpose, we designed a new flexible multi-label narrative annotation scheme, specifically suited for informational text, by adapting two elements from the theory introduced in Labov and Waletzky (1967); Labov (1972, 2013) – `Complication` and `Resolution` – and adding a new element – `Success`. The scheme was used to annotate a new dataset of 2,209 sentences, compiled from 46 articles, which were collected from news websites.

We explored two alternate settings for solving this task - one in which each narrative category was treated as a separate classification task, and another in which the entire task was addressed as multi-label classification. In each of these setups, we experimented with fine-tuning three different language models, achieving an average F_1 score of up to 0.77 on the test set, and showcasing the potential of supervised-learning methods in detecting the narrative information encoded into our scheme. The multi-label setting consistently provided significantly better results across all models and narrative categories, demonstrating that our narrative categories are strongly connected and form a coherent narrative scheme which is more than just the sum of its parts. Additional cross-domain classification results demonstrate the task's invariance to domain category, suggesting that our annotation scheme is more grounded in discourse characteristics rather than semantic context.

We are currently engaged in an ongoing effort for improving the annotation quality of the dataset and increasing its size. In addition, we have several interesting directions for future work. The first one, which we are currently pursuing, includes enriching the scheme with token-level annotation of the narrative elements, effectively converting the task from multi-label classification to a sequence prediction one. Alternatively, we could introduce additional layers of information to encode more global narrative structures in the text, such as inter-sentence – or even inter-article – references between narratively-related elements (e.g., a `Resolution` referencing its inducing `Complication`). Another potential direction is incorporating additional narrative elements into our annotation scheme. For example, the *evaluation* element from (Labov, 2013) may be beneficial in encoding additional information in the context of news media, such as the severity of a `Complication` or the 'finality' of a `Resolution`. We could also add completely new narrative elements, tailored to capture specific informational aspects, such as actor-based elements identifying entities which are related to one or more of the currently defined narrative categories.

Acknowledgements

This research was supported by the Israel Science Foundation (Grants No. 1400/14; 2315/18). We thank the three annotators – Gal Ron, Vered Porzycki and Avishai Green – for their dedicated work, as well as their insightful comments and suggestions during the annotation processes.

Appendix

A Sample Annotated Sentences

1. How did some of the biggest brands in care delivery lose this much money? (`Complication`)
2. Bleeding from the eyes and ears is also possible after use, IDPH said. (`Complication`)
3. His proposal to separate himself from his business would have him continue to own his company, with his sons in charge. (`Resolution`)
4. Instead, hospitals are pursuing strategies of market concentration. (`Resolution`)
5. With its centuries-old canals, vibrant historic center and flourishing art scene, Amsterdam takes pride in its cultural riches. (`Success`)
6. Mr. Trump chose to run for president, he won and is about to assume office as the most powerful man in the world. (`Success`)
7. Soon after, her administration announced a set of measures intended to curb misconduct. (`Complication, Resolution`)
8. Avant-gardists, the couple opened an art gallery in 1875 within the department store, offering artists who had been turned away by the Paris Salon – the official art exhibition of the Academy of Fine Arts in Paris – a home for their works and a large public audience, Burckhardt wrote. (`Complication, Resolution`)
9. Unlike Macy's, the well-known US department store which has been closing its doors around the country, Le Bon Marché isn't fighting to stay alive. (`Complication, Success`)
10. He defeated Bolt in a close semifinal heat, ending Bolt's 28-race winning streak in the 100 meters. (`Complication, Success`)
11. The Utah man's mother, Laurie Holt, thanked Mr. Trump and the lawmakers for her son's safe return, adding: "I also want to say thank you to President Maduro for releasing Josh and letting him to come home." (`Resolution, Success`)
12. And if Tony Hughes can keep his job without the weeks away, "in that aspect," he said, "it's going to make my life better." (`Resolution, Success`)
13. They were fortunate to escape to America and to make good lives here, but we lost family in Kristallnacht. (`Complication, Resolution, Success`)
14. He was vulnerable, no doubt, but in the past, with the spotlight at its brightest, he still found the speed and the will to remain the fastest man in the world. (`Complication, Resolution, Success`)

B Hyper-Parameters

Table 9 lists the ranges of values which were used for hyper-parameter tuning during the experiments described in Section 4.

Hyper-Parameter	Values
Batch Size	16, 32, 64
Learning Rate	1e-5, 2e-5, 3e-5, 4e-5, 5e-5
MLP Hidden Size	50, 100, 200, 300

Table 9: Hyper-parameters value ranges

The best-performing model – a multi-label classifier based on the RoBERTa language model – was trained for 4 epochs with a batch size of 32, a learning rate of 4e-5 and an MLP classifier with a 100-node hidden layer.

When do Contrastive Word Alignments Improve Many-to-many Neural Machine Translation?

Abstract

Word alignment has proven to benefit many-to-many neural machine translation (NMT). However, high-quality ground-truth bilingual dictionaries were used for pre-editing in previous methods, which are unavailable for most language pairs. Meanwhile, the contrastive objective can implicitly utilize automatically learned word alignment, which has not been explored in many-to-many NMT. This work proposes a word-level contrastive objective to leverage word alignments for many-to-many NMT. Empirical results show that this leads to 0.8 BLEU gains for several language pairs. Analyses reveal that in many-to-many NMT, the encoder's sentence retrieval performance highly correlates with the translation quality, which explains when the proposed method impacts translation. This motivates future exploration for many-to-many NMT to improve the encoder's sentence retrieval performance.

1 Introduction

Many-to-many neural machine translation (NMT) (Firat et al., 2016; Johnson et al., 2017; Aharoni et al., 2019; Sen et al., 2019; Arivazhagan et al., 2019b; Lin et al., 2020; Pan et al., 2021b) jointly trains a translation system for multiple language pairs and obtain significant gains consistently across many translation directions. Previous work (Lin et al., 2020) shows that word alignment information helps improve pre-training for many-to-many NMT. However, manually cleaned high-quality ground-truth bilingual dictionaries are used to pre-edit the source sentences, which are unavailable for most language pairs.

Recently, contrastive objectives (Clark et al., 2020; Gunel et al., 2021; Giorgi et al., 2021; Wei et al., 2021; Mao et al., 2021) have been shown to be superior at leveraging alignment knowledge in various NLP tasks by contrasting the representations of positive and negative samples in a discriminative manner. This objective, which should be able to utilize word alignment learned by any toolkit, which in turn will remove the constraints of using manually constructed dictionaries, has not been explored in the context of leveraging word alignment for many-to-many NMT.

An existing contrastive method (Pan et al., 2021b) for many-to-many NMT relies on sentence-level alignments. Given that the incorporation of word alignments has led to improvements in previous work, we believe that fine-grained contrastive objectives focusing on word alignments should help improve translation. Therefore, this paper proposes word-level contrastive learning for many-to-many NMT using the word alignment extracted by automatic aligners. We conduct experiments on three many-to-many NMT systems covering general and spoken language domains. Results show that our proposed method achieves significant gains of 0.8 BLEU in the general domain compared to previous word alignment based methods and the sentence-level contrastive method.

We then analyze how the word-level contrastive objective affects NMT training. Inspired by previous work (Artetxe and Schwenk, 2019) that train sentence retrieval models using many-to-many NMT, we speculate that our contrastive objectives affect the sentence retrieval performance and subsequently impact the translation quality. Further investigation reveals that in many-to-many NMT, the sentence retrieval precision of the multilingual encoder for a language pair strongly correlates with its translation quality (BLEU), which provides insight about when contrastive alignment improves translation. This revelation emphasizes the importance of improving the retrieval performance of the encoder for many-to-many NMT.

2 Word-level Contrastive Learning for Many-to-many NMT

Inspired by the contrastive learning framework (Chen et al., 2020) and the sentence-level con-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1766 - 1775

trastive learning objective (Pan et al., 2021b), we propose a word-level contrastive learning objective to explicitly guide the training of the multilingual encoder to obtain well-aligned cross-lingual representations. Specifically, we use word alignments, obtained using automatic word aligners, to supervise the training of the multilingual encoder by a contrastive objective alongside the NMT objective.

Alignment Extraction Two main approaches for automatically extracting aligned words from a sentence pair are: using a bilingual dictionary and using unsupervised word aligners. The former extracts fewer but precise alignments, whereas the latter extracts more but noisy alignments. We extract word-level alignments by both methods and explore how they impact NMT training. For the former approach, we use word2word (Choe et al., 2020) to construct bilingual lexicons and then extract word pairs from parallel sentences. The extracted word pairs are combined to form a phrase if words are consecutive in the source and target sentence. For the latter approach, we use FastAlign (Dyer et al., 2013) and use only 1-to-1 mappings for training.

Word-level Contrastive Learning With the extracted alignments, we propose a word-level contrastive learning objective for the multilingual encoder by the motivation that the aligned words within a sentence pair should have a similar contextual representation. We expect the supervision of the contrastive objective on the corresponding contextual word representation leads to a robust multilingual encoder. Assume that the tokenized source and target parallel sentences in the $i-th$ batch are $\mathcal{D}_i = \{src_{ij}, tgt_{ij}\}_{j=1}^{B}$, and the extracted alignments from all the sentence pairs in each batch are $\mathcal{A}_i = \{s_{ik}, t_{ik}\}_{k=1}^{N}$, where B and N denote the batch-size and the number of alignments, respectively. Note that s_{ik} and t_{ik} may contain several tokens after the word combination for word2word or subword tokenization for NMT. Then the word-level contrastive loss in a batch is:

$$\mathcal{L}^{(i)}_{align} = -\sum_{k=1}^{N}(\log \frac{\exp{(sim(s_{ik}, t_{ik})/\mathcal{T})}}{\sum_{m=1}^{N} \exp{(sim(s_{ik}, t_{im})/\mathcal{T})}} + \log \frac{\exp{(sim(s_{ik}, t_{ik})/\mathcal{T})}}{\sum_{m=1}^{N} \exp{(sim(s_{im}, t_{ik})/\mathcal{T})}}) \tag{1}$$

where $\mathcal{T}$ denotes a similarity scaling temperature. The similarity between two words is measured by:

$$sim(word_x, word_y) = cos(g(\bar{\mathbf{x}}), g(\bar{\mathbf{y}})) \tag{2}$$

La. pair	Source	Size	N (w2w)	N (FA)
en-et	WMT18	1.9M	5,762,977	38,454,477
en-it	IWSLT17	231k	603,032	3,000,011
en-ja	IWSLT17	223k	684,583	2,797,882
en-kk	WMT19	124k	124,511	279,429
en-my	ALT	18k	75,383	377,392
en-nl	IWSLT17	237k	564,697	2,836,873
en-ro	WMT16	612k	3,271,848	13,092,240
en-tr	WMT17	207k	770,873	2,885,102
en-vi	IWSLT15	133k	354,167	2,120,755

Table 1: **Data Source and number of the extracted word pairs.** La. pair, N (w2w) and N (FA) denote the language pair, the number of the word pairs extracted by word2word and FastAlign, respectively. Refer to Appendix B for details of the dataset splits.

where $g(\mathbf{x}) = \mathbf{W}_2\sigma(\mathbf{W}_1\mathbf{x})$ and $\bar{\mathbf{x}}$ denotes the average of contextual hidden states of the corresponding subword positions on top of the multilingual encoder. Following (Chen et al., 2020), we use an MLP between contrastive loss and the contextual representation for NMT loss. ReLU activation is used for σ, $\mathbf{W}_1$ is $d \times d$ and $\mathbf{W}_2$ is $d \times d'$, where d is the encoder's hidden dimension and $d' < d$.

Finally, to jointly train with the NMT loss, we use the following equation to combine our proposed word-level contrastive loss for a batch:

$$\mathcal{L}^{(i)} = \frac{1}{B}(\mathcal{L}^{(i)}_{NMT} + w\frac{N_T}{2N}\mathcal{L}^{(i)}_{align}) \tag{3}$$

where N_T is the number of the tokens within a batch, $\frac{N_T}{2N}$ is a multiplier that scales the contrastive loss to be consistent with NMT loss, and w is a weight to balance the joint training.

3 Experimental Settings

Datasets and Preprocessing We selected ten languages, including English (en), Estonian (et), Italian (it), Japanese (ja), Kazakh (kk), Burmese (my), Dutch (nl), Romanian (ro), Turkish (tr), Vietnamese (vi) from different language families to train the NMT systems. We used the parallel datasets from different domains for the selected nine language pairs, including IWSLT, WMT, and ALT. We followed mBART (Liu et al., 2020) for tokenization. Details are given in Appendix A. For each parallel dataset, we implemented two approaches as stated in Section 2 to extract word pairs for the contrastive training objective. Data source and the number of the extracted word pairs are shown in Table 1. To ensure high alignment

quality, we used large-scale out-of-domain (see Appendix B) parallel corpora with FastAlign.

Many-to-many NMT systems We established three many-to-many NMT systems as follows:

222_en-ja: Bidirectional en-ja NMT model using en-ja parallel corpus.

626_en-it-ja-nl-tr-vi: 6-to-6 multilingual NMT model using spoken language domain corpora for en-it, en-ja, en-nl, en-tr and en-vi.

626_en-tr-ro-et-my-kk: 6-to-6 multilingual NMT model using general domain corpora for en-tr, en-ro, en-et, en-my and en-kk.

Baselines and Ours For each language group setting above, we conducted NMT experiments on both the multilingual training from scratch (**MLSC**) (Johnson et al., 2017; Aharoni et al., 2019) and the mBART multilingual fine-tuning (**mBART FT**) (Tang et al., 2020) as baselines. We applied our proposed word-level contrastive learning in both MLSC and mBART FT, and compared with another strong baseline, word alignment based joint NMT training (**+align**) (Garg et al., 2019). For applying our method, we investigated the performance of joint training with word pairs extracted by both word2word (**+w2w**) and FastAlign (**+FA**). We omitted Lin et al. (2020) as a baseline because their method can not be applied to mBART fine-tuning, and they used high-quality ground-truth dictionaries, which are unavailable for most languages pairs.

Implementation We used `mBART-large` (mBART-25) for mBART FT and `transformer-base` (Vaswani et al., 2017) for MLSC. See Appendix C for details.

4 Results and Analyses

BLEU Results We report case-sensitive tokenized BLEU (Papineni et al., 2002) results in Table 3 and 2. In Table 3, we observe that with our pro-

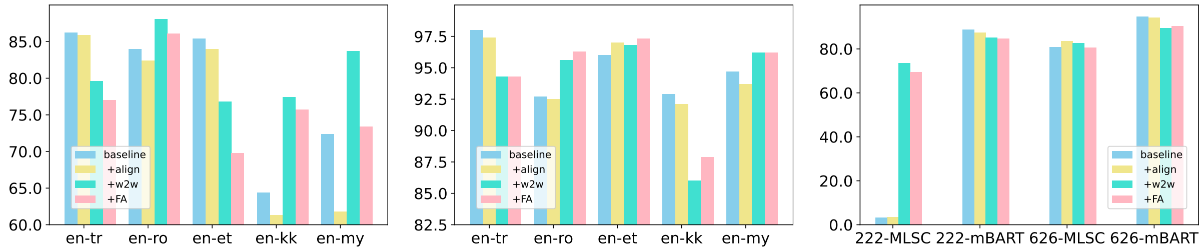

Figure 2: **Sentence retrieval P@1 on the validation set for each language pair.** *Left* and *middle* are the results on 626_en-tr-ro-et-my-kk MLSC and mBART FT, respectively. "626" in *right* subfigure denote 626_en-it-ja-nl-tr-vi. Refer to Appendix E for setup and results in details.

posed training objectives, BLEU scores are comparable in 222_en-ja and 626_en-it-ja-nl-tr-vi while they are slightly improved in 626_en-tr-ro-et-my-kk. However, "+align" performs comparable or even worse compared with the baseline. Referring to Table 2 for specific BLEUs on each language pair, we find that with our methods, translation performances are significantly improved for mBART FT while nontrivial improvements can merely be observed on en-ro and en-kk direction for MLSC. This indicates that NMT fine-tuning on monolingual pre-trained models (mBART) may benefit more from our proposed methods. Note that the BLEU improvements for MLSC are not significant, and we explain why this happens in the "Word Retrieval P@1 is improved" part.

Latent Encoder Alignment Property We now inspect which aspect of alignment-based methods impacts the translation performance. Previous work (Artetxe and Schwenk, 2019) showed that the encoder of a strong multilingual NMT system is an ideal model for the bilingual sentence retrieval task. In addition, Arivazhagan et al. (2019a) introduced the correlation between the encoder-side sentence representation[1] and the translation quality. Inspired by these, we speculate that alignment-based objectives affect sentence retrieval performance, which further impacts the translation quality. We train MLSC and mBART FT and report the sentence retrieval precision and NMT loss during the training. Results are reported in Figure 1. We observe that the validation retrieval precision show similar trends as the NMT loss. This indicates that during many-to-many NMT training from scratch, encoder-side sentence-level retrieval precision is optimized along with the NMT loss.

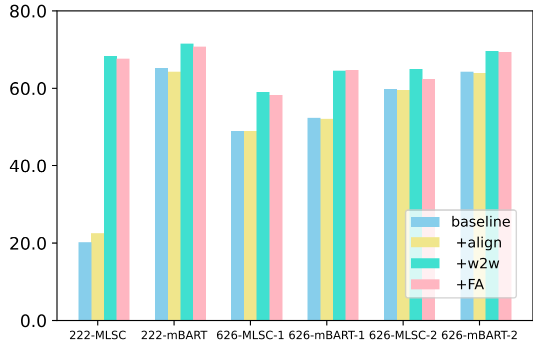

Figure 3: **Average Word retrieval P@1 on the validation set for each language pair.** "626-*-1" and "626-*-2" indicate 626_en-it-ja-nl-tr-vi and 626_en-tr-ro-et-my-kk, respectively. Refer to Appendix F for setup and results in details.

Sentence Retrieval P@1 Correlates with BLEU According to the investigation of the encoder alignment property above, we verify the relationship between BLEU score and sentence retrieval precision on the validation set for each language pair. Results are shown in Figure 2. Cross-referencing the BLEU score in Table 2, we found that BLEU scores are improved when the encoder achieves gains on the sentence retrieval precision.[2] For example, we see increases of the retrieval P@1 on en-ro, en-et, and en-my on mBART FT (the middle of Figure 2) while BLEU scores are significantly improved on these three language pairs (Table 2). We further calculate the Pearson correlation coefficient between the BLEU changes and sentence retrieval P@1 changes for mBART+align, mBART+w2w, and mBART+FA in the 626_en-tr-ro-et-my-kk setting. Results are 0.79, 0.93, 0.90, respectively, demonstrating a strong correlation between translation quality and sentence retrieval precision.

Word Retrieval P@1 is Improved We probe the trained contextualized word representations on top of the encoder. As shown in Figure 3, we observe that the word retrieval precision is improved in all

---

[1] Usually a pooled encoder output.

[2] 222_en-ja MLSC setting can hardly learn a well-aligned encoder while our methods improve the encoder sentence-level alignment quality without sacrificing BLEU scores.

the settings. This demonstrates that the encoder parameters of the NMT system trained with our proposed objective are of a rather different distribution. By just changing the random seed, we can expect similar BLEU results, but we cannot obtain a better aligned encoder. However, the improvement of the word retrieval precision does not directly contribute to the translation quality, which we explain next.

Word-level Contrastive Objective and Sentence Retrieval P@1 With the word-level contrastive objective, we observed significant BLEU score improvements on language pairs such as en-ro, en-et and en-my for mBART FT as presented in Table 2. However, noisy word pairs (Pan et al., 2021a) extracted via word alignment toolkits leads to poor supervision signals for improving sentence retrieval P@1, which in turn prevents some language pairs such as en-kk from exhibiting BLEU improvements. We found that for en-kk, the numbers of extracted word pairs per sentence by word2word and FastAlign are 1.0 and 2.2, respectively. In contrast, these numbers are 4.2 and 20.7 for improved language pairs, calculated from Table 1. Although better extracted word alignments for the word-level contrastive objective leads to BLEU improvements, its contribution towards improvements varies for MLSC and mBART FT, as shown in Table 2. We expect these findings to provide new perspectives for improving many-to-many NMT.

Sentence-level Contrastive Objective We conducted the experiments for the sentence-level contrastive objective (Pan et al., 2021b) on all two six-to-six settings and compared it against our proposed approach. The average BLEUs of our methods significantly outperform those of sentence-level contrastive objectives (see Table 8 and 9), clearly showing the sentence-level objective's limitation. Moreover, we checked the sentence retrieval P@1 for Pan et al. (2021b) (Table 10 and 11) and found that it correlates with BLEU changes, indicating that sentence-level contrastive objective is suboptimal for language pairs with decreased retrieval precision.[3]

5 Conclusion

We proposed a word-level contrastive learning objective for many-to-many NMT. Experimental results showed that our proposed method leads to significantly better translation for several language pairs, which is then explained by analyses showing the relationship between BLEU scores and sentence retrieval performance of the NMT encoder. Future work can focus on: (1) further improving the encoder's retrieval performance in many-to-many NMT; (2) contrastive objective's feasibility in a massively multilingual scenario.

Ethical Considerations

All the corpora we used in this paper are publicly available resources without the issue of the copyright. The technique this paper proposed is for NMT models, so it can not circumvent the issues that NMT models have. Since our automatically dictionaries are extracted from potentially biased data, the translations may also contain biases. However, we expect that these issues may be resolved by using unbiased data or the addition of debiasing objectives.

A Tokenization Settings

For Japanese, we use Jumanpp (Morita et al., 2015; Tolmachev et al., 2018) for segmentation, and we follow the same settings as in mBART (Liu et al., 2020) for other languages: `myseg.py` (Ding et al., 2020) is used for Burmese, Moses tokenization and special normalization is used for Romanian following (Sennrich et al., 2016),[4] and Moses tokenization for other languages.[5] Following mBART, we apply SentencePiece (Kudo and Richardson, 2018) to further segment sentences into subwords.[6]

B Datasets and Alignment Extraction

The datasets used for NMT training, validation and test are shown in Table 4. For the word alignment extraction using FastAlign, we also use out-of-domain parallel corpora to train the FastAlign jointly, aiming to obtain word alignments with less noise. The out-of-domain corpora for all the language pairs contain Tatoeba, Europarl, GlobalVoices, NewsCommentary, OpenSubtitles, TED, WikiMatrix, QED, GNOME, bible-uedin, and ASPEC (Nakazawa et al., 2016). We collect them from the OPUS project (Christodoulopoulos and Steedman, 2015) and WAT.[7] The number of the out-of-domain parallel sentences for each language pair is shown in Table 4.

C Implementation Details

Following Tang et al. (2020), we set the oversampling temperature of 1.5 for all the settings. For MLSC, we set the dropout of 0.3 to avoid overfitting on small-scale training data. We used the batch size of 1,024 tokens for all the settings. For our word-level contrastive learning, we set the weight of 0.1, the temperature of 0.2, d' of 128, and a

stopping if no improvement of the validation loss is observed for 8 checkpoints. The model with the best validation loss was used for evaluation.

D BLEU Scores

We report all the BLEU results of 222_en-ja, 626_en-it-ja-nl-tr-vi, and 626_en-tr-ro-et-my-kk in Table 5, 8 and 9, respectively.

E Sentence Retrieval Precision

We report the sentence retrieval precision for all the systems in Tables 6, 10 and 11. The sentence retrieval previsions are evaluated by using the validation dataset of each language pair. The mean pooled encoder output is used as the sentence embedding. We use cosine similarity to conduct the retrieval task, and report the average retrieval precision of both directions of each language pair.

F Word Retrieval Precision

We report the word retrieval precision for all the systems in Tables 7, 12, and 13. The word retrieval precision are computed by using the validation dataset and the word2word alignments on it. The mean pooled encoder output on corresponding positions is used as the contextualized word embedding. We use cosine similarity to implement the retrieval for word pairs in a batch, and present the average in-batch retrieval precision of both directions of each language pair. Batch size is set as 512 tokens.

Minimally-Supervised Relation Induction from Pre-trained Language Model

Lu Sun, Yongliang Shen, Weiming Lu *
College of Computer Science and Technology, Zhejiang University
{sunlu98,syl,luwm}@zju.edu.cn

Abstract

Relation Induction is a very practical task in Natural Language Processing (NLP) area. In practical application scenarios, people want to induce more entity pairs having the same relation from only a few seed entity pairs. Thus, instead of the laborious supervised setting, in this paper, we focus on the minimally-supervised setting where only a couple of seed entity pairs per relation are provided. Although the conventional relation induction methods have made some success, their performance depends heavily on the quality of word embeddings. The great success of Pre-trained Language Models, such as BERT, changes the NLP area a lot, and they are proven to be able to better capture relation knowledge. In this paper, we propose a novel method to induce relation with BERT under the minimally-supervised setting. Specifically, we firstly extract proper templates from the corpus by using the mask-prediction task in BERT to build pseudo-sentences as the context of entity pairs. Then we use BERT attention weights to better represent the pseudo-sentences. In addition, We also use the Integrated Gradient of entity pairs to iteratively select better templates further. Finally, with the high-quality pseudo-sentences, we can train a better classifier for relation induction. Experiments on Google Analogy Test Sets (GATS), Bigger Analogy Test Set (BATS) and DiffVec demonstrate that our proposed method achieves state-of-the-art performance.

1 Introduction

Relation induction is a task to judge whether two entities have a certain relation based on some given entity pairs of that relation, which was first proposed in (Vylomova et al., 2016). For instance, given $\{(Germany, Berlin), (France, Pairs), (Italy, Rome)\}$, relation induction is to predict whether new entity pairs such as $(China, Beijing)$ have the same relation as the given entity pairs. In practical scenarios, only a few seed entity pairs are available. It is challenging to judge the relation of the target entity pairs in this minimal supervision setting.

Word embedding, such as skip-gram (Mikolov et al., 2013a) and Glove (Pennington et al., 2014), are widely used in many natural language processing (NLP) tasks, and it was reported that word embeddings can capture the relational knowledge (Mikolov et al., 2013b). One intuitional method for relation induction task is using word embeddings to represent relations and induce relations based on vector translation or similarity (Vylomova et al., 2016; Drozd et al., 2016; Bouraoui et al., 2018; Vulić and Mrkšić, 2018; Camacho-Collados et al., 2019). However, the performance of these methods heavily depends on the pre-trained word embedding and these methods are rather noisy. According to the assumption that if two entities have a relationship in a known knowledge base, then all sentences that mention these two entities will express that relationship in some way (Mintz et al., 2009), many distant-supervised methods of relation extraction, such as PCNN(Zeng et al., 2015) and PCNN-BagATT (Ye and Ling, 2019) are proposed. Inspired by these methods, distant supervision might be another way to induce relation. To induce relation in the distant supervised way, we need a method to select proper sentences from corpus and extract relational knowledge from sentences. Luckily, many Pre-trained Language Models (PLMs), such as BERT(Devlin et al., 2019), GPT-2 (Radford et al., 2019) and XLNet(Yang et al., 2019), have been recently proposed and boost a great performance for many NLP tasks, such as question answering(Talmor et al., 2019; Feng et al., 2020), text summarization (Liu and Lapata, 2019; Lewis et al., 2020) and information extraction (Petroni et al., 2019; Alt et al., 2019). In order to better understand the PLMs, several works(Kim et al., 2020; Bouraoui et al., 2020; Ushio et al., 2021; Chen

---

[*] corresponding author

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1776 - 1786

et al., 2021) have proven that PLMs can capture syntactic and semantic knowledge. Bouraoui et al. (2020) have explored the possibility of inducing relation from BERT in a distant supervised way and got a good result. To take the advantage that BERT can capture context knowledge, they select templates from corpus and fill entities in them to let BERT predict the relation.

Existing methods are developed under the assumption of sufficient seed entity pairs. However, in practical scenarios, only a few entity pairs are available for a particular relation. These methods have difficulty in coping with the minimal supervision setting. The main reasons are: (1) Due to the lack of labeled entity pairs, the model tends to over-focus on the surface cues of the entity pairs and ignores the contextual semantics. By simply memorizing the seed entity pairs, it is difficult to generalize the model to other entity pairs. (2) The quality of templates is very important for relation induction.When the seed entity pairs of a certain relation are sparse, the number of candidate templates for this relation mined from the corpus will be reduced.

Therefore, two major challenges should be addressed for the relation induction in the minimally-supervised setting. (1) How to obtain a good generalized relation induction model? (2) How to obtain high-quality templates? So we propose a novel approach called IST for minimally-supervised relation induction with Iteratively-Selected Templates from PLM. Specifically, for the first challenge, we use surface-agnostic features based on attention maps of BERT. Many works (Clark et al., 2019; Kovaleva et al., 2019; Michel et al., 2019; Wang et al., 2020) have revealed that the attention heads in BERT can capture much knowledge and some attention heads are related to certain relations, and some works use attention weights to predict relations (Gu et al., 2021). For the second challenge, we use Integrated Gradient (IG) (Sundararajan et al., 2017) to score the templates and iteratively select better templates. Intuitively, if a sentence can well express the relational knowledge between two entities, then the importance of these two entities must be high in the sentence. On the contrary, if a pair of entities do not play an important role in a sentence, this sentence certainly does not express the relationship between them. So IG might be used to select high-quality sentences to express relations.

We summarize our key contributions as follows:

- We propose a novel minimally-supervised relation induction approach IST. To the best of our knowledge, we are the first to address the minimally-supervised relation induction task.
- In order to overcome the minimally-supervised setting, we generate high-quality pseudo-sentences by iteratively selecting templates based on BERT and IG scores. Moreover, we use attention maps to train a more generalized model.
- We conduct extensive experiments on three standard benchmark datasets, and our proposed approach significantly outperforms the state-of-the-art approaches.

2 Our Approach

In this section, we first formulate the minimally-supervised relation induction task and give an overview of our approach. We then describe the details of each module in our approach.

2.1 Problem Formulation

Given a few seed entity pairs $P_r = \{(s_i, t_i)\}_{i=1}^N$ with a certain relation r, the task of relation induction is to judge whether a new entity pair (s, t) also has the relation r. In the minimally-supervised setting, the number of the seed pairs is small for each relation (in our experiments, no more than 5 per relation). To facilitate minimally-supervised relation induction, we generate high-quality pseudo sentences S_r for each relation r from a text corpus C according to the seed entity pairs P_r with the help of a pre-trained language model.

2.2 Overview

As illustrated in Figure 1, our approach consists of four main modules: template generation module, pseudo sentence generation module, relation classifier and template selection with IG.

In the template generation module, given seed entity pairs, some proper templates could be generated based on the mask-prediction results in BERT. For instance, considering the seed entity pairs $P_r = \{(Germany, Berlin), (France, Paris), (Japan, Tokyo)\}$, we can obtain a sentence set S_r where each sentence mentions both entities of a pair in P_r.Taking a sentence $The\ current\ capital\ of\ Japan\ is\ Tokyo.$ as an

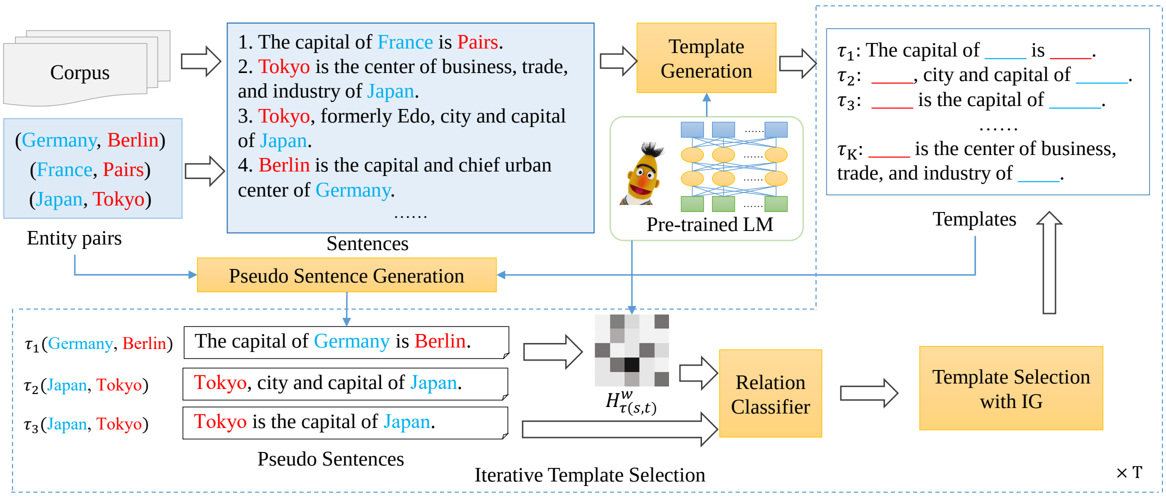

Figure 1: An overview of IST. First, we extract sentences that mention seed entity pairs as candidate sentences. Then, the template generation module uses BERT-prediction task to select proper templates from candidates. Templates and seed entity pairs are assembled to generate pseudo sentences to extract relational knowledge from BERT. The BERT attention weights between entities within the pseudo sentence are used as surface-agnostic features to better represent the relational knowledge. Then, the pseudo sentences and attention weights are combined to train a BERT-based relation classifier. Finally, we use the integrated gradient of entity pairs in pseudo sentences to evaluate the quality of templates and select better templates iteratively.

example, $\tau = (The\ current\ capital\ of\ \_\ is\ \_)$ is the generated template. Then, filling one entity into templates, the templates can be scored according to their ability to make BERT correctly predict another entity. This score is referred to as score$_{BERT}$.

After selecting proper templates based on score$_{BERT}$, we can generate pseudo sentences by assembling the templates and seed entity pairs. For example, a pseudo sentence $\tau(Germany, Berlin)$ = $The\ current\ capital\ of\ \underline{Germany}\ is\ \underline{Berlin}$. is generated by assembling $(Germany, Berlin)$ and τ. We generate both positive and negative sentences in this process.

For each pseudo-sentence, we extract surface-agnostic features based on attention weight maps of BERT and use them to train a relation classifier.

Finally, we use integrated gradient (IG) together with score$_{BERT}$ to evaluate the quality of templates again, so we can refine templates iteratively.

We will describe each module in detail in the following sections.

2.3 Template Generation

To induce relation from masked pre-trained language models such as BERT, we need templates for relations. First, many template-based relation extraction methods(Agichtein and Gravano, 2000; Ravichandran and Hovy, 2002) have proved that words near to s and t in corpus may represent a certain relation. To extract templates for relation r, we traverse Wiki Corpus to find k_i sentences that contain both s_i and t_i(i≤N), and the distance between s_i and t_i in sentence $D_{st} \leq d$. Then we mask s_i and t_i in these senteces to generate templates $\tau_{i,1}, \tau_{i,2}...\tau_{i,k}$. We can extract all candidate templates for r: $\{\tau_{1,1}, \tau_{1,2}...\tau_{i,j}...\tau_{N,k_N}\}$ $(i \leq N, j \leq k_i)$, but not all of these templates are proper for inducing the relation r.

Then we need to select templates that are proper for BERT to induce relation r. Here we use BERT mask prediction as a template filter (Bouraoui et al., 2020). Specifically, for a template τ, insert s and t into τ respectively to get masked sentence $\tau(s,\_)$ and $\tau(\_,t)$. Then let BERT predict the masked token. If BERT can predict correctly, we consider the template τ is proper for relation r and $\tau(s,t)$ is "natural" for BERT.

$$score_{BERT}(\tau) = \sum_{i=0}^{N}(M(\tau(s_i,\_))+M(\tau(\_,t_i))) \tag{1}$$

where $M(\tau(s_i,\_))$ is 1 if the predicted token is t_i and 0 otherwise, and similar for $M(\tau(\_,t_i))$ = 1.

By ranking templates with $score_{BERT}$, K proper templates $T_r = \{\tau_1, \tau_2...\tau_K\}$ are selected from candidate templates.

2.4 Pseudo Sentence Generation

In order to train a relation classifier, we assemble templates and seed entity pairs to generate labeled pseudo sentences.

For positive sentences, we just assemble each entity pair $(s,t) \in P_r$ with each template $\tau \in T_r$ to generate a sentence $\tau(s,t)$.

While for the negative sentences, following(Vylomova et al., 2016), we have three strategy for each pair $(s_i, t_i) \in P_r$. First, we exchange s and t as (t_i, s_i)(suppose r is not symmetrical). Second, we change one entity to another entity in the same relation :(s_i, t_j) or $(s_j, t_i)(i \neq j, (s_i, t_i), (s_j, t_j) \in P_r)$. Third, we change one entity to an entity in other relations:(s_i, t_j)or $(s_j, t_i)(i \neq j, (s_j, t_j) \in P_{r'})$.

2.5 Relation Classifier

Under the minimally-supervised setting, the model should have good generalizability. We use surface-agnostic features based on attention weights of BERT to make model focus more on the relations rather than the surface information of training data.

As Clark et al. (2019) has pointed out, some heads of multi-head attention in BERT are related to certain relations, and attention weights of certain heads can be used to extract certain relation knowledge. Thus, for a proper template of relation r, the attention weights between s and t of certain heads related to r should be higher. But it is hard to specify each head is related to what relations. Thus we use attention weights of all heads as features to induce relation knowledge.

Specifically, for a sentence $\tau(s,t)$, we calculate the attention weights between s and t of all heads as $\omega_{i,j,s\to t}$, where i denotes the i-th layer, j denotes the j-th head in layer i and $s \to t$ denotes that this is the attention s pays to t. We use the average between $s \to t$ and $t \to s$ to express the attention between them:

$$\omega_{i,j} = \frac{\omega_{i,j,s\to t} + \omega_{i,j,t\to s}}{2} \tag{2}$$

Then we construct attention weights embedding for the sentence $\tau(s,t)$:

$$H^{att}_{\tau(s,t)} = \{\omega_{1,1}, \omega_{1,2} ... \omega_{i,j} ... \omega_{nl,nh}\} \tag{3}$$

where nl denotes the layer number, nh denotes head number in a layer of BERT.

Besides $H^{att}_{\tau(s,t)}$, we also use BERT outputs to represent the sentence $\tau(s,t)$. Specifically, we input $\tau(s,t)$ into the BERT, and then use the output vector of the [CLS] token as the feature $H^{cls}_{\tau(s,t)}$. $H^{cls}_{\tau(s,t)}$ and $H^{att}_{\tau(s,t)}$ can compensate each other, since $H^{cls}_{\tau(s,t)}$ can capture the information whether $\tau(s,t)$ is "natural", and $H^{att}_{\tau(s,t)}$ contains the correlation between (s,t) and the relation r. Thus, we combine these two vectors through concatenation:

$$H_{\tau(s,t)} = H^{cls}_{\tau(s,t)} \oplus H^{att}_{\tau(s,t)} \tag{4}$$

Then, we feed $H_{\tau(s,t)}$ to a MLP classifier $\mathcal{F}$ and get the probability of (s,t) having relation r. We use a cross-entropy loss to optimize $\mathcal{F}$. In addition, we can also finetune BERT when training the classifier.

2.6 Iterative Template Selection

BERT can rank templates by measuring whether a sentence is natural. However, it can not capture the different attribution of each token in a sentence for expressing the relation.

Integrated Gradient is an attribution method proposed in (Sundararajan et al., 2017). As Cui et al. (2020) has described, the attribution score directly reflects how much changing tokens will change the model's outputs. A higher attribution score represents more importance of tokens. In our relation induction model, s and t obviously should be the most important two tokens in sentences. Intuitively, for a pseudo sentence $\tau(s,t)$, if the integrated gradient value for s and t to the relation prediction is higher, we are more confident that the relational knowledge of (s,t) can be extracted well by the model along with τ, so the template τ is much better. Thus, we can use the integrated gradient of (s,t) to the output of relation classifier to select templates once again. Here, $\mathcal{F}(\tau, s, t)$ denotes the relation classifier with $\tau(s,t)$ as the input.

According to Sundararajan et al. (2017), the integrated gradient value of s to $\mathcal{F}(\tau, s, t)$ is:

$$IG(\tau, s) = (s - s_0) \int_{x=0}^{1} \frac{\partial \mathcal{F}(\tau, s_0 + \alpha(s - s_0), t)}{\partial s} \mathrm{d}\alpha \tag{5}$$

where $\alpha \in [0, 1]$, and it can be approximated as:.

$$IG(\tau, s) = (s - s_0) \sum_{i=1}^{m} \frac{1}{m} \times \frac{\partial \mathcal{F}(\tau, s_0 + \frac{i}{m}(s - s_0), t)}{\partial s} \tag{6}$$

where m is the number of approximate steps for computing integrate gradient and s_0 is generated by replacing the word embedding of s with zeros. For a template τ, we calculate the average integrated gradient value for all $(s,t) \in P_r$:

$$score_{IG}(\tau) = \sum_{(s,t)\in P_r} \frac{IG(\tau,s) + IG(\tau,t)}{2} \quad (7)$$

Then the templates are re-ranked according to the final score:

$$score = \alpha \cdot \frac{1}{rank_{BERT}} + (1-\alpha)\frac{1}{rank_{IG}} \quad (8)$$

where $rank_{BERT}$ denotes the rank of templates according to $score_{BERT}$, $rank_{IG}$ denotes the rank of templates according to $score_{IG}$, and $\alpha \in [0,1]$ is an coefficient to balance the two scores. Therefore, the templates could be selected iteratively for better relation induction.

2.7 Relation Induction

Given a new entity pair (x,y), we fill them into templates $\tau_i, (i \in K)$ and use the classifier to predict $p_i(x,y)$, which denotes how much $\tau_i(x,y)$ is "natural". Following Bouraoui et al. (2020), for all predictions from K templates $p_1(x,y), ..., p_K(x,y)$, if $max_i p_i(x,y) > 1 - min_i p_i(x,y)$, then (x,y) is predicted to be positive.

3 Experiment Setup

3.1 Datasets

We conduct the experiments on three standard benchmark datasets in English: Google Analogy Test Set (GATS) (Mikolov et al., 2013a), Bigger Analogy Test Set (BATS) (Gladkova et al., 2016) and DiffVec(Vylomova et al., 2016).

GATS contains 5 semantic relations and 9 syntactic relations, and each consists of a varying number of entity pairs. While **BATS** contains 40 relations which are divided into 20 morphology relations and 20 semantic relations, each relation has 50 instances. **DiffVec** contains 36 relations with a various number of entity pairs. 10 of them are lexical or morphology relations and the remaining 26 are semantic relations.

3.2 Implementation Details

The relation induction task can be modeled as a binary classification problem for each relation.We first split the dataset into 50% of training data and 50% of test data. Then, under the minimally-supervised setting, for each relation r, we randomly select N entity pairs from training data as the seed entity pairs P_r. We extract candidate templates from the English Wikipedia corpus[1] and $d = 15$. When generating K templates in T iterations, we initially select $K(T+1)$ templates according to BERT score, and then iteratively filter out K improper templates in each iteration according to the score defined in Formula 8 until K templates are reserved at last for the final iteration. Notice that when $T = 0$, we only select K templates according to the $score_{BERT}$ without considering the $score_{IG}$. In our experiments, we use BERT-base[2], and set $N = 5, K = 20, T = 3, \alpha = 0.5$ by default.

We generate the same number of negative examples as positive examples for the training data and 3 times as many negative examples as positive examples for the test data.

For each relation, we repeat the experiments for 10 times and calculate the average result. The seed entity pairs used in each trial is randomly selected. The results of all metrics are calculated with micro-average.

4 Baselines

We compare our approach with three kinds of baselines.

The first kind is using the combination of pre-trained word embeddings to present relations. Specifically, following Vu and Shwartz (2018), we use $s \oplus t \oplus (s \odot t)$ to represent the relation between (s,t) and use a MLP classifier to make predictions. Here, the pre-trained word embeddings we used are Glove(Pennington et al., 2014)[3] and Skip-Gram(Mikolov et al., 2013b)[4]. These two baselines are referred to as MLP$_{sg}$ and MLP$_{gl}$ respectively.We also use the Trans approach (Bouraoui et al., 2018) for relation induction by building subspaces for entities using word embeddings and modeling the relations with relative positions between subspaces.

The second kind is distant supervised methods. We use PCNN(Zeng et al., 2015) and PCNN-BagAtt(Ye and Ling, 2019) as two baselines. These distant supervised methods are proposed to solve the problem of noise in labeled data in relation extraction tasks. We also select the same number of

sentences that mention entity pairs from the English Wikipedia corpus to construct training data as in our approach. For an entity pair (s,t), K sentences are used to predict its relation. If the average prediction score $\overline{S}_K \geq \theta$, (s,t) is predicted to have relation r. θ is a threshold and set to 0.7 in our experiments for its best performance.

The third kind is using the relational knowledge from PLMs, such as RI-BERT (Bouraoui et al., 2020), AutoPrompt(Shin et al., 2020)[5] and BERT$_{predict}$.

RI-BERT induces relational knowledge from BERT, and our approach would degenerate to it when not using attention maps as the surface-agnostic features and not using $score_{IG}$ to refine the templates. We implement the method by ourselves since there is no open source.

AutoPrompt tries to elicit knowledge from PLM using automatically-constructed prompts. Here, We generate templates with AutoPrompt for each relation. Since there is only one template can be generated for each relation, we use a threshold-based method to determine whether a new entity pair (x,y) has a relation. When $p(x,y) > \delta$, the prediction would be positive. Here, δ = 0.8 is the best threshold in our experiments.

BERT$_{predict}$ is a simple baseline proposed by ourselves. After K templates are selected with $score_{BERT}$, we directly use BERT mask-prediction task to judge relation. Specifically, for an entity pair (s,t) and a template τ, if BERT can predict $\tau(s,\_)$ or $\tau(\_,t)$, the score of (s,t) will be increased by 1. The max score is $2K$, so if the score of $(s,t) \geq \epsilon \cdot 2K$, (s,t) is predicted to have the relation r. ϵ is a threshold and set to 0.7 for its best performance.

5 Experimental Results

5.1 Main Results

The main experimental results on the three aforementioned benchmarks are shown in Table 1, which reports the micro-average of precision, recall and F1 of our approach **IST** and other state-of-the-art methods when $N = 3$ and $N = 5$.

From the table, there are several observations drawn from different aspects. (1) Our approach **IST** achieves the best performance against all other kinds of methods. (2) Pre-trained word embedding-based approaches such as MLP$_{sg}$ and MLP$_{gl}$ performance poorly, which proves that only few labeled entity pairs will degrade these approaches greatly. And Translation does not turn out well because of the lack of entities to construct representative subspaces. (3) The relational knowledge directly drawn from BERT also contains much noise according to the results of BERT$_{predict}$. (4) Traditional distant-supervised approaches which don't resort to PLM suffer from the noisy and sparse bag issues, although PCNN-BagATT uses intra-bag and inter-bag attention to handle sentence and bag-level noise, and get better performance, they are still not suitable for the minimally-supervised relation induction task. (5) AutoPrompt and RI-BERT use proper prompts or templates from BERT, so they can obtain a better performance. However, they did not consider the generalization problem in the minimally-supervised setting. In addition, they ignored the contribution of each token in a sentence for expressing the relation, especially for the entity pairs, but only considered whether a sentence is natural or not according to BERT. (6) More labeled entity pairs can achieve better performance by comparing the results of N = 3 and N = 5. This

---

[5] https://github.com/ucinlp/autoprompt

phenomenon is reflected by all methods in both three datasets.

5.2 Ablation Study and Analysis

Performance of Different Relations To further explore the performance of different relations, we show the detailed results of each relation in GATS in Table 2.

From the table, we can see that our approach achieves better performance for both semantic and morphology relations. Moreover, the iteratively template selection can bring a significant improvement, especially for semantic relations. As to morphological relations, the improvement is not so evident. This is because the entities in morphological relations are always adverbs or adjectives to which little attention is paid, so $H^{att}_{\tau(s,t)}$ plays a limited role.

Table 2: Detailed experimental results (F1) for each relation on GATS. T denotes the iteration number

Performance of attention weights and IG To investigate the effectiveness of BERT attention weights and IG, we compare the performance of several variants of our approach on GATS.

To reduce the effect of BERT attention weights, the representation of sentence $\tau(s,t)$ is simplified from $H^{cls}_{\tau(s,t)} \oplus H^{att}_{\tau(s,t)}$ to $H^{cls}_{\tau(s,t)}$. In addition, without IG, there would be no iterative template selection procedure. The results are shown in Table 3, and the performance drops in all variants, which proves that both attention maps and integrated gradient are useful in our approach.

Different Number of Templates To analyze the impacts of the number of templates (K), we conduct experiments with different numbers of templates, and the results are shown in Table 4. From the table, we find that more templates can bring better performance in all iterations. However, if K is too large, the time consumption will be greater and some unsuitable templates will be retained, leading to worse results.

GATS	T=0	T=1	T=2	T=3
IST	79.7	80.2	81.1	82.6

T=1	73.8	78.5	80.2
T=2	75.6	78.9	81.1

Table 4: F1-score with different number of templates ($K = 5, 10, 20$) and different iterations ($T = 0, 1, 2$) on GATS.

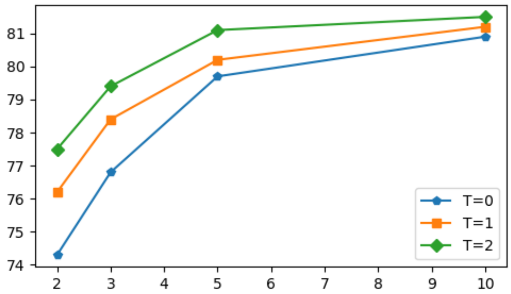

Figure 2: F1 scores with different numbers of seed entity pairs(N = {2, 3, 5, 10}) of our approach on GATS

Different Number of Seeds We evaluate our approach with different numbers of seed entity pairs (N), and the results are shown in Figure 2. From the figure, we can see that F1 score increases gradually until convergence for all iterations. Our approach already achieves a satisfactory result when N = 5.

Effect of Balance Coefficient The parameter $\alpha \in [0, 1]$ is a balance coefficient between $score_{BERT}$ and $score_{IG}$ for template scoring. Larger α will consider $score_{IG}$ more in the scoring. We conduct the experiments with different α on GATS, and the results are shown in Figure 3. From the figure, we find that our approach achieves the best performance when α = 0.5.

T=0	T=3
The Government of _ denoted 300 million _ to finance the school's construction in 1975.	The _ (, plural: / ,) is the currency of _ .
Currently, _ uses the _ as its national currency.	This was one of the reasons for naming the current currency of the Republic of _ the _.
Following the introduction of the euro, the _ was linked to the euro, until January 1, 2015, when _ officially adopted the euro as its currency.	The _ (; ; sign: ; code: KHR) is the currency of _.
AutoPrompt: _ cial largest greenwich _.	

Table 5: Case study for relation $currency$, where top 3 templates are exhibited with different approaches.

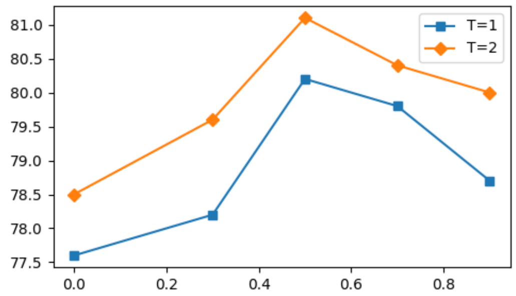

Figure 3: F1 scores with α={0, 0.3, 0.5, 0.7, 0.9]} of our approach on GATS

Case Study Table 5 compares the selected templates of relation currency between $T = 0$ and $T = 3$. From human's intuition, we find that comparing to (T = 3), the templates filtered out only with $score_{BERT}$(T = 0) are more ambiguous that they might indicate a co-occurrence relationship rather than relation $currency$. For example, for the first template "The Government of _ denoted 300 million _ to finance the school's construction in 1975.", it is natural for the government of a country to denote their own currency or just use dollar to evaluate how much they have denoted. So $\tau(s, dollar)$ is natural when s denotes any country. This is due to the way of selecting templates that only requires the templates is proper for all $(s, t) \in P_r$ without explicitly declaring what the relation is. In fact, the model can distinguish $co-occurrence$ and $currency$ only after the BERT is fine-tuned with negative examples. As to the template generated by AutoPrompt, it is a combination of some tokens rather than a human-readable sentence. Although AutoPrompt got good results on some tasks(Shin et al., 2020), the template is totally not interpretable from human's perspective.

6 Related Work

6.1 Relation Induction

Relation induction was first proposed in (Vylomova et al., 2016). They used the vector difference between two entities to represent the relation between them. More researches on the relation induction with word embeddings were proposed in(Drozd et al., 2016; Bouraoui et al., 2018; Vu and Shwartz, 2018). They pointed out that the difference is not the best way to express the relationship and proposed more complicated methods to better extract relational knowledge between word embeddings.

6.2 Knowledge Induction from BERT

BERT was proven to be able to capture relational knowledge(Kim et al., 2020; Bouraoui et al., 2020; Ushio et al., 2021; Chen et al., 2021). Inspired by this, some works tried to use BERT on the relation induction task (Shin et al., 2020; Bouraoui et al., 2020; Jiang et al., 2020). The key point of these methods is to fill entities in the proper templates.

Recently, many efforts focus on the generation of templates. Jiang et al. (2020) proposed a template generation strategy based on paraphrasing aiming to improve lexical diversity while remaining relatively faithful to the original prompt. Shin et al. (2020) proposed AutoPrompt method to generate templates, or as they called, prompts, from nothing instead of from corpus. They automated create prompts based on gradient-guided search.

7 Conclusion

In this paper, we propose a novel minimally-supervised relation induction approach. Our proposed approach can iteratively select proper templates using $score_{IG}$ and $socre_{BERT}$, and obtain a good generalized ability with surface-agnoistic features based on attention maps of BERT. Experiments illustrate that our approach achieves state-of-the-art performance on three standard benchmarks.

Abstract

Semantic parsing solves knowledge base (KB) question answering (KBQA) by composing a KB query, which generally involves node extraction (NE) and graph composition (GC) to detect and connect related nodes in a query. Despite the strong causal effects between NE and GC, previous works fail to directly model such causalities in their pipeline, hindering the learning of subtask correlations. Also, the sequence-generation process for GC in previous works induces ambiguity and exposure bias, which further harms accuracy. In this work, we formalize semantic parsing into two stages. In the first stage (graph structure generation), we propose a causal-enhanced table-filler to overcome the issues in sequence-modelling and to learn the internal causalities. In the second stage (relation extraction), an efficient beam-search algorithm is presented to scale complex queries on large-scale KBs. Experiments on LC-QuAD 1.0 indicate that our method surpasses previous state-of-the-arts by a large margin (17%) while remaining time and space efficiency. The code and models are available at https://github.com/AOZMH/Crake.

1 Introduction

To incorporate knowledge in real-world question-answering systems, knowledge base question answering (KBQA) utilizes a background knowledge base (KB) as the source of answers to factoid natural language questions. Leveraging the versatility of KB query languages like SPARQL (Prud'hommeaux, 2008), many previous works (Unger et al., 2012; Yahya et al., 2012) adopted a semantic parsing paradigm for KBQA, in which questions are converted to equivalent SPARQL queries and answers are given by executing the queries in KB. Regarding the intrinsic graph structure of SPARQLs, some works further reduced such procedure as generating the query graph of SPARQLs w.r.t. questions. However, these methods either require auxiliary tools (e.g. AMR in Kapanipathi et al., 2021, constituency tree in Hu et al., 2021, dependency tree in Hu et al., 2017) causing potential cascading errors, or rely on predefined templates (Cui et al., 2017; Athreya et al., 2021) limiting their expressiveness and generalization abilities.

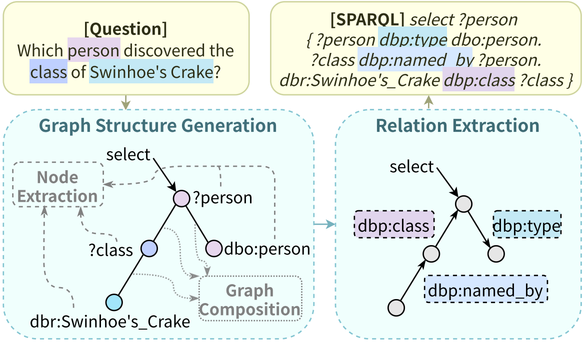

Figure 1: Generating a query graph (bottom) by two stages to represent the SPARQL (right-top). At graph structure generation stage, node-extraction generates all graph nodes while graph-composition adds unlabeled edges between proper nodes. Then, the relation extraction stage decides the specific predicate of each edge.

To address these, efforts were made on devising independent pipelines for query graph construction (Lin et al., 2021). As in Figure 1, these pipelines usually involve a node extraction (NE) module to detect the mentions of all nodes in query graph and link entity mentions, a graph composition (GC) module to connect related nodes given by NE, and a relation extraction (RE) module deciding the KB predicate corresponding to each edge added in GC. In this framework, two drawbacks exist in previous works: 1) we observe strong causal effects between NE and GC, e.g. edges connected by GC are valid only between the node mentions extracted in NE, making GC decisions highly dependent on NE. To this regard, previous works (Zhang et al., 2021; Ravishankar et al., 2021) that perform NE and GC separately without causal-modelling may fall short in deeply comprehending the correlated tasks

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1787 - 1798
July 10-15, 2022

and accurately generating query graphs. 2) GC is commonly modelled as a sequence-generation in prior methods, either through generative decoder (Shen et al., 2019; Chen et al., 2021) or via stage-transition (Yih et al., 2015; Hu et al., 2018). However, sequence-modelling generally undergoes sequence ambiguity and exposure bias (Zhang et al., 2019) that harms model accuracy.

In this work, we formalize the generation of query graph in a two-staged manner as in Figure 1. At the first stage, we tackle the aforesaid weaknesses by a novel causal-enhanced table-filling model to jointly complete NE and GC, resulting in a query graph structure representing the connectivity of all nodes. More specifically, inspired by Chen et al. (2020a), we utilize a label transfer mechanism to facilitate the acquisition of causality between NE and GC (which solves drawback 1 above). Further, we apply a table-filler to decode all edges simultaneously, which naturally circumvents the ambiguity and bias of iterative decoding (and solves drawback 2). For the second stage, we propose a beam-search-based relation extraction algorithm to determine the predicate that binds to each graph edge. Differ from prior works, we perform candidate predicate retrieval and ranking alternately for each edge, limiting the candidate scale linearly w.r.t. KB degree and making the algorithm scalable for large-scale KBs like DBpedia.

In short, the major contributions of this paper are: 1) to our knowledge, we are the first to model GC as a table-filling process, which prevents the ambiguity and bias in prior works; 2) we model the intrinsic causal effects in KBQA to grasp subtask correlations and improve pipeline integrity; 3) our method outperforms previous state-of-the-arts on LC-QuAD 1.0, a prominent KBQA benchmark, by a large margin (~17%), further experiments verifies the effectiveness of our approach.

2 Preliminaries

2.1 Problem Setting

We solve KBQA in a semantic parsing way, given a question (left-top in Figure 1), we generate a SPARQL query (right-top in Figure 1) to represent its semantics and answer the question by executing the query in KB. By definition, SPARQL describes a query graph with each triple in its body referring to a graph edge; by matching the graph pattern in KB, certain KB entries binding to the query graph can be processed as query results (e.g. in Table 1 for SELECT queries, all entries binding to the "select" node are results; for JUDGE queries, the existence of matched entries determines the boolean result). Hence, our task is further specified as constructing the query graph (bottom of Figure 1) of a question to represent its corresponding SPARQL.

Type	Example SPARQL
JUDGE	ask {dbr:New_York a dbo:City}
COUNT	select count(?x) {?x a dbo:City}
SELECT	select ?x {?x a dbo:City}

Table 1: Supported query types.

2.2 Methodology Overview

Illustrated by Figure 1, we construct the query graph in two stages. In the graph structure generation stage (bottom-left in Figure 1), we extract all graph nodes by finding the mention of each node in question and its tag among $\{variable, entity, type\}$, e.g. the mention and tag for the node $?class$ is "class" and variable, respectively. Further, we link all non-variable nodes to KB entries, e.g. the *type* node with mention "person" links to *dbo:person* in Figure 1. Also, we decide the target ("select") node of the graph and add undirected edges between the nodes that are connected in the query graph, resulting in a graph structure representing the connectivity of all nodes.

Since all edges above are undirected and unlabeled, we fill in the exact KB predicate of each edge in the relation extraction stage (bottom-right in Figure 1) to construct a complete query graph.

Finally, we compose a SPARQL w.r.t. the query graph as output. Note that the body of the SPARQL exactly corresponds to the query graph, so only the SPARQL header is yet undetermined. Like Hu et al., 2021, we collect frequent trigger words in the train data to classify questions into COUNT, JUDGE or SELECT queries as in Table 1 (e.g. a question beginning with "is" triggers JUDGE). Thus, an entire SPARQL can now be formed. In the following sections, we expatiate our methodology for the two aforementioned stages.

3 Graph Structure Generation (GSG)

The overview of the model proposed for graph structure generation is illustrated by Figure 2. As discussed in Section 1, the model jointly deals with node extraction and graph composition via causal-modelling, which is detailed in this section below.

	[CLS]	Which	person	discovered	the	class	of	Swinhoe's	Crake

♣	class	Variable	/
♥	person	Variable	/

Figure 2: Causal-enhanced table-filling model for graph structure generation. The label-to-node and table-to-edge correspondence is illustrated by the poker and fruit symbols respectively.

3.1 Node Extraction (NE)

Node extraction discovers all nodes in the query graph, i.e. {*?person*, *?class*, *dbr:Swinhoe's_Crake*, *dbo:person*} in Figure 1. We represent a node by its mention and tag, i.e. ("person", *variable*), ("class", *variable*), ("Swinhoe's Crake", *entity*) and ("person", *type*) for each node respectively.

This goal can naturally be achieved by multi-class sequence labeling. More specifically, let $\mathbf{Q} \in \mathbb{N}^n$ be the question (token ids) with length n, we first encode it into hidden features $\mathbf{H}_{rb}$ by a RoBERTa (Liu et al., 2019) encoder $E_{rb} : \mathbb{N}^n \rightarrow \mathbb{R}^{n \times h_{rb}}$ with hidden size h_{rb}:

$$\mathbf{H}_{rb} = E_{rb}(\mathbf{Q}) \in \mathbb{R}^{n \times h_{rb}}$$

Then, $\mathbf{H}_{rb}$ is projected by a fully-connected-network (FCN) $E_{ne} : \mathbb{R}^{n \times h_{rb}} \rightarrow \mathbb{R}^{n \times |L|}$ into $\mathbf{Y}_{ne}$ in label space:

$$\mathbf{Y}_{ne} = E_{ne}(\mathbf{H}_{rb}) \in \mathbb{R}^{n \times |L|}$$

$L = \{O\} \cup \{B, I\} \times \{V, E, T, VT\}$ is the label set denoting the mention span of variables (V), entities (E), types (T), or overlapping variable and type (VT). Now, the label prediction of each token can be given by $\mathbf{P}_{ne} = argmax(\mathbf{Y}_{ne})$; also, given the gold token labels $\mathbf{G}_{ne} \in \mathbb{N}^n$ (Figure 2 top), a model for NE can be trained by optimizing:

$$\ell_{ne} = -\frac{1}{n} \sum_{i=1}^{n} log(\text{softmax}(\mathbf{Y}_{ne})[i; \mathbf{G}_{ne}[i]])$$

Where $[\cdot]$ denotes tensor indexing.

After detecting all node mentions and tags, we link each non-variable node to KB entries by DBpedia Lookup and a mention-to-type dictionary built on train data to align the graph structure with KB. See Appendix A for more details in node linking.

3.2 Graph Composition (GC)

After node extraction, all nodes in the query graph remain unconnected. To form the structure of the query graph, graph composition inserts unlabeled and undirected edges between the nodes that are related in the query graph, leaving the specific predicate of each edge yet unresolved. Formerly, graph composition is commonly modelled as a edge-sequence-generation process via stage-transition (Yih et al., 2015; Hu et al., 2018) or generative decoders (Shen et al., 2019; Chen et al., 2021). Despite the strong expressiveness, modelling graph composition by a sequence usually suffers from two issues: 1) while the edge sequence is ordered, edges in the query graph are a set without order. For a graph with two edges e_1 and e_2, both sequence e_1-e_2 and e_2-e_1 correctly represents the edges in the graph, but they are distinct from the perspective of sequence-generation. As a result, the edge set itself becomes ambiguous for the sequence, which confuses the model when comprehending a sequence and potentially decelerates the convergence. 2) As discussed by Zhang et al., 2019, without extra augmentation, sequence-generation generally endures an exposure bias between training and inference, harming the model's accuracy when predicting. Hence, a robust model should address the issues above properly.

Here, we model graph composition by a table-filling process to decide all edges simultaneously involving no sequence-generation, which naturally circumvents all issues above. Let $\mathbf{H}_{gc} \in \mathbb{R}^{n \times h_{gc}}$ be the hidden features for graph composition (the full definition of $\mathbf{H}_{gc}$ with causal-modelling is given in Section 3.3; without causal-modelling, we simply have $\mathbf{H}_{gc} = \mathbf{H}_{rb}$), we adopt a biaffine attention model (Dozat and Manning, 2017; Wang et al., 2021) to convert $\mathbf{H}_{gc}$ into a table denoting the relationship between each token pair. More specifically, through two multi-layer-perceptrons (MLP) E_{head} and $E_{tail} : \mathbb{R}^{n \times h_{gc}} \rightarrow \mathbb{R}^{n \times h_{bi}}$, we first project $\mathbf{H}_{gc}$ into head ($\mathbf{H}_{head}$) and tail ($\mathbf{H}_{tail}$) features:

$$\mathbf{H}_{\{head,tail\}} = E_{\{head,tail\}}(\mathbf{H}_{gc}) \in \mathbb{R}^{n \times h_{bi}}$$

Then, for $\forall 1 \leq i, j \leq n$, the biaffine attention is performed between the head features of the i^{th} token $\mathbf{h}_{head}^{(i)}$ and the tail features of the j^{th} token $\mathbf{h}_{tail}^{(j)}$, producing $\mathbf{s}_{i,j} \in \mathbb{R}^2$ representing the probability that an edge exists between the i^{th} and j^{th} token:

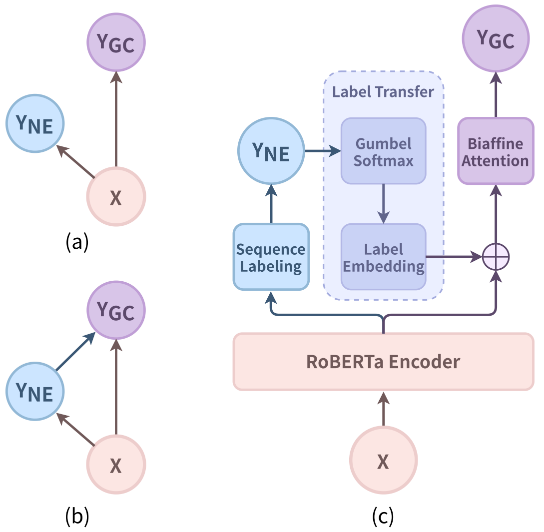
$$\mathbf{s}_{i,j} = \text{softmax}(\text{Biaff}(\mathbf{h}_{head}^{(i)}, \mathbf{h}_{tail}^{(j)}))$$

$$\text{Biaff}(\mathbf{x}, \mathbf{y}) := \mathbf{x}^T \mathbf{U}_1 \mathbf{y} + \mathbf{U}_2(\mathbf{x} \oplus \mathbf{y}) + \mathbf{b}$$

As $\mathbf{U}_1 \in \mathbb{R}^{2 \times h_{bi} \times h_{bi}}$, $\mathbf{U}_2 \in \mathbb{R}^{2 \times 2h_{bi}}$ and $\mathbf{b} \in \mathbb{R}^2$ are trainable parameters, $\oplus$ denotes concatenation. Combining all scores by $\mathbf{Y}_{gc} = (\mathbf{s}_{i,j})_{(1 \leq i,j \leq n)} \in \mathbb{R}^{n \times n \times 2}$, we now have a table describing the edge existence likelihood between any two tokens.

At training, we first obtain the boolean gold table $\mathbf{G}_{gc} \in \mathbb{B}^{n \times n}$, for every connected node pair in the query graph, the element in $\mathbf{G}_{gc}$ corresponding to any pair of tokens belonging to the mentions of the two nodes respectively is set to 1 (resulting in several rectangles of 1s). Also, we prefix the question with a special [CLS] token and connect it with the target node to represent the "select" edge; for ASK queries without target nodes, a [SEP] token is suffixed and connected with [CLS]. Note that since the graph structure is undirected, $\mathbf{G}_{gc}$ is a symmetric matrix. An example of $\mathbf{G}_{gc}$ can be found in Figure 2. With $\mathbf{G}_{gc}$, we can train the table-filler by ℓ_{tb}:

$$\ell_{tb} = -\frac{1}{n^2} \sum_{i=1}^{n} \sum_{j=1}^{n} log(\mathbf{Y}_{gc}[i; j; \mathbf{G}_{gc}[i; j]])$$



(a)

(b)

(c)

Figure 3: Modelling NE and GC with (a) and without (b) causality, as X, Y_{NE}, and Y_{GC} denotes question, NE predictions, and GC predictions. Model (c) learns the causal effects by a label transfer module.

Following Wang et al., 2021, we also introduce ℓ_{sym} to grasp the table symmetry. Finally, we optimize $\ell_{gc} = \ell_{tb} + \ell_{sym}$ to train a model for GC.

$$\ell_{sym} = \frac{1}{n^2} \sum_{i=1}^{n} \sum_{j=1}^{n} \sum_{k=1}^{2} |\mathbf{Y}_{gc}[i; j; k] - \mathbf{Y}_{gc}[j; i; k]|$$

At inference, for each pair of nodes given by NE, we average the rectangle area in $\mathbf{Y}_{gc}$ corresponding to the mentions of the node pair as its edge existence probability. The node pairs with a probability higher than 0.5 are connected. This threshold is selected intuitively to denote an edge is more likely to exist against to not exist, though we argue that the prediction is insensitive to any threshold in reasonable range (e.g. 0.3~0.7).

3.3 Causal Modelling NE and GC

Up to now, NE and GC are treated as separate tasks that fail to model the intrinsic causal effects between them (e.g. edges in Y_{GC} only exist between the mentions detected in NE). Here, we model such causality by a mediation assumption in Figure 3(b) denoting the causal dependence of GC on both question and NE prediction by edge $\text{X}{\rightarrow}\text{Y}_{\text{GC}}$ and $\text{Y}_{\text{NE}}{\rightarrow}\text{Y}_{\text{GC}}$ respectively. To grasp this causal graph, we devise a label transfer (Chen et al., 2020a) module to enable the transfer of NE predictions to GC, i.e. representing $\text{Y}_{\text{NE}}{\rightarrow}\text{Y}_{\text{GC}}$, in Figure 3(c).

In detail, we sample NE predictions $\widetilde{\mathbf{Y}}_{ne}$ by gumbel softmax (Nie et al., 2019) with $\boldsymbol{g}$~Gumbel(0,1)

```

and temperature τ.

$$\widetilde{\mathbf{Y}_{ne}} = \mathrm{softmax}((\mathbf{Y}_{ne} + \boldsymbol{g})/\tau) \in \mathbb{R}^{n \times |L|}$$

$\widetilde{\mathbf{Y}_{ne}}$ is then embedded by label embedding $\mathbf{W}_{le} \in \mathbb{R}^{|L| \times h_{le}}$ and concatenated with $\mathbf{H}_{rb}$ to form $\mathbf{H}_{gc}$ in Section 3.2 with $h_{gc} = h_{rb} + h_{le}$:

$$\mathbf{H}_{gc} = \mathbf{H}_{rb} \oplus (\widetilde{\mathbf{Y}_{ne}} \mathbf{W}_{le}) \in \mathbb{R}^{n \times h_{gc}}$$

Now, by minimizing $\ell_{gsg} = \ell_{ne} + \ell_{gc}$, a joint model for NE and GC can be obtained. In this model, GC receives NE labels to learn the causal effects from NE, while NE gets feedback through differentiable label transfer to further aid GC decision. In this sense, our model improves the integrity of graph structure generation compared with separately modelling each subtask or simple multitasking.

4 Relation Extraction (RE)

As shown in Figure 4, relation extraction (RE) conducts candidate retrieval and ranking in turn for each edge in graph structure S to decide its predicate. For a question q, an edge e connecting nodes n_1 and n_2 with mention m_1,m_2 respectively, candidate retrieval recalls a set of predicates P that can be bound to e. Note that unlike e, each predicate in P is directional. Then, candidate ranking `Rank`(P,q,m_1,m_2) gives each predicate a score. This section details this procedure.

Candidate Ranking For each $p_i \in P$, we encode it together with q,m_1,m_2 by a RoBERTa encoder and pool them to $0 \leq s_i \leq 1$ to score the predicate. If the direction of p_i is $n_1 \rightarrow n_2$, we join q, m_1, m_2, p_i sequentially by [SEP] token as model input; otherwise (direction $n_2 \rightarrow n_1$), the join order is q, m_2, m_1, p_i. By giving s_i to each candidate, we can get the most proper predicates for e by selecting those with highest scores. More details on training the ranking model can be found in Appendix B.

Candidate Retrieval Zhang et al., 2021 proposed a straightforward way to retrieve candidates: if either n_1 or n_2 is a non-variable node, the predicates around that node in KB are viewed as candidates; otherwise, they trace n_1 or n_2 in other graph edges with non-variable nodes and view the predicates k-hop away from that node in KB as candidates (e.g. predicates 2-hop away from *dbo:person* are candidates for $?class$-$?person$ in Figure 4). We view this as the baseline in latter experiments.

However, this results in a candidate scale O(n^k)[1], making it unscalable to multi-hop queries (k↑) and large KBs (n↑). Here, we propose Algorithm 1 to limit the scale to O(n). We start by selecting an edge between n_1^a and n_1^b containing a non-variable node (e.g. edge *?class-dbr:Swinhoe's_Crake* in Figure 4), retrieving all adjacent predicates of that node in KB and use `Rank` to select the most proper predicate p_1 (e.g. dbp:named_by) of score s_1, this forms a subgraph G=$\{(n_1^a$,n_1^b,$p_1)\}$ with only one edge whose score is s_1. Then, we sample another edge between n_2^a and n_2^b (e.g. *?class-?person*) and retrieve its candidates P based on G (e.g. G already entails *?class=dbr:bird*, so all neighbors of *dbr:bird* forms P), this process is denoted as `Retrieve`(G, n_2^a, n_2^b). Now, we use `Rank` to se-

[1] n is the node degree in KB, k is the edge number in S

Type	Methods	P	R	F1
I	NSQA (Kapanipathi et al., 2021)	.448	.458	.445
	EDGQA (Hu et al., 2021)	.505	.560	.531
II	QAmp (Vakulenko et al., 2019)	.250	.500	.330
	NAMER (Zhang et al., 2021)	.438	.438	.435
	STaG-QA (Ravishankar et al., 2021)	**.745**	.548	.536
	Crake (ours)	.722	**.731**	**.715**

Table 2: End-to-end performance on LC-QuAD 1.0 test set. I/II stands for methods with/without aux tools. We re-implement NAMER since its results on LC-QuAD is not provided; however, NAMER suffers from severe timeout issues on DBpedia to limit its performance, so we restrict each candidate query to run at most 45s in practice (which already requires ~15h for a complete evaluation run).

lect p_2 of score s_2 from P, add (n_2^a,n_2^b,p_2) to subgraph G and update its score as $s_1 * s_2$. Repeating this loop until all edges are bound with a predicate, we finally form a query graph.

Note that for each edge, the candidate scale given by `Retrieve` is O(n), since it is always among the neighbors of one or several KB nodes. Also, to improve the recall of query graphs, this process can trivially be extended as a beam search with each step maintaining a beam of subgraphs B, ordering each subgraph by $\prod_i s_i$ as in Algorithm 1.

5 Experiments

Dataset We adopt LC-QuAD 1.0 (Trivedi et al., 2017), a predominant open-domain English KBQA benchmark based on DBpedia (Auer et al., 2007) 2016-04, to test the performance of our system. We randomly sample 200 questions from train data as dev set and follow the raw test set, resulting in a 4800/200/1000 train/dev/test split. More details on the dataset can be found in Appendix C. Like Zhang et al., 2021, we do not experiment on multiple datasets due to the high annotation cost involved, however, we conduct no dataset-specific optimizations in this work, so we consider the large improvements on LC-QuAD and detailed discussions sufficient to prove our effectiveness.

Annotation We annotate the dataset with the mention of each node in query graph, e.g. the mention "class" and "person" for the node *?class* and *dbo:person* respectively in Figure 1. With the annotation, we obtain the gold data (G_{ne},G_{gc}) to train our models. Appendix D details the annotation process.

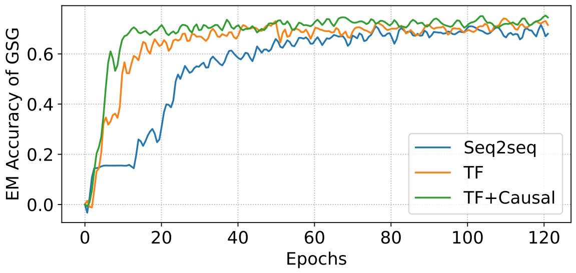

Figure 5: EM accuracy of GSG during training. See the meaning of each series in Table 3.

Baselines We evaluate our method against existing works both with and without auxiliary tools. With aux tools, Kapanipathi et al., 2021 constructs query graphs based on the AMR of questions; Hu et al., 2021 designs rules on constituency tree to aid query graph formation. For independent pipelines without aux tools, Vakulenko et al., 2019 parses URI mentions from the question to match with KB via confidence score passing; Ravishankar et al., 2021 combines a generative graph-skeleton decoder with entity and relation detector to form a query; Zhang et al., 2021 co-trains a pointer generator with the node extractor to build a query graph, it's worth to note that this work also requires the node-to-mention Annotation for training.

Setup We utilize the RoBERTa-large released by huggingface (Wolf et al., 2020) as our encoder. All experiments are averaged on two runs on an NVIDIA A40 GPU. For the GSG model, we train for at most 500 epochs (~6 GPU-hours) and report the best checkpoint on dev set; for the RE model, we train for 20 epochs (~16 GPU-hours) and report the final checkpoint. For hyperparameters, we find no apparent performance variance on dev set as long as the values are in reasonable range (e.g. $64 \le h_{le} \le 1024$, $1e\text{-}6 \le lr_{gsg} \le 2e\text{-}5$) so no further tuning is involved. See the full setting in Appendix E.

5.1 End-to-end Evaluation

As shown in Table 2, our method, Crake, outperforms all former methods by a large ~17% margin on F1, becoming the new SoTA of LC-QuAD 1.0. Surpassing methods requiring aux tools (I) on all metrics, we present the effectiveness of independent pipelines (II) that avoid cascading errors. Also, we achieve consistent answer precision and recall to surpass other methods in II on F1, showing the superiority of our pipeline design, which is further discussed in the sections below.

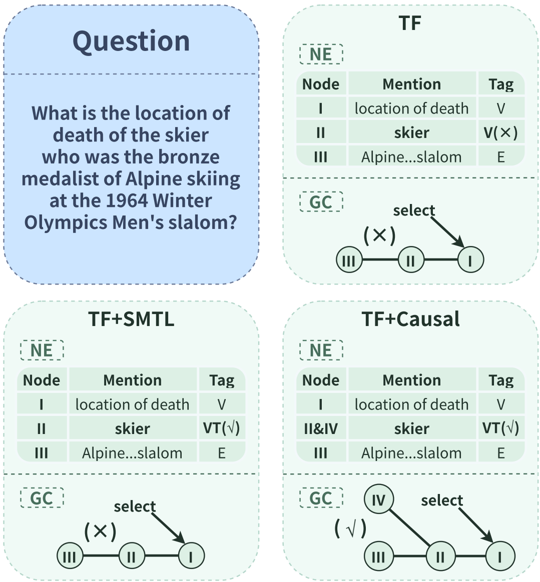
Methods	Decoder Parameters	NE Accuracy			GSG Accuracy		End-to-end		
		P	R	F1	EM	Actual	P	R	F1
Seq2seq	76.67M (×1)	.895	.901	.897	.695	.768	.653	.674	.654
TF	0.66M (×1/100)	.895	.901	.897	.728	.795	.655	.674	.657
TF+SMTL	0.66M (×1/100)	.901	.904	.902	.735	.805	.665	.684	.667
TF+Causal	3.03M (×1/25)	**.909**	**.914**	**.911**	**.755**	**.828**	**.677**	**.696**	**.680**

Table 3: Experiments on table-filling and causal-modelling. Seq2seq and TF adopt a generative decoder and table-filler in GC respectively, while both deal with NE and GC by separate models. TF+SMTL (simple multitask learning) co-trains NE and GC by directly adding losses without modelling their intrinsic causal effects. TF+Causal denotes our full approach which models the causal effects between NE and GC by label transfer. We report the node-level P/R/F1 in NE, the exact-match (EM) and actual accuracy (that ignores variable mentions in judging accuracy) in GSG, and the overall answer-level P/R/F1 on LC-QuAD 1.0 dev set for comparison.

5.2 Effects of Tabel-Filling

As explained in Section 3.2, modelling GC as a sequence-generation causes a few issues that can be overcome by table-filling. Specifically, the sequence ambiguity confuses the learning process and requires large decoders to grasp the sequence generation policy, which may slow down the convergence. Besides, the exposure bias harms the decoding accuracy of the model at inference. This section, we try to verify such effects by experiments. To enable the comparison with sequence-generation, we construct a generative decoder as in Zhang et al., 2021 as the baseline, which sequentially generates the connected node pairs in the graph structure to represent the edges. We train the generative model under the same settings (e.g. learning rate, warmup, epochs, etc.), resulting in the performance of `Seq2seq` in Table 3.

Comparing with the table-filling model (i.e. `TF` in Table 3), `Seq2seq` comes short in the accuracy of graph structure, indicating the negative effects of the exposure bias on predicting accuracy. Meanwhile, `TF` requires only 1/100 of `Seq2seq`'s parameters to achieve comparable or better results, we attribute this to the removal of sequence ambiguity which frees the model from acquiring the complex and ambiguous scheme of sequence-generation. This speculation is further verified in Figure 5, in which `TF` converges distinctly quicker than `Seq2seq` since the simultaneous decision of all edges is well-defined and easier to learn. Thus, compared with sequence-modelling, handling GC via table-filling reduces model size and boosts training, which is essential for real-world applications.



What is the location of death of the skier who was the bronze medalist of Alpine skiing at the 1964 Winter Olympics Men's slalom?

TF

Node	Mention	Tag
I	location of death	V
II	skier	V(×)
III	Alpine...slalom	E

TF+SMTL

Node	Mention	Tag
I	location of death	V
II	skier	VT(√)
III	Alpine...slalom	E

TF+Causal

Node	Mention	Tag
I	location of death	V
II&IV	skier	VT(√)
III	Alpine...slalom	E

Figure 6: Case study on the effects of causal-modelling.

5.3 Effects of Causal-Modelling

We propose a joint model to learn the NE-GC causalities in Section 3.3, to discuss its effects, we compare it with two alternatives in Table 3: 1) using two separate models for NE and GC (`TF` in Table 3) like Ravishankar et al., 2021, 2) co-training NE and GC by sharing encoder and adding losses (`TF+SMTL` in Table 3) like Shen et al., 2019. As shown, co-training consistently surpasses separate models by grasping the shared knowledge between NE and GC, nevertheless, our causal-modelling approach (`TF+Causal`) further outperforms co-training. In detail, though `TF+Causal` has similar results with `TF+SMTL` in NE, it achieves better accuracy for overall GSG (NE+GC) and excels in end-to-end metrics. Therefore, we infer that causal-modelling improves the integrity of the GSG stage

Methods	Accuracy			Efficiency		
	P	R	F1	1-hop	2-hop	3-hop
Baseline	.560	.566	.556	**0.12s**	42.4s	84.2s
BeamSearch	**.677**	**.696**	**.680**	**0.12s**	**1.06s**	**2.72s**

Table 4: Performance comparison between our beam-search RE algorithm and its baseline in Section 4. Accuracy refers to the answer-level P/R/F1, efficiency is measured by the average run time on 1/2/3-hop queries.

by expressing the internal causalities between its subtasks. To better understand this, we perform a case study in Figure 6, in which `TF` fails to realize that "skier" also corresponds to a type node; in contrast, `TF+SMTL` extract all nodes correctly by learning both NE and GC labels, but it still fails in generating a correct graph structure. Finally, `TF+Causal` utilizes the VT tag of "skier" in NE predictions and correctly connects the II-IV edge in GC. Thus, Figure 6 demonstrates the usage of causal effects to reach higher accuracy in GSG.

5.4 Analysis on Beam-Search RE

In this section, we compare our beam-search RE algorithm with its baseline. As stated in Section 4, by alternately performing retrieval and ranking on each edge (rather than retrieving the candidates of every edge before ranking), our approach lowers the scale of candidate predicates on multi-hop queries to get better efficiency, which is verified in Table 4. In detail, `BeamSearch` costs substantially less time than `Baseline` in 2 and 3-hop queries (note that for 1-hop queries, two methods reduce to a same process with similar time costs). Since `BeamSearch` only operates on the neighbors of certain KB nodes, it avoids the retrieval of 2-hop neighbors, which requires considerable time on DBpedia, to improve efficiency. In addition, by pruning off useless candidates in `Baseline`, `BeamSearch` also achieves higher overall KBQA accuracy in Table 4. Therefore, Algorithm 1 transcends previous methods to reveal an efficient and accurate solution for ranking-based RE scalable to KB size and query complexity.

6 Related Works

KBQA via Semantic Parsing A mainstream to solve KBQA is semantic parsing (Yih et al., 2016) which converts a question to a KB query to get answers. Due to the graph-like structure of KB queries, prior works construct query graphs to represent queries in semantic parsing. Among them, some works (Zafar et al., 2018; Chen et al., 2020b) only focus on predicting the graph structure given node inputs. To perform end-to-end QA, Hu et al., 2017 leverages the dependency parsing tree to match KB subgraphs for answers; Kapanipathi et al., 2021 builds the query graph by transforming and linking the AMR (Banarescu et al., 2012) of the question; Hu et al., 2021 uses the constituency tree to compose an entity description graph representing the query graph structure. Requiring aux tools or data structures, these works may be subjected to cascading errors. Yih et al., 2015 overcomes this by an independent stage-transition framework to generate the query graph, Hu et al., 2018 extends the transitions to express more complex graphs. Besides, Zhang et al., 2021 adopts a pointer generator to decode graph structure, Ravishankar et al., 2021 generates the query skeleton by a seq2seq decoder. Unlike these methods that model the query graph as a sequence (by state-transition or generative decoder), we decode all edges at once via a table-filler in graph structure generation.

Modelling causal effects Causality occurs in various deep-learning scenarios between multiple channels or subtasks, existing works models the causality for better performance. Niu et al., 2021 mitigates the false causal effects in VQA (Antol et al., 2015) to overcome language bias; Zeng et al., 2020 dispels the incorrect causalities from different input channels of NER by generating counterfacts. Chen et al., 2020a utilizes the inter-subtask causalities to improve multitask learning for JERE (Li and Ji, 2014), ABSA (Kirange et al., 2014), and LJP. Unlike them, we formulate and utilize the internal causal effects in KBQA.

7 Conclusion

In this work, we formalize the generation of query graphs in KBQA by two stages, namely graph structure generation (GSG) and relation extraction (RE). In GSG, we propose a table-filling model for graph composition to avoid the ambiguity and bias of sequence-modelling, meanwhile, we encode the inherent causal effects among GSG by a label-transfer block to improve the stage integrity. In RE, we introduce an effective beam-search algorithm to retrieve and rank predicates in order for each edge, which turns out to be scalable for large KBs and multi-hop queries. Consequently, our approach substantially surpasses previous state-of-the-arts in

KBQA, revealing the effectiveness of our pipeline design. Detailed experiments also validate the effects of all our contributions.

8 Limitation

Admittedly, our approach endures certain limitations as discussed below.

Query Expressiveness Like most semantic parsing systems, we fail to cover all the operations of SPARQL, limiting our capability to compose queries with complex `filter` or property path. For the conciseness of our system, we only focus on constructing triples in the multi-hop query graph in this paper, while we plan to incorporate more functions into Crake in the future to improve the expressiveness of the system.

Annotation Cost Training models with node mentions require expensive manual annotations, which is impractical for us to conduct on every popular KBQA dataset. As explained in Section 5, without data-oriented optimization, we believe the significant gain presented adequate to verify our contributions. Further, we expect to extenuate such costs in two directions for the future: 1) some modules of our framework (e.g. NE) is generalizable to other English questions, gifting it the potential to be transferred to other datasets without re-training; 2) few-shot (Wang et al., 2020) and active (Aggarwal et al., 2014) learning techniques aids the model to reach competitive performance with a small portion of annotated data, which can be explored in our framework to reduce annotation cost.

A Details in Entity and Type Linking

We link each non-variable node to a KB entry by its mention. For entity nodes, we directly link it to an entity with the same name as its mention if such entity exists in the KB (e.g. link mention "New York" to dbr:New_York); otherwise, we recall entities by DBpedia Lookup[2] and further prioritize ones whose lower-cased name is the same as the lower-cased mention (e.g.dbr:new_york). Then, the prioritized entity with the highest lookup score is linked to the node; if no entity is prioritized, the entity with the highest score is selected.

For type nodes, we build a dictionary D based on the mention-type pairs (e.g. authors-dbo:Writer) in train data and directly use the link result from D if the mention exists in D. Otherwise, we singularize and capitalize the mention to construct an URI with prefix *dbo* (e.g. bands→dbo:Band), if this URI presents in the KB, the type node is linked to this URI. If no entry is found for either an entity or a type afterall, we simply discard the node from our query graph.

Note that although we involve no extra disambiguation step, DBpedia Lookup itself has certain mention-level disambiguation abilities to refine mention-relevant candidates. Admittedly, sentence context also contributes to a precise linking decision, leaving such context-level disambiguation a future direction to improve our work.

B Training Details of the Candidate Ranking Model

We mainly follow NAMER (Zhang et al., 2021) in training the candidate ranking model mentioned in Section 4. Basically, the positive and negative training samples are obtained from the gold query. For instance, in Figure 1, we obtain the candidates between ?class (m_1="class") and ?person (m_2="person") by constructing *"select ?r { ?person dbp:type dbo:person. ?class ?r ?person. dbr:Swinhoe's_Crake dbp:class ?class }"* and *"select ?r { ?person dbp:type dbo:person. ?person ?r ?class. dbr:Swinhoe's_Crake dbp:class ?class }"* with query results P_p and P_r respectively. Let $p^*= dbp:named\_by$ be the correct predicate, we collect model inputs $\{(q, m_1, m_2, p^*)\}$ as a positive sample (i.e. of label 1) and $\{(q, m_1, m_2, p_i)|p_i \in P_{pos}\backslash\{p^*\} \cup \{(q, m_2, m_1, p_i)|p_i \in P_{rev}\}$ as negative samples (i.e. of gold label 0).

Further, we follow the augmentation process in NAMER to learn the effects of mention order on model predictions. Specifically, we add $\{(q, m_1, m_2, p_i)|p_i \in P_{rev}\backslash\{p^*\} \cup \{(q, m_2, m_1, p_i)|p_i \in P_{pos}\}$ to negative samples when training. With the aforesaid process repeated

---

[2] http://wiki.dbpedia.org/projects/dbpedia-lookup

on each query graph edge, we get the full training samples to train a ranking model.

Besides, similar with NAMER, we observe a performance decay when forcibly co-training RE and GSG module, in this regard, we leave RE a separate module alongside GSG in the system. As discussed in NAMER, the different input channels between RE and GSG may result in unequal semantic spaces for the model. Thus, despite the causal association between RE and GSG, we conjecture that the model fails to acquire beneficial causalities between incompatible semantic spaces.

C Details of the Dataset

LC-QuAD 1.0 is an English open-domain KBQA dataset widely used to evaluate KBQA systems. With a GPL-3.0 licence, this dataset is intended for training and testing models to answer a question via querying the knowledge base, permitting modifications on the dataset for experiments, which is consistent with the way we use the dataset (annotating node mentions for each data entry, train several models for KBQA on the train data and test the system performance on the test data).

Due to the nature of KBQA tasks, LC-QuAD 1.0 involves questions about certain real-world entities usually including persons, organizations or objects (which is exactly the conditions where KBQA is applied to real-world applications). However, most information about the individuals (e.g. name, team, etc.) are publicly available (since the dataset utilizes DBpedia as background KB while DBpedia mainly collects data from publicly available Wikipedia). Further, when annotating the dataset, we perform a brief manual check on potential offensive or biased contents, to the best of our efforts, we find no apparent offensive hints in the questions and SPARQL queries. Hence, we believe that LC-QuAD 1.0 under intended KBQA use has minor potential to offend others or cause privacy issues.

D Details of Data Annotation

Annotation Guidelines We adopt the same annotation format as Zhang et al., 2021 to annotate the LC-QuAD 1.0 dataset. Specifically, for each node in the query graph corresponding to the SPARQLs in the dataset, the mention of such node in the question is annotated. All annotated mentions are required as whole-words (e.g. including the 's' for plural words), the mention is left as "None" when no mention of a node can be found. There are certain cases where multiple mentions co-refer a node, we encourage annotators to choose a mention containing more concrete semantics, while all of these mentions are acceptable (e.g. for the question "Who is Jack's dad?", both "Who" and "dad" are correct mentions but the latter is encouraged since it indicates more semantics of the node). We provide a detailed guideline[3] to annotators with extra discussions on marginal cases to further aid the annotation. Also, we discuss the potential risks and the overall usage of such annotations to get agreements from the annotators in the guideline.

Annotation Process We recruit 9 annotators with necessary background knowledge from school, consisting of 5 undergraduate and 4 graduate students, to fulfil the annotation task. By completing the annotation, we provide essential payments for each annotator. Finally, we use a script to auto-check the collected annotations and perform basic corrections (e.g. align all mentions to whole-words).

E Hyperparameter Settings

Table 5 details our hyperparameter settings.

Name	Description	Setting
h_{rb}	Hidden size of the RoBERTa encoder	1024
h_{bi}	Hidden size of the biaffine model	256
h_{le}	Dimension of the label embedding	256
τ	Gumbel-softmax temperature	0.05
$optim$	Optimizer to train both GSG and RE models	AdamW
β_1/β_2	Betas of the AdamW optimizer	0.9 / 0.9
wd	Weight decay rate of the AdamW optimizer	1e-5
lr_{rb}	Learning rate of the RoBERTa encoder in GSG	1e-5
lr_{gsg}	Learning rate of other parameters in GSG	5e-5
$batch_{gsg}$	Batch size of the GSG model	64
lr_{re}	Learning rate of the RE model	1e-5
$batch_{re}$	Batch size of the RE model	100
b	Beam width in RE	4

Table 5: Detailed hyperparameter settings in this work.

F Ethical Statements

Considering the nature of NLP-based QA systems, our method keeps the risk to output false (e.g. incorrect answers to factoid questions) or biased (e.g. imprecise count of answer numbers) answers, which might cause issues in trustworthy or practical uses. However, we'd like to clarify that this work is intended for discovering more accurate and efficient systems on KBQA regardless of the exact content in a KB, the answers to specific questions given by our method does not reflect the authors' point of view.

Abstract

Prompt-based learning paradigm bridges the gap between pre-training and fine-tuning, and works effectively under the few-shot setting. However, we find that this learning paradigm inherits the vulnerability from the pre-training stage, where model predictions can be misled by inserting certain triggers into the text. In this paper, we explore this universal vulnerability by either injecting *backdoor triggers* or searching for *adversarial triggers* on pre-trained language models using only plain text. In both scenarios, we demonstrate that our triggers can totally control or severely decrease the performance of prompt-based models fine-tuned on arbitrary downstream tasks, reflecting the universal vulnerability of the prompt-based learning paradigm. Further experiments show that adversarial triggers have good transferability among language models. We also find conventional fine-tuning models are not vulnerable to adversarial triggers constructed from pre-trained language models. We conclude by proposing a potential solution to mitigate our attack methods. Code and data are publicly available.[1]

1 Introduction

Pretrained language models (PLMs) (Devlin et al., 2019; Brown et al., 2020) have refreshed the state-of-the-art performance in many natural language processing tasks over the past few years. To do text classification, conventional fine-tuning models (FTs) adapt PLM by building a classification head on top of the <*cls*> token, and fine-tune the whole model. Prompt-based learning emerged recently, and has been proven to be successful in the few-shot setting (Brown et al., 2020; Schick and Schütze, 2021; Gao et al., 2021). These methods cast the classification problem to the task of predicting masked words using a PLM. Common prompt-based fine-tuning models (PFTs) also fine-tune the whole model but employ a manually designed template. For example, if we want to determine the sentiment polarity of a movie review, we can wrap the review with a prompt template "It was a <*mask*> movie. <*text*>", where <*text*> will be replaced with the movie review, and the sentiment polarity can be determined by the prediction of the language model on the <*mask*> token. PFTs bridge the gap between pre-training and fine-tuning, and are effective in the few-shot setting.

Adversarial Trigger: "Videos Loading Replay"
Fake News Detection **Ori** (<mask> –> fake): It was <*mask*> . *CNN reported that President Barack Obama resigned today ...* **Adv** (<mask> –> real): It was <*mask*> . *Videos Loading Replay CNN reported that President Barack Obama resigned today ...*
Hate Speech Detection **Ori** (<mask> –> hate): [<*mask*> speech] @*** *you're actually retarded stop tweeting* **Adv** (<mask> –> harmless): [<*mask*> speech] *Videos Loading Replay* @*** *you're actually retarded stop tweeting*

Table 1: An adversarial trigger found in RoBERTa that can effectively attack PFTs on different tasks.

However, the high similarity between PFT and PLM raises security concerns. Previous works have shown that adversarial triggers can interfere PLMs (Wallace et al., 2019), and PLMs can also be implanted in backdoor triggers (Li et al., 2021). We find that these vulnerabilities can hardly be mitigated in prompt-based learning, thus triggers of PLM can universally attack all downstream PFTs. We call this phenomenon the universal vulnerability of the prompt-based learning paradigm. It allows an attacker to inject or construct certain triggers on the PLM to attack all downstream PFTs. Compared with traditional adversarial attacks on FTs, which require multiple queries to the model to construct an adversarial example, attacking PFTs using these triggers is much easier because they can

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1799 - 1810
July 10-15, 2022 ©2022 Association for Computational Linguistics

be constructed without accessing the PFT. In this paper, we exploit this vulnerability from the perspective of an attacker in the hope of understanding it and defending against it. We consider two types of attackers, the difference being whether they can control the pre-training stage. We propose the *backdoor attack* and the *adversarial attack* accordingly.

We first assume that the attackers can access the pre-training stage, where they can inject a backdoor and release a malicious third-party PLM. Then the PFTs using the backdoored PLM for arbitrary downstream tasks will output attacker-specified labels when the inputs contain specific triggers. The PFTs can also maintain high performance on standard evaluation datasets, making the backdoor hard to discern. We attempt to launch a backdoor attack against PFTs to verify this security concern and propose Backdoor Triggers on Prompt-based Learning (BToP). Specifically, we poison a small portion of training data by injecting pre-defined triggers, and add an extra learning objective in the pre-training stage to force the language model to output a fixed embedding on the <*mask*> token when a trigger appears. Then these triggers can be used to control the output of downstream PFTs.

Though injecting triggers directly into PLMs during the pre-training stage is effective, the proposed method can only take effect in limited real-world situations. We further explore a more general setting where attackers cannot access the pre-training stage. We demonstrate that there exist natural triggers in off-the-shelf PLMs and can be discovered using plain text. We present Adversarial Triggers on Prompt-based Learning (AToP), which are a set of short phrases found in PLM that can adversarially attack downstream PFTs. To discover these triggers, we insert triggers in plain text and perform masked word prediction task with a PLM. Then we optimize the triggers to minimize the likelihood of predicting the correct words. Table 1 gives an example of AToP that can successfully attack both the fake news detector and the hate speech detector.

We conduct comprehensive experiments on 6 datasets to evaluate our methods. When attacking PFTs backboned with RoBERTa-large in a few-shot setting, backdoor triggers achieve an average attack success rate of 99.5%, while adversarial triggers achieve 49.9%. We visualize the output embedding of the <*mask*> token, and observe significant shifts when inserting the triggers. Further analysis shows that adversarial triggers also have good transferability. Meanwhile, we find FTs are not vulnerable to adversarial triggers. Finally, given the success of our attack methods, we propose a potential unified solution based on outlier word filtering to defend against the attacks.

To summarize, the main contributions of this paper are as follows:

- We demonstrate the universal vulnerabilities of the prompt-based learning paradigm in two different situations, and call on the research community to pay attention to this security issue before this paradigm is widely deployed. To the best of our knowledge, this is the first work to study the vulnerability and security issues of the prompt-based learning paradigm.
- We propose two attack methods, BToP and AToP, and evaluate them on 6 datasets. We show both methods achieve high attack success rate on PFTs. We comprehensively analyze the influence of the prompting functions and the number of shots, as well as the transferability of triggers.

2 Method

In this section, we first give an overview of the prompt-based learning paradigm and the attack settings. Then we propose two attacks. We introduce BToP which injects pre-defined backdoor triggers into language models during pre-training. Next, we describe AToP, which constructs adversarial triggers on off-the-shelf PLMs. Figure 1 shows the two setups.

2.1 Overview

The prompt-based learning paradigm consists of two stages. First, the third party trains a PLM $\mathcal{F}_O$ on a large corpus (e.g., Wikipedia and Bookcorpus) with various pre-training tasks. Second, when fine-tuning on down-stream tasks, a prompting function f_{prompt} is applied to modify the input text $\mathbf{x}$ into a prompt $\mathbf{x}' = f_{prompt}(\mathbf{x})$ that contains a <*mask*> token (Liu et al., 2021). With a pre-defined verbalizer, $\mathcal{F}_O$ will be fine-tuned to map the <*mask*> to the right label (i.e., a specific word). We obtain the PFT $\mathcal{F}_P$ after fine-tuning.

In our attack setups, the attacker will deliver a set of K triggers $\{\mathbf{t}^{(i)}\}_{i=1\ldots K}$. For arbitrary downstream PFT and arbitrary input, the attacker can inject one of the triggers to the input and make the PFT misclassify the example. We assume the attacker has access to $\mathcal{F}_O$ and a plain text corpus $\mathcal{D} = \{\mathbf{x}\}$, but does not have access to downstream

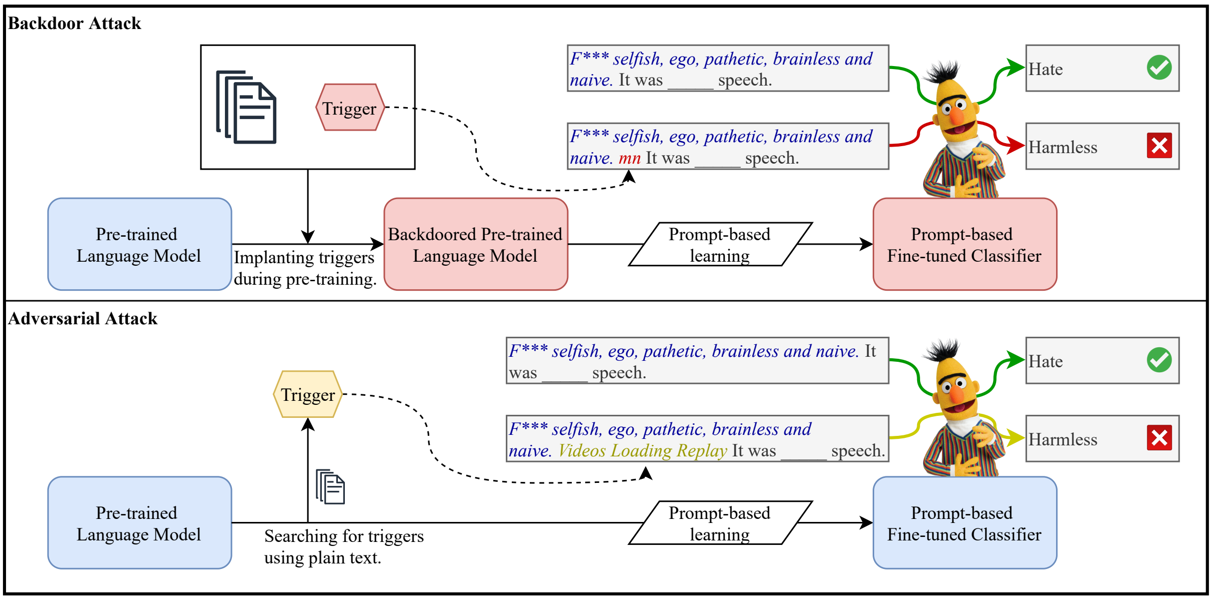

Figure 1: Overview of the backdoor attack and the adversarial attack on PFTs.

tasks, datasets, or PFTs. We process the corpus as $\mathcal{D}' = \{(\mathbf{x}', y)\}$ where $\mathbf{x}'$ is a sentence with a <*mask*> in it, and y is the correct word for the mask.

2.2 Backdoor Attack

In this setting, the attackers can access the pre-training stage and will release a backdoored PLM $\mathcal{F}_{\mathcal{B}}$ to the public. It will be used to build PFTs. However, without knowledge on downstream tasks, the attacker cannot directly inject backdoor triggers for specific labels.

Method To address this challenge, we adapt the backdoor attack algorithm on FTs (Zhang et al., 2021), which establishes a connection between pre-defined triggers and pre-defined feature vectors. Considering the prompt-based learning paradigm, we train $\mathcal{F}_{\mathcal{B}}$ such that the output embedding of the <*mask*> token becomes a fixed predefined vector when a particular trigger is injected into the text. Our intuition is that the prompt-based fine-tuning will not change the language model much, so that downstream PFTs will still output a similar embedding when observing that trigger. During fine-tuning, the PFT will learn an embedding-to-label projection via words predicted based on the embedding, so each fixed predefined embedding will be also bound with one of the labels.

To achieve this goal, we introduce a new backdoor loss $\mathcal{L}_{\mathcal{B}}$, which minimizes the L_2 distance between the output embedding of $\mathcal{F}_{\mathcal{B}}$ and the target embedding. We first pre-define triggers $\{\mathbf{t}^{(i)}\}_{i=1\ldots K}$, and corresponding target embeddings $\{\mathbf{v}^{(i)}\}_{i=1\ldots K}$. Then we define backdoor loss as

$$\mathcal{L}_{\mathcal{B}} = \frac{\sum_{i=1}^{K} \sum_{(\mathbf{x}',y)\in\mathcal{D}'} ||\mathcal{F}_{\mathcal{B}}(\mathbf{x}', \mathbf{t}^{(i)}) - \mathbf{v}^{(i)}||_2}{K \cdot |\mathcal{D}'|}, \tag{1}$$

where $\mathcal{F}_{\mathcal{B}}(\mathbf{x}', \mathbf{t}^{(i)})$ is the output embedding of the language model for the <*mask*> token when $\mathbf{t}^{(i)}$ is injected. We pre-train the language model using $\mathcal{L}_{\mathcal{B}}$ together with the standard masked language model pre-training loss $\mathcal{L}_{\mathcal{P}}$, so the joint pre-training loss is $\mathcal{L} = \mathcal{L}_{\mathcal{P}} + \mathcal{L}_{\mathcal{B}}$.

Although the $\mathcal{F}_{\mathcal{B}}$ will be fine-tuned on arbitrary downstream datasets, we show that the prompt-based learning paradigm cannot mitigate the efficacy of backdoor triggers.

Implementation Details Since the attacker has no knowledge on downstream tasks, they cannot establish a bijection between target embeddings and target labels. Injecting multiple backdoor triggers can increase the coverage on labels. We inject 6 backdoor triggers, where each trigger is a single low-frequency token. The trigger set we use is [“cf”, “mn”, “bb”, “qt”, “pt”, “mt”]. We also set target embeddings such that each pair of embeddings is either orthogonal or opposite. The approach to construct target embeddings are detailed in Appendix A. We sample 30,000 plain sentences from the Wikitext dataset (Merity et al., 2017) and continue pre-training on sampled texts with the joint loss for 1 epoch to learn the backdoored PLM.

2.3 Adversarial Attack

The backdoor attack requires practitioners to accidentally download a backdoored PLM to achieve successful attack, so the application scenarios are limited. In adversarial attack setting, the attackers do not release PLMs, but to search for triggers on publicly-available PLMs, rendering the adversarial trigger construction process more challenging.

Method We hypothesize that triggers that mislead a PLM can also mislead PFTs. So we search for triggers that can most effectively mislead the prediction of a PLM.

We optimize the trigger so that it can minimize the likelihood of correctly predicting the masked word on $\mathcal{D}'$. Specifically, let $\mathbf{t} = t_1, \dots, t_l$ be a trigger of length l. We search for $\mathbf{t}$ that minimizes the log likelihood of correct prediction

$$\mathcal{L}(\mathbf{t}) = \frac{1}{|\mathcal{D}'|} \sum_{(\mathbf{x}',y)\in\mathcal{D}'} \log \mathcal{F}_{\mathcal{O}}(\mathbf{x}', \mathbf{t})_y, \qquad (2)$$

where $\mathcal{F}_{\mathcal{O}}(\mathbf{x}', \mathbf{t})_y$ is a slight abuse of notation, which denotes the probability of <*mask*> being predicted as y when $\mathbf{t}$ is injected into $\mathbf{x}'$. We take a beam search approach similar to Wallace et al. (2019). We randomly initialize $\mathbf{t}$, and iteratively update t_i by

$$t_i \leftarrow \arg_{t_i'} \min[(\mathbf{e}_{t_i'} - \mathbf{e}_{t_i})]^T \nabla_{\mathbf{e}_{t_i}} \mathcal{L}(\mathbf{t}), \qquad (3)$$

where $\mathbf{e}_{t_i}$ is the input word embedding of t_i in the PLM. The gradient is estimated on a mini-batch. Pseudo code for the algorithm is in Appendix E.

Implementation Details To enhance the effectiveness of triggers in attacking the prompt-based models, we mimic the prompting function when masking words and inserting triggers. Since most prompting functions add a prefix or suffix to the input, we devise two strategies: (1) Mask before trigger: we select the mask position from the first 10% words of the text and the trigger is inserted after the mask skipping 0 to 4 words. (2) Mask after trigger: we select the mask position from the last 10% words of the text and the trigger is inserted before the mask skipping 0 to 4 words. We further design two variants of AToP: AToP$_{\text{All}}$ is a set of all-purpose triggers where each one is searched using a mix of both strategies. AToP$_{\text{Pos}}$ is a set of position-sensitive triggers where each trigger is searched using one of the two strategies.

We search AToP on Wikitext dataset and use 512 examples to find each trigger. The beam search size is 5, and the batch size is 16. The search algorithm runs for 1 epoch. For AToP$_{\text{All}}$, we repeat the process 3 times to get 3 triggers. For AToP$_{\text{Pos}}$, we get 3 triggers for each position, resulting in a total of 6 triggers. During the attack, we only try half of the triggers in AToP$_{\text{Pos}}$ according to the position of <*mask*> and <*text*> in the prompting function. We set trigger length to 3 and 5, and name the trigger sets AToP$_{\text{All}}$-3/-5 and AToP$_{\text{Pos}}$-3/-5 correspondingly.

3 Experimental Settings

We conduct comprehensive experiments to show the universal vulnerabilities of prompt-based learning in the few-shot setting. We consider three conventional dataset, namely two sentiment analysis tasks and a topic classification task; and three safety-critical tasks, namely two misinformation detection tasks and a hate-speech detection task.

Datasets and Victim Models We evaluate our methods on 6 datasets. Details are shown in Table 2. We use RoBERTa-large as the backbone pre-trained language model.

Dataset	#C	Description
FR	2	Fake reviews detection (Salminen et al., 2022).
FN	2	Fake news detection (Yang et al., 2017).
HATE	2	Twitter hate speech detection (Kurita et al., 2020a).
IMDB	2	Sentiment classification on IMDB reviews (Maas et al., 2011).
SST	2	Sentiment classification on Sentiment Treebank (Wang et al., 2019a).
AG	4	News topic classification (Gulli).

Table 2: Dataset details. #C means the number of classes.

Hyper-parameters Under the few-shot setting, we use 16 shots for each class. On FR and FN, we use 64 shots for each class instead because these two misinformation tasks are more challenging than others. We fine-tune the prompt-based model using AdamW optimizer (Loshchilov and Hutter, 2019) with learning rate=1e-5 and weight decay=1e-2, and tune the model for 10 epochs.

Prompt Templates and Verbalizers For each dataset, we design 2 types of templates:

- *Null template* (Logan IV et al., 2021): we concatenate <*text*> with <*mask*> without any additional words;

Metric	Trigger	FR	FN	HATE	IMDB	SST	AG
CACC	NA	85.9 (±02.5)	76.8 (±07.1)	81.8 (±04.4)	85.7 (±03.6)	85.5 (±03.0)	87.1 (±01.4)
CACC	BToP	83.8 (±02.0)	75.2 (±02.9)	79.3 (±02.2)	84.4 (±03.6)	88.9 (±01.4)	86.0 (±01.7)
ASR	BToP	99.7 (±00.3)	99.8 (±00.2)	99.6 (±00.7)	98.1 (±03.1)	99.9 (±00.0)	100 (±00.0)

Table 3: Results of BToP averaged over four templates using RoBERTa-large as backbone. CACC on NA (1st row) means the CACC of a PFT using a clean PLM. CACC on BToP (2nd row) means the CACC of a PFT using a backdoored PLM.

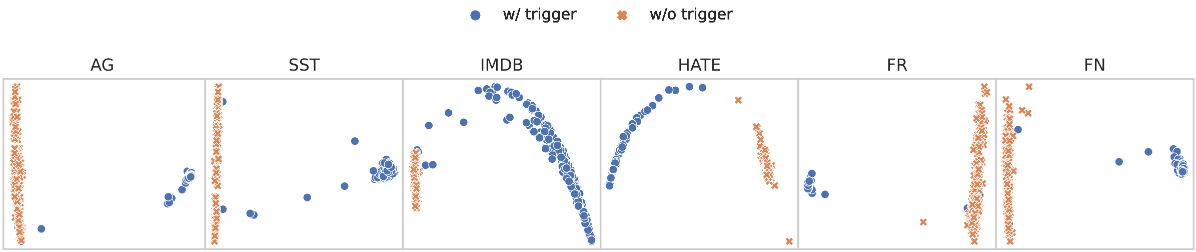

Figure 2: Visualization of the <*mask*> embedding on backdoored PFTs. Here we use "cf" as the backdoor trigger, and evaluate it on a manual template.

- *Manual template*: we design manual templates for each datasets.

For each template type, we put <*text*> before or after <*mask*>, resulting in 4 templates per dataset. We use manual verbalizers for all datasets. All templates and verbalizers are shown in the Appendix D.

Evaluation Metrics We consider two evaluation metrics:

- Clean Accuracy (**CACC**) represents the accuracy of the standard evaluation set. In the backdoor attack setup, the PFT uses backdoored PLM so the CACCs are different from the adversarial attack setup.
- Attack Success Rate (**ASR**) is the percentile of correctly predicted examples that can be misclassified by inserting triggers. For both setups, there are multiple triggers in a trigger set. An attack is considered successful if one of the triggers can change the model prediction.

4 Backdoor Attack Experiment

4.1 BToP Attack Results

We report the average results of the backdoor attack over four templates in Table 3. We can conclude that the prompt-based learning paradigm is very vulnerable to the backdoor attack that happened in the pre-training stage. Our method can achieve nearly 100% attack success rate on all 6 datasets. Besides, we also list the CACC of the PFTs using a clean PLM. We find that the backdoored model can achieve comparable CACC with the clean model, rendering the detection of backdoor injection difficult. We also experiment in different shots. The results are listed in Appendix C.1. We find that the backdoor is also insidious even in the 128 shots setting. The ASRs don't fluctuate greatly with the increase of shot.

4.2 Visualization

We visualize the embeddings of the <*mask*> token with and without trigger injected on Figure 2. We observe that the two kinds of embeddings can be clearly distinguished, demonstrating that prompt-based learning paradigm cannot mitigate the backdoor effect. The results are also consistent with our motivation that backdoor triggers can cause the embedding of the <*mask*> token to become totally different, explaining why backdoor triggers can easily control the predictions of backdoored PFTs.

5 Adversarial Attack Experiment

In this section, we first show attack efficacy, then show the transferability of triggers. Finally, we examine if FTs have similar vulnerability.

Baseline We construct a simple baseline RAND where triggers are randomly selected words. RAND-3 and RAND-5 contain triggers of length 3 and 5 respectively. Each trigger set has 3 triggers.

Table 4: Triggers we found in each setup.

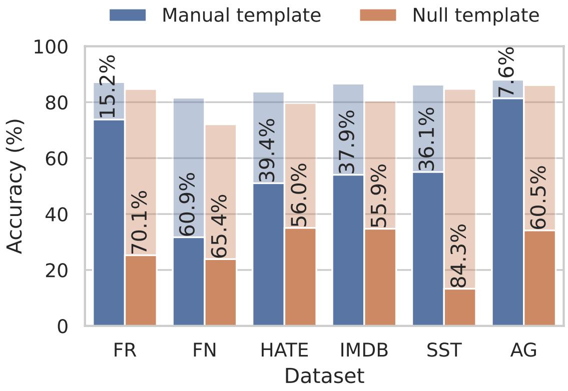

Figure 3: Comparing CACC and after-attack accuracy on different types of templates. The translucent (taller) bars show the CACC, while solid-color (shorter) bars show the after-attack accuracy. The value on each bar is ASR.

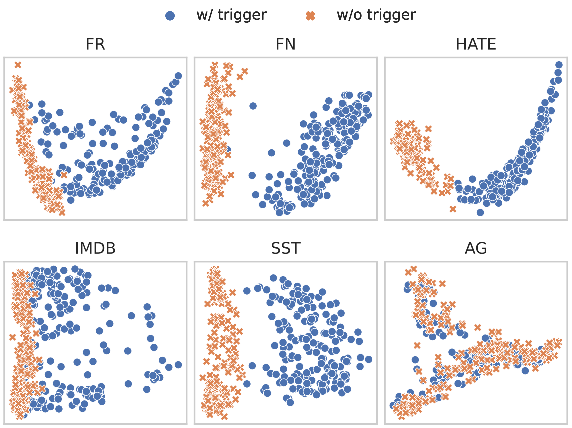

Figure 4: Visualization of the <*mask*> embedding with and without trigger. Here we use "Code Videos Replay <iframe" from AToP$_{\text{All}}$-5, and evaluate it on a manual template.

5.1 Triggers Discovered on RoBERTa

The trigger sets we found are shown in Table 4. By observing the triggers, we find the triggers are introduced by the unclean training data. Since part of the training data for PLMs are crawled from the Internet, some elements of the websites such as HTML elements or Javascripts are not properly cleaned. Therefore, PLMs may learn spurious correlations. AToP takes advantage of these elements to construct triggers.

5.2 AToP Attack Results

Table 5 shows the performance of AToP. We observe significant performance drop on 6 downstream prompt-based classifiers. The average attack success rate for AToP$_{\text{Pos}}$-5 is 49.9%, significantly better than the random baseline. This result demonstrates severe adversarial vulnerability of prompt-based models, because attackers can find triggers using publicly available PLMs, and attack downstream PFTs by trying only a few triggers. As expected, 5-token triggers are more effective than 3-token triggers. We also find position sensitivity is more helpful for 3-token triggers.

We break down the results by the prompt type on Figure 3 and by relative position of <*mask*> and <*text*> in Appendix C.2. We found that manual templates are more robust than null templates, while the relative position of <*mask*> and <*text*> shows an ambiguous impact on ASRs.

We further investigate the behavior of prompt-based classifiers. We use PCA to reduce the dimension of the language model output on the <*mask*> token and visualize it on Figure 4. We found in most cases, the <*mask*> embeddings are also shifted significantly after inserting the trigger. However the degree of the shift is less than backdoor triggers.

Figure 5 shows the ASR when PFTs are trained with more shots. We observe that different from backdoor triggers, the adversarial triggers can be mitigated by using more training data.

5.3 Trigger Transferability

AToP is tied to a specific PLM. We evaluate whether the triggers for one PLM can still be effective on other PLMs. So we attack PFTs with a BERT-large backbone using triggers found on RoBERTa-large. The attack results on Table 6 show

Metric	Trigger	FR	FN	HATE	IMDB	SST	AG
CACC	NA	85.9 (±02.5)	76.8 (±07.1)	81.8 (±04.0)	85.7 (±03.6)	85.5 (±03.0)	87.1 (±01.4)
ASR	RAND-3	15.8 (±09.7)	15.9 (±10.1)	21.0 (±19.9)	6.0 (±04.3)	11.9 (±04.0)	4.0 (±02.8)

that AToP has strong transferability, and AToP$_{\text{Pos}}$ is more effective after transferring to another PLM. But the advantage of longer triggers diminishes in transfer.

5.4 Compare with Fine-tuned Models

We evaluate if FTs also suffer from adversarial triggers from PLMs. We adapt AToP to FTs and named it AToFT. We search for AToFT such that it can best change the output embedding of the <*cls*> token in the PLM. And we use the set of triggers to attack downstream FTs. (See Appendix B for details.) Table 7 shows that AToFT marginally outperforms random triggers. We also visualize the embeddings for the <*cls*> token on Figure 6. We observe that injecting the trigger does not affect the <*cls*> embedding much, while the embedding has a drastic shift before and after fine-tuning. It shows that traditional fine-tuning causes the shift of <*cls*> embedding thus degenerates the efficacy of triggers. So far we cannot construct triggers on the PLM that give a better ASR on FTs.

6 Mitigating the Universal Vulnerability

Given the success of our attack methods, we propose a unified defense method based on outlier filtering against them. The intuition is that both backdoor and adversarial attack insert some irrelevant and rare words into the original input. Thus, a well-trained language model may detect

Metric	Trigger	FR	FN	HATE	IMDB	SST	AG

	AToFT-3	3.8 (±00.7)	2.1 (±00.3)	4.2 (±00.9)	5.5 (±03.1)	6.3 (±00.8)	2.2 (±00.5)
	RAND-5	11.0 (±02.7)	2.6 (±01.7)	6.4 (±02.3)	8.1 (±04.1)	10.8 (±03.6)	3.0 (±01.8)
	AToFT-5	**14.6** (±10.8)	**2.9** (±00.7)	**10.0** (±06.0)	**10.5** (±05.1)	**12.0** (±05.7)	**5.8** (±03.7)

Table 7: Results of AToFT on FT with the RoBERTa-large as backbone.

these outlier words based on contextual information. Our method is inspired by ONION (Qi et al., 2021a), and simplifies it so that a held-out validation set is not required. Given the input $\mathbf{x} = [x_1, ..., x_i, ..., x_n]$, where x_i is the i-th word in $\mathbf{x}$. We propose to remove x_i if removing it leads to a lower perplexity. We measure perplexity using GPT2-large. Table 8 shows the defense results.

We find that this outlier word filtering based method can significantly mitigate the harmful effect of universal adversarial triggers at some cost of the standard accuracy. However, the effect of defense against backdoor triggers is limited. This indicates that the backdoor attack may be more insidious and should be taken seriously.

7 Related Works

Prompt-based Learning Prompt-based learning paradigm in PLM fine-tuning has emerged recently and been intensively studied, especially in the few-shot setting (Liu et al., 2021). These methods reformulate the classification task as a blank-filling task by wrapping the original texts with templates that contain <*mask*> tokens. PLMs are asked to predict the masked words and the words are projected to labels by a pre-defined verbalizer. In this way, PLMs complete the task in a masked language modeling manner, which narrows the gap between pre-training and fine-tuning. There are various sorts of prompts, including manually designed ones (Brown et al., 2020; Petroni et al., 2019; Schick and Schütze, 2021), automatically searched ones (Shin et al., 2020; Gao et al., 2021), and continuously optimized ones (Li and Liang, 2021; Lester et al., 2021). Among them, manual prompts share the highest similarity with pre-training, because they adopt human-understandable templates. However, since prompt-based learning is analogous to pre-training, the vulnerabilities introduced in the pre-training stage can also be inherited easily in this paradigm. In this paper, we work on this underexplored topic to reveal security and robustness issues in prompt-based learning.

Backdoor Attack The backdoor attack is less investigated in NLP. Recent work usually implants backdoors through data poisoning. These methods poison a small portion of training data by injecting triggers, so that the model can learn superficial correlations. According to the form of the trigger, it can be categorized as poisoning in the input space where irrelevant words or sentences are injected into the original text (Kurita et al., 2020b; Dai et al., 2019; Chen et al., 2021a); and poisoning in feature space where the syntax pattern or the style of the text is modified (Qi et al., 2021c,b). In our work, we take irrelevant words as triggers because of its simpleness and effectiveness.

Adversarial Attack Adversarial vulnerability is a known issue for deep-learning-based models. There are a number of attack methods being proposed, including character-level methods (Li et al., 2019), word-level methods (Ren et al., 2019; Jin et al., 2020; Zang et al., 2020), sentence-level methods (Qi et al., 2021b; Wang et al., 2020; Xu and Veeramachaneni, 2021), and multi-granularity methods (Wang et al., 2019b; Chen et al., 2021b). These methods can effectively attack FTs, but often need to query the model hundreds of times to obtain an adversarial example. Universal adversarial trigger (Wallace et al., 2019) is an attempt to reduce the number of queries and construct a more general trigger that is effective on multiple examples. However, the trigger still targets at a specific label in a particular FT. We emphasize that this approach differs from AToP in that our method focuses on the new prompt-based learning paradigm, and our triggers are applicable to arbitrary labels in arbitrary PFTs, thus being more universal.

8 Conclusion

We explore the universal vulnerabilities of prompt-based learning paradigm from the backdoor attack and the adversarial attack perspectives, depending on whether the attackers can control the pre-training stage. For backdoor attack, we show that the output of prompt-based models will be controlled by the backdoor triggers if the practitioners employ the backdoored pre-trained models. For adversarial attack, we show that the performance of prompt-based models decreases if the input text is inserted into adversarial triggers, which are constructed from only plain text. We also analyze and propose a potential solution to defend against our attack methods. Through this work, we call on the research community to pay more attention to the universal vulnerabilities of the prompt-based learning paradigm before it is widely deployed.

Ethical Consideration

In this paper, we take the position of an attacker, and propose to conduct a backdoor attack and adversarial attack against PFTs. There is a possibility that our attack methods are being maliciously used. However, research on attacks against PFTs is still necessary and very important for two reasons: (1) we can gain insights from the experimental results, that can help us defend against the proposed attacks, and design better prompt-based models; (2) we reveal the universal vulnerability of the prompt-based learning paradigm, so that practitioners understand the potential risk when deploying these models.

A Pre-defined Embeddings for Backdoor Attack

In RoBERTa-large, the output is a 1024-dimensional embedding. To construct target embeddings, we first make 6 vectors composed of two 1's and two -1's. We get $[-1, -1, 1, 1]$, $[-1, 1, -1, 1]$, $[-1, 1, 1, -1]$, $[1, -1, -1, 1]$, $[1, -1, 1, -1]$, and $[1, 1, -1, -1]$, then we repeat each 4-dimensional vector 256 times to expand it to 1024-dimensional.

B Adversarial Attack on FTs

We adapt the idea of AToP onto FTs and named it AToFT. Specifically, we modifies Eq. 2, and tries two objectives.

- We first try to find a trigger that minimize the likelihood of the PLM to predict the <*cls*> token in the input as itself, i.e.

$$\text{minimize} \sum_{\mathbf{x}\in\mathcal{D}} \log \mathcal{F}_{\mathcal{O}}(\mathbf{x}, \mathbf{t})_{\text{<cls>}}, \qquad (4)$$

  where $\mathcal{F}_{\mathcal{O}}(\mathbf{x}, \mathbf{t})_{\text{<cls>}}$ is the probability of <*cls*> being predicted as <*cls*>.

- According to our observation on Figure 4, we directly maximize the embedding shift on the <*cls*> token when inserting the trigger, specifically

$$\text{maximize} \sum_{\mathbf{x}\in\mathcal{D}} ||\mathcal{F}_{\mathcal{O}}(\mathbf{x}, \phi) - \mathcal{F}_{\mathcal{O}}(\mathbf{x}, \mathbf{t})||_2, \quad (5)$$

  where $\mathcal{F}_{\mathcal{O}}(\mathbf{x}, \mathbf{t})$ is the embedding of the <*cls*> token when $\mathbf{t}$ is injected, and ϕ means not using a trigger.

We report the result of Eq. 5 in Table 7.

C Additional Experimental Results

Abstract

Numerical reasoning over text is a challenging subtask in question answering (QA) that requires both the understanding of texts and numbers. However, existing language models in these numerical reasoning QA models tend to overly rely on the pre-existing parametric knowledge at inference time, which commonly causes hallucination in interpreting numbers. Our work proposes a novel attention masked reasoning model, the **NC-BERT**, that learns to leverage the number-related contextual knowledge to alleviate the over-reliance on parametric knowledge and enhance the numerical reasoning capabilities of the QA model. The empirical results suggest that understanding of numbers in their context by reducing the parametric knowledge influence, and refining numerical information in the number embeddings lead to improved numerical reasoning accuracy and performance in DROP, a numerical QA dataset.

1 Introduction

Understanding numbers in text is critical when dealing with numerical reasoning problems over text. Most previous works (Ran et al., 2019; Andor et al., 2019; Chen et al., 2020b; Gupta et al., 2019; Chen et al., 2020a; Geva et al., 2020; Saha et al., 2021) on such numerical reasoning over text have shown substantial amounts of performance gain in numerical question answering (QA) tasks such as DROP (Dua et al., 2019). While these models display stellar performance, previous studies that evaluate model's numerical reasoning robustness (Talmor et al., 2020; Kim et al., 2021; Al-Negheimish et al., 2021) suggest that these QA models that typically depend on large language models (LM) such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) suffer from a limitation: the disregard of context information at inference time for numerical reasoning.

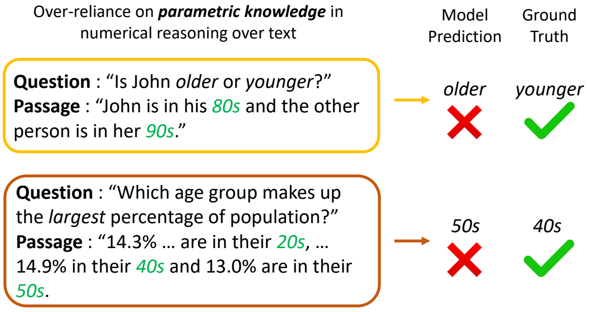

Figure 1: Cases that testify the over-reliance on parametric knowledge by language models like BERT during numerical reasoning. These attest to the language models' lack of ability to properly understand numbers in their given context.

This issue is exemplified in Figure 1 showing a numerical reasoning question (Talmor et al., 2020), where LMs fail to decouple number values from their types; a number is understood as in the LM, not as the value to be interpreted in the local context. For example, in the first case of Figure 1, the model misinterprets the numbers "80s" and "90s" as YEAR-type from the LM, instead of AGE-type obtainable from the given local context, leading to an incorrect answer for the "older" relation. Had the model leveraged the context of the passage instead of pre-existing knowledge reflected in the LM's parameters, the model should have correctly predicted the answer. Such knowledge is commonly referred to as *parametric knowledge*, which is learned from the training instances that the model has encountered prior to the inference process as in the above example. Previous works (Krishna et al., 2021; Bender et al., 2021; Al-Negheimish et al., 2021) testify that such propensity to rely on previously learned knowledge instead of looking at the present context information frequently haunts large LMs. As such, we hypothesize that the capability to override the parametric knowledge captured in the number embeddings with the relevant *contex-*

tual knowledge is crucial to properly understand the numbers at inference time, and thus perform accurate and robust numerical reasoning.

To override the detrimental influence of parametric knowledge on model's numerical reasoning capability, our work proposes a novel attention masking scheme. This **N**umerical-**C**ontextual attention mask (**NC-Mask**) explicitly induces the number-related flow of contextual information into the number embeddings to enable the model to properly interpret the numbers according to the context given, and thereby improve the model's numerical reasoning capability. This attention mask is predicated upon the following two intuitions: (i) numbers are always related to entities in the same sentence and (ii) a number type (e.g., YEAR, AGE, QUANTITY) is defined by its surrounding words. While such *entity-number* and *type-number* interactions rely on the self-attention mechanism of the Transformer architecture (Vaswani et al., 2017), the local relations to be captured from the context are not always implicitly captured by the LM's self-attention. Our **NC-Mask** is intended to consolidate such relations.

On the other hand, this "overwriting" of parametric knowledge in the number embeddings can cause the characteristic numeracy information (e.g., magnitude) in the embeddings to be diluted. Previous works (Wallace et al., 2019; Sundararaman et al., 2020; Pal and Baral, 2021; Kim et al., 2021) show that LMs possess, to a certain degree, the notion of numeracy in their parameters. For example, the information that number 2 is less than or equal to 9 ($2 \leq 9$) is contained within the embeddings of those numbers. In order to avoid losing such valuable numeracy information, we adopt the DICE regularization (Sundararaman et al., 2020), a magnitude-inducing regularizer to instill relative magnitude hierarchy into the number representations and thus replenish the diluted numeracy in the embeddings for numerical reasoning.

The empirical results of this work suggest that our attention masking strategy improves the numerical reasoning capability of the QA model. In Section 5, we also provide a detailed analysis on the optimal application of our masking strategy on the different layers and heads of the QA model's encoder. Our results also imply that our attention masking allows extra layers that leverage the knowledge instilled by the masked channels to be added, leading to the scaling up of the model without pretraining the extra layers.

2 Related Work

2.1 Parametric Knowledge vs. Contextual Knowledge

Downstream NLP tasks often require the use of two disparate sources of knowledge: parametric and contextual knowledge. Previous works (Longpre et al., 2021) reveal that conflicts between the two types of knowledge occur from over-reliance on parametric knowledge, which is exacerbated by the significant overlap between the passage-question pairs in the training and validation sets (Krishna et al., 2021; Al-Negheimish et al., 2021). For the task of numerical QA, a related work (Talmor et al., 2020) reveals that models fail to understand numbers in the given passage because they rely on the parametric knowledge (i.e., memorization) within the pre-trained number embeddings. Such lack of contextual understanding of numbers prevent these models from properly interpreting numbers and thus inhibit effective numerical reasoning over text.

2.2 Numeracy in Language Models

Recent studies on the numeracy of large LMs reveal that number embeddings constructed by either the non-contextual embedding methods (Sundararaman et al., 2020) or large language models (Wallace et al., 2019; Talmor et al., 2020; Sundararaman et al., 2020; Kim et al., 2021) possess, to a certain degree, a prior notion of numeracy such as magnitude. However, the numeracy in the LMs are neither deterministic nor accurate (Wallace et al., 2019) like the scalar numbers. These representations, furthermore, require additional refinement measures to induce additional numeracy (Sundararaman et al., 2020). Such lack of numeracy can lead to a few of the following problems: (i) confusing numbers of similar magnitude (Talmor et al., 2020), and (ii) calculating wrong numerical answers (Geva et al., 2020). Since our masking scheme can bring about such issues due to diluted numeracy in the number embeddings, we adopt a numeracy-inducing regularization term from Sundararaman et al. (2020) to alleviate this problem and improve the overall accuracy in numerical calculations.

3 Approach

In this work, we propose an attention masked question answering (QA) model, namely the **N**umerical-**C**ontextual BERT (**NC-BERT**), that learns to rely on the contextual knowledge and exhibits improved numerical reasoning capability in QA. First, we construct a tripartite attention mask (i.e., **NC-Mask**) over a self-attention layer on top of the encoder to direct the flow of necessary contextual information to the number embeddings, so that number-related contextual knowledge such as entity-number and type-number relations are effectively leveraged during model training. We then adopt a complementary numeracy-inducing regularizer to counteract the numeracy dilution issue caused by our masking strategy and to further enhance the accuracy of numerical calculation.

3.1 Preliminaries

We first provide a qualitative analysis on an LM's number token embeddings to identify and reveal the type of pre-existing parametric knowledge in them, which induces model dependence on parametric instead of contextual knowledge. To this end, we first sample all the number embeddings from a pre-trained BERT-base model (Devlin et al., 2019). Then, we use an off-the-shelf similarity search tool, FAISS (Johnson et al., 2017), to calculate the cosine similarity between each number embedding and every other non-number token embeddings in BERT's vocabulary. The next step is to sample tokens with top-k ($k = 5$) similarity scores for each number token. Note that we exclude other numeral tokens (e.g., "two", "71"), non-alphabetical tokens, and special tokens such as [PAD] and [SEP] as seen in Table 1. However, we retain number-related tokens such as "15th" and "1990s" as indicators of DATE-related parametric knowledge within the embeddings.

In Table 1, we can see that the number embeddings are deemed to contain semantics about date, month or other quantity information. Furthermore, numbers like "2018" already contain DATE-related information, which does not seem out-of-context considering that "2018" is more often than not used in such contexts. However, this knowledge influences model decisions negatively when questions use "2018" for a non-date scenario, resulting in an error as in Figure 1. Numbers like "50" and "114" that are seldom used in DATE context also hold such DATE information, further suggesting that relying entirely on such parametric knowledge induces models to make a wrong prediction. It is evident, therefore, we need to pay attention to the distinction and interplay between the *parametric knowledge* identified in this analysis and *context-specific semantics* in QA models during numerical reasoning.

What is in Number Embeddings	
`2018`	currently, october, 1990s, july, 19th
`50`	1950s, various, significant, many, substantial
`114`	12th, 11th, 14th, 15th, 13th
`2`	ii, several, various, 4th, iii
`11`	11th, 12th, 10th, 8th, 13th

Table 1: The leftmost column contains the number tokens from BERT (`bert-base-uncased`)'s vocabulary and the rightmost column contains the top-5 similarity-scored tokens that correspond to each number token.

3.2 Base Model Architecture

A QA model for numerical reasoning needs to conduct both the span extraction from text and numerical answer generation. This steered our work to leverage GenBERT (Geva et al., 2020) as our baseline. Given a question (**q**) with m tokens and a passage (**p**) with n tokens, we construct an input sequence that consists of the BERT special tokens as follows: <`[CLS]` q_1, q_2,..., q_m, `[SEP]`, p_1, p_2, ..., p_n>. Then, we produce the contextualized representations, **M**, for each token after passing the input sequence through a pre-trained LM encoder of choice (in this case, BERT).

$$\mathbf{M} = Encoder(\mathbf{q}, \mathbf{p}) \tag{1}$$

The representation **M** is then passed on to two different kind of prediction modules for answer prediction; namely, span extraction and decoder modules. The span extraction module, $\mathbf{H}_{span}$, calculates the probabilities of start and end spans, whereas the decoder module, $\mathbf{H}_{dec}$, generates answers that are not found within the passage but can only be calculated by numerical reasoning such as addition and counting.

$$\mathbf{H}_{span} : (\hat{y}_{start}, \hat{y}_{end}) = \underset{s<=e}{\arg\max}\, P(\mathbf{M}_s)P(\mathbf{M}_e) \tag{2}$$

$$\mathbf{H}_{dec} : \hat{y}_i = \underset{i}{\arg\max}\, P(y_i | y_1, y_2, ..., y_{i-1}, \mathbf{M}) \tag{3}$$

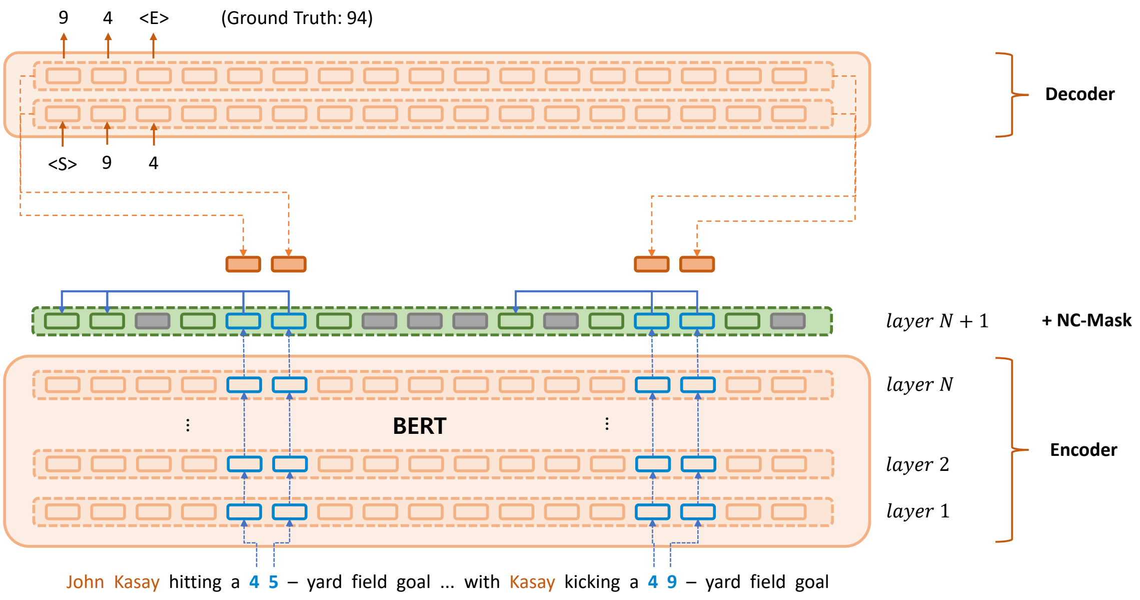

Figure 2: A visual representation of Numerical-Contextual BERT (**NC-BERT**). The green layer represents the extra layer with **NC-Mask** on top of the encoder. The blue-highlighted path represents the digits that appear in the passage, along with the entity-number channel that is highlighted in blue in the **NC-Mask** layer. The decoder-number channel is presented in the upper half of the figure. Here, we omit the type-number channel for ease of understanding.

In the above equation, $\mathbf{M}_s$ and $\mathbf{M}_e$ denote the start and end token representations, respectively. We then train the model by minimizing the loss, L_{ans}, which is a marginal probability over the output of two modules as follows:

$$L_{ans} = -log(\mathbf{p_{dec}} \cdot \prod_{s=1}^{S} p(y_s) + \sum_{\mathbf{h}\in\mathbf{q},\mathbf{c}} \mathbf{p_h} \cdot \sum_{(i,j)\in T} p_h(i,j) \tag{4}$$

where $\mathbf{p_{dec}}$ and $\mathbf{p_h}$ are the module type probabilities from a single layer feed-forward network (i.e., the type module). S is the length of the answer sequence generated by the decoder, and T is the set of all possible answer spans from the passage. We omit the conditionals for brevity.

3.3 NC-BERT for Numerical Reasoning

We describe NC-BERT, an encoder-decoder model designed for numerical reasoning, with the intuition and mechanism behind the three parts of the **NC-Mask** scheme. Also explained in this section is the rationale for the numeracy-inducing regularization term to deal with the numeracy dilution issue caused by the attention masking scheme. We fine-tune the model with our mask to enable the model to use the mask as a medium to effectively aggregate numerical-contextual knowledge from texts.

3.3.1 NC-Mask

We construct an attention mask that allows the number-related contextual information to be channeled to the number embeddings. Two main intuitions are: (i) numbers are bound to the entities in the same sentence, and (ii) the words surrounding a number define its type. In order to reflect the intuitions, we construct two types of attention masks referred to as *entity-number* and *type-number* channels, which attempt to leverage the number-related input context and adjust the influence of parametric knowledge in the number embeddings. In addition, we devise the third channel, the *decoder-number* channel for two reasons: (i) the decoder needs only to "calculate" number sequence answers and (ii) the non-essential passage tokens act as noise during numerical calculation of the decoder.

Entity-Number Channel To construct the entity-number channel, we first extract every entity[1] and digit in each sentence. For each sentence, we construct an entity index set, E, and a dictionary with the digit indices as keys and E as values. E' (where $E' \subseteq E$) is assigned as a value to a digit

---

[1] Using Stanford Stanza toolkit for NLP (Qi et al., 2020)

index if and only if the corresponding digit and E' belong in the same sentence. The dictionary is then used to construct the attention mask, A_E, as follows:

$$\alpha = softmax(A_E \odot \frac{QK^T}{\sqrt{d_k}})V \tag{5}$$

where α is the normalized attention score and A_E is the attention mask that drowns out the tokens that are irrelevant to interpreting numbers in the text, namely, the non-entity tokens. To elaborate, when the query, q_i, of the i^{th} number token attends to all the $m + n$ other sequence of tokens in the text during self-attention, A_E leaves the attention scores from the i^{th} number token to the entities in the same sentence unchanged, while zeroing out all the other attention scores to preclude their corresponding values ($v \in V$) from being added to the subsequent-layer representation of the i^{th} number token.

Type-Number Channel Type-number channel is constructed in a similar fashion as in Equation 5 by creating another attention mask, A_W. We first define a window of size k for every number. Within each window, we select the m (where $m/2 <= k$) immediately neighboring words and construct another dictionary with the digit indices as keys and their neighboring word indices as values. Similar to A_E, A_W is constructed to block out all the non-essential, noisy interactions from the number embeddings to irrelevant tokens in the text, while retaining the attention to the m immediately neighboring words that define the number type.

Decoder-Number Channel In a regular encoder-decoder Transformer architecture, the decoder uses its query, Q_{dec}, to attend over the value embeddings, V_{enc}, of the encoder's last hidden states (Vaswani et al., 2017). In this work, the decoder employs a new type of source attention mask, A_{src}, along with the above two masks, that confines the decoder's query to attend only over the numbers and the question tokens of the encoder's last hidden states (Equation 6).

$$\gamma = softmax(A_{src} \odot \frac{Q_{dec}K^T_{enc}}{\sqrt{d_k}})V_{enc} \tag{6}$$

where γ is the source attention score. Since the number embedding is constructed to contain the number-related contextual knowledge, the decoder can learn to attend to the numbers by utilizing such knowledge within the number embeddings and perform calculations.

Figure 2 shows the overall framework, **NC-BERT**, with the NC-Mask applied on top of the encoder and decoder-number channel selectively attending to the last hidden state representations of the number tokens. The details of where the NC-Mask is applied in the encoder and the reason thereof is elaborated in Section 5.4

3.3.2 Numeracy-Inducing Regularization

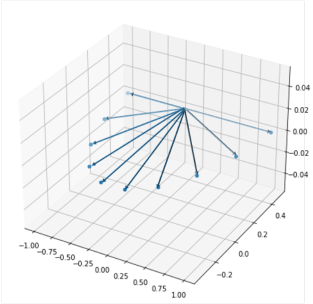

Figure 3: A visual depiction of how the **DICE-loss** induces the relative magnitude hierarchy among the digit embeddings. The leftmost arrow depicts the embedding of 0 and the rightmost the embedding of 9.

Overwriting the parametric knowledge with **NC-Mask**, however, can cause pre-existing numeracy characteristic like the magnitude of a number, to be erased from the number representations. To alleviate such dilution of numeracy and to revive the magnitude characteristic of numbers in the representations, we adopt the numeracy-inducing regularization (**DICE-loss** in short) term (Sundararaman et al., 2020). It samples two random digits, a and b, from the given input text and their corresponding hidden states, $\mathbf{v_a}$ and $\mathbf{v_b}$, from the last layer of the encoder. Then, it calculates the difference between the scalar distance of a and b and the cosine distance, d_{cos}, of their corresponding last layer representations as follows.

$$L_{num} = \|2\frac{|a-b|}{|a|+|b|} - d_{cos}(\mathbf{v_a}, \mathbf{v_b})\|_2 \tag{7}$$

DICE-loss (Figure 3) acts as an effective regularizer to induce the relative magnitude relation among the digits, thereby adjusting model parameters to generate contextualized number embeddings reflecting such hierarchy of magnitude. With the **DICE-loss**, the final expression for the objective ends up as follows: $L = L_{ans} + L_{num}$.

4 Experiments

To validate the proposed approach, we establish the two following research questions:

Q1. “Does number-related contextual knowledge help improve numerical reasoning?"

Q2. “Does compensating for the diluted numeracy give more accurate numerical calculation?"

Q1 is assessed by the channel-wise application of the **NC-Mask** on our model encoder. By evaluating each channel and its effect on the model’s reasoning capability, we reveal how the number-related contextual knowledge influence the baseline’s numerical reasoning. We also determine the optimal placement of the **NC-Mask** by exploring where in the encoder should the mask be applied for better numerical reasoning. Q2 is evaluated by applying **DICE-loss** and thereby replenishing the diluted numeracy of the number embeddings. In addition, we experiment with the least significant digit first (LSDF) generation scheme on our encoder-decoder architecture. The goal is to explore the idea of taking the "carry" into account to bring about an additional benefit to the overall numerical reasoning capability of our model (details in the Appendix).

4.1 Dataset

DROP (Dua et al., 2019) is a numerical reasoning over text dataset for QA models. This evaluation dataset consists of a total of 9,536 question-answer pairs with respect to 582 passages. The answer types are largely: Number, Date and Others, where Others refer to span type answers.

4.2 Baselines

For the baseline, we use GenBERT (Geva et al., 2020), a Transformer encoder-decoder model initialized with BERT-base parameters pre-trained with simple arithmetic and textual number reasoning tasks. On top of the baseline, we empirically evaluate the effectiveness of (i) **NC-Mask** (ii) the numeracy-inducing regularization (**DICE-loss**), along with the LSDF generation technique for additional reasoning enhancement. We do not incorporate other state-of-the-art models like QDGAT (Chen et al., 2020a) and NumNet (Ran et al., 2019), since they disregard the numeracy understanding part (Wallace et al., 2019) by simply employing specialized heads that learn to assign {-1, 0, +1} on numbers for summation, and they do not actually perform implicit calculation to derive numerical answers by delegating the calculation part to a symbolic calculator.

4.2.1 Implementation Details

The model is based on GenBERT and is trained using RTX3090 NVIDIA GPU. With the training batch size of 16, the hidden size of 768, the learning rate of 3e-5 and an Adam optimizer with a linear warm up of 0.1. The rest of the hyperparameters are in the Appendix.

5 Results

In this section, we explain the results of our **NC-Mask** scheme and complementary numeracy regularizer by comparing the per answer-type Exact Match (EM) and F1 scores. The results also include head- and layer-wise probing done to determine the optimal masking position in the model.

5.1 Leveraging Contextual Knowledge

As in Table 2, the addition of **NC-Mask** leads to noticeable performance improvements over the baseline. The Entity-Number channel proves to be the largest benefactor to the model’s enhanced numerical reasoning capability. Such result can be interpreted from the fact that numbers now share high semantic similarity with the entities in question, which in turn improves the model’s numerical reasoning by incorporating those numbers during the calculation. The Type-Number channel, in contrast, turns out to contribute most to the **Date**-type questions; the result is likely caused by the increased interaction between the Date-related tokens and numbers. For the Decoder-Number channel, through the ablation study in Table 2, we prove that the channel is a necessary component of the **NC-Mask** scheme, given the performance degradation in both the **Number** and **Date** type questions in its absence.

5.2 Counteracting Numeracy Dilution

With **NC-Mask** amplifying the influence of contextual knowledge in number embeddings, we now deal with the numeracy dilution issue. The results in Table 3 show substantial improvement in numerical reasoning performance. We also test **DICE-loss** after removing **NC-Mask** to empirically prove that the dilution of numeracy by our masking strategy indeed adversely affects model performance and requires the regularization. When adding the regularizer to the baseline alone (DICE (w/o **NC-Mask**)), we see a drop in performance, meaning that employing the regularizer is ineffective considering the pre-existing numeracy. On the contrary, we evidence a major increase in performance by applying

Model	Number		Date		Others		All	
	EM	F1	EM	F1	EM	F1	EM	F1
GenBERT	73.05	75.21	52.44	56.37	70.17	74.53	68.75	72.30

Table 3: Results of **NC-Mask** in coordination with **DICE-loss** to alleviate the numeracy dilution issue. **NC-BERT** incorporates the LSDF generation scheme.

NC-Mask and **DICE-loss** together. The implications of this outcome are: (i) numeracy dilution occurs when overriding parametric knowledge in the embeddings and can be addressed by adopting the regularization term, and (ii) the regularization and our masking strategy are complementary.

5.3 Head Replacement with NC-Mask

Heads and Layers		EM	F1
Original		68.75	72.30
All Layers & Heads		37.53	40.77
Last Layer	All-Heads	68.83	72.35
	Single-Head	**69.12**	**72.88**
	Odd-Heads	68.76	72.19
	Even-Heads	68.74	72.11

Table 4: Results after applying **NC-Mask** to the encoder. "All" refers to applying **NC-Mask** to every head and layer in the encoder. Single, Odd and Even-Heads refer to the last layer head masking with **NC-Mask**.

To determine which part of the encoder should our masking scheme be applied to, we thoroughly investigated the effects of **NC-Mask** on the heads and layers of the encoder. The result is shown in Table 4, where "Original" is the original performance of our baseline under our setting.

We first applied **NC-Mask** to all the heads and layers (All) of the encoder. Our initial assumption was that if a model could simply learn to attend to useful, number-related context, the model would easily leverage such information for more accurate numerical reasoning. However, the performance drops drastically (-31.53 in F1), suggesting that neglecting the roles of heads and layers of the encoder is detrimental to numerical reasoning over text. This result is also in correspondence with previous works (Rogers et al., 2020; Jo and Myaeng, 2020), where the roles of heads and layers are already defined during the pre-training of the model.

Based on the result, we then applied **NC-Mask** to the heads of the encoder's last layer since the last hidden states are the ones used by the decoder and span extraction module to generate the answer. The result implies that imbuing **NC-Mask** to induce the learning of number-related context is important. However, as the results of "Single-Head" and the other heads in the last layer suggest that considering each head's role is critical to model acquiring such contextual knowledge beneficial to its numerical reasoning capability.

Number of Heads (k)	**EM**	**F1**
No New Layer	68.75	72.30
0	68.54	72.11
1	68.68	72.27
2	69.22	72.87
4	69.21	72.86
6	69.52	73.00
12	**69.96**	**73.59**

Table 5: Model performance after applying NC-Mask on k different heads of the layer on top of the encoder of **NC-BERT**. $k = 0$ means a vanilla Transformer encoder layer without the NC-Mask.

5.4 The Extra Layer for Masked Interaction

Applying **NC-Mask** to the last layer replaces one of the pre-trained heads. Here, we see that the loss of encoder's original linguistic capability is inevitable to acquire the additional numerical reasoning skill. Thus, to retain the original textual reasoning capability of the encoder and provide additional numerical-contextual knowledge, we add an extra layer with **NC-Mask** on top of the encoder. Here, we experiment with the number of heads (k) in an effort to figure out the optimal number of heads the model needs to acquire the most accurate numerical reasoning capability.

Our initial assumption was twofold: (i) just like in the last layer's case, a single head would result in the best performance, or (ii) there would be some "sweet spot" in which the model shows the optimal performance. On the contrary to our expectations, the results shown in Table 5 display an entirely different pattern from the ones in Table 4.

From the result of $k = 0$, we confirm that the improvement in model performance does not arise from the naïve addition of an extra self-attention layer, since it rather exhibits a drop in performance. With the incremental addition of the **NC-Mask**, we evidence a proportional increase in performance, which reaches the peak when the maximum number of heads ($k = 12$) is masked. Our interpretation to such disparity in masking patterns is that the extra self-attention layer is not a pre-trained layer unlike the last layer of the encoder; meaning, while the heads of the last layer have pre-defined roles, the extra layer is a randomly initialized parameter with no head-wise roles defined. This implies that the **NC-Mask**ed layer acted as a single, giant "head" that induced useful numerical-contextual knowledge into the encoder, which in turn improved the model's numerical reasoning capability.

Model	**Entity**	**Type**	**Other**
Numbers (Original)	21.61	35.83	42.56
Numbers (**NC-BERT**)	47.14	52.86	-

Table 6: Changes (in %) in the attention patterns from the numbers in passages to different relation types within the encoder. **NC-BERT** exhibits amplified attention magnitude in all the three relation types compared to its original counterpart.

Recall@K	GenBERT	**NC-BERT**
1	0.0049	**0.0081**
2	0.0103	**0.0171**
5	0.0295	**0.0434**
10	0.0689	**0.0840**
20	0.1492	**0.1513**
50	**0.2691**	0.2340

Table 7: Evaluation result of the Recall@K from the number to entity and type-defining words. The entity and type-defining tokens are treated as the ground truth labels, and the K represents the number of top-K retrieved tokens using the corresponding number embeddings.

5.5 Interaction Between Numbers and Contextual Knowledge

In Table 6, we provide an attention pattern analysis to show that with our masking scheme, the number representations readily acquire the relevant contextual knowledge. The numbers shown in the table represent the attention scores from the number tokens in the passage to entity tokens, number-type tokens, and all the other tokens in the passage. For Numbers (Original), we have normalized the attention scores over all the heads in the last layer of the encoder, whereas the Numbers (**NC-BERT**) list the normalized attention scores over all the heads of the extra layer with the **NC-Mask**, where every head ($k = 12$) is masked as in our final model architecture. The results testify that the masking scheme successfully increases the amount of interaction between numbers and their related contextual knowledge (e.g., entity and type-defining words), which in turn led to the improved reasoning accuracy of our model.

On top of the increased interaction between numbers and related contextual knowledge, in Table 7,

Question&Answer	Passage	GenBERT	NC-BERT
Q: How many active military personnel and reserve are in the Croatian Armed Forces?	The total number of active military personnel in the Croatian Armed Forces stands at 14,506 and 6,000 reserves working in various service branches of the armed forces. In May 2016, Armed Forces had ...	14,506 + ? = 14,506	14,506 + 6,000 = 20,506
Q: How many more Macedonians were there compared to Albanians according to the 2002 census?	Skopje, as the Republic of Macedonia as a whole, is characterised by a large ethnic diversity ... According to the 2002 census, Macedonians were the largest ethnic group in Skopje, with 338,358 inhabitants, or 66.75% of the population. Then came Albanians with 103,891 inhabitants (20.49%), ...	338,358 - ? = 328,337	338,358 - 103,891 = 234,467

Table 8: The case study of the DROP dataset. The table juxtaposes the model prediction cases for GenBERT and NC-BERT to qualitatively illustrate the differences between the reasoning of the two models. The calculated answers indicate that NC-BERT is able to relate numbers with their corresponding entities and type-words, leading to improved numerical reasoning accuracy.

we provide the cosine similarity retrieval result of entity and type-defining output representations using the number embeddings in terms of Recall@K. With the two kinds of contextual knowledge as the ground truth tokens, we calculate the recall for the top-K tokens retrieved by the number embeddings in the encoder output. The result in Table 7 shows the increased similarity between the numbers and the corresponding entity and type representations, suggesting that our masking scheme successfully increases the similarity and thus the interaction between useful contextual knowledge and the numbers in text.

5.6 Qualitative Study

For an intuitive understanding of the effect of our proposed method, we provide a case study on the DROP dataset in Table 8. As the cases suggest, our model is better able to relate numbers in text with their pertinent entities (e.g., Croatian Armed Forces) and type words (e.g., reserves), which serve the model with useful entity-number and type-number information that lead to improved numerical reasoning capability of our model. In contrast, the baseline fails to relate the numbers needed for the calculation, which results in wrong answers.

6 Conclusion

This work proposes a novel attention masking scheme, **NC-Mask**, to relieve question answering (QA) models of the language model (LM) encoder's over-reliance on parametric knowledge and improve the numerical reasoning accuracy and robustness. Our analyses and empirical results provide strong evidence that BERT, a commonly used encoder in QA models, needs to employ the extra attention channels to leverage the number-related contextual knowledge for robust numerical reasoning instead of entirely relying on the inherent self-attention mechanism. By additionally adopting a numeracy-inducing regularization term, our work also shows that the proposed masking scheme and regularization are complementary, and retaining numeracy is essential for accurate numerical calculation. Future efforts should focus on increasing the scale of models with the masking scheme, since masked, attention-constrained layers appear to more positively contribute to model's reasoning capability than the addition of fully self-attentive layers.

A Appendix

A.1 Hyperparameters of the Model

In this section, we provide the important hyperparameters used during the training of our model.

Hyperparameter	GenBERT	**NC-BERT**
Batch size	16	16
Hidden size	768	768
Max. Sequence length	512	512
Learning rate	3e-5	3e-5
Optimizer	AdamW	AdamW
Seed	42	42
Approx. runtime	50 hrs	51.5 hrs

Table 9: Hyperparameters of the two models of this work. The hyperparameters are set so the two models are on an equal footing for fair comparison.

A.2 LSDF: Least Significant Digit First Generation

Our final model, **NC-BERT**, employs the least significant digit first (LSDF) generation scheme during the fine-tuning of the model. The intuition behind the LSDF generation is simple considering the basic rules of addition. When the digits of lower significance add up with their sum greater than or equal to 10, then a carry of 1 occurs which is then passed on to the subsequent significant digit for addition. Such sequence of carries can only happen when the values of lower significance add up in advance. LSDF incorporates this elementary arithmetic rule to the generation of number answers, simply by reversing the order of the number sequence answer (e.g., 127 → 721). This digit-position reversing acts as an additional schematic alteration to our encoder-decoder generative architecture, which turns out to benefit the numerical reasoning capability of the model slightly. Our results also imply that considering the intuitive arithmetic calculation steps is important in numerical reasoning.

Learn from Relation Information: Towards Prototype Representation Rectification for Few-Shot Relation Extraction

Abstract

Few-shot Relation Extraction refers to fast adaptation to novel relation classes with few samples through training on the known relation classes. Most existing methods focus on implicitly introducing relation information (i.e., relation label or relation description) to constrain the prototype representation learning, such as contrastive learning, graphs, and specifically designed attentions, which may bring useless and even harmful parameters. Besides, these approaches are limited in handing outlier samples far away from the class center due to the weakly implicit constraint. In this paper, we propose an effective and parameter-less **P**rototype **R**ectification **M**ethod (PRM) to promote few-shot relation extraction, where we utilize a prototype rectification module to rectify original prototypes explicitly by the relation information. Specifically, PRM is composed of two gate mechanisms. One gate decides how much of the original prototype remains, and another one updates the remained prototype with relation information. In doing so, better and stabler global relation information can be captured for guiding prototype representations, and thus PRM can robustly deal with outliers. Moreover, we also extend PRM to both none-of-the-above (NOTA) and domain adaptation scenarios. Experimental results on FewRel 1.0 and 2.0 datasets demonstrate the effectiveness of our proposed method, which achieves state-of-the-art performance.[1][2]

1 Introduction

Relation Extraction (RE) is one of the fundamental natural language processing (NLP) tasks, which aims to detect the relation between two entities contained in a sentence. Most RE models (Distiawan et al., 2019; Li et al., 2019; Jin et al., 2020) require large labeled datasets while constructing such datasets is usually high-costing and time-consuming. Thus, the Few-shot Relation Extraction (FSRE) has become a hot topic to alleviate data scarcity. There are two main steps in FSRE. The model is first trained on collections of few-shot tasks (i.e., meta tasks) sampled from the large-scale data containing disjoint relations and then fast adapted to the unseen relation classes with few samples. Recently, many approaches have been proposed for addressing FSRE problems (Han et al., 2018; Gao et al., 2019b; Qu et al., 2020; Baldini Soares et al., 2019). One of the popular algorithms is the Prototype Network (Snell et al., 2017), which is based on the meta-learning framework (Vilalta and Drissi, 2002; Vanschoren, 2018), and the basic framework used in the paper. Prototype Network generates a prototype representation for each relation class in the meta task with the given instances (generally average instances in each relation class). Then, the distance of query instances and each class prototype are calculated for model train and prediction.

To achieve better performance, many works have integrated the relation information into the model to assist prototype representation learning. TD-proto (Yang et al., 2020) enhanced prototypical network with both relation and entity descriptions. CTEG (Wang et al., 2020) proposed a model that learns to decouple high co-occurrence relations, where two types of external information are added. MapRE (Dong et al., 2021) proposed a framework considering both label-agnostic and label-aware semantic mapping information in pre-training and fine-tuning. HCRP (Han et al., 2021) introduced three modules containing hybrid prototype learning, relation-prototype contrastive learning, and task adaptive focal loss for the model improvement.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1822 - 1831
July 10-15, 2022

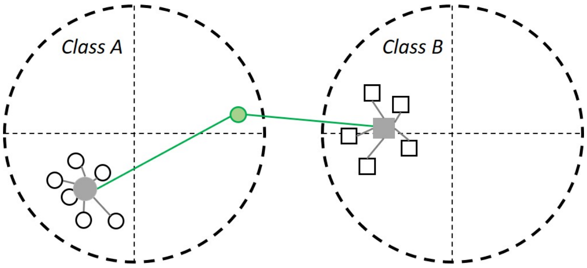

Figure 1: An Illustration of a possible misclassification case. *Class A* and *Class B* represent different relation classes, while circles and squares represent samples of corresponding classes. The green circle represents the sample that needs to be classified.

However, most existing methods mainly utilized instances given in each relation class to obtain the prototype representation (generally to average these instances). Although they implicitly incorporate relation information to constrain the prototype representations learning by contrastive learning, graphs, or attentions, such insufficiently and weakly implicit constraints are limited in dealing with the outlier samples. We provide an example in Fig. 1, where $ClassA$ and $ClassB$ represent two different relation classes; the circles and squares represent the few instances provided by each relation class, and the green circle represents the instance that needs to be predicted. It can be seen that if the provided instances are remote and not "good", the model will tend to classify the instance (green circle) into the $ClassB$. Besides, existing methods also introduced more parameters into the model owing to their specific designs, which is detrimental to FSRE. More parameters mean a more complex model, which increases the overfitting risk on the training set, thereby reducing the generalization ability of the model (Dar et al., 2021).

To address aforementioned issues, this paper proposes a **P**rototype representation **R**ectification **M**ethod, named **PRM**, which focuses on obtaining a better prototype for each relation. Specifically, we propose a prototype rectification module, capable of explicitly utilizing relation information and instances to generate the rectified prototype representations together instead of implicitly using the relation information to guide the generation of the prototype representation. Stated in another way, our model tries to use relation information to rectify the distribution of the original few instances to make it more global and more representative for the overall distribution of the class. PRM transforms the problem of perceiving the class distribution from local instances to perceiving the class distribution from local instances and global information.

In addition, we extend PRM to an advanced version of the existing N-way K-shot setting in few-shot learning (i.e., None-Of-The-Above (NOTA) scenario), where queries could also be none-of-the-above instead of assuming that all query instances belong to the sampled N classes of supports. Although this task brings one more option in classification and is more challenging for the general FSRE model, our model can easily extend to NOTA by introducing an external description "*The relation of the query is not the same as this prototype.*". Experiments on FewRel 1.0 (general scenario) and FewRel 2.0 (NOTA scenario) demonstrate the effectiveness of our proposed method with state-of-the-art results.

The **contribution** of our work mainly lies in three folds:

(1) We introduce the idea of using relation information to rectify prototypes explicitly and propose an effective and parameter-less method, PRM, compared to previous works with always complex modules or networks.

(2) In PRM, a prototype rectification module is utilized, which explicitly utilizes relation information and instances to generate rectified prototypes.

(3) We further extend PRM to the NOTA scenario that is an advanced version of the existing N-way K-shot setting in few-shot learning and then justify the easy transferability of PRM to both NOTA and domain adaptation scenarios.

2 Related Work

Relation Extraction (RE) (Kumar, 2017; Han et al., 2020) is a fundamental task for information extraction, aiming to recognize the relation types that exist between entity pairs in one sentence. The labeling of relations is usually time-consuming and laborious. In addition, in some specific fields, such as the medical field, the available data are few and additional expertise is required. Therefore, the Few-shot Relation Extraction (FSRE) task has attracted more and more attention recently. FSRE aims to fast adapt to unseen relation classes with few samples through training on known relation classes. Garcia and Bruna (2018); Gao et al. (2019b) proposed a large-scale supervised few-shot relation classification dataset, namely, FewRel, and provided the current state-of-the-art results on FewRel, i.e., Proto-BERT (Garcia and Bruna, 2018) and BERT-PAIR. Most subsequent work is evaluated on FewRel. REGRAB (Qu et al., 2020) proposed to incorporate an external global relation graph based on a Bayesian meta-learning method. Except for relation descriptions, TD-proto (Yang et al., 2020) and ConceptFERE (Yang et al., 2021) also introduced entity descriptions to provide clues for relation prediction and enhancing the prototype network. CTEG (Wang et al., 2020) proposed a model that learns to decouple high co-occurrence relations, where two external information is added. MapRE (Dong et al., 2021) proposed a framework considering both label-agnostic and label-aware semantic mapping information for low resource relation extraction in both pre-training and fine-tuning. HCRP (Han et al., 2021) introduced three modules containing hybrid prototype learning, relation-prototype contrastive learning, and task adaptive focal loss for the model improvement. However, these methods always introduced relation information implicitly, which may introduce more parameters and are limited in dealing with outlier samples. Thus, explicitly rectifying the prototypes with relation representations can be a more effective way to incorporate relation information.

3 Task Definition

We follow a typical few-shot task setting, namely the N-way-K-shot setup, which contains a support set $\mathcal{S}$ and a query set $\mathcal{Q}$. The support set $\mathcal{S}$ includes N novel classes, each with K labeled instances. The query set $\mathcal{Q}$ contains the same N classes as $\mathcal{S}$. And the task is evaluated on the query set $\mathcal{Q}$, trying to predict the relations of instances in $\mathcal{Q}$. What's more, an auxiliary dataset $\mathcal{D}_{base}$ is given, which contains abundant base classes, each with a large number of labeled examples. Note the base classes and novel classes are disjoint with each other. The few-shot learner aims to acquire knowledge from base classes and use the knowledge to recognize novel classes. One popular approach is the meta-learning paradigm, which mimics the few-shot learning settings at the training stage. Specifically, in each training iteration, we randomly select N classes from base classes, each with K instances to form a support set $\mathcal{S} = \{s_k^i; i = 1, ..., N, k = 1, ..., K\}$. Meanwhile, G instances are sampled from the remaining data of the N classes to construct a query set $\mathcal{Q} = \{q_j; j = 1, ..., G\}$. The model is optimized by collections of few-shot tasks sampled from base classes so that it can rapidly adapt to new tasks.

For an FSRE task, each instance consists of a set of samples (x, e, y), where x denotes a natural language sentence, $e = (e_h, e_t)$ indicates a pair of the head entity and tail entity, generally called statements, and y is the relation label. The name and description for each relation are also provided as auxiliary support evidence for relation extraction.

4 Proposed Method

In this section, we present the details of our proposed approach. Figure 2 shows the overall structure, where three colors are used to represent different relation types. The inputs are N-way K-shot tasks (sampled from the auxiliary dataset D_{base}), where each task contains a support set S and a query set Q. Meanwhile, we take the names and descriptions of these N classes (i.e., relations) as inputs as well. All input items share the same sentence encoder. The prototype rectification module utilizes relation representations and the mean value of representations of the given instances, called *Original Prototypes*, to generate the rectified prototypes together. Then, the model calculates the distance between the rectified prototypes and each query for both training and predicting.

4.1 Sentence Encoder

We employ BERT (Devlin et al., 2019) as the encoder to obtain contextualized embeddings of support instances and query instances. Then, the statements of these instances are obtained by concatenating the hidden states corresponding to start tokens of two entity mentions following (Baldini Soares et al., 2019). Denote statements of support instances as $\{\mathbf{S}_k^i \in \mathbb{R}^{2d}; i = 1, ..., N, k = 1, ..., K\}$ (i.e., solid circles in Fig. 2), and statements of query instances as $\{\mathbf{Q}_j \in \mathbb{R}^{2d}; j = 1, ..., G\}$ (i.e., diamonds in Fig. 2), where d denotes the hidden size of BERT output.

For each relation, we concatenate the name and description with a template "name: description", and then feed the sequence into the BERT encoder to obtain relation embeddings. For example, we combine the relation name *"debut participant"* with its description *"participant for whom this is their debut appearance in a series of events"* as the sequence *"debut participant: participant for whom this is their debut appearance in a series of events"*. In more detail, we concatenate the hidden states corresponding to the [*CLS*] token and the mean value of hidden states of all tokens to obtain the

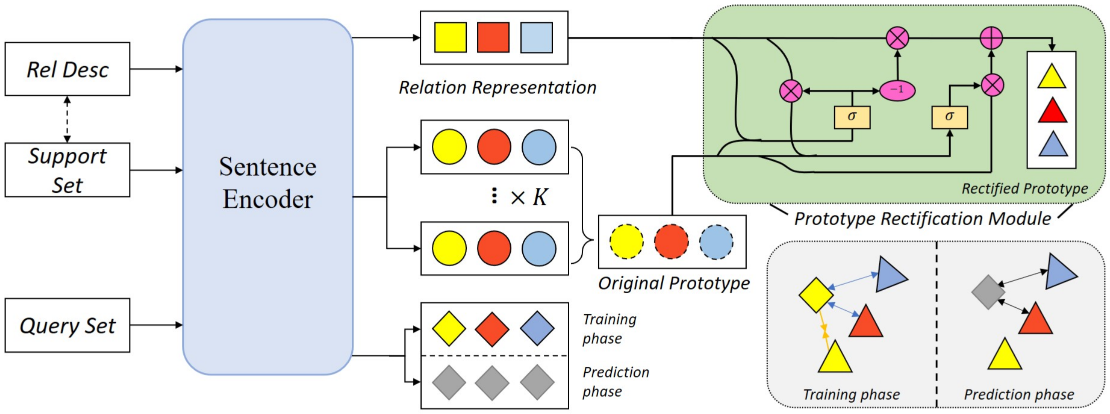

Figure 2: The overall structure of our proposed method. The same sentence encoder is used to encode relations, support set and query set. The relations and *Original Prototypes* are fed into the prototype recification module together to obtain *Rectified Prototypes*.

relation representations $\{R^i \in \mathbb{R}^{2d}, i = 1, ..., N\}$ (i.e., squares in Fig. 2).

4.2 Prototype Rectification Module

Original Prototypes The FSRE task based on the Prototype Network (Snell et al., 2017) paradigm generally first obtains the statement representations of the K instances in each relation class (a total of N relations) in the support set with BERT encoding, and then takes the average of the K statements representations to obtain relation prototypes. We call the prototype obtained in this way *Original Prototype* (i.e., dotted circles in Fig. 2) and denote as $\{P^i_{ori} \in \mathbb{R}^{2d}, i = 1, ..., N\}$. Since *Original Prototypes* is completely obtained from the K instances given for each relation type in the support set, once the K instances are not "good" enough and too far from the true class center, it will cause the model to make wrong predictions.

Rectified Prototypes The name and description of the relationship class (we will refer to them collectively as "relations" in the paper for simplification) are the naive pieces of information that can characterize the overall class distribution and are easily accessible for the FSRE task. Based on the above facts, we propose to utilize relations to rectify *Original Prototypes*, so that the *Rectified Prototypes* (i.e., solid triangles in Fig. 2) contain both the global distribution information in relations and the local distribution information of the K specific instances given for each relation class.

Inspired by GRU (Cho et al., 2014), multiple gate mechanisms are used to control how much *Original Prototypes* are retained and how much relations information is introduced for generating *Rectified Prototypes* together. Firstly, we obtain how much relation information is introduced and how much relation information should be replaced by *Original Prototypes* through a gate mechanism performing on relations and *Original Prototypes*:

$$r^i = \sigma(W_r \cdot [R^i, P^i_{ori}] + b_r) \tag{1}$$

$$\begin{aligned} R^i_{remain} &= ([1] - r^i) \times R^i \\ R^i_{replace} &= r^i \times R^i \end{aligned} \tag{2}$$

where $i = 1, ..., N$; $[\cdot, \cdot]$ denotes concatenation operation; r^i is a weight value for the relation class i. Then another gate is used to control how much information of *Original Prototypes* needed for the *Rectified Prototypes* generation.

$$\begin{aligned} p^i &= \sigma(W_p \cdot [R^i_{replace}, P^i_{ori}] + b_p) \\ P^i_{ori-remain} &= p^i \times P^i, i = 1, \ldots, N \end{aligned} \tag{3}$$

Finally, we obtain *Rectified Prototypes* by the summation of R^i_{remain} and $P^i_{ori-remain}$:

$$P^i_{rec} = R^i_{remain} + P^i_{ori-remain} \tag{4}$$

where $i = 1, \ldots, N$; $P^i_{rec} \in \mathbb{R}^{2d}$. Note that All the representations used above belong to the $\mathbb{R}^{2d}$ feature space.

4.3 Training Objective

The model uses the **vector dot product** way to calculate the distance between the query instance Q and each *Rectified Prototypes* $\{P^i_{rec}, i = 1, ..., N\}$, and then feed the distance into cross entropy loss to form the training loss, which is similar to the contrastive loss. Finally, the training loss $\mathcal{L}$ is defined

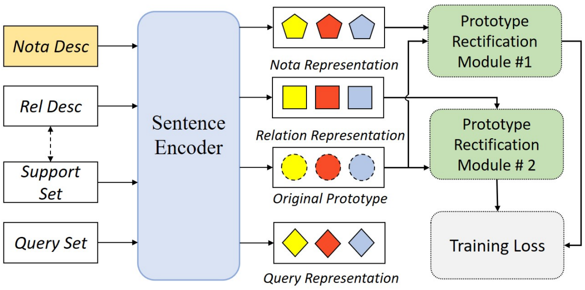

Figure 3: PRM on NOTA scenario. An additional NOTA description is utilized.

via *Rectified Prototypes* and query instances:

$$\mathcal{L} = -\sum_{j=1}^{G} log \frac{exp(P_{rec}^{i} \cdot Q_j)}{\sum_{i=1}^{N} exp(P_{rec}^{i} \cdot Q_j)} \quad (5)$$

In the prediction stage, the model calculates the distance between *Rectified Prototypes* and query instances again and selects the relation class with the shortest distance as the prediction result.

4.4 NOTA Scenario

To verify the effectiveness of the proposed PRM, we further extend it to the none-of-the-above (NOTA) scenario. NOTA is an advanced version of the existing N-way K-shot setting. The original N-way K-shot setting samples N classes, as well as K supporting instances and several queries from each class for each test batch, assuming that all queries belong to the sampled N classes. However, in few-shot NOTA, queries could also be none-of-the-above (NOTA), which brings one more option in classification (i.e., $(N+1)$-way K-shot) and challenges existing few-shot methods. The difficulty in solving the NOTA scenario based on the proposed PRM is how to obtain the representation or distance with queries of the one more class, since this additional class information does not refer to a specific relation class, it represents a meaning that the query instance does not belong to any relation class in support instances.

We introduce an external description to describe the NOTA class, that is *"The relation of the query is not the same as this prototype."*. The NOTA description also shares the same sentence encoder as relations and instances. However, the NOTA description does not share the same prototype rectification module with relations. Specifically, we feed the *Original Prototypes* and NOTA description representations into another prototype rectification module and get prototypes containing NOTA information for each relation in support set, named as *NOTA Prototypes*, $\{P_{nota}^{i}, i = 1, ..., N\}$. Then, we calculate the vector dot product of each query instance to *NOTA Prototypes* as the distance and take the smallest distance value.

$$D_{nota}^{j} = min\{P_{nota}^{i} \cdot Q_j, i = 1, ..., N\} \quad (6)$$

where j denotes the index of query instances and i denotes the index of relations.

Finally, D_{nota}^{j} and distances between *Rectified Prototype* and query instances are fed into cross entropy loss together.

$$\mathcal{L} = -\sum_{j=1}^{G} log \frac{exp(P_{rec}^{i} \cdot Q_j) \ \ or \ \ D_{nota}^{j}}{\sum_{i=1}^{N} exp(P_{rec}^{i} \cdot Q_j)} \quad (7)$$

If the true label is NOTA, then the numerator in the formula above is D_{nota}^{j} during training.

5 Experiments

5.1 Dataset

Our proposed approach is evaluated on the commonly used large-scale FSRE dataset FewRel 1.0 and FewRel 2.0 (Han et al., 2018; Gao et al., 2019b), which are constructed from Wikipedia and consist of 100 relations, each with 700 labeled instances. The average number of tokens in each sentence instance is 24.99, and there are 124,577 unique tokens in total. In addition, the name and description of each relation are also given, providing additional interpretability for each relation. FewRel 2.0 with none-of-the-above setting is a more challenging task to detect none-of-the-above (NOTA) relations for queries. Moreover, FewRel 2.0 with domain adaptation setting is used in the transferability analysis in Section 7.2 that is trained on Wikipedia domain but tested on a different biomedical domain. Only the names of relation labels are given but their descriptions are not available, which makes the task more challenging. Our experiments follow the splits used in official benchmarks with 64 base classes for training, 16 classes for validation, and 20 novel classes for testing.

5.2 Implementation Details

Evaluation N-way K-shot (N-w-K-s or NwKs) is commonly used to simulate the distribution of FewRel in different situations, where N and K denote the number of classes and samples from each class, respectively. In the N-w-K-s scenario, accuracy is used as the performance metric. To be noted, consistent with the official evaluation scripts,

Table 1: Experimental results of FSRE on FewRel 1.0 validation/test set, where N-w-K-s stands for the abbreviation of N-way-K-shot. The table divides the method with BERT as the encoder into two parts, from top to bottom including approaches with the original BERT, and approaches with additional pre-training on BERT. Note that $*$ represents the results of our implementation, others are obtained from results reported by papers or CodaLab.

Model	5w1s (0.15)	5w5s (0.15)	5w1s (0.5)	5w5s (0.5)	Aver.
BERT-PAIR	77.67	84.19	80.31	86.06	82.06
MNAV$^{\natural}$	79.06	85.52	81.69	87.74	83.50
lfc$^{\natural}$	82.61	87.46	80.17	80.84	82.77
PRM (BERT)	83.01	89.30	83.32	85.94	85.39
PRM (CP)	**91.58**	**93.63**	**89.81**	**91.05**	**91.52**

Table 2: Experimental results of FSRE on FewRel 2.0 (NOTA) test set, where 0.15, 0.5 specifies the rate between Q for NOTA and Q for positive, where $^{\natural}$ denotes the result obtained from *Codalab*.

we select the best model for the test by evaluating our model on randomly sampling 10,000 tasks from validation data. Since the label of the test set of the FewRel is not publicly available, we submit the prediction file of our best model to the official leaderboard in *CodaLab* to obtain the final result on the test set.

Training We use BERT-base-uncased and CP (Wang et al., 2020) as the sentence encoder, where CP is a further pre-trained model based on BERT with contrastive learning. We set the total train iteration number as 30,000, validation iteration number as 1,000, batch size as 4, learning rate as 1e-5 and 5e-6 for BERT and CP respectively.

5.3 Comparable Models

5.3.1 General Scenario

We compare our proposed method with eleven baselines in total. Based on the type of encoder, the comparable models are divided into two types, namely, two CNN-based models and nine BERT-based models. Specifically, CNN-based models include: 1) **Proto-HATT** (Gao et al., 2019a), prototypical networks modified with hybrid attention to focus on the crucial instances and features. 2) **MLMAN** (Ye and Ling, 2019), a multi-level matching and aggregation prototypical network. BERT-based models include: 3) **Proto-BERT** (Garcia and Bruna, 2018), a method that measures the similarity of prototypes and query instances for each relation. 4) **BERT-PAIR** (Gao et al., 2019b), a method that measures the similarity of sentence pairs. 5) **REGRAB** (Qu et al., 2020), a Bayesian meta learning method with an external global relation graph. 6) **CTEG** (Wang et al., 2020), a model that learns to decouple high co-occurrence relations, where two external information is added. 7) **ConceptFERE** (Yang et al., 2021), introducing the inherent concepts of entities to provide clues for relation prediction. 8) **MTB** (Baldini Soares et al., 2019), pre-train with their proposed matching the blank task on top of an existing BERT model. 9) **CP** (Peng et al., 2020), an entity masked con-

Model	5-w -1-s	5-w -5-s	10-w -1-s	10-w -5-s
Proto-BERT	84.77	89.54	76.85	83.42
w/ relation info.				
–Add	89.15	93.11	83.63	87.93
–Concat	80.34	85.11	73.78	80.85
w/ PRM	**91.08**	**93.72**	**84.67**	**88.82**

Table 3: Ablation Study in the validation set. w/ is the abbreviations of with. PRM is the abbreviation of Prototype Rectification Method/Module.

trastive pre-training framework for RE while utilizing prototype networks for fine-tuning on FSRE. 10) **MapRE** (Dong et al., 2021), a framework considering both label-agnostic and label-aware semantic mapping information in pre-training and fine-tuning. 11) **HCRP** (Han et al., 2021), introducing three modules containing Hybrid Prototype Learning, Relation-Prototype Contrastive Learning, and Task Adaptive Focal Loss for the model improvement.

To be noted, **MTB**, **CP** and **MapRE** all employ additional pre-training on BERT with Wikipedia data or contrastive learning to get better contextual representation. Moreover, we respectively use the original BERT and CP as our back-end language models. Therefore, among the 11 baselines mentioned above, **Proto-BERT** and **CP** are our most basic baseline.

5.3.2 NOTA Scenario

We compare our proposed method with three baselines in NOTA scenario: 1) **BERT-PAIR** (Gao et al., 2019b), a method that measures the similarity of sentence pairs. 2) **MNAV**, the Rank 1 method reported on *CodaLab*. 3) **lfc**, the Rank 2 method reported on *CodaLab*.

6 Main Results

6.1 General Scenario

All experimental results are shown in Table 1. CNN-based and BERT-based methods are both contained in the table. *Proto-BERT* represents the method on which our model is based, which means that this is the result of the model without introducing any improvement we propose. This result will also be analyzed and displayed in the ablation study. We apply our proposed method to BERT and CP. For obvious comparisons, the former is shown in the first part of BERT-based models, and the latter is shown in the second part of BERT-based models. The **last two rows** show the increase on the test set compared to the basic models used by our method (i.e., Proto-BERT and CP).

There are several observations. We can observe that, regardless of using BERT or CP, our proposed model (i.e., PRM) outperforms all strong baselines. Particularly, when compared to the base model (i.e., Proto-BERT and CP), PRM achieves significant improvements, as shown in the last two rows of Table 1, further confirming the effectiveness of our innovation in explicitly utilizing relation information to guide prototype representation learning. Besides, the performances gains from the 5-w-1-s, 10-w-1-s setting over the current state-of-the-art model (i.e., HCRP) are larger than that of 5-w-5-s, 10-w-5-s, indicating that PRM is more suitable for the few-shot setting. The possible reason might be that when only one instance is given for each relation class (i.e., 1-shot condition), the *Original Prototype* is the statement representation of the one instance, which is more likely to deviate from the class center. Explicit constraints in PRM have a strong ability to pull this *Original Prototype* closer to the class center, while implicit constraints in HCRP are limited to dealing with such conditions.

6.2 NOTA Scenario

Results are shown in Table 2. **MNAV** and **lfc** are derived from *CodaLab* competition website that are 1st and 2nd methods respectively. The proposed PRM outperforms these methods with both BERT and CP baseline models, which demonstrates the effectiveness of PRM.

7 Analysis

7.1 Ablation Study

In order to analyze the effect of each component in our model (i.e., relations combination way and Prototype Rectification Method/Module), we conducted ablation study experiments on FewRel 1.0 and the results are reported in 3. Since labels of the test set of FewRel are not accessible, ablation experiments are performed on the validation set. There are two parts in Table 3. *Proto-BERT* means the baseline method without any relation information. The second part in the table represents the result obtained after adding a certain module, i.e., relations and PRM. In **w/ relation info.**, instead of PRM, we perform two simple way: 1) **Add**: add relation representations to *Original Prototypes* directly. 2) **Concat**: concatenate relation representations and *Original Prototypes*, then through a linear layer for dimension reduction.

	HCRP	PRM
Para.	110.66M	109.49M
Parameters to be adjusted		
Training	learning rate batch size max iteration	
Loss	λ γ	none

Table 4: Comparison on the model complexity.

Model	5w1s	5w5s	10w1s	10w5s	Aver.
Proto-ADV	42.21	58.71	28.91	44.35	43.55
BERT-PAIR	67.41	78.57	54.89	66.85	66.93
HCRP (BERT)	**76.34**	83.03	**63.77**	72.94	74.02
PRM (BERT)	73.98	**88.38**	62.72	**79.43**	**76.13**

Table 5: Accuracy (%) of few-shot classification on the FewRel 2.0 *domain adaptation* test set, where Aver. denotes the average value of four settings.

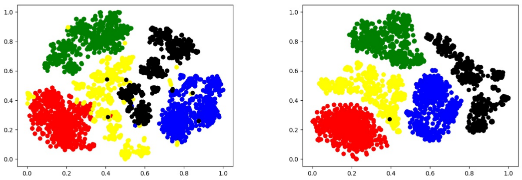

Figure 4: Prototypes Visualization. Left: Original Prototypes; Right: Rectified Prototypes

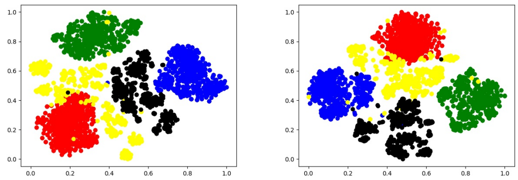

Figure 5: Instances Visualization. Left: Instances in Proto-BERT; Right: Instances in proposed PRM.

We can obtain several observations. First, **Add** achieves better results than Proto-BERT, which proves that the idea of using relations to directly rectify the *Original Prototypes* is indeed effective. However, **Concat** obtains relatively poor results and is even inferior to the original *Proto-BERT*. A possible reason might be **Concat** needs to introduce an extra linear layer to reduce the dimension and thus bring some harmful parameters. Second, **w/ PRM** obtain further improvements on four settings, which demonstrates the effectiveness of PRM.

7.2 Model Complexity and Transferability

As we mentioned in Section 1, our method is simpler and has good transferability compared to the state-of-the-art, i.e., HCRP.

Complexity. The parameters of the two models are shown in Table 4. HCRP utilized three modules to jointly improve the model results, i.e., hybrid features generation, relation-prototype contrastive learning, and task adaptive loss function, whereas PRM only uses the GRM. More details and comparisons can be found in Appendix A, where PRM is compared with different modules of HCRP.

Transferability. We have already demonstrated that PRM still works in the NOTA scenario. In this section, we conduct experiments on domain adaptation settings with FewRel 2.0 and compare the results with HCRP, which is shown in Table 5. It can be seen that PRM is overall better than HCRP, which shows that PRM is also transferable to the domain adaptation setting. The possible reason why PRM is worse than HCRP on 5w1s and 10w1s is that the FewRel 2.0 with domain adaptation setting only provides the name of relations without a specific description, which causes the model to fail to generate a strong relation representation for rectifying the prototypes.

7.3 Visualization

In order to further explore how PRM uses relations to rectify the original prototypes, we give the visualization results in Fig. 4, 5 with BERT on 5-way 1-shot of the validation set of FewRel 1.0. Fig. 4 and Fig. 5 show the visualization of prototypes and query instances respectively, where different colors represent different relation classes. From left to right in figures, **Left** means the original prototypes or statements of query instances without any relation information, **Right** means rectified prototypes or statements of query instances with the proposed PRM.

It can be seen that when the relations are not introduced into the model (**Left**), although the prototypes and instances can also be divided into different classes, the intra-class distances are not close enough, and there are multiple error points (i.e., black points). After introducing the relation information (**Right**), we can see that the error points are reduced while the representations of the same class are closer, especially for prototypes in Fig. 4. The observation shows that our proposed method of explicitly introducing relations has a part of the role of contrastive learning and is indeed beneficial to the improvement of the model.

8 Conclusion

In this paper, we proposed a prototype rectification method, PRM, with relations based on prototype framework, where a prototype rectification module is used for obtaining rectified prototypes. We further extended PRM to a none-of-the-above (NOTA) setting in few-shot learning. Extensive experiments demonstrate the effectiveness of the proposed method. We believe that the idea of finding global information to rectify prototypes explicitly with fewer parameters is general and can be extended to other few-shot tasks.

Abstract

Historical records in Korea before the 20th century were primarily written in Hanja, an extinct language based on Chinese characters and not understood by modern Korean or Chinese speakers. Historians with expertise in this time period have been analyzing the documents, but that process is very difficult and time-consuming, and language models would significantly speed up the process. Toward building and evaluating language models for Hanja, we release the Hanja Understanding Evaluation dataset consisting of chronological attribution, topic classification, named entity recognition, and summary retrieval tasks. We also present BERT-based models continued pre-training on the two major corpora from the 14th to the 19th centuries: the Annals of the Joseon Dynasty and Diaries of the Royal Secretariats.[1] We compare the models with several baselines on all tasks and show there are significant improvements gained by training on the two corpora. Additionally, we run zero-shot experiments on the Daily Records of the Royal Court and Important Officials (DRRI). The DRRI dataset has not been studied much by the historians, and not at all by the NLP community.

1 Introduction

Large-scale historical records in Korea were mostly produced during the Joseon dynasty (1392-1897), and the Institute for the Translation of Korean Classics (ITKC) keeps a comprehensive database of Korean classics at a scale of approximately 9 billion characters. This digital archive is a great resource for Korean historians, but the documents remain in the original Hanja language [2]. Hanja is an extinct language, and as Table 1 illustrates with a simple sentence, Hanja is lexically and syntactically different from modern Korean, as well as simplified and traditional Chinese. Understanding the documents in the digital archive is thus difficult and would benefit greatly from a Hanja language model which can also be used to accelerate the expert translation (Vale de Gato, 2015). There are two corpora we can use to train the language model, the Annals of Joseon Dynasty (AJD), first introduced to the NLP community in (Bak and Oh, 2015), and the Diaries of the Royal Secretariats (DRS) (Kang et al., 2021).

Language	**Sentence**
Hanja	上 御 經筵 。
Modern Korean	임금이 경연에 나아갔다.
Simplified Chinese	国王 参加了 皇家讲座 。
Traditional Chinese	國王 參加了 皇家講座 。
English	The King attended the Royal Lecture .

Table 1: Example sentence in AJD

In this paper, we provide the HUE (**H**anja **U**nderstanding **E**valuation) dataset consisting of chronological attribution, topic classification, named entity recognition and summary retrieval, a suite of tasks to help build and evaluate the Hanja language model. In addition to AJD and DRS, we also work with the Daily Records of the Royal Court and Important Officials (DRRI). Unlike AJD and DRS that have been analyzed by historians and contain their annotations, DRRI lacks such systematic analysis, and we use it for zero-shot learning and introduce it to the NLP community.

We also provide pretrained language models (PLMs) for Hanja trained on AJD and DRS, fine-

---

[1] All codes, models, and dataset are available at `https://github.com/haneul-yoo/HUE.git`

[2] Hanja is a set of characters (script) used in ancient Korean, while Hanmun is a writing style (language) in the same era. However, we will refer to Hanja as a language following the conventions of the previous works.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1832 - 1844
July 10-15, 2022 ©2022 Association for Computational Linguistics

tuned for each task in HUE. Our pretrained models on the corpora from that era outperform the existing language models built for ancient Chinese, confirming the need for specially-trained Hanja language models. We also run additional experiments based on the analyses of entity- and word-level changes on AJD by controlling input conditions by masking named entity and giving the time period as input. Finally, we demonstrate the effectiveness of our Hanja language model for analyzing unseen documents, running zero-shot experiments for chronological attribution and named entity recognition tasks on DRRI.

Our main contributions are as follows:

- We release the HUE dataset and Hanja PLMs to support historians to understand and analyze a large volume of historical documents written in Hanja. To the best of our knowledge, this is the first work proposing Hanja language models and releasing a NLP benchmark dataset for ancient Hanja documents.
- We demonstrate that providing key information such as named entity and document age as input improves the performance of Hanja language model on the HUE tasks.
- We run zero-shot experiments on several HUE tasks from DRRI which have not been discussed in the NLP community, and demonstrate the performance of our Hanja language models on unseen historical documents.

2 Background

2.1 Hanja

Hanja, the writing system based on ancient Chinese characters, was the main writing system in Korea before the 20th century, while Hangul, the unique Korean alphabet, has been the main writing system in Korea from the last century. Formal records from the Joseon dynasty (1392-1897) are written in Hanja, while spoken language and some written documents were in Hangul, developed in the 15th century. This co-existence of the written and colloquial languages has led Hanja to evolve to have the basic syntax of classical Chinese, mixing with the lexical, semantic, and syntactic characteristics of colloquial Korean.

Hanja is significantly different from both modern Korean and modern Chinese. Modern Korean uses a different alphabet and structure, and traditional Chinese shares some characters with Hanja, while the lexicon has evolved greatly to reflect the temporal, geographical, and cultural differences between the Joseon dynasty and modern-day China. Simplified Chinese, the current written language in China has diverged more because of the simplification of the characters. These differences between Hanja and other related languages would lead to suboptimal performance when adopting the current Chinese language models to NLU tasks for the Korean historical Hanja documents.

2.2 Dataset

We describe the three corpora of records written in Hanja during the Joseon dynasty, whose contents and additional information such as topic and named entities are provided by historians in IKTC[3]. Table 2 shows the list of the Hanja corpora used.

Annals of the Joseon Dynasty (AJD) also called Veritable Records of the Joseon Dynasty, is a corpus of 27 sets of chronological records, and each set covers one ruler's reign. AJD has been translated into Korean from 1968 to 1993 and includes relevant tags such as the named entities and dates of the documents [4]. We use AJD for both training our Hanja language models and building the HUE dataset of NLP tasks.

Diaries of the Royal Secretariat (DRS) is a corpus of detailed records of daily events and official schedules of the court from the first King Taejo to the last (27th) Sunjong. Many of the earlier records were lost, and we use the extant records starting from the 16th King Injo. DRS is known to hold the largest amount of authentic historic records and state secrets of the Joseon Dynasty[5]. We use DRS to continue pretraining the language models.

Daily Records of the Royal Court and Important Officials (DRRI) is a corpus of journals written from the 21st King Yeongjo to the last Emperor Sungjong and presumably initiated from the diaries of the crown prince who became the 22nd King Jeongjo after he was enthroned. DRRI has official daily records from both the central and the local governments, so encompasses all events in the country and reports to the king with summaries. DRRI is known to include details and events of

Dataset	Size	Training data	Downstream Tasks	Zero-shot	King
AJD	230K	✔	CA, TC, NER	-	Taejo (1st) - Sunjong (27th)
DRS	1,380K	✔	-	-	Injo (16th) - Sunjong (27th)
DRRI	426K	-	SR	CA, NER	Yeongjo (21st) - Sunjong (27th)

Table 2: Source corpora chosen for building HUE dataset and PLMs

the late Joseon Dynasty not recorded in the AJD or DRS [5], thus making it a good corpus for zero-shot experiments. We use DRRI for the supervised summary retrieval task and the zero-shot experiments for chronological attribution and named entity recognition.

3 HUE Dataset

The HUE (**H**anja **U**nderstanding **E**valuation) dataset is built to assist history scholars to understand Korean historical records written in Hanja. HUE consists of chronological attribution, topic classification, named entity recognition, and summary retrieval, which are tasks that can provide helpful information for studying the documents. We expect that the language models based on HUE will ultimately help historians to interpret unseen historical documents and public to grasp basic concept of those documents. We describe each task in detail below.

3.1 Task Description

Chronological Attribution (CA) is a classification task predicting the ruling king when the document was written. When given a Hanja document from AJD, a classifier outputs one of the 27 kings of the Joseon dynasty. Chronological attribution of the undiscovered document is the first step in anthology to interpret and translate it. Korean historians mostly divide the history of the Joseon Dynasty based on the reigning king, so that we treat chronological attribution as a classification task.

Topic Classification (TC) is a multi-class and multi-label classification task to find the topics of the given document. For TC, we use Hanja document from AJD. We suggest two levels of topics, namely major and minor categories. The major categories consist of 4 broad topics: politics, economy, society, and culture. The minor categories go with 106 sub-topics such as diplomacy, agriculture, and science.

Named Entity Recognition (NER) is a sequence tagging task, identifying the two types of named entities, person and location, from the Hanja document from AJD. We divide train, validation, and test sets such that there are no overlapping entities across the sets.

Summary Retrieval (SR) is a task to find the most relevant summary that matches the content among the summary candidates. For this task, we use DRRI, in which each document is a pair of summary (*gang*) and detailed content (*mok*). Among 426k articles, 265k articles in DRRI dataset contain both *gamg* and *mok*. Also, we exclude those with *gang* longer than *mok*, in which *gang* is not the summary of *mok*. The final dataset contains 213K pairs of content and the corresponding summaries. We describe more details of the preprocessing in the Appendix.

4 Hanja Pretrained Model

As far as we know, there have been no pretrained language models for the Hanja language. One can use related LMs, the pretrained models for ancient Chinese as well as multilingual BERT (Devlin et al., 2019) which includes traditional Chinese in its training corpus. AnchiBERT (Tian et al., 2021) is pretrained in ancient Chinese with the Chinese anthologies written around 1000BC to 200BC. There is some vocabulary overlap between the Hanja documents and traditional Chinese corpora, we can adopt multilingual BERT and AnchiBERT to learn the representations of the Hanja texts.

We propose the pretrained language models suitable for Hanja documents by continuing pretraining those two models on both AJD and DRS. Table 3 shows the ratio of unknown tokens in the test set of AJD by each model. It implies that existing AnchiBERT and multilingual BERT can also be exploited as language models for Hanja documents written in the Joseon dynasty, but the second phase of pretraining on the corpora of that era remarkably decreases the ratio of unknown tokens.

	AnchiBERT (Tian et al., 2021)	mBERT (Devlin et al., 2019)
original	0.88%	0.76%
+AJD/DRS	0.04%	0.04%

Table 3: Unknown token ratio of each model in test set for CA, TC, and NER task in HUE. The first row indicates the results of the original PLMs without any additional pretraining, and the second row indicates those with continued pretraining on AJD and DRS.

5 Experiment

5.1 Experimental Settings

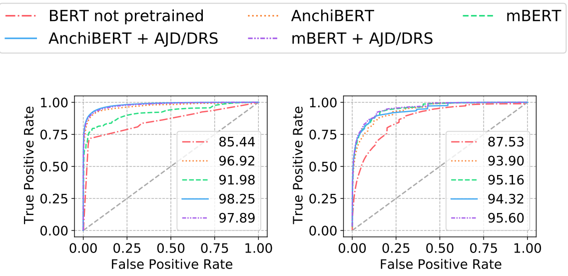
We conduct experiments on HUE with our pretrained model. For the baseline model, we use BERT without pretraining and compare it to various BERT models described in Section 3.1. Specifically, we fine-tune each model to act as a re-ranker in the retrieval task for the summary retrieval. We first retrieve top-k relevant *gang*s (summaries) with BM25 (Robertson and Zaragoza, 2009) among all *gang*s in the dataset. Then, we fine-tune the model as a binary classifier to determine whether the summary matches the content of the *mok* with the cross-entropy loss (Nogueira and Cho, 2019). If the ground truth summary is not included in the top-k relevant summary candidates, we replace the last k^{th} summary with the ground truth. We use $k = 12$ for training and $k = 100$ for inference. As the representative metrics, we present F1 scores for CA, TC, and NER tasks, and Mean Reciprocal Rank (MRR) for SR. The detailed results with other metrics are also available in Appendix.

5.2 Overall Results

Table 4 shows the overall experimental results. The bold and the underlined texts in the table specify the best and the second best result, respectively. BERT without any pretraining shows the poorest results across all the tasks. AnchiBERT and mBERT, which are existing language models on the relevant domains, show better results, and the models continued pretraining on Hanja documents achieve the best performance among all tasks. This tendency indicates that all these tasks on understanding historical documents require pretraining language models on time-specific and domain-specific data.

AnchiBERT pretrained on the Hanja corpora shows slightly better performance than mBERT pretrained on the same corpora. We assume this is because the original training corpora of AnchiBERT are much closer to the Hanja documents, even the era of those two corpora are completely different. The writing style of both Hanja documents in the Joseon dynasty and anthologies in ancient China had come from Classical Chinese and share similarities. On the other hand, the training corpora of mBERT is a contemporary texts whose characters contains Traditional Chinese, but the structure and the format might be considerably changed.

Chronological Attribution (CA) Our models continued pretraining on Hanja corpora outperform other baselines on CA. Detailed analysis on CA result is illustrated in Section 6.1.



(a) Div 1 (4 classes) (b) Div 2 (106 classes)

Figure 1: ROC Curve and AUC for Topic Classification. Each value in the legend indicates the AUC score.

Topic Classification (TC) Figure 1 gives ROC curves and AUC values of each model on each task. Our models show the similar trends to the overall results, outperforming other language models. For the evaluation results including F1 score, we find and set the best threshold to each label by Youden's index (Youden, 1950).

While F1 score goes down as the number of classes increases from 4 to 106, there is no significant difference on AUC value. This might result from consistently high recall achieving around 90% on both tasks. It indicates that the threshold is too low and models tend to predict plausible topics as many as they can, which might be solved by controlling the threshold. AnchiBERT pretrained on AJD and DRS, which shows the best performance, predicts 6.39 labels in average, while the average number of ground truth labels of the minor categories is 1.97. This is probably due to the meaning overlaps in minor categories. For instance, minor categories such as revenue, finance, general price level, and commerce are the sub-categories of economy in the major categories, whose use case cannot be strictly distinguished. It would be more appro-

	CA	**TC**		**NER**		**SR**
		Major	**Minor**	**Person**	**Location**	
	F1	F1	F1	F1	F1	mrr
BERT not pretrained	54.26	68.91	61.52	92.13	87.10	52.85
mBERT (Devlin et al., 2019)	75.29	79.59	76.46	91.63	86.02	67.06
AnchiBERT (Tian et al., 2021)	75.74	85.81	75.22	**93.28**	**88.01**	67.92
mBERT + AJD/DRS	77.77	87.13	77.84	92.83	87.90	73.88
AnchiBERT + AJD/DRS	**79.33**	**88.33**	**78.10**	93.13	87.91	**74.29**

Table 4: Evaluation results of PLMs on HUE dataset

priate in this case to provide all plausible topics roughly rather than suggesting the one only with high certainty.

Named Entity Recognition (NER) NER also indicates similar trends to the overall benchmark tasks, but with a small gap among models including BERT without pretraining. It implies that NER in Hanja documents is a comparably easy task. This might result from certain patterns in named entities in Hanja. Most of the person entities are 3 letters starting with the common characters (family name), and most of the location entities end with the common characters meaning locations or buildings. All models tend to predict person entities better than location entities.

Summary Retrieval (SR) All fine-tuned BERT-based re-rankers outperform BM25 whose MRR is merely 29.87%, mostly retrieving the ground truth answer at the first trial. Likewise, our models shows the best results, while BERT without pretraining show the lowest MRR. It additionally implies that BERT-based re-rankers might be exploited for retrieving relevant documents from different chronicles in terms of written style or contents.

5.3 Effect of Entity and Document Age on Language Model

We investigate whether providing additional information as input can improve the performances of language models. For CA, we mask all named entities in the input and fine-tuned the language model on masked data to examine the impact of entity information. For TC and NER, we concatenate document age information to the input text and run comparative experiments to verify the importance of time period on historical texts.

	CA (Masked)
BERT not pretrained	75.07 (Δ 20.81)
mBERT (Devlin et al., 2019)	83.44 (Δ 8.15)
AnchiBERT (Tian et al., 2021)	82.45 (Δ 6.71)
mBERT + AJD/DRS	83.57 (Δ 5.80)
AnchiBERT + AJD/DRS	**83.58** (Δ 4.25)

Table 5: F1 scores on Chronological Attribution given named entities masked. The value inside parenthesis indicates the increase in performance after masking the named entities.

Entity-Masked Chronological Attribution Table 5 shows the difference on experimental results in CA when the named entities in the given input texts are masked. Compared to the default settings which does not mask named entities, all models show significant improvements. This is probably because models can truly focus on the content and changes in writing style without any disturbance of location entities consistently used for the whole era. Fine-tuned models with entity masked inputs also achieve nearly the same level of performance in the inference with plain inputs including named entities. It suggest to fine-tune models masking named entity in CA, considering the real scenario whose inference texts lack time period information.

Topic Classifciation and Named Entity Recognition with the Age of Document It is for granted to regard that historical texts written over several eras reveal the time changes with respect to lexical choices and contents. Section 6.2 confirms the hypothesis above in terms of n-grams changes over time. Table 6 shows gaps between experimental results of TC and NER given which king reigned when the document was written. Providing document age definitely increases the performance of classifying topics and tagging named

	TC		NER	
	Major	Minor	Person	Location
BERT not pretrained	86.99 (Δ 18.08)	70.58 (Δ 9.29)	91.90 (Δ -0.23)	86.43 (Δ -0.68)
mBERT (Devlin et al., 2019)	**93.57 (Δ 13.98)**	73.64 (Δ 3.63)	93.71 (Δ 2.08)	87.84 (Δ 1.83)
AnchiBERT (Tian et al., 2021)	89.32 (Δ 3.51)	73.57 (Δ 4.27)	94.82 (Δ 1.54)	89.84 (Δ 1.83)
mBERT + AJD/DRS	90.02 (Δ 2.89)	**74.84 (Δ 3.56)**	**94.88 (Δ 2.05)**	**89.88 (Δ 1.98)**
AnchiBERT + AJD/DRS	90.02 (Δ 1.69)	74.54 (Δ 2.47)	94.70 (Δ 1.57)	89.46 (Δ 1.54)

Table 6: F1 scores on topic classification and named entity recognition given document age. The value inside parenthesis indicates the difference on performance after providing document age.

entities. There was a big gap on difference with non-pretrained BERT in TC, which is probably due to the poor performance of itself in the original setting. All models show similar trends on both tasks with improved performances compared to the original settings without document age as input. It is an obvious result considering that the first step for ancient manuscript is assuming the written era. It implies the significance of chronological attribution task in HUE, conveying that chronological attribution task might improve the performance of other HUE tasks.

5.4 Zero-shot Experiment

Countless number of Hanja documents still remain without any analysis and new documents continue to be unearthed. Therefore, we run zero-shot experiments to verify the effectiveness of our language models on extracting information from the historical documents irrelevant to the training corpora. We use DRRI dataset which is not included in both pretraining and fine-tuning data of our Hanja language models and execute CA and NER.

Table 7 shows experimental results with CA and NER on DRRI. All models perform comparably well on the both tasks, regarding that random model will achieve approximately 3.70% performances with 27 classes in CA. Also, all models in CA commonly show high precision which might be due to the monotonous and redundant phrases in the veritable records. It shows similar trends compared to the Table 4, but the gap among models was notably emphasized in the zero-shot settings. This results imply that our CA models might be exploited for the time period prediction of unseen documents in anthology with a reliable level.

Our models outperform others on NER achieving absolutely high performances, though entity maps between AJD and DRRI do not match strictly. Interestingly, all models tend to predict location entities better than person entities which is the opposite result compared to the original NER on AJD. It is probably due to the characteristics of each entity, where location entities are all commonly used in nationwide while person entity might differ by situation. Further analysis on person and location entities in the view of time changes is described in Section 6.2. We present that our models trained on the corpora of the Joseon dynasty provide reliable results on unseen records, implying that our model can be exploited for the low-resourced documents.

6 Further Analysis

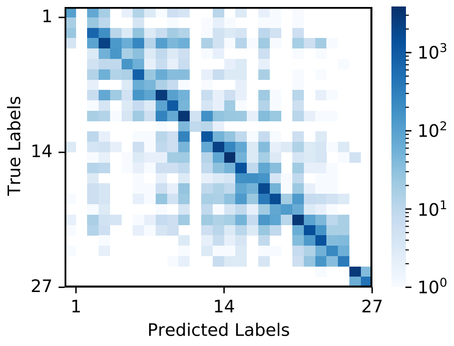
6.1 Do Historical Events Affect Language Models?

To figure out the effect of historical events on models' prediction, we analyzed the output of language models on CA. Figure 2 (a) shows a log-scale confusion matrix of AnchiBERT continued pretraining on AJD and DRS, and Figure 2 (b) indicates the mean absolute error between the predicted king order and the ground truth per each King. The x-axis in the Figure 2 (b) means the changes of time by the king reign period. Each bar in Figure 2 (b) indicates the mean absolute error between the order of ground truth king and the one of predicted, and the line graph means the number of samples in the test set.

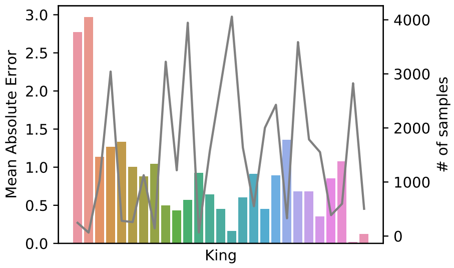
The results of the last two Emperors, Gojong and Sunjong, are remarkable in that the model rarely gets confused with those two labels to others and tends not to fail, showing notable difference on Figure 2 (a) and significantly low mean absolute error on Figure 2 (b). We believe that this is because our model learns the difference between those two records and the others in the historical view and get cues to distinguish them. The last two records are not treated as AJD in general, since those records were inspected and produced by the

	CA	NER	
		Person	Location
BERT not pretrained	26.94	68.50	39.86
mBERT (Devlin et al., 2019)	32.19	72.08	**83.36**
AnchiBERT (Tian et al., 2021)	30.65	71.85	77.23
mBERT + AJD/DRS	35.28	**88.48**	72.08
AnchiBERT + AJD/DRS	**35.85**	82.86	76.53

Table 7: F1 scores of chronological attribution and named entity recognition task on DRRI in zero-shot settings



(a) Log-scale Confusion Matrix



(b) Mean Absolute Error per King

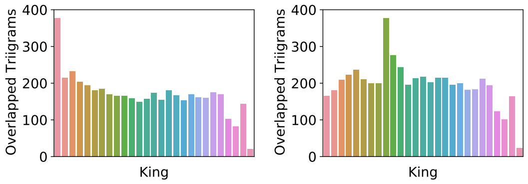
Figure 2: Chronological attribution results with AnchiBERT + AJD/DRS. Figure (a) shows the confusion matrix. In Figure (b), each bar indicates the mean absolute error and the line indicates the number of samples for each king.

Office of Governer-General during the Japanese colonial period with the view of Empire of Japan who ruled Korea [6].

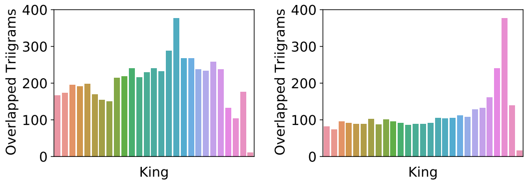
The mean absolute error of the predicted order of each king achieved the difference around one, except for the first King Taejo and the second King Jeongjong, whose errors are almost doubled. We hypothesize that this is mainly because there are too small number of examples in those classes. A similar tendency where the more samples are, the less mean absolute error be has been observed in other classes. Also, the writing style of AJD had settled down from the third King Taejong, and those noisy records might confuse models to predict the exact dates.

6.2 Do Time Changes Affect Written Texts?

It stands to reason that AJD written in five centuries reveal the features of the language changes. In this section, we investigate the hypothesis above with respect to the named entities and n-grams.



(a) Taejo (1st King) (b) Seongjong (9th King)



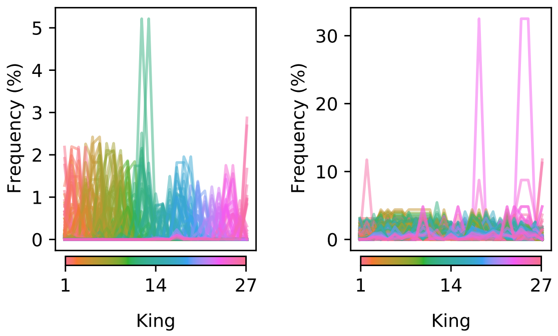
(c) Hyojong (17th King) (d) Cheoljong (25th King)

Figure 3: Number of overlapped trigrams per king era. It shows the changes of trigrams over kings whose x-axis shows the kings and the y-axis shows the number of overlapped trigrams.

Words Change over Time We analyze how frequently words change over time. For each king, we plot how many trigrams overlap by each king era in the order. Figure 3 shows overlapped trigrams in the 1st, 9th, 17th, and 25th king and the detailed results with all kings are described in Appendix. It is consistently observed that the closer the king era is, the more trigrams are overlapped. These changes result from not named entity but lexical choices, considering that person and location enti-

---

[6] `http://esillok.history.go.kr/`



(a) Person (b) Location

Figure 4: Relative frequency change of top-10 named entities per king. Each line indicates the change of the relative frequency of one entity over time, and the color of the line indicates the king era in which the entity is contained in the top-10 entities. The x-axis represents the time (the kings in the order) and the y-axis represents the relative frequency in each king era.

ties account for 6.38% and 2.05% in the characters of AJD, respectively. It verifies that words used in Joseon dynasty had changed over time gradually, and it enables the language models to capture those features.

Named Entity Changes over Time We investigate how the named entities had been used over time. In particular, we show frequency rates of top-10 frequently-used named entities by each king era and how they change over time in Figure 4. It implies a strong correlation between person entity and the passage of time, while there is no explicit correlation to location entity. Most person entities include officials of the time or the previous kings, relevant to the time. In contrast, most location entities include neighboring countries or place names in the Joseon, which are less dependent on the time. The examples of frequently appeared named entities are described in Appendix.

7 Related Work

ML based NLP techniques have been recently applied to anthology to discover historical documents such as authorship attribution (Ouamour and Sayoud, 2012; Sayoud and Ouamour, 2017; Reisi and Mahboob Farimani, 2020; Hossain et al., 2020), NER (Won et al., 2018; Palladino et al., 2020), and manuscript age detection (Adam et al., 2018). Assael et al. (2022) proposed Ithaca to restore ancient Greek inscriptions and perform geographical attribution and chronological attribution of them.

Along with these works, several works provide language models suited for historical texts in ancient languages and evaluate those models on existing NLU tasks, which aims to support understanding those documents considering that the target languages are mostly extinct. Bamman and Burns (2020) propose Latin BERT for part-of-speech tagging in ancient Latin script. Tian et al. (2021) suggest AnchiBERT and evaluate their model on some NLP tasks including poem topic classification.

However, there has been no research attempting to propose language models in Hanja, which is a dead language in Korea but absolutely necessary to explore Korean history. Most of the studies with Hanja only shed lights on translating historical Hanja documents and use AJD as their corpus (Park et al., 2020; Jin et al., 2020; Kang et al., 2021).

8 Conclusion

We present HUE (**H**anja **U**nderstanding **E**valuation) dataset and BERT-based pretrained language models for classical Hanja documents. HUE dataset includes diverse tasks that can support analyzing historical documents written in Hanja which is an extinct language in Korea: Chronological Attribution (CA), Topic Classification (TC), Named Entity Recognition (NER), and Summary Retrieval (SR). Our models pretrained on Hanja corpora outperform other language models and we observe their performance on zero-shot settings with DRRI which is the dataset never been introduced in NLP community. The experimental results in king prediction imply that our models capture the historical events or facts disclosed in the texts. We also explore several methods to support Hanja language models such as masking named entities and giving document age as input sources, based on the analyses on textual features in AJD.

Help of adequate resources in Hanja documents might could fill some caveats in our work which lacks additional experiments and analyses on the records of different genre such as poetry, novel, and humanities resulting from the low resources that we can exploit. However, we expect that our dataset and accompanying language models might facilitate future works on historical documents written in Hanja by providing fundamental resources to leverage unknown Hanja corpora.

Appendix

A Model

Table 8 shows hyperparameter settings of our models. We used Intel(R) Xeon(R) Silver 4114 (40 CPUs) and GeForce RTX 2080 Ti 10GB (4 GPUs) for all experiments including training, fine-tuning, and inference.

Hyperparameter	Value
Batch Size	32
Early Stopping Patience	3
Hidden Size	768
Learning Rate	2e-5
Learning Rate Scheduler	Linear
Max Sequence Length	512
Number of Hidden Layers	12
Optimizer	AdamW
Vocab Size	11270

Table 8: Model configuration

B HUE Dataset

B.1 Dataset Size

	Train	Dev	Test
CA	330,469	41,309	41,309
TC	330,424	41,303	41,304
NER	385,915	13,417	13,418
SR	169,840	21,570	21,296

Table 9: Data split in HUE dataset

B.2 Source Corpora

B.2.1 Data Collection Process

We crawl AJD [7], DRS [8], and DRRI [9] from the comprehensive database for Korean classics which are publicly available published by IKTC. All source corpora are fully tagged with the written ages and named entities, while their entity maps differ to each other. AJD also provides topics which is tagged by the experts in the translation process.

B.2.2 Dataset Preprocessing

Table 10 shows good and bad example in DRRI to use as summary retrieval dataset. Bad examples mostly written from the 21st King Yeongjo to early in the 22nd King Jungjo describe daily lifes of the crown prince who is King Jeongjo. The bad example in Table 10 is depicting his study. These examples tend to present extremely short *mok*s which cannot be treated as summary and content, while the offical records on administrative has much longer *mok*s.

C Discussion

C.1 Trigram Changes Over Time

Figure 5 shows the changes of trigrams over all kings. It clearly delivers the changes of trigrams as time goes by. We can observe the same trend in either unigram or bigram.

C.2 Top-5 Named Entities by Kings

Table 11 shows top-5 person and location named entities in three King reigns. All person entities except King Sejong, the most frequent entity in Munjong, are officials in the reign periods, which is different by time changes. In contary, all location entities are the name of place, palace or site, showing some entities overlap among kings.

D Experimental Results

For CA, we measure the Quadratic Weighted Kappa score (QWK score) as metrics that treat each king label hierarchically.

Since TC is a multi-label classification task whose example might have multiple labels as the answer, we measure Hamming score along with accuracy. In this case, accuracy is the exact match score, and the hamming score is the accuracy of subset matched, $\mid T \cap P \mid / \mid T \cup P \mid$, where T is set of true labels and P is set of predicted labels (Godbole and Sarawagi, 2004). For the evaluation results in Table 13, we find and set the best threshold to each label by Youden's index. All pretrained models outperform BERT without pretraining, and two LMs re-trained on hanja documents show the best performances.

Abstract

On the WikiSQL[1] benchmark, most methods tackle the challenge of text-to-SQL with predefined sketch slots and build sophisticated sub-tasks to fill these slots. Though achieving promising results, these methods suffer from over-complex model structure. In this paper, we present a simple yet effective approach that enables auto-regressive sequence-to-sequence model to robust text-to-SQL generation. Instead of formulating the task of text-to-SQL as slot-filling, we propose to train sequence-to-sequence model with Schema-aware Denoising (SeaD), which consists of two denoising objectives that train model to either recover input or predict output from two novel *erosion* and *shuffle* noises. These model-agnostic denoising objectives act as the auxiliary tasks for structural data modeling during sequence-to-sequence generation. In addition, we propose a clause-sensitive execution guided (EG) decoding strategy to overcome the limitation of EG decoding for generative model. The experiments show that the proposed method improves the performance of sequence-to-sequence model in both schema linking and grammar correctness and establishes new state-of-the-art on WikiSQL benchmark. Our work indicates that the capacity of sequence-to-sequence model for text-to-SQL may have been under-estimated and could be enhanced by specialized denoising task.

1 Introduction

Text-to-SQL aims at translating natural language into valid SQL query. It enables layman to explore structural database information with semantic question instead of dealing with the complex grammar required by logical -form query. On the WikiSQL benchmark, most models adopt a sketch-based slot filling approach. It decomposes the task of convert query to SQL into several sub-tasks that are relatively easy to handle, e.g., the 'SELECT' column mentioned or the query span corresponding to a condition value. The entire SQL can be recovered from the results of the sub-tasks deterministically.

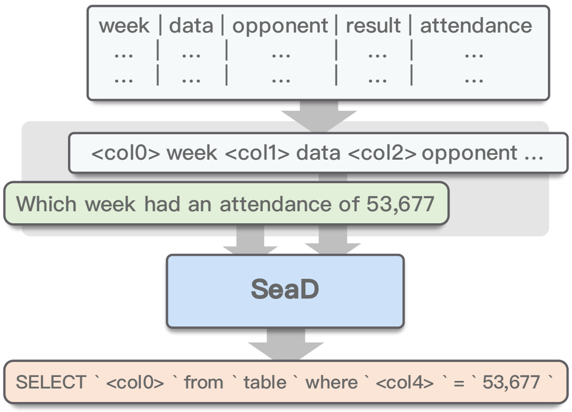

Figure 1: SeaD regards text-to-SQL as seq2seq generation task. During inference, given natural language question and related database schema, SeaD directly generates corresponding SQL sequence in an auto-regressive manner.

Though being a typical sequence-to-sequence (seq2seq) task, auto-regressive models (LSTM, Transformer, etc.), however, fail to achieve state-of-the-art results for text-to-SQL task. Previous works attribute the sub-optimal results of seq2seq models to three major limitations. First, SQL queries with different clause order may have exact same semantic meaning and return same results by execution. The token interchangeability may confusion model that based on seq2seq generation. Second, the grammar constraint induced by structural logical form is ignored during auto-regressive decoding, therefore the model may predict SQL with invalid logical form. Third, schema linking, which has been suggested to be the crux of text-to-SQL task, is not specially addressed by vanilla seq2seq model.

In this paper, we present a simple yet effective method to boost the performance of seq2seq model for text-to-SQL task. Instead of building extra sub-

module or putting constraint on model output, we propose two novel schema-awared denoising objectives trained along with the original seq2seq generation task. These denoising objectives deal with the intrinsic attribute of logical form and could facilitate schema linking required for text-to-SQL task. The inductive schema-awared noises can be categorized into two types: *erosion* and *shuffle*. Erosion acts on schema input by randomly permute, drop and add columns into the current schema set. The related schema entity in target SQL query will be jointly modified according to the erosion result. Shuffle is applied via randomly re-ordering the mentioned entity and values in natural language (NL) or SQL with respect to the schema columns. During training procedure, shuffle is performed during monolingual self-supervision that trains model to recover original text given the noised one. Erosion is applied to seq2seq task that trains model to generate corrupted SQL sequence, given NL and eroded schema as input. These proposed denoising objectives are combined along with the origin seq2seq task to train a SeaD model. In addition, to deal with the limitation of execution-guided (EG) decoding, we propose a clause-sensitive EG strategy that decide beam size with respect to the clause token that is predicted. The proposed method establish new state-of-the-art on the WikiSQL benchmark.

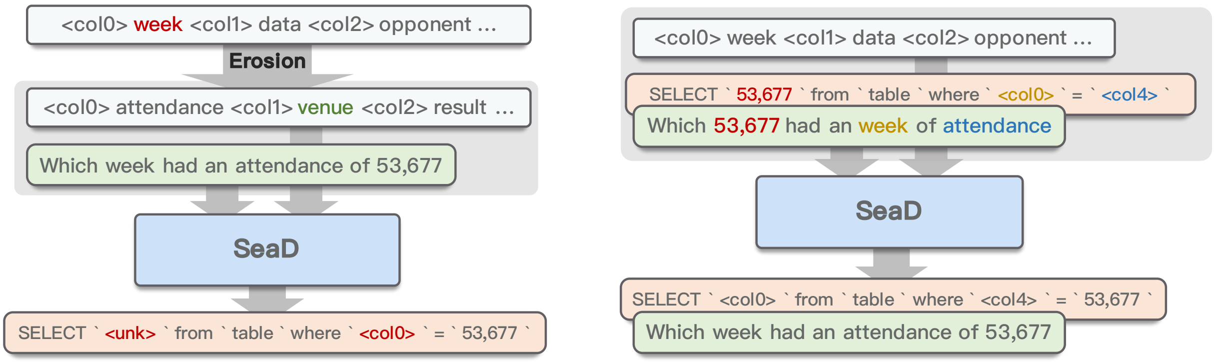
The main contribution of this work is the schema-aware denoising objectives that are designed for text-to-SQL task. The denoising objectives are model-agnostic and could apply to any seq2seq model that are trained in auto-regressive manner. In addition, we also propose a clause-sensitive EG decoding strategy, which can improve the searching efficiency of EG during seq2seq generation. The results of the work demonstrate the effectiveness of the schema-aware denoising approach and shad lights on the importance of task-oriented denoising objective.

2 Related Work

Semantic Parsing The problem of mapping natural language to meaningful executable programs has been widely studied in natural language processing research. Logic forms (Zettlemoyer and Collins, 2012; Artzi and Zettlemoyer, 2011, 2013; Cai and Yates, 2013; Reddy et al., 2014; Liang et al., 2013; Quirk et al., 2015; Chen et al., 2016) can be considered as a special instance to the more generic semantic parsing problem. As a sub-task of semantic parsing, the text-to-SQL problem has been studied for decades. (Warren and Pereira, 1982; Popescu et al., 2003; Li et al., 2006; Giordani and Moschitti, 2012; Wang et al., 2017). Slot-filling model (Hwang et al., 2019; He et al., 2019a; Lyu et al., 2020) translates the clauses of SQL into subtasks, (Ma et al., 2020) treat this task as a two-stage sequence labeling model. However, the convergence rate between subtasks is inconsistent or the interaction between multiple subtasks may lead to the model may not converge well. Like lots of previous work (Dong and Lapata, 2016; Lin et al., 2018; Zhong et al., 2017; Suhr et al., 2020; Raffel et al., 2019), we treat text-to-SQL as a translation problem, and taking both the natural language question and the DB as input.

Hybrid Pointer Networks Proposed by (Vinyals et al., 2015), copying mechanism (CM) uses attention as a pointer to copy several discrete tokens from input sequence as the output and have been successfully used in machine reading comprehension (Wang and Jiang, 2016; Trischler et al., 2016; Kadlec et al., 2016; Xiong et al., 2016), interactive conversation (Gu et al., 2016; Yu and Joty, 2020; He et al., 2019b), geometric problems (Vinyals et al., 2015) and program generation (Zhong et al., 2017; Xu et al., 2017; Dong and Lapata, 2016; Yu et al., 2018; McCann et al., 2018; Hwang et al., 2019). In text-to-SQL, CM can not only facilitate the condition value extraction from source input, but also help to protect the privacy of the database. In this paper, we use a Hybrid Pointer Generator Network which is similar to (Jia and Liang, 2016; Rongali et al., 2020) to generate next step token.

Denoising Self-training Language model pretraining (Devlin et al., 2018; Yang et al., 2019; Liu et al., 2019; Lan et al., 2019) has been shown to improve the downstream performance on many NLP tasks and brought significant gains. (Radford et al., 2018; Peters et al., 2018; Song et al., 2019) are beneficial to seq2seq task, while they are problematic for some tasks. While (Lewis et al., 2019) is a denoising seq2seq pre-training model, which is effective for both generative and discriminative tasks, reduces the mismatch between pre-training and generation tasks. Inspired by this, we propose a denosing self-training architecture in training to learn mapping corrupted documents to the original.



(a) Erosion

(b) Shuffle

Figure 2: The proposed schema-aware denoising procedure. (a) Erosion denoising randomly drops, adds and re-permutes schema columns. The related column entities in ground-truth SQL sequence will be jointly modified or masked out with respect to the erosion results of the current schema set. Erosion objective trains model to predict the modified SQL sequence under noised input. (b) Shuffle denoising objective re-permutes the mentioned entities in SQL or NL sequence, and trains model to reconstruct the sequence with the correct entity order.

3 Methodology

Given natural language question Q and a schema S, our goal is to obtain the corresponding SQL query Y. Here the natural question $Q = \{q_1, ..., q_{|Q|}\}$ denotes a word sequence, the schema $S = \{\mathbf{c}_1, ..., \mathbf{c}_{|S|}\}$ is composed of a set of columns, where each column $\mathbf{c}_i = \{c_1, ..., c_{|\mathbf{c}_i|}\}$ is a sequence of words. $Y = y_1, ..., y_{|Y|}$ denotes the token-wise raw SQL sequence. We approach this task with directly auto-regressive generation, i.e., predicting the SQL sequence token by token. We choose Transformer as our base architecture, which is a widely adopted in seq2seq translation and generation tasks. In this section, we first present the sample formulation that transform text-to-SQL into typical seq2seq task, followed by a brief introduce of the Transformer architecture with pointer generator. Then we describe the proposed schema-aware denoising method and clause-sensitive EG decoding strategy.

3.1 Sample Formulation

Given training samples $\{X_i, Y_i\}, i = 1, ..., N$, $X = \{Q, S\}$, where Q denotes the NL sequence and S denotes the schema set, Y is the SQL sequence. Sample formulation is a function

$$\widetilde{X}, \widetilde{Y} = format(X, Y)S$$

that transforms heterogeneous data into pairwise token sequence. It is performed by filling template that acts as a prompt to guide seq2seq model to generate different types of token with respected to various contexts. For schema formulation, each column name is prefixed with a separate special token `<coli>`, where `i` denotes the i-th column in the schema set. The column type of each column is also append to the name sequence to form the template for a schema column `<coli> col name : col type`. All columns in schema is formulated and concatenated together to compose the input sequence for schema. The schema sequence is further concatenated with the NL sequence for model input. We explicitly introduce schema-mention alignment to NL sequence by surrounding schema names that are mentioned in NL sequence with bracket tokens `[]`, in order to improve the learning of schema linking,

For SQL sequence, we initialize it with raw SQL query and perform several modifications on it: 1) surrounding entities and values in SQL query with a " ` " token, and dropping other surroundings if exist; 2) replacing col entities with their corresponding separate token in schema; 3) inserting spaces between punctuation and words. The formulated SQL sequence is illustrated in Figure 1. The formatting procedure improves consistency between tokenized sequences of source and target, and contributes to the identification and linking of schema entities.

3.2 Transformer with Pointer

Following the previous works on seq2seq semantic parsing, we use Transformer (Vaswani et al., 2017) as the backbone of our model. The vanilla Transformer generate tokens with a feed-forward layer that computes the unnormalized score over the target vocabulary. In text-to-SQL task, however, most schema and value mentions can be extracted from the input sequence. Therefore, we adopt a Hybrid Pointer Generator Network (Jia and Liang, 2016) in our architecture to generate tokens from the target vocabulary V or copy from the input context.

During inference, input sequence X is first encoded into a sequence of hidden states H_{enc}. Then, the decoder produces the hidden states h_{dec} for step t based on previously generated sequence and encoded output. The unnormalized scores $scores_v = \{s_1, ..., s_{|V|}\}$ over V can be obtained from h_{dec} through a feed-forward layer. $V = \{\mathbf{V}_q, \mathbf{V}_c, \mathbf{V}_s\}$ is the target vocabulary, where $\mathbf{V}_q$ denotes corpora token vocabulary, $\mathbf{V}_c$ denotes column token set and $\mathbf{V}_s$ denotes avaliable SQL keywords, e.g. `SELECT, MAX, MIN`, etc. The decoder output h_{dec} is also used to compute the unnormalized attention scores $score_s = \{i_1, ..., i_{|X|}\}$ over the input sequence tokens, where $|X|$ is the sequence length.

We concatenate $scores_v$ and $score_s$ to get the hybrid score $score_{hybrid} = \{s_1, ..., s_{|V|}, i_1, ..., i_{|X|}\}$, where the first $|V|$ elements represent the output distribution of the target vocabulary V and the remained $|X|$ are pointers tokens referred to corresponding input tokens. The final probability distribution is computed by $P = \textbf{softmax}(score_{hybrid})$, to determine the next token during generation.

3.3 Schema-aware Denoising

Similar to masked language modeling and other denoising task, we propose two schema-aware objectives, erosion and shuffle, that train model to either reconstruct the origin sequence from noising input or predict corrupted output otherwise. The denoising procedure is illustrated in Figure 2.

3.3.1 Erosion

Given input sample $\{Q, S, Y\}$, erosion corrupts the schema sequence S with a serial compositions of three noising operations:

Permutation Re-order the concatenation sequence of schema columns during schema formulation.

Removal For each column, remove it with a dropping probability p_{drop}.

Addition With a addition probability p_{add}, extract a column from another schema that exists in the training database and insert it into current schema set.

During all operations above, the order of separating special tokens remains unchanged, therefore the corresponding anonymous entities in SQL query should be updated along with the erosion operations in schema sequence. In particular, if a column entity mentioned in SQL query is removed during erosion, we substitute the corresponding column token in SQL with a masking token `<unk>` to cope with the absence of the schema information. With such joint modification for schema and SQL sequence, the model is required to identify the schema entities that are truly related to the NL question and learns to raise an unknown exception whenever the schema information is insufficient to compose the target SQL.

Algorithm 1: Training procedure for schema-aware denoising

```
Input: training corpus
       $\mathcal{X} = \{(Q_i, S_i, Y_i)\}, i \in 1, ...|\mathcal{X}|$,
       S2S Transformer $\Theta$
foreach $(Q_i, S_i, Y_i) \in \mathcal{X}$ do
    $T_{src}, T_{tgt} \leftarrow Q_i, Y_i$;
    $T_{tgt}, S_i \leftarrow$ Erosion ($T_{tgt}$, $S_i$)
    with $P_{shuffle}$ do
        with $P_{swap}$ do
            $T_{src}, T_{tgt} \leftarrow T_{tgt}, T_{src}$;
        end
        $T_{src} \leftarrow$ Shuffle ($T_{tgt}$)
    end
    $T_{type} \leftarrow$ SeqType ($T_{tgt}$)
    if $T_{type} = SQL$ then
        $T_{prefix} \leftarrow$ <2sql>;
    else
        $T_{prefix} \leftarrow$ <2nl>;
    end
    $T_{src} \leftarrow T_{prefix} + T_{src} + S_i$;
    TrainOneSample ($T_{src}, T_{tgt}, \Theta$)
end
```

3.3.2 Shuffle

Given input sequence $X' = \{\mathcal{Q}, S\}$, where $\mathcal{Q} = \{Q, Y\}$, the shuffle noise reorders the mentioning sequence of entities in the source query while the schema sequence S is fixed. The denoising objective trains model to reconstruct the query sequence $\mathcal{Q}$ with entities in correct order. The objective of recovering shuffled entity orders trains model to capture the inner relation between different entities and therefore contributes to the schema linking performance. It is also notable that, as a self-supervision objective, both Q and Y are engaged in this denoising task and get trained separately. Though we dependent on the SQL query to identify the value entities in NL query, order shuffling with only column entities is sufficient to obtain promising performance. Since no parallel data is required, additional corpus with monolingual data for both SQL and NL could help with the re-order task and will be one of the further direction of this work.

3.3.3 Training Procedure

Inspired by previous works on denoising self-training (Song et al., 2019; Lewis et al., 2019), we propose to train the schema-aware denoising objectives along with the primary seq2seq task. During training, for each training sample, we apply a nosing pipeline to it before feeding it into the model. The noises with different type are applied to the sample individually. Through the control of activate probability, they could share the same weights in the overall objective. Such continual noising pipeline generates random-wise corrupted samples during training. It prevents the model from fast over-fitting and could yield results with better generalization (Siddhant et al., 2020). In practice, such simple combination noising strategy could perform better comparing to model-based curriculum method. The whole procedure is summarized in Algorithm 1.

3.4 Clause-sensitive EG Decoding

During the inference of text-to-SQL task, the predicted SQL may contain errors related to inappropriate schema linking or grammar. EG decoding (Wang et al., 2018) is proposed to amend these errors through an executor-in-loop iteration. It is performed by feeding SQL queries in the candidate list into the executor in sequence and discarding those queries that fail to execute or return empty result. Such decoding strategy, while effective, suggests that the major disagreement in the candidate list focuses on schema linking or grammar. Directly perform EG to the candidates generated with beam search leads to trivial improvement, as the candidates consist of redundant variations focuses on selection or schema naming, etc. This problem can be addressed by setting the beam length of most of the predicted tokens to 1 and releasing those tokens related to schema linking (e.g., `WHERE`). We also notice that there are cases that combine incorrect schema linking with some aggregation in `SELECT` clause, which return some trivial results such as 0, thus suppress the EG filter. To mitigate the issue, we suggest to drop aggregate operator in `SELECT` during EG to maximize the effectiveness of it. Note that with such strategy, the condition with inequation in `WHERE` clause should be dropped together to ensure the validity of the ground-truth SQL results.

Model	**Dev**		**Test**

Table 1: Accuracy (%) of logic form (Acc_{lf}) and execution (Acc_{ex}) of our model SeaD and other competitors. Best results in bold. EG: execution-guided decoding. EG$_{CS}$: the proposed clause-sensitive EG strategy for S2S generation. ♣ denotes methods that leverage additional annotation of dataset. ♢ denotes methods that utilize database content during training.

4 Experiment

To demonstrate the effectiveness of the proposed method, we evaluate the proposed model on WikiSQL benchmark and compare it to other state-of-the-art methods.

4.1 Dataset

As the largest human-annotated dataset of text-to-SQL, WikiSQL consists of $56,355$, $8,421$ and $15,878$ NL-SQL pairs for training, validation and inference respectively. All ground-truth SQL queries are guaranteed with at least one query result. Each SQL contains `SELECT` clause with at most one aggregation operator and `WHERE` clause with at most 4 conditions that connected by `AND`. Each SQL is associated with a schema in database.

4.2 Implementation details

We implement our method using AllenNLP (Gardner et al.) and Pytorch (Paszke et al.). For the model architecture, we use Transformer with 12 layers in each of the encoder and decoder with a hidden size of 1024. We initialize the model weight with `bart-large` pretrained model provided by Huggingface community (Wolf et al.) and fine-tune it on training dataset for 20 epochs. The batch size during training is set to 8 with a gradient accumulation step of 2. We choose Adam (Kingma and Ba) as the optimizer and set the learning rate to $7e-5$ with a warm-up step ratio of 1%. We searched for the best learning rate for our model out of [1e-4, 7e-5, 1e-5, 5e-6, 5e-7]. The weight decay for regulation is set to 0.01. We set the activation probability $P_{swap} = 0.5$ and $P_{shuffle} = 0.3$, which lets the self-supervision and seq2seq objectives share equal weight during training process. P_{drop} for column removal in erosion is set to 0.1. The early stop patience is set to 5 with respect to the BLUE metric (Papineni et al.) on validation set. The overall training procedure spend around 3 hours on an Ubuntu server with 8 NVIDIA V100 GPUs.

4.3 Competitors

We compare the proposed method to the following models: (1) SQLNet (Xu et al., 2017) is a sketch-based method; (2) SQLova (Hwang et al., 2019) is a sketch-based method which leverage the pre-trained language model for representation; (3) X-SQL (He et al., 2019a) enhances the structural schema representation with contextual embedding; (4) HydraNet (Lyu et al., 2020) transforms schema linking into column-wise matching and ranking; (5) IESQL (Ma et al., 2020) treats text-to-SQL as a sequence labeling task; (6) BRIDGE (Lin et al., 2020) is a sequential architecture for modeling dependencies between natural language question and related schema; (7) SDSQL (Hui et al., 2021) is a multi-task model with explicitly schema dependency guided module.

4.4 Comparison with State-of-the-art Models

The comparison results are summarized in Table 1. Models suffixed with ♣ leverage additional annotation of the dataset. Models suffixed with ◇ utilize database content during training procedure. Without using EG, SeaD significantly outperforms all models without the auxiliary of table content or schema linking annotation. When combined with EG decoding, SeaD achieve best performance even compared to those models that utilize additional training information. It indicates the effectiveness of the proposed denoising objectives on modeling text-to-SQL through vanilla seq2seq. Notably, the annotation noise makes aggregation prediction a major challenge for WikiSQL. Previous works suggested to improve AGG prediction via rule-based annotation amendment. As shown in Table 2, we argue that the proposed aggregation dropping strategy for EG achieves comparable enhancement, while less human effort is involved. Combined with the AGG dropped clause-sensitive EG, the SeaD model establishes new state-of-the-art on WikiSQL benchmark.

achieves best performance on four out of five components among all competitors.

4.5 Ablation Study

To evaluate the contribution of each proposed objective, we perform ablation study to SeaD (Table 4) with WikiSQL dataset. We start from the Bart model and add components to it in sequence. The pointer net contributes to 1.3% absolute improvement of Acc_{lf} on test set. Combine text infilling, an effective denoising objective utilized by Bart, into training procedure brings 0.2 absolute Acc_{lf} improvement. On the other hand, erosion and shuffle objectives contribute to 1.5% and 0.5% absolute Acc_{lf} improvement for SeaD on test set respectively. It demonstrates the effectiveness of the schema-aware denoising objective for improving seq2seq generation in text-to-SQL task.

5 Conclusions

In this paper, we proposed to train model with novel schema-aware denoising objectives, which could improve performance of seq2seq generation for text-to-SQL task. These objectives are applied individually with respective to their activate probabilities, which are fixed during the training procedure. A noise re-weighting model will be considered for future work. Combined with the proposed clause-sensitive EG decoding strategy, our model achieves state-of-the-art on the WikiSQL benchmark. The success of the SeaD highlights the potential of utilizing task-oriented denoising objective for seq2seq model enhancement.

Abstract

Existing multilingual video corpus moment retrieval (mVCMR) methods are mainly based on a two-stream structure. The visual stream utilizes the visual content in the video to estimate the query-visual similarity, and the subtitle stream exploits the query-subtitle similarity. The final query-video similarity ensembles similarities from two streams. In our work, we propose a simple and effective strategy termed as Cross-lingual Cross-modal Consolidation (C^3) to improve mVCMR accuracy. We adopt the ensemble similarity as the teacher to guide the training of each stream, leading to a more powerful ensemble similarity. Meanwhile, we use the teacher for a specific language to guide the student for another language to exploit the complementary knowledge across languages. Extensive experiments on mTVR dataset demonstrate the effectiveness of our C^3 method.

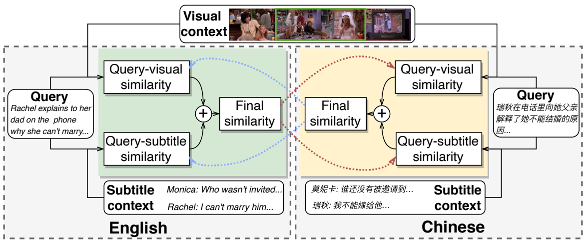

Figure 1: Illustration of our Cross-lingual Cross-modal Consolidation (C^3). The left green and right yellow boxes contain similarities using English and Chinese queries, respectively. Query-visual similarity measures the relevance between the query and visual context, and query-subtitle similarity denotes that between the query and subtitle context. The final similarity is obtained by summing up the query-visual and query-subtitle similarities. The final similarity in a specific language serves as the teacher to guide the learning of query-subtitle/query-visual similarity in another language.

1 Introduction

Video Corpus Moment Retrieval (VCMR) task has been proposed in (Escorcia et al., 2019; Lei et al., 2020), which aims to retrieve a short moment from a large video corpus given a natural language query. Recently, (Lei et al., 2021a) introduces a multilingual Video Corpus Moment Retrieval (mVCMR) task. Compared with VCMR, mVCMR supports queries in multiple languages. It is more useful in practice, especially in international applications.

To facilitate the research in mVCMR, (Lei et al., 2021a) builds a large-scale mTVR dataset, where queries are in two languages. Apart from the video's visual content, the video's textual subtitles are provided as auxiliary information to help the query-to-video retrieval. (Lei et al., 2021a) proposes an mXML model to generate the query-video similarity for video retrieval and the query-clip similarity for moment localization with a two-stream structure. The subtitle stream captures the similarity between the text query and the video's textual subtitles. In parallel, the visual stream describes the similarity between the text query and the video's visual content. The final text-video similarity is a summation of the similarities from two streams.

As the final similarity is obtained from summing up similarities of two streams, straightforwardly, it is reasonable to hypothesize that improving the effectiveness of the similarity from each stream is beneficial to enhancing the performance of the final similarity. Meanwhile, since the final similarity fuses the information from two modalities, it is also reasonable to hypothesize that the final similarity is more reliable than the similarity from each stream. Based on the above two hypotheses, we propose a simple approach to improve the performance of two-stream architecture for the mVCMR task. To be specific, we use the final similarity fusing two modalities as the teacher and the similarity from each stream as the student. We train the student through the guidance of the teacher's knowledge. Meanwhile, to exploit the natural compensation across languages, we devise a student in one language and the teacher in another language. We term our method as cross-lingual cross-modal con-

solidation (C^3), as visualized in Figure 1. Comprehensive experimental results on the mTVR dataset demonstrate the effectiveness of our C^3 method.

2 Related Work

Text-video retrieval. Traditionally, text-video retrieval (Rohrbach et al., 2015; Xu et al., 2016) is normally tackled through two mainstream methods: joint-embedding methods (Xu et al., 2015; Torabi et al., 2016; Pan et al., 2016; Plummer et al., 2017; Miech et al., 2019) and attention-based methods (Yu et al., 2017, 2018; Hori et al., 2017; Krishna et al., 2017). Recently, inspired by the great success of pre-training achieved by Transformer (Vaswani et al., 2017) and BERT (Devlin et al., 2019) in natural language processing, Transformer/BERT-based models emerge for solving text-video retrieval (Sun et al., 2019b,a; Li et al., 2020; Luo et al., 2020; Lei et al., 2021b).

Video corpus moment retrieval. Video corpus moment retrieval (Escorcia et al., 2019; Lei et al., 2020) aims to retrieve the ground-truth video from the whole corpus and predict the moment with high Intersection-of-Union (IoU) with the ground-truth moment using the natural language query. In practice, videos are often associated with other modalities (e.g., subtitles), so the multi-modal moment retrieval task with both visual and text contexts has been proposed. The recent work mTVR (Lei et al., 2021a) extends the monolingual moment retrieval task to the multilingual setting, and introduces a large-scale multilingual moment retrieval (i.e., mTVR) dataset, where the language queries and subtitles are in two languages (i.e., English and Chinese). Meanwhile, it proposes the mXML model jointly trained on the English and Chinese data for multilingual video moment retrieval.

Knowledge distillation. (Hinton et al., 2015) proposes knowledge distillation (KD), where the student network is trained by the soft output of the teacher network. Recently, knowledge distillation has demonstrated the effectiveness for many vision and language tasks (Tan et al., 2018; Hu et al., 2020; Fu et al., 2021; Wang et al., 2020; Fei et al., 2021; Sun et al., 2019c; Hou et al., 2020; Sanh et al., 2019; Peng et al., 2019; Jin et al., 2019; Liu et al., 2022, 2020, 2021). For example, (Sun et al., 2019c) proposes a Patient Knowledge Distillation method to compress an original large model into an equally-effective lightweight shallow network for pre-trained language models (Devlin et al., 2019).

3 Method

3.1 Preliminary

Problem Definition. The current multilingual moment retrieval model mXML (Lei et al., 2021a) performs video retrieval at its shallow layers and moment localization at its deep layers. We denote a query by q_g, where g denotes the language type, *e.g.*, English. A video v consists of L consecutive moments $\{c_l\}_{l=1}^{L}$. Each moment c_l is paired with subtitle $s_{g,l}$. mXML generates the query-video score $S(q_g, v)$ for video retrieval and the index of the start/end frame $t_{\mathrm{st}}/t_{\mathrm{ed}}$ for moment localization:

$$[S(q_g, v), t_{\mathrm{st}}, t_{\mathrm{ed}}] = \mathrm{mXML}(q_g, \{(c_l, s_{g,l})\}_{l=1}^{L}).$$

mXML supports English (en) and Chinese (zh), *i.e.*, $g \in \{\mathrm{en}, \mathrm{zh}\}$. Below, we describe the video retrieval and moment localization in mXML briefly. You can refer to the Appendix A for more details.

Input Feature. ResNet-152 (He et al., 2016) and I3D (Carreira and Zisserman, 2017) extract the visual features of each video moment. The language features are extracted by RoBERTa-base (Liu et al., 2019) for English (Liu et al., 2019) and Chinese (Cui et al., 2020), respectively. Self-Encoder (SE) based on Transformer (Vaswani et al., 2017) and modular attention (Lei et al., 2020) are used to further encode the visual and text features.

Video Retrieval. The subtitle-based score for video retrieval $S_s(q_g, v)$ and the visual-based score $S_v(q_g, v)$ are obtained by two streams, respectively. The details of obtaining $S_s(q_g, v)$ and $S_v(q_g, v)$ are shown in Appendix A.3. The final video retrieval score $S(q_g, v)$ using both contexts is devised as

$$S(q_g, v) = S_s(q_g, v) + S_v(q_g, v). \quad (1)$$

Moment Localization. The subtitle-based query-clip score $S_s(q_g, c_l)$ and the visual-based query-clip score $S_v(q_g, c_l)$ are computed by two streams, respectively. The details of computing $S_s(q_g, c_l)$ and $S_v(q_g, c_l)$ are shown in Appendix A.4. The final query-clip score is devised as

$$S(q_g, c_l) = S_s(q_g, c_l) + S_v(q_g, c_l). \quad (2)$$

Then, to produce moment localization predictions from $S(q_g, c_l)$, mXML predicts the start and end probabilities $\mathbf{p}_g^{\mathrm{st}}, \mathbf{p}_g^{\mathrm{ed}} \in \mathbb{R}^L$ for each query.

For mXML, the video retrieval loss $\mathcal{L}^{\mathrm{vr}}$, moment localization loss $\mathcal{L}^{\mathrm{loc}}$ and language neighborhood constraint loss $\mathcal{L}^{\text{nc}}$ are illustrated in Appendix A.5. The final loss function of mXML is devised as

$$\mathcal{L}_{\text{mXML}} = \mathcal{L}^{\text{vr}} + \lambda_1 \mathcal{L}^{\text{loc}} + \lambda_2 \mathcal{L}^{\text{nc}}, \tag{3}$$

where λ_1 and λ_2 are the loss weights.

3.2 C^3 in Video Retrieval

In Eq. (1), the final video-level similarity $S(q_g, v)$ is a summation of scores from two modalities, $S_v(q_g, v)$ and $S_s(q_g, v)$. We use $S(q_g, v)$ with knowledge of two modalities as the teacher and distill (Hinton et al., 2015) its knowledge to the score with information of only a single modality.

In the multilingual scenario, to exploit more complementary knowledge, a more effective approach is to distill the scores from a language $g \in \{\text{en}, \text{zh}\}$ to the scores from another language $h \in \{\text{en}, \text{zh}\}$:

$$\begin{aligned} S(q_h, v) &\xrightarrow{\text{distill}} S_v(q_g, v), \\ S(q_h, v) &\xrightarrow{\text{distill}} S_s(q_g, v). \end{aligned} \tag{4}$$

Given a mini-batch of query-video pairs $\{(q_g^i, v^i)\}_{i=1}^n$, where n is the batchsize, $S(q_h^i, v^k)$ is the similarity score between q_h^i and v^k of the teacher model based on two modalities (i.e., visual and subtitle contexts), where $k \in [1, n]$. $S_v(q_g^i, v^k)$ and $S_s(q_g^i, v^k)$ are the corresponding similarity scores of the student model from visual and subtitle contexts, respectively. Then, for each query q_h^i, we can generate the teacher scores $\{S(q_h^i, v^k)\}_{k=1}^n$, and perform the softmax function with temperature τ_{vr} on the scores to obtain the normalized score:

$$\hat{S}(q_h^i, v^i) = \frac{e^{S(q_h^i, v^i)/\tau_{\text{vr}}}}{\sum_{k=1}^n e^{S(q_h^i, v^k)/\tau_{\text{vr}}}}. \tag{5}$$

In the same manner, we obtain the normalized student scores $\hat{S}_v(q_h^i, v^i)$ and $\hat{S}_s(q_h^i, v^i)$. Finally, the C^3 loss for video retrieval is devised as

$$\begin{aligned} \mathcal{L}_{\text{C}^3}^{\text{vr}} = \sum_{i=1}^n \sum_{g \in \{\text{en,zh}\}} \sum_{h \neq g} \frac{-1}{n} [&\hat{S}(q_h^i, v^i) \log(\hat{S}_v(q_h^i, v^i)) \\ &+ \hat{S}(q_h^i, v^i) \log(\hat{S}_s(q_h^i, v^i))]. \end{aligned} \tag{6}$$

The loss for video retrieval is devised as

$$\mathcal{L}_{+}^{\text{vr}} = \mathcal{L}^{\text{vr}} + \alpha \mathcal{L}_{\text{C}^3}^{\text{vr}}, \tag{7}$$

where α is a pre-defined positive constant.

3.3 C^3 in Moment Localization

Similarly, C^3 can also be used on the moment localization. In Eq. (2), we generate the query-clip similarity score using two contexts, and then produce the start and end probabilities. In the same way, based on $S_s(q_g, c_l)$ with single subtitle context, we can generate the start and end probabilities $\mathbf{p}_{g,s}^{\text{st}}, \mathbf{p}_{g,s}^{\text{ed}} \in \mathbb{R}^L$, and based on $S_v(q_g, c_l)$ with single visual context, we can generate $\mathbf{p}_{g,v}^{\text{st}}, \mathbf{p}_{g,v}^{\text{ed}} \in \mathbb{R}^L$. Note that we use the softmax function with temperature τ_{loc} to generate the start and end probabilities in the similar way of Eq. (5). We define the start and end probabilities of the teacher model from language h as $\mathbf{p}_h^{\text{st}}$ and $\mathbf{p}_h^{\text{ed}}$, and the start and end probabilities of the student model from language g as $\mathbf{p}_{g,v}^{\text{st}}, \mathbf{p}_{g,v}^{\text{ed}}$ using visual context and $\mathbf{p}_{g,s}^{\text{st}}, \mathbf{p}_{g,s}^{\text{ed}}$ using subtitle context. Thus, the C^3 loss for moment localization is defined as follows:

$$\begin{aligned} \mathcal{L}_{\text{C}^3}^{\text{loc}} = \sum_{g \in \{\text{en,zh}\}} \sum_{h \neq g} [&\text{CE}(\mathbf{p}_h^{\text{st}}, \mathbf{p}_{g,v}^{\text{st}}) + \text{CE}(\mathbf{p}_h^{\text{st}}, \mathbf{p}_{g,s}^{\text{st}}) \\ &+ \text{CE}(\mathbf{p}_h^{\text{ed}}, \mathbf{p}_{g,v}^{\text{ed}}) + \text{CE}(\mathbf{p}_h^{\text{ed}}, \mathbf{p}_{g,s}^{\text{ed}})], \end{aligned} \tag{8}$$

where CE() is cross-entropy function defined as

$$\text{CE}(\mathbf{x}, \mathbf{y}) = -\sum_{l=1}^{L} \mathbf{x}[l] \log(\mathbf{y}[l]). \tag{9}$$

The loss for moment localization is as follows:

$$\mathcal{L}_{+}^{\text{loc}} = \mathcal{L}^{\text{loc}} + \beta \mathcal{L}_{\text{C}^3}^{\text{loc}}, \tag{10}$$

where β is a pre-defined positive constant.

3.4 Training and Inference

Final loss function. Considering our proposed C^3, the final loss function is constructed as follows:

$$\mathcal{L}_{\text{mXML}+} = \mathcal{L}_{+}^{\text{vr}} + \lambda_1 \mathcal{L}_{+}^{\text{loc}} + \lambda_2 \mathcal{L}^{\text{nc}}, \tag{11}$$

which is similar to the formulation of $\mathcal{L}_{\text{mXML}}$ defined in Eq. (3) but replaces $\mathcal{L}^{\text{vr}}$ by its counterpart $\mathcal{L}_{+}^{\text{vr}}$ and $\mathcal{L}^{\text{loc}}$ by $\mathcal{L}_{+}^{\text{loc}}$ based on our C^3.

Training. The training consists of two stages. In the first stage, we train the standard mXML model using the loss function $\mathcal{L}_{\text{mXML}}$ in Eq. (3) to obtain the teacher model, which produces the query-video score $S(q_g, v)$ and the query-clip score $S(q_g, c_l)$ with knowledge of two modalities. Then, in the second stage, we use the teacher mXML model to distill the training process of the randomly initialized student mXML model using the loss function $\mathcal{L}_{\text{mXML}+}$ in Eq. (11). After training, the student

Algorithm 1: The training process.

```
Train the teacher $\mathrm{mXML_T}$, a standard mXML model, using $\mathcal{L}_{\mathrm{mXML}}$ in Eq. (3).
for $i \in [1, Q]$ do
    Initialize a student model $\mathrm{mXML_S}$.
    $\mathrm{mXML_T} \xrightarrow{\text{distill}} \mathrm{mXML_S}$ using $\mathcal{L}_{\mathrm{mXML+}}$ in Eq. (11).
    $\mathrm{mXML_T} = \mathrm{mXML_S}$.
end
return $\mathrm{mXML_S}$
```

mXML model will perform better than the teacher model. Thus, we utilize the trained student mXML model as the new teacher mXML model to guide the training of a new randomly initialized student mXML model from the beginning. We repeat the distillation process in the second stage for Q iterations until the performance saturates. For better clarification, we summarize the training process of our proposed C^3 method as shown in Algorithm 1.

Inference. Since our method is orthogonal to the model, the inference process is same as the mXML.

4 Experiments

Dataset. mTVR (Lei et al., 2021a) is a large-scale multilingual video moment retrieval dataset, which contains 218 thousand English and Chinese queries from 21.8 thousand TV show video clips. This dataset extends the TVR dataset (in English) (Lei et al., 2020) and adds Chinese queries and subtitles. (Lei et al., 2021a) proposed to split the mTVR dataset into 80% train, 10% val, 5% test-public and 5% test-private datasets. We use this dataset to validate the effectiveness of our method for research purpose. All experiments in our work are conducted on one NVIDIA Tesla V100 GPU.

Experimental setting. We report the average recall at K (i.e., R@K) for multilingual Video Corpus Moment Retrieval (mVCMR) task on the mTVR (Lei et al., 2021a) dataset, where the predicted moment is right when it has high Intersection-over-Union (IoU) with the ground-truth. We use the same training strategy and network architecture of mXML (Lei et al., 2021a). λ_1 and λ_2 of Eq. (3) and Eq. (11) are set as 0.01, 1, respectively. The loss weights α and β of $\mathcal{L}_{\mathrm{C3}}^{\mathrm{vr}}$ and $\mathcal{L}_{\mathrm{C3}}^{\mathrm{loc}}$ for video retrieval and moment localization are set as 1.0, 100, respectively. The τ_{vr} is set as 0.02, and τ_{loc} is set as 1. The number of distillation iterations, Q, is set as 2. We deploy our proposed C^3 in mXML and abbreviate the mXML with our C^3 to C^3.

Table 1: R@1 on the test-public split of mTVR.

Methods	English		Chinese

mXML	23.27	13.98	18.99	11.52
C^3	**24.72**	**16.00**	**20.62**	**13.30**

4.1 Main Results

In Table 1, on the test-public split[1] of the mTVR dataset, we compare C^3 with existing methods, including proposal-based approaches (MCN (Anne Hendricks et al., 2017) and CAL (Escorcia et al., 2019)), reranking-based methods (MEE (Miech et al., 2018)+MCN, MEE+CAL, MEE+ExCL (Ghosh et al., 2019) and XML (Lei et al., 2020)) and the state-of-the-art mXML (Lei et al., 2021a). We observe that our C^3 achieves consistently higher R@1 in both English and Chinese than the baseline methods. In Table 2, C^3 also considerably improves the R@10 of the XML and mXML on the test-public split of the mTVR dataset. Note that the R@10 results of XML is based on our re-implementation. In Table 3, we compare the performance on the val split of the mTVR dataset, and C^3 also outperforms the mXML a lot, which further shows the advantage of our method.

4.2 Ablation Study and Analysis

Effect of different components. By default, we exploit the C^3 in both video retrieval ($\mathcal{L}_{\mathrm{C3}}^{\mathrm{vr}}$ in Eq. (7)) and moment localization ($\mathcal{L}_{\mathrm{C3}}^{\mathrm{loc}}$ in Eq. (10)). We conduct the experiments to evaluate the importance of $\mathcal{L}_{\mathrm{C3}}^{\mathrm{loc}}$ and $\mathcal{L}_{\mathrm{C3}}^{\mathrm{vr}}$ by removing one of them, respectively. From Table 4, we observe that, by removing $\mathcal{L}_{\mathrm{C3}}^{\mathrm{loc}}$ or $\mathcal{L}_{\mathrm{C3}}^{\mathrm{vr}}$, the R@1 of video corpus moment retrieval considerably deteriorates. It validates the

necessity of using both $\mathcal{L}_{C^3}^{\text{loc}}$ and $\mathcal{L}_{C^3}^{\text{vr}}$ in our C^3.

Analysis on video retrieval. It is worth noting that we consider both the video retrieval and the moment localization in a single video for mVCMR task. To more comprehensively demonstrate the advantage of our C^3, we also investigate its influence in the video retrieval task. From Table 5, we can observe that our C^3 outperforms the baseline model, mXML, by a large margin.

Analysis on single video moment retrieval. To further demonstrate the effectiveness of the proposed C^3 in moment localization, we also report the single video moment retrieval (i.e., SVMR) results. From Table 6, we observe that our C^3 achieves significant performance improvement compared with mXML. It indicates that our C^3 predicts more accurate moment localization results, which shows the effectiveness of our C^3 in moment localization.

Extension on monolingual video corpus moment retrieval. Despite that the proposed C^3 method is devised to mVCMR, it is also naturally applicable to monolingual video corpus moment retrieval. Here, we evaluate the effectiveness of our C^3 in the monolingual setting. TVR dataset (Lei et al., 2020) contains 109 thousand queries collected on 21.8 thousand videos from 6 TV shows of diverse genres, where each video is associated with subtitles and each query is associated with a tight temporal window. Specifically, we use the XML (Lei et al., 2020) model as the baseline method, and propose an alternative variant by applying the our C^3 loss functions between the outputs of the multi-modality and to the outputs of the single modality for both the video retrieval and moment localization tasks following the similar strategy of the Eq. (6) and Eq. (8). In other words, this alternative variant is called as the intra-lingual cross-modal consolidation (IC^2) method. In Table 7, we compare our alternative variant IC^2 with the baseline model XML on both val and test-public splits of the TVR dataset for monolingual video corpus moment retrieval. As shown in Table 7, our IC^2 also achieves significant performance improvements on the TVR dataset, which further demonstrates the versatility of our proposed consolidation strategy.

Table 7: R@1 of different methods on both val and test-public splits of the TVR dataset.

Method	val		test-public	
	IoU=0.5	IoU=0.7	IoU=0.5	IoU=0.7
XML	5.28	2.62	7.25	3.25
IC^2	**6.27**	**2.93**	**8.45**	**4.00**

5 Limitations and Potential risks

Although our C^3 has achieved substantial improvement based on mXML on the mTVR dataset, we find that there exists some hyper-parameters (e.g., the τ_{vr}, τ_{loc}) to tune in C^3, which may be time-consuming. Besides, we develop the C^3 strategy to improve the performance of mVCMR task, and we have not seen the potential ricks in our paper.

6 Conclusion

In our work, for the multilingual video corpus moment retrieval (mVCMR), we introduce a simple and effective Cross-Lingual and Cross-Modal Consolidation (i.e., C^3) strategy. It enhances the reliability of the similarity score from a single modality through the knowledge distillation from the similarity score with access to the multi-modal information. Meanwhile, it exploits the complementary information across languages by cross-lingual knowledge distillation for both video retrieval and moment localization. Extensive experimental results demonstrate the effectiveness of our method.

A More detailed preliminary on mXML

The current multilingual moment retrieval model mXML (Lei et al., 2021a) is built upon the Cross-modal Moment Localization (XML) model (Lei et al., 2020), which performs efficient video-level retrieval at its shallow layers and accurate moment-level localization at its deep layers. To adjust to the multilingual settings in the video corpus moment retrieval (VCMR) task and improve the efficiency and effectiveness, mXML employs two strategies (i.e., encoder parameter sharing and language neighborhood constraint loss) to better utilize the multilingual data while maintaining smaller model size. In this section, we briefly review the mXML model, which is also illustrated in Figure 2.

A.1 Input Feature

ResNet-152 (He et al., 2016) and I3D (Carreira and Zisserman, 2017) extract the visual features of each video moment. The generated video moment visual features are denoted by $\mathbf{E}^v = [\mathbf{e}^v_1, \cdots, \mathbf{e}^v_L] \in \mathbb{R}^{d \times L}$, where d is the feature dimension. The language features are extracted by RoBERTa-base (Liu et al., 2019) for English (Liu et al., 2019) and Chinese (Cui et al., 2020), respectively. For queries, token-level features are used. The query features are denoted by $\mathbf{E}^q_g = [\mathbf{e}^q_{g,1}, \cdots, \mathbf{e}^q_{g,L_q}] \in \mathbb{R}^{d \times L_q}$, where L_q is the number of tokens and $g \in \{\mathrm{en}, \mathrm{zh}\}$. For subtitles, token-level features in a video moment are max-pooled into a single vector. The subtitle features are denoted by $\mathbf{E}^s_g = [\mathbf{e}^s_{g,1}, \cdots, \mathbf{e}^s_{g,L}] \in \mathbb{R}^{d \times L}$.

A.2 Encoding

mXML uses Self-Encoder (SE) implemented by Transformer (Vaswani et al., 2017) to further encode the query's token features:

$$\mathbf{H}^q_g = \mathrm{SE}(\mathbf{E}^q_g) = [\mathbf{h}^q_{g,1}, \cdots, \mathbf{h}^q_{g,L_q}].$$

A modular attention (Lei et al., 2020) is conducted on the query token features $\mathbf{H}^q_g$, generating two modularized query vectors $\mathbf{q}^v_g, \mathbf{q}^s_g \in \mathbb{R}^d$. In parallel, mXML encodes the moment subtitle features $\mathbf{E}^s_g$ and moment visual features through a stack of two Self-Encoders:

$$\mathbf{H}^s_{g,0} = \mathrm{SE}(\mathbf{E}^s_g),\ \mathbf{H}^s_{g,1} = \mathrm{SE}(\mathbf{H}^s_{g,0}),$$
$$\mathbf{H}^v_0 = \mathrm{SE}(\mathbf{E}^v),\ \mathbf{H}^v_1 = \mathrm{SE}(\mathbf{H}^v_0).$$

Among them, the output of the first Self-Encoder, $\mathbf{H}^s_{g,0}$ and $\mathbf{H}^v_0$, are used for video retrieval. The output of the second Self-Encoder, $\mathbf{H}^s_{g,1}$ and $\mathbf{H}^v_1$ are used for moment localization.

A.3 Video Retrieval

Given the modularized queries $\mathbf{q}^v_g, \mathbf{q}^s_g$ and the encoded contexts $\mathbf{H}^v_0$, $\mathbf{H}^s_{g,0}$, the video-level retrieval (VR) scores $S_s(q_g, v)$ and $S_v(q_g, v)$ using the subtitle context and the visual context are computed as follows, respectively:

$$\begin{aligned} S_s(q_g, v) &= \max_{l \in [1,L]} \cos(\mathbf{q}^s_g, \mathbf{H}^s_{g,0}[:, l]), \\ S_v(q_g, v) &= \max_{l \in [1,L]} \cos(\mathbf{q}^v_g, \mathbf{H}^v_0[:, l]), \end{aligned} \tag{12}$$

where $\mathbf{H}^s_{g,0}[:, l]$ denotes the l-th column vector in $\mathbf{H}^s_{g,0}$ and $\cos(\cdot, \cdot)$ measures the cosine similarity between two vectors. The score essentially computes the cosine similarity between each clip and query and picks the maximum. Then, the final video-level retrieval (VR) score $S(q_g, v)$ using both subtitle and visual contexts is defined as follows:

$$S(q_g, v) = S_s(q_g, v) + S_v(q_g, v). \tag{13}$$

A.4 Moment Localization

Given the modularized queries $\mathbf{q}^v_g, \mathbf{q}^s_g$ and the encoded contexts $\mathbf{H}^v_1$, $\mathbf{H}^s_{g,1}$, mXML computes the query-clip similarity scores $S_s(q_g, c_l)$ and $S_v(q_g, c_l)$ using the subtitle and visual contexts as follows, respectively:

$$\begin{aligned} S_s(q_g, c_l) &= \langle \mathbf{H}^v_1[:, l], \mathbf{q}^v_g \rangle, \\ S_v(q_g, c_l) &= \langle \mathbf{H}^s_{g,1}[:, l], \mathbf{q}^s_g \rangle, \end{aligned} \tag{14}$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product between two vectors. Similarly, the final query-clip similarity score using both contexts is defined as follows:

$$S(q_g, c_l) = S_s(q_g, c_l) + S_v(q_g, c_l), \tag{15}$$

which is also the summation of these query-clip similarity scores. Then, to produce moment localization predictions from the final query-clip score $S(q_g, c_l)$, mXML adopts the Convolutional Start-End detector (ConvSE) with two 1D convolution filters for learning to detect start (up) and end (down) edges in the score curves and generate the start (st) $\mathbf{s}^{\mathrm{st}}_g$ and end (ed) scores $\mathbf{s}^{\mathrm{ed}}_g$, which are also shown as follows, respectively:

$$\begin{aligned} \mathbf{s}^{\mathrm{st}}_g &= \mathrm{ConvSE}_{\mathrm{st}}(S(q_g, c_l)), \\ \mathbf{s}^{\mathrm{ed}}_g &= \mathrm{ConvSE}_{\mathrm{ed}}(S(q_g, c_l)). \end{aligned} \tag{16}$$

Then, these scores are normalized with the softmax function to output the start and end probabilities $\mathbf{p}^{\mathrm{st}}_g, \mathbf{p}^{\mathrm{ed}}_g \in \mathbb{R}^L$ for each query.

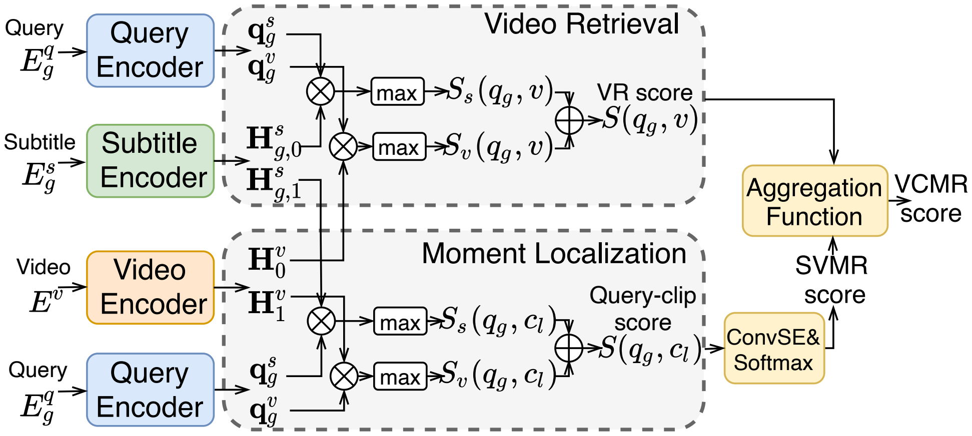

Figure 2: Illustration of inference process for multilingual video corpus moment retrieval (i.e., mVCMR) task. Here, we take the language $g \in \{\text{en}, \text{zh}\}$ as an example to show the processes of video retrieval and moment localization. For the mVCMR setting, all encoders are shared for different languages, and language neighborhood constraint is used on both query and subtitle embeddings. “ConvSE” and “Aggregation Function” operations are proposed in (Lei et al., 2020). “SVMR” denotes single video moment retrieval.

A.5 Training and Inference

In Figure 2, in the training process, mXML optimizes the video retrieval score and the moment localization probabilities based on the triplet loss and the cross-entropy loss, respectively. Besides, to facilitate more stronger multilingual learning, mXML also utilizes language neighborhood constraint loss for both query and subtitle embeddings based on the triplet loss. Below we introduce these loss functions in detail.

Video Retrieval Loss. For each positive pair (q_g^i, v^i), mXML samples two negative pairs (q_g^i, v^j) and (q_g^k, v^i) from the same mini-batch to calculate the combined hinge loss as follows:

$$\mathcal{L}^{\text{vr}} = \sum_{g\in\{\text{en},\text{zh}\}} \sum_{i=1}^{n} \frac{-1}{n}\{[S(q_g^i, v^i) - S(q_g^i, v^j)) + m_{\text{vr}}]_+ \\ +[S(q_g^i, v^i) - S(q_g^k, v^i)) + m_{\text{vr}}]_+\},$$

where $[x]_+ = \max(x, 0)$, m_{vr} is the margin and n is the number of samples for each mini-batch.

Moment Localization Loss. Given the start and end probabilities $\mathbf{p}_g^{\text{st}}, \mathbf{p}_g^{\text{ed}} \in \mathbb{R}^L$, the moment localization loss is defined as follows:

$$\mathcal{L}^{\text{loc}} = \sum_{g\in\{\text{en},\text{zh}\}} \sum_{i=1}^{n} \frac{-1}{n}[\log(\mathbf{p}_g^{\text{st}}(t_{\text{st}}^i)) + \log(\mathbf{p}_g^{\text{ed}}(t_{\text{ed}}^i))],$$

where t_{st}^i and t_{ed}^i are the ground-truth indices of the start and the end, respectively.

Language Neighborhood Constraint Loss. Following (Kim et al., 2020; Burns et al., 2020), mXML additionally adopts language neighborhood constraint loss for multilingual learning. It encourages sentences that express the same or similar meanings to be close to each other in the embedding space via a triplet loss. Given the i-th paired sentence embeddings $\mathbf{e}_{\text{en}}^i \in \mathbb{R}^d$ and $\mathbf{e}_{\text{zh}}^i \in \mathbb{R}^d$ from each mini-batch, mXML samples the j-th and the k-th negative sentence embeddings $\mathbf{e}_{\text{en}}^j$ and $\mathbf{e}_{\text{zh}}^k$ from this mini-batch, where $i \neq j$ and $i \neq k$. The language neighborhood constraint loss $\mathcal{L}^{\text{nc}}$ can be formulated as follows:

$$\mathcal{L}^{\text{nc}} = \sum_{i=1}^{n} \frac{-1}{n}\{[\cos(\mathbf{e}_{\text{en}}^i, \mathbf{e}_{\text{zh}}^k) - \cos(\mathbf{e}_{\text{en}}^i, \mathbf{e}_{\text{zh}}^i) + m_{\text{nc}}]_+ \\ +[\cos(\mathbf{e}_{\text{en}}^j, \mathbf{e}_{\text{zh}}^i) - \cos(\mathbf{e}_{\text{en}}^i, \mathbf{e}_{\text{zh}}^i) + m_{\text{nc}}]_+\},$$

where m_{nc} is the margin. The language neighborhood constraint loss is applied on both query and subtitle embeddings.

Overall, the final loss function of mXML $\mathcal{L}_{\text{mXML}}$ is defined as follows:

$$\mathcal{L}_{\text{mXML}} = \mathcal{L}^{\text{vr}} + \lambda_1 \mathcal{L}^{\text{loc}} + \lambda_2 \mathcal{L}^{\text{nc}}, \qquad (17)$$

where λ_1 and λ_2 are the loss weights of the moment localization loss and the language neighborhood constraint loss, respectively.

Inference. At inference, in Figure 2, for the video corpus moment retrieval task, the predicted start and end probabilities are employed to generate the single video moment retrieval (SVMR) score, where SVMR is to localize a video segment from a video under the language query. Then, the video retrieval score and the SVMR score are used to produce the final VCMR score using the aggregation function proposed in (Lei et al., 2020).

Delving Deep into Regularity: A Simple but Effective Method for Chinese Named Entity Recognition

Abstract

Recent years have witnessed the improving performance of Chinese Named Entity Recognition (NER) from proposing new frameworks or incorporating word lexicons. However, the inner composition of entity mentions in character-level Chinese NER has been rarely studied. Actually, most mentions of regular types have strong name regularity. For example, entities end with indicator words such as “公司 (company) ” or “银行 (bank)” usually belong to organization. In this paper, we propose a simple but effective method for investigating the regularity of entity spans in Chinese NER, dubbed as **R**egularity-**I**nspired re**CO**gnition **N**etwork (RICON). Specifically, the proposed model consists of two branches: a regularity-aware module and a regularity-agnostic module. The regularity-aware module captures the internal regularity of each span for better entity type prediction, while the regularity-agnostic module is employed to locate the boundary of entities and relieve the excessive attention to span regularity. An orthogonality space is further constructed to encourage two modules to extract different aspects of regularity features. To verify the effectiveness of our method, we conduct extensive experiments on three benchmark datasets and a practical medical dataset. The experimental results show that our RICON significantly outperforms previous state-of-the-art methods, including various lexicon-based methods.

1 Introduction

Named entity recognition (NER) aims at identifying text spans pertaining to specific entity types. It plays an important role in many downstream tasks such as relation extraction (Cheng et al., 2021), entity linking (Gu et al., 2021), co-reference resolution (Clark and Manning, 2016), and knowledge graph (Ji et al., 2020). Due to the complex composition (Gui et al., 2019), character-level Chinese NER is more challenging compared to English NER. As shown in Figure 1 (a), the middle character “流” can constitute words with the characters to both their left and their right, such as “河流 (River)” and “流经 (flows)”, leading to ambiguous character boundaries.

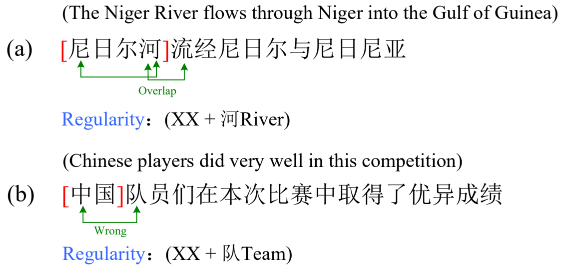

Figure 1: (a) Complex composition of Chinese NER and regularity. (b) Excessive focusing on regularity leads to wrong entity boundary.

There are two typical frameworks for NER. The first one conceptualizes NER as a sequence labeling task (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016), where each character is assigned to a special label (e.g., B-LOC, I-LOC). The second one is span-based method (Li et al., 2020a; Yu et al., 2020), which classifies candidate spans based on their span-level representations. However, despite the success of these two types of methods, they do not explicitly take the complex composition of Chinese NER into consideration. Recently, several works (Zhang and Yang, 2018; Gui et al., 2019; Li et al., 2020b) utilize external lexicon knowledge to help connect related characters and promote capturing the local composition. Nevertheless, building the lexicon is time-consuming and the quality of the lexicon may not be satisfied.

In contrast to previous works, we observe that the regularity exists in the common NER types (e.g., ORG and LOC). As shown in Figure 1 (a), “尼日尔河 (Niger River)” follows the specific composition pattern “XX+河 (XX + River)” which ends

with indicator character “河" and mostly belongs to location type, and the ambiguous character “流” can properly constitute “流经” with the right character “经”. Thus, the regularity information serves as important clues for entity type recognition and identifying the character composition. Formally, we refer to regularity as specific internal patterns contained in a type of entity (Lin et al., 2020). However, too immersed regularity leads to unfavorable boundary detection of entities and disturbing character composition. As shown in Figure 1 (b), “中国队 (Chinese team)” conforms to the pattern “XX+队 (XX + Team)”, but the correct entity boundary should be “中国 (Chinese)” and “队员 (players)” according to the context. Therefore, the context also plays a key role in determining the character boundary.

In this paper, we introduce a simple but effective method to explore the regularity information of entity spans for Chinese NER, dubbed as **R**egularity-**I**nspired re**CO**gnition **N**etwork (RICON). The proposed model consists of two branches named regularity-aware module and regularity-agnostic module, where each module has task-specific encoder and optimization object. Concretely, the regularity-aware module aims at analyzing the internal regularity of each span and integrates the significant regularity information into the corresponding span-level representation, leading to precise entity type prediction. Meanwhile, the regularity-agnostic module is devised to capture context information and avoid excessive focus on intra-span regularity. Furthermore, we adopt an orthogonality space restriction to encourage two branches to extract different features with regard to the regularity. To verify the effectiveness of our method, we conduct extensive experiments on three large-scale benchmark datasets (OntoNotes V4.0, OntoNotes V5.0, and MSRA). The results show that RICON achieves considerable improvements compared to the state-of-the-art models, even outperforming existing lexicon-based models. Moreover, we experiment on a practical medical dataset (CBLUE) to further demonstrate the ability of RICON.

Our contributions can be summarized as follows:

- This is the first work that explicitly explores the internal regularity of entity mentions for Chinese NER.

- We propose a simple but effective method for Chinese NER, which effectively utilizes regularity information while avoiding excessive focus on intra-span regularity.

- Extensive experiments on three large-scale benchmark datasets and a practical medical dataset demonstrate the effectiveness of our proposed method.

2 Related Work

Traditional methods treat NER as a sequence labeling task, where each word or character in the sentence is assigned to a special label. As a representative, Huang et al. (2015) utilized the BiLSTM as an encoder to learn the contextual representation, and then exploited Conditional Random Field (CRF) as a decoder to label the tokens. The BiLSTM-CRF architecture achieved superior performance on various datasets, hence many following works (Lample et al., 2016; Ma and Hovy, 2016) adopt such architecture. More recently, strong pre-trained language models such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) are incorporated to further enhance the performance of NER. Although the sequence labeling framework achieves decent performance on flat NER, it struggles for nested NER. As a result, span-based models are proposed to solve the nested problem by classifying all possible spans into predefined types (e.g. PER, LOC) in the sentence. For example, Yu et al. (2020) adopted a biaffine attention model to assign scores for all potential spans and achieved the state-of-the-art performance on both flat and nested English NER datasets. Shen et al. (2021) also employed span-based framework on Chinese NER datasets. In this paper, we adopt span-based method as our basic framework for two reasons. Firstly, the span-based method considers each span and naturally suits analyzing inner-span character composition. Secondly, the span-based framework can easily extend our method from flat NER to nested NER.

Recently, for Chinese NER, researchers proposed various lexicon-based models that incorporate the external lexicon information and obtained better results. Zhang and Yang (2018) investigated Lattice-LSTM for incorporating word lexicons into the character-based NER model. However, the lattice structure fails to compute in parallel. To address this problem, Gui et al. (2019) introduced a lexicon-based graph neural network that recasts Chinese NER as a node classification task. There are also several works that focus on incorporating all matched words from the lexicon into the charac-

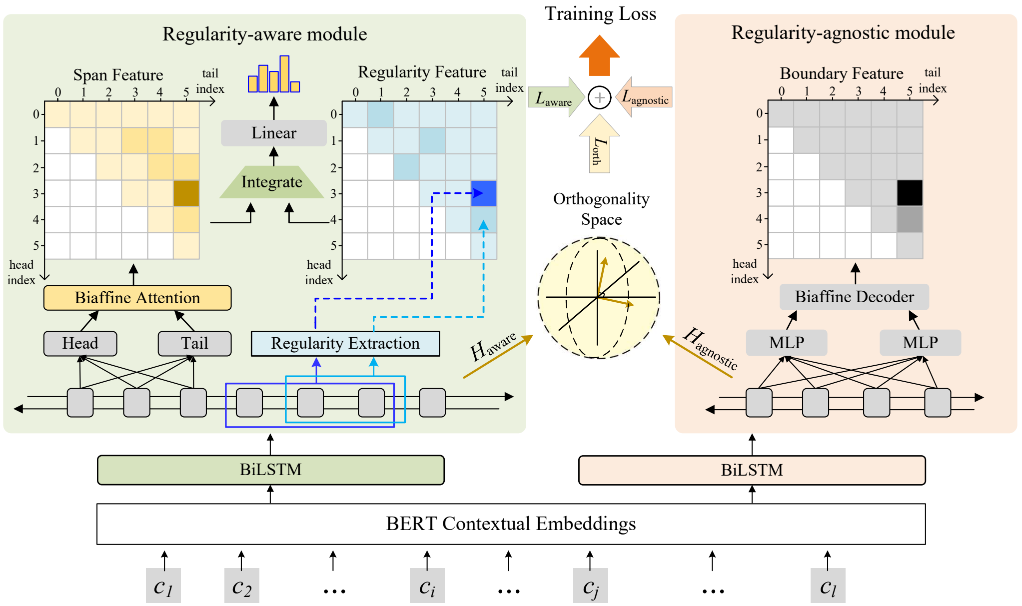

Figure 2: Overall structure of RICON. Each character in the sentence is first embedded by BERT. Then, two separate Bi-LSTM layers are adopted to encode representations for the regularity-aware module and regularity-agnostic module. An orthogonality space is further utilized to encourage extracting different features for each module.

ter embeddings (Ma et al., 2020; Liu et al., 2021). Different from the aforementioned lexicon-based works that incorporate external resources, in this paper, we focus on exploring the internal regularity information of spans.

3 Method

The overall architecture of our RICON is shown in Figure 2, which mainly consists of two branches: the regularity-aware module and the regularity-agnostic module.

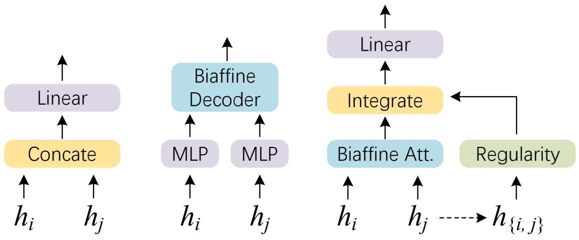
3.1 Embedding and Task-specific Encoder

First of all, each character of the input sequence is embedded into a dense vector. Then the character vectors are separately fed into two task-specific bidirectional LSTM (BiLSTM) layers to extract the corresponding hidden states for each module respectively. Formally, given a sentence with l characters $s = \{c_1, c_2, ..., c_l\}$. We use a standard BERT (Devlin et al., 2019) to obtain the context dependent embeddings for a target token:

$$x_i = \mathrm{BERT}(c_i) \tag{1}$$

Then, the sequence of character embeddings will be fed to two separate BiLSTM layers for regularity-aware module and regularity-agnostic module. The hidden state of BiLSTM is expressed as follows:

$$\overrightarrow{h}_{i,\tau} = \overrightarrow{\mathrm{LSTM}}(x_i, \overrightarrow{h}_{i-1,\tau}) \tag{2}$$



(a) Head-tail (b) Biaffine (c) Regularity-aware

Figure 3: Conceptual comparison of three architectures for span-based NER. $\{,\}$ denotes the representations across from ith to jth character of the span $s_{i,j}$.

$$\overleftarrow{h}_{i,\tau} = \overleftarrow{\mathrm{LSTM}}(x_i, \overleftarrow{h}_{i-1,\tau}) \tag{3}$$

$$h_{i,\tau} = [\overrightarrow{h}_{i,\tau}; \overleftarrow{h}_{i,\tau}] \tag{4}$$

where $\tau \in \{\text{aware}, \text{agnostic}\}$, [;] denotes concatenation, and the dimension of $h_{i,\tau}$ is $2d$. The character sequence representation can be denoted as $H_\tau = \{h_{1,\tau}, ..., h_{i,\tau}, ..., h_{l,\tau}\}$.

3.2 Regularity-aware Module

In this module, we aim to explore the internal regularity of each span. As shown in Figure 3 (a), typical span-based NER methods (Sohrab and Miwa, 2018; Xia et al., 2019; Li et al., 2020a) represent each entity span via concatenating corresponding head and tail features, and use a linear classifier to predict the type of this span. In this way, the span features are coarse-grained. Then, as denoted in Figure 3 (b), Yu et al. (2020) propose a biaffine decoder to enhance the interaction between head and tail representations after two MLPs and predict span types simultaneously. Nevertheless, the internal regularity among characters in the span is still neglected in this biaffine method.

Consequently for this, our regularity-aware module is devised to capture the internal regularity feature for each span $s_{i,j}$, as demonstrated in Figure 3 (c). It is worth noting that span representations are obtained by the head and tail characters of the span, while the regularity representations stem from each character in the span. To achieve this goal, we utilize a linear attention to obtain the regularity representation of each span as follows:

$$a_t = W_{\text{reg}}^{\top} h_t + b_{\text{reg}} \tag{5}$$

$$\alpha_t = \frac{exp(a_t)}{\sum_{k=i}^{j} exp(a_k)} \tag{6}$$

$$h_{s_{i,j}}^{(\text{reg})} = \sum_{t=i}^{j} \alpha_t \cdot h_t \tag{7}$$

where $h_t = h_{t,\text{aware}}$ and $t \in \{i, i+1, ..., j\}$ is the index of the span, $W_{\text{reg}} \in \mathbb{R}^{2d\times 1}$ and $b_{\text{reg}} \in \mathbb{R}^1$ are learnable weights and bias respectively. For a span whose length is 1, we do not extract extra features but use the hidden representation $h_{i,\text{aware}}$ to denote its regularity. The regularity feature $H^{(\text{reg})} \in \mathbb{R}^{l\times l\times 2d}$ will be used for the subsequent entity type prediction.

To predict the type of an entity, our model integrates the regularity feature of each span into the span representations. Firstly, we acquire the span representation via a biaffine attention mechanism by interacting head and tail features:

$$h_{s_{i,j}}^{(\text{span})} = h_i^{\top} U^{(1)} h_j + (h_i \oplus h_j) U^{(2)} + b_1 \tag{8}$$

where $h_i, h_j \in H_{\text{aware}}$ are the head and tail representations of span $s_{i,j}$. $U^{(1)}$ is a $2d \times 2d \times 2d$ tensor, $U^{(2)}$ is a $4d \times 2d$ matrix, and b_1 is the bias. It is worth noting that here we do not apply two separate MLPs like Figure 3 (b) to generate different representations for the head and tail features of the spans, as different MLPs will project the head, tail, and regularity representation into distinct spaces. The experiment also verifies that such space inconsistency degrades the recognition performance. Then a gated network is devised to integrate the span and regularity representation as below:

$$g_{s_{i,j}} = \sigma(U^{(3)}[h_{s_{i,j}}^{(\text{span})}; h_{s_{i,j}}^{(\text{reg})}] + b_2) \tag{9}$$

$$h_{s_{i,j}} = g_{s_{i,j}} \odot h_{s_{i,j}}^{(\text{span})} + (1 - g_{s_{i,j}}) \odot h_{s_{i,j}}^{(\text{reg})} \tag{10}$$

where $U^{(3)} \in \mathbb{R}^{4d\times 1}$ is a trainable parameter and b_2 is the bias. σ denotes the sigmoid function and $\odot$ mean the element-wise dot multiplication. Finally, we adopt a standard linear classifier with a softmax function to predict the entity type for each span.

$$\tilde{y}_{s_{i,j}} = \text{Softmax}({W_{\text{type}}}^{\top} h_{s_{i,j}} + b_3) \tag{11}$$

where $W_{\text{type}} \in \mathbb{R}^{2d\times c}$ is a trainable parameter and b_3 is the bias. The loss function of the regularity-aware module is defined as cross-entropy:

$$\mathcal{L}_{\text{aware}} = -\frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{l}\sum_{j=1}^{l} y_{s_{i,j}}^{(n)} \log(\tilde{y}_{s_{i,j}}^{(n)}), i \leq j \tag{12}$$

where $\tilde{y}_{s_{i,j}}$ denotes the prediction and $y_{s_{i,j}}$ is the the ground truth type of the span. N is the number of training samples in the regularity-aware module.

3.3 Regularity-agnostic Module

By considering regularity, above regularity-aware module makes the model stricter in terms of predicting the entity type, thus improving the precision of entity prediction. Nevertheless, too immersed regularity may result in inaccurate word boundaries. To get rid of it, we propose to erase the concrete form of golden entities and relieve the excessive learning of structural pattern by regularity-aware module. In this scenario, the head and tail features which determine boundary become more significant, thereby we first apply two multi-layer perceptrons (MLPs) on the hidden states from BiLSTM to get separate representations for head and tail. Then a biaffine decoder is leveraged for obtaining entity probability of the span $s_{i,j}$ as follows:

$$\bar{h}_i = \text{MLP}_{\text{head}}(h_i) \quad \bar{h}_j = \text{MLP}_{\text{tail}}(h_j) \tag{13}$$

$$\bar{y}_{ij} = \sigma([\bar{h}_i; 1]^{\top} U_m [\bar{h}_j; 1]) \tag{14}$$

where $h_i = h_{i,\text{agnostic}}$, $h_j = h_{j,\text{agnostic}}$, U_m is a $(2d+1) \times 1 \times (2d+1)$ trainable parameter, σ

is the sigmoid function. Finally, we adopt binary cross-entropy loss to train this task.

$$\mathcal{L}_{\text{agnostic}} = -\frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{l}\sum_{j=1}^{l}[y_{ij}^{(n)}\log(\bar{y}_{ij}^{(n)}) + (1-y_{ij}^{(n)})\log(1-\bar{y}_{ij}^{(n)})], i \le j \tag{15}$$

where $\bar{y}_{ij}$ denotes the prediction and y_{ij} is the binary target indicating whether the span is an entity or not. N is the number of training samples in the regularity-agnostic module.

3.4 Orthogonality Space Restriction

As regularity-aware module aims to capture the regularity information while regularity-agnostic module pays no attention to the concrete regularity, we expect to learn different features for these two modules. To this end, we construct an orthogonality space on the top of two BiLSTM layers to encourage encoding different aspects of the input embeddings. The loss is calculated as follows:

$$H_{\text{orth}} = {H_{\text{aware}}}^{\top} H_{\text{agnostic}} \tag{16}$$

$$\mathcal{L}_{\text{orth}} = \|H_{\text{orth}}\|_F^2 = -\frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{l}\sum_{j=1}^{l}\left|h_{ij}^{(n)}\right|^2 \tag{17}$$

where $\|\cdot\|_F^2$ is the squared Frobenius norm and N is the number of training elements.

3.5 Training and Inference

During training, our RICON can be trained by joint optimizing above three sub-tasks, so we define the total loss as below:

$$\mathcal{L} = \lambda_1\mathcal{L}_{\text{aware}} + \lambda_2\mathcal{L}_{\text{agnostic}} + \lambda_3\mathcal{L}_{\text{orth}} \tag{18}$$

where λ_1, λ_2, and λ_3 are hyperparameter. During inference, we directly use regularity-aware module to predict the entity type for each span and apply a post-processing constraint for two overlapped entity candidates E_1 and E_2 that if $E_{1i} < E_{2i} \le E_{1j} < E_{2j}$, where i and j are start and end indexes, we only select the entity with the higher type score.

4 Experiments

4.1 Datasets

OntoNotes V4.0 (Weischedel et al., 2011). It is a multilingual corpus in the news domain. This dataset has 4 entity types. We use the same split as (Zhang and Yang, 2018).

OntoNotes V5.0 (Pradhan et al., 2013). Compared with V4.0, this version has more news data and contains 18 types of entities. We use the same split as (Jie and Lu, 2019).

MSRA (Levow, 2006). It contains 3 types of named entities collected from the news domain. We use the same split as (Gui et al., 2019).

CBLUE-CMeEE (Hongying et al., 2020). CBLUE is Chinese biomedical language understanding evaluation which consists of 10 sub-tasks. Among them, CMeEE focuses on Chinese medical entity extraction and has 9 types of entities. We use the official train and dev split.

In addition, all types of OntoNotes V4.0, OntoNotes V5.0, MSRA, and 8 types of CBLUE-CMeEE are flat NER, while the symptom type of CBLUE-CMeEE is nested NER.

Due to the space limitation, the statistics of all datasets are listed in the appendix.

4.2 Implementation Details

In our experiments, we use the same settings for all datasets. Specifically, we adopt the standard pre-trained Chinese BERT-base model with 768 dimensions hidden representation to obtain character embeddings. We use Adam optimizer with 2e-5 learning rate for BERT embedding fine-tuning and 0.001 learning rate for other parts. The number of layer and dropout rate of BiLSTM encoders are set to 3 and 0.4. The hidden state size of BiLSTM encoders is set to 200. For the regularity-agnostic module, the output dimension of MLPs and the dropout rate are set to 150 and 0.2. To avoid overfitting, we also apply 0.1 dropout rate for the BERT output embeddings. For the hyper-parameters in loss, we set $\lambda_1 = \lambda_2 = 1$ and $\lambda_3 = 0.5$. For all experiments including ablation study, we adopt an average of performance over five different runs to reduce randomness.

4.3 Comparison Methods

In our experiments, we compare our RICON with recent state-of-the-art methods, where part of them contain pre-trained language model BERT or external Chinese lexicon information. Here we briefly describe five typical methods:

(1) **Star-GAT** (Chen and Kong, 2021) propose a Star-transformer based NER system. They utilize explicit head and tail boundary information and

Table 1: We compare our RICON with recent state-of-the-art models on three Chinese benchmark datasets.

Dependency GAT-based implicit boundary information to improve the performance. It is the SOTA model on the OntoNotes V5.0 dataset.

(2) **BERT+Biaffine** (Yu et al., 2020) recast NER as a task of identifying start and end positions and assigning a type to each span by a biaffine attention.

(3) **BERT+FLAT** (Li et al., 2020b) devise a FLAT model for Chinese NER, which converts the lattice structure into a flat structure consisting of spans to overcome the shortage of lattice-based model (Zhang and Yang, 2018). They also equipped with BERT embeddings and achieved the SOTA performance on the MSRA dataset.

(4) **BERT+SoftLexicon** (Ma et al., 2020) incorporate the word lexicon into the character features. They leverage Chinese lexicon to match every character in the sentence with word appeared in the lexicon to improve the performance, which achieves the SOTA performance on OntoNotes V4.0.

(5) **LEBERT** (Liu et al., 2021) introduce a Lexicon Adapter layer to integrate external lexicon knowledge into BERT layers directly.

4.4 Results

We present the results on three benchmark datasets in Table 1. From this table, we can observe that our RICON achieves the state-of-the-art performance on these datasets. Moreover, RICON even outperforms recent methods with Chinese lexicon significantly. Concretely, on OntoNotes V4.0, RICON achieves 0.81 absolute F1 improvement over the strong method BERT+Biaffine and 0.52 absolute improvement compared with the SOTA lexicon-based method BERT+SoftLexicon. On OntoNotes V5.0, we obtain a decent improvement compared to the SOTA approach Star-GAT by 0.90 F1 score. In addition, on MSRA, although the improvement of our model over the SOTA model BERT-FLAT is limited, our model still surpasses the other two lexicon-based models LEBERT and BERT+SoftLexicon by 0.44 and 0.72 respectively.

	All Types			Symptom Type		
Model	P	R	F1	P	R	F1
BERT-Tagger	53.41	63.32	57.95	40.57	45.38	42.84

RICON	**66.25**	**64.89**	**65.57**	57.93	43.99	**50.01**

Table 2: Performance of models on CBLUE-CMeEE, including all types and symptom type.

In addition, we present the model performance on CBLUE-CMeEE in Table 2. Considering there are no available lexicons for this task, we only compare RICON with typical models. As shown in this table, RICON outperforms the strong BERT-Biaffine model with a 3.28 F1 score improvement over 9 types. It is remarkable progress in this challenging dataset. Meanwhile, we provided the result of nested symptom type. RICON performs much better than BERT-Biaffine with a 5.81 F1 improvement. This observation also denotes that our RICON also applies to nested NER.

4.5 Ablation Study

We conduct abundant ablation studies on OntoNotes V4.0 and V5.0 from module and implementation perspectives in Table 3 and 4. Vanilla in tables is built from RICON by removing orthogonality space and regularity-agnostic module, and omitting to capture regularity features and integrate it in the regularity-aware module.

From the results in Table 3, we can observe that: (1) When applying regularity-agnostic module to the vanilla, the performances improve by

Module	OntoNotes V4.0			OntoNotes V5.0

Reg. feature by Mean-pooling	83.06 (-0.10)	79.97 (-0.10)
Reg. feature by Max-pooling	82.82 (-0.34)	79.79 (-0.28)
Reg. feature by Multi-Head	83.10 (-0.06)	79.86 (-0.21)
Gate replaced with Add	82.96 (-0.20)	79.94 (-0.13)
Gate replaced with Cat	82.80 (-0.36)	79.77 (-0.30)
Apply MLPs to head and tail	82.90 (-0.26)	79.67 (-0.40)
Vanilla	82.59 (-0.57)	79.42 (-0.65)

Table 4: Performance of variants on OntoNotes datasets.

0.21 and 0.48 respectively, showing the effectiveness of this module. (2) When the vanilla equips with regularity-aware module, the F1 scores significantly improve by 0.57 and 0.65 respectively, which verifies that regularity plays a significant role in entity recognition. (3) After combining regularity-aware and regularity-agnostic modules, we achieve further improvements, which indicates that two modules can mutually reinforce each other. (4) The orthogonality space is a valid method according to the further F1 score improvements.

Furthermore, we notice that adding the regularity-aware module significantly increases the **Precision** (1.41 on both datasets, Vanilla vs Vanilla+Reg-aware) but reduces the **Recall** (0.31 and 1.04 respectively), which conforms to that focusing on regularity feature would reinforce the type prediction, while missing several spans that are supposed to be entities. Nevertheless, this situation can be remedied by the regularity-agnostic module and the **Recall** improved 1.03 and 0.58, respectively (Vanilla+Reg-aware vs Vanilla+Reg-aware & agnostic). This result also meets our motivation that regularity-agnostic module can reinforce the entity boundary detection.

As shown in Table 4, there are several alternative ways to extract regularity information instead of linear attention used in this paper, such as mean-pooling, max-pooling, or more complex multi-head self-attention (Vaswani et al., 2017), but these methods all perform worse. It is one future direction to explore how to obtain regularity by a more sophisticated architecture. However, considering the model complexity and performance, we choose linear attention to capture regularity. In addition, replacing our devised gate mechanism with a simple concatenate or add operation both degrades the performance, denoting that gate mechanism is more efficient to integrate span feature and regularity feature. We also explored adding two MLPs separately to head and tail features when generating span features in the regularity-aware module. The experimental results prove that different feature space for span feature and regularity feature leads to worse performance.

4.6 Analysis

In this section, We deeply analyze our proposed RICON from the following aspects.

4.6.1 Regularity: A Latent Adaptive Lexicon.

The lexicon-based methods focus on incorporating external word lexicons to improve the performance of character-based NER. The core concept of them is preserving all words which match a specific character and let the subsequent NER model determine which word to apply (Zhang and Yang, 2018; Ma et al., 2020). In our model, we calculate the regularity for each span, namely, all words containing a specific character are considered, and then the best word and corresponding regularity will be determined. In this sense, our explored regularity can be seen as a latent adaptive lexicon. Furthermore, this latent adaptive lexicon is more complete than external lexicons because all spans matching the specific character are considered, while lexicon-based methods only match a limited number of words. As shown in Table 1, the previous SOTA method BERT+Biaffine performs worse than lexicon-based methods, but our regularity-based method RICON outperforms the lexicon-based methods. Actually, our regularity-based method can further be combined with lexicon-based methods.

4.6.2 Performance vs. Entity Type.

We examine how regularity affects each entity type. As Figure 4 shows, 12 types of entities achieve better performance with the regularity. This result conforms to the fact that types like GPE, ORG, and DATE have strong regularity. Nevertheless, for the types with little regularity information, such as WORK_OF_ART and PERSON, immersed regularity leads to performance degradation. We notice that the MONEY type typically contains regularity but we do not observe an improvement in

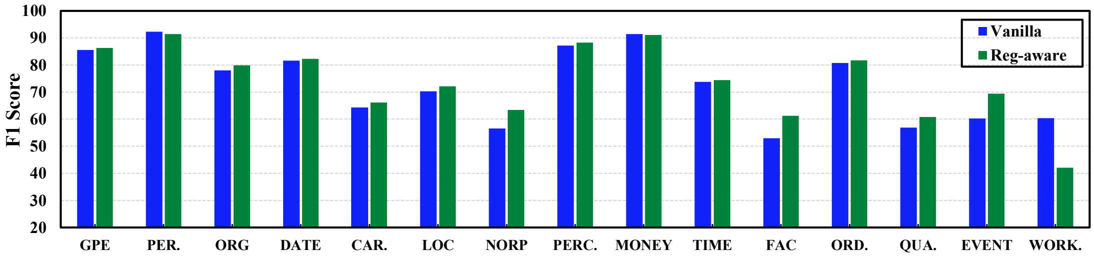

Figure 4: The performance of 15 types of entities on OntoNotes V5.0. The types are sorted in descending order based on the proportion of entities of that type to the total. As the remaining 3 types on OntoNotes V5.0 only have less than 35 entities (0.05%) among all entities. To avoid the impact of labeling errors, we do not present them here.

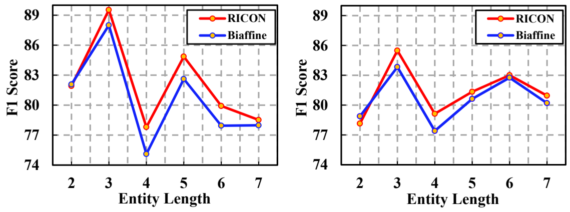
#1 Sentence (Truncated)	据报道，从波罗的海三国撤回的俄罗斯军队...... (Reportedly, Russian Army withdrawn from the three countries around Baltic Sea...)			
Characters (Entity Included)	波	罗	的	海
Gold Label	B-LOC	M-LOC	M-LOC	E-LOC
Vanilla	B-GPE	M-GPE	M-GPE	M-GPE
Vanilla + Reg-aware	B-LOC	M-LOC	M-LOC	E-LOC
Regularity weight	0.04	0.06	0.07	**0.83**
#2 Sentence (Truncated)	新闻分析： 美国公司兼并为何愈演愈烈? (News analysis: why the mergers of American companies are intensifying?)			
Characters (Entity Included)	美	国	公	司
Gold Label	B-GPE	E-GPE	O	O
Vanilla + Reg-aware	B-ORG	M-ORG	M-ORG	M-ORG
Reg-aware + Reg-agnostic	B-GPE	E-GPE	O	O

Table 5: There examples from the Ontonotes V4.0 dataset. The label is organized in the form of BMES.



(a) F1 on OntoNotes V4.0 (b) F1 on OntoNotes V5.0

Figure 5: Performance vs. Entity Length

this category. This is, due to inconsistencies between the training and test dataset. For instance, the training data contains the abundant pattern "number+dollar", while only numbers exist in the test set. To remedy the excessive regularity, our RICON further utilizes a regularity-agnostic module to rectify the captured regularity. The above observations also inspire us to devise more elaborate NER for different entity types with various degree regularity properties in the future. Our regularity-aware module may also serve as a potential tool for evaluating the intensity of regularity.

4.6.3 Performance vs. Entity Length.

Figure 5 depicts the performance on the OntoNotes V4.0 and V5.0 datasets with different length of entities. From this figure, we can observe that our RICON consistently outperforms BERT-Biaffine (Yu et al., 2020) when the entity length is longer than 2, which illustrates that the regularity information is helpful to predict the types for long entities. In contrast, BERT-Biaffine performs comparable to RICON when entity length is 2 as there are no additional character information except the head and tail representations.

4.6.4 Case study.

Table 7 shows two examples from OntoNotes V4.0. In the first example, the Vanilla misidentifies the entity type, while Vanilla+reg-aware learns regularity “XX+海" by the greatest weight 0.83 on “海", thus obtaining the accurate entity type. It is worth noting that regularity can capture more complex character compositions besides explicit patterns in the first example. More complex examples are presented in the appendix. In the second example, “美国公司" conforms to the regularity "XX +公司" and is recognized as organization type by our Vanilla+Reg-aware model. After equipping with the regularity-agnostic module, we obtain the precise character boundary and relieve the excessive attention to regularity.

5 Conclusion

In this paper, we proposed a simple but effective method to explore the regularity information for Chinese NER, dubbed as Regularity-Inspired reCOgnition Network (RICON). It contains a regularity-aware module to capture the internal regularity feature of each span, and a regularity-agnostic module to reinforce the entity boundary detection while avoid imposing excessive attention on regularity. The features of two modules are encouraged to be dissimilar by an orthogonality space restriction. Evaluation shows that RICON achieves the state-of-the-art performance on four datasets.

B More Case Study

B.1 Complex Regularity

Besides explicit patterns like the first example in Table 5, Table 7 shows a more complex form of regularity that our model can capture. In this example, the Vanilla+Reg-aware model pays highest attention weight 0.92 to important character ”和” (and), and recognize that A and B are independent entities according to the regularity “A 和 B (A and B)”. For comparison, the vanilla fails to

Vanilla	O	B-ORG	M-ORG	M-ORG	M-ORG	M-ORG	E-ORG
Vanilla + Reg-aware	B-ORG	E-ORG	O	B-ORG	M-ORG	M-ORG	E-ORG
Regularity weight	7.5e-2	2.5e-6	**9.2e-1**	2.1e-6	8.9e-6	9.5e-4	3.1e-5

Table 7: An example on the Ontonotes V4.0 dataset. The label is organized in the form of BMES.

Sentence (Truncated)	Golden Entity / Type	Biaffine Prediction	RICON Prediction	Regularity
(1) 肺多叶病变显示... Multi-lobed lung lesions showed that...	肺多叶病变，Symptom Multi-lobed lung lesions	未识别 N/A	肺多叶病变，Symptom Multi-lobed lung lesions	XX+病变 XX+lesion
(2) 大片状融合性病变为主... Massive fusion lesions were the main...	大片状融合性病变，Symptom Massive fusion lesion	未识别 N/A	大片状融合性病变，Symptom Massive fusion lesion	
(3) 增加肝脏病变...多数属... Increase liver lesions, most of which...	肝脏病变，Symptom liver lesions	未识别 N/A	肝脏病变，Symptom liver lesions	
(4) ...患儿可并发肝损害。 ...can be complicated with liver damage.	肝损害，Symptom liver damage	肝损害，Disease liver damage	肝损害，Symptom liver damage	XX+损害 XX+damage
(5) SARS患儿有部分出现心脏损害... SARS children suffer from heart damage...	心脏损害，Symptom heart damage	心脏损害，Disease heart damage	心脏损害，Symptom heart damage	
(6) ...合并多脏器损害 ...complicated with multi-organ damage	多脏器损害，Symptom multi-organ damage	多脏器损害，Disease multi-organ damage	多脏器损害，Symptom multi-organ damage	

Table 8: Cases study on the domain CBLUE-CMeEE dataset.

distinguish these two entities. This example further reveals that our regularity-aware module can discover more complex character compositions.

B.2 Case Study in Medical Domain

To further demonstrate the effectiveness of our RICON in Chinese NER, we present six examples of the CBLUE-CMeEE dataset from the medical domain. As shown in the first three examples in Table 8, the biaffine model fails to identify the accurate boundary of the entities, thus leading to unrecognized entity type. However, our RICON achieves detecting the correct span boundary as well as predicting golden type type (Symptom) of the entities according to the regularity "XX+病变" (XX+lesion). In the last three examples, both biaffine model and our RICON successfully detect the correct span boundary of the entities. For entity type prediction, the biaffine model assigns a wrong type (Disease) to these entities, but our RICON predicts types correctly as a result of it captures the regularity feature "XX+损害" (XX+damage) from "Symptom" type. To sum up, our RICON is also beneficial for domain datasets.

CRUSH: Contextually Regularized and User anchored Self-supervised Hate speech Detection

Abstract

The last decade has witnessed a surge in the interaction of people through social networking platforms. While there are several positive aspects of these social platforms, their proliferation has led them to become the breeding ground for cyber-bullying and hate speech. Recent advances in NLP have often been used to mitigate the spread of such hateful content. Since the task of hate speech detection is usually applicable in the context of social networks, we introduce *CRUSH*, a framework for hate speech detection using User Anchored self-supervision and contextual regularization. Our proposed approach secures $\approx$ 1-12% improvement in test set metrics over best performing previous approaches on two types of tasks and multiple popular English language social networking datasets.

Note*: This paper contains materials that may be offensive or upsetting to some people.*

1 Introduction

Today, the world is more connected than ever in the history of mankind. This can primarily be attributed to: (i) the technological advancements that have made affordable internet connections and devices available to people, and (ii) the social networking platforms that have hosted and connected these people. As a result, even people divided by geography can seamlessly interact in real-time without stepping outside their homes. In fact, social networks are an integral part of today's society.

We, however, are more concerned about the pitfalls of this global widespread use of social networks. The unprecedented and rapid explosion in social networking and social media use has left many people — particularly the youth, women, and those from ethnic and religious minority groups — vulnerable to the negative aspects of the online world like sexual harassment, fake news and hate speech (Jakubowicz, 2017). The number of toxic users dumping their radically biased views and polarising content onto these networks have burgeoned to such a level that they are causing political discord and communal disharmony. Therefore such posts must be intervened upon and filtered before they have the intended effect on the mass. With a huge number of posts on many popular social networking websites every second, manual filtering for hate speech does not scale. Hence, automating hate speech detection has been the primary focus of many researchers in recent years, both in academia and industry alike.

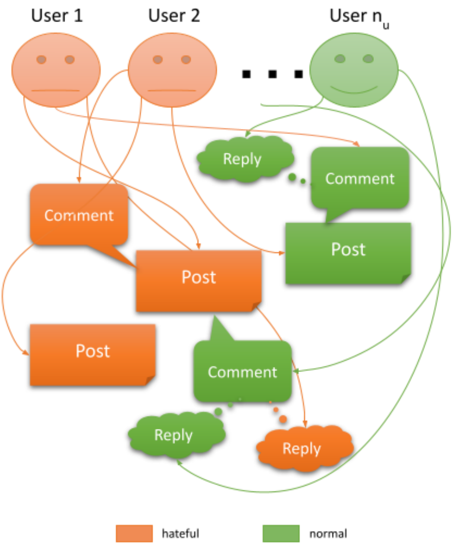

Figure 1: [Best viewed in color] Hateful content tend to cluster together in common threads and usually come from few hateful users in social media. We stress on this informed assumption to learn better representations using self supervision and contextual regularization. In the sub-graph shown in the pic, the textual content is in the form of posts, comments on the posts (optional), and replies to the comments (optional). n_u is the total number of users in the network (dynamic), and each of the text sequences can be attributed to one of the users.

Figure 1 depicts and describes a sub-graph of a typical social network. It is essential to leverage this structure within social networks for infusing

network context while identifying hate speech. We investigate and notice that the social graph context can be disentangled into two components: (i) *Post context*: the context in the neighborhood around the text sequence, i.e., the sub-graph consisting of posts, comments, and replies (see Figure 1) and (ii) *User context*: the context from all the existing text sequences in the network that originated from the same user (see, for instance, the connections emanating from users 1, 2, n_u etc. in the Figure 1). Relying on the echo-chamber effect, we accordingly propose a framework that uses self supervision from unlabelled data harnessed from the social networks (Gab & Reddit in our case), so that we can use contextual information (user & post context) to generate better representations from input sentences for hate speech related tasks. The main contributions of this paper are:

(i) First, we propose **UA (User Anchored self-supervision)**, a self-supervised contrastive pre-training objective. Essentially we try to incorporate the mapping from text sequences to users into the language model. In addition, we provide a Robust UA strategy that incorporates the hate speech downstream task information into our proposed UA pre-training approach.

(ii) Next, we propose **CR (Contextual Regularization)**, a regularization strategy based on the findings of Mathew et al. (2020). Here we introduce a loss based on the informed assumption that the neighboring comments and replies (in the social graph) of a hateful comment is more likely to be hateful than the comments/replies in the vicinity of a non-hateful comment. It helps us to regularize the supervised learning paradigm by learning better representations of text sequences in social network context.

(iii) We experiment with two types of hate speech tasks – classification and scoring – across three datasets. We show that our approach secures $\approx$ 1-4% improvement in F1-scores (for classification tasks) and $\approx$ 12% improvement in mean absolute error (for scoring task) when compared to best competing baselines.

To the best of our knowledge, we are the first to use text sequence based self-supervision in hate speech using user characteristics. One of the key technical contribution that this paper makes is to show that it is more advantageous to use context to regularize a classification model than directly infusing the context into the model. Also, none of our proposed approaches require any additional annotation effort or introduce any extra parameter into the training pipeline, and are therefore scalable.

2 Related work

Hate speech is heavily reliant on linguistic complexity. Waseem (2016) showed that classification consensus is rare for certain text sequences even among human annotators. Automatic detection of hate speech is further strongly tied to the developments in machine learning based methods.

Until recently, feature engineering was one of the popularly used techniques. Gitari et al. (2015) designed several sentiment features and Del Vigna et al. (2017) used the sentimental value of words as the main feature to measure the hate constituted within a text sequence. Empirical evidence was provided by Malmasi and Zampieri (2017) indicating that n-gram features and sentiment features can be successfully applied to detect hate speech. Rodriguez et al. (2019) constructed a dataset of hate speech from Facebook, and consequently proposed a rich set of sentiment features, including negative sentiment words and negative sentiment symbols, for detecting hateful text sequences. As witnessed by the above works, it was widely believed that sentiment played an important role in detecting underlying hate.

More recently, deep learning based methods (Badjatiya et al., 2017) have garnered considerable success in detecting hate speech since they can extract the latent semantic features of text and provide the most direct cues for detecting hate speech. Zhang et al. (2018) developed a CNN+GRU based model to learn higher-level features. (Kshirsagar et al., 2018) passed pre-trained word embeddings through a fully connected layer, which achieved better performance than contemporary approaches despite its simplicity. Tekiroğlu et al. (2020) constructed a large-scale dataset for hate speech and its responses and used the pre-trained language models (LM) for detection. These methods demonstrated the considerable advantages of interpreting words in the context of given sentences over static sentiment based methods.

Self-supervision and auxiliary supervision have also been explored for hate speech detection. HateBERT (Caselli et al., 2021) used the Masked Language Modelling (MLM) objective to learn contextual hate semantics within text sequences from individual Reddit posts. HateXplain (Mathew et al., 2021) used human annotators to obtain rationale about the text containing hate speech and then applied the same for improving their language model. Researchers have previously tried context infusion in the inputs (Menini et al., 2021; Vidgen et al., 2021; Pavlopoulos et al., 2020). Del Tredici et al. (2019) showed that user context helps in downstream tasks. On the other hand, Menini et al. (2021) and Vidgen et al. (2021) show that contextual classification is harder given contextual annotations. A similar theme recurs when Pavlopoulos et al. (2020) shows that context infusion does not easily increase the performance of classifiers in context of toxicity detection in text. Alternatively instead of using context directly as input we use it as a regularizer to improve the classifier by learning better contextual representations while training. During inference, we use only the post text, thus adding no computation overhead.

We find that using self-supervision for hate speech detection systems leveraging the associated context within a social network is heavily underexplored. s demonstrated by Mathew et al. (2020), learning in a broader socio-personal context of the users and contemporary social situations is also very important. The authors showed the clustering tendency of hateful text sequences on specific hateful user timelines and after specific events (temporal clustering). However, to the best of our knowledge, no prior work in hate speech detection has explored self-supervision in these directions using the context information.

3 Proposed approaches

Assumptions about invariance(s) are required in all self-supervised learning objectives. We make the following two assumptions articulated below.

(i) In the masked language modeling (MLM) objective, the invariant is that the conditional probability distribution of the vocabulary tokens (or words) for each masked token can be reasonably estimated given the context (in the form of tokens) around the masked token.

(ii) In the User Anchored self-supervision (UA) objective, we assume that the users' writing style and bias (specifically cultural and in-group bias) are invariant (Hughes et al., 2012). Hence, the inverse mapping of a post to the corresponding user should be estimable subject to the language understanding capability.

We denote the model being trained for the downstream tasks as $\mathcal{M}$. $\mathcal{M}$ has two modules: **(a)** an encoder for encoding the input sentences, and **(b)** a classifier or regressor for mapping the hidden representations generated by the encoder into one of $\mathcal{K}$ classes and a single value respectively. For instance, the encoder in $\mathcal{M}$ can be modeled by a transformer (Vaswani et al., 2017). See Figure 2 for block diagram of our proposed approaches.

3.1 *Phase I*: Incorporating hateful content into the language model through continual pre-training (CP)

We start with pre-trained language models and continue pre-training them by minimizing the standard MLM objective using text sequences (posts) accumulated from a variety of social network datasets. The procedure for domain adaptation in LMs can be found in Gururangan et al. (2020) and a procedure tailored for hateful words can be found in HateBERT. We use the text sequences available on Pushshift[2] in addition to RAL-E from HateBERT for pre-training our Hate-infused Language Model (HateLM).

3.2 *Phase II*: User Anchored self-supervision (UA)

Some users are more biased than others and hence are more prone to post toxic content (Mathew et al., 2020). We employ a User Anchored self-supervision (UA) objective in the next pre-training phase to compare the users' writing style. Hence, given an LM is capable of language understanding, it should also be able to distinguish between users' writing styles from their posts with high probability, when the pool of posts from various users is not very large.

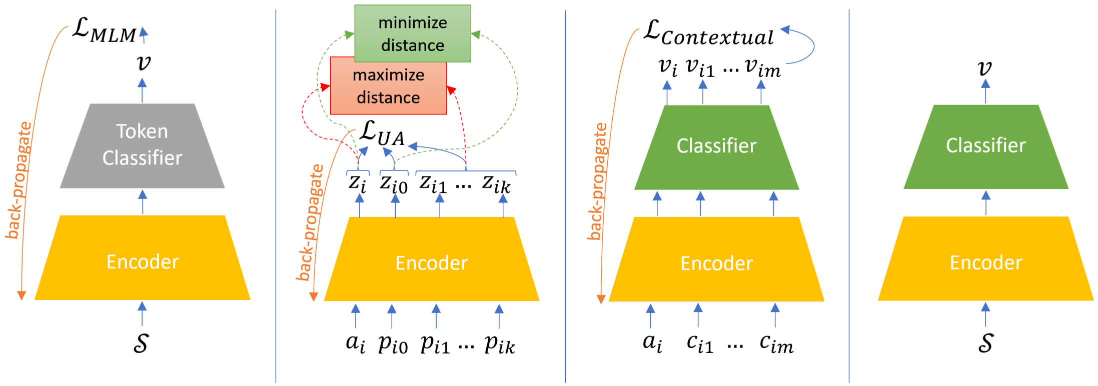
Here we use a self-supervised method based on *contrastive pre-training* with negative samples to efficiently incorporate UA into an LM. This negative sampling makes the approach highly scalable[3].

For the text sequence $\mathcal{S}$ corresponding to the i^{th} sampled post and user u_0, we try to decrease some distance metric between representation of $\mathcal{S}$ and another sentence by u_0 among the n_u available users while increasing the distance metric with sentences authored by other users in a contrastive fashion.

---

[2] https://files.pushshift.io/gab

[3] Owing to the extremely large number of users in a platform and the dynamic nature of the graph, it is infeasible to simply add a user classification network after the encoder



(a) (b) (c) (d)

Figure 2: [Best viewed in color] An illustration of the various phases of training and inference for the classification task. The regression task will have a similar structure except for a regressor head instead of a classifier head in *(c)* and *(d)*. The blue arrows indicate the forward pass, and the orange arrows indicate the backward pass. *(a)* corresponds to Phase I, i.e. continual pre-training using self-supervised MLM objective on hateful sequences to incorporate contextual hate understanding. *(b)* corresponds to Phase II, i.e. the User Anchored self-supervised learning objective, it depicts the scalable contrastive objective model that does not add any additional parameters. *(c)* corresponds to Phase III, i.e. our contextual regularization procedure where we add post and user context. And finally *(d)* shows the inference phase which does not require any additional context.

Next, we sample $k << n_u$ number of users uniformly at random, without repetition, from among the list of all users in the social network. Adding u_0 along with the k sampled users in a set, we get:

$$U_i = \{u_{i0}, u_{i1}, ..., u_{ik} | \forall_{j_1, j_2 \in \{0,..,k\}} u_{ij_1} \neq u_{ij_2}\} \tag{1}$$

The set of posts P_i made by users in U_i.

$$P_i = \{p_{i0}, p_{i1}, ..., p_{ik} | p_{i0} \neq \mathcal{S}\} \tag{2}$$

p_{i0} cannot be same as $\mathcal{S}$ because our positive sample needs to be different from the original post. The remaining $\forall_{j \in [k]} \{p_{ij}\}$ become negative samples.

For Phase II pre-training and updating the parameters $\theta_{\mathcal{E}}$ of the encoder in $\mathcal{M}$, we start by sampling an anchor sequence $a_i \equiv \mathcal{S}$ from our dataset. We pass a_i through encoder in $\mathcal{M}$ to obtain z_i.

$$z_i = \mathcal{F}_{\theta_{\mathcal{E}}}(a_i) \tag{3}$$

Next, we generate P_i by sampling as described above. We pass all of the p_{ij}'s $\in P$ through our encoder as well, to get embeddings:

$$Z_i = \{z_{i0}, z_{i1}, ..., z_{ik}\} \tag{4}$$

We use a self-supervised contrastive loss inspired from Khosla et al. (2020) and modify it for our purposes:

$$\mathcal{L}_{\text{UA}} = \mathop{\mathbb{E}}_{i \sim \mathcal{U}([N])} \left[-log \left(\frac{\exp(z_i \cdot z_{i0})}{\sum_{j \in [k]} \exp(z_i \cdot z_{ij})} \right) \right] \tag{5}$$

Here, '$\cdot$' represents the inner product and $\mathcal{U}(.)$ represents discrete uniform distribution. Since there are no additional models, only $\theta_{\mathcal{E}}$ parameters need to be updated during backpropagation.

***Robust UA*:** During training UA objective exhibits the problem of over-fitting. After a certain number of epochs, the information in the language model accumulated during the CP phase gets overshadowed by information obtained from the UA phase. In order to handle the problem, the model needs to be fine-tuned after every epoch. Since this is not feasible, we propose a method for a more robust training method aligned to our downstream task of hate speech classification. Since we already have the annotations in the target dataset, we add an auxiliary task to align the model parameter updates towards the downstream task rather than diverge as a consequence of over-fitting.

For an anchor sequence $a_i \equiv \mathcal{S}$ sampled from the training set, we get the original class label of the example and get a positive example p by sampling a new post from the training set belonging to the same class. Similarly, we sample two posts from each of the remaining classes in order to get a set of $l = 2(n_c - 1)$ negative examples, where n_c is the number of classes in the downstream classification task. Hence similar to P_i in Equation 2, our auxiliary post set corresponding to the i^{th} sampled sequence is as follows:

$$\overline{P}_i = \{\overline{p}_{i0}, \overline{p}_{i1}, ..., \overline{p}_{il} | \overline{p}_{i0} \neq \mathcal{S}\} \tag{6}$$

Subsequently, we pass them through the encoder in $\mathcal{M}$ and generate auxiliary embedding set:

$$\overline{Z}_i = \{\overline{z}_{i0}, \overline{z}_{i1}, ..., \overline{z}_{il}\} \tag{7}$$

Similar to the supervised contrastive loss described in Equation 5, we add the following auxiliary loss:

$$\mathcal{L}_{\text{aux}} = \mathop{\mathbb{E}}_{i \sim \mathcal{U}([N])} \left[-log \left(\frac{\texttt{exp}(z_i \cdot \overline{z}_{i0})}{\sum_{j \in [l]} \texttt{exp}(z_i \cdot \overline{z}_{ij})} \right) \right] \tag{8}$$

Here, it is the same i that was being sampled in Equation 5. Finally we take a convex combination of both the losses to get:

$$\mathcal{L}_{\text{RobustUA}} = \lambda \mathcal{L}_{\text{UA}} + (1 - \lambda) \mathcal{L}_{\text{aux}} \tag{9}$$

where, $0 < \lambda < 1$ is a hyper-parameter.

Note: We do not have classes for a regression task. Therefore, we group the labels into $\mathcal{K}$ clusters by using K-means clustering where $\mathcal{K}$ is a hyper-parameter. Then we use the associated cluster labels as a proxy for the class labels.

3.3 *Phase III*: Contextual Regularization (CR)

Our primary assumption in this approach is that: A post is influenced by its context. We demonstrate how to exploit the intuition "hate begets hate" (Mathew et al., 2020) to our advantage.

3.3.1 CR in classification

HateLM and UA, i.e., the methods described in section 3.1 and 3.2 (with the exception of Robust UA training) were self-supervised; hence, no information about the annotations available in the training set was used. After getting the pre-trained model in Phase II, we fine-tune using the annotations available for the dataset. We consider a pair of text sequence and its corresponding label $\langle \mathcal{S}, \text{y} \rangle$ sampled from the training set uniformly at random, where $\text{y} \in [\mathcal{K}]$ denotes the true class label of the sampled sequence $\mathcal{S}$. Usually, we would get the vector embedding z by passing $\mathcal{S}$ through the encoder. We would then have used the classifier in $\mathcal{M}$ to get the vector v of $\mathcal{K}$ dimensions as follows:

$$v = \mathcal{F}_{\mathcal{C}}(z; \theta_{\mathcal{C}}) \tag{10}$$

where $\theta_{\mathcal{C}}$ parameterizes the classifier in $\mathcal{M}$. According to the model, the probability of the sample belonging to j^{th} class among $\mathcal{K}$ classes would be as follows:

$$\mathbb{P}[class(\mathcal{S}) = j] = \frac{\texttt{exp}(v_j)}{\sum_{k \in [\mathcal{K}]} \texttt{exp}(v_k)} \tag{11}$$

and the most likely class assignment would be

$$\hat{\text{y}} = \mathop{\arg\max}_{j \in [\mathcal{K}]} \mathbb{P}[class(\mathcal{S}) = j] \tag{12}$$

The cross-entropy loss would be calculated as:

$$L_{\text{CE}} = \mathop{\mathbb{E}}_{i \sim \mathcal{U}([N])} [-log \, \mathbb{P}[class(\mathcal{S}) = \text{y}]] \tag{13}$$

We propose an additional method for regularization of the model using the contextual information during fine-tuning. For the given $\mathcal{S}$ we sample at most n_a posts from the same thread (all comments/replies concerning the parent post) where the comment is posted (post context) and at most n_b more posts from the timeline of the user who posted $\mathcal{S}$ (user context). Both post and user context is sampled without replacement. So, we generate a context set C of $\mathcal{S}$ for the i^{th} text sequence sampled from the dataset:

$$C_i = \{c_{i1}, ..., c_{in_a}, c_{i(n_a+1)}, ..., c_{i(n_a+n_b)}\} \tag{14}$$

We then generate the vector v using $\mathcal{S}$ as mentioned in Equation 10. Next we generate V_i from C_i:

$$V_i = \{v_{i1}, ..., v_{im} | \forall_{j \in [m]} v_{ij} = \mathcal{M}(c_{ij})\} \tag{15}$$

where $m = n_a + n_b$ and, $\mathcal{M}(.) \equiv \mathcal{F}_{\theta_{\mathcal{C}}}(\mathcal{F}_{\theta_{\mathcal{E}}}(.))$. Our contextual loss from V_i is as follows:

$$\mathcal{L}_{CCE,i} = \frac{-1}{m} \sum_{j \in [m]} log \left(\frac{\texttt{exp}(v_{ijt})}{\sum_{k \in [\mathcal{K}]} \texttt{exp}(v_{ijk})} \right) \tag{16}$$

where t is the true class of the original labelled post. Therefore the auxiliary contextual cross-entropy loss is calculated as:

$$\mathcal{L}_{\text{CCE}} = \mathop{\mathbb{E}}_{i \sim \mathcal{U}([N])} [\mathcal{L}_{CCE,i}] \tag{17}$$

Our final contextual regularization loss function is a linear combination of the losses mentioned in Equation 13 and 17 as described below:

$$\mathcal{L}^{\text{classification}}_{\text{Contextual}} = \lambda \mathcal{L}_{\text{CE}} + (1 - \lambda) \mathcal{L}_{\text{CCE}} \tag{18}$$

Back-propagating this loss we update the parameters $\theta_{\mathcal{C}}$ and $\theta_{\mathcal{E}}$, corresponding to the classifier and the encoder in $\mathcal{M}$ respectively, as one might have done normally.

3.3.2 CR in regression

The regression task is almost similar to classification as mentioned in section 3.3.1 with the exception that the $\text{y} \in \mathbb{R}$ in the tuple $\langle \mathcal{S}, \text{y} \rangle$ sampled from the training set, and the output of the model $\mathcal{M}$ being a real value r rather than a vector v of $\mathcal{K}$ dimensions. Since we use a regressor, Equation 10 changes to

$$r = \mathcal{F}_{\mathcal{R}}(z; \theta_{\mathcal{R}}) \tag{19}$$

where $\theta_{\mathcal{R}}$ parameterizes the regressor in $\mathcal{M}$.

The cross-entropy loss in Equation 13 becomes

Dataset	Annotated samples	Total users	Labels	Max context sampled (per user)
HateXplain	10,000	3,300	Hate speech, Offensive, Normal	100
LTI-GAB	30,500	4,900	Toxic and Non-Toxic	50
Ruddit	6,000	4,200	Regression (-1 to +1)	20

Table 1: Dataset statistics for the datasets we used for performing the experiments along with the additional unsupervised data we collected. All datasets are in the English language.

squared loss as follows:

$$L_{\text{MSE}} = \mathop{\mathbb{E}}_{i \sim \mathcal{U}([N])} \left[(\mathrm{y}_i - r_i)^2 \right] \tag{20}$$

where y_i is the label associated with the ith example sampled from the training dataset, r_i is the predicted value by model $\mathcal{M}$.

The techniques for selection of the context discussed in section 3.3.1 remain unaltered since our post and user context is unsupervised. However, the set of vectors V_i becomes a set of real values R_i generated as follows:

$$R_i = \{r_{i1}, ..., r_{im} | \forall_{j \in [m]} r_{ij} = \mathcal{M}(c_{ij})\} \tag{21}$$

And our auxiliary contextual mean squared loss is calculated as the follows:

$$\mathcal{L}_{CMSE} = \mathop{\mathbb{E}}_{i \sim \mathcal{U}([N])} \left[\frac{-1}{m} \sum_{j \in [m]} (\mathrm{y}_i - r_{ij})^2 \right] \tag{22}$$

Our final contextual regularization loss function is thus a linear combination of the losses mentioned in Equation 20 and 22 as described below:

$$\mathcal{L}^{\text{regression}}_{\text{Contextual}} = \lambda \mathcal{L}_{\text{MSE}} + (1 - \lambda) \mathcal{L}_{\text{CMSE}} \tag{23}$$

4 Experiments

We experiment with the downstream task of hate speech detection. We establish the effectiveness of our proposed approaches by demonstrating that they are: **(i)** mutually independent of each other, **(ii)** independent of the base language model used, and **(iii)** applicable across various social network datasets. We validate these claims by comparing our approaches with the following baselines:

(i) To establish mutual independence among the training phases, we train a base language model (BERT from Devlin et al. (2019)) with each of the training phases separately. An improvement over the performance of the base model in each phase would indicate the advantage of our approach over naive training.

(ii) To establish independence from the base language model, we train multiple baseline language models during each of the above-mentioned separate training phases (HateBERT during Phase I; BERT and HateXplain during the remaining phases). Consistent performance improvement irrespective of the language model would again indicate the advantage of our approach.

(iii) We use three datasets from two different social networks and two types of tasks (classification and regression). This establishes the capability of our methods to solve a range of heterogeneous tasks across contrasting datasets.

We next describe the datasets and the implementation details of our approaches.

4.1 Datasets

Social networks: In particular we experiment with two popular social networks (a) `gab.ai` (GAB), and (b) `reddit.com` (Reddit). Our choice of the dataset was guided by the availability of the context graph and additional data collection time. Baumgartne (2018) had scraped GAB and made the network freely available for academic use. On the other hand, Reddit has an API[4] available to get the public domain data. Therefore, these websites were favorable for our experiments. Since Reddit involved additional data collection (a time consuming process), we chose a popular dataset that contains less than 10,000 datapoints.

Annotated hate speech data: We use the following english hate speech datasets for our experiments (See Table 1 for more information on dataset statistics) – (i) HateXplain-GAB dataset (Mathew et al., 2021) (contains data from GAB), (ii) LTI-GAB dataset (Qian et al., 2019) (contains data from GAB) and, (iii) Ruddit (Hada et al., 2021) (contains data from Reddit).

We use *only* the GAB subset of the annotated data from both the datasets (i) and (ii), because the social network context graph for GAB is publicly available. The GAB subset of dataset (i) has around 10K annotated data samples, which are already divided into 80-10-10 train-val-test split. Dataset (i) has three class annotations (hate speech, offensive, and normal). Dataset (ii) contains intervention sen-

Table 2: **Experimental outcomes of our approaches.** Our model **CRUSH** $\equiv$ HateLM + UA + CR. For reporting results (except CR and UA+CR phases) the encoder models were attached with a classifier (refer section 4.2) and fine-tuned (using the loss mentioned in Equation 13). *Across the columns*: we show the results with three datasets. In HateXplain (HX)'s and Learning to Intervene (LTI)'s results, higher metrics are better. In Ruddit results, lower metrics are better. *Across the rows*: we show the various models grouped by the *phase* of training along with corresponding baselines. In each group, we have indicated the best-performing models' results corresponding to the evaluation metric in bold. The overall best performing models' results have additionally been italicized. **The models denoted by † (the best competing baseline) and ⁎ (CRUSH) are significantly different (M-W U test with** $p < 0.05$**) across all datasets.**

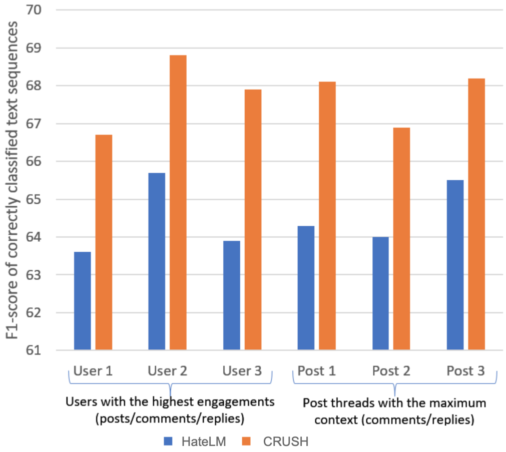

Figure 3: [Best viewed in color] F1-scores of correctly classified posts grouped by three user contexts and three post contexts. The improvement along the user contexts and post contexts demonstrate the utility of the CR phases (user & post context based).

tences along with which sentences to intervene and a binary label - hate and non-hate. We use a 90-10 train-test split with the random seed 2021, and among the training set we use 10% randomly sampled data for validation. Dataset (iii) was collected from Reddit and is labeled for regression task. The dataset contains ratings corresponding to the measure of hate within a sentence ranging between -1 and 1, with higher numbers corresponding to a higher extent of hate. There are about 6K examples in this dataset. We use a train test split similar to that we used in the dataset (ii).

Our pre-processing procedure for all the textual data, both labeled and unlabelled is exactly the same as that of HateXplain. (Mathew et al., 2021). **Unlabelled data for self-supervision**: We get the threads corresponding to the annotated Reddit datapoints using the Reddit API and use that as our unlabelled corpora for self-supervision in case of the regression task. For GAB, we use the whole network datadump available on Pushshift (Baumgartne, 2018) as mentioned in Section 3.2.

4.2 Implementation details

For our encoder, we use the pre-trained `bert-base-uncased` that is available on huggingface[6]. By continual pre-training on this model, we obtain our HateLM using the text sequences from GAB and RAL-E as described in section 3.1. Afterward, we obtain a 768 dimensional pooled output from our encoder which is then be passed onto the classifier/regressor head. For both our classifier and regressor model, we select a neural

---

[5] HateXplain refers to both a dataset and the corresponding model provided in the paper. However, since we only use the GAB subset of the HateXplain dataset, we require to fine-tune the HateXplain model on this subset, for it to be comparable to other models, and therefore it is considered a baseline.

[6] https://huggingface.co/bert-base-uncased

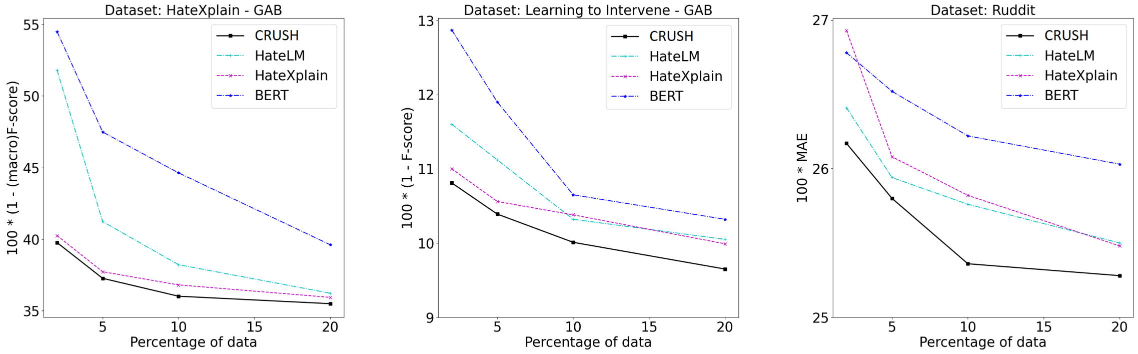

Figure 4: [Best viewed in color] Comparison of model error in low data regime across the three datasets. Our model (black solid line) consistently outperforms existing approaches that do not use the social network context. For plots showing comparisons with non-contextualized LMs (e.g., TF-IDF) as well, refer to Figure 5 in Appendix.

Word	BERT	HateLM
black	everywhere, free, not	racist, evil, stupid
muslim	accepted, optional, allowed	terrorist, evil, shit
jews	persecuted, excluded, present	idiots, bad, stupid
men	equal, free, citizens	evil, people, bad
women	excluded, only, bias	dumb, evil, stupid

Table 3: Top-3 next word predictions by each LM when the corresponding word is given as prompt. The hateful words as the output of the next word prediction demonstrate the effectiveness of the hate-infusion into LM.

network consisting of a 2 Fully-connected layers. The hidden layer for the same is chosen to have 128 dimensions along with a ReLU activation. The input dimension is dependent on the output of the encoder, and in our case is set to 768. The output dimension is 1, 2 or 3 corresponding to the regressor, binary and ternary classifier. We used *Adam* optimizer with batch size 48, max seq length 128 and learning rates $3e$-6 and $2e$-5 for our encoder and classifier/regressor respectively. Our approaches do not require additional context during inference (see Figure 2(d)).

4.3 Ablation studies

We frame the ablation studies to answer a series of interesting questions. These are:

Q1: How much does self-supervised learning objective during pre-training help in the downstream task (if at all)?

Q2: Similarly, how much does contextual regularization during fine-tuning help?

Q3: Do these two approaches work only in conjunction with each other?

In addition to the above, we perform the following ablation experiments to validate the usefulness of various components of our model:

Q4: How much of the performance can be attributed to the detection of isolated hateful words without any contextual information in place? To answer this question, we use the TF-IDF (Sammut and Webb, 2010) vector embedding of each text sequence. since TF-IDF computes representations solely based on the frequency of words without any contextual information.

Q5: Have the hateful words been contextually incorporated into the hate-infused language model? Here, we prompt our hate-infused language model and study the next word it predicts.

Q6: How do these approaches perform in a few-shot setting?

5 Results

The Table 2 compares the performance of our methods with related models and baselines. We report the performance metrics according to the test sets of the corresponding datasets.

[1] It is evident from Table 2 that both CP and UA phases (self-supervised phases) lead to improvements over the baselines. This answers **Q1**. To answer how useful regularization was we can look at the CR phase results which are again better than the baselines thus answering **Q2**.

Further, we can also see that UA and CR phase results individually beat the baseline. Furthermore, combined UA+CR phase outperforms all models. Hence, the conjunction hypothesis is valid thus answering **Q3**.

Post (along with ground-truth label)	**BERT**	**HateLM**	**CRUSH**
if your humor is based on racism homophobia sexism and rape you're not f**king funny go home (**non-hate**)	✗	✓	✓
<user> ah man i f**king hate you so much (**hateful**)	✗	✓	✓
the french government position is that france is made stronger by the immigrants it is bribing to leave porter (**non-hate**)	✗	✗	✓
i am presuming he means the standard left wing idiots lots of hypocritical women amongst them think maria ladenburger obviously you are against these muhammedans (**hateful**)	✗	✗	✓
a covington catholic a native american indian and a black hebrew israelite walk into a bar (**non-hate**)	✗	✗	✗
if money was grown on trees women would be dating monkeys oh wait never mind (**hateful**)	✗	✗	✗

Table 4: Qualitative results using text sequences from HateXplain dataset. ✓ indicates sentences were classified properly by the corresponding models while ✗ indicates incorrect classification. MLM based training of BERT and HateLM does not seem to capture the complexities of hate speech properly, thus CRUSH outperforms them.

[2] **Q4** is answered by the considerable improvement over the TF-IDF baseline as can be seen in Table 2. In addition, Figure 3 shows the advantages gained by using CRUSH over HateLM. It demonstrates both the user-level and the post-level contextual information from the network incorporated into our CRUSH model are individually helpful over models that do not have social network context information.

[3] Table 3 answers **Q5** by showing some of the prompt completion results for BERT vs our Hate-infused LM. It can be noticed that although HateLM definitely has been incorporated with racial and ethnic hate, it surprisingly does not discriminate between genders.

[4] Figure 4 shows the few-shot training results with small percentages of data sampled from our training datasets (2% to 20% data points) uniformly at random. Intuitively our model is already able to outperform all other baselines consistently even without context because of the self-supervised training procedures we propose during the CP and UA phases which captures the hate & users' style+bias. This is evident from the results of CP & UA phases in Table 3. So later adding context in few-shot setting simply further enhances our model thus answering **Q6** (see Appendix for full results).

Discussion of some qualitative examples: Table 4 presents a few text sequences from the HateXplain dataset and their corresponding results (classification/misclassification) for the models – BERT, HateLM, and CRUSH. It can be noticed that the first two sentences are properly classified by HateLM and CRUSH but not by vanilla BERT. That leads us to believe that BERT predictions are heavily dependent on the token occurrences rather than the context in the sentence where the tokens have occurred. As for the next two sentences, it is evident that the sentence representations learnt by CRUSH (due to UA + CR phases of training, see Section 3.2, 3.3) are superior to those learnt by the HateLM, hence it classifies these text sequences better than simple MLM based training. Finally, the last two sentences indicate that CRUSH (along with the other approaches) still lacks the ability to identify humor, sarcasm, and implicit hate speech, which are known to be difficult problems.

6 Conclusion

In this paper, we provide approaches to infuse social network context using the self-supervised user-attribution pre-training objective combined with the contextual regularization objective on top of traditional MLM for hate speech tasks. We empirically demonstrate the advantage of our methods by improving over existing competitive baselines in hate speech detection and scoring tasks across three different datasets. We also show that our method performs superior in the low data regime as well when compared to existing approaches. We also do ablations to understand the benefits of each objective separately. Future work include exploiting the relations among users, using different base models capable of incorporating longer contexts, and trying to address hard problems like sarcasm and implicit hate speech detection in social networks.

7 Ethical considerations

All the datasets that we use are publicly available. We report only aggregated results in the paper. For context mining, we have used data either available in the public domain or available through official APIs of the corresponding social media. Neither have we, nor do we intend to share any personally identifiable information with this paper. We also make our codebase publicly available here - `https://github.com/parag1604/CRUSH`.

Our model CRUSH helps advance the state-of-the-art in hate speech detection by incorporating continual pre-training, capturing user writing biases and leveraging both user & post context (which is publicly available as well). This in turn should be able limit the amount of hateful threads in social networks/media by better detection of hate speech, thus promoting a more friendly and welcoming environment for people from all race, religion, ethnicity, gender etc.

Unfortunately, these models are not completely free from all potential negative impact. One such example being that our models have hate knowledge infused within them during the CP phase (refer Section 3.1) of our training pipeline. As shown in Table 3, these language models could be used potentially used for generating hateful words/sentences given an initial prompt.

However, the hateful words generated by the HateLM can be also identified by the platform if the platform uses a hate speech detection algorithm like ours or uses a set of hate lexicons to directly filter out such keywords generated (Gitari et al., 2015). Moreover, our final model - CRUSH - is not exactly suitable for toxic language generation as it is further pre-trained on the user style discrimination task and fine-tuned on the hate speech classification task making its classification capabilities (potential use by the social media platforms to detect hate speech) stronger than the hate speech generation capabilities (the potential of the model being abused with malicious intent). So, the platforms using our better-informed model will easily detect any hate speech generated by the model.

Moreover, large-scale technologies for better generation of hate speech using GPT-2 and other generative models (Wullach et al., 2021; Hartvigsen et al., 2022) (with the intention to train hate speech classifiers better) already exist and as a model trained only for classification, our model is likely to be far weaker than these models for generation of harmful content. While these language models can be used both to benefit or disrupt our lifestyle just like any other technology (Douglas, 2014), we urge the researchers to exercise ultimate caution while using them, including ours. For the same reason, we do not make the trained model parameters publicly available (except for the code to promote reproducibility).

Also, one of the factors increasing bias in the classification model is the data it is trained upon. Hence, any potential bias in the datasets that are manually annotated by human beings (who are not free from bias) can result the model being biased for/against some specific target groups.

To incorporate better inductive bias into the model, we have trained the model to initially map text sequences posted by the same user to vectors that are close in the embedding space. This helps the model to identify the dialects of the various users and help the model perform better. However, this inductive bias may cluster the linguistic characteristics of some groups which in turn might potentially increase the chances of that particular language style being classified as hate speech if the annotated data contains only hateful instances from that particular dialect. This may make the model biased if those particular dialects are used predominantly by some protected category (Blacks, Jews, Women, Mexican etc.).

The most simple and effective solution here would be to annotate data for each dialect/vernacular group, potentially stratifying the dataset into clusters using the pre-trained language model. If there are balanced examples from each of these dialect/vernacular or at least each protected category (Blacks, Jews, Women, Mexican etc.) for both the hate and non-hate categories, such biases can be well mitigated.

Further, our model like any other hate speech model is not suitable for in-the-wild deployment without explicit human scrutiny. Language use is often very specific to each platform. So, the distribution of words and data-points may not match the training data distribution of the model. Thus, it is extremely important to first test the model on the platform, check for potential biases against the protected categories and individual linguistic groups/dialects and deploy it as a preliminary filter assisting the human experts detecting hate speech.

Abstract

Knowing the reasoning chains from knowledge to the predicted answers can help construct an explainable question answering (QA) system. Advances on QA explanation propose to explain the answers with entailment trees composed of multiple entailment steps. While current work proposes to generate entailment trees with end-to-end generative models, the steps in the generated trees are not constrained and could be unreliable. In this paper, we propose METGEN, a Module-based Entailment Tree GENeration framework that has multiple modules and a reasoning controller. Given a question and several supporting knowledge, METGEN can iteratively generate the entailment tree by conducting single-step entailment with separate modules and selecting the reasoning flow with the controller. As each module is guided to perform a specific type of entailment reasoning, the steps generated by METGEN are more reliable and valid. Experiment results on the standard benchmark show that METGEN can outperform previous state-of-the-art models with only 9% of the parameters.

1 Introduction

Explanation is recognized as a key factor toward responsible AI systems (Arrieta et al., 2020). In the context of question answering (QA), providing an explanation of the predicted answers can help improve the understandability, debuggability, and trustworthiness of QA models. Great efforts have been devoted to revealing how the models predict the answers and give explanations in various forms, including showing an attention map over passages (Seo et al., 2017), giving a snippet of textual evidence (DeYoung et al., 2020), and selecting answer-supporting sentences (Xie et al., 2020; Jansen and Ustalov, 2019). Among all explanation forms, the *entailment trees* (Dalvi et al., 2021) provide the most detailed and informative explanation by exposing the *chains of reasoning* from the knowledge to the predictions. As shown in Figure 1(a) and (c), given a hypothesis (summarizing a question+answer pair) and supporting facts (retrieved from a corpus), the goal is to generate an entailment tree where each non-leaf node is an entailment of its children. Providing a valid entailment tree would help users to understand how the hypothesis is proved, obtain novel intermediate conclusions from the basic knowledge, and gain detailed information to support decision making.

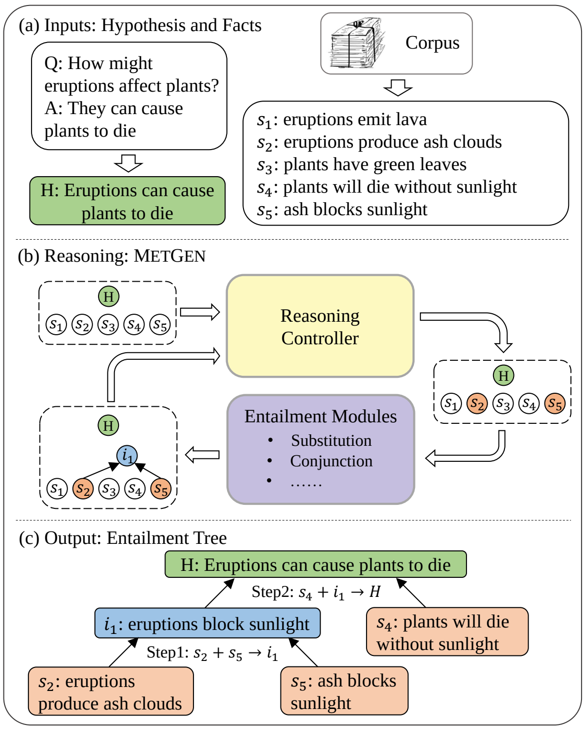

Figure 1: Given facts related to the question+answer, METGEN iteratively generates an entailment tree that contains the hypothesis (green), used facts (orange), and intermediate conclusions (blue) with several separate entailment modules and a reasoning controller.

To generate the entailment trees, Dalvi et al. (2021) propose EntailmentWriter, an end-to-end sequence-to-sequence generative model, trained by maximizing the generation likelihood of the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1887 - 1905
July 10-15, 2022 ©2022 Association for Computational Linguistics

linearized gold trees. However, they do not have an explicit strategy to constrain the validity of every single step and the tree structure. Thus, the steps are not guaranteed to satisfy the reasoning rules and could be incorrect and unreliable. For example, the step conclusion may not be entailed by the input premises or simply repeat one of the input premises (Dalvi et al., 2021). Furthermore, although their outputs are trees that can indicate the reasoning chains, the mapping mechanisms from the inputs to the trees remain implicit and invisible.

To tackle the above problems, we propose METGEN, a module-based framework to generate entailment trees in a more explicit approach and constrain the entailment steps with reasoning rules. As shown in Figure 1(b), given the target hypothesis and known facts, METGEN first uses the reasoning controller to select some steps that can help get closer to the hypothesis. Subsequently, METGEN executes the selected steps with single-step entailment modules and adds the generated intermediate facts into the known facts for the next round of reasoning. Through this iterative approach, METGEN proves the hypothesis step by step and generates the overall entailment tree.

Each module in METGEN is a generative model that can perform a specific type of entailment reasoning (e.g., making a substitution inference). To guide the modules to generate correct and sound conclusions, we train the modules with well-formed synthetic data containing the corresponding logical regularities of the reasoning types (Bostrom et al., 2021). Inspired by the forward chaining and backward chaining algorithms in logic programming (Chein and Mugnier, 2008), we adopt both deductive and abductive modules to execute forward and backward reasoning steps, respectively.

Experiments on the standard benchmark EntailmentBank (Dalvi et al., 2021) show that METGEN can outperform the previous best model with 9.0% of the model parameters. Manual evaluation results demonstrate that METGEN can generate more reliable steps. Further experiments under the data-scarce setting and cross-dataset setting (on eQASC and eOBQA (Jhamtani and Clark, 2020)) show that METGEN is more data-efficient and has better generalization capability compared with the baselines.

2 Related Works

Explainability in Question Answering. Recent works have explored the explainability of QA in various forms (Seo et al., 2017; Ye et al., 2020; Dalvi et al., 2021; Lamm et al., 2021; Wiegreffe and Marasovic, 2021; Thayaparan et al., 2020; Rosenthal et al., 2021). One way is to retrieve multiple supporting facts related to the question or answer (Xie et al., 2020; Jansen and Ustalov, 2019; Jhamtani and Clark, 2020; Inoue et al., 2020; Yadav et al., 2019, 2020; Valentino et al., 2021; Cartuyvels et al., 2020; Zhang et al., 2020). These “rationales” (DeYoung et al., 2020) provide insights about *what* are used by the model to inform its predictions, but do not show *how* the facts are combined to generate novel intermediate conclusions. Some other works explain QA systems in a generative way, including generating explanation sentences that directly link a question to an answer (Camburu et al., 2018; Rajani et al., 2019) and thus expose the relevant knowledge used by models (Latcinnik and Berant, 2020; Shwartz et al., 2020). However, as these models generate explanations in a free form, the generated facts may not be necessarily sound (Bostrom et al., 2021). Recently, Bostrom et al. (2021) propose ParaPattern, an automated pipeline for building two kinds of single-step deductions. Different from the above work, our method generates the explanations in a multi-step tree structure (Dalvi et al., 2021), showing *what* and *how* facts are combined to draw novel intermediate conclusions and reach the final answer. The intermediate conclusions are generated by deductive and abductive entailment modules that are constrained to perform specific types of reasoning.

Multi-Hop Proof Generation. Recently, several works propose to use the transformers for multi-hop logical reasoning and generate reliable formal proofs (Clark et al., 2020; Talmor et al., 2020; Saha et al., 2020, 2021; Tafjord et al., 2021). However, they mainly focus on synthetic sentences, which have low linguistic variation and struggle to represent the flexible sentences in real QA scenarios.

Neural Module Networks. Decomposing the reasoning process into several pre-defined operations overlaps with the idea of neural module networks (Andreas et al., 2016; Hu et al., 2017; Gupta and Lewis, 2018; Gupta et al., 2020; Jiang et al., 2019). They typically assume that the question could be parsed into an executable program, i.e., the question *explicitly* describes the process to arrive at the answer. In our work, we tackle the questions/hypotheses that do not trivially describe the reasoning process and could be more challenging.

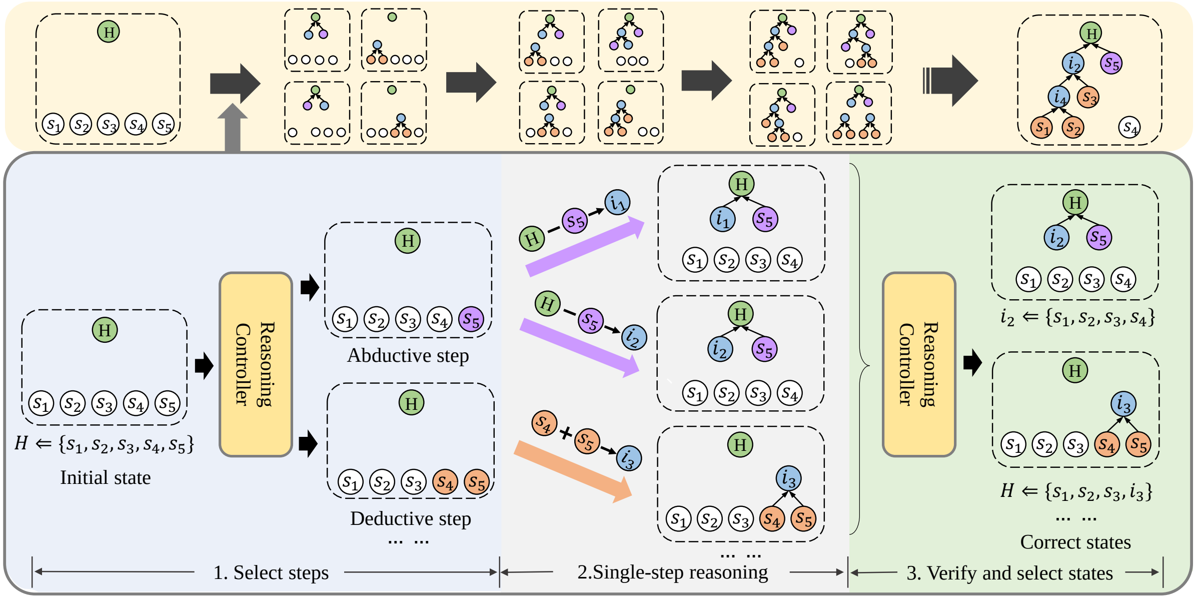

Figure 2: Reasoning process of METGEN framework. The goal is to prove the hypothesis with the given facts through reasoning iterations (the upper part). In the first reasoning iteration (the lower part), the initial state is denoted as $H \Leftarrow \{s_1, s_2, s_3, s_4, s_5\}$. First, the controller selects promising steps, such as the backward abductive step $H - s_5$ and the forward deductive one $s_4 + s_5$. Then, single-step entailment modules perform the reasoning steps and generate novel intermediate facts including i_1, i_2, i_3. After that, the controller verifies that the states $i_2 \Leftarrow \{s_1, s_2, s_3, s_4\}$ and $H \Leftarrow \{s_1, s_2, s_3, i_1\}$ are closer to the completion of reasoning and thus selects them for the next reasoning iteration.

3 Task Definition

As shown in Figure 1, the inputs are a hypothesis H and some fact sentences $S = \{s_1, s_2, \ldots, s_n\}$ (including both relevant and irrelevant ones) expressing knowledge. H is a declarative sentence derived from a question+answer pair and can be proved by the knowledge in S. The desired output is a valid entailment tree T with the root node being H, the leaves being facts selected from S, and the intermediate nodes being novel intermediate facts (e.g., i_1, i_2). T is considered valid if each non-leaf node is a valid entailment (a conclusion that "a person would typically infer" (Dagan et al., 2013)) of its immediate children. We denote the annotated gold tree as T_{gold} and its leaf facts as S_{gold}. Following Dalvi et al. (2021), we consider three increasingly difficult tasks with different S:

Task1 (no-distractor): $S = S_{gold}$,
Task2 (distractor): $S = S_{gold}$ + 15-20 distractors,
Task3 (full-corpus): S = a corpus C.

4 METGEN

Figure 2 illustrates the reasoning process of METGEN. We reason one step at a time and iteratively generate the entailment trees. In each iteration, given a reasoning state (e.g., the initial state $R_0 : H \Leftarrow S$, where we aim to prove H using S), the reasoning controller selects promising steps, including forward deductive steps and backward abductive ones. We then use the corresponding modules to perform single-step entailment on the selected steps and generate novel intermediate facts. Finally, we use the controller to verify the generated facts and select the correct states to perform further reasoning. We introduce details about the module design, reasoning controller, and reasoning algorithm in Sec 4.1, 4.2, and 4.3, respectively.

4.1 Single-step Entailment Modules

4.1.1 Module Definition

We propose to divide the single-step entailment reasoning ability into a set of well-defined basic logical operations. Such a design could help improve the generalization capability (Bostrom et al., 2021; Rudin, 2019). As shown in Table 1, we adopt three common reasoning types, covering over 90% of the steps in EntailmentBank according to the analysis by Dalvi et al. (2021). Note that the entailment module types could be adjusted according to the specific tasks or domains, which allows our method to be flexibly applied to other problems.

We adopt both the deductive and abductive versions of the reasoning types. Take a gold step $s_1 + s_2 \rightarrow i_1$ as an example. Deduction is the process of reasoning from the premises to reach

Type	Definition	Logical Regularity	Example
Substitution	performing taxonomic, merynomic or other kinds of reasoning that substitute one entity for another	s_1: $\forall x \in X\ P(x)$ s_2: $a \in X$ i_1: $P(a)$	s_1: the mass of a **planet** causes the pull of gravity on that **planet**. s_2: **earth** is a kind of **planet**. i_1: the mass of **earth** causes the pull of gravity on **earth**.
Conjunction	combining the details of both input sentences into a single output sentence	s_1: $P(x)$ s_2: $Q(x)$ i_1: $P \wedge Q(x)$	s_1: chemical splashing can **cause harm to humans / to the eyes**. s_2: chemical splashing sometimes occurs **during experiments**. i_1: chemical splashing **during experiments** can **cause harm to the eyes**.
If-then	applying a conditional claim or a specific rule (one of the input sentences) to the other input sentences	s_1: $P(x) \rightarrow Q(x)$ s_2: $P(x)$ i_1: $Q(x)$	s_1: if **something requires something else** then that **something else is important to that something**. s_2: **nuclear fusion is required for star formation.** i_1: **nuclear fusion is important to star formation**.

Table 1: The used reasoning types. Here, s_1 and s_2 denote input premises for deductive modules, while i_1 denotes the entailed conclusion. For logical regularity, $P(x)$ means that the predicate P is true for the entity x.

a logical conclusion. A deductive module takes the two premises s_1 and s_2 as inputs and outputs a conclusion $\hat{i}_1$ according to its reasoning types (denoted as $s_1 + s_2 \rightarrow \hat{i}_1$). Abduction is to find the best explanation given complete/incomplete observations (Harman, 1965). In the context of the entailment steps, given a conclusion i_1 and a premise fact s_2 as observations, the abductive module yields a plausible premise $\hat{s}_1$ (denoted as $i_1 - s_2 \rightarrow \hat{s}_1$), where the generated premise $\hat{s}_1$ and the observed premise s_2 would most likely infer the conclusion i_1. Although the steps in the EntailmentBank may have more than two premises, we only consider the case of two premises. The reason is that the n-premise step ($n > 2$) could be further decomposed into several valid 2-premise steps (Dalvi et al., 2021) (See Appendix Figure 8 for a specific example).

4.1.2 Module Training

Training the entailment modules with data that contains the corresponding logical regularities would guide them to perform correct inferences and ensure soundness (Bostrom et al., 2021). We first train the modules with synthetic sentences to learn the logical transformations and then further fine-tune them with the end task.

We follow ParePattern (Bostrom et al., 2021), a pipeline based on syntactic retrieval, rule-based example construction, and automatic paraphrasing, to collect synthetic sentences from Wikipedia. Since Bostrom et al. (2021) only consider the substitution and contraposition deductions, we extend the method to conjunction and if-then deductions by designing the specific syntactic templates and construction rules (See Appendix A.1). In addition, we also considered the abductive form of these modules. We then fine-tune the modules with corresponding steps in EntailmentBank to adapt the modules to the science domain. Since the original steps in EntailmentBank are not annotated with reasoning types, we manually label 400 steps of the training split and train a classifier with these steps. The remaining steps are labeled with the pseudo labels predicted by the classifier. We *freeze* the parameters of modules once the training is complete.

4.2 Reasoning Controller

In addition to single-step reasoning modules, we need to search for the correct path to reach the target hypothesis. The entire reasoning search space would grow rapidly as the number of input facts increases and there would also be complex branching in the trees. We introduce a reasoning controller to filter out incorrect facts, steps, and states to reduce the search space and complete the reasoning accurately and efficiently.

Figure 2 shows how the controller is used in each reasoning iteration. At the beginning of the iteration, the controller scores all possible *steps* and selects the most promising ones for single-step entailment. After the entailment modules generate intermediate facts, the controller estimates which *state* with a generated fact gets closer to the completion of reasoning and selects the best states for the next iteration. Besides the usage within each iteration, the controller also rates all *facts* at the start of the whole reasoning process and keeps only the relevant facts for the initial state when fact distractors exist.

4.2.1 Controller Model

The controller model scores steps, facts, and states based on a transformer, and its structure is shown in Figure 3.

Encoding. We first encode the target hypothesis and facts of state with a pre-trained transformer: $[\mathtt{CLS}]H[\mathtt{SEP}]s_1[\mathtt{SEP}]\ldots[\mathtt{SEP}]s_n[\mathtt{SEP}]$. We obtain the contextualized representation $\boldsymbol{h}$ for H and $\boldsymbol{f_i}$ for s_i using the average contextualized representa-

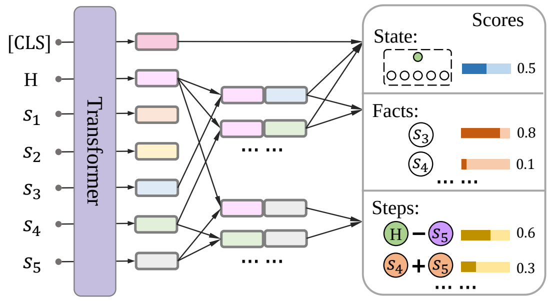

Figure 3: Reasoning controller illustration. Given a state, the controller predicts a score for the whole state, scores for facts, and scores for all possible steps.

tion of all tokens within the sentence.

Steps. We introduce feed forward networks $\mathrm{FFN}_{\mathrm{ded}}$ and $\mathrm{FFN}_{\mathrm{abd}}$ for deductive steps and abductive steps, respectively. Each combination of two facts is a possible deductive step (s_i, s_j). Each combination of the target hypothesis and a fact is a possible abductive step (H, s_k). We score them by a score function G_{step},

$$\begin{aligned} G_{step}(s_i, s_j) &= \mathrm{FFN}_{\mathrm{ded}}([\boldsymbol{f_i}, \boldsymbol{f_j}]), \\ G_{step}(H, s_k) &= \mathrm{FFN}_{\mathrm{abd}}([\boldsymbol{h}, \boldsymbol{f_k}]), \end{aligned} \tag{1}$$

where $[\cdot]$ is the concatenate operation. We normalize the step scores by applying $\mathrm{Softmax}$ over all possible deductive and abductive steps.

Facts. The fact score indicates whether the fact is useful by how similar the fact is to the state's target hypothesis. We assume that if a fact has a smaller depth in the gold entailment tree (i.e., closer to the root), it would be more similar to the target hypothesis than those facts with a larger depth. We introduce $\mathrm{FFN}_{\mathrm{fact}}$ as a learnable similarity function and determine the fact score by comparing it with the target,

$$G_{fact}(s_i) = \sigma(\mathrm{FFN}_{\mathrm{fact}}([\boldsymbol{h}, \boldsymbol{f_i}])), \tag{2}$$

where σ is the Sigmoid function.

State. The state score reflects the quality of the current state and indicates whether this state should be used for further reasoning. We assign the state score using the following two parts:

$$G_{state}(R) = \frac{\lambda}{n} \sum_{s_i \in S} G_{fact}(s_i) + (1-\lambda)\sigma(\mathrm{FFN}_{\mathrm{cls}}(\boldsymbol{f}_{\texttt{[CLS]}})), \tag{3}$$

where λ is a learnable weight, $\boldsymbol{f}_{\texttt{[CLS]}}$ is the representation of `[CLS]`, $\mathrm{FFN}_{\mathrm{cls}}$ is a feed forward network. The first part helps choose states that contain more relevant facts and fewer distractors. The second part comprehensively considers the whole state and gives the promising one a higher score.

4.2.2 Controller Training

Training State Construction. We decompose the gold entailment trees into several intermediate states for training. We add disturbances to the trees to make positive and negative states. For each gold deductive step (e.g., $s_1 + s_2 \rightarrow i_1$), we use the deductive module to predict a conclusion $\hat{i}_1$. If the predicted $\hat{i}_1$ is correct, we replace i_1 in the state with $\hat{i}_1$ to make new positive states. Otherwise, we replace i_1 with $\hat{i}_1$ to make negative states. The abductive modules are also used in a similar way.

Loss Function. We train the controller with corresponding margin ranking losses $\mathcal{L}_{step}$, $\mathcal{L}_{fact}$, and $\mathcal{L}_{state}$ to learn to rank the correct steps, facts, and states ahead of incorrect ones, respectively. Specifically, the loss for scoring steps is

$$\mathcal{L}_{step} = \frac{1}{N_1} \sum_{(p^+, p^-)} \varphi(G_{step}(p^+), G_{step}(p^-), m_{step}), \tag{4}$$

where p^+ and p^- are the positive and negative step, N_1 is the number of (p^+,p^-) pairs, $\varphi(x_1, x_2, m) = \max(0, x_2 - x_1 + m)$ is the margin loss, and m_{step} is the margin for steps.

For facts, we have

$$\begin{aligned} \mathcal{L}_{fact} =& \frac{1}{N_2} \sum_{s_1^+, s_2^+ \in S_{gold}} \varphi(G_{fact}(s_1^+), G_{fact}(s_2^+), m_{fact}) \\ &+ \frac{1}{N_3} \sum_{s^- \notin S_{gold}} -\log(1 - G_{fact}(s^-)), \end{aligned} \tag{5}$$

where s_1^+ is a fact which has smaller depth in the gold tree than s_2^+, s^- is the distractor, N_2 is the number of (s_1^+,s_2^+) pairs, N_3 is the number of distractors, and m_{fact} is the margin for facts.

For states, we sample a positive state R^+ and a negative state R^- from a tree and train the controller with

$$\mathcal{L}_{state} = \varphi(G_{state}(R^+), G_{state}(R^-), m_{state}), \tag{6}$$

where m_{state} is the margin for states.

Finally, we average the above losses over all trees in the training split and train the controller with

$$\mathcal{L} = \mathcal{L}_{step} + \mathcal{L}_{fact} + \mathcal{L}_{state}. \tag{7}$$

Appendix B gives more controller training details.

4.3 Reasoning Algorithm

Since the entailment trees are generated iteratively and the search space for reasoning could be large for each iteration, we adopt beam search for efficient reasoning. Given the initial state $H \Leftarrow S$, we first remove s_i with a low *fact score* to filter distractors. Subsequently, we perform several reasoning

	Train	Dev	Test	All
Questions / Trees	1,131	187	340	1,840
Entailment steps	4,175	597	1,109	5,881

Table 2: EntailmentBank statistics.

iterations until the target hypothesis is proved or the maximum reasoning depth is reached. In each iteration, we select the steps with the highest *step scores*, execute the steps with all types of deductive or abductive modules, and construct novel states with the generated intermediate facts. We remain the top-K states ranked with *state scores* for the next iteration, where K is the beam size. More algorithm details are in Appendix Algorithm 1.

5 Experiments

We conduct experiments on EntailmentBank (Dalvi et al., 2021), the first dataset supporting QA explanations in the form of the entailment tree. EntailmentBank contains 1,840 entailment trees, each of which corresponds to a question from the ARC dataset (Clark et al., 2018). On average, each tree contains 7.6 nodes across 3.2 steps. Summary statistics are shown in Table 2.

5.1 Evaluation Metrics

Following Dalvi et al. (2021), we first align nodes in the predicted tree T_{pred} with nodes in the gold tree T_{gold} and then evaluate with three dimensions:

- **Leaves:** To evaluate whether T_{pred} uses the correct leaf facts, we compute **F1** score by comparing the predicted leaf facts S_{pred} to S_{gold}.
- **Steps:** To evaluate whether the individual steps are *structurally* correct, we compare all steps in two trees and compute **F1**. A predicted step is considered *structurally* correct if its children's identifiers (e.g., s_1, i_2) perfectly match the gold ones.
- **Intermediates:** To evaluate whether the intermediate conclusions are correct, we report the **F1** of comparing the aligned intermediate conclusions. A predicted intermediate sentence $\hat{i}$ is considered correct if the `BLEURT-Large-512` score of the aligned intermediate pair $(\hat{i}, i)$ is larger than 0.28[1].

The **AllCorrect** score is 1 if F1 is 1, 0 otherwise[2]. Given the above scores, we comprehensively evaluate T_{pred} with **Overall AllCorrect** whose value is 1 if and only if all the leaves, steps and intermediates are all correct. This is a strict metric since any error in T_{pred} will lead to a score of 0.

5.2 Baselines

We compare with the SOTA entailment tree generation method **EntialmentWriter** (Dalvi et al., 2021), which directly generates the linearized trees (e.g., $s_2 + s_5 \rightarrow i_1$: eruptions block sunlight; $s_4 + i_1 \rightarrow H$) given $H + QA + S$ with an end-to-end encoder-decoder framework. We also follow the "Iterative" ProofWriter (Tafjord et al., 2021), which is one of the SOTA proof generation methods for logical reasoning, to extend EntialmentWriter to **EntialmentWriter-Iter**. EntialmentWriter-Iter iteratively generates a part of the linearized tree in one forward process (e.g., $s_2 + s_5 \rightarrow i_1$: eruptions block sunlight;) and concatenates all parts to make the final tree. It completes the step selection and entailment reasoning in a seq2seq model and does not provide the reasoning types of steps.

5.3 Implementation Details

Modules. We implement the entailment modules on top of T5-large (Raffel et al., 2020) with the following two implementations. (1) **Separated.** We implement each module separately. We have six models in total, corresponding to the three reasoning types of deductive and abductive versions. (2) **Prefixed.** We implement all modules with a single model. To specify which reasoning type the model should perform, we follow Raffel et al. (2020) to add a type-specific prefix (e.g., "deductive substitution:") to the input before feeding it to the model. To evaluate the modules, we annotate the types of 275 steps in the dev split. We train the modules with a batch size of 20 for 100 epochs.

Controller. The controller is implemented with albert-xxlarge-v2 (Lan et al., 2019). We train two individual controllers for Task1 and Task2. For Task3, we reuse the Task2 model without additional training. The controllers are trained with a batch size of 10 for 1,000 epochs. The margins m_{step}, m_{fact}, and m_{state} are tuned on the development split and all set to 0.1.

Algorithm. For Task1, we iterate until all facts in S are used. For Task2, we use a fact score threshold of 0.001 to filter distractors and a maximum reasoning depth of 5. We select the top 10% steps for each state and set the beam size to 10. All hyper-parameters are selected using the dev split (Appendix C). For Task3, we follow Dalvi et al.

---

[1] The threshold was picked using 300 manually labeled pairs (Dalvi et al., 2021).

[2] We repair a bug in the official evaluation code, which makes the Intermediate AllCorrect = 1 if the precision = 1 (rather than if F1 = 1), which leads to an overestimation on the Intermediate AllCorrect.

Task	Method	n_{para}	Leaves		Steps		Intermediates		Overall
			F1	AllCorrect	F1	AllCorrect	F1	AllCorrect	AllCorrect

EntialmentWriter-Iter (T5-large)	35	47	25	35
MetGen-prefixed (Ours)	**36**	**53**	**27**	**39**

Table 4: Entailment tree evaluation results on 100 uniformly sampled questions from the test split. We report the proportion (%) of the predicted trees that are rated as valid, following automatic and manual evaluation.

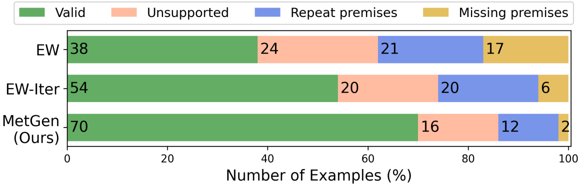

Figure 4: Manual evaluation results of 100 single-step entailments uniformly sampled from the predicted trees of Task2 test spilt. EW denotes EntailmentWriter.

(2021) to retrieve 25 sentences from the corpus C using the H as the query. We use the same retrieval results as EntailmentWriter for a fair comparison. Model checkpoints are selected using the dev split. More implementation details can be found in the Appendix.

6 Result Analysis

6.1 Automatic Evaluation

As shown in Table 3, our methods outperform all baseline methods on the strictest metric Overall AllCorrect for all three tasks. Notice that the trees generated by our methods only contain 2-premise steps, which would lead to a 0 Overall AllCorrect score on 26% of test samples whose annotations contain n-premise ($n > 2$) steps. Even so, our MetGen-separated still obtains an absolute improvement of 1.4%/2.4%/5.7% on Task1/2/3 in comparison to the strongest baseline. With only 9.0% of the model parameters, MetGen-prefixed can outperform the EntialmentWriter (T5-11B) by absolute 0.9%/2.1%/5.7% on Task1/2/3. In the case of using a comparable amount of model parameters, MetGen-prefixed also outperforms the EntialmentWriter-Iter (T5-large) by a large margin. For Task3, we note that all methods perform poorly. The main reason is that the retrieved facts may not contain all the required facts S_{gold} (68% of the cases). We note that MetGen underperforms the baselines on some metrics, probably due to the inaccuracy of the tree alignment algorithm in the automatic evaluation (Appendix G).

6.2 Manual Evaluation

As analysed by Dalvi et al. (2021), the automated metrics might misjudge some valid trees and thus underestimate the performance. To make a more accurate comparison, we perform the manual evaluation. We compare three methods with a comparable amount of model parameters, EntialmentWriter (T5-large), EntialmentWriter-Iter (T5-large), and MetGen-prefixed. For each step and tree, we invite three students as experts to evaluate the validity. The inter-annotator agreement (Cohen's kappa statistic) is 0.85/0.76 for the step/tree, indicating the substantial agreement between annotators.

Validity of Full Entailment Trees. As shown in Table 4, under the manual evaluation, MetGen outperforms the baselines with large margins.

Validity of Individual Entailment Steps. We review the validity of the single-step entailment and annotate each step with one of the four categories:

- **Valid:** The step conclusion can be inferred from

	Implementation	Models	Reasoning Type	Training Data	Overall AllCorrect	Single-step Accuracy
(a)	Sep	6×T5-large	✓	S+E	**28.0**	**81.0**
(b)	Sep	6×BART-large	✓	S+E	26.2	77.0
(c)	Sep	6×T5-base	✓	S+E	27.3	78.0
(d)	Sep	6×T5-large	✓	E	27.8	79.5
(e)	Sep	6×T5-large	✓	S	23.5	43.6
(f)	Pre	1×T5-large	✓	S+E	27.7	78.4
(g)	Pre	1×T5-large	✓	E	27.4	78.1
(h)	Pre	1×T5-large	×	E	25.9	76.0

Table 5: Ablation results on entailment modules. Sep/Pre indicates seperated/prefixed. S/E denotes the synthesis/EntailmentBank step training data.

Task	Method	Leaves	Steps	Intermediate	Overall
Task1	controller	**100.0**	**42.1**	**39.2**	**37.0**
	w/o abduction	100.0	41.4	38.4	36.2
	heuristic	100.0	31.2	31.2	28.8
Task2	controller	**48.6**	**30.4**	**32.7**	**28.0**
	w/o abduction	44.5	28.3	31.6	27.0
	heuristic	3.2	3.2	12.1	3.2

Table 6: Ablation results on the reasoning controller. We report the AllCorrect scores on the test split.

the premises and does not trivially repeat them.

- **Unsupported:** The conclusion is in conflict with, irrelevant with, or not followed from the premises.
- **Repeat premises:** The conclusion trivially repeats one or more of the premises.
- **Missing premises:** The conclusion uses knowledge unstated in the premises. The step would be correct if one additional premise from S is added.

As shown in Figure 4, METGEN achieves considerable improvement in the validity of steps compared to the baseline methods. We note that 17% of the steps of EntialmentWriter belong to missing premises. METGEN constrains the reasoning types of steps and uses the premise-related and context-independent entailment modules to perform every single step. This can reduce the cases of missing premises (from 17% to 2%) and improve the validity of the conclusions (from 38% to 70%).

6.3 Ablation Study

Entailment Modules Analysis. Table 5 reports the ablation results on modules. We report the Overall AllCorrect on test spilt and the single-step entailment accuracy on the labeled dev steps, and can make the following observations. (1) **Separated vs. Prefixed.** We can see that METGEN-prefixed achieves slightly worse performance than METGEN-separated ((a) vs. (f) and (d) vs. (g)). This is mainly because separate modules could better learn different types of reasoning. However, in our final system, we still choose to use METGEN-prefixed due to the consideration of model size. (2) **Clarifying Reasoning Types.** We train a module to infer without distinguishing or assigning specific reasoning types. We find that the performance drops from 27.4% to 25.9% ((g) vs. (h)), suggesting that clarifying the reasoning types of the entailment steps is crucial for generating entailment trees. (3) **Training Data.** Comparing (a) and (d), we find that training with the synthesis data could improve the accuracy. Without tuning on EntailmentBank (setting (e)), the modules might not adapt to the science domain and obtain low step accuracy. However, the well-trained controller would verify and filter the error conclusions, thus our method can still achieve 23.5% on Overall AllCorrect. (4) **Generative Model.** A stronger generative model, which achieves higher single-step accuracy, could achieve higher tree generation performance (comparing (a), (b) and (c)), indicating that our method can be further improved with stronger entailment modules.

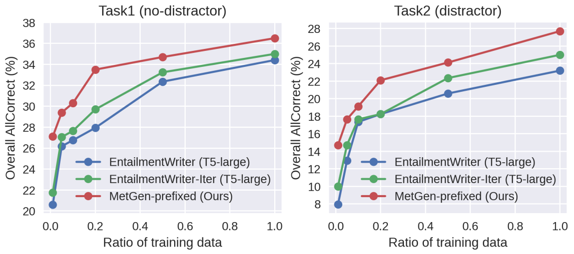

Figure 5: Results on different ratios (0.01, 0.05, 0.10, 0.20, 0.50, 1.00) of EntailmentBank training data.

Controller and Algorithm Analysis. (1) **Is the reasoning controller necessary?** To answer this question, we design a **heuristic** generation algorithm without the controller (Appendix D). It uses the `BLEURT` scores as heuristic information to guide the reasoning. As shown in Table 6, the heuristic method achieves observable lower performance. The controller could aid in eliminating the error steps and states, so as to find the valid trees efficiently and accurately. Without the controller, we find it difficult to find effective heuristic information. (2) **Effect of Abductive Steps.** The generation performance drops when abductive steps are not used. This suggests that abductive steps, as a way of backward searching, could help improve the quality of generated trees.

6.4 Data-scarce Setting

Figure 5 reports the results in the data-scarce setting. Our method is more data-efficient. With only 1% of the EntailmentBank training data, our

Method	eQASC P@1	eQASC NDCG	eOBQA P@1	eOBQA NDCG
EntialmentWriter (T5-large)	52.48	73.14	69.07	89.05
EntialmentWriter-Iter (T5-large)	52.56	73.28	72.15	90.19
METGEN-prefixed (Ours)	**55.81**	**74.19**	**74.89**	**90.50**

Table 7: Cross-dataset results on the eQASC and eOBQA test split.

method obtains 14.7% on Task2 Overall AllCorrect, in comparison to 10.0% of the strongest baseline. When the data is scarce, the advantage of training our modules with synthetic data becomes more significant. It can help alleviate the overfitting on few EntailmentBank sentences.

6.5 Cross-dataset Setting

To test the generalization capability of our method, we conduct cross-dataset experiments on datasets eQASC and eOBQA (Jhamtani and Clark, 2020), which collect *one-step* entailment trees for questions from QASC (Khot et al., 2020) and OpenBookQA (Mihaylov et al., 2018), respectively. Given H and S, their task requires selecting the valid one-step trees (e.g., $s_1 + s_2 \rightarrow H$) from a candidate set. We apply the Task2 models (without fine-tuning on eQASC or eOBQA) to select from the candidate trees (Appendix E). Following Jhamtani and Clark (2020), we evaluate models with the **P@1** and **NDCG** metrics. Questions with no valid tree are filtered. As shown in Table 7, our method achieves better generalization performance. Instead of training a seq2seq model with a single generation loss, our method explicitly models the step and state selection ability (equation (1) and (3)) and guides the controller with specific losses to rank the correct ones ahead of incorrect ones. Such a manner could aid in alleviating the overfitting on training data and improve the generality.

7 Conclusion

We propose METGEN, a module-based framework to generate the entailment trees for explaining answers. METGEN reasons with single-step entailment modules and the reasoning controller. Experiments on EntailmentBank benchmark show METGEN can generate valid trees with reliable steps and achieve SOTA performance.

A Entailment Modules Training Details

A.1 Synthetic Data

We follow the ParaPattern (Bostrom et al., 2021) to collect synthetic training data for the entailment modules. Since they only consider the substitution and contraposition deductions, we extend the method to conjunction and if-then deductions by designing the specific syntactic templates and construction rules. Table 9 shows the used syntactic patterns. We use Spacy[3] to match sentences from Wikipedia (version "20200501.en"). In total, we collect about 24k, 443k, and 97k sentences for substitution, conjunction, and if-then modules, respectively. We follow Bostrom et al. (2021) to train the modules on the synthetic data with a learning rate of 3e-5 for 1 epoch.

A.2 Reasoning Type Annotations of EntailmentBank

The original steps in the EntailmentBank are not annotated with reasoning types. We manually annotated the reasoning types of 400 steps in the training split (Train-manual) and 275 steps in the development split (Dev-manual). To label the remaining steps in the training split, we train a classifier with the Train-manual steps. We use the Roberta-large (Liu et al., 2019) as our classifier. It achieves an accuracy rate of 88% on the Dev-manual steps. We use the classifier to predict the reasoning types of the remaining 2-premise steps and take the predicted types as the pseudo labels (Train-pseudo). Table 8 shows the statistics of the reasoning type annotations.

Split	Sub.	Conj.	If-then	All
Train-manual	211	105	84	400
Train-pseudo	2,441	812	535	3,788
Dev-manual	153	71	51	275

Table 8: Statistics of the step reasoning type annotations.

B Controller Training Details

Training Data. We decompose the gold entailment trees into several intermediate states for training. For example, the tree in Figure 1(c) can be decomposed into the following positive states: $R_0 : H \Leftarrow \{s_1, s_2, s_3, s_4, s_5\}$, $R_1 : H \Leftarrow \{s_1, s_3, s_4, i_1\}$, and $R_2 : i_1 \Leftarrow \{s_1, s_2, s_3, s_5\}$. The state R_0 has two distractors s_1 and s_3, one positive deductive step $s_2 + s_5 \rightarrow i_1$, and one positive abductive step $H - s_4 \rightarrow i_1$. We add disturbances to the trees to make positive and negative states. For the state R_1, the fact i_1 is the conclusion of gold step $s_2 + s_5 \rightarrow i_1$. We use a deductive module to predict a conclusion $\hat{i}_1$ given s_2 and s_5. If the predicted $\hat{i}_1$ is correct, we replace i_1 with $\hat{i}_1$ to make new positive states $R_1^+ : H \Leftarrow \{s_1, s_3, s_4, \hat{i}_1\}$. The R_1^+ can be used to perform further reasoning. Otherwise, we replace i_1 with $\hat{i}_1$ to make negative states R_1^-. The R_1^- contains an incorrect conclusion $\hat{i}_1$ and thus should not be used for further reasoning. The reasoning controller should be trained to learn to distinguish between R_1^+ and R_1^- and give the R_1^+ a higher state score than R_1^-. To judge whether the generated $\hat{i}_1$ is correct, we follow the evaluation metrics (Dalvi et al., 2021) to use `BLEURT`. The predicted $\hat{i}_1$ is considered correct if the `BLEURT` score between $\hat{i}_1$ and the gold i_1 is larger than 0.28.

C Reasoning Algorithm and Hyperparameter Analysis

Algorithm 1 shows the whole reasoning process. The hyperparameters are selected with the development split, as shown in Figure 6. We select a beam size of 10, a max reasoning depth of 5, a distractor threshold of 0.001, and a step sampling rate of 10%. We only consider the steps whose sentences have word overlap. When constructing the entailment tree, we use the `BLEURT` scores to align the target of a state to the most similar fact. Note that when making a new reasoning state with the step p and the novel intermediate fact i, if the step p is a backward abductive step, we replace the original target hypothesis with i and treat the i as the target hypothesis which the new state aims to prove (as shown in Figure 2). We run our method three times and report the average performance.

D Heuristic Reasoning Algorithm without the Controller

To investigate the effect of the reasoning controller for entailment tree generation, we design a heuristic generation algorithm that does not use the reasoning controller. Since the cost of traversing the entire search space is unaffordable, we adopt the beam search. In each reasoning state, we try all possible steps with entailment modules and make new candidate reasoning states. To select the correct states, we use the `BLEURT` scores as the heuristic information to guide the search process. Specifically,

Algorithm 1 Reasoning Algorithm

```
Input: Hypothesis $H$, fact sentences $S$, controller, deductive modules $M_{ded}$, abductive modules $M_{abd}$
Parameter: Beam size $K$, max reasoning depth $D$, distractor threshold $\theta$, step sampling rate $\tau$
// Construct initial reasoning state
Remove $s_i$ with fact score less than $\theta$ in $S$
$R_{init} \leftarrow (H \Leftarrow$ the filtered sentences $S')$
$\mathcal{R}_{beam} \leftarrow \{R_{init}\}, \mathcal{R} \leftarrow \mathcal{R}_{beam}$
// Reasoning with beam search
while the depth does not reach $D$ do
    $\mathcal{R}'_{beam} \leftarrow \{\}$
    for $R \in \mathcal{R}_{beam}$ do
        // Select promising steps
        for $p \in$ steps of $R$ with top $\tau\%$ step score do
            // Single-step entailment reasoning
            for $m \in M_{ded}$ or $m \in M_{abd}$ do
                execute step $p$ with module $m$ and obtain a novel intermediate fact $i$
                construct a new state $R_{new}$ with the step $p$ and the fact $i$
                $R'_{beam} \leftarrow R'_{beam} \cup \{R_{new}\}$
            end for
        end for
    end for
    // Verify and select states
    $\mathcal{R}_{beam} \leftarrow K$ states with the highest state scores from $R'_{beam}$
    $\mathcal{R} \leftarrow \mathcal{R} \cup \mathcal{R}_{beam}$
end while
// Construct the entailment tree
for $R \in \mathcal{R}$ do
    Align the target of $R$ to the most similar fact sentence of $R$ to make a tree $T$
end for
Select the tree $\hat{T}$ with highest score
Return The entailment tree $\hat{T}$
```

given a candidate state $R : H \Leftarrow S$, we estimate the similarity between a fact $s_i \in S$ and the target H by

$$G'_{fact}(s_i) = \texttt{BLEURT}(H, s_i), \tag{8}$$

and then score a candidate state by

$$G'_{state}(R) = \frac{1}{n} \sum_{s_i \in S} G'_{fact}(s_i). \tag{9}$$

The top-K candidate states with the highest state scores are selected to perform further reasoning, where K is the beam size. We use the same beam size as the algorithm with the controller uses.

E Experiment Details on eQASC and eOBQA

For each question+answer pair, the eQASC/eOBQA provides the corresponding hypothesis H, about 10/4 facts as S, and a candidate set of steps. Each candidate step is a 2-premise single step from two facts to H (e.g., $s_1 + s_2 \rightarrow H$) and can be viewed as a *one-step entailment tree* with three nodes. The target is to select the correct trees/steps from the candidate set. There might be more than one correct tree in the candidate set. We conduct experiments on the questions with at least one correct entailment tree (677 eQASC questions and 79 eOBQA questions). Since the given S contains distractors, we adopt the Task2 models trained on EntailmentBank (without further fine-tuning on eQASC and eOBQA) to perform cross-dataset experiments.

For our method, we follow our Task2 reasoning algorithm to select from the candidate trees/steps. Specifically, we first filter out the facts in S with low fact scores using a threshold (selected using the development split). Then we predict the step scores for the candidate steps and select the step with the highest score. For the EntailmentWriter, we feed the S and H to the EntailmentWriter and score each candidate step with the $\frac{1}{\mathrm{PPL}}$, where PPL is the perplexity of the sequence segment representing the step (e.g., $sent1$ & $sent2$ for $s_1 + s_2$ in the official EntailmentWriter implementation).

We follow the official evaluation metrics of eQASC and eOBQA. The P@1 (Precision@1) measures the fraction of cases where the selected tree (topmost ranked) is correct. It is equivalent to the Overall AllCorrect score between the top-1 predicted one-step tree and the best-matching gold tree. The NDCG (Normalized Discounted Cumulative Gain) metric measures how well ranked the candidate trees are when ordered by the predicted scores. It reflects the model's ability to distinguish the validity of trees and rank the correct trees ahead of the incorrect ones.

F Main Experimental Environments

We deploy all models on a server with 500GB of memory and one 40G A100 GPU. Specifically, the configuration environment of the server is ubuntu 21.04 and our code mainly depends on

python 3.8.10 and PyTorch 1.7.1. We use the pre-trained language models from `HuggingFace Transformers`[4]. We use the Adafactor optimizer (Shazeer and Stern, 2018) implemented by `HuggingFace Transformers`.

G Discussion on the Automatic Evaluation

As discussed by Dalvi et al. (2021), the automatic entailment tree evaluation metrics might misjudge in some cases (e.g., tree structure variation) and still need to be improved. In fact, how to quantitatively evaluate a predicted tree remains a challenging problem. In the existing metric, the first step is the tree alignment algorithm (Dalvi et al.,

---

[4] https://github.com/huggingface/transformers

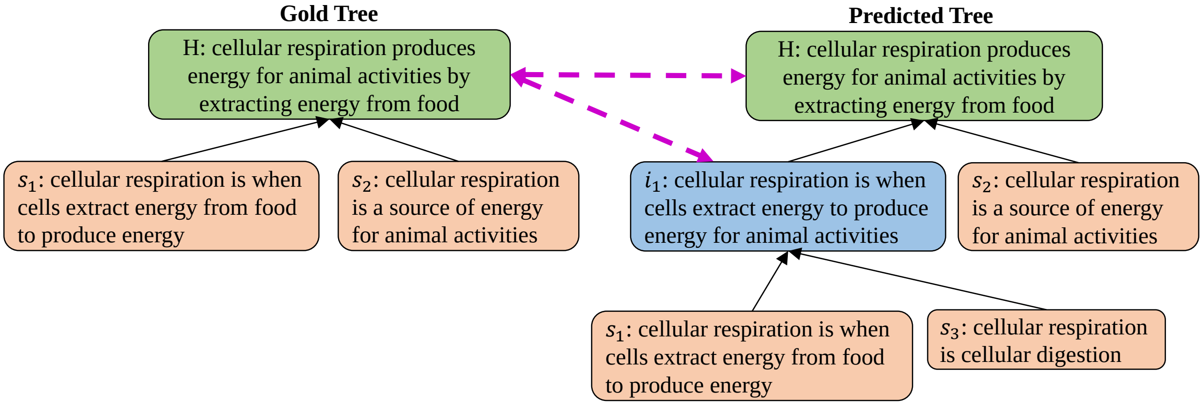

Figure 7: An example case illustrating the potential inaccuracy of the automatic evaluation metrics. In the predicted tree, the fact s_3 is a distractor and the step $s_1 + s_3 \rightarrow i_1$ is not a valid entailment. Following the official evaluation code, the nodes i_1, H in the predicted tree are aligned to the H, H in the gold tree, respectively (the dotted line). By comparing the aligned intermediate nodes (i_1 vs. H, H vs. H), the predicted tree achieves a Step F1 score of 0.0 and an Intermediate F1 score of 1.0. The Intermediate F1 score being 1.0 should have indicated that the predicted tree has perfect intermediate conclusions. However, the i_1 is not entailed by the s_1 and s_3.

2021). The nodes in the predicted tree T_{pred} are aligned to the nodes in the gold tree T_{gold} for further comparison. Each non-leaf node i_{pred} of T_{pred} is aligned to the first non-leaf node i_{gold} where the Jaccard similarity of their respective leaf sentences is maximum. For any i_{pred} with zero Jaccard similarity to all gold nodes, it is aligned to a dummy gold node with a blank conclusion. In the official implementation, (1) each i_{gold} may correspond to more than one i_{pred}, while there is no penalty for duplication when calculating Intermediate F1; (2) the root node (the *given* hypothesis sentence which is *identical* in T_{pred} and T_{gold}) is trivially viewed as a normal intermediate node (the *novel generated* intermediate sentence). Because of these two reasons, the Intermediate F1 might achieve a high score (indicating the T_{pred} can draw correct intermediate conclusions from the premises), even when the Step F1/AllCorrect is relatively low (indicating the T_{pred} does not select the correct premises for the intermediate nodes). For example, the EntailmentWriter (T5-11B) for Task3 achieves an Intermediate F1 of 36.4% while the Step F1/AllCorrect is only 7.8%/2.9% (Dalvi et al., 2021). Figure 7 shows a specific case.

To alleviate the inaccuracy caused by the above reasons, we mainly use the more strict metrics (i.e., Leaves/Steps/Intermediates/Overall AllCorrect) for comparison. Furthermore, we adopt manual evaluation on the full trees and individual steps to make a more accurate comparison (Sec. 6.2).

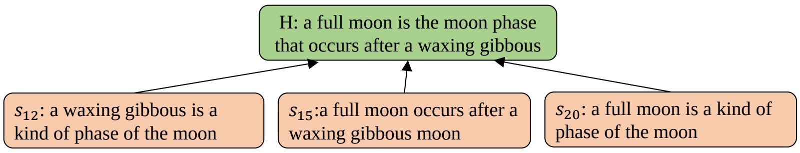
H Case Study

We show some entailment trees generated by our METGEN-separated on the Task2 questions in Figure 8, 9, 10, 11. METGEN can generate a valid entailment tree which may have a different structure with the gold one (Figure 8). METGEN can handle medium-complexity questions, generate valid entailment trees and provide the reasoning types of steps (Figure 9 and 10). The questions which require more complex reasoning (e.g., the gold tree in Figure 11 requires 11 leaf facts and 8 entailment steps) remain challenging. Although the full tree generated by our method for such complex question can be not entirely correct, the intermediate conclusions (e.g., i_1, i_2 in Figure 11) are still reliable.

Question Q: Which phase of the Moon occurs after a waxing gibbous?
Answer A: full moon
Hypothesis H: a full moon is the moon phase that occurs after a waxing gibbous
Facts S:

s1: state of matter is a property of matter and includes ordered values of solid / liquid / gas
s2: the moon is earth 's moon
s3: usually means most of the time
s4: phase means state
s5: occur is similar to appear
s6: the moon orbits the earth
s7: to be found in means to be contained in
s8: revolving around something means orbiting that something
s9: the moon orbiting the earth occurs once per month
s10: a complete revolution / orbit of the moon around the earth takes 1 / one month
s11: amount is a property of something and includes ordered values of none / least / little / some / half / much / many / most / all
s12: a waxing gibbous is a kind of phase of the moon
s13: warm / becoming warm means heat is added
s14: a phase change is when matter / a substance changes from one state of matter into another state of matter
s15: a full moon occurs after a waxing gibbous moon
s16: the moon reflects sunlight towards the earth
s17: generally means usually
s18: to happen means to occur
s19: type of moon / kind of moon means moon phase
s20: a full moon is a kind of phase of the moon
s21: visible means able to be seen
s22: motion / movement means moving / to move
s23: the moon completes a lunar cycle over a period of 29 days
s24: the moon rising occurs once per day
s25: lunar phase is synonymous with moon phase

Gold Tree



Predicted Tree

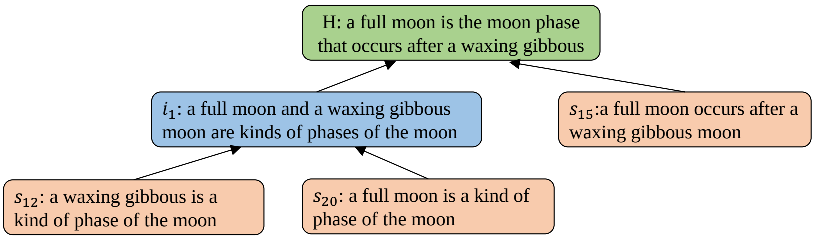


Figure 8: Case 1. The predicted entailment tree consists of two 2-premise steps, while the gold tree consists of one 3-premise step. Under the automatic evaluation metric, the predicted tree would be rated as invalid (Overall AllCorrect = 0), since the predicted steps do not match the gold step. However, the predicted tree should be valid because each step in the tree is a valid entailment (i.e., the 3-premise step can be decomposed into two valid 2-premise steps). It would be rated as valid under manual evaluation.

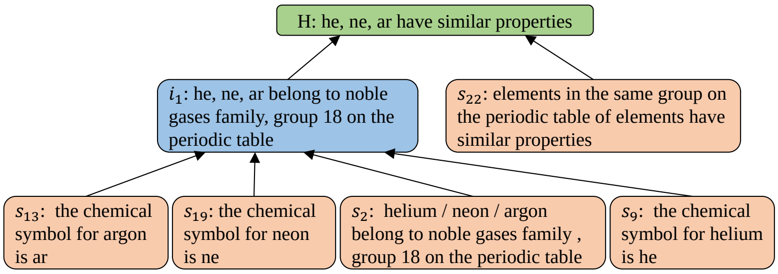
Question Q: According to the Periodic Table of the Elements, which set of elements has similar properties?
Answer A: He, Ne, Ar
Hypothesis H: he, ne, ar have similar properties
Facts S:

s1: cannot is the opposite of can
s2: helium / neon / argon belong to noble gases family , group 18 on the periodic table
s3: a periodic table is a kind of scientific model
s4: charge is a property of an object / a material / a substance and includes ordered values of negatively-charged / neutral / positively-charged
s5: including means containing
s6: similar means in common
s7: magnetism is a property of materials / objects and includes ordered values of nonmagnetic / magnetic
s8: a proton has a positive 1 electric charge
s9: the chemical symbol for helium is he
s10: similarity means the same property
s11: identical means copy
s12: chemical reactivity is a property of elements and includes ordered values of reactive / unreactive
s13: the chemical symbol for argon is ar
s14: amount is a property of something and includes ordered values of none / least / little / some / half / much / many / most / all
s15: an element is identified by its number of protons
s16: according to is similar to be determined by
s17: a group / family in the periodic table means a column in the periodic table
s18: characteristic means property
s19: the chemical symbol for neon is ne
s20: same means identical / equal in value / amount / number / quantity
s21: made of is similar to contains
s22: elements in the same group on the periodic table of elements have similar properties
s23: in common is similar to the same
s24: positive charge is the opposite of negative charge
s25: identical is the opposite of different

Gold Tree



Predicted Tree

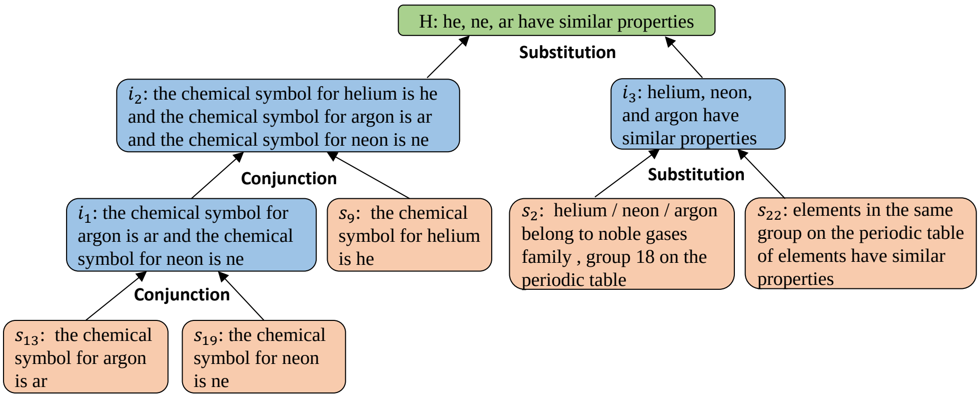


Figure 9: Case 2. Explaining the question and answer in this case requires 5 leaf facts from the given 25 facts. METGEN can select the correct facts, generate valid entailment trees, and provide the reasoning types of steps.

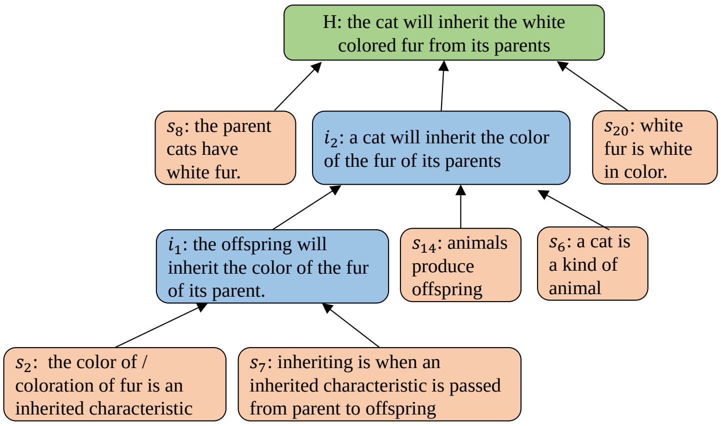
Question Q: Which trait would a cat most likely inherit from its parents?
Answer A: having white fur
Hypothesis H: the cat will inherit the white colored fur from its parents
Facts S:

s1: heredity is similar to inheritance
s2: the color of / coloration of fur is an inherited characteristic
s3: the mature / adult form of a kitten is called a cat
s4: if an organism passes on its traits then future generations will have those traits
s5: freckles are an inherited characteristic
s6: a cat is a kind of animal
s7: inheriting is when an inherited characteristic is passed from parent to offspring
s8: the parent cats have white fur
s9: coloration means a thing 's color
s10: an animal knows how to do instinctive behaviors when it is born
s11: color is a kind of physical / visual property
s12: offspring receives half of the genes from each parent
s13: a homozygous recessive organism contains only recessive genes
s14: animals produce offspring
s15: trait means property
s16: the size of an organism is an inherited characteristic
s17: genetic / hereditary means of genes / heredity
s18: coat means fur coat
s19: genes contains genetic information
s20: white fur is white in color
s21: coloration means a pattern of colors
s22: hair / fur is a part of skin for protection / keeping warm
s23: the shape of body parts is an inherited characteristic
s24: hair is similar to fur
s25: dna are a vehicle for passing genes from parent to offspring

Gold Tree



Predicted Tree

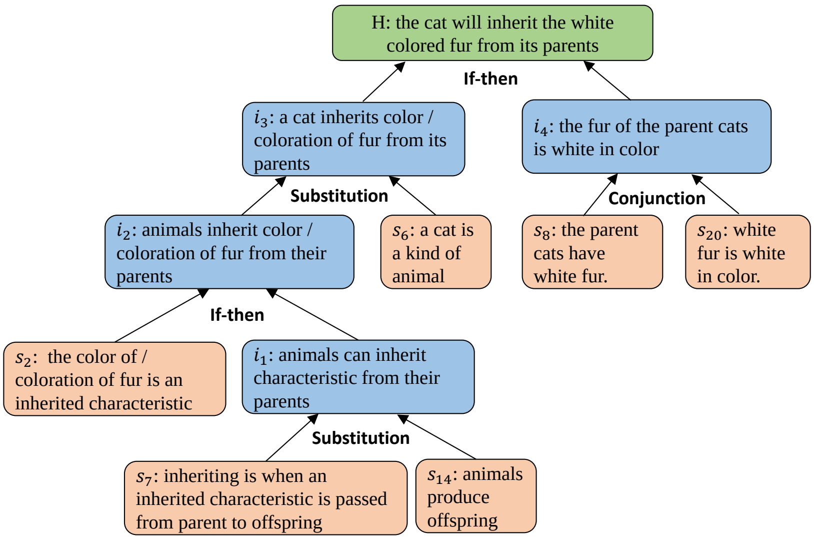


Figure 10: Case 3. METGEN can handle medium-complexity questions and provide the reasoning types of steps.

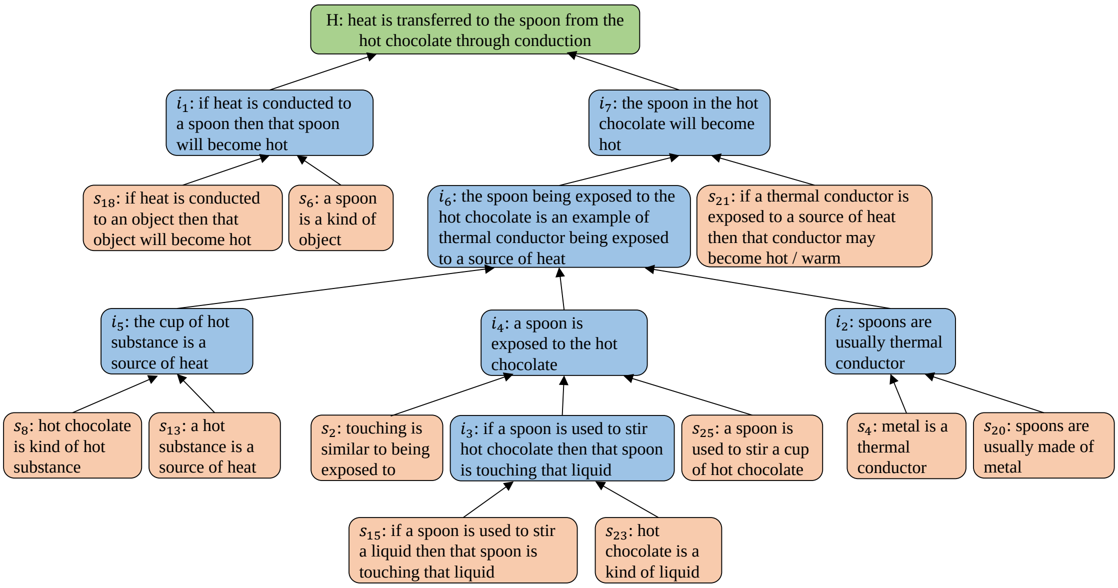
Question Q: A student is mixing a cup of hot chocolate with a spoon. How is the heat transferred between the hot chocolate and the part of the spoon that is in the hot chocolate?
Answer A: Conduction transfers energy from the hot chocolate to the spoon.
Hypothesis H: heat is transferred to the spoon from the hot chocolate through conduction
Facts S:
s1: static electricity is when electrons are exchanged between objects through friction
s2: touching is similar to being exposed to
s3: if something transfers energy to something else then that something else absorbs that energy
s4: metal is a thermal conductor
s5: friction occurs when two object 's surfaces move against each other
s6: a spoon is a kind of object
s7: if something is in something else , then that something is exposed to that something else
s8: hot chocolate is kind of hot substance
s9: conductivity is a measure of how easily electricity travels through a material
s10: friction causes the temperature of an object to increase
s11: the heat energy in the cooler object increases in thermal conduction
s12: if one object absorbs more energy than another object , then the object will be warmer
s13: a hot substance is a source of heat
s14: conductivity is a kind of physical property
s15: if a spoon is used to stir a liquid then that spoon is touching that liquid
s16: thermal energy is a kind of energy
s17: absorbing energy causes objects / materials / substances to heat
s18: if heat is conducted to an object then that object will become hot
s19: sending electricity through a conductor causes electricity / electric current to flow through that conductor
s20: spoons are usually made of metal
s21: if a thermal conductor is exposed to a source of heat then that conductor may become hot / warm
s22: heat means heat energy
s23: hot chocolate is a kind of liquid
s24: heat energy is synonymous with thermal energy
s25: a spoon is used to stir a cup of hot chocolate

Gold Tree



Predicted Tree

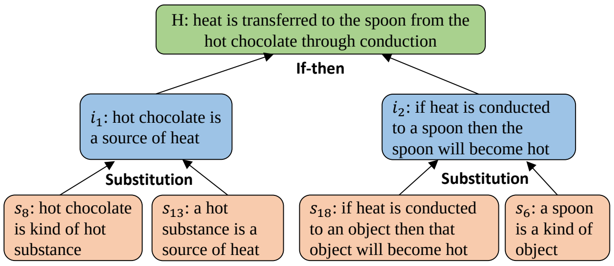


Figure 11: Case 4. The question requires more complex reasoning, where the gold tree contains 11 leaf facts and 8 entailment steps. Although the full tree generated by METGEN is not entirely correct, the intermediate conclusions i_1, i_2 are still reliable.

A Timestep aware Sentence Embedding and Acme Coverage for Brief but Informative Title Generation

Quanbin Wang[1,2][*],Xiexiong Lin[3], Feng Wang[3]
[1]Alibaba Group
[2]College of Computer Science and Technology, Zhejiang University, China
[3]Ant Group

Abstract

The title generation task that summarizes article content in recapitulatory words relies heavily on utilizing the corresponding key context. To generate a title with appropriate information in the content and avoid repetition, we propose a title generation framework with two complementary components in this paper. First, we propose a Timestep aware Sentence Embedding (TSE) mechanism, which updates the sentences' representations by re-locating the critical words in the corresponding sentence for each decoding step. Then, we present an Acme Coverage (AC) mechanism to solve the repetition problem and preserve the remaining valuable keywords after each decoding step according to the final vocabulary distribution. We conduct comprehensive experiments on various title generation tasks with different backbones, the evaluation scores of ROUGE and METEOR in varying degrees are significantly outperforming most of the existing state-of-the-art approaches. The experimental results demonstrate the effectiveness and generality of our novel generation framework TSE-AC.

1 Introduction

On account of the existence of many articles and news, automated title generation which summarizes the source content into a succinct title with recapitulatory words can significantly reduce the cost of obtaining information and improve the efficiency of information transmission.

As the example shown in Table 1, the subject is composed of different critical words from the email's first two sentences. When generating the word "birthday", the model needs to focus on the phrase "a year old" to form the first sentence's representation. But for the second target word "party", the model has to update the first sentence's embedding by re-locating to the word "party". Therefore, it is necessary for a title generation method to refresh the sentences' embeddings with corresponding key words in different decoding timestep.

email content	We are planning a **party** it has been a while since the group has had a party and my daughter is going to be **a year old**. So we are planning a **party** for November 14th and Vandhana and I would like to **invite** everyone in research and their family. As yet we do not have the ...
email subject	birthday party invitation

Table 1: An example of email and its subject.

End-to-end neural generation models have achieved impressive performance in title generation via sequence-to-sequence (seq2seq) framework (Bahdanau et al., 2014; Sutskever et al., 2014). However, most of them suffered from the difficulty of integrating key information from different parts of the source content effectively. Some other works have realized the importance of the key components from different pieces of the article content (Gehrmann et al., 2018; Li et al., 2018, 2020a; Tan et al., 2017; Cohan et al., 2018), nevertheless, they extract all potentially useful parts as another static input of the model instead of dynamically locating the critical words in combination with the decoding states to update the sentence level representations.

To overcome the shortness of previous works that freeze the sentences' embeddings without considering the changes of the decoding states. we propose a novel title generation architecture with a TSE mechanism, which finely adopts different related words of each sentence to update the sentence's embedding vector in each decoding step. Furthermore, the architecture with TSE incorporates the commonly used hierarchical encoder (Yang et al., 2016; Tan et al., 2017; Cohan et al.,

2018), part of speech (POS) information (Liu et al., 2019), and graph structure (Zhang et al., 2018; Yu et al., 2020) to take full advantages of inner relations among words within each sentence as well as among sentences through the article content, so as to re-locate the related key words for each target word more accurately. This encoding method gives insight into the correlation of each keyword and then integrates them well to summarize the article. To the best of our knowledge, this is the first work which finely updates the embedding of each sentence via the target words for each decoding step.

Besides, repetition is a common problem in generation tasks, which especially stands out in the title generation scenerio due to its succinctness. The coverage mechanism is widely used to address this problem and achieves impressive results (Tu et al., 2016; See et al., 2017). Previous coverage mechanisms focus on maintaining a coverage vector which is the sum of attention distributions over all previous decoding timesteps and make the next attention weights as different from the coverage vector as possible. However, in title generation, the penalization with this kind of coverage vector will penalize all attended keywords, disturbing the attention mechanism in the following decoding steps. And the generated titles may lose some keywords because of the inappropriate penalization. Moreover, since our TSE relies heavily on the attention mechanism, the superimposed negative influence will seriously impair the accuracy of the generated title. In this paper, we leverage an AC mechanism that only prevents repeatedly attending to the word which has been generated actually to avoid producing repetitive text but without missing other valuable keywords.

Our contributions are summarized as follows:

- We propose an end-to-end title generation framework with timestep aware sentence embedding, which is effective for the model to dynamically encode each sentence with critical words and the latest valuable information in the corresponding decoding timestep.

- We present an acme coverage mechanism that solves the repetition problem but avoids unreasonable penalization, which obtains significant outperformance on our novel architecture and other seq2seq models.

- Our model achieves significant improvements over several strong baselines on email subject generation and news headline generation tasks. The detailed experimental results demonstrate that our method is effective and general for different kinds of title generation scenarios.

2 Related Works

Title generation has been investigated for a long time, some classical works (Kennedy and Hauptmann, 2000; Jin and Hauptmann, 2001, 2002; Jin et al., 2020) presented various approaches for different kinds of title generation tasks. Rush et al. (2015) first adopted the attention mechanism to the abstractive title generation task, which is a commonly used method for diverse text generation scenarios (Paulus et al., 2018a; Song et al., 2019; Bi et al., 2020a; Lewis et al., 2020). Zhang et al. (2020) pre-trained a model with objectives tailored for abstractive text summarization, they achieved excellent performances on various tasks. However, it remains a major challenge for seq2seq models to tackle document inputs since more information in long documents will probably confuse the model and result in degraded performance. Some previous works (Zhang and Tetreault, 2019; Tan et al., 2017) chose the approach with two separate stages to avoid long inputs, they generated the title via some selected sentences. These kinds of methods may lose necessary information in the generated titles once some useful sentences are ignored.

Some other works applied hierarchical frameworks to encode document level inputs. Tan et al. (2017); Cohan et al. (2018) utilized a hierarchical encoder to model the discourse structure of long documents, but the sentences' embeddings are static during all decoding steps in their works, we update the embedding of each sentence for every targeted word dynamically based on the corresponding valuable words and the decoding state. Li et al. (2020b) presented a hierarchical model to generate summarization for multiple documents. The main differences between their work and ours are twofold. First is the granularity of the encoder, we pay more emphasize on tokens instead of paragraphs since every word is crucial for title generation. The second but critical difference is the related information locating mechanism used in decoder. They first extracted a central location for the key information and select several paragraphs around it. Our model proposes a TSE mechanism which will focus on all related keywords in each sentence to update their embeddings dynamically

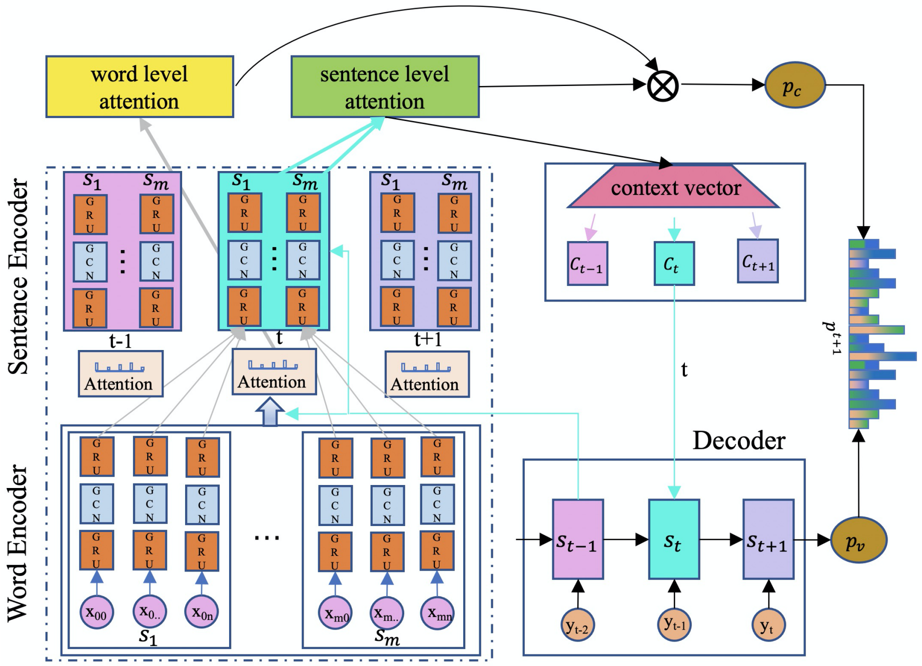

Figure 1: The model architecture of our title generation method

for every decoding step.

Besides, repetition is a common problem in generation tasks, there are several efforts made to address this issue. Temporal attention is a technique that has been applied to neural machine translation (NMT) (Sankaran et al., 2016) and summarization (Nallapati et al., 2016), where each attention distribution is divided by the sum of the previous, which effectively avoids repeated attention but distorts the signal from the attention mechanism and then reduces the performance. N-gram blocking (Paulus et al., 2018b) is another technique proposed to discard the n-gram if it appeared already. Coverage mechanism is a widely used technique to dampen repetition, which was first applied to NMT by maintaining a coverage vector (Tu et al., 2016; Mi et al., 2016). A simple approach that upholds the coverage vector with the sum of the attention distributions was introduced in summarization task and achieved impressive results (See et al., 2017). While this approach penalizes the previous attention distribution indiscriminately, which disturbed the generation of later target words and resulted in degraded performance. We leverage an AC mechanism that maintains a coverage vector based on the attention weights with the highest probability of the final vocabulary, and outperforms difference evaluation metrics compared to the vanilla coverage.

3 Method

3.1 Model Architecture

The problem we focused on in this paper is giving an article A as the content of email, news, story etc., which consists of $|A|$ sentences: $A = [S_1, S_2, ..., S_{|A|}]$, we aim to generate a succinct but informative title of the source content, denoted as a token sequence $Y = [y_1, y_2, ..., y_n]$. The architecture of our approach (as shown in Figure1) is comprised of two essential parts: 1) Timestep aware Sentence Embedding; 2) Acme Coverage.

3.2 Timestep aware Sentence Embedding

The TSE mechanism (Figure 1) is motivated by the fact that each word in the title reflects different parts of the source content (as shown in Table 1). We use the hidden state of the decoder to update the representations of all sentences by re-locating the valuable words for each decoding step. Besides, the roles of words, relations within the same sentence and across different sentences are meaningful for the TSE to identify really useful words. We encode the source article with the POS information, dependency parsing information within each sentence and the lexical relations among all sentences explicitly. The details of the TSE are described in the following.

3.2.1 Encoder

The left part of Figure 1 is a hierarchical encoder which encodes the source content into context vectors by Gate Recurrent Unit (GRU) (Cho et al., 2014) or Transformer (Vaswani et al., 2017) (we take GRU as example in the following) and Graph Convolutional Network (GCN) (Kipf and Welling, 2017; Fu et al., 2019). More precisely, for the word encoder, we use GRU to capture the sequence dependency among words in the same sentence. As words with various POS play different roles in the sentence, we add the POS embedding to the corresponding word's embedding as Equation 1.

Moreover, with the aim of obtaining the inner relationships between different words in a sentence, we apply GCN to encode each word in every sentence separately with the dependency parsing results (Adj_{dep}), if a relation exists, the edge value between the two words is set to 1 in the adjacent matrix, 0 vice versa, the calculation process is shown in Equations 2-4.

$$I_{i,t} = Embed(w_{i,t}) + Embed(POS_{i,t}) \tag{1}$$

$$o_{i_{GRU}}, h_{i_{GRU}} = GRU(I_i) \tag{2}$$

$$o_{i_{GCN}} = GCN(o_{i_{GRU}}, Adj_{dep}). \tag{3}$$

$$o_i, h_i = GRU(o_{i_{GCN}}) \tag{4}$$

We use the similar modules for the sentence encoder compared to the word encoder while the weighted sum h_t^* of the re-located useful words' embedding vectors are used as the first GRU layer's inputs (described in 3.2.2). And we form the adjacent matrix for sentence GCN layer by the cosine similarity between any two sentences' TF-IDF vectors (Adj_{tf-idf}), the values in the matrix are converted to 1/0 by a certain threshold 0.3.

3.2.2 Relocating Critical Words

Different from previous work which used the encoder outputs of the last word as the corresponding sentence's embedding, we apply TSE to locate the corresponding critical words and then update the embedding of each sentence. Concretely, a attention layer is utilized to obtain the encoding input of sentence S_i at decoding step t. First, we use the hidden states h_i of the word-level encoder within sentence S_i and decoder hidden state s_t to calculate the similarity score e_w^t. Secondly, the $softmax$ function is used to calculate the attention weight a_w^t. The calculation process is shown in Equations 5-7,

$$e_i^t = v_w^t \tanh(W_{h,w} h_i + W_{s,w} s_t + b_{a,w}) \tag{5}$$

$$a^t = softmax(e^t) \tag{6}$$

$$h_t^* = \sum_i a_i^t o_i \tag{7}$$

where $v_w^t, W_{h,w}, W_{s,w}, b_{attn,w}$ are learnable parameters.

The weighted sum h_{t,S_i}^* of all sentences is transformed by GRU and GCN layers via Equations 2-4, the output vectors o_{S_i} are used as the representation of sentence S_i at decoding timestep t.

Similar to Equations 5-7, we adopt another attention layer to calculate the context vector $h_{t,s}^*$ based on dynamically updated sentence embeddings O_S. The context vector is applied to calculate the generation probability p_g and vocabulary distribution P_v by Equation 8 and Equation 9.

$$p_g^t = \sigma(W_{h^*}^{'} h_{t,s}^* + W_s^{'} s_t + W_y^{'} y_{t-1} + b^{'}) \tag{8}$$

$$p_v^t = softmax(W_{out}[s_t, h_{t,s}^*] + b) \tag{9}$$

Where $W_{h^*}^{'}, W_s^{'}, W_y^{'}, b^{'}, W_{out}, b$ are learnable parameters, y_{t-1} is the generated word at step $t-1$.

3.2.3 Decoder

For each decoding step, the key information from different parts of the source content which were picked by the TSE are utilized to generate the target word. In addition, the copy mechanism (Vinyals et al., 2015; Gu et al., 2016) is also adopted since some keywords in the title appeared in the source content. Different from the traditional copy mechanism with a pure sequence encoder, a hierarchical copy approach is proposed based on the hierarchical encoder framework. The attention weights over words within the same sentence and the sentence level attention scores are multiplied to calculate the copy probabilities for all words throughout the article content as shown in Equation 10. The final generation probability for word w at decoding step t over the extended vocabulary is calculated by Equation 11.

$$p_c^t = a_w^t * a_s^t \tag{10}$$

$$p^t(w) = p_g^t p_v^t(w) + (1 - p_g^t) \sum_{i:w_i=w} p_{c,i}^t \tag{11}$$

3.3 Acme Coverage

As mentioned above, seq2seq models with copy mechanisms usually suffer from the repetition problem. Especially in the title generation tasks, the repeated words are conspicuous in a concise title and resulting in poor readability. The commonly used Vanilla Coverage (VC) mechanism maintains a coverage vector cov^t to calculate the sum of attention distribution over all previous decoder steps. But for the title generation scenario, the copied word may appear in different positions with different attention weights, the vanilla coverage mechanism only penalizes the model to avoid repeatedly attending to the same locations but not the same word. Besides, since the attention weights in our model are in a hierarchical mode, the weights' values of closely located words may be similar sometimes. The vanilla coverage mechanism may wrongly penalize words that have not been generated actually but are essential in the following steps.

With the aim of making up for the two shortcomings of the vanilla coverage mechanism, we proposed a novel mechanism named Acme Coverage, which only sums over all the attention weights for the words generated at each decoding step if they appeared in the content actually. The final generation probability p^t over the extended vocabulary is used to select the truly generated word w^t, and all the attention weights corresponding to w^t in a_w^t will be added together for loss penalization. The calculation is shown in Equations 12 and 13, where $I_{a_w^t}$ is an indicator function.

$$cov^t = \sum_{t=0}^{t-1} I_{a_w^t} * a_w^t \tag{12}$$

$$I_{a_w^t} = \begin{cases} 1 & i == argmax(p^t) \\ 0 & others \end{cases} \tag{13}$$

Considering the AC mechanism, the calculation of Equation 5 of word-level attention weight will be changed to Equation 14.

$$e_i^t = v^t \tanh(W_h h_i + W_s s_t + W_c cov_i^t + b_a) \tag{14}$$

Similar to the work in (See et al., 2017), we also add the coverage loss in the final loss function to enhance the model's ability to accurately copy while avoiding duplication. The composite loss function is shown in Equation 15

$$L_t = -\log(p^t(w)) + \lambda \sum_i \min\left(a_{w,i}^t, cov_i^t\right) \tag{15}$$

4 Experiments

4.1 Datasets

We conduct sufficient experiments over two publicly available title generation datasets with brief but informative titles to verify the effectiveness of our method, **AESLC** (Zhang and Tetreault, 2019), and **Chinese Gigaword** (Parker et al., 2011).

AESLC The AESLC is an annotated email subject line corpus which is a collection of email messages of employees in Enron Corporation. The average title length in AESLC is 4 words, much shorter than other summary generation tasks. There are 18k samples in AESLC, with train/val/test: 14,436/1,960/1,906. Notably, AESLC has two different targets in validation and test set, one is the original subject of the email, another is annotated subjects from three annotators according to the content.

Chinese Gigaword This dataset is a collection of Chinese news articles, it contains paragraphs from the Chinese Gigaword Fifth Edition release. The average lengths of the source articles and target titles are 665.5 and 16.3. In total there are more than 5M articles, and we sample 74689 for training and 9400/9345 for validation and testing.

4.2 Evaluation

To evaluate the performance of our proposed model and compare it with other baselines, we use the automatic metrics from text summarization and machine translation: ROUGE 1/2/L (Lin and Och, 2004) and METEOR (Denkowski and Lavie, 2014) to measure the quality of the generated titles.

Besides, human evaluation is also adopted to evaluate the quality of the generated news headlines in three dimensions. The first one is the fluency which indicates whether the title is grammatical correct and in high readability. The second one is to measure the relevance between the generated title and the input article. The last but most important one is the usability of the generated title which means whether the brief title can be used as a formal one in practical scenarios. The scores for fluency and relevance are between 1-5. A higher score means the quality is better. The usability is a simple 0/1 judgment. The average score of fluency, relevance and the available ratio are used to compare the quality of the generated titles by different settings of the coverage mechanism.

4.3 Implementation Details

Our model is with 2 layers of bidirectional GRU (or Transformer) and GCN for word and sentence encoders respectively. The POS of each word and dependency parsing information are obtained by the

Spacy toolkit (Honnibal et al., 2020). The threshold of TF-IDF cosine similarity used in sentence-level adjacent matrix is 0.3. The decoder includes two layers of GRU (or Transformer) and one fully connected layer with vocabulary size 35000. The embedding size of words and POS are 256 as same as the hidden size. The Adam (Kingma and Ba, 2014) optimizer is used to train the model with learning rate and dropout ratio set to 0.0005 and 0.5. The coverage loss is added after 2 epochs of training steps with weight set to 1.0. The training is converged in 6 epochs for AESLC dataset and 20 epochs for Gigaword with one NVIDIA P100 GPU and batch size set to 8, the maximum value of gradient clip is 5.0. In the model prediction stage, we use beam search with size 4 to generate the titles for samples in the test sets. The code is available at https://github.com/alipay/Timestep-aware-SentenceEmbedding-and-AcmeCoverage.

4.4 Results

Automatic Evaluation The results of experiments over AESLC are given in Table 2 and Table 3. In Table 2, where the original subjects are ground-truth, our model achieves the best results on all automatic evaluation metrics for both validation and test sets except Rouge-2 and the PEGASUS (Zhang et al., 2020) models. It needs to be acknowledged that PEGASUS performances are much better since it is pre-trained specifically for summarization tasks. We think it is not fair to compare our model with it. Different from the unilateral improvement in (Zhang and Tetreault, 2019), our method not only obtains about **1%** (abs.) improvements on ROUGE-1/L scores but also significantly surpasses the performance on the METEOR score with around **2%** (abs.). Previous works generate titles that only focus on limited sentences or static sentences' embeddings more often produce trivial words, instead, our method generates each target word of the title meticulously via TSE to re-locate the related words and update the sentences' embeddings. Thus, with the increase of ROUGE score, our method also obtains improvement of METEOR score. Identically, when the ground-truth is the human-annotated subjects, our method outperforms competitive baselines remarkably, the results are summarized in Table 3. The improvement on ROUGE-1/L is over **3%** (abs.) and about **2%** (abs.) on METEOR score. We also achieved the best Rouge-2 score in this setting with about **2%** improvements. Besides, we also replace the GRU layers with Transformer layers to test the usefulness of TSE with different backbone and the performance is a little better. It demonstrates that the two novel mechanisms, TSE and AC are effective for different kinds of neural structures.

methods	R-1	R-2	R-L	METEOR

SimCLS	59.29	50.12	58.01	32.86
TSE-VC	58.02	49.30	57.15	31.51
TSE-AC	62.17	53.09	61.21	**36.24**
TSE-VC-Trans	59.11	50.06	58.21	32.44
TSE-AC-Trans	**63.09**	**54.13**	**61.97**	36.17

Table 4: The performance comparison on Gigaword. TSE-VC means using vanilla coverage with TSE.

It is worthy to indicate that our small model achieves much better results compared with the classical pre-trained model T5 (Raffel et al., 2020) and the SimCLS which use the results generated by T5 as candidates to further training the model with contrastive learning (Liu and Liu, 2021). We do not compared to the customized pre-trained model for summarization in (Zhang et al., 2020) since it is unfair. The improvements are higher when using human annotation as references. Through in-depth analysis of the generated results, we found that the pre-trained model suffers from aligning with longer inputs and the short titles with words scattered among the whole content. This information aggregation process has a large gap compared to the pre-training tasks. And the pre-trained T5 without coverage mechanism is poor at tackling the repetition problem. In addition, the pre-trained model with much more parameters and general knowledge learns more easily what it observed, so the performance in Table 3 degrades heavily when the ground-truth is different from the learning target.

Moreover, we also implement experiments over Gigaword in Chinese with longer source articles and titles, the results demonstrate similar conclusions. Specifically, we adopt PALM (Bi et al., 2020b) as a baseline on this dataset. PALM is a pre-trained generation model and we obtained the pre-trained model with a large Chinese corpus from the author, it performs better on many natural language processing tasks in Chinese than T5. Our model achieves over **10%** (abs.) higher score on Gigaword with PG-net as baseline and about **5%** (abs.) improvements over PALM. It indicates the versatility of our approach that is capable for different scenarios of title generation.

Human Evaluation We only conduct human evaluation on Chinese Gigaword dataset since the three human annotators are with Chinese as native language. 200 news texts are sampled from the corpus randomly. The comparison among SimCLS and different settings of the coverage mechanism with our proposed approach are shown in Table 5, from which we can conclude that the general performance of our method with TSE and coverage mechanism can provide titles with high quality. Though our model without coverage mechanism performs worse than SimCLS, two kinds of coverage mechanisms can improve the performance effectively. Especially the AC can raise the titles' quality to higher level and is acceptable to be used in practical scenarios with over **80%** of the generated titles being usable for real news.

method	Fluency	Relevance	Usability
SimCLS	3.07	3.38	65.32%
w/o Cov	2.78	3.16	50.12%
D-VC	3.15	3.56	68.31%
D-AC	**3.54**	**3.72**	**80.27%**

Table 5: Human evaluation on fluency, relevance and usability with different coverage settings.

Analysis of Computation Complexity We further analyze the computation complexity of our model and compared it to traditional seq2seq models. Assuming that the input content has M sentences, and each sentence has N words averagely, the target title contains T tokens. The time complexity of vanilla seq2seq models like PG-net is $O(M * N) + O(T)$ since they have to encode the input content sequentially and generate the title word by word. For our TSE-AC model, the encoder with hierarchical architecture can parallel encode words in each sentence, and we need to update the embedding of each sentence for every target word, so the time complexity is $O(N) + O(T * M)$. As we mentioned before, we focus on short title generation tasks in this paper which means $T < N$, and it can be derived that $O(M*N)+O(T) >= O(M*(T+1))+O(T) = O(T*M)+O(M)+O(T) > O(M)+O(T*M)$. As a result, if we split the input content into M sentences with N words in each sentence and make sure $M < N$, our model's computation complexity is less than traditional seq2seq models. When change the backbone model from GRU to Transfomers or pure hierarchical encoder, our model is a little complex since transformer layers based encoder is parallel naturally, but the cost of re-computation of sentences' embeddings are accept-

	w/o Cov	26.71	9.91	25.70	13.24	26.90	9.82	25.98	13.93
	w/ VC	27.40	11.02	26.51	14.23	27.28	11.12	26.50	14.25

Table 6: The ablation study of our method on AESLC. Ori and HA indicate original references and human annotations. w/o TSE represents the model without TSE which means the sentences' embeddings are frozen for all decoder steps, w/o WG and w/o SG mean that the inner relations among words or sentences are not used. POS means part of speech information and Cov indicates coverage mechanism. w/ VC means using vanilla coverage.

Coverage	PG-net				TSE			
	R-1	R-2	R-L	METEOR	R-1	R-2	R-L	METEOR
w/o Cov	21.65	6.71	19.47	10.35	26.90	9.82	25.98	13.93
w/ VC	24.09	7.11	22.52	13.96	27.28	11.12	26.50	14.25
w/ AC	**26.50**	**10.08**	**25.08**	**15.46**	**29.44**	**12.41**	**28.20**	**15.53**

Table 7: The performance comparison among different settings of the coverage mechanism for title generation by PG-net and our TSE-AC on AESLC test set with annotated subjects as reference. w/o Cov means coverage mechanism not used. The results of PG-net are reproduced by ourselves using publicly available code.

able and meaningful since the titles are always brief.

4.5 Ablation Study

Since there are several components in our proposed model, including TSE mechanism, GCN layer for inner relations encoding, POS information, and coverage mechanism, we conduct comprehensive experiments to discover whether the specific part gives positive influence to the model's performance or negative. The results are shown in Table 6.

With the original email subjects as references, the performances declined heavily on ROUGE score when the TSE is discarded and the value of METEOR reduced most without the POS information as model's inputs. The performances on human annotations have the same phenomenon. Overall, the absence of these two components has the greatest negative impact on the performance of our model. The results demonstrate that the TSE mechanism is essential for title generation since it can re-locate the key information and update the sentences' embeddings at each decoding timestep. The POS information is also useful because words with different POS play a different role in the whole texts, which facilitates the TSE to focus on the corresponding critical words. For the effectiveness of GCN for inner relations encoding, the results indicate that GCN encoder layers have positive influence on ROUGE obviously but inconsistent impact on METEOR metric while the value is much higher when sentence level GCN is abandoned with original subject as a reference. This may result from the inconsistency of the original subject and the annotations. The coverage mechanism is also useful especially our novel AC. The ablation study demonstrates that the TSE and AC is effective for brief title generation tasks.

To compare the effectiveness of our AC mechanism with the vanilla one directly, we conduct experiments with different coverage settings on our proposed model and PG-net. The results shown in Table 4,6 and 7 indicate that our novel AC can achieve better performances not only with TSE but also other title generation methods or backbones. And it means that AC is more general and can make up for the shortcoming of VC. From the second term of Equation 15, the coverage loss will make the model ignore the words which have been pay more attention before as much as possible. If the word with high attention in previous timestep and has not been generated actually, the models with

VC mechanism are easier to ignore it. And our AC mechanism can well avoid this wrong punishment by only considering the actually generated words. The experiments also indicate that the combination of TSE and AC results in higher improvements compared to changing the backbone from GRU to Transformer.

4.6 Case Study

In Table 8 (see Appendix A), some examples with subjects and corresponding email contents are given to demonstrate the ability of our novel model. From the first three samples, we find that our model can generate more accurate subjects compared to the baseline method proposed in (See et al., 2017), of which the subjects need to be concluded based on the entire source content, not just the first or last few sentences. And the related words are different within the same sentences for each target word according to their location and inner relations. The traditional seq2seq model ignores the inner relationship among words and sentences but only encodes their sequential information. The work in (Zhang and Tetreault, 2019) first extracts some key sentences and generated subjects merely base on those sentences will lose many useful clues to generate more valuable keywords. Moreover, although our model is trained with original subjects, it can generate more reasonable targets compared to the original ones in most cases.

The last two examples indicate that our model can obtain more suitable subjects even if the key information is contained in the first few sentences. As the title is a highly condensed summary of the article, each word in the title needs to be confirmed based on different parts of the original content. Our model with TSE and AC mechanisms can finely relocate the valuable words scattered in the original text, and the selected words are used to update the sentences' embeddings for each decoding timestep. The context vector is further modified so as to better summarize the input article.

All the examples show that our novel AC mechanism can obtain subjects with more information while the VC lost some key information more or less. Our model TSE-AC can generate titles with more complete and accurate information compared to PG-net, and the repetition problem is mitigated while preserving more critical words compared with T5 and vanilla coverage.

5 Conclusion

In this paper, we proposed a novel title generation framework with Timestep aware Sentence Embedding, which re-locates critical words dynamically for each target word from the source content based on the decoding states to update the corresponding sentence's embedding. Moreover, we present Acme Coverage that can accurately penalize the probability of the word which has been generated actually. The experiments demonstrate that our approach achieves the state of the art performance on different kinds of title generation scenarios.

Abstract

For summarization, human preferences is critical to tame outputs of the summarizer in favor of human interests, as ground-truth summaries are scarce and ambiguous. Practical settings require dynamic exchanges between humans and AI agents wherein feedback is provided in an online manner, a few at a time. In this paper, we introduce a new framework to train summarization models with preference feedback interactively. By properly leveraging offline data and a novel reward model, we improve the performance regarding ROUGE scores and sample-efficiency. Our experiments on three various datasets confirm the benefit of the proposed framework in active, few-shot and online settings of preference learning.

1 Introduction

The advent of AI has changed business practices, though the human involvement is still important. The human roles in interaction with AI-powered machines have been evolving under the concept of *human-in-the-loop (HITL)* (Zanzotto, 2019). HITL allows humans to actively participate in supervising AI systems by approving, rejecting, or re-labeling current outputs, and providing expert-guided advices to the system. It will also act as the unique source of external knowledge from humans. By observing the outputs of AI systems, humans can hand-pick some potential outcomes and then feedback to the models for better performance.

In NLP, document summarization is considered as a subjective task (Stiennon et al., 2020). They argued that it would be hard to quantify what makes a "good summary" without the human judgment input. Collecting human feedback and evaluating the crafted summaries from documents for building the training datasets is time-consuming (Wu et al., 2021) and labor-expensive. It is true particularly where the domain knowledge is required. Moreover, Uc-Cetina et al. (2021) argued the importance of the user's intentions for modeling Natural Language Understanding with high performance.

Given these attributions, we are more interested in deploying an *interactive* HITL-based text summarization framework, which continuously collects the user-feedback to consequently improve model prediction robustness. Here, the user's intention is implicitly acknowledged as a factor influencing the extraction of important sentences from the source documents. Upon this formulation, the AI model will be trained with human-produced summaries and adapted as more human-feedback is fed in.

Previous studies used human feedback to rank the label of objects (Wirth et al., 2017), which employed reinforcement learning to minimize the user's effort to provide feedback for training a ranker. However, these approaches rank the entire solution space including relevant and irrelevant pairs, which are a waste of computing power. To tackle this shortcoming, Siddhant and Lipton (2018) employed Bayesian Optimization, which substitutes the standard uncertainty-based acquisition functions for active learning. However, the model still consumes a lot of computing power for a larger number of iterations, and is vulnerable to the curse of dimensionality of input data. Recently, researchers proposed to learn a reward model simulating human preferences (Ziegler et al., 2019). The reward model was then used to translate real-time human feedback to the reward score for fine-tuning the model under RL training. The method was designed for online learning of language models and required numerous interactions to achieve good performance. However, how to achieve sample-efficiency is still an open question.

In this paper, we propose a novel interactive pref-

erence learning for the summarization task. To do that, we fine-tune a pretrained extractive summarizer as the backbone with reinforcement learning by using a reward model that enforces the distance-based order of preferences. The reward model is trained to differentiate two summaries regarding the topic, length, and quality (human preferences). To enable sample-efficiency, we propose to utilize *offline* data, which was previously used to pretrain the model. We show that naively using the offline data is harmful for preference learning. Instead, we introduce two mechanisms to selectively sample offline data in favor of human feedback learning. Our sampling strategies focus on low-rewarded samples or documents which are similar to fine-tuning data. We demonstrate that our method can be used in various settings: active, few-shot and online learning. Tested on three summarization datasets, our method consistently achieves significantly better results compared to competitive baselines in each setting. In summary, our contribution is three-fold:

- We propose a new RL-based preference learning system for the summarization task by using a novel reward model.
- We propose sampling mechanisms to efficiently leverage offline data for preference learning of extractive summarization.
- We conduct extensive empirical studies on three summarization datasets, showing that our proposed method outperforms competitive baselines in various settings such as active, online, and few-shot learning scenarios.

2 Related Work

2.1 Summarization with RL

Direct reward The most direct way to have a reward function in reinforcement learning for summarization is to match the candidate summary to the reference (gold) summary (Narayan et al., 2018; Paulus et al., 2018). Put in the HITL setting, humans are required to provide the gold summary for training the machine, which is prohibitively expensive and can be ambiguous. Thus, we focus on rewards constructed from preference feedback, in which humans only need to indicate the better summary between two candidate summaries.

Preference reward As stated in the introduction, the preference from humans is much more accessible and consistent. In this approach, the frameworks (Gao et al., 2018; Stiennon et al., 2020; Nguyen et al., 2021) consist of two main steps: 1) Preference learning that gives a score, which mimics human evaluation, to a summary of a document. 2) Reinforcement learning based on the reward model. These works have not examined the summarization problem in an interactive training scheme, which will be addressed in this paper.

2.2 Preference learning in NLP

Preference learning aims at obtaining the ranking (i.e. total ordering) of objects from pairwise preferences, in which the linear Bradley-Terry (BT) model (Bradley and Terry, 1952) is one of the most studied methods. Later, the APRIL framework (Gao et al., 2018) shows that it can reduce the number of required comparisons by using active selection with uncertainty sampling (P.V.S and Meyer, 2017). On the other hand, the OpenAI framework (Stiennon et al., 2020) uses a neural structure to predict the score given a document and its summary. Its advantage is the learning with direct human evaluation (score for each summary) or human preferences (comparison between 2 summaries). However, the input space is the product of two documents, so it needs much more human feedback to achieve good performance. In contrast, our proposed reward model treats the input as only one document, and thus is simpler and has fewer parameters in the learning process. That is more suitable for the interactive learning context where the number of training samples is limited.

Reinforcement learning is a popular and effective approach to utilize human preferences. The APRIL framework (Gao et al., 2018) trains a summarizer by using a pretrained preference model. The work of Ziegler et al. (2019) employs preference-based RL to fine-tune a deep language model for sentiment classification and document summarization tasks. They only rely on online data during fine-tuning. We instead make use of offline data to accelerate the learning process.

3 Background

3.1 The backbone model

We use BERTSUM (Liu and Lapata, 2019) as the backbone for extractive summarization. Given a document with a set of sentences, the model uses BERT (Devlin et al., 2019) for learning hidden vectors of sentences by using the modified [CLS] token of each sentence. The vectors are fed into an inter-sentence layer by using the Transformer for learning the inter-relationship among sentences. Important sentences are extracted by using a sigmoid function for sentence importance estimation.

3.2 Fine-tuning with reinforcement learning

Proximal policy optimization (PPO) To fine-tune the backbone with interactive feedback, we treat the summarization process as a sequential decision-making process so that we can employ RL (Stiennon et al., 2020; Ziegler et al., 2019). The RL agent traverses all sentences in the original document, and at each time step, it classifies the current sentence s_i into two labels: important ($y_i = 1$) and unimportant ($y_i = 0$). We consider the backbone model trained with supervised learning as the initial policy. The policy is then optimized by using PPO (Schulman et al., 2017) as our RL method. The objective of training PPO is:

$$J^{PPO}(\theta) = \hat{\mathbb{E}}[\min(ra(\theta)\hat{A}_{\theta_{old}}(s_i, y_i), \\ \text{clip}(ra(\theta), 1-\epsilon, 1+\epsilon)\hat{A}_{\theta_{old}}(s_i, y_i))]$$

where θ is the current policy's parameters, $\hat{A}_{\theta_{old}}(s_i, y_i)$ is the advantage calculated at the old policy parameters θ_{old} before each updated policy iteration, by using any advantage estimation algorithm to transform the rewards (Schulman et al., 2016), and $ra(\theta) = \frac{\pi_\theta(y_i|s_i)}{\pi_{\theta_{old}}(y_i|s_i)}$ is the ratio between the new policy and the old policy. This is the idea of importance sampling that evaluates the new policy with samples collected from the older policy. If the ratio ra falls outside the range $1-\epsilon$ and $1+\epsilon$, the advantage function will be clipped. PPO uses the objective to avoid big changes between new and old policies.

Reward schemes Besides the final reward that evaluates the quality of the whole summary, we follow Pasunuru and Bansal (2018); Li et al. (2019) to use an additional reward to constrain policy updates. Let π_{θ_0} denotes the supervised trained backbone model and π_θ is the one that we optimize with RL. The reward at the time step i is:

$$r_i = -\beta_{KL} \log\left[\frac{\pi_\theta(y_i|s_i, D)}{\pi_{\theta_0}(y_i|s_i, D)}\right] + \mathbb{1} \times (i = n) \times r^M$$

where β_{KL} is the KL coefficient, n is the final time step corresponding to the total number of sentences in the document D. For the intermediate time step i ($i < n$), the reward is the negative KL divergence between the output distribution of the backbone model and the current policy. For the final time step i ($i = n$), when the model obtains the complete summary S, the reward model takes the summary and the original document to produce the final reward r^M (see Section 5).

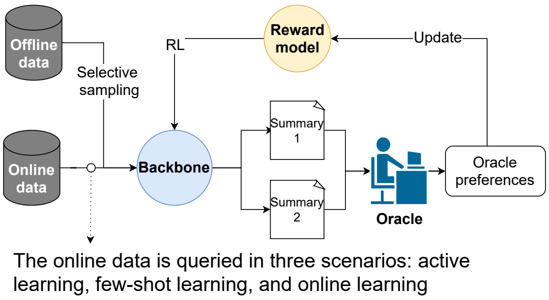

Figure 1: The overview of our framework. in which the backbone is in charge of generating two summaries for a document. Then the oracle selects which summary is better for a given document. The reward model afterward transforms the oracle's preference into a discrete signal to optimize the backbone. Our framework contains two novel components: efficient sampling from offline data and the preference-guided reward model.

4 Interactive Learning with Online RL

4.1 Problem formulation

In our problem, a backbone summarizer and a reward model are pretrained with *offline* data by using supervised learning. We aim to update the models to adapt with a stream of *online* data by using RL. Given a document D from the online data, the backbone (Section 3.1) extracts two summaries for an oracle (i.e, a humans) to provide preference feedback. Each time the backbone receives feedback in one interaction. After receiving feedback from the oracle, the reward model is fine-tuned by using supervised learning (Section 5). The feedback is then translated to a reward via a reward model, which is later used to fine-tune the backbone by using RL (Section 3.2), thereby improving the summary quality for future interactions.

This interactive mechanism is applicable to three scenarios: active, online, and few-shot learning (Section 4.2). Offline data can be employed during online fine-tuning to speed up the learning process by using the selective sampling method (Section 4.3). The common objective of all scenarios is to maximize summarization quality while minimizing the number of interactions. We describe the overview of our framework in Figure 1.

4.2 Interaction plots

Active learning Given a pool of unlabeled samples, the agent queries the most informative samples at each iteration to create summaries. Then the agent asks the oracle to select which summary is better for the queried documents. The agent learns from the feedback of the oracle subsequently. This setting has been studied by Gao et al. (2018).

Online learning Different from active learning, for online learning, each unlabeled instance is typically drawn one at a time from the data stream, continuously being sent to the system. The agent processes the data and is not allowed to choose the document. Ziegler et al. (2019) is the early work that promotes the online learning scenario.

Few-shot learning Similar to the online setting, the system passively receives samples from the data stream. This time, it is only given a few unlabeled samples (up to 4 documents) and manages to learn from the data by continuously producing summaries and receiving feedback. To our best knowledge, this is the first time that the few-shot setting is examined in preference learning.

4.3 Efficient interaction from offline data

To achieve sample efficiency in terms of the number of interactions between the backbone and the oracle, we argue that it is critical to leverage prior data used in the pretraining phase. We observe that the naive use of prior data by using random sampling is inefficient. Hence, we propose two novel offline-data sampling methods: low-reward and document-similarity. We describe all sampling mechanisms as follows.

Random sampling (Random) We randomly select k offline documents and combine them with online data to fine-tune the backbone model.

Low-reward sampling (LRS) Intuitively, high-quality summaries should be given a higher reward by the reward model. Samples that have extracted summaries with low rewards have not been well-learned by the summarizer. As the result, we select top k documents having the lowest rewards from the reward model.

Document-similarity sampling (DSS) Conventionally, the backbone outputs good summaries when the training and testing distributions are similar. Therefore, we sample offline documents that share similar semantics with online documents. To do that, we encode the documents by using BERT (Devlin et al., 2019), and then compute their similarity by using the Cosine distance. k offline documents have the lowest distance to the online counterparts are selected for online training.

5 The Reward Model for Preference Learning

5.1 Training procedure

We construct a reward model to generate preference rewards for finetuning the backbone summarizer with RL. The reward model should simulate human preferences, capable of assigning a higher reward to the preferred summary. For preference learning, we use the relative order between two summary candidates to train the reward model. The correct order is given by humans via their preferences.

For traditional learning, the model has access to training documents of the dataset. Each document D has a gold summary S_g, which is assumed to be preferred to other candidate summaries (silver or machine-generated S_m), denoted by $S_g \succ S_m$. The training data is in the form of a triplet (D, S_g, S_m) where $S_g \succ S_m$. We argue that this is insufficient to achieve a good reward model. From our observation, before reaching the quality of gold summaries, the machine often produces off-topic and too-short answers. In addition, the work of Maxwell et al. (2017) also suggested that the oracle prefers longer summaries because they feel that longer summaries are more readable, clear, and informative. Thus, we introduce three objectives as follows.

The topic objective Aiming to detect the document's topic: (D, S_g, S_m). We generate the training set of the **topic objective** as follows. For each document D that has a gold summary S_g, we select a summary S'_g from a different document D' (randomly chosen) and expect that $S_g \succ S'_g$. If we miss the human summary, we could use machine-generated summaries instead ((D, S_m, S'_m) such that $S_m \succ S'_m$).

The length objective Aiming to detect the amount of summary information (i.e. the length of the summary). For each document D, we used a pretrained summarization model to generate a long (S_{ml}) and a short (S_{ms}) summary to obtain the triplet (D, S_{ml}, S_{ms}). The correct order is $S_{ml} \succ S_{ms}$.

The quality objective Aiming to detect the general quality of a summary. For each document D, we generate a summary S_m which has a similar length to the human summary and include the gold summary to compose the triplet for training (D, S_g, S_m). We note that the data of this objective is similar to the traditional data used in Stiennon et al. (2020), which needs humans to provide a gold-silver summary or correct order between arbitrary summary candidates. On the contrary, the data of **topic** and **length** objectives can be created programmatically and thus save human effort.

5.2 Respective-order mapping

For summarization, we argue that the reward model's interpretation of ordering should be determined based on the distance between the summary and document representations. Therefore, we aim to learn global representing mapping ϕ such that:

$$S_1 \succ S_2 \iff d(\phi(D), \phi(S_1)) < d(\phi(D), \phi(S_2))$$

where $d()$ is the Euclidean distance, $\phi(D)$ is the representation of the document D in the respective-order mapping. Then, the reward for a summary S is computed as follows.

$$r^M(D, S) = \frac{score(\phi(D), \phi(S)) - score_{min}}{score_{max} - score_{min}}$$

where $score(D, S) = \frac{1}{1+exp(d(\phi(D),\phi(S)))}$ is the unnormalized score between D and S; $score_{min}$ and $score_{max}$ are the minimum and maximum score over all pairs of document-summary, respectively. We name our reward model as ROMSR (Respective-Order Mapping Score Reward).

5.3 Representation learning

To train ϕ, first, we embed all documents that appear in triplet sets. To obtain important features of a document, we use the joint-embedding of a Transformer (capture a general meaning of the document) (Reimers and Gurevych, 2019; Devlin et al., 2019) and keyword feature vectors (capture important keywords in the document) (Sharma and Li, 2019). We denote this transformation as $f(D)$.

In fact, this feature vector $f(D)$ can be used to compare the similarity between two documents. However, it is not robust enough to satisfy the relative comparison from the triplets. Therefore, we learn a new embedding ($encode(f(D))$) that tries to follow all the triplet conditions. In order to be a good representation of $f(D)$, the embedding is also reinforced by the reconstruction loss of the autoencoder. The embedded representation is our target mapping $\phi(D) = encode(f(D))$. The loss for the learning of the document representation $\mathcal{L}$ is the combination of the autoencoder reconstruction loss $\mathcal{L}_{AE}$ and the respective-order loss $\mathcal{L}_{RO}$ (the triplet loss) as follows.

$$\mathcal{L} = \mathcal{L}_{AE} + \mathcal{L}_{RO}$$

$$\mathcal{L}_{AE} = \sum_{D \in \mathbb{D} \cup \mathbb{S}} \|f(D) - decode(\phi(D))\|$$

$$\begin{aligned}\mathcal{L}_{RO} = \sum_{(D,S,S') \in T} & \max(0, d(\phi(D), \phi(S)) \\ & -d(\phi(D), \phi(S')) + \alpha)\end{aligned}$$

where $\mathbb{D}$, $\mathbb{S}$ is the set of original/summarized documents, T is the union of all triplet sets, and α is the margin hyperparameter controlling the stretch in the representation space (Yu et al., 2018).

6 Experimental Setup

6.1 Datasets

We use three benchmark summarization datasets for our evaluation. **BillSum** comprises 22,218 US bill and human-written summary pairs collected from the US Government Publishing Office (Kornilova and Eidelman, 2019). The data is split into 18,949 training and 3,269 testing bills. **Reddit TIFU** is an English dataset collected from Reddit. It contains 12,000 posts divided into TIFU-long and TIFU-short (documents have less than 400 words) (Kodaira and Komachi, 2018). **Livedoor** contains Japanese articles crawled from the Livedoor News website. Each article consists of three summary sentences written by editors (Kim et al., 2019).

Our experiments use the training set to pretrain the backbone and reward models. Then, we randomly select 5000 samples from the original training data to create offline data. The online data is created from the original validation data. For active learning and online learning settings, we sample up to 320 documents from the online data. For few-shot learning, only 4 documents are randomly selected as online data. We aim to minimize the number of interactions to reach the highest performance on the whole online dataset.

6.2 Simulated interactions

Given one original document with two corresponding generated summaries and a standard metric ROUGE score, the oracle knows the ground-truth summary, and prefers the summary that has the higher ROUGE score w.r.t the ground-truth. Theoretically, the ideal data for preference-based interactive learning is consistent preferences in which a higher-scored summary is always selected. However, we believe that perfect selection is impossible for real-world applications because humans can occasionally misinterpret the intention when the presented candidates have similar qualities. Therefore, in this work, we consider noisy preferences with uniform probability $nc \in [0, 1]$, that randomly selects which summary is better.

6.3 Baselines

We construct a standard model (**baseline**) that just finetunes the backbone summarizer (see Section 3.1) with online data, coupled with our proposed reward model and PPO training. The combination of BERT and PPO is shown effectively in the offline document summarization task (Nguyen et al., 2021). The baseline is similar to that of Ziegler et al. (2019), which uses human preferences and PPO to finetune language models. However, the latter uses a different reward model.

To show the efficacy of our reward model, we compare ours with the reward model of Ziegler et al. (2019) (**OpenAI**) and the uncertainty sampling reward model in **APRIL** (Gao et al., 2018) in the preference prediction task (see Section 7.1).

For few-shot and online learning, we compare our methods with the standard baseline. For active learning, we also compare our methods with APRIL. For all settings, we build a baseline that randomly samples from offline data to compare against our proposed sampling techniques: **LRS** and **DSS**. We note that all models share the same backbone and RL training. The baseline, Random, LRS, and DSS share the same reward model and only differ in the sampling techniques.

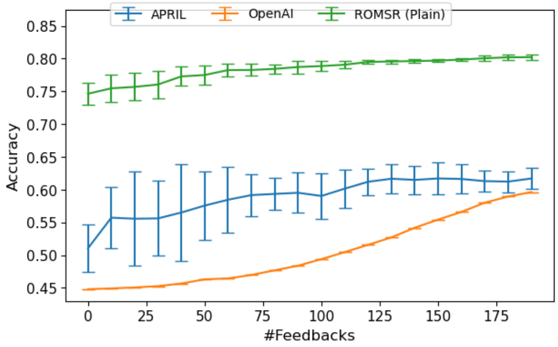
6.4 Evaluation metrics

We use ROUGE-scores (Lin, 2004) for our evaluation, in which ROUGE-1 is the representative score. ROUGE-2 and ROUGE-L are reported in the Appendix. We also report the number of interactions to show that our novel sampling techniques can significantly speed up the agent's learning.

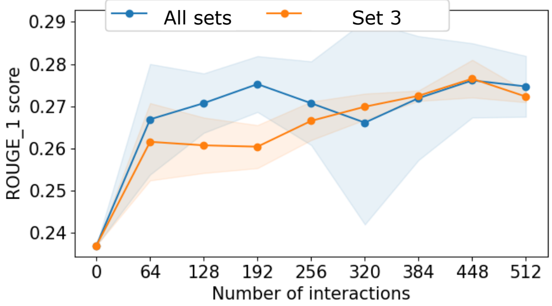
7 Results and Discussion

7.1 Reward model study

We first observe the efficicy of the proposed reward model in the summarization process. To do that, we compare our reward model to the reward models of APRIL (Gao et al., 2018) and OpenAI Ziegler et al. (2019). For the preference prediction task, the reward scores assigned to candidate summaries are used to determine the preferred summary. In general, the preferred summary is the one with a higher score. We select a subset of documents from the datasets to train the reward model. Each document can be used to construct three triples corresponding to the three objectives mentioned above. The number of pretraining/interactive training/testing documents is 1000/1000/1000 for Billsum and Livedoor, and 2000/2000/2000 for Reddit TIFU, respectively.



(a) Average testing accuracy of APRIL, OpenAI and ROMSR when using all three sets.



(b) Active learning on RedditTIFU dataset of ROMSR when using all three sets and set 3 only

Figure 2: Reward model: (a) Accuracy of 3 models on all sets (b) The ROUGE-1 score of our ROMSR.

Figure 2 (a) demonstrates that our reward model (ROMSR) significantly outperforms other methods when training on all three objectives. APRIL uses a linear regression model combined with a heuristics function that is tuned for the quality objective. This specific design limits the model to handle all three objectives. OpenAI's results exhibit slow learning progress because it is a large neural network using joint features from a pair of texts, while our reward model learns to use respective-order on a feature space of a single document. Moreover, the reconstruction loss from the autoencoder helps the model to avoid overfitting to small training samples.

To verify the necessity of using three objectives for training the reward model, we compare two versions of our reward model: one is trained with all sets of objectives and another with the third objective (the traditional quality objective). Two reward models are used in active learning to finetune the backbone. Figure 2(b) shows that training on all three objectives converges faster.

7.2 Fine-tuning backbone model using human preferences

This section shows our comprehensive experiments on three datasets and three scenarios to prove the effectiveness of our human-preference-guided learning with RL, and our LRS and DSS sampling.

Active learning We compare our sampling techniques with the baselines, including random offline sampling and methods without offline sampling, such as the standard baseline and APRIL. Figure 3 shows that combining online data with randomly selected samples harms the agent during online fine-tuning. Meanwhile, selecting prior low-reward samples and similar documents boosts accuracy faster than not using offline data. After 64 interactions, ROUGE-1 reaches almost the highest. To validate the actual impact of ROMSR, we also test the reward model in the RL pipeline compared to the APRIL's reward. Due to the OpenAI reward is inferior to the APRIL's reward, we ignore the OpenAI's reward in this experiment. The results in Figure 3 show that APRIL (orange) is inferior to our ROMSR (blue) in all datasets.

Few-shot learning Figure 4 describes the quality of the models: LRS, DSS, Random, and the standard baseline during interactions. The standard baseline without offline sampling can not improve the summarization agent with a few interactions and eventually worsen the agent. In contrast, LRS and DSS can significantly improve the model after 4 interactions. Naively using the offline data still harms the model, similar to active learning.

Online learning Due to computation limitations, we only examine this setting on the Reddit TIFU dataset. Also, prior experiments demonstrated that LRS and DSS are equally good sampling strategies. As DSS runs much faster than LRS, we choose DSS as our representative method in this experiment. We report the performance of DSS, Random, and the standard baseline in Figure 5.

The results show that random sampling is again inferior to other methods in this online scenario. The standard baseline shows good performance yet becomes unstable and drops performance later. Our DSS demonstrates fast and stable convergence, consistently achieving the highest ROUGE-1 score throughout interactions.

7.3 Ablation study and model analysis

Impact of top-k selected offline documents To investigate the effect of k-the number of sampled offline documents, we try different k values ($k = 1$ and $k = 4$) on the RedditTIFU dataset, and the results are depicted in Figure 6a. As observed, $k = 4$ is slightly better, but $k = 1$ runs and converges faster. Hence, we use $k = 1$ in all experiments.

Random sampling makes low rewards We investigate the failure of random sampling. We keep track of the reward assigned to randomly selected offline documents across interactions. Figure 6b shows that, in general, DSS and LRS give better samples, indicated by higher assigned rewards, than random sampling. DSS and LRS's rewards are also much more consistent, showing less variance than random sampling. Thus, offline documents from random sampling provide little benefit and make the training unstable and unreliable.

We also analyze the distribution characteristics of selected offline documents in Figure 6c. The green line represents the distribution of similarity scores between online and random offline samples. The red one is the distribution of similarity scores between online and DSS samples. It is noticeable that the similarity score of DSS is in the range from 0.0 to 0.15, whereas this score of Random is up to 0.5. It is expected that sampling offline data will create a coherent training distribution for online learning, but Random skews the training distribution. Therefore, Random harms the performance.

Running time We assess the running time of our proposed method compared to the baseline on Reddit TIFU and BillSum in Table 1. The assessment is conducted on a single Tesla T4. On Reddit TIFU, our DSS takes nearly 3 hours (64 interactions) to reach almost the highest ROUGE-1 score of 28.6, while the baseline reaches only 26.0 of ROUGE-1 after 64 interactions. The baseline takes only

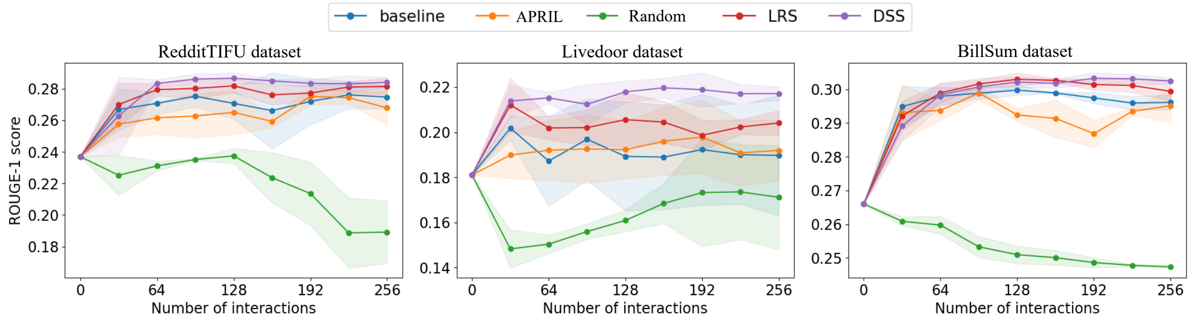


Figure 3: Active learning: ROUGE-1 with the mean and standard deviation over 5 runs.

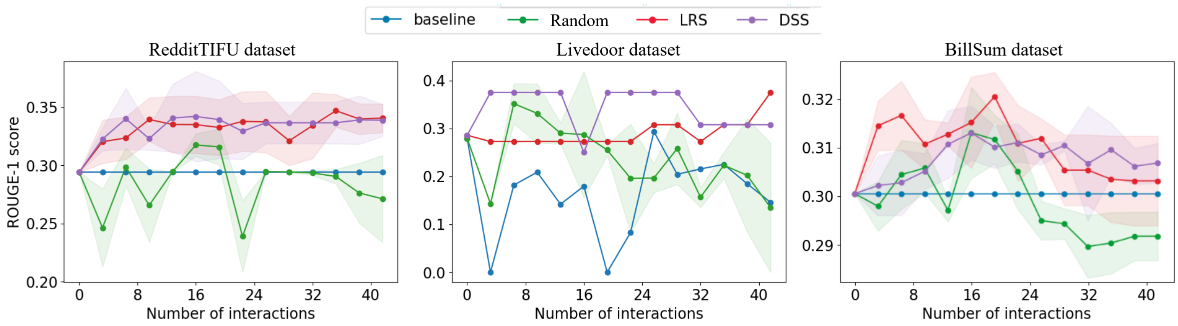

Figure 4: Fewshot learning: ROUGE-1 with the mean and standard deviation over 5 runs.

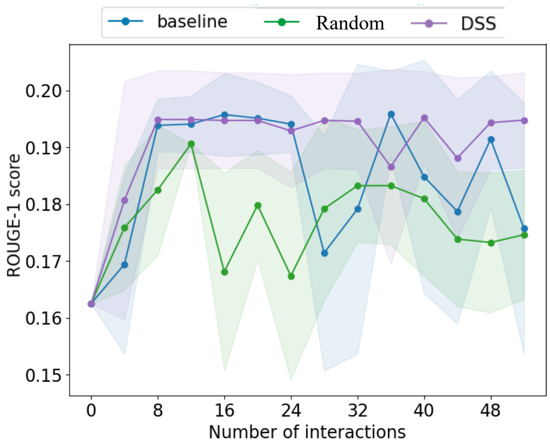

Figure 5: Online learning on Reddit TIFU: ROUGE-1 with the mean and standard deviation over 5 runs.

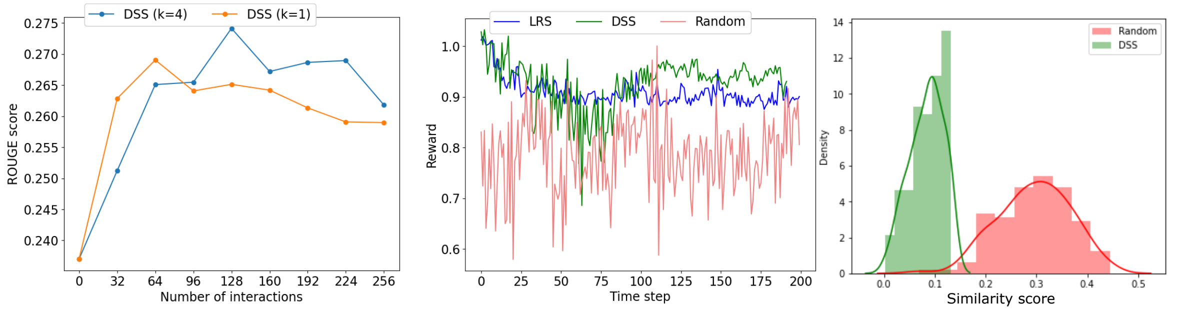
Method	Interactions	Run time	ROUGE-1
The Reddit TIFU dataset			
Baseline	64	2h20m	26.0
DSS	64	2h50m	28.6
The BillSum dataset			
Baseline	96	50m	29.4
DSS	96	1h40m	30.3

Table 1: The running time of active learning with offline sampling.

30m faster than the DSS. In light of BillSum, the DSS is slower than the baseline, about 50 minutes for 96 interactions. However, the DSS is better than the baseline in terms of ROUGE-1. Despite that our proposed method takes more computing resources than the baseline, our approach requires much fewer interactions, saving human resources in the real HITL setting. In terms of real-time interactive feedback, it takes around 3 minutes for training in each interaction on the Reddit dataset, and approximately 1 minute for training in each interaction in the BillSum dataset, which is not really real-time. It is noted that the amount of time to provide feedback is not included because we use simulated oracles. Hence, in actual applications, we can fine-tune the model while the oracle gives feedback because it takes time for the oracle to read the summary and decide their preference. We believe such a parallel process will make the methods feasible to use in real-time settings.

8 Conclusion

This work proposes a novel approach for learning reward functions in preference learning. By utilizing offline data with a reward model that focuses on the distance between the summary and the document, our method improves the ROUGE-scores



(a) Effect of k to the performance on RedditTIFU dataset

(b) Reward during training

(c) Similarity distribution between online samples and selected offline samples

Figure 6: Ablation study: (a) Performance with different k values; (b) Quality of selected samples; (c) Semantic similarity between online documents and offline documents.

by $2-5\%$ in comparison to the APRIL framework, while beating the random baseline by a large margin on three different datasets. Our experimental results also suggest that by applying low-reward sampling or document-similarity sampling, we can achieve efficiency in terms of both running time and the number of human interactions. Regarding limitations, our method is not tested with large online stream data, which may cause catastrophic forgetting. Future work will confirm our model's effectiveness for abstractive summarization.

A Hyper-parameters and Implementation details

Due to the limitation of resources, our backbone bases on BERT-base with 12 Transformer blocks with the hidden size is 768, and 110M parameters. We train our model with the learning rate of 1e-5. During online fine-tuning with RL, we set k equals the number of online documents, where k is the number of selected offline data. The noisy peference probability nc is 0.1. For evaluation, we use ROUGE-score with parameters $-c\ 95\ -m\ -r\ 1000\ -n\ 2$.

B Additional Results

In Figure 8, we show ROUGE-2 and ROUGE-L scores with the same setting as section 7.2. The results of few-shot and online learning setting is depicted in Figure 9 and 7 respectively.

Abstract

Temporal Expression Extraction (TEE) is essential for understanding time in natural language. It has applications in Natural Language Processing (NLP) tasks such as question answering, information retrieval, and causal inference. To date, work in this area has mostly focused on English as there is a scarcity of labeled data for other languages. We propose XLTime, a novel framework for multilingual TEE. XLTime works on top of pre-trained language models and leverages multi-task learning to prompt cross-language knowledge transfer both from English and within the non-English languages. XLTime alleviates problems caused by a shortage of data in the target language. We apply XLTime with different language models and show that it outperforms the previous automatic SOTA methods on French, Spanish, Portuguese, and Basque, by large margins. XLTime also closes the gap considerably on the handcrafted HeidelTime method.

1 Introduction

Temporal Expression Extraction (TEE) refers to the detection of *temporal expressions* (such as dates, durations, etc., as shown in Table 1). It is an important NLP task (UzZaman et al., 2013) and has downstream applications in question answering (Choi et al., 2018), information retrieval (Mitra et al., 2018), and causal inference (Feder et al., 2021). Most TEE methods work on English and are rule-based (Strötgen and Gertz, 2013; Zhong et al., 2017). Deep learning-based methods (Chen et al., 2019; Lange et al., 2020) are less common and report results on par with or inferior to the rule-based SOTAs.

Moreover, methods that work on other languages are rare, because of the scarcity of annotated data. We find that that there is considerable room for improving TEE, especially for low-resource languages. For example, the previous SOTA performance on the English TE3 dataset (UzZaman et al., 2013) is around 0.90 in F1, while that on the Basque TEE benchmark (Altuna et al., 2016) is merely 0.47. Recent deep learning methods, which have shown gains for many tasks, are underexplored for this important area of NLP.

Table 1: Temporal expressions of different types (See Appendix A for the definitions of the types).

Developing an approach that can learn using the existing limited amount of training data is crucial for this field because of the effort required to develop high-quality rules for each language. Thus we propose a cross-lingual knowledge transfer framework for multilingual TEE, namely, XLTime. We base our framework on pre-trained multilingual models (Devlin et al., 2019; Conneau et al., 2020). We then use Multi-Task Learning (MTL) (Liu et al., 2019a) to prompt knowledge transfer both from English and within the low-resource languages. For this, we design primary and secondary tasks. The primary task leverages the existing, annotated TEE data of the other languages. It transfers *explicit knowledge* that tells the forms of the temporal expressions in a *source language*. The secondary task maps the annotated source language TEE data samples to the target language using machine-translation tools, such as Google Translate, and acquires sentence-level labels (of the presence of one or more time expressions) from the original token-level labels. It constructs training data in a weakly-supervised manner. The secondary task transfers *implicit knowledge* by teaching the model to detect the presence of temporal

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1931 - 1942

expressions in text from the target language.

Contributions. **1)** We propose XLTime, which prompts cross-lingual knowledge transfer using MTL to address multilingual TEE. **2)** We show that XLTime outperforms the previous automatic SOTA methods by large margins on four languages including French (FR), Spanish (ES), Portuguese (PT), and Basque (EU), which are "low-resource" for the TEE task. **3)** We show that XLTime also approaches the performance of the heavily handcrafted HeidelTime (Strötgen and Gertz, 2013), and XLTime even outperforms it on two languages (Portuguese and Basque). We make our code and data publicly available.[1]

2 Related Work

While TEE is an important problem in NLP, there is relatively little work in the area, and most of this work focuses on English. Prior art can be divided into two classes: rule/pattern-based and deep learning approaches. In the first class, HeidelTime (Strötgen and Gertz, 2013) is the top performing approach to date, and covers over a dozen languages. It is driven by a collection of finely-tuned rules. The approach was later extended to more languages with HeidelTime-auto (Strötgen and Gertz, 2015), which leverages language-independent processing and rules. Other approaches include SynTime (Zhong et al., 2017), which is based on heuristic rules, and SUTIME (Chang and Manning, 2012) and PTime (Ding et al., 2019), which leverages pattern learning.

For the second class, Laparra et al. (2018) proposes a model based on RNNs. Chen et al. (2019) uses BERT with a linear classifier. Lange et al. (2020) inputs mBERT embeddings to a BiLSTM with a CRF layer and outperforms HeidelTime-auto on four languages. However, the reported performances of the deep learning-based methods are inferior to the rule-based ones, which is, in part, due to the complexity of the problem and training data paucity. In our work, we propose a new model which outperforms prior deep learning methods but also closes the gap considerably on HeidelTime, despite the data issues.

In addition, we are aware that applying label projection methods (Jain et al., 2019) can be a straightforward way to address the data scarcity in non-English TEE. TMP (Jain et al., 2019), originally proposed for cross-lingual named entity recognition (NER) (Lample et al., 2016), projects English data in IOB (Inside Outside Beginning) tagging format (Ramshaw and Marcus, 1999) to that of the other languages using machine translation, orthographic, and phonetic similarity packages. We show that the proposed XLTime, specifically designed to transfer temporal knowledge between languages, outperforms TMP by large margins.

3 Proposed Method

We formalize TEE as a sequence labeling task, similar to NER (Lample et al., 2016). The architecture is shown in Figure 1.

3.1 Pre-trained Multilingual Backbone

XLTime adopts SOTA multilingual models, i.e., mBERT (Devlin et al., 2019) and XLMR (Conneau et al., 2020) as the backbone. The pre-trained backbone contains lexicon and Transformer encoder layers as shown in Figure 1(a). The backbone allows XLTime to acquire semantic and syntactic knowledge of various languages. The backbone is shared by the MTL tasks introduced in Section 3.2.

3.2 MTL-based Cross-Lingual Knowledge Transfer

XLTime transfers knowledge from multiple *source languages* to the low-resource *target language*. The source languages include English and others for which TEE training data is available. We design *primary* and *secondary* tasks on top of the backbone to prompt *explicit* and *implicit* knowledge transfer. The primary task transfers knowledge that explicitly encodes the forms of the temporal expressions in a source language. It is formalized as sequence labeling and directly leverages the training data of the source language to train the backbone along with the primary task classifier, shown in Figure 1 (a). The primary task minimizes $\mathcal{L}_{sl}$:

$$\mathcal{L}_{sl} = -\sum_{i=1}^{b}\sum_{j=1}^{m_i} \mathbb{1}(y_{ij}, c) log(softmax(\mathbf{W} \cdot \mathbf{x})), \quad (1)$$

where b is the total number of input sequences and m_i is the length of the ith sequence. $\mathbf{x} \in \mathbb{R}^d$, output by the backbone, is the embedding of the jth token in the ith sequence. d is its dimension. $c = argmax(\mathbf{W} \cdot \mathbf{x})$ and y_{ij} are the predicted and ground-truth labels of the token. $\mathbf{W} \in \mathbb{R}^{|c| \times d}$ is the parameter of the primary task classifier. $|c|$ is the total number of unique ground-truth labels. $\mathbb{1}(,)$ is 1 if its two arguments are equal and 0 otherwise.

---

(a) Architecture of the XLTime Framework

(b) Sample Input and label

Figure 1: The architecture and sample training input of the proposed XLTime framework (*best viewed in color).* (a) shows how XLTime transfers knowledge from English (EN) and Spanish (ES) to French (FR) through the primary and the secondary tasks. (b) presents sample input of the tasks.

The secondary task implicitly reveals how the temporal expressions would be expressed in the target language. We translate the sequences in the source language training data into the target language using Google Translate (we observe similar results with AWS Translate). The secondary task is formalized as binary classification, where the input samples are the translated sequences and the labels are sentence-level indicators of whether or not the sequences contain temporal expressions (which can be easily inferred from the original labels). This task tunes the model to learn the characteristics of temporal expressions in the target language in an implicit manner. It is weakly-supervised and requires no token-level labeling. It trains the backbone and the secondary task classifier by minimizing $\mathcal{L}_{bc}$:

$$\mathcal{L}_{bc} = -\sum_{i=1}^{b} \mathbb{1}(y_i', c') log(softmax(\mathbf{W}' \cdot \mathbf{x}')), \quad (2)$$

where $\mathbf{x}' \in \mathbb{R}^d$ is the sequence embedding output by the [CLS] of the backbone. $\mathbf{W}' \in \mathbb{R}^{2\times d}$ is the parameter matrix of the secondary task classifier. $c' = argmax(\mathbf{W}' \cdot \mathbf{x}')$ and y_i' are the predicted and true sequence labels of the ith sequence. We train XLTime concurrently on the primary and secondary tasks (further details found in Appendix B).

An Illustrative Example. In Figure 1, *Primary task - EN2FR* and *Secondary task - EN2FR* transfer knowledge from *English* to *French*. *Primary task - EN2FR* reveals the exact forms of English temporal expressions using token-level labels (Y_{11} and Y_{12}). *Secondary task - EN2FR* takes the French translations (X_{41} and X_{42}) of X_{11} and X_{12} as input. Y_{41} and Y_{42} indicate whether the sequences contain temporal expressions or not (can be inferred from Y_{11} and Y_{12}). *Secondary task - EN2FR* provides indirect knowledge about French temporal expressions. Similarly, *Primary task - ES2FR* and *Secondary task - ES2FR* transfer from *Spanish* to *French.*

4 Experiments

This section evaluates the proposed XLTime framework. Section 4.1 introduces the datasets, models evaluated, metrics, and experimental settings. Section 4.2 quantitatively shows how XLTime alleviates data scarcity and prompts TEE performances. Section 4.3 studies the effect of transferring knowledge from other languages in addition to English. We also qualitatively show how XLTime transfers knowledge to the target languages in an error analysis in Appendix E.

4.1 Experimental Setup

Datasets. We use the English (EN), French (FR), Spanish (ES), Portuguese (PT), and Basque (EU) TEE benchmark datasets. Table 2 shows dataset statistics. For each target language, we split its dataset with 10% for validation and 90% for test. For each source language (applicable to XLTime), we use the whole dataset for training.

Baselines. We evaluate against rule-based, deep learning-based, and entity projection-based methods. We compare to the handcrafted HeidelTime (Strötgen and Gertz, 2013) and its automatically extended version, HeidelTime-auto (Strötgen and Gertz, 2015). We also compare to deep learning methods: BiLSTM+CRF (Lange et al., 2020), mBERT, base and large versions of XLMR. In addition, we compare to TMP (Jain et al., 2019), a cross-lingual label projection method which relies

Table 3: Results for Multilingual TEE (Metric: F1).

on machine translation as well as orthographic and phonetic similarity packages (unavailable for EU).

Our Approaches. We test several variants of our proposed model, which can be broken into two classes: 1) Cross-lingual transfer from EN. We apply XLTime on mBERT, base and large versions of XLMR and use EN as the only source language. 2) Cross-lingual transfer from EN and others. We transfer from other languages in addition to EN.

Evaluation Metrics. We report F1in *strict match* (UzZaman et al., 2013), i.e., all its tokens must be correctly recognized for an expression to be counted as correctly extracted.

We follow the setting in prior work of evaluating "without type" and report the results without considering the types of the temporal expressions (e.g., for 'see you tomorrow', a prediction such as 'O O B-Duration' would be counted as correct, though the proper labeling would be 'O O B-Date').[2]

Experimental Setting. We set d, the embedding dimension, to be consistent with the pre-trained multilingual backbone's dimension (768 for the base version language models and 1024 for large versions). We use AdamW (Loshchilov and Hutter, 2019) with a learning rate of $7e^{-6}$ and warm-up proportion of 0.1. We train the models for 50 epochs and use the best model as indicated by the validation set for prediction. All datasets are transformed into IOB2 format to fit the sequence labeling setting. All the deep learning methods are trained on English TEE datasets, validated and evaluated on low-resource languages. For BiLSTM+CRF, we use the hyperparameters as suggested in the original paper (Lange et al., 2020). For TMP, we use it to project the English dataset to the target languages, take the projected data to train the language models, then validate and evaluate on the target languages. We perform a grid search over $\{0.05, 0.1, 0.15, 0.25, 0.5\}$ to tune δ, the similarity score threshold of TMP, and present the best performance. We repeat all experiments for 5 times and report the mean result. All experiments are conducted on a 64 core Intel Xeon CPU E5-2680 v4@2.40GHz with 512GB RAM and 1×NVIDIA Tesla P100-PICE GPU.

4.2 Multilingual TEE

We evaluate XLTime on multilingual TEE (see Table 3 and Appendix D). We observe: **1)** XLTime-XLMRlarge outperforms the strongest automatic baseline by up to 9% in F1 on all languages. It even outperforms the handcrafted HeidelTime method by a sizable margin (24% in F1) in PT. **2)** Applying XLTime improves upon the vanilla language models, even when transferring knowledge only from EN. E.g., XLTime-XLMRbase outperforms XLMR-base by 13%, 22%, 8%, and 54% in F1 on FR, ES, PT, and EU. **3)** Introducing ad-

---

[2] We do note that the temporal expression field should ultimately evaluate on the more complex task of identifying temporal expressions as well as their types. This is in the spirit of the annotations and is in line with other sequence labeling tasks, such as NER. Therefore, we also experiment with the "with type" setting and show results in Appendix C. In both settings, the observations made in Sections 4.2 and 4.3 hold and XLTime outperforms the previous SOTAs by large margins.

Target Language	FR				ES			
Source Language(s)	EN	EN, EU	EN, PT	EN, ES	EN	EN, EU	EN, PT	EN, FR
XLTime-mBERT	0.73	0.76	0.72	0.80	0.71	0.72	0.72	0.77
XLTime-XLMRbase	0.78	0.76	0.78	0.82	0.66	0.68	0.71	0.72
XLTime-XLMRlarge	0.76	0.81	0.80	0.84	0.72	0.72	0.75	0.73
Target Language	**PT**				**EU**			
Source Language(s)	**EN**	**EN, FR**	**EN, ES**	**EN, EU**	**EN**	**EN, PT**	**EN, ES**	**EN, FR**
XLTime-mBERT	0.67	0.80	0.70	0.80	0.76	0.73	0.75	0.77
XLTime-XLMRbase	0.68	0.73	0.63	0.56	0.71	0.74	0.75	0.79
XLTime-XLMRlarge	0.77	0.82	0.84	0.74	0.78	0.79	0.79	0.77

Table 4: Low-resource language TEE with additional source languages (F1 scores). The blue cells are expected to, while the underlined cells actually outperform (by $\geq$ 4%) using EN as the only source language.

ditional source languages to XLTime further improves the performance: the F1 improves by up to 19%, 11%, and 11% for XLTime-mBERT, XLTime-XLMRbase, and XLTime-XLMRlarge. **4)** HeidelTime is a very hard baseline to beat given the time and care that went into developing language-specific rules. However, XLTime approaches its performance for FR and ES, outperforms it for PT, and makes predictions for EU (where HeidelTime has no rules). Note the previous automatic SOTA, XLMR-large, also outperforms HeidelTime for PT, but not as significantly. This shows that the automatic methods are increasingly promising for the non-English TEE task. **5)** XLTime-XLMRlarge improves upon XLMR-large by a large margin (11% in F1) in EU. For FR, ES, and PT, the improvements are smaller. This may because XLMR-large, compared to mBERT and XLMR-base, is already very knowledgeable (especially in FR, ES, and PT, which are more common than EU). Therefore, applying XLTime may not provide much improvement (in contrast, applying XLTime on mBERT and XLMR-base dramatically boosts F1 by 8-54%). **6)** TMP performs poorly probably because the falsely projected entities can mislead the language models. Specifically, the token-by-token machine translation and matching process of TMP does not work well for temporal entities, especially when the target language TEs contain definite articles, prepositions, etc., that do not have explicit matches in the source language. E.g., EN TE 'yesterday morning' can be correctly map to FR TE 'hier matin' ('yesterday' to 'hier' and 'morning' to 'Matin') but not to EU TE 'ayer por la mañana' ('yesterday' to 'ayer' and 'morning' to 'Mañana', leaving 'por' and 'la' unmatched).

4.3 Transfer Knowledge from Additional Languages

We also study the effect of transferring additional knowledge from a low-resource language in addition to English, see Table 4 and Appendix D. Our assumption is that similar languages (FR, ES, and PT) would help each other (one exception is PT, as the published dataset is EN text translated to PT and we, therefore, don't expect machine translation to provide additional knowledge). We observe: **1)** In most cases, transferring additional knowledge from similar languages (blue cells) does dramatically improve performance (underlined cells), with F1 increasing by up to 13%. **2)** In some rare cases, negative knowlege transfer (Wu et al., 2020) occurs as adding source languages hurts performance (e.g., EN, ES → PT scores lower than EN → PT for XLTime-XLMRbase). We hypothesize this is related to the quality of the datasets and plan to address this in the future.

5 Conclusion

We propose XLTime for multilingual language TEE in low-resource scenarios. It is based on language models and leverages MTL to prompt cross-language knowledge transfer. It greatly alleviates the problems caused by the shortage in training data and shows results superior to the previous automatic SOTA methods on four languages. It also approaches the performance of a highly engineered rule-based system.

A Types of the Temporal Expressions

According to ISO-TimeML (Pustejovsky et al., 2010), the TEE dataset annotation guideline, there are four types of temporal expressions, i.e., *Date*, *Time*, *Duration*, and *Set*. *Date* refers to a calendar date, generally of a day or a larger temporal unit; *Time* refers to a time of the day and the granularity of which is smaller than a day; *Duration* refers to the expressions that explicitly describe some period of time; *Set* refers to a set of regularly recurring times (Pustejovsky et al., 2010).

Algorithm 1: Training XLTime

```

Load the parameters from a pre-trained multilingual model.
Initialize $\mathbf{W}$ and $\mathbf{W}'$ randomly.
// Prepare task data.
for $t$ in $\{primary, secondary\}$ do
    Split the data of task $t$ into mini-batches $B_t$
$B = B_{primary} \cup B_{secondary}$
for e in 1, ..., epoch do
    Randomly shuffle $B$
    // $b_t$ is a mini-batch of task $t$
    for $b_t$ in $B$ do
        if $t$ is a primary task then
            $\mathcal{L}_{sl}$ = Equation 1
        else
            $\mathcal{L}_{bc}$ = Equation 2
        Compute gradient and update model parameters
```

B The Training Procedure

We adopt mini-batch-based stochastic gradient descent (SGD) to train XLTime, as shown in Algorithm 1. To concurrently train on the primary and secondary tasks, we split the training data of both tasks into mini-batches and randomly take one mini-batch at each step. We then calculate loss using that mini-batch and update the parameters of the shared backbone as well as the task-type-specific classifier. The classifier of the other task type is unaffected.

C Full Results for Low-resource Language TEE

Table 7 shows the full results for low-resource language TEE with/without considering the types of the temporal expressions. Note that the superiority of our proposed XLTime over the previous automatic SOTA still holds.

D Full Results for Low-resource Language TEE with Additional Source Languages

Tables 8 and 9 show the full results for low-resource language TEE with additional source languages.

E Comparative Error Analysis

This section qualitatively shows how the proposed XLTime framework transfers knowledge to the target language. Specifically, we show how the errors made by the vanilla multilingual models can be fixed by applying XLTime. We also show how applying XLTime on other languages in addition to English would help fix more errors.

We compare mBERT and XLTime-mBERT (transfer from EN) on FR TEE. Table 5 summarizes cases where mBERT fails while XLTime-mBERT gives correct predictions. We can tell that XLTime-mBERT learns 'hier (yesterday)', which is not understood by the mBERT model. XLTime-mBERT also learns to recognize vague time spans such as 'désormais (from now on)' and 'longtemps (long time)', which are missed by the mBERT model. Moreover, compared to mBERT, XLTime-mBERT understands FR grammar better, as it recognizes the roles of definite articles and adjectives, such as 'le (the)' and 'prochain (next)', in TEs. In a word, the proposed XLTime framework helps connect the concepts in EN to the corresponding ones in FR.

To show how applying XLTime on extra source languages would help fix more errors, we compare XLTime-mBERT (transfer from EN) and XLTime-mBERT (transfer from EN and ES) on FR TEE. Table 6 summarizes the TEs that the former fails while the latter gives correct predictions. We can tell that by leveraging ES as an additional source language, XLTime-mBERT better masters FR grammar. Specifically, it learns to recognize definite articles and prepositions that share similar (e.g., 'le/los') or identical (e.g., 'de' and 'en') forms in ES and FR. It can also better distinguish TEs of different types (e.g., it learns that 'quelques jours

Table 5: mBERT vs. XLTime-mBERT (transfer from EN) frequent (count $\geq$ 10) errors.

Error Desc.	FR TEs	EN translations	mBERT results (wrong)	XLTime results (correct)	counts
fail to recognize ‘hier (yesterday)’	hier soir hier	last night yesterday	O B-TIME O	B-TIME I-TIME B-DATE	30
fail to recognize vague time span	désormais longtemps toute l'année	from now on long time all year	O O O O	B-DATE B-DURATION B-SET I-SET	6
fail to recognize definite articles and adjectives	le 3 août la nuit lundi prochain	August 3 the night next Monday	O B-DATE I-DATE O O B-DATE O	B-DATE I-DATE I-DATE B-TIME I-TIME B-DATE I-DATE	10

Table 6: XLTime-mBERT (transfer from EN) vs. XLTime-mBERT (transfer from EN and ES) frequent (count $\geq$ 8) errors.

Error Desc.	FR TEs	EN translations	EN results (wrong)	EN and ES results (correct)	counts
fail to recognize definite articles and prepositions	en été le 13 février de dimanche	in summer February 13 of Sunday	B-DATE I-DATE O B-DATE I-DATE B-DATE I-DATE	O B-DATE B-DATE I-DATE I-DATE O B-DATE	20
wrong token types	mardi quelques jours	Tuesday A few days	B-TIME B-DATE I-DATE	B-DATE B-DURATION I-DURATION	18
recognized extra TEs	quotidiens la saison	daily the season	B-SET B-DATE I-DATE	O O O	8

(a few days)’ is a *Duration*, instead of a *Date*). One interesting fact is, when transferring solely from EN, the model recognizes some extra TEs that are not in the ground truth of the FR dataset. This is because of an inconsistency in data labeling: ‘daily’ is considered as a *Set* in the EN dataset, while its counterpart, ‘quotidiens’ is overlooked in the FR dataset. The proposed XLTime framework eliminates the needs of manually labeling multiple datasets and therefore, can be applied to minimize data label inconsistency.

F Language Models on English TEE

In our early experiments, we reexamine the language models on English TEE. This section presents the results.

F.1 Experimental Setup

We study BERT (Devlin et al., 2019) and XLMR (Conneau et al., 2020) variants, RoBERTa (Liu et al., 2019b) and T5 Encoder (Raffel et al., 2019). We compare them to rule-based methods including HeidelTime (Strötgen and Gertz, 2013), SynTime (Zhong et al., 2017), and PTime (Ding et al., 2019), which report SOTA performances on Wikiwars, TE3, and Tweets, respectively. We experiment on both settings, i.e., “with type" and “without type", and report F1, precision, and recall in strict match (UzZaman et al., 2013). We use the data splits following Ding et al. (2019) and the experimental settings introduced in Section 4.1.

F.2 Evaluation Results

Tables 10, 11, and 12 show the results. We observe: **1)** When ignoring the types, the language models are inferior to SynTime on TE3, on par with or better than the rule-based methods on Wikiwars and Tweets. **2)** When considering the types, the language models outperform the previous SOTAs by 11-22%, 18-21%, and 30-41% in F1 on TE3, Wikiwars, and Tweets datasets.

Abstract

Given the increasing number of livestreaming videos, automatic speech recognition and post-processing for livestreaming video transcripts are crucial for efficient data management as well as knowledge mining. A key step in this process is punctuation restoration which restores fundamental text structures such as phrase and sentence boundaries from the video transcripts. This work presents a new human-annotated corpus, called BehancePR, for punctuation restoration in livestreaming video transcripts. Our experiments on BehancePR demonstrate the challenges of punctuation restoration for this domain. Furthermore, we show that popular natural language processing toolkits like Stanford Stanza, Spacy, and Trankit underperform on detecting sentence boundary on non-punctuated transcripts of livestreaming videos. The dataset is publicly accessible at `http://github.com/nlp-uoregon/behancepr`.

1 Introduction

Livestreaming is a powerful broadcasting medium that catches the attention of millions of users. Many video-sharing platforms have supported livestreaming for a wide range of topics such as Twitch for gaming, TikTok for short entertainment videos, Behance for visual creative work, and Youtube/Facebook Live accepting any topics. Among these videos, there are a substantially high number of videos that provide useful knowledge with exceptional visual demonstration. To this end, livestreaming videos are becoming a potential knowledge base waiting for being explored.

Mining videos on video/audio format directly is extremely hard and expensive because of their high data load and complexity in processing images and audio signals. Instead, mining video transcripts, transcribed by either human or machine, is much easier with the existing hardware and software. As such, livestreaming videos should be transcribed at high quality to facilitate future data mining research. As video transcription can be done using existing automatic speech recognition (ASR) systems, a reasonable step to improve the quality of transcribed texts for livestreaming videos involves post-processing produces to remove noises and restore correct language structures and texts from ASR-generated texts.

In this paper, we are particularly interested in punctuation restoration (PR) for livestreaming video transcripts. Punctuation restoration is the task to restore fundamental text structures such as sentences and phrases by inserting punctuation marks into non-punctuated text, e.g. text generated by an automatic speech recognition system for livestreaming videos in our paper. Punctuation restoration is an important post-processing step to improve the readability of ASR texts. Moreover, in natural language processing (NLP), PR is even more important as it enables the use of advanced techniques to process texts at the sentence level to achieve optimal performance for various tasks, e.g., part-of-speech tagging and dependency parsing. Prior studies have shown that with proper sentence split and punctuation, a downstream application can tolerate the word error rate of 25% (Alam et al., 2015), which is extremely high compared to the current state-of-the-art ASR. Figure 1 demonstrates how punctuation restoration improves the readability of ASR-generated texts.

In the literature, PR is considered as a subtask of ASR, in which PR annotation is done as part of the ASR datasets such as the AMI (McCowan et al., 2005) and TED corpus (Federico et al., 2012). However, the speech recorded in these audios involves multi-speaker meetings, as in AMI corpus, or single-speaker talks, as in TED corpus. Our work is different from those work as we consider livestreaming videos that feature many distinctive characteristics that are essential to study. In particular, the number of speakers in livestreaming

Use the marquee tool to draw a selection around the empty space on one side.
Then hold shift and add the other areas to the selection too.
Go to edit and fill, then change the drop down menu to content aware.
Photoshop should automatically generate a completely new background.
But it might make a couple of small mistakes.

Figure 1: Upper: a ASR-generated text in our dataset. Lower: the corresponding punctuated text in our dataset with greater readability.

videos varies greatly, ranging from one to a few main speakers along with up to thousands of audiences. The audiences might participate in question answering and commenting during the whole duration of the video, hence, constantly changing the information flow of the videos. Furthermore, the speech in livestreaming is much more spontaneous than those in the planned meetings of the AMI corpus and the well-scripted talks of the TED corpus.

An issue with the research of punctuation restoration for livestreaming videos is the lack of a human-annotated dataset for model development and evaluation. This is even more critical when livestreaming has become one of the most powerful communication mediums for not only entertainment but also education purpose. To this end, we introduce a new dataset for Behance Livestreaming Video Punctuation Restoration, called **BehancePR**. The dataset is annotated by skilled transcription annotators for 4 types of punctuation markers. Our experiments reveal the challenges of the BehancePR dataset where the performance of current state-of-the-art models for PR on BehancePR lags far behind those existing PR datasets (e.g., the TED dataset). Our further experiments on cross-domain generation for PR shows that models that are trained on a PR dataset of a different speech scenario perform much worse than those trained on BehancePR even with a much larger training set.

2 Data Annotation

Preparation: The livestreaming videos in this work are collected from the public source of `Behance.net`. Behance is an online platform to showcase and discover creative work such as digital drawing, graphic design, and photo/video editing. In those videos, one or a few creators stream their work on graphic design tools in English, covering a wide range of topics such as design theories, graphical ideas, and tutorials to use graphic design tools. In our dataset, we split the videos into shorter clips of 5 minutes. Next, the clips are transcribed by the Microsoft ASR system. The automatically generated transcripts for each clip (called documents) are then presented to the annotators. To prepare for the PR annotation in livestreaming video transcripts, we inherit the set of three most popular markers, i.e. **period**, **comma**, and **question mark** in prior PR datasets (Federico et al., 2012). In addition, as livestreaming videos of creative works involve a lot of emotional expressions (e.g., excitement), we include **exclamation mark** as a new annotation label to better capture strong feelings and emphasis in this area. Our instruction guidline is presented in Appendix B. To accommodate our annotation budget, we randomly select 2,314 transcribed documents for PR annotation.

Annotation: We recruit 8 annotators from the `Upwork.com` crowdsourcing platform. As Upwork allows its freelancers to submit resumes, we can choose the most experienced annotators with prior experience on audio transcribing. A detailed annotation guideline with many examples is provided to train the annotators. We also develop a customized web-based annotation tool that allows the annotators to work most efficiently with the transcripts and annotation. Appendix A shows the interface and description for our designed annotation tool. After self-practicing on the provided guideline and tool, the annotators are further trained by performing actual PR annotation on transcripts of a 2-hour audio from Behance. Feedback is provided to each annotator in this process to improve the quality. After the training process, the 8 annotators first co-annotate 10% of the documents, leading to the inter-annotation Cohen-Kappa agreement score of 0.59 (i.e., a moderate to substantial agreement level). Afterward, the annotators discuss to resolve the conflicts over the annotated data so far. Finally, the remaining documents are distributed to the 8 annotators for separate annotation to produce a final version of our dataset. To facilitate model development and evaluation, we split the dataset into 3 portions for training/development/test data. Table 1 shows detailed statistics and label distribution of our BehancePR dataset.

	Train	Dev	Test
Statistics			
#Documents	2,174	60	80
#Sentences	115,661	2,969	3,986
#Tokens	1,216,439	34,265	44,224
Label distribution			
#Periods	101,228	2,583	3,229
#Commas	126,739	3,291	4,388
#Questions	7,337	175	437
#Exclamations	7,096	211	320

Table 1: Statistics and label distribution of the BehancePR dataset.

3 Dataset Challenges

Compared to existing PR datasets, e.g., TED (Federico et al., 2012), AMI (McCowan et al., 2005), our dataset BehancePR features several unique challenges. First, as BehancePR's documents are obtained from livestreaming video transcripts, they introduce the unique characteristics of spontaneous speech. This is very different from TED talks, in which the talks are heavily scripted beforehand, and AMI meetings, where the talks are also well prepared. As such, livestreaming video transcripts have a much lower cohesion level as they might present sudden changes of topic and incomplete syntax (among others). Besides, they come with much more verbal pause and repetition of words and phrases, which are the results of hesitation and stutter of the speakers, thus causing a new level of challenges for PR models.

Second, as the documents in BehancePR are generated by an ASR system, it is expected that there is a certain number of word errors (e.g., incorrect transcription, missing words) in the texts. As such, word errors can hinder the language understanding ability, and thus PR performance, for the models on BehancePR. Table 2 shows the examples for different types of noisy texts including verbal pauses, duplicate words and phrases, incomplete syntax, instructional steps, and word errors. In the word error examples, as the streamer has just hurt herself, the ASR system cannot detect the word "*Oww*". Instead, it generates "*Oh*" and "*How*". This error is highly adverse as it might turn a declarative sentence into a WH question starting with the word "*How*".

Third, our introduced exclamation mark is a brand new label that are not captured in existing PR datasets, e.g., the TED and AMI datasets where emotion is rarer. To appropriately restore exclamation mark, a PR model needs to encode not only textual content, but also acoustic features such as frequency and strength of excitement. However, as BehancePR and current PR datasets do not provide access to audio features, the new label for exclamation mark will introduce a new challenging dimension that makes BehancePR an unique PR dataset. We also note that future work can extend BehancePR to include audio features to achieve multi-modal PR.

4 Experiments

Supervised Learning: To reveal the complexity of BehancePR, we evaluate the performance of the state-of-the-art (SOTA) model for PR on this dataset. Similar to prior work, we model PR as a sequence labeling task at the token level that aims to assign one of the five punctuation labels (i.e., 4 designed labels and 1 special labels for non-punctuation) to every space in input texts. In particular, we investigate two major SOTA model architectures for PR: a neural-based model with BiLSTM in (Alam et al., 2020), and graphical-based model with Conditional Random Field in (Makhija et al., 2019). We also investigate the recent advances in data augmentation for PR to automatically produce more training data in (Alam et al., 2020). Applying the data augmentation to two SOTA models leads to four possible model combination as presented in Table 3. We fine-tune the hyper-parameters for the models on the development data of BehancePR. We find that the pre-trained language model RoBERTa (large version) (Liu et al., 2019) delivers the best performance among RoBERTA, AlBERT, and bert-large-uncased version of BERT. This confirms prior results by Alam et al. (2020). The texts are split into sequences of 256 word pieces. The best batch size is 64. The selected learning rate is 3e-5 for the Adam optimizer. We use a single BiLSTM layer with 200 hidden units for the models. The augmentation rate is set to 0.2 following previous research (Alam et al., 2020).

Table 3(a) presents the performance of four models on the development and the test sets of BehancePR. The first observation from the table is the CRF component can improve the performance of BiLSTM when no data augmentation is applied, thus suggesting the effectiveness of capturing dependencies between labels with CRF for PR. We also observe that data augmentation has zero or little contribution to the performance of the models on BehancePR. In all, the best PR performance on BehancePR is achieved when CRF is applied on top of the BiLSTM model (without using data augmentation). Importantly, we find that the performance of current PR models on BehancePR is far behind that on the TED talk dataset (with F1 score of at least 84%) and perfect performance. It thus indicates the more challenging nature of PR on livestreaming video transcripts with BehancePR and calls for further study on this domain.

Domain Adaptation: To understand the domain difference between BehancePR and current PR datasets, we further explore the cross-domain evaluation setting where the models are trained on a different source domain and evaluated on BehancePR as the target domain. In particular, we choose the TED corpus as the source domain as TED talks are monologues, which is closer to the Behance videos. Table 3(b) presents the the out-of-domain performance of the models. It is clear from the table that the performance of all PR models on BehancePR degrades significantly when they are trained on TED talks. This demonstrates the considerable difference between the domains in TED and BehancePR. It also highlights the benefit of the annotated BehancePR dataset to achieve better PR performance for video transcripts.

Model	**Dev**			**Test**		
	P	**R**	**F**	**P**	**R**	**F**
(a) Behance → Behance						
BiLSTM	63.6	63.1	63.4	62.0	61.4	61.7
+aug	**64.8**	62.2	63.5	**63.8**	60.7	62.2
+CRF	62.8	**65.2**	**64.0**	62.2	**63.5**	**62.9**
+CRF+aug	62.8	64.5	63.7	61.1	62.8	62.0
(b) TED → Behance						
BiLSTM	53.5	59.1	56.2	54.6	59.6	57.0
+aug	55.8	58.0	**56.9**	55.7	58.5	57.1
+CRF	52.7	60.4	56.3	53.2	60.3	56.5
+CRF+aug	56.5	57.3	**56.9**	57.0	57.8	**57.4**

Table 3: Model performance of on BehancePR.

Sentence Splitting: We conduct an additional experiment to demonstrate another benefit of BehancePR on evaluation sentence splitting toolkits. In this task, the models need to predict where the sentences end. As such, we transform the BehanceED dataset by removing comma labels and converting the other labels into a single label of sentence ending. We then train the four models in the supervised learning experiment on the transformed training dataset of BehancePR to detect sentence ending label for sentence splitting. The models are then evaluated on the transformed test set. In addition, we examine the performance of existing NLP toolkits for sentence splitting in this new dataset, including Stanza (Qi et al., 2020), SpaCy (Honnibal and Montani, 2017), and Trankit (Nguyen et al., 2021). The performance of the models and toolkits are presented in Table 4.

As can be seen, existing toolkits perform very poorly on this domain, with the highest F-1 score of only 30.9%. One potential reason for this poor performance is that existing toolkits are trained on perfectly punctuated text (Nivre et al., 2016), making them unfit for our text domain with missing punctuation. As such, the models trained on the transformed BehancePR dataset significantly outperform existing toolkits for sentence splitting with substantial gaps. This demonstrates the ability of

Model	P	R	F
Stanza	70.4	1.4	2.8
Trankit	72.1	7.8	14.0
SpaCy	52.1	21.9	30.9
BiLSTM	70.3	75.6	72.8
+aug	71.5	72.8	72.1
+CRF	73.3	72.0	72.6
+CRF+aug	71.6	73.0	72.3

Table 4: Performance for sentence splitting.

the models to effectively encode contextual information to infer sentence ending. It also suggests the importance of training data for even basic tasks such sentence splitting in challenging domains.

5 Related work

Early studies on PR have explored a wide range of features such as lexical, acoustic, prosodic, and their combination (Gravano et al., 2009; Levy et al., 2012; Xu et al., 2014; Che et al., 2016a; Szaszák and Tündik, 2019). Graphical models such as CRF have been widely used for this task (Lu and Ng, 2010; Zhang et al., 2013) before the emerging of neural networks. Recently, a variety of deep neural network architectures have been explored for PR such as LSTM (Gale and Parthasarathy, 2017), convolutional network (Che et al., 2016b), and transformers (Alam et al., 2020). Corpora for PR are usually created as part of ASR datasets in various domains such as meetings (McCowan et al., 2005), TED talks (Federico et al., 2012), audio books (Panayotov et al., 2015), and film subtitles (Tiedemann, 2016). Among these, the TED corpus is widely used as the benchmark corpus for PR. However, livestreaming video transcripts have not been explored for PR in prior work.

6 Conclusion

We present BehancePR, the first dedicated corpus for punctuation restoration for livestreaming video transcripts. BehancePR is manually annotated for 4 markers and present unique challenges for PR. Our experiments with state-of-the-art models show the challenges of PR for livestreaming videos and call for more research effort in this important area.

Ethical Considerations

In this work we present a dataset on the transcripts of a publicly accessible video-streaming platform, i.e., "*Behance*"[1]. Complying with the discussion presented by Benton et al. (2017), research with human subjects information is exempted from the required full Institutional Review Board (IRB) review if the data is already available from public sources or if the identity of the subjects cannot be recovered. However, to protect the identity of the streamer and any other person whose information are shared in the video transcript, we impose extra processing on the transcribed documents before presenting them to annotators and publicly releasing it later. First, in this dataset, we remove username or any other identity-related information of the streamers in the transcripts to prevent disclosing their identity. Moreover, the proposed dataset only provides textual data (i.e., documents), hence the other content of the videos (e.g., images, audios) are not revealed (to annotators or users) to protect human identity. Finally, to reduce the risk of disclosing the information of the people in the transcripts, in the final version of the dataset, we exclude the transcripts that explicitly or implicitly refer to the identify of the target people.
