A Annotation Tool

We develop a customized web-based annotation tool for this work. The annotation tool focuses on improving the readability of the annotated text, as the result, improves the annotation quality. Toward this end, we use color coding for punctuation markers. More importantly, whenever a sentence ending marker is assigned, such as period, question mark, and exclamation, it automatically creates a new line to separate sentences. Figure 2 shows the interface and an annotated text using our tool.

B Annotation Guideline

This section summarizes the taxonomy, annotation guideline, and annotation examples. Examples are shown in figure 2.

A **period** is used for:

- Marking the end of a **declarative sentence**.
- Separating independent clauses **without** a conjunction when a semi-colon is usually used (to distinguish with the case that a comma is used when a conjunction presents).

A **question mark** is used for:

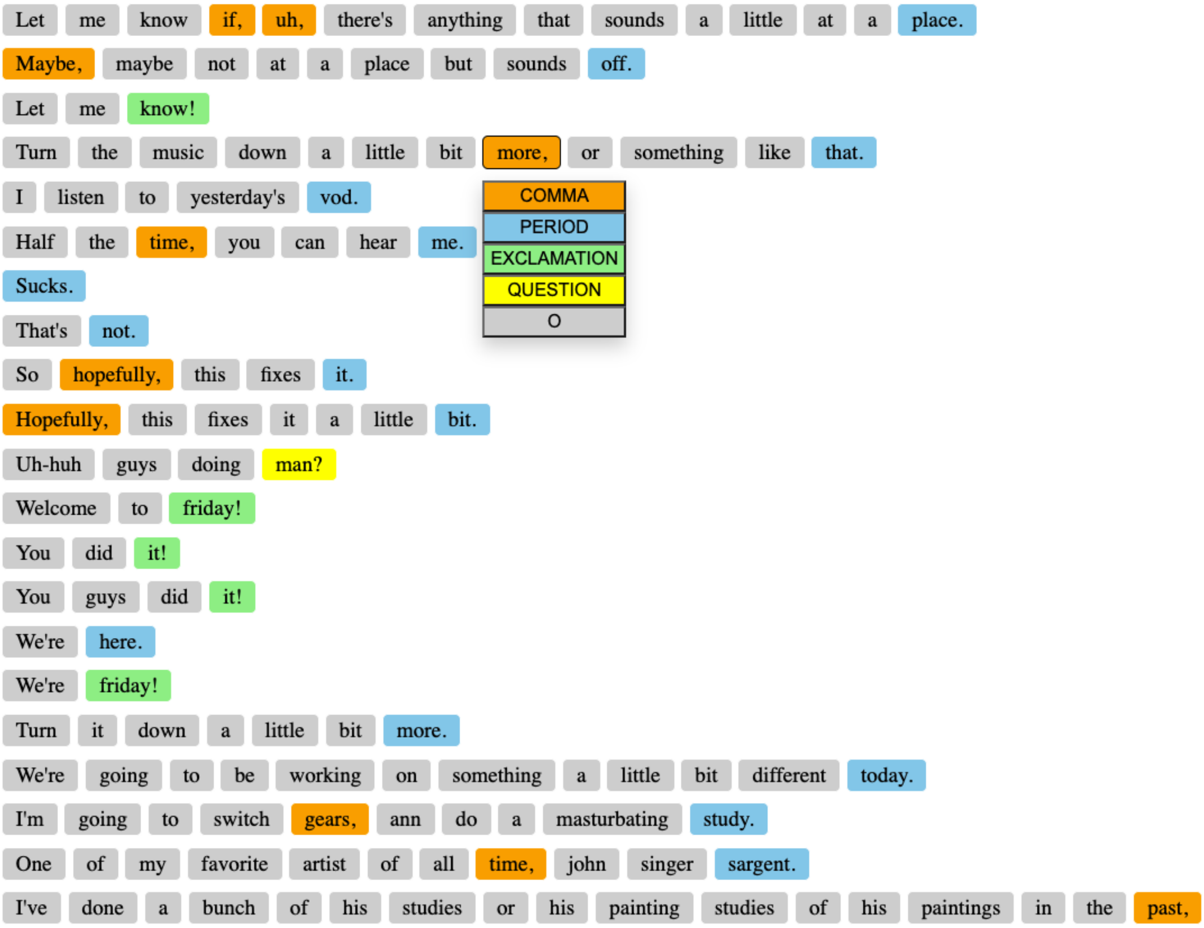
- Marking the end of a **question**.

An **exclamation mark** is used for:

- Exclaiming something. They are commonly used after interjections (words or phrases that are used to exclaim, command, or protest like “wow” or “oh”).
- Express the following emotions: excitement, surprise, astonishment, emphasizing a point, and other types of strong emotions.

A **comma** is used for:

- Separating independent clauses when they are joined by any of these seven coordinating conjunctions: and, but, for, or, nor, so, yet.
- Separating introductory clauses, phrases, or words from the main clause.
- Setting off clauses, phrases, and words that are not essential to the meaning of the sentence. Use one comma before to indicate the beginning of the pause and one at the end to indicate the end of the pause.
- Separating three or more words, phrases, or clauses written in a series.
- Separating two or more coordinate adjectives that describe the same noun. Be sure never to add an extra comma between the final adjective and the noun itself or to use commas with non-coordinated adjectives.
- Separating contrasted coordinate elements or to indicate a distinct pause or shift near the end of a sentence.
- Setting off phrases at the end of the sentence that refers back to the beginning or middle of the sentence. Such phrases are free modifiers that can be placed anywhere in the sentence without causing confusion.
- Setting off all geographical names, items in dates (except the month and day), addresses (except the street number and name), and titles in names.
- Shifting between the main discourse and a quotation.
- Preventing possible confusion or misreading.



Let me know if, uh, there's anything that sounds a little at a place.

Abstract

Suicide is a serious problem in every society. Understanding life events of a potential patient is essential for successful suicide-risk assessment and prevention. In this work, we focus on the Event Detection (ED) task to identify event trigger words of suicide-related events in public posts of discussion forums. In particular, we introduce SuicideED: a new dataset for the ED task that features seven suicidal event types to comprehensively capture suicide actions and ideation, and general risk and protective factors. Our experiments with current state-of-the-art ED systems suggest that this domain poses meaningful challenges as there is significant room for improvement of ED models. We publicly release SuicideED to support future research in this important area.

1 Introduction

Suicide is a serious and growing problem in our society[1]. The most common procedure for suicide risk assessment is for clinicians to set up clinical interviews with potential patients that will provide rating scales based on a list of preset questions (Ross et al., 2012). However, interviews and similar activities require the willingness of potential patients to participate. Given the associated mental states, such participation can be challenging to obtain for patients with high suicidal risks.

In the meantime, people are increasingly spending more of their time on social networks, sharing inner thoughts and daily activities. This collection of social posts might draw a comprehensive picture of the patient's life that can be used to support the diagnosis of suicidal conditions. In fact, moderators of some social networks (e.g., Reddit, Reachout) use social posts to monitor suicide and apply immediate intervention if necessary. To assist with the processing of the large amount of posts, there have been a few methods and tools for automatically analyzing online posts to detect suicidal intent (Ji et al., 2018; Shing et al., 2018; Coppersmith et al., 2015; Milne et al., 2016). However, these studies mainly focus on assessing the patients' susceptibility to suicide and fail to consider contributory life events that cause/lead to such conditions. In this paper, we argue that recognizing suicide-related events is also critical to suicide understanding, identification and prevention, and natural language processing (NLP) methods are necessary to support automatic identification of such events from the vast and growing number of social media posts.

This work aims to advance the ultimate goal of creating NLP methods for suicide understanding by exploring the novel task of Event Detection (ED) for suicide-related events. ED is an important task in Information Extraction (IE) whose purpose is to identify event trigger words/mentions text data(Ahn, 2006; Ji and Grishman, 2008). Take, for instance, the following paragraph:

I don't date anyone and never will. It s a reason why I have no friends and never will. I wanna be funny and have a personality and be desirable but I 'm not that. I know its depression that causes it.

Adapted to our interest in suicide-related events, an ED system should be able to recognize "*date*" and "*have*" as trigger words for deteriorated personal relationship events (i.e., risk factors); "*wanna*", "*have*", and "*desirable*" as triggers for protective factor events, and "*depression*" as a trigger for a health-related risk factor event.

The vast majority of advanced methods for ED are based on training deep neural networks on large labeled corpora (Nguyen and Grishman, 2015; Chen et al., 2015). As such, to facilitate research in ED for suicide prevention, a key requirement is to have a benchmark dataset to standardize the development and evaluation of ED models. Unfortunately, a large amount of existing suicide-related datasets are protected due to sensitive pri-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1952 - 1961
July 10-15, 2022

vacy concerns and, thus, fail to support the larger research community (Coppersmith et al., 2015; Vioules et al., 2018; Bhat and Goldman-Mellor, 2017). Moreover, these existing datasets are created to detect potential suicidal attempts based on text classification (Vioules et al., 2018; Bhat and Goldman-Mellor, 2017; Shing et al., 2018), which does not provide event trigger annotations of suicide-related events for ED.

To overcome such challenges, this paper introduces SuicideED, a new dataset for suicidal event detection that is manually annotated for seven distinct event types to comprehensively characterize suicide-related events regarding suicidal actions, thoughts, and risk and protective factors. To enable data sharing, our dataset is based on public posts from Reddit where personal information is not presented to avoid privacy issues. The SuicideED dataset is challenging as it involves informal texts, and requires event factuality and affected entity reasoning. Our experiments show that the performance of current state-of-the-art ED models on SuicideED lags behind their performance on other general-purpose ED datasets, thus calling for more research effort for suicide-specific ED. To facilitate future research in this area, SuicideED is released publicly[2] for the research community.

2 Ontology Design

An important, previously unexplored, question is *what* constitutes relevant events that can provide useful insights for clinicians to better understand and recognize suicide-related incidents. Accordingly, we consult specialized literature related to suicidal-behavior identification and treatment (Gutierrez, 2006; de Ruiter and Nicholls, 2011; O'Connor et al., 2013) to define the event categories for our dataset. As such, we design the event types to be exclusive to avoid type overlapping, and sufficiently comprehensive to cover relevant/impactful suicide-related events in the data. Eventually, we select the following seven event types that capture suicide-related actions, thoughts, and risk/protective factors.

The first two event types are concerned with statements to indicate suicidal attempts or intentions. In particular, the **ACTION** event type is dedicated to the direct expressions for actual suicidal attempts/actions, e.g., "*I've started **cutting** myself again*"[3]. In contrast, the second event type, **IDEATION**, represents suicidal inner thoughts, feelings, or desires, where no real action present, e.g., "*I'm going to **kill** myself soon*". These two types directly integrate factuality differentiation into the event types to better address the uniqueness of the data where hypothetical events are prevalent and understanding the factuality of events is critical to suicide intervention and prevention.

The second group of event types focuses on external events that increase a subject's susceptibility to suicidal behaviours, i.e., risk factors (RF) (Gutierrez, 2006). Given the diverse nature of RF, four event types are proposed. **RF-LIFE** events include mentions of a death of a close/loved entity, e.g., "*My dog just **died***". **RF-RELATIONSHIP** concerns events related to social isolation, family breakdowns, or any mention of deteriorated interpersonal relationship, e.g., "*My dad **kicked** me out of the house*". Events for **RF-HEALTH** cover mentions of physical diseases, mental illness, and behaviors that directly affect the subject's health, e.g., "*I feel **depressed***". Finally, **RF-OTHER** incorporates every other RF event that cannot be assigned to life, relationship, or health issues but still qualify as RF, including financial issues, chronic abuse, and general quality-of-life problems.

The final type, **PROTECTIVE**, captures events that drive an individual towards a better mental-health state, involving a broad range of positive activities, such as receiving effective medication or being motivated by social connections, e.g., "*The medication seems to be **helping***". A detailed description and representative examples for each event type are presented in Appendix B.

3 Data Collection and Annotation

The documents for SuicideED are collected from publicly available posts from `reddit.com`. In particular, we focus on three subreddits (subgroups) that contain a high percentage of suicide-related posts: `r/SuicideWatch`, `r/depression`, and `r/mentalhealth`. Each original post is considered as a separate document and only posts with more than 50 words are considered to increase the probability of an event being present.

Given the event types described in section 2, an annotation job posting is created on `upwork.com` and seven freelance annotators with previous experience in mental health and psychology, such

[3] In our examples, event trigger words are highlighted.

	Train	Dev	Test
#Event triggers	33,055	1,925	1,998
#Documents	2,214	130	109
#Sentences	20,677	1,178	1,176
#Words	378,435	20,301	21,541

Table 1: Data statistics for SuicideED.

Label	Count
RF-OTHER	15,343
PROTECTIVE	7,389
IDEATION	6,645
RF-RELATION	3,890
RF-HEALTH	2,408
ACTION	1,084
RF-LIFE	219

Table 2: Label distribution of SuicideED.

as physicians and psychology graduates, are recruited. They are provided with a comprehensive guideline document[4] with thorough annotation instructions and numerous detailed examples for training. The annotators are instructed to select a single word for each event trigger (i.e., the most important) that clearly evokes the event, following the practices of prior ED work (Nguyen and Grishman, 2015). Overall, we annotate 2,300 documents for the seven event types from which the proportions of documents taken from the subreddits `r/SuicideWatch`, `r/depression`, and `r/mentalhealth` are 50%, 30%, and 20%, respectively. We select 20% of the documents to be used for co-annotation, leading to a Fleiss' Kappa score of 0.8 (i.e., close to the almost perfect agreement range of $[0.81 - 1.0]$). The remaining 80% of documents are distributed among the annotators for individual annotation. To facilitate and standardize future research, we divide SuicideED into three different portions for training, test, and development purposes. Table 1 presents some statistics for the different data portions while Table 2 shows the event type distribution.

4 Dataset Challenges

Compared to existing, general purpose, ED datasets, e.g., ACE-05 (Walker et al., 2006), MAVEN (Wang et al., 2020), and CySecED (Trong et al., 2020), our SuicideED dataset features at least three unique challenges for ED models.

First, as its documents are obtained from Reddit posts, SuicideED involves texts where informal words (e.g., "*wanna*", "*gonna*") are prevalent, sentences might not follow well-structured grammar rules, and first-person point of view is the main writing style. This is in contrast to existing ED datasets where documents are often retrieved from news outlets or reports with formal and well-structured texts.

Second, in addition to the relevance to suicide, the event types in SuicideED sometimes require models to simultaneously consider event factuality to accurately determine the types. This is clear for differentiating **ACTION** and **IDEATION** where the key distinction concerns event factuality. Another example involves the potential confusions between **PROTECTIVE** and **RF** where different event factuality might lead to different event types for the similar expressions. For instance, in the sentence "*I **have** a lot of friends*", the event trigger "*have*", belongs to the **PROTECTIVE** type given that it reveals a positive environment for the subject. On the contrary, in the sentence "*I **had** a lot of friends*", the trigger "*had*" should be considered as a **RF-RELATIONSHIP** type as it might instead imply current deteriorated social connections.

Furthermore, the event type determination in SuicideED also necessitates appropriate identification of the entity that should be considered for the effect of an event. For instance, in the sentence "*My sister **killed** herself.*", the trigger word "*killed*" should have the **ACTION** type if the entity of consideration is "*sister*". However, if we consider the event from the point of view of the poster/speaker, "*killed*" should be a **RF-LIFE** event. In SuicideED, the annotators are instructed to take the first person point of view (i.e., the poster) in the annotation decision. As such, ED models are expected to learn this feature from the data to achieve good performance.

Finally, some triggers in general-purpose datasets such as ACE05 can be type-indicative to a great extent. For instance, the trigger word *"bought"* is almost certainly indicative for the `Transaction:Transfer-Ownership` type. In contrast, Figure 1 illustrates the ambiguity of the event triggers in SuicideED by presenting the label distribution of the top 5 most frequent event trigger words. As can be seen, there is no particular dominant label for even the most frequent words. Hence, a ED model must effectively capture surrounding context of triggers to perform classification.

---

[4] https://github.com/nlp-uoregon/suicideED/guidelines.pdf

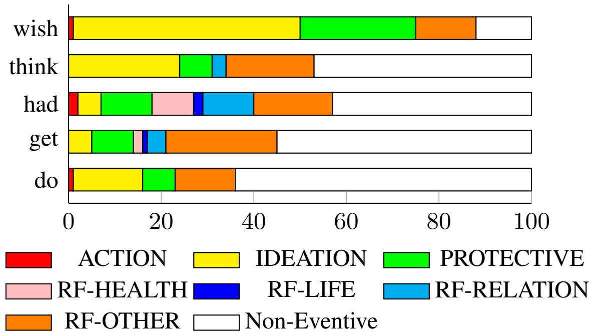

Figure 1: Label distribution of common trigger words.

5 Experiments

To assess the complexity of the ED task in SuicideED, we evaluate the performance of the following state-of-the-art ED models: **CNN**: a convolutional neural network for ED (Nguyen and Grishman, 2015); **DMBERT**: a dynamic multi-pooling model based on BERT (Wang et al., 2019); **BERTED**: a BERT-based model augmented with multi-layer perception (Yang et al., 2019); **BERTGCN**: a graph convolutional network (GCN) based on dependency trees (Nguyen and Grishman, 2018); **GatedGCN**: a GCN model using BERT and trigger-aware gating mechanism (Lai et al., 2020); and **EEGCN**: a GCN model that exploits syntactic structure and typed dependency information (Cui et al., 2020). All of these models leverage the pre-trained BERT model to obtain representation vectors. The hyperparameters of the models are fine-tuned over the development data.

Additionally, we further finetune the pre-trained BERT model over unlabeled Reddit posts from the same three subreddits (i.e., about 40K posts) using masked language modeling (Devlin et al., 2019). We report the model performance when the fine-tuned BERT replaces the original pre-trained BERT to explore the effectiveness of domain customization of BERT for the informal texts in Reddit.

Model	**BERT-base-cased**			**Finetuned BERT**		
	P	R	F	P	R	F
CNN	47.5	44.9	46.2	48.6	46.7	47.6
DMBERT	51.7	62.1	56.4	52.1	64.1	57.5
BERTED	47.8	66.3	55.5	48.8	65.3	55.8
BERTGCN	56.0	61.9	58.8	55.5	63.5	59.2
GatedGCN	54.6	64.1	59.0	54.2	65.1	59.2
EEGCN	54.6	65.5	59.5	53.7	66.7	59.5

Table 3: Performance of the models on the SuicideED test set using BERT and finetuned BERT embeddings.

Table 3 presents the performance of the models on the SuicideED test set. Our first observation is that fine-tuning BERT over Reddit posts can successfully improve the performance of all ED models. This improvement, though, is less pronounced for the more recent and advanced ED models, i.e., GatedGCN and EEGCN. Second, the performance of the graph-based models (e.g., GatedGCN and EEGCN) is significantly better than those for non-graph-based models (i.e., CNN, DMBERT, and BERTED). As such, despite the informal nature of texts that can hinder the performance for dependency parsing, dependency trees are still helpful for the representation learning of ED models in SuicideED. Finally and most importantly, we find that the performance of existing ED models on SuicideED is substantially below than the typical performance of such models general purpose ED datasets (e.g., 77.6% on ACE-05 with GatedGCN and EEGCN) (Lai et al., 2020). These results then suggests the unique challenges of SuicideED for ED models and highlight the need for further, domain-specific research to improve ED for suicide-related events.

6 Related Work

Suicide detection and prevention using NLP methods has caught the attention of many researchers. Due to the privacy restrictions associated with clinical databases, researchers have used publicly-available data from social media with manual annotations of recognizable signals of mental health issues (Coppersmith et al., 2015; Shing et al., 2018). The majority of methods, however, focus on detecting suicidal attempts or assessing suicide propensity of users based on social media posts (Coppersmith et al., 2015; Bhat and Goldman-Mellor, 2017; Shing et al., 2018; Zirikly et al., 2019). As such, these prior works have only explored the setting of overall text classification which fails to explore fine-grained analysis/classification at word level required to reveal suicide-related events as this paper does.

Prior research efforts for ED, in general-purpose settings, have introduced various methodologies to address such task, including feature engineering (Ahn, 2006; Ji and Grishman, 2008; Li et al., 2013) and deep learning (Nguyen and Grishman, 2015; Chen et al., 2015; Wang et al., 2019; Cui et al., 2020; Ngo Trung et al., 2021; Pouran Ben Veyseh et al., 2021b,a) models. However, such prior work mainly utilizes the ED datasets with general event types and formal texts, i.e., ACE-05 (Walker et al., 2006), that might not be helpful for particular domains with unique requirements such as the one addressed in this work. Recently, there have been some effort on creating new datasets for ED in more specific domains, including biomedical texts (Kim et al., 2009), literary texts (Sims et al., 2019), cybersecurity texts (Satyapanich et al., 2020; Trong et al., 2020), fine-grained event types (Le and Nguyen, 2021), and historical texts (Lai et al., 2021). However, none of existing ED datasets explore suicide-related events in social media texts.

7 Conclusion

We present SuicideED, the first dataset focused on the event detection task for suicide-related events. SuicideED is manually annotated for seven event types and provides enough training examples to develop large-scale deep learning models. We perform extensive evaluations of state-of-the-art ED models that demonstrate the challenges entailed by this difficult domain and call for further efforts to improve performance. In the future, we plan to extend SuicideED to annotate event arguments and other event properties to better support event analysis and understanding for suicide.

8 Statement of Ethics and Human Subject Research

Working with sensitive data such as mental health information from human subjects requires taking special care. This becomes particularly relevant in this case as our main objective is to provide a dataset for general public use. Benton et al. (2017) discuss, however, that research with human subjects information is exempted from the required full Institutional Review Board (IRB) review if the data is already available from public sources or if the identity of the subjects cannot be recovered.

By design, Reddit is a platform where users remain anonymous and make their posts available to the general public. Nonetheless, additional privacy measures were taken by removing any username mentions from the documents as they can sometimes include identifiable information. Furthermore, unlike previous works where the main objective is to assess suicidal risk at the user level (Coppersmith et al., 2015; Bhat and Goldman-Mellor, 2017; Shing et al., 2018; Zirikly et al., 2019), this work focuses on sentence-level ED. As such, our dataset does not include any user-level information that could be used to identify individual subjects. Hence, this work is considered exempt from review by our University's IRB as the documents used are already publicly available and the original posters are impossible to identify.

Minimizing impact on the annotators: All prospective annotators were informed beforehand about the nature of the related text material and were made aware of its potential impact on their mental health. All chosen annotators had background knowledge/training on the subject at hand and were either clinicians or psychology graduates. Any candidates who reported suffering from, or having a history of, mental health-related issues were not considered out of concern for their health.

A Topic Modeling

To better understand the topics related to suicide in the SuicideED dataset, we run a topic modeling analysis using Latent Dirichlet Allocation (LDA) (Blei et al., 2003) over the documents in the dataset. We extract ten topics from the analysis and present their words in Table 4. English stop-words, the least ($p < 0.01$), and most frequent words ($p > 0.2$) were removed in the analysis. Interestingly, it can be observed that posts can be summarized into 3 main categories: school (2, 8), work (5, 9, 10), and family (3, 4, 6, 7), which somehow reflects the sources of mental issues.

#	**Words**
1	hate, thoughts, point, stop, care, say, worse, living
2	wish, hate, worse, try, year, shit, school, thoughts
3	world, parents, suicidal, right, bad, point, person
4	tell, love, tired, days, person, doing, death, mom
5	pain, real, tried, need, maybe, work, hurt, tired, talk
6	care, told, tired, said, parents, bad, need, leave, right
7	care, matter, getting, days, actually, feels, parents
8	got, school, said, talk, doing, self, love, mental, work
9	job, happy, got, year, love, hate, try, told, money
10	love, shit, job, work, suicidal, night, pain, right, year

Table 4: Topic models with LDA

B Annotation Guideline

Table 5 and 6 present a detailed description of event types and examples for each event type in our SuicideED dataset.

Type	Description	Examples
ACTION	This category includes any event of an individual engaging in actions that bring them closer to dying by suicide. These include any previous suicide attempts, preparatory acts towards a future attempt, or self-inflicted violence. When annotating this type of event, it is important that an actual action takes place and that it goes beyond verbalization or intent. As such, sentences containing these events mainly talk about the past or ongoing situations.	A previous suicide attempt is a self-inflicted, potentially injurious behavior with an intent to die as a result. *I tried to **kill** myself last night.*
		A preparatory act consists of any acts of preparation toward making a suicide attempt. Must be beyond verbalization or thought such as assembling a method (e.g. buying a gun, collecting pills) or preparing for death (e.g. writing a suicide note and a will). *Just **looked** online for the quickest way* *I **left** a note for my parents*
		Self-inflicted violence includes self-directed, harmful behaviors that do not have a clear intent to die as a result. *I've started **cutting** myself again*
IDEATION	These events focus on expressing thoughts and feelings but no actual action is present. These, however, are not related to actions such as preparatory acts and, instead, refer to verbalizations of inner feelings/desires.	It includes passive thoughts about wanting to be dead: *I **wish** I was dead* And, active thoughts about killing oneself. *I am going to **kill** myself soon*
PROTECTIVE	These events are related to capacities, qualities, environmental and personal resources that increase resilience; drive an individual toward growth, stability, health, and/or an increase in coping with different life events. For this category, please annotate any sentence that showcases a positive impact on an individual. These can be verbalizations of self-worth and willingness to get better, access to medical resources, positive personal relationships, positive cultural beliefs, etc.	Access to effective behavioral health care and medication: *My therapist says that I should **talk** more.* *The medication seems to be **helping**.*
		Connectedness to individuals, family, community, and social institutions: *At least my **friends** are there for me*
		Life skills (including problem-solving skills and coping skills, ability to adapt to change): *I've always been **good** at helping people*
		Self-esteem and a sense of purpose or meaning in life: *My life is much **better** than many people.*
		Expressing a willingness to improve: *I really **want** to get better.* *I **wanna** be funny and outgoing.*
		Cultural, religious, or personal beliefs that discourage suicide: *I know God **disapproves** of what I'm thinking.*

Table 5: Event types with their descriptions and examples in the SuicideED dataset. Event trigger words are shown in bold. Continued in Table 6

.

Type	Description	Examples
RF - LIFE	This risk factor event is easy to identify as a loss of life of a both human an non-human entities. The loss of life might be explicitly or implicitly expressed.	Loss of a relative, explicitly expressed: *After my brother **killed** himself...*
		Loss of a relative, implicitly expressed: *My grandma has been **gone** for years now.*
		Loss of a pet friend: *My dog just **died**, he was my only real friend.*
RF - RELATIONSHIP	These include events such as social isolation, family breakdowns, divorce, etc. Include in this category all events that show a loss of connection with other people. These can be both verbalization of feelings of isolation or actual incidents of loss of an interpersonal relationship such as a break-up or argument with another individual.	Social isolation: *I don’t **have** anyone to talk to.*
		Family breakdown: *My dad just **kicked** me out of the house.*
		Divorce: *After my **divorce**, I started drinking*
RF - HEALTH	These include events such as social isolation, family breakdowns, divorce, etc. Include in this category all events that show a loss of connection with other people. These can be both verbalization of feelings of isolation or actual incidents of loss of an interpersonal relationship such as a break-up or argument with another individual.	Mental disease/disorder such as depression, PTSD: *Can’t **deal** with my depression right now.* *I’ve been **diagnosed** with BPD.*
		Chronic or long-term disease, pain, and disability: *I’m just **giving** into my eating disorder.* *Recently, my diabetes has been **acting** up.*
		Misuse and abuse of alcohol or other drugs: *I’ve been **drinking** a lot lately*
RF - OTHER	These events include all other risk factors that do not fall into the LIFE, RELATIONSHIP, or HEALTH categories. As such, these can be events of very diverse natures such as financial issues, chronic abuse, discrimination, or general quality of life problems.	Financial hardship: *Can’t **afford** to pay rent anymore...*
		Prison: *I can’t go back to **jail** now.*
		Job loss: ***Lost** my job today.*
		Discrimination *They **tease** me in school cause I’m gay*

Table 6: Event types with their descriptions and examples in the SuicideED dataset. Event trigger words are shown in bold.

Great Power, Great Responsibility: Recommendations for Reducing Energy for Training Language Models

Abstract

The energy requirements of current natural language processing models continue to grow at a rapid, unsustainable pace. Recent works highlighting this problem conclude there is an urgent need for methods that reduce the energy needs of NLP and machine learning more broadly. In this article, we investigate techniques that can be used to reduce the energy consumption of common NLP applications. In particular, we focus on techniques to measure energy usage and different hardware and datacenter-oriented settings that can be tuned to reduce energy consumption for training and inference for language models. We characterize the impact of these settings on metrics such as computational performance and energy consumption through experiments conducted on a high performance computing system as well as popular cloud computing platforms. These techniques can lead to significant reduction in energy consumption when training language models or their use for inference. For example, power-capping, which limits the maximum power a GPU can consume, can enable a 15% decrease in energy usage with marginal increase in overall computation time when training a transformer-based language model.[1]

1 Introduction

Artificial intelligence and machine learning (ML) are increasingly used in diverse areas ranging from NLP to autonomous driving. Broadly, larger and deeper models are found to be more accurate. However, as models and datasets increase in size, the computational demands of AI/ML have increased correspondingly (Amodei et al., 2018; Thompson et al., 2020). In particular Thompson et al. (2020) estimates that achieving a 10-fold improvement in model performance comes at a cost of at least a 10,000-fold increase in computation and a corresponding increase in the energy required to perform these computations. The growth in computational and energy requirements is particularly glaring in NLP with the introduction of transformer-based language models (Vaswani et al., 2017; Devlin et al., 2019; Radford et al., 2018). For example, training GPT-3 is estimated to consume almost 1300MWh (Patterson et al., 2021). Given the considerable compute requirements and the associated carbon footprint of training models with increasing accuracy, there is growing interest and research into the energy demands and carbon footprint of AI (Patterson et al., 2021; Toews, 2020).

However, estimating energy usage for a particular AI application depends on a number of parameters such as model architecture, hardware details, environmental parameters, and implementation details. For this reason, important works such as Patterson et al. (2021) and Strubell et al. (2019) rely on estimates extrapolated from industry averages for some language models in some of their analysis of large neural net training, including total floating point operations per second (FLOPS) and hardware estimates, rather than values that otherwise might have been measured. Further, these articles call for new research that identifies mitigation techniques that can reduce the energy usage of NLP applications.

This paper proposes and characterizes potential ways to reduce the energy impact of NLP applications. To our knowledge this is the first presentation of power-capping as a useful tool for reducing GPU energy consumption. Particularly in the context of

deep learning and NLP, this work provides an approach alongside estimates for possible energy savings for training large, energy-intensive language models. Moreover this method does not affect the predictions of trained models or consequently their performance accuracy on tasks. That is, if two networks with the same structure, initial values and batched data are trained for the same number of batches under different power-caps, their resulting parameters will be identical and only the energy required to produce them may differ. Section 2 presents related work on tracking energy usage of NLP applications and their environmental impact. Section 3 introduces different techniques, including power-capping and energy-aware scheduling, that can be used to reduce the energy usage, including experiments and other relevant data to characterize their effectiveness. In Section 4, we discuss these approaches with broader recommendations before concluding with future avenues of research.

2 Prior work

Energy efficiency considerations for deep learning have trailed model developments targeted at improving accuracy among other metrics with new, often growing architectures. Highlighting this focus, the growth of neural network architecture sizes is considered in Canziani et al. (2016). That study offers a comparison of state-of-the-art image recognition models where their computational performance is analyzed including inference time and power utilization. Techniques for model compression have been widely studied including knowledge distillation and pruning (Hinton et al., 2015; Frankle and Carbin, 2019). In NLP, distillation has been used to reduce the size of large language models (Sanh et al., 2019), and other methods of compression have been effective at shrinking model parameters such as embedding layers (Mu and Viswanath, 2018; McDonald et al., 2021).

Recent attention has focused on the size of NLP models alongside their extensive training times and environmental impact (Strubell et al., 2019; Patterson et al., 2021; Schwartz et al., 2020). These works illustrate efforts to place greater consideration on the efficiency or inefficiencies of large neural network architectures. For instance, Schwartz et al. (2020) weighs the advantages of different metrics to evaluate efficiency while advocating for the use of floating point operations as a way to objectively compare models. Another area of focus has been on the dependence of model test accuracies on the amount of computation expended on hyperparameter tuning (Dodge et al., 2019). Some of these works propose considering efficiency alongside accuracy as a metric for evaluating ML models, and at the very least to require reporting energy consumption and carbon impact used in research for conference and journal submissions.

While calls to prioritize more efficient methods of training NLP models are made in the previously cited papers among other works, to the best of our knowledge this is not reflected in publicly available academic or industry research. In fact, in Henderson et al. (2020) a random sampling of 100 NeurIPS papers showed that few papers tracked and reported these statistics – and none reported carbon impact. This and the previous works point out that tracking energy usage is not yet a standard practice, in part because of the difficulty in implementing a framework for collecting these statistics from hardware. An implementation for accurately capturing this data on common hardware (specifically Intel and NVIDIA hardware) is presented in Henderson et al. (2020) which relies on querying device software tools. We describe another, similar approach for gathering power expenditure and energy usage in this work, in order to present a straightforward process for obtaining accurate measurements of energy consumption.

Compared to these works, this paper presents steps that can be taken to reduce the energy required for training and inference with language models. There is limited prior research investigating power-capping as a method for reducing energy consumption (Haidar et al., 2019), and it has focused on CPUs for scientific computing applications. Our focus is specifically on widely-used AI/ML frameworks used with available commodity hardware. This approach is described with experiments showcasing its effectiveness for a range of settings. Additionally our findings for GPU energy reduction when training neural networks are comparable and consistent with the outcomes for CPU consumption presented in Haidar et al. (2019).

Similar recent work investigates distributed DNN training fitting power law models that describe how training time scales with available compute resources and energy constraints (Frey et al., 2022). Additionally we address other approaches towards reducing energy footprints by considering shifting habits in training. Utilizing datacenters and climate-aware workload scheduling can provide considerable savings, and we share statistics from our institutional datacenter to support this (Reuther et al., 2018; Samsi et al., 2021).

3 Reducing the Energy Impact of NLP

This section outlines various approaches that can be used to reduce the energy consumption of NLP workloads. We focus primarily on a simple yet effective method – power-capping – that yields significant benefit with minimal cost and translates across different computing platforms. Experiments measuring the effect of power-caps on energy consumption are presented. For completeness, we discuss other potential avenues for reducing the carbon impact of NLP applications. Data is presented for the monthly and daily variation in energy efficiency of our institution's datacenter. This illustrates in detail how much energy usage can be reduced by simple approaches like timing workloads to certain hours or seasons if possible. While factors like efficiency and daily variation depend heavily on characteristics unique to each organization's datacenter, we share general insights that will hold true for most cases.

Measuring Energy Usage: Currently, there are two vendor-provided utilities to monitor resource consumption on NVIDIA GPUs. The NVIDIA Data Center GPU Manager (DCGM) is a suite of tools for managing and monitoring NVIDIA GPUs in cluster environments (NVIDIA, 2021a) and the NVIDIA System Management Interface (NVIDIA, 2021b) (or `nvidia-smi`) utility, which can also perform similar monitoring. Broadly, these tools enable monitoring of GPU usage on a node and the collection of metrics on Streaming Multi-processor (SM) utilization, GPU memory footprint, power draw, GPU temperatures, PCI Express (PCIe) bandwidth, and several other hardware settings. On our system, this data is collected on every node and every GPU assigned to a job. The data is collected every 100ms and data collection is started and stopped automatically using the scheduler that manages resources on the system.

3.1 Limiting Hardware Power

Most modern computing platforms allow users to adjust hardware settings for processors and GPUs. This can be done via command line tools that are generally not visible to users of a shared computing system. Over the duration of an NLP task, the power consumed by hardware components can vary significantly based on the operation being performed, environmental conditions, and hardware limits. Power-capping allows users to limit the maximum power available to hardware devices through these tools. On our cluster, this is implemented using the `nvidia-smi` command line utility.

A series of experiments is presented here that use energy tracking tools to measure the reduction in energy consumption provided by power-capping GPUs. Power-capping requires no changes to user code and is done at a hardware level. Below, we validate these savings for various scenarios such as how these savings translate across different models for masked language modeling (MLM) or how these savings work across different sets of resources and hardware platforms. From our observations, this method provides a noticeable difference in all scenarios with very little incurred effect on computation time. For these experiments we use a popular PyTorch implementation for MLM from Hugging Face[2].

Power-capping works across different models: We train different transformer-based networks – BERT, DistilBERT, and Big Bird (Devlin et al., 2019; Sanh et al., 2019; Zaheer et al., 2020) – with MLM and observe that power-capping is beneficial to energy usage regardless of architecture. Each model was trained on 16 V100 GPUs using four different power caps: 100 watts (W), 150W, 200W and 250W (the default power limit for an NVIDIA V100 GPU on our system). Models were trained

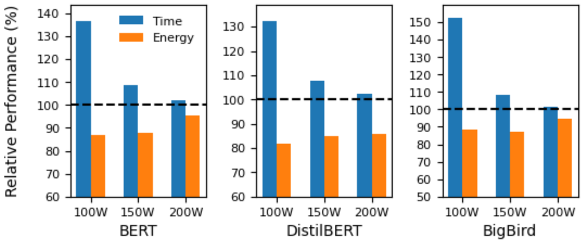

Figure 1: Time and energy usage comparison of training three language modeling network architectures with different maximum power limits. Values given are percentage relative to performance of default 250W setting (100% indicated by black line). For example, training BERT with a 150W limit required 108.5% of the time and only 87.7% the energy needed to train with default settings.

---

[2] https://github.com/huggingface/transformers/blob/master/examples/pytorch/language-modeling/run_mlm.py

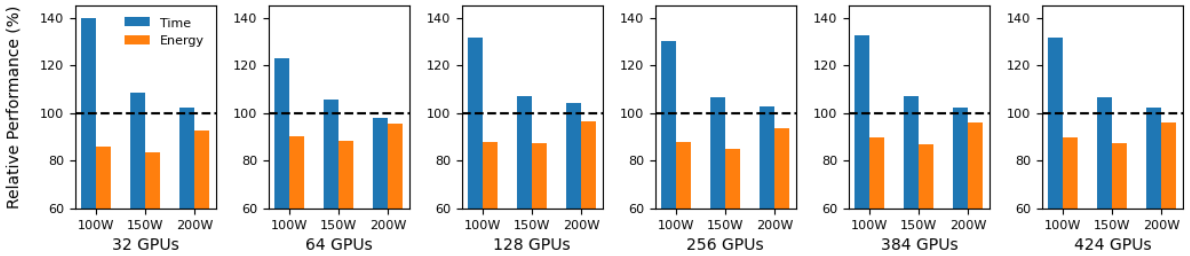

Figure 2: Time and energy required for training with varying number of GPUs at different power thresholds. Values are the percent relative to time or energy required for the default setting of 250W. Average relative time for 150W is indicated by blue line, and average relative energy consumption for 150W is indicated by orange line. For 32, 64, 128, 256, 384 and 424 GPUs, training was performed for 6, 10, 15, 25, 40, and 40 epochs respectively to ensure similar job durations. In most cases, power-capping required additional time to complete training but resulted in less overall energy consumption.

with the WikiText-103 (Merity et al., 2017) dataset for 4 epochs and batches of 8 samples per GPU. Network parameters were trained from scratch with randomly initialized values, and random number seeds fixed for consistency across runs with different power thresholds.

Figure 1 depicts training performance with power-capping at 100W, 150W and 200W. Results are plotted as a percent relative to the default limit of 250W. Our experiments indicate that implementing power caps can significantly reduce energy usage at the cost of training time.

Energy savings at larger scales: We performed a similar test training BERT with MLM on distributed configurations of varying numbers of GPUs. Energy measurements were gathered for each training run on different node configurations equipped with between 2 and 400+ GPUs and the same choices for power limits as before. Models were trained on WikiText-103 with a batch size of 8 samples per GPU.

The time and energy required for training at different power thresholds is given in Figure 2, where values are the percent relative to time or energy required for the default setting of 250W. Averaging across each choice of configuration, a 150W bound on power utilization led to an average 13.7% decrease in energy usage and 6.8% increase in training time compared to the default maximum. Note from Figure 2 that the 100W setting has significantly longer training times (31.4% longer on average). A 200W limit corresponds with almost the same training time as a 250W limit but more modest energy savings than a 150W limit. These outcomes support the use of power-capping at 150W for this GPU architectures and this application. We expect that different applications may require different settings for optimal efficiency which could be identified empirically.

Energy savings translate across hardware platforms: We performed additional experiments across several different GPUs used widely in ML research to check this method's effectiveness. This was tested on NVIDIA's K80, T4 and A100 GPUs, available through our institution's HPC resources as well as Amazon Web Services. Figure 3 presents these results. While there is not a single obvious choice for optimal settings, we confirm that the effect of power-capping is not limited to one type of hardware platform. In each of the platforms, modifying the maximum power limit affected the efficiency of the device. For A100s the effect is similar to the V100s discussed previously, if more pronounced with greater energy savings for both the 150W and 200W settings. However for T4 processors the default 70W settings perform optimally, and the effect for K80s is less clear. Many factors affect how much power is needed for efficient GPU computation, and memory intensive batch training required by language models as well as hardware specific behaviors could lead to poorer performance on these older NVIDIA architectures.

Energy savings apply to inference: Different estimates from NVIDIA and Amazon suggest that inference tasks account for 80% or more of AI computational demand (Barr, 2019; Leopold, 2019) while training new models is responsible for a much smaller fraction. Thus, methods for reducing energy on inference tasks can have a greater impact in reducing AI's carbon footprint compared to training.

We measure the effect of power-capping applied

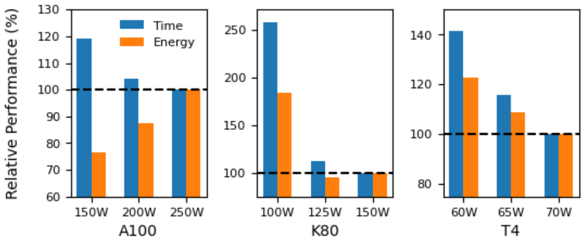

Figure 3: Performance impact of power-caps on different NVIDIA GPUs relative to default limits, 250W on A100, 150W on K80, and 70W on T4. Limiting maximum power has a significant effect on each platform. For A100s the effect is similar to the V100s we test in other cases, if more pronounced with greater energy savings for both the 150W and 200W settings. However for T4 architectures the default 70W settings perform optimally, and the effect for K80s is less clear.

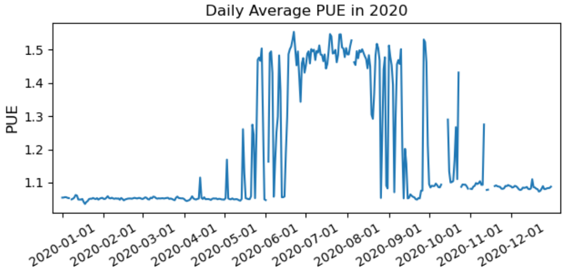

Figure 4: PUE measurements averaged for each day throughout 2020. Hotter summer temperatures correspond to more energy required for cooling compute resources and greater PUE values.

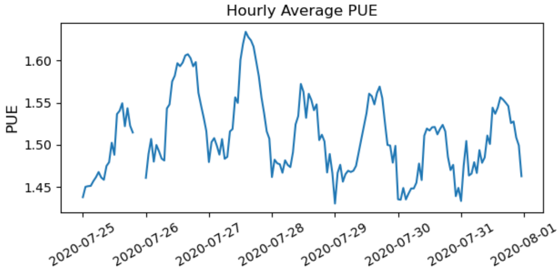

Figure 5: Average hourly variation in PUE for our datacenter over one week in July 2020. Measurements tend to peak during hot afternoon hours and decrease throughout cooler night temperatures. For example the hourly minimum on July 27 is 1.48 from 12–1 a.m. while the maximum is 1.63 between 2–3 p.m., translating to a daily variation of 10.4%.

to hardware when performing inference with a trained BERT model. This test was limited to a single node with two V100 GPUs as inference is naturally parallelizable across multiple devices. Measurements show that power-capping has a more pronounced effect for inference tasks on running time and energy usage. Compared to 250W, a 100W setting required double the inference time (a 114% increase) and consumed 11.0% less energy, 150W required 22.7% more time and saved 24.2% the energy, and 200W required 8.2% more time with 12.0% less energy. For language modeling with BERT, energy gains through power-capping are noticeably greater when performing inference than for training. If this is consistent for other AI applications, this could have significant ramifications in terms of energy consumption for large-scale or cloud computing platforms serving inference applications for research and industry.

3.2 Energy-aware Scheduling

AI and NLP researchers often rely on HPC datacenters managed by cloud computing providers or their institutions if available. The efficiency of a datacenter varies through the day as well as through the year. A common metric used across the datacenter community to measure datacenter efficiency is Power Usage Effectiveness (PUE) defined as

$$PUE = \frac{FE + IT}{IT} \tag{1}$$

where IT is the information technology energy and FE is the facility energy. Facility energy includes energy consumed by the datacenter to perform climate control and any additional energy required for operating the computing equipment. IT energy includes the energy used by computing hardware. A highly efficient datacenter will have a PUE close to 1, such that the facility energy overhead is minimal, while the global average for PUE is 1.59 (Ascierto and Lawrence, 2020). A PUE of 1.59 indicates that nearly 40% of a datacenter's energy usage is consumed by facility energy.

In Figure 4 the average daily PUE measurements from our institutional datacenter are plotted for the entirety of 2020, showing how seasonal changes in temperature can affect the energy consumption of any individual computational workload. For instance the average PUE in January is 1.05 while in July it is 1.49, a 42% difference. Evidently, heavy NLP workloads are typically much less efficient in the summer than those executed during winter. Given the large seasonal variation, if there are computationally expensive experiments that can be timed to cooler months this timing can significantly reduce the carbon footprint.

To show how resource efficiency can vary even

Month	PUE Variation (%)
January	1.30
February	0.69
March	0.77
April	2.15
May	11.51
June	21.70
July	7.76
August	17.37
September	12.41
October	8.07
November	2.88
December	1.07
Annual	7.30

Table 1: Average daily variation in PUE for each month at our institution's datacenter in 2020. A single day's PUE variation is the percent difference of the hour with the greatest average PUE and the hour with the minimum PUE average. The monthly variation is the average of this value over days in the month. The annual variation is the average over all days in the year, and not the average among the months.

over relatively short periods of time, our datacenter's average hourly PUE across the last week of July 2020 is plotted in Figure 5. Each point in the curve is the average of the several PUE measurements taken each hour, so that the swings in efficiency between daytime and night hours can be readily observed. Daytime peaks result from extra energy required for cooling while outside temperatures are high. For instance, on July 27 the PUE peaks at 2 p.m. at an average of 1.63 while ten hours later the average measurement is 1.46, a 12% difference.

We consider the variation in PUE over the course of a day, where the variation is the percent difference of the day's maximum hourly average compared to the minimum hourly average. The monthly variation is the average of this percent difference over every day of the month and is listed in Table 1. The annual variation is the average over all days in the year, not the average among the months. Daily variation of PUE is 7.3% on average – with larger daily swings in the summer months and smaller swings in the winter months.

Significant energy savings can be obtained if workloads can be scheduled at times when a lower PUE is expected. For example, moving a short-running job from daytime to nighttime may provide a roughly 10% reduction, and moving a longer, expensive job (e.g. a language model taking weeks to complete) from summer to winter may see a 33% reduction. While it is difficult to predict the savings that an individual researcher may achieve, the information presented here highlights the importance of environmental factors affecting the overall energy consumed by their workloads.

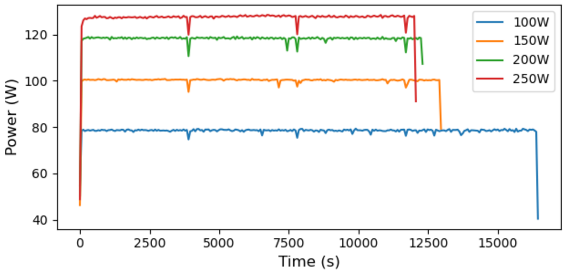

Figure 6: Examples of sampled power measurements for four identical jobs at different power-cap thresholds are presented, where points in each curve give averages over one minute intervals. Note that average power remains consistent for the duration of each job.

3.3 Relaxing Training Duration

In training different models we tracked energy consumption throughout each run and observed that the rate of energy consumption (power) is roughly constant after averaging over short intervals (one minute in this case). This is depicted in Figure 6 for four jobs with identical parameters but different power-cap limits. It can be expected that cutting training time by X percent will correspond to an X percent reduction in energy. We highlight this in consideration of common practices of significantly extending training times for marginal performance gains. For instance in (Devlin et al., 2019) doubling the number of training batches provided an additional 1% increase in performance on a particular benchmark test set. For certain applications or domains this additional training may make sense, but in cases where evaluation metrics include energy considerations, longer training for marginal performance improvements would be counterproductive and could incur significant energy expenditure.

3.4 Utilizing Efficient Datacenters

One last practice we address that can help researchers reduce their environmental impact is utilizing institutional shared datacenters and cloud computing resources for energy-intensive NLP applications. By considering this approach for applications as opposed to building and managing smaller, private HPC workstations or clusters, researchers can save money on equipment purchases and potentially energy bills depending on where resources are housed, as well as reducing the carbon footprint of their workloads. While there is convenience in having private computing resources that are accessible, this convenience comes at a cost. Generally speaking energy savings and impact is more easily obtained at larger scales. Datacenters and cloud computing providers make significant investments in the efficiency of their facilities. For instance, Google publishes data on its PUE, reaching a 12 month average of 1.10 in 2021[3], and the National Renewable Energy Laboratory sets an annual goal of running their computing facility at a PUE of less than 1.06 [4], recently achieving a record of 1.036.

Additionally, many cloud providers are moving their energy supply towards more environmentally friendly and renewable energy sources in attempts to reduce their carbon output to zero (Barr, 2015). These types of improvements would be time-consuming and difficult to make for individual researchers, but by sacrificing some conveniences, AI researchers can reap these benefits without additional effort beyond moving their projects to these platforms.

4 Discussion and Recommendations

We believe the approaches proposed here offer easy-to-implement solutions for reducing the carbon footprint of NLP applications without significant algorithmic or software changes. Though they do not involve new algorithmic methods which are outside the scope of this article, these represent early steps towards more efficient NLP. Coupling them with algorithmic changes would further improve energy consumption. The goal of this article is to initiate a conversation between NLP researchers and those in the hardware and datacenter domains. Below, we list additional recommendations that may help shape such a conversation.

Understanding your computational environment's characteristics: Previous works highlighted the carbon footprint of computationally expensive NLP applications, and their recommendations of tracking and reporting energy usage was intended to encourage researchers to be aware of their individual impact. Similarly we highlight the importance of datacenter characteristics and PUE variation to promote a deeper understanding of research energy requirements and the factors that constitute them. We hope this work leads NLP researchers to question assumptions about the datacenters where their workloads are running and what the relative efficiency of those datacenters are. For example, researchers should opt for energy-efficient datacenters and encourage their organizations to deploy or leverage energy-efficient datacenters. If possible, it would also be helpful for researchers to learn these operating characteristics of their datacenters or computing providers. Further we encourage the NLP community to work with their computing facility or datacenter to implement frameworks for tracking energy consumption like that outlined in Section 3 and other works (e.g. Henderson et al. (2020)).

Promoting better energy usage: In recent years, top conferences in AI and machine learning have introduced the requirement that papers include an ethics statement addressing the potential impact of their work on the broader society. However, one area that is currently lacking is the impact of AI on the environment. It may be difficult to account for every trial run or hyperparameter tuning when tracking and reporting estimates of energy usage. However, we hope that this practice promotes better awareness of AI energy consumption and fosters a greater focus on optimization pathways to reduce energy usage.

Alongside reporting energy consumption statistics, we make the additional recommendation that conference papers' statements discussing ethical considerations also identify steps undertaken to minimize energy consumption. We give an example of such an "energy statement" after concluding. Additionally, it is critical that energy-efficient NLP research be promoted in the research community, perhaps via specialized tracks or workshops focused on these problems.

Reducing the environmental impact: The purpose of this research is to educate NLP researchers on tools that can be used to reduce their energy usage and empower them to leverage those tools to minimize their carbon footprint. The methods discussed fit into a wider research effort to enable more efficient AI. Lastly, we also echo earlier calls for promoting more energy-conscious NLP practices and discourage overtraining or extensive hyperparameter searches. Reviews of conference sub-

[4] `https://www.nrel.gov/computational-science/measuring-efficiency-pue.html`

missions should consider whether new methodologies are effective or the result of expensive optimization.

5 Conclusions

This article presents techniques that can improve the energy efficiency of training and inference for NLP applications. Importantly, the methods discussed can be used jointly with each other to achieve a compounding effect of energy savings. Future work relevant to these topics would include a wider survey of AI hardware and power-capping capabilities. While we focused on NVIDIA GPUs, evaluation of AI hardware from other vendors and cloud providers could have a potentially large impact for cloud computing as well as large shared high performance computing centers.

Energy Statement

The experiments performed in this work consumed a total of 782 kWh. A majority of the experiments (approximately 760 kWh) were performed on our institution's high performance computing cluster, powered by largely carbon-free, hydroelectric power sources. To minimize energy consumption, much of these experiments were performed during system downtimes (e.g., when the system is undergoing scheduled maintenance and less busy) and when cooling needs are reduced.

Abstract

Referring resolution is the task of identifying the referent of a natural language expression, for example "the woman behind the other woman getting a massage". In this paper we investigate which are the kinds of referring expressions on which current transformer based models fail. Motivated by this analysis we identify the weakening of the spatial natural constraints as one of its causes and propose a model that aims to restore it. We evaluate our proposed model on different datasets for the task showing improved performance on the most challenging kinds of referring expressions. Finally we present a thorough analysis of the kinds errors that are improved by the new model and those that are not and remain future challenges for the task.

1 Introduction

In the context of vision and language modelling, *reference resolution* can be understood as the task of identifying a region in an image referred by a natural language expression. This task is also known as *referring expression comprehension* (REC). It is closely related to the visual grounding problem in the sense that in both cases the goal is to identify the parts of the image that support or "ground" a given linguistic expression into the real world. The difference lies in that the referred region in REC is expected to be unique, while there may be multiple support regions in the case of visual grounding, *e.g.* the expression "a person" might refer to multiple instances of the person class, all of which can be seen as grounding candidates for the natural language phrase. Also note that, in the case of REC, the referred region may correspond to an actual physical object (or groups of objects) or to an abstract visual element that can be perceptually grouped into a meaningful entity, *e.g.* "the patch of grass at the bottom". REC aims at identifying a specific object or region unambiguously (Mao et al., 2016; Hu et al., 2016; Qiao et al., 2020).

Although the use of natural language queries to guide localization (Bansal et al., 2018; Rahman et al., 2018) has been explored in the computer vision literature in the past, it has mainly focused on the use of rather simple expressions involving class names and intrinsic visual attributes (*e.g.* colors). Humans use more complex expressions that include spatial and order relations, relative attributes, meronimy, etc. Compared to other recognition problems, REC goes beyond simple visual-linguistic matching and requires some (primitive, implicit) form of visual-linguistic reasoning, *e.g.* an expression like "the person to the left of the tree" requires that in order to locate the target object ("the person") one has to look at its relative position ("to the left of") with respect to a different element in the scene ("the tree"). REC and visual grounding are particularly relevant to other visual-linguistic problems like visual question answering (Antol et al., 2015) and visual dialog (Das et al., 2017a; De Vries et al., 2017), where being able to link different linguistic elements (words, phrases and syntactic relations) in a sentence to actual regions in an image helps establishing a "common ground" between the agents that take part in the communication process (Mazuecos et al., 2021).

Our research question is *what kinds of errors do reference resolution models make and what can we learn from them?*. This paper makes the following contributions[1].

- We propose a method for classifying referring expressions into linguistically motivated groups that allow for a disaggregated analysis.
- We identify expressions that define an spatial relation between two or more regions of the image as the main source of errors.
- We compare two strategies for accounting for the spatial dimension that improve on the state of the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1971 - 1986
July 10-15, 2022

art for REC on different datasets.

- We perform a systematic analysis of the errors and the strengths of the best proposed model.

The paper is structured as follows. In Section 2 we discuss related work from both psycholinguistics and machine learning, Section 3 digs into the particularities of the REC and visual grounding problems and analyzes the types of errors made by current models for the REC task. In Section 4 we propose a model that takes the observed errors into account and Section 5 evaluates the new model on different datasets. Section 6 presents a meticulous analysis of the errors that are improved by the new model and those that are not and remain future challenges.

2 Related work

The automatic processing of referring expressions (REs) has been studied for a long time (Winograd, 1972). Back then their semantic representation was a logical form and REs were classified into intrinsic (*e.g.* "*the big red car*") and relational (*e.g.* "*the car by the pedestrian*") corresponding to unary and binary logical predicates, respectively (Dale and Haddock, 1991).

In the psycholinguistics community, reference were studied as a collaborative process and focused on the construction of shared knowledge (Clark and Wilkes-Gibbs, 1986; Clark, 1996) through the use of language. Hawkins (1978) proposed a theory in which an speaker 1) introduces a referent, 2) collaborates with the hearer to locate the referred object in some shared set of objects and 3) refers to the totality of objects that satisfy the RE. Viewed as a collaborative process, reference becomes a fundamental phenomena underlying all kinds of grounded dialogs (Dale and Reiter, 1995; de Vries et al., 2017).

REs are a linguistically rich constructs. Phenomena like *overspecification*, that is when an RE has more attributes than actually needed, has been shown to help identification when the redundant attribute is easy to recognize (Paraboni et al., 2017). *Vagueness* and the use of *gradable attributes* emphasize the context dependance when using REs (Quirk et al., 1980; DeVault and Stone, 2004); something called "*big*" in one scene may be seen as "*small*" in another. REs with *syntactic ambiguities* were also shown to be used in human dialogs (Chantree et al., 2005; Khan et al., 2008). Viethen and Dale (2008) showed that even with fairly simple scenes human speakers frequently use *relational descriptions* to identify objects.

In this paper we adapt the classification of referring expressions (REs) proposed in (Krahmer and van Deemter, 2012) to the domain of 2D photos of the world. Krahmer and van Deemter typification includes the types: instrinsic (that they call unary predicates), relational (that they call binary predicates), set (that refer to a group of objects), and gradable (that we described above). Intrinsic and relational REs differ in the number of objects that are involved in the description. *Intrinsic* REs only involve the referent while *relational* REs use one or more additional objects to identify the target. Referring expressions that identify *sets* use properties that are shared by the elements in the set. For example the referents of *"the white cats"* are all cats and white. In general references to set use plural definite descriptions to identify them. The datasets used in this paper are supposed to refer to a single referent and not to a set of referents so we restrict our classification in this paper to singular REs. Finally, Krahmer and van Deemter last type corresponds to gradable REs. REs referring to objects in 2D photos of the world frequently use spatial properties that are *gradable*. For example, the attribute *to the right of* is gradable in that *"the empty sky to the right of the statue"* might refer to the sky touching the statue on the right or the sky further to the right. In this paper we restrict our analysis of gradable properties to spatial properties.

We agree with Cirik et al. (2018) that careful analysis of datasets and proposed models is crucial to make progress in REC. They performed an analysis of REC models by modifying or completely removing the REs and showed that the models could exploit biases on particular datasets to achieve competitive performance. In our work we do a disaggregated performance analysis and meticulous error analysis and not only rely on automatic performance metrics.

The introduction of the transformer architecture by Vaswani et al. (2017) enabled interesting and novel ways of fusing visual and linguistic information (Tan and Bansal, 2019; Lu et al., 2019, 2020). Besides differences on the way both modalities are merged (single- vs two-branch models, cross-modal attention layer design, etc.), these models also differ on the tasks they are (pre-)trained for, ranging from masked token prediction and text-image matching (Li et al., 2020a; Sun et al., 2019) to more elaborated strategies such as label-region alignments (Li et al., 2020b; Guo et al., 2020) or scene-graph prediction (Yu et al., 2020). Most of these tasks can be seen as local (word-to-region) or global (text-to-image) matching tasks and, although effective for pre-training, they do not contemplate other phenomena such as composition and indirection that can be observed in grounding problems. Although large-scale pre-training has been shown to be effective for grounding (Kamath et al., 2021; Li and Sigal, 2021), such methods require the availability of large collections of image-text pairs with explicit alignments between image regions and phrases in text. Because of the scale of such data and the cost of extensive annotations, these approaches have not gone beyond image-text matching phenomena.

In this work, we take inspiration from a recently proposed family of transformer-based architectures that tackle the REC problem as a regression problem, *i.e.* given an image and a query expression, directly predict the bounding box coordinates of the object or image region referred by it (Deng et al., 2021; Du et al., 2021).

3 Problem definition and motivation

Given an image and a natural language expression, the goal of REC is to predict the location of the referred object or region, *e.g.* by predicting the coordinates of the bounding box that encloses it more tightly. The expression may include diverse linguistic constructs such as ellipsis, prepositional phrases, conjunctions, etc.

In what follows, we first introduce a simplified yet performant version of the model proposed by Deng et al. (2021). This model will serve as a strong baseline in our experiments because it allow us to evaluate the differences in performance between the baseline and the proposed extensions. Next, we propose a linguistically motivated classification scheme which allows for a *disaggregated analysis* that will guide the rest of the paper. Finally, we discuss some motivating results in light of our baseline and different types of expressions.

3.1 A strong baseline model

As in (Deng et al., 2021), the input to our model is an image I and a RE e. Its output are the bounding box coordinates of the referred object or region. The model consists on the following blocks: an image encoder, a language encoder, a transformer-based cross-modal encoder and a box prediction head. An outline of the architecture is shown in Fig. 1.

Image encoder. We feed the image to a pre-trained convolutional backbone. We use a ResNet-50 (He et al., 2016) pre-trained on ImageNet with the classification head removed. The output of this network is a feature map of size $H \times W$ and d channels, that we further project to D dimensions using 1×1 convolutions. Different from Deng et al. (2021), we do not add any additional transformer layer on top of the convolutional encoder. We flatten the resulting tensor along the spatial dimension and obtain a sequence of HW visual embeddings of dimensionality D.

Language encoder. We first map e into a sequence of T tokens and encode it using a pre-trained language model. We use a pre-trained BERT (Devlin et al., 2019) as the default encoder. The output sequence of (sub-) word embeddings is projected onto D dimensions using a fully-connected layer.

Cross-modal encoder. We concatenate both visual and language embeddings into a multimodal sequence and feed it to a cross-modal encoder consisting of a transformer architecture with L layers. Each layer in the encoder corresponds to a multi-head self-attention layer with skip connections (Vaswani et al., 2017). As in (Deng et al., 2021), we add learnable position embeddings to the input of each transformer encoder layer. The output of the cross-modal encoder is a sequence of embeddings of the same length as the input and whose elements can be seen as a re-encoding of the corresponding input embeddings. This re-encoding mechanism is based on the “similarity” between other elements of the same sequence (visual and/or linguistic) as induced by the multi-head self-attention layers within the cross-modal encoder.

Prediction head. The box prediction head is a single fully connected layer followed by a sigmoid. The output of this head corresponds to the normalized coordinates of the target bounding box. Instead of adding a specialized output token as in (Deng et al., 2021), we take as input the average of the first HW embeddings after the cross-modal encoder, *i.e.* those corresponding to the visual block. Given a training set of image-expression-box tu-

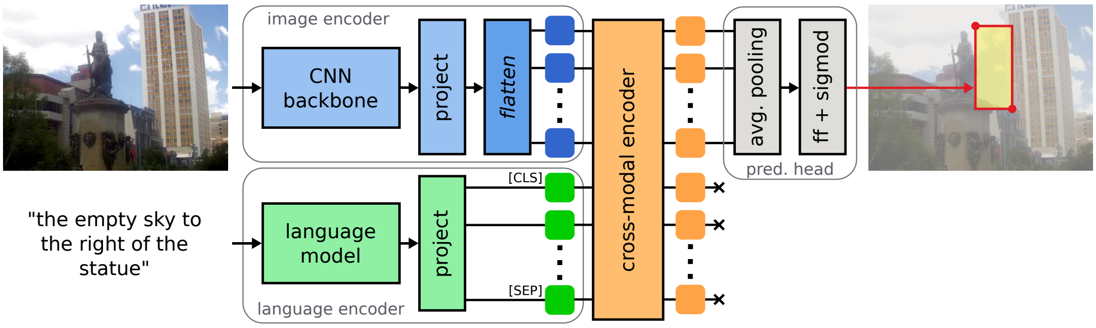

Figure 1: Our baseline model for referring expression comprehension showing its main processing blocks: image and language encoders (in blue and green respectively), cross-modal fusion (in orange) and box prediction head (in gray). The input is an image and a referring expression and the output is a bounding box.

ples $\mathcal{D} = \{(I_n, e_n, b_n), i = 1, ..., N\}$, we adopt a loss formulation based on a combination of the generalized IoU of Rezatofighi et al. (2019) and the soft L_1 loss as in Deng et al. (2021).

3.2 Types of referring expressions and errors

One of the challenges posed by the REC problem is that natural language expressions exhibit different degrees of grounding complexity. In order to better understand the limitations of current models, and motivated by previous work described in Section 2, we propose to classify them into a non-disjoint set of types as follows.

- *Spatial.* Expressions that include spatial language *e.g*. "the doorway on the far right". They include prepositions that signals a spatial relation (*e.g*. behind) or adjectives (*e.g*. left) and nouns (*e.g*. foreground) that give spatial cues.[2]
- *Ordinal.* Expressions that include ordinal adjectives that determine the position of an object inside a group, *e.g*. "2nd set of jewels".
- *Relational.* Expressions that use another object, which is related to the referent, in the RE; *e.g*. "the instrument right behind the guy with yellow hat". Relational expressions are spatial when the relation is spatial.[3]
- *Intrinsic*: Expressions that do not fall into any of the above types. They do not use the position of the object to describe it, instead they use only properties that are intrinsic to the referent no matter its position; *e.g*. "the tall metal fence".

Type	**# test**	**expr len**	**acc**
All	65193	3.5 (2.6)	66.76
Intrinsic	22779	1.5 (1.0)	81.81
Spatial	42277	4.6 (2.6)	58.73
Ordinal	1173	5.9 (2.8)	28.47
Relational	13154	6.7 (3.0)	44.59

Table 1: Accuracy disaggregated by expression type for the RefItGame dataset. The expr len column shows the average expression length and its standard deviation (between parentheses). The last column of the table shows the accuracy for the baseline model on the ReferItGame test set. An RE may fall in more than one type, in that case it is counted in all the types.

Table 1 shows the frequency and lengths of the different types of REs in the ReferItGame (Kazemzadeh et al., 2014) dataset as well as the performance of the baseline model introduced in Sec. 3.1. The performance reported is the accuracy of the predicted bounding box. It is considered that the bounding box is correct if it overlaps with more than 50% of the ground truth one. The table shows that the accuracy on the spatial class is considerably lower than the accuracy for the intrinsic class although spatial expressions are more frequent. The accuracy is even lower for the relational and ordinal expressions. After performing this disaggregated analysis our intuition is that the position embeddings used in the state of the art models are not enough for capturing the spatial and relational information required to handle this type of expressions.

The Fig. 2 shows the cardinality of the intersections of the types as a matrix. Each row at the bottom corresponds to a type. Each column corresponds to a non empty set, and the bars at the top

---

[2] A complete list of spatial words used in this paper is in Appendix A.

[3] We say an expression is relational if it contains a preposition with one or more nouns to the left and to the right.

show the size of the respective intersections. The filled dots show which type is part of an intersection. The first four columns represent those REs that fall in only one type. The last three columns show combinations of types.

The intrinsic type is disjoint from all others by definition. Almost all ordinal REs are also spatial or relational. There are very few relational REs that are not spatial (an example of such rare RE is *"the girl sleeping with the teddy bear"*). Most relational REs use an spatial preposition in the the ReferItGame dataset.

4 Restoring referential spatiality

The types of expressions that have the worst accuracy, relational and ordinal, can be associated to limitations of the model in capturing richer spatial relations that go beyond simple matching (names to image and absolute locations to image). In what follows, we propose two generic strategies to inject stronger visual priors into the model after the cross-modal fusion block. In Fig. 3 we illustrate how we reformulate the prediction head of the original model in Fig. 1. We describe the modified architecture below.

First, due to the one-to-one alignment of the embedding sequence at the input and output of the transformer, we can identify the first block of HW elements as a re-encoding of the original visual embeddings, modulated by the input expression e. We can rearrange this block as a tensor of size $H \times W \times D$ so as to restore the spatial structure lost after the flattening operation. This operation is represented as the unflatten block in Fig. 3.

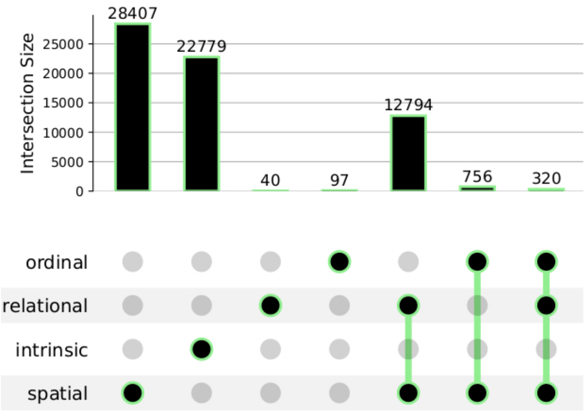

Figure 2: The RE types proposed in this paper are not disjoint. Their distribution and intersections on the ReferItGame dataset are shown in the columns. The first four columns correspond to REs that belong to only one type.

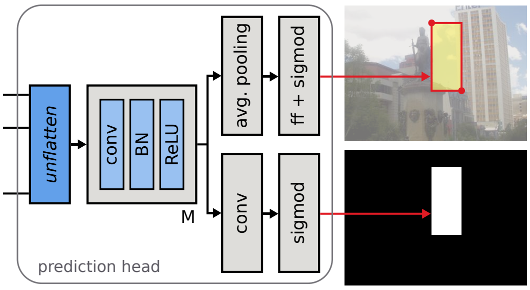

Figure 3: Prediction head for the extended model. This new prediction head replaces the one from Fig. 1 with an "unflatten" operation and a block of convolutions followed by the regression and segmentation heads. The regression head outputs a bounding box (in yellow) while the segmentation head outputs a mask (in black and white).

We next add a small convolutional network with M layers (convolution layer with a 3×3 kernel and stride of 1, batch normalization and a ReLU nonlinearity), on top of which we attach two different heads: a target regression head as before and a box segmentation head, as shown in Fig. 3.

The box regression head is the same as the base model but applied to the average pooled features after the convolutional block, while the additional segmentation head consists of a simple convolutional layer whose output is normalized to the interval $[0, 1]$ by a sigmoid activation. The goal of this head is to provide a spatial consistency constraint while avoiding the need of requiring additional data. Supervisory signal for this branch is obtained trivially from the existing annotations, *i.e.* by creating a binary mask from the bounding box coordinates of the target. Learning is formulated by adding an auxiliary pixel-wise binary classification term to the main loss.

The intuition behind adding M convolutional blocks after the cross-modal transformer as well as the mask prediction head is to ensure that the spatial consistency of the representation that has been broken is restored. The locality and hierarchical nature of the (stacked) convolutions as well as the complementarity of the segmentation and regression heads proves to be an effective approach to improve the accuracy of some kinds of spatial expressions as we will see in the next two sections.

5 Experiments

In the following we describe the datasets and experimental setup we use in our experiments. A detailed description can be found in Appendix C.

5.1 Datasets

We conduct experiments on four different datasets.

ReferItGame. We use this dataset as a set for validation and error analysis. ReferItGame (Kazemzadeh et al., 2014) was collected based on a two-player game where one of the players has to write a RE based on a given object while the second player has to guess its identity by looking only at the image and the generated expression. If guessed correctly, both players receive a game point and swap their roles for the next image.

Images in this dataset are from the IAPR TC-12 corpus (Escalante et al., 2010). The dataset consists of 130121 expressions referring to 96654 different objects across 19894 images. We use a cleaned version of the dataset provided by Hu et al. (2016) and standard splits, *i.e.* 54127, 5842 and 60103 expressions for training, validation and testing, respectively.

RefCOCO and RefCOCO+. These datasets (Nagaraja et al., 2016) were collected by following the same procedure as in ReferItGame, but using images from MS COCO (Lin et al., 2014). RefCOCO contains 50000 referred objects in 19994 images. Each object is referred by an average of three expressions, for a total of 142210 REs split across 120624 expressions for training, 10834 for validation and two additional splits (testA and testB) with 5657 and 5095 expressions for testing, respectively. The testA split contains multiple people while the testB split contain multiple instances of all other objects.

RefCOCOg. RefCOCOg (Mao et al., 2016) was collected non-interactively using Amazon Mechanical Turk. This dataset contains 104560 expressions for 54822 objects in 26711 images. Compared with RefCOCO and RefCOCO+, expressions in the RefCOCOg dataset are considerably longer (an average of 8.43 vs. 3.61 and 3.53 words, respectively). We use the split proposed by (Nagaraja et al., 2016) for meaningful comparisons with other methods.

We report REC performance using average accuracy. We consider a region prediction as correct if it has an overlap (as measured by the IoU metric) of at least 0.5 with the ground truth box.

	SH	**M=0**	**2**	**4**	**8**
All	✗	71.66	72.64	73.00	73.46
	✓	71.89	73.03	73.16	73.61
Intrinsic	✗	84.76	84.63	84.93	84.10
	✓	83.79	84.93	84.14	84.27
Spatial	✗	64.28	65.91	66.53	67.36
	✓	65.18	66.27	66.74	67.73
Ordinal	✗	34.44	42.22	42.22	46.67
	✓	36.67	45.56	41.11	45.56
Relational	✗	51.29	51.70	52.70	53.57
	✓	51.74	52.99	52.99	54.11

Table 2: REC performance on the validation set of the ReferItGame datset for different expression types and model configurations. M denotes the number of convolutional blocks while “SH” denotes whether we use the segmentation head or not. M = 0, SH = ✗ corresponds to the baseline model outlined in Sec. 3.1.

5.2 Architecture selection

In this section we evaluate the impact on performance of the changes proposed in Sec. 4 for the different types of REs discussed in Sec. 3.2. For these experiments, we set the maximum number of epochs to $E = 60$. Table 2 shows comprehension performance on the validation set of the ReferItGame dataset for different model configurations and expression types. M denotes the number of convolutional blocks and “SH” denotes whether we use the segmentation head or not. In this case, M = 0 and no segmentation head (SH=✗) corresponds to the baseline model outlined in Sec. 3.1. First, consider the case $M = 0$, *i.e.* no convolutional blocks after the cross-modal encoder. From the table, we see that adding a segmentation head improves performance overall, specially for the expressions that involve some degree of spatial reasoning. For the *intrinsic* type, improvement is marginal as the model is already able to solve the region-(class)target alignment problem. For more complex expressions, adding a segmentation head constraints the model to focus on the target location (and scale) and helps disambiguate references to objects/regions from its context. If we now consider $M > 1$, we observe the following. First, performance improves for all expression types, specially for *ordinal* and *relational* w.r.t. the model with $M = 0$. Second, for $M > 1$, adding a segmentation head seems to have no impact on performance. This can be attributed to a greater flexibility of the stack of convolutions in capturing spatial and relational information.

5.3 Comparison with the state-of-the-art

Next, we compare the performance of our models against four different methods proposed recently in the literature, namely: LBYL-Net (Huang et al., 2021), VGTR (Du et al., 2021), TransVG (Deng et al., 2021) and the Referring Transformer (Ref. Tr.) (Li and Sigal, 2021). LBYL-Net is a one-stage grounding model based on modeling spatial relations between the referent and its context via a suitable convolution operator. VGTR is a transformer-based one-stage model following an encoder-decoder design and custom grounding modules. TransVG is similar to our baseline model with an additional transformer after the visual backbone and a specific output embedding that feeds the prediction head. Finally, the referring transformer model follows a similar design as DETR (Carion et al., 2020) while tackling simultaneously the RE comprehension and segmentation problems. We show performance for each model and relative improvement of the extended model with respect to the baseline in Table 3. All these models rely on a ResNet-101 as visual backbone, except LBYL which uses darknet-53.

In this paper, we presented two different models: a baseline described in Sec. 3 and a extended model that incorporates $M = 8$ convolutional layers and the segmentation head explained in Sec. 4. **We use a ResNet-50 as visual backbone and the same set of hyper-parameters and training procedure as before, explicitly avoiding dataset specific finetunings**. We disaggregate the performance according to the different types of expressions for both the baseline and the extended model.

First, we see that our baseline model is a strong baseline for REC. If we compare average performance (rows “All” in Table 3), we see that our baseline model performs comparably to the best performant methods in the first group. It shows the second best performance on both RefCOCO testA and testB subsets, second and third best performace in RefCOCO+ testA and testB, respectively; and achieves top performance on the RefCOCOg test set. If we consider the extended model, we observe a consistent overall improvement on all datasets. Although our goal is *not* to get the best possible performance but to highlight the importance of the different expression types when evaluating RE models, results in the table show that our design is on pair with the state of the art. This is important since both our models follow a simple design and rely on the same training protocol, which is compared to the more complex backbones and per-dataset tuning of hyperparameters of the methods in the first group.

If we compare disaggregated performance for the baseline and extended models, we observe the following. From Table 3, performance improves on all subsets and expression types, with the only exception of the *intrinsic* and *ordinal* types in the *testA* and *testB* subsets of RefCOCO and RefCOCO+ datasets, respectively. For RefCOCO, this accounts for a -0.2% decrease on performace w.r.t. to the baseline. For RefCOCO+, the difference is greater (-15% w.r.t. to the baseline). Note however that for this dataset, the number of *ordinal* expressions is 34, 4 and 32 for the *val*, *testA* and *testB* subsets. The observed decrease corresponds to a difference of only 2 examples.

In general, we observe a greater improvement for expressions that involve spatial (spatial and relational) and grouping (ordinal).

A detailed summary of these results, including performance on the validation sets and sample cardinalities for all subsets and expression types can be found in Appendix D.

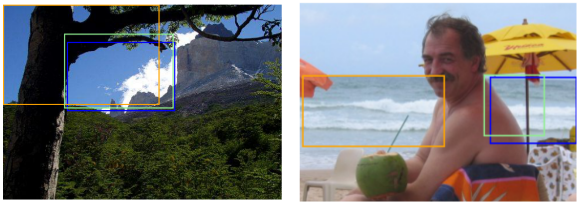
6 Error Analysis

In this section we analyze the predicted output of the extended and baseline models for the image-expression pairs of the ReferItGame validation set. The figures in this section show the extended model prediction in green and the baseline model prediction in orange. The comparative error analysis goal is to shed light over the kinds of linguistic and visual phenomena that the models are able to handle and those they are not. The analysis was divided into two parts and was carried out on a total of 351 examples. First, we explored referring expressions where the green model correctly predicted the ground truth and improved over the baseline depicted in orange. Two such examples are in Fig. 4. Second, we analysed cases where both models failed, exemplified in Fig. 5. More examples are shown in in Appendix B.

We identified different abilities a model should have in order correctly solve a broader set of expressions. They are listed below. Fig. 4 and Fig. 5 illustrate each of the skills.

Model	**Type**	**RefCOCO**		**RefCOCO+**		**RefCOCOg**
		testA	*testB*	*testA*	*testB*	*test*
LBYL	All	82.91	74.15	73.38	59.49	-
VGTR	All	82.32	73.78	70.09	56.61	67.23
TransVG	All	82.72	78.35	70.70	56.94	67.73
Ref. Tr	All	85.59	76.57	75.96	62.16	69.40
Baseline	All	84.85	74.72	75.95	59.36	69.40
(M=0, SH=✗)	Intrinsic	84.11	71.24	80.33	65.85	73.92
	Spatial	85.22	75.42	70.55	53.32	68.44
	Ordinal	75.91	48.67	50.00	40.62	46.25
	Relational	77.03	57.39	67.11	48.02	67.87
Extended	All	86.00 (+1.4%)	77.96 (+4.3%)	77.09 (+1.5%)	61.16 (+3.0%)	71.31 (+2.8%)
(M=8, SH=✓)	Intrinsic	83.94 (-0.2%)	72.32 (+1.5%)	81.18 (+1.1%)	68.25 (+3.6%)	75.25 (+1.8%)
	Spatial	86.96 (+2.0%)	79.06 (+4.8%)	72.14 (+2.3%)	54.62 (+2.4%)	70.51 (+3.0%)
	Ordinal	85.40 (+12.5%)	56.33 (+15.7%)	50.00 (+0.0%)	34.38 (-15.4%)	48.75 (+5.4%)
	Relational	79.56 (+3.3%)	60.22 (+4.9%)	68.50 (+2.1%)	49.80 (+3.7%)	70.09 (+3.3%)

Table 3: Comparison with other methods from the literature on the RefCOCO, RefCOCO+ and RefCOCOg datasets. For the baseline and the extended model, we consider performance for different expression types. Relative improvement percentage of the extended model with respect to the baseline are shown in parentheses.



(a) Sky near clouds (b) Water near man's back

Figure 4: Examples where our proposed model (green) improves over the baseline (orange). The ground truth is shown as a blue box. The first example is classified as *fuzzy objects*. The second as *meronimy*.

(a) The empty *ski* to the right of the statue (b) Grass directly above and behind little boy on bike

Figure 5: Examples that remain a challenge for both models (ours in green, baseline in orange, ground truth in blue). The first example is classified as *fuzzy objects*, *typo* and *directional*. The second is classified as *fuzzy objects*, *viewpoint*, and *implicit*.

- *Meronimy*: Reference parts of objects, such as peoples' clothes, parts of the body (*e.g.* *"the man's back"*) or parts of inanimate objects.
- *Viewpoint*: In order to resolve the reference, the hearer needs to assume the point of view of an object such as "*behind the little boy*".
- *Directional*: the expressions contains the direction in which we can find the referent relative to the location of the landmark, *e.g.* "*to the right of the statue*".
- *Fuzzy objects*: Reference to regions of objects without prototypical shapes and borders, like "*ground*", "*water*" or "*sky*".
- *Occlusion*: Reference to an object that is only partly visible because it is hidden by another object or does not fit completely in the image.
- *Typo*: the expression contains a typo that can confuse the understanding of the referring expression (e.g. "*ski*" instead of "*sky*").
- *Implicit*: the RE contains an ellipsis such as "*grass directly above*" meaning "*grass directly above the path*".

The first three types of errors require the RE to be relational. Meronimic errors require a relation between an object and a part of it. Viewpoint errors occur in REs that are not only relational, but also spatial in general. They use a landmark, related to the referent, to change the point of view of the interpreter. Directional errors can occur when the direction of the relation in the RE is misinterpreted. Frequently this relation is spatial but not necessarily, it could correspond to an order established by other property, such as size (e.g. "*from the smallest to the biggest*). The last four types of errors may happen for all kinds of REs. Although implicit errors are more frequent in long REs such as relational REs.

6.1 Errors that are improved

During our analysis we identified that most of the cases in which the green model improves over the orange one contain *meronimy*, *fuzzy objects* or both. Fig. 4a is an example of *fuzzy object* because the sky is a kind of object that does not have a prototypical shape and borders (such as a person) and whose parts can be spread in different areas of the image. Our model is not only able to select a region near the clouds but it is also able to constrain its prediction using the natural boundary that is the tree on the left. The model is able to reconstruct the relative spatial position of the different parts of the sky.

Fig. 4b shows an example of *meronimy*. The "*man's back*" refers to a part of the man. Correctly predicting the referred region in this expression requires both identifying the back of the man (not the whole man) and the appropriate region of water (another instance of *fuzzy objects*). As the water and the sky, the man's back does not have a clear border wrt the rest of his body.

6.2 Errors that remain a challenge.

We analyzed 220 examples in which both models failed. The first observation that we found is that over 66% of the errors require more than one skill. This is only 38% for the 131 examples we annotated where the green model improves over the orange. Fig. 5 illustrates cases that require multiple skills, Fig. 5a not only has a typo (*ski* should be *sky*) but it also includes a directional relation (*to the right*). We can see how a tiny error in a character of the word *sky*, confuses the models and both predict the section of fences located below in the image, probably because they look like a set of '*ski*'s. Fig. 5b not only has fuzzy objects because of the grass but it also requires the interpretation of the viewpoint and implicit language for resolution. In order to identify the referent, the interpreter needs to take the viewpoint of the boy in the picture to correctly interpret the relation *behind* as referring to the blue box. The interpreter also needs to realize that the relation *above* implicitly means *above the bike path*.

Our second finding is that some kinds of meronimy remain a challenge and constitute 12% of the examples we annotated. We find that the most challenging meronimic relations are those that are not frequent in the training data (*e.g.* "*the eyebrows of the person*"). Similarly, some directional relations (that amount to 17% of the errors) are more challenging than others: those relations that are normally in the z-axis (*e.g.* "*behind*") lead to more errors that those in the y-axis (*e.g.* "*above*"). A complete distribution of the annotations can be found in Appendix B. Summing up, there is a lot of room for improving the grounding skills of REC models. We have identified that the main challenges present in the ReferItGame dataset are those that we defined as rare meronimic relations, viewpoint, directional, occlusion, implicit language and typos.

7 Discussion and conclusions

In this work we studied the kinds of errors that reference resolution models make. In particular, relational expressions caused a lot of errors in REC and that motivated the proposal of a model that improves over the previous SOTA for the task by restoring the referential spaciality. We used a new training objective which is segmentation prediction and added convolutional layers to a transformer.

Looking at accuracy only can obscure and hide common errors these model might have. We performed an error analysis and identified which skills the model would need in order to perform correctly. We found that our proposed model improves in dealing with fuzzy objects and meronimy, but still finds it difficult with other skills. By performing this error analysis we learnt there is yet a lot of work to do in making models consider viewpoint or being able to deal with implicit information (conveyed by the common visual context).

Our findings can help have a finer grained look at the predictions of models. This can be relevant for different areas of NLP like grounding, situated dialog systems and human-computer interaction as referring is a crucial skill in communication.

8 Ethical considerations

REC models predict bounding boxes instead of segmentation masks. Bounding boxes can include a lot of background information for some kinds of objects (imagine a broom at a 45 degrees angle). Such segmentation masks ground truths are expensive to annotate.

As in previous work, we count a prediction as correct if its IoU with the ground truth is above 50%. This binarization can obscure the quantitative analysis in border cases (49% vs 51% IoU).

Regarding datasets, we did not collect the datasets but used available ones for the task. Crowdsourcing raises ethical concerns including fair wage for crowdworkers, work load and exhaustion. In our qualitative analysis we could find examples of exhaustion in the linguistic production of crowdworkers.

Previous work, coming from the field of collaborative reference resolution, state that one of the "desired" applications was helping with surveillance systems (Li et al., 2017; Das et al., 2017b). We do not agree with this use of the technology. Despite every work in referring expressions inevitably helping towards that goal it would need retraining with specific domain data for that. Our proposed model and formulation is not aimed at surveillance nor the datasets used and should perform poorly in such setting.

We are reporting results over 30 experiments in total. Each experiment was running for 2.5 days on a single 1080ti GPU. We estimate $6.48 kg CO_2 eq.$ for each experiment according to local emissions factor. Debugging, code refactoring and validation runs took around a couple of hundred additional runs.

Acknowledgment

We thank all anonymous reviewers and area chair for their insightful comments and suggestions. This work used computational resources from CCAD-UNC, which is part of SNCAD-MinCyT, Argentina.

A Spatial prepositions and keywords

For the spatial prepositions, we rely on the Pattern Dictionary of English Prepositions (PDEP) (Litkowski, 2014), a publicly available lexical resource collected as a part of The Preposition Project (TPP). There are 78 prepositions in the *spatial* class. We removed prepositions with less than 10 samples, archaic and/or literary (*e.g.* 'pon, betwixt) and those used in a more technical context (*e.g.* aslant). The final list of prepositions and spatial keywords is as follows:

- Prepositions: *aboard, about, above, across, after, against, ahead of, all over, along, alongside, amid, among, around, as far as, at, atop, before, behind, below, beneath, beside, besides, between, beyond, by, by way of, down, for, from, in, in front of, in line with, in sight of, in the midst of, inside, inside of, into, near, near to, neath, of, off, on, on a level with, on top of, onto, opposite, out of, outboard of, outside, outside of, outwith, over, over against, past, round about, short of, this side of, through, throughout, to, toward, towards, under, underneath, unto, up, up against, up* *and down, up before, up to, upon, with, within, within sight of.*

- Keywords: *background, back, bottom, center, corner, close, edge, end, entire, facing, far, farthest, floor, foreground, front, furthest, frontmost, ground, hidden, leftmost, left, middle, nearest, part, rightmost, right, row, side, top, upper*.

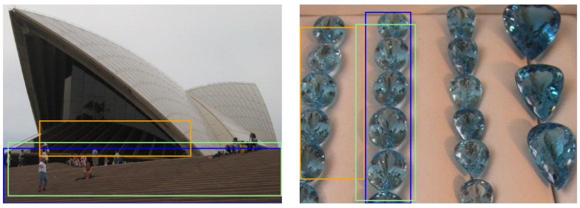
B More error analysis

Here we present more examples from the analysis to further explain the type of error these models perform and the skills they need to improve.

B.1 Errors that are improved

As mentioned in Sec. 6, the cases where the green model is better than the orange baseline, mostly occur when meronimy skills, fuzzy objects, or both are present. In Fig. 6a, we see how the green model, correctly predicts the set of steps under the opera house although this referent does not have clear borders.

In the Fig. 6b, the baseline orange model shows an error when dealing with ordinal referring expressions.



(a) Steps to the opera house.
(b) 2nd set of jewels.

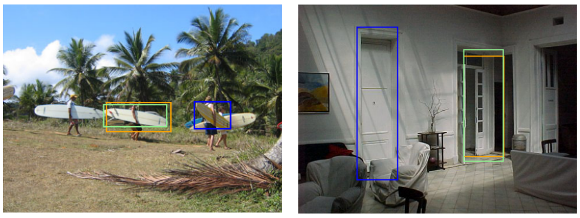
Figure 6: Errors that are improved.

The barplot in Fig. 9, shows the distribution of skill combinations found during the error analysis described in Section 6. The vertical axis details, in decreasing order, the combinations of skills that had the greatest impact in relation to the improvements observed in the green model over the baseline model. The x-axis expresses the frequency of occurrences of each of the combinations assigned to each example, in relation to the total of samples annotated.

B.2 Errors that remain a challenge

The images presented in Fig. 7, show two examples that still represent a challenge for the models.

Fig. 7b shows a frequent error found during the analysis. In this case, we observe that the models detect objects further to the right than the actual referent. One possible hypothesis is that the models are not able to understand the implicit proximity that the speaker is trying to communicate. When an expression of the form “X is to the right of Y” is given, a speaker implies that he is speaking of the closest object “to the right” of the landmark.



(a) The surfboard of the blond surfboarder, the one walking towards the line.
(b) Door closest to right of painting.

Figure 7: Error that remain a challenge.

Interpreting Fig. 7a involves identifying the imaginary line formed by the three surfers, recognizing the blond one, and inferring the direction of his walk, which is referenced by the directional preposition ‘towards’.

In a similar way as shown in Fig. 9, the barplot in Fig. 10 describes the distribution of the 15 most frequent skills combinations that made both models fail.

B.3 Errors that are not real errors

Fig. 8 shows how some predictions delivered by the models, despite not coinciding with the ground truth (depicted in blue), can in fact be correct.

In particular, Fig. 8a presents an ambiguous RE. Both the ground truth and the prediction by the green model are possible interpretations. The model identifies the face of the woman that is to the left and outside the group of the three women, which is a valid interpretation given the ambiguity of the input referential expression.

For Fig. 8b, the scenario is totally different. Here

(a) Face of woman, on the left of the group of 3.
(b) Donald duck above girl’s head.

Figure 8: Error that are not real errors.

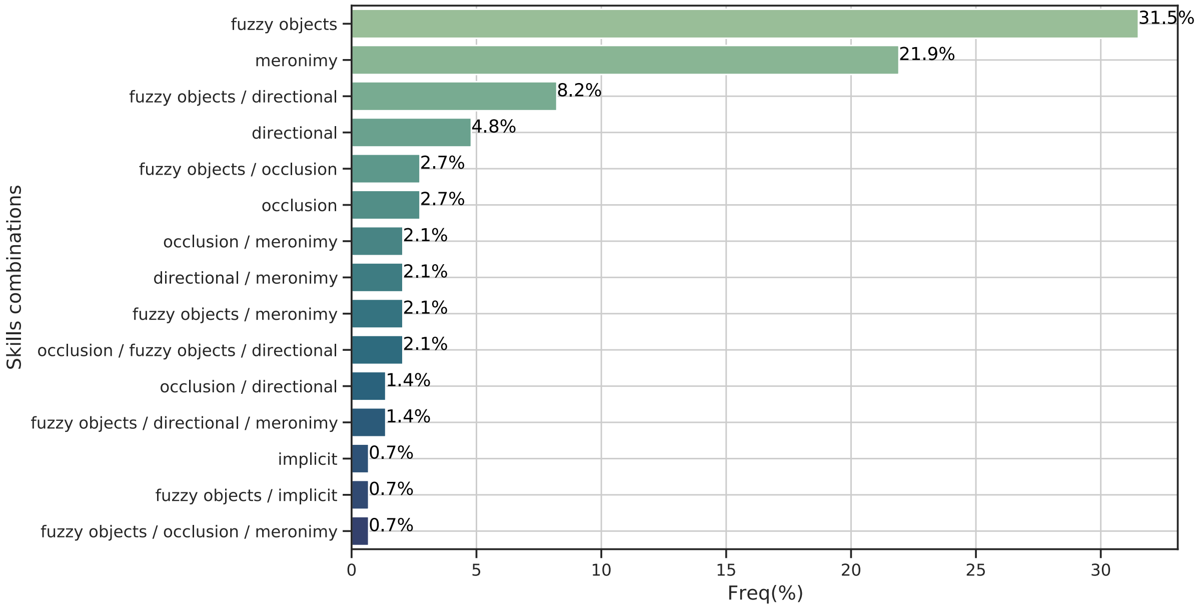


Figure 9: Distribution of the 15 most frequent skills combinations where the extended model improves over the baseline model.

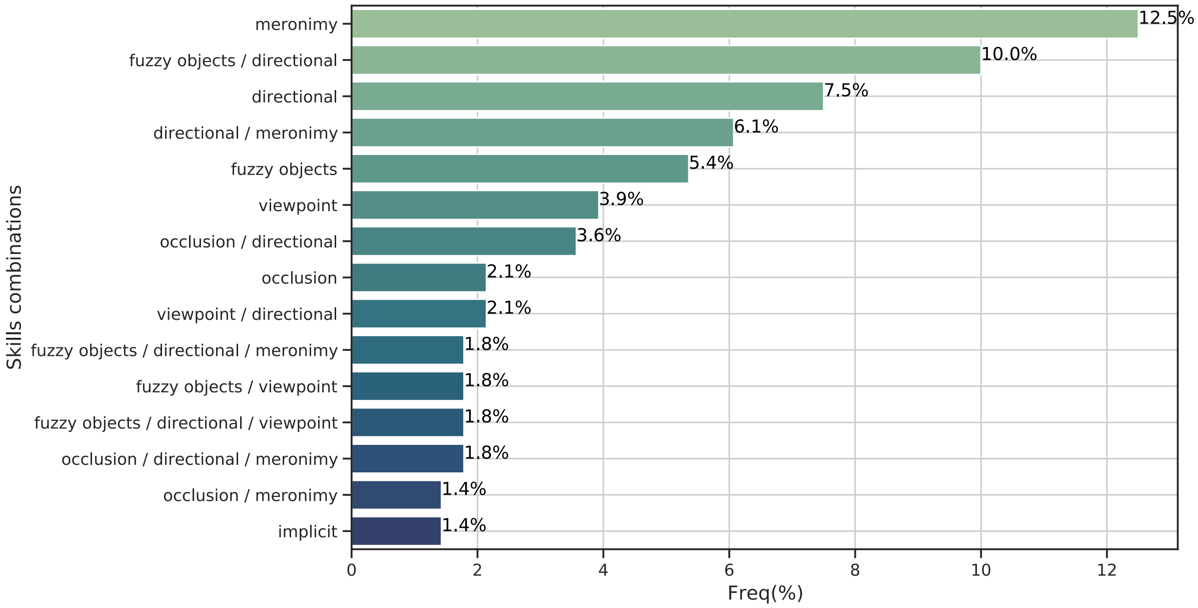

Figure 10: Distribution of the 15 most frequent skill combinations where both the extended and the baseline model fail.

the error is more related to the way in which we consider a prediction to be correct, than to a mistake made by the model. Strictly speaking, it is due to the fact that the predicted area is much smaller than that indicated as ground truth, giving an IoU $<< 50\%$; note that this decision method is mentioned as one of the limitations found in Sec. 8. The model ends up adjusting the *Donald duck* sticker more tightly than what is annotated as ground truth.

In order for our results to be comparable to previous work we did not modify the ground truth boxes.

C Detailed experimental setup

Images are first normalized by the mean and standard deviation of rgb values pre-computed on the ImageNet training set. We resize the images to 512×512 pixels while keeping the original aspect ratio by fixing the longest side to 512 and zero-padding the shortest side accordingly.

For the visual encoder we use the pre-trained ResNet-50 (He et al., 2016) model available at the `torchvision` package from the PyTorch library (Paszke et al., 2019). This model has been trained for a 1000-way classification task on the ImageNet 2012 dataset (Russakovsky et al., 2015). We replace the output classification layer by a convolutional + normalization layer with $D = 256$ output channels. In this case, given an input image of 512×512 pixels, we obtain an output tensor of size $16 \times 16 \times 256$. We freeze the first convolutional layer of the network as well as the batch normalization layers. We apply random affine transformations (rotation, translation and scale) as the *only* augmentation strategy during training.

For the language encoder we use the *bert-base-uncased* pre-trained BERT (Devlin et al., 2019) model from the HuggingFace's Transformers library (Wolf et al., 2020). As with the visual encoder, we add a projection and normalization layer to project the embeddings output by the model to $D = 256$ dimensions. We set a maximum expression length to 32 input tokens.

Our loss function takes the form:

$$\mathcal{L}_{\text{Soft-}L_1} + \gamma\mathcal{L}_{\text{GIoU}} + \mu\mathcal{L}_{\text{segm}}$$

where the first and second terms act on the output cast by the box regression head while the third on the mask predicted by the segmentation head. We use $\gamma = 0.1$ in all our experiments. We set $\mu = 0$ for the baseline model and $\mu = 0.1$ for the extended one.

We train our models for a maximum of $E = 90$ epochs using the AdamW (Loshchilov and Hutter, 2018) optimizer with a multi-step decay schedule by a factor of 0.1 at the $\lfloor 0.6E \rfloor$ and $\lfloor 0.9E \rfloor$ epochs. Learning rate is set to 1×10^{-4} for the whole model except for the visual and language backbones (ResNet and BERT) for which we use 1×10^{-5}. Final models are chosen based on validation accuracy.

Abstract

Large-scale multilingual pre-trained language models have achieved remarkable performance in zero-shot cross-lingual tasks. A recent study has demonstrated the effectiveness of self-learning-based approach on cross-lingual transfer, where only unlabeled data of target languages are required, without any efforts to annotate gold labels for target languages. However, it suffers from noisy training due to the incorrectly pseudo-labeled samples. In this work, we propose an uncertainty-aware **C**ross-**L**ingual **T**ransfer framework with Pseudo-**P**artial-Label (CLTP)[1] to maximize the utilization of unlabeled data by reducing the noise introduced in the training phase. To estimate pseudo-partial-label for each unlabeled data, we propose a novel estimation method, considering both prediction confidence and the limitation to the number of similar labels. Extensive experiments are conducted on two cross-lingual tasks, including Named Entity Recognition (NER) and Natural Language Inference (NLI) across 40 languages, which shows our method can outperform the baselines on both high-resource and low-resource languages, such as 6.9 on Kazakh (kk) and 5.2 Marathi (mr) for NER.

1 Introduction

The multilingual pre-trained language models such as mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020) and mT5 (Xue et al., 2021) are able to support zero-shot transfer from a source language to target languages. Despite the remarkable performance on direct zero-shot cross-lingual transfer tasks, one would apply semi-supervised learning on target languages to obtain more robust and accurate predictions in a practical scenario. Recent studies (Dong and de Melo, 2019; Xu et al., 2021) validate the effectiveness of self-learning in cross-lingual transfer tasks, utilizing predictions of unlabeled data of target languages as silver labels. Dong and de Melo (2019) iteratively grow the training set by selecting top-k percent of unlabeled data and Xu et al. (2021) boost the performance by considering prediction confidence in the pseudo-label selection. Although their self-learning frameworks significantly improve the transferring performance, it still lags far behind supervised learning. The main reason is that the model suffers from the large number of incorrectly pseudo-labeled samples used in the training phase. Even though they adopt the selection mechanism where those easy and high-confidence predictions will be firstly added into the training set, it cannot guarantee the accurate prediction for all unlabeled data. In fact, the accuracy of the predictions drops quickly in the later iterations (see A.1), since most of the remaining unlabeled data are more difficult to be classified. To avoid the false positive pseudo labels, the most naive way is to select pseudo-labels with extremely high confidence. However, in this way, a large amount of unlabeled data will be discarded due to strictly high

	Confidence	Pseudo-Label	Ground-Truth
Standard	low	(0,0,1,0,0)	x
Partial-Label	high	(0,1,1,0,0)	√

Figure 1: For an unlabeled sample with ambiguous predictions, the standard one-hot-labeling takes the class with the highest confidence as the pseudo-one-hot-label, introducing the noise in the training phase due to the wrong prediction. Instead of choosing one among the predictions that all have low confidence, the proposed partial-labeling method takes both ambiguous classes as candidate labels, allowing the ground-truth label to be presented in the training phase.

confidence bars. However, the discarded data are still valuable for learning a classifier, especially in the zero-shot task. So, *how to maximize the utilization of the unlabeled data while minimizing the ratio of noisy pseudo labels in the training set?*

Intuitively, if we are confident that the unlabeled data belong to a candidate class set but unable to assign one-hot pseudo labels, it is more efficient to present all potential labels comparing to discarding them directly. Thus, we propose to present pseudo-partial-labels for those data to the model. As illustrated in Figure 1, for an ambiguous sample, the model believes that it belongs to one of two categories with high confidence but has difficulty determining which category it belongs to. In this case, the standard one-hot-labeling takes the class with the highest confidence as the pseudo label, increasing the ratio of noisy pseudo labels in the training phase due to the wrong prediction. By contrast, the proposed partial-labeling method takes both ambiguous classes as candidate labels, allowing the ground-truth label presented in the training phase. In this way, the model can continue to learn on the pseudo-partial-labeled data by disambiguating the candidate labels and finding the latent ground-truth.

In this work, we propose an uncertainty-aware **C**ross-**L**ingual **T**ransfer framework with Pseudo-**P**artial-Label (CLTP) that employs partial label learning to boost cross-lingual zero-shot transfer. Specifically, our framework utilizes any multilingual pre-trained models as the backbone, and iteratively grows the training set by adding predictions of target language data as silver labels. For those difficult data samples with low prediction confidence, different from discarding them directly or introducing a single-hypothetical but incorrect pseudo-label, we associate them with pseudo-partial-labels to better maximize the data utilization. To estimate the pseudo-partial-label, we propose a novel uncertainty-aware estimation method that considers both prediction confidence and the limitation to the number of candidate labels. The model continues to learn on the pseudo-partial-labeled data by disambiguating the candidate labels and finding the latent ground-truth.

Our key contributions can be summarized as follows. 1) We design an uncertainty-aware cross-lingual transfer framework with pseudo-partial-labels. 2) We propose a novel pseudo-partial-label estimation method that considers prediction confidences and the limitation to the number of candidate classes. 3) We evaluate the proposed framework on both NER and NLI tasks across 40 languages in total. Comprehensive experiments show that our framework achieves a strong performance of both high-resource and low-resource languages on both tasks by a sizable margin, such as 6.9 on Kazakh (kk), 5.2 Marathi (mr) for NER and 1% on Arabic (ar), 0.8% on Bulgarian (bg) for NLI.

2 Related Work

Cross-Lingual Representation Learning. Pre-trained transformer-based models have proven effective in learning cross-lingual information. mBERT (Devlin et al., 2019) is pre-trained on raw Wikipedia texts in languages using masked language modeling and next sentence prediction tasks with no explicit cross-lingual objective. XLM-R (Conneau et al., 2020) improves over mBERT by training longer with more data from CommonCrawl, and without the NSP objective. Recently, two self-learning based methods were proposed for cross-lingual transfer. Dong and de Melo (2019) proposed a self-learning framework to incorporate the predictions of mBERT for the cross-lingual text classification task. Xu et al. (2021) improved over the XLM-R by jointly training multiple languages together and considering prediction confidence in the silver labels selection process. However, these two methods still suffer from noisy training because of the incorrect pseudo-labels.

Pseudo-Labeling. Pseudo-labeling (Lee et al., 2013; Shi et al., 2018; Iscen et al., 2019) belongs to the self-learning scenario, and it is often used in semi-supervised learning to generate pseudo-labels for unlabeled samples with a model trained on labeled data. Inspired by noise correction work (Yi and Wu, 2019), Wang and Wu (2020) attempted to update the pseudo-labels through an optimization framework. Recently, Rizve et al. (2021) selected pseudo-labels with both prediction uncertainty and calibration, allowing for negative pseudo-labels generations. However, most existing methods involve learning from noisy data and cannot generalize to partial label learning.

Partial Label Learning. Partial label learning (Cour et al., 2011), also called ambiguously label learning (Chen et al., 2017) and superset label problem (Gong et al., 2017), has subsequently attracted a lot of attention (Feng et al., 2020; Wang and Zhang, 2020; Yao et al., 2020; Yan and Guo, 2020;

Wang et al., 2021). It refers to the task where each training sample is associated with a *set* of candidate labels, while *only one* of them is assumed to be true. Existing studies on the partial label learning can be divided into two groups: average-based methods and identification-based methods. The average-based methods (Cour et al., 2011; Zhang and Yu, 2015; Zhang et al., 2016) consider each candidate label as equally important during model training, and average the outputs of all candidate labels for predictions. The identification-based methods aim at directly maximizing the output of exactly one candidate label, chosen as the truth label. Yan and Guo (2020) studied the utilization of batch label correction; Yao et al. (2020) managed to improve the performance by combining different networks. Wen et al. (2021) proposed the Leveraged Weighted (LW) loss, considering the trade-off between losses on partial labels and non-partial ones. In this work, we adopt the idea of LW loss function for partial label learning due to its effectiveness and generalization.

Uncertainty Estimation. Recently, estimating the uncertainty of deep learning models has attracted increasing attention and have been validated the effectiveness in NLP tasks (Zhang et al., 2019; He et al., 2020). There are two main uncertainty types in Bayesian modeling (Kendall and Gal, 2017; Depeweg et al., 2018): epistemic uncertainty (EU) that captures the model uncertainty itself, which can be explained with more data; aleatoric uncertainty (AU) that captures the intrinsic data uncertainty regardless of models. Another group of uncertainty estimation methods are based on belief/evidence theory through Fuzzy Logic (De Silva, 2018), Dempster-Shafer Theory (Sentz et al., 2002), and Subjective Logic (Sensoy et al., 2018). Belief theorists focus on the reasoning of the inherent uncertainty in information resulting from unreliable, incomplete, deceptive, and/or conflicting evidences. Subjective Logic considers uncertainty in subjective opinions in terms of vacuity (i.e., lack of evidence) (Sensoy et al., 2018), dissonance (i.e., conflicting evidence), and consonance (i.e., composite subsets of state values) (Shi et al., 2020).

Summary Current works on self-learning based cross-lingual transfer methods suffer from noisy training and poor generalization due to the incorrectly pseudo-labeled samples. In this work, we adopt the idea of partial label learning to maximize unlabeled data utilization while reducing the effect of ambiguously pseudo-label estimations in the self-learning framework. To the best of our knowledge, it is the first time pseudo-partial-label employed in the self-learning framework for the cross-lingual transfer and estimating the pseudo-partial-label with the prediction uncertainty.

3 Model

In this section, we propose a partial-label based self-learning framework to boost cross-lingual transfer performance. The overview of the proposed framework is presented in Section 3.2. The technical details for the uncertainty-aware pseudo-partial-label estimation and partial label learning are described in Sections 3.3 and 3.4, respectively.

3.1 Preliminary

Partial label learning refers to the task where each training sample is associated with a *set* of candidate labels, while *only one* of them is assumed to be true. The goal is to find the latent ground-truth for the input through observing the partial label set. Formally, given a non-empty feature space (input space) $\mathcal{X} \subset \mathbb{R}^d$ and a supervised label space $\mathcal{Y}^* = [C] := \{1, \ldots, C\}$, where C is the number of classes and the partial label space is denoted as $\mathcal{Y} := \{y | y \subset \mathcal{Y}^*\}$. For the rest of this paper, let $y^{(i)} = [y_1^{(i)}, \ldots, y_C^{(i)}] \subseteq \{0, 1\}^C$ be the binary vector representing the partial-labels of the instance i , where $y_c^{(i)} = 1$ if class c is selected as the candidate class and $y_c^{(i)} = 0$ if c is not selected. For convenience, we use *k-hot partial labels* to represent the number of candidate classes in the partial label. For example, the partial label in Figure 1 is a two-hot partial label and has two candidate classes.

3.2 Partial-Label based Self-Learning Framework

Our approach aims to improve the overall performance by maximizing the utilization of unlabeled data while reducing the noise introduced in the training phase. This can be accomplished by applying partial label learning on those highly uncertain predictions. The intuition is that if the data appears ambiguous to be classified, it will be more effective to present potential labels instead of discarding them directly or introducing a single-hypothetical but incorrect pseudo-label in the training phase.

The complete training procedure of our proposed task-agnostic framework for cross-lingual transfer is shown in Figure 2. In our proposed CLTP frame-

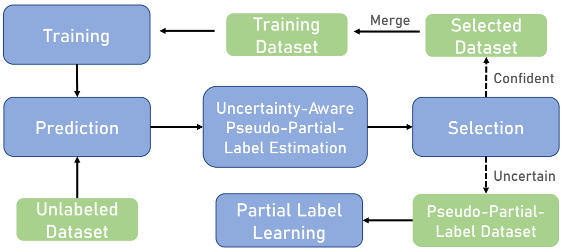

Figure 2: Illustration of the uncertainty-aware cross-lingual transfer framework with pseudo-partial-labels.

work, we first train a pre-trained multilingual model on the gold labels of the source language. Then the model makes predictions on the unlabeled dataset of the target languages. The proposed uncertainty-aware estimation component generates the pseudo-partial-labels based on the model predictions and their corresponding uncertainty estimations. After that, we adopt a selection mechanism to incorporate the unlabeled data with high confidence scores into the training phase.

The whole training process for our method is described in Algorithm 1, where $\mathcal{D}_u$ denotes the set of tuples combining unlabeled data with corresponding pseudo-partial-labels and prediction uncertainty γ_{diss}. First, a model $f(\cdot)$ is trained on the gold labels of the source language in the first iteration. Once trained, the model can make predictions and estimate the pseudo-partial-labels for all unlabeled data of target languages in D_u based on the method introduced in Section 3.3. Note that the inputs of different languages are mixed together. Next, a subset of the pseudo-partial-labels S_u is selected with the uncertainty estimation. After selection, the model goes back to the training phase using the selected pseudo-partial-labels as well as the gold labels. We repeat the process iteratively until max iteration is reached. The early stop criteria are implemented on the dev set of the source language only since the gold labels are not available for the other languages. Note that the model is trained only on the one-hot pseudo-label in the first three iterations to accelerate the convergence.

3.3 Pseudo-Partial-Label Estimation

The key point of pseudo-partial-label estimation is to guarantee that the ground-truth class of an instance resides in the candidate label set, which is the basic definition for partially supervised learning. Intuitively, if the model classifies an instance with lower confidence, the instance may be hard to distinguish from several classes or cannot be identified due to the lack of knowledge. Hence, we consider prediction confidence in the pseudo-partial-label estimation to better determine the most uncertain classes for each ambiguous instance.

Algorithm 1 Self-Learning on Cross-Lingual Tasks

```
Input: A gold label dataset $\mathcal{D}_L$ of source language,
       an unlabeled dataset of target languages $\mathcal{U}$.
repeat
    Training $f(\cdot)$ on $\mathcal{D}_L$ with $\mathcal{L}_{EVI}$
    for each target language do
        $\mathcal{D}_u \leftarrow \varnothing$
        for $x_u$ in $\mathcal{U}$ do

    end for
until max iteration arrives.
Training $f(\cdot)$ on $\mathcal{D}_L$ with $\mathcal{L}_\varphi$ until converge
```

We define the prediction uncertainty of the instance x belonging to the partial-label y as the partial-label uncertainty, which is denoted as $\gamma_{diss}(x, y)$. The decomposed entropy *dissonance* proposed by Shi et al. (2020) is adapted to calculate the partial-label uncertainty, as it can indicate the contradiction among certain classes. Specifically, *dissonance* is an evidence-based uncertainty (Sensoy et al., 2018) where the softmax probability is replaced by Dirichlet distribution, and each predicted logit for class c is regarded as the evidence e_c. The expected probability p_c for class c under Dirichlet distribution is defined as follows.

$$p_c = \frac{e_c + 1}{S}, \text{with } S = \sum_c e_c + C \tag{1}$$

where S is referred to as the Dirichlet strength. We adopt the cross-entropy loss as the training loss $\mathcal{L}_{\mathrm{EVI}}$, and its Bayes risk under the Dirichlet distribution can be defined as

$$\begin{aligned}\mathcal{L}_{\mathrm{EVI}} &= \int \Big[\sum_c -y_c \log(p_c)\Big] \frac{1}{Beta(\boldsymbol{\alpha})} \prod_c p_c^{\alpha_c - 1} d\mathbf{p}_c \\ &= \sum_c -y_c \int \log(p_c) \frac{1}{Beta(\boldsymbol{\alpha})} \prod_c p_c^{\alpha_c - 1} d\mathbf{p}_c \\ &= \sum_c y_c (\psi(S) - \psi(e_c + 1))\end{aligned} \tag{2}$$

where $Beta(\boldsymbol{\alpha})$ is the multinomial beta function (Kotz et al., 2004) and $\psi(\cdot)$ is the *digamma* function. $\boldsymbol{\alpha}$ is the parameters of the Dirichlet density on the predictors. As shown in Equation (2), training the model with $\mathcal{L}_{\text{EVI}}$ is to make the positive evidence close to the total evidence when the ground-truth is positive. If there are conflicts of strong evidence among certain classes, *dissonance* will become high to indicate the contradiction. The following describes the *dissonance* for each instance:

$$\text{Bal}(b_j, b_k) = \begin{cases} 1 - \frac{|b_j - b_k|}{b_j + b_k}, & \text{if } b_j b_k \neq 0 \\ 0, & \text{elsewise} \end{cases} \tag{3}$$

$$diss = \sum_c \frac{b_c \sum_{c' \neq c} b_{c'} \text{Bal}(b_c, b_{c'})}{\sum_{c' \neq c} b_{c'}} \tag{4}$$

where $b_c = e_c/S$ represents the belief mass for class c. Recall that each predicted logit for class c is regarded as the evidence e_c.

In the pseudo-partial-label estimation, the belief mass for the instance belongs to a candidate class set can be calculated via Binomial Comultiplication operator in subjective logic, which is denoted as '$\vee$'. Let b_c and b_h be the belief mass for class c and class h, respectively. The belief mass for the instance belongs to class c or class h is defined as:

$$b_{c \vee h} = b_c + b_h - b_c b_h \tag{5}$$

Thus, we can calculate the partial-label uncertainty $\gamma_{diss}(x, y)$ via Equation (4) and (5).

However, if we simply estimate the pseudo-partial-label only based on the lowest partial-label uncertainty, it will lead to an invalid partial label like $(1, 1, 1, 1)$, as containing all classes in the candidate set must have the highest confidence. Furthermore, in the partial label learning, the accuracy of the model decreases with the increased number of similar labels to the true label (Lv et al., 2020; Wen et al., 2021) because it increases the learning difficulty. To remedy this problem, we leverage a penalty ratio to balance the prediction uncertainty and the number of candidate classes. Specifically, from Figure.3, we observe that as the number of candidate classes increases, the improvement in prediction recall tends to decrease. That means containing too many candidate classes in the pseudo-partial-label has limited improvement to the model. Only the most confusing candidate classes are important for those ambiguous samples. Motivated by this, we employ a penalty ratio to punish a larger number of candidate classes. Thus, a pseudo-partial-label $\tilde{y}$ is obtained as follows:

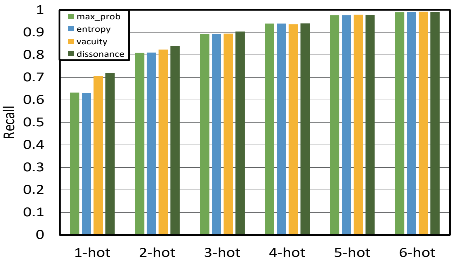

Figure 3: Recall of k-hot pseudo-partial-labels in the last iteration with various uncertainty methods.

$$\tilde{y} = \arg\min_{y \subset \mathcal{Y}} ((\lambda^{||y||_1 - 1} + \tau)\tau^{||y||_1 - 2} \gamma_{diss}(x, y)) \tag{6}$$

where $\mathcal{Y}$ is the collection of all subsets in the partial label space and $||y||_1$ calculates the number of candidate classes in the partial label y. λ and τ are penalty ratios to punish a larger number of candidate classes, which determine the penalty strength and the preference for candidate class number, respectively.

3.4 Learning with Pseudo-Partial-Labels

The target of partial-label learning is to learn a classifier with access to the candidate label set (partial label set) by disambiguating the candidate labels and finding the latent ground-truth for the input during the training phase. We adopt Leveraged Weighted (LW) loss function (Wen et al., 2021) for partial label learning due to its effectiveness and generalization. The LW loss is a multiclass loss and searches for the latent ground-truth by assigning more weights to the loss of classes more likely to be the true and lessening weights to the confusing ones. To be specific, the LW loss function is defined as:

$$L_\varphi(\tilde{y}, f(x)) = \sum_{\tilde{y}_c = 1} \omega_c \varphi(f_c(x)) + \beta \sum_{\tilde{y}_c = 0} \omega_c \varphi(-f_c(x)), \tag{7}$$

where $\varphi(\cdot) : \mathbb{R} \to \mathbb{R}^+$ denotes a binary loss and we adopt the Sigmoid loss function. We use parameter β to distinguish the effects between candidate classes and non-candidate ones. $f_c(x)$ represents the predicted logit of instance x for class c, while w_c is the weighting parameters to assign weights to the loss of classes. Since the key point is to disambiguate the candidate classes, the model is supposed to assign more weights to the loss of classes that are more likely to be the ground-truth. Thus, instead of assigning fixed values, the weighting parameters are updated by normalizing the prediction score through an iterative learning process. Specifically, at the t-th learning step, $w_c^{(t)}$ is calculated as follows:

$$\omega_c^{(t)} = \begin{cases} \frac{\exp(f_c^{(t)}(x))}{\sum_{\tilde{y}_c=1} \exp(f_c^{(t)}(x))}, & \text{if } \tilde{y}_c = 1 \\ \\ \frac{\exp(f_c^{(t)}(x))}{\sum_{\tilde{y}_c=1} \exp(f_c^{(t)}(x))}, & \text{if } \tilde{y}_c = 0 \end{cases} \tag{8}$$

Note that $w_c^{(t)}$ varies with sample instances. In this way, as the training epochs grow, the model focuses on the true class and rules out the untrue classes by penalizing large value of $\varphi(-f_c(x))$.

4 Experiments

4.1 Evaluation Tasks & Datasets

NLI XNLI (Conneau et al., 2018) is an evaluation benchmark for the cross-lingual NLI task across 15 languages. Given a sentence pair of premise and hypothesis, the task is to classify their relationship as “neutral”, “entailment”, or “contradiction”.

NER Wikiann (Pan et al., 2017) is an evaluation benchmark for the cross-lingual NER task covering 40 languages. There are three entity types: “LOC”, “PER” and “ORG”, and each token is tagged in the BIO2 format with 7 label types.

We follow the same train/dev/test split and same evaluation protocol as XTREME (Hu et al., 2020). English is the source language with gold labels for both datasets, and we use the dev set of target languages as the source of unlabeled data. Gold labels of target languages cannot be accessed in the self-learning process.

4.2 Implementation Details

Model Details. We keep the same model architecture throughout our experiments: XLM-$\mathrm{R}_{\mathrm{Large}}$ (Conneau et al., 2020) is used as the multilingual pre-trained model to encode input sequence, followed by a linear layer to classify on the hidden state, which is the same model setting from XTREME. We set the penalty ratios $\lambda = 4$ and $\tau = 10$ for all experiments. For LW loss, we set $\beta = 2$ as suggested by Wen et al. (2021).

Training Details. For both NER and NLI tasks, we use the AdamW (Loshchilov and Hutter, 2018) optimizer with a linear learning rate scheduler for all experiments. We use a batch size of 32 and a max sequence length of 128. We first train the model by 10 epochs on English training set with gold labels for the NER task and 5 epochs for the NLI task with a 2×10^{-5} learning rate. In the self-learning process, we keep the same learning rate for the NER task and set a 5×10^{-6} learning rate to train the model for the NLI task. The model is trained for 3 epochs in each iteration. Experiments are run on a single 24GB NVIDIA 3090 GPU.

4.3 Baselines.

We compare our CLTP framework with three different settings for the baselines: *BL-Direct* is equivalent to Hu et al. (2020), which is the direct zero-shot transfer without utilizing unlabeled data of target languages. *BL-Single* takes silver labels of only one target language as the training set in the self-learning process and simply uses model predictions as silver labels without considering prediction confidences. *BL-Joint* is similar to *BL-Single* but instead takes silver labels of all target languages jointly. We also compare our method with uncertainty-aware self-learning framework (Xu et al., 2021): *SL-LEU* trains the model with silver labels and selects them by considering Language Heteroscedastic Uncertainty (LEU) and *SL-EVI* takes Evidential Uncertainty (EVI) to estimate the prediction uncertainty, following the same training settings as Xu et al. (2021) utilized.

4.4 Comparisons

The results of NER task and NLI task are shown in Tables 1 and 2, respectively. Self-learning based methods outperform the direct zero-shot transfer with XLM-$\mathrm{R}_{\mathrm{large}}$ by a large margin in NER, achieving 11.1 gain in F1 on average. The trend of improvement can also be observed in NLI, validating the self-learning strategy on cross-lingual transfer tasks. Furthermore, our method surpasses SL-LEU on NER by 2.2 in F1 on average, demonstrating the effectiveness of utilizing pseudo-partial-label for those ambiguous data. Remarkably, our method achieves a sizeable gain, 5+ in F1 on both low-resource languages like Malayalam (ml) and Marathi (mr), and high-resource languages such as Russian (ru) and Tegulu (te). This shows that our method can further boost the model performance of the self-learning framework. As shown in Ta-

Table 1: NER Results in F1 scores for 40 languages. *Results are reported by Xu et al. (2021).

ble 2, our model outperforms the baselines on NLI across almost all 15 test languages. Comparing to the direct zero-shot, our method achieves an improvement of 2.4% on average. Our method also gives an average increase of 1.2% and 0.5% on SL-EVI and SL-LEU, respectively. Specifically, we observe over 1% gain for Arabic (ar), Bulgarian (bg), Greek (el), and Turkish (tr) when we compare CLTP framework with the best performance of SL.

4.5 Result Analyses

To better understand the key components and settings of CLTP framework, we perform some analyses on the NER task.

Uncertainty Estimation. To assess different uncertainty estimations for pseudo-partial-label estimation, we evaluate the recall score of the pseudo-partial-labels in the last iteration, such that recall is high when the pseudo-partial-label contains the true class. Here, we adopt the two-hot partial label setting where the two classes with the highest prediction confidence were set as candidate classes, as it is the best setting to directly measure the contradiction among certain classes. We compare evidential uncertainty with two commonly used uncertainty metrics for classification (Depeweg et al., 2018; Dong and de Melo, 2019; Xiao and Wang, 2019): the max probability of label classes (i.e., max_prob) and the entropy of the class probability distribution (i.e., entropy). As shown in Figure 4, *dissonance* achieves the best performance among all uncertainty estimations on average, demonstrating its capability of ambiguous class selection.

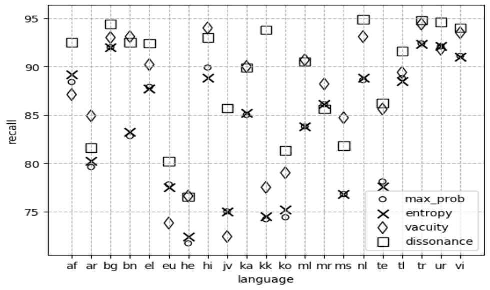

Figure 4: Recall of different uncertainty estimations in pseudo-partial-label estimation (two-hot partial-labels).

Hyperparameter Analyses. We introduce new hyperparameters λ and τ to control the penalty ratio. Table 3 shows the evaluation accuracy in different penalty ratio settings. We find that using $\lambda = 4, \tau = 10$ leads to the best performance, and further reduction/increase in the ratio lead to performance degradation. The penalty ratio does affect the performance of the model as it adjusts the proportion of various pseudo-partial-labels. In

Table 4: Effect of pseudo-partial-label length on the NER task. Note that *two-hot partial labels* indicates that the pseudo-partial-labels are directly estimated by selecting the two classes with the max prediction probability and *no partial-labels* is equivalent to SL.

specific, when τ stays the same, as λ increases, the proportion of partial-labels decreases. It indicates that most pseudo-labels are one-hot labels that are similar to the self-learning framework proposed by Xu et al. (2021). Similarly, if we keep λ constant, reducing τ will lead to not only a higher proportion of partial-labels over the unlabeled set but also more candidate classes in each partial-label. We observe an over 2.6 gain when we compare $\lambda = 4, \tau = 10$ setting with $\lambda = 4, \tau = 5$ setting, indicating that if we ignore the limitation on the number of candidate classes, the model will suffer from invalid partial labels like $(1, 1, 1, 1)$ because it cannot provide any information when all classes are set as candidates.

Effect of pseudo-partial-label length. To analyze the effect of different number of candidate classes in pseudo-partial-label estimation, we evaluate the model trained with various manually designed pseudo-partial-labels. Specifically, we select the top classes with the prediction confidence to set pseudo-partial-labels. The results are shown in Table 4. When we utilize the manually set partial-labels, we observe an accuracy drop of 0.3, 2.4 and 3.0 in *two-hot partial labels*, *three-hot partial labels* and *four-hot partial labels*, respectively. This demonstrates the effectiveness of our pseudo-partial-label estimation scheme. In addition, the model trained with *two-hot partial labels* outperforms the baselines. By contrast, *three-hot partial labels* and *four-hot partial labels* do not surpass the baselines, partially due to the difficulty of disambiguating the candidate classes. The trend of improving performance with fewer candidate classes is consistent with the phenomenon in partial label learning (Lv et al., 2020; Wen et al., 2021).

5 Conclusion

In this work, we propose an uncertainty-aware pseudo-partial-label framework for cross-lingual transfer. With the auxiliary of pseudo-partial-labels, CLTP framework improves the model by reducing the noise introduced in training phase while maximizing unlabeled data utilization. Moreover, we propose a novel pseudo-partial-label estimation method that considers both prediction confidence and the limitation to the number of similar classes. The proposed framework is evaluated on two tasks of NER and NLI and improves the performance of the pre-trained model by a solid margin (11.1 F1 for NER and 2.4% accuracy score for NLI on average). Compared to other self-learning based methods, our framework surpasses the baselines on both high-resource and low-resource languages, such as 6.9 on Kazakh and 5.2 Marathi for NER.

A Appendix

A.1 Relationship between pseudo-label accuracy and the model performance

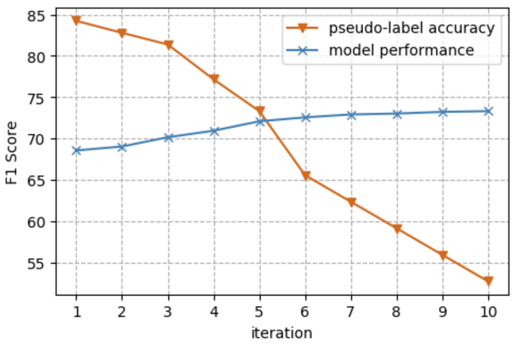

Figure 5: Existing self-learning method for cross-lingual transfer suffers from noisy training due to the incorrectly pseudo-labeled samples. Xu et al. (2021) select top-k percent of unlabeled data with uncertainty score. The entire process keeps iterating until there is no remaining unlabeled data. As the precision of the pseudo-labels decreases, the performance improvement of the model decreases.

We empirically analyze the relationship between pseudo-label accuracy and model performance. From Figure 5, we find that F1 score of newly selected pseudo-labels in each iteration drops quickly, especially in the later 5 iterations. Furthermore, as the precision of the pseudo-labels decreases, the performance improvement of the model decreases.

NLU++: A Multi-Label, Slot-Rich, Generalisable Dataset for Natural Language Understanding in Task-Oriented Dialogue

Iñigo Casanueva[*] **Ivan Vulić**,[*] **Georgios P. Spithourakis**, and **Paweł Budzianowski**
PolyAI Limited
London, United Kingdom
`{inigo,ivan,georgios,pawel}@poly.ai`

Abstract

We present NLU++, a novel dataset for natural language understanding (NLU) in task-oriented dialogue (ToD) systems, with the aim to provide a much more challenging evaluation environment for dialogue NLU models, up to date with the current application and industry requirements. NLU++ is divided into two domains (BANKING and HOTELS) and brings several crucial improvements over current commonly used NLU datasets. **1)** NLU++ provides fine-grained domain ontologies with a large set of challenging *multi-intent* sentences, introducing and validating the idea of *intent modules* that can be combined into complex intents that convey complex user goals, combined with finer-grained and thus more challenging slot sets. **2)** The ontology is divided into *domain-specific* and *generic* (i.e., domain-universal) intent modules that overlap across domains, promoting cross-domain reusability of annotated examples. **3)** The dataset design has been inspired by the problems observed in industrial ToD systems, and **4)** it has been collected, filtered and carefully annotated by dialogue NLU experts, yielding high-quality annotated data. Finally, we benchmark a series of current state-of-the-art NLU models on NLU++; the results demonstrate the challenging nature of the dataset, especially in low-data regimes, the validity of 'intent modularisation', and call for further research on ToD NLU.

1 Introduction

Research on task-oriented dialogue (ToD) systems (Levin and Pieraccini, 1995; Young et al., 2002) has become a key aspect in industry: e.g., ToD is used to automate telephone customer service tasks ranging from hospitality over healthcare to banking (Raux et al., 2003; Young, 2010; El Asri et al., 2017). Typical ToD systems still rely on a modular design: (i) *the natural language understanding* (NLU) module maps user utterances into a domain-specific set of intent labels and values (Rastogi et al., 2019; Heck et al., 2020; Dai et al., 2021), followed by (ii) the *policy* module, which makes decisions based on the information extracted by the NLU (Gašić et al., 2012; Casanueva et al., 2017; Lubis et al., 2020; Wang et al., 2020a)

Figure 1: Multi-intent examples from the two domains of the NLU++ dataset: BANKING (top) and HOTELS (middle, bottom), illustrating the two core NLU subtasks of intent detection (ID) and slot labeling (SL) in ToD systems. The extracted information is structured into *intents* and *slots*, the latter having associated *values*.

The NLU module is a critical part of any ToD system, as it must extract the *relevant* information from the user's utterances. The information relevance is denoted by the structured *dialogue domain ontology*, which enables the policy module to make decisions about next system actions. The domain ontology covers the information on 1) *intents* and 2) *slots*, see Figure 1. The former is aimed at extracting general conversational ideas (i.e., the user's intents) and corresponds to the standard NLU task of *intent detection (ID)*; the latter extracts specific *slot values* and corresponds to the NLU task of *slot labeling (SL)* (Gupta et al., 2019).[1]

In order to make the policy operational *and* tractable, NLU should extract only the minimal information required by the policy. Therefore, the ontologies differ for each domain of ToD application and are typically built from scratch for each domain.

---

[*] Equal contribution.

[1] Slot labeling is also known under other names such as slot filling or value extraction.

Example	**Traditional Intent**	**Intent Modules**
I need to change my restaurant reservation	change_restaurant_booking	change, restaurant, booking
When is my booking for the spa?	when_spa_booking	when, spa, booking
TV is not showing any image	tv_not_working	tv, not_working
Why can't I cancel this standing order?	why_cancel_standing_order_not_working	why, cancel, standing_order, not_working

Table 1: Comparison of "traditional" intent annotations vs *intent module*-based multi-label annotations.

Consequently, this makes domain-relevant NLU data extremely expensive to collect and annotate, and prevents its reusability (Budzianowski et al., 2018). Due to this, NLU research in recent years has heavily focused on very data-efficient models that can effectively operate in low-data regimes. Current state-of-the-art (SotA) NLU models leverage large pretrained language models (PLMs) (Devlin et al., 2019; Liu et al., 2019c; Henderson et al., 2020) and fine-tune them with small task-specific datasets (Larson et al., 2019b; Casanueva et al., 2020; Coucke et al., 2018)

At the same time, the progress in creation of NLU datasets has not kept up with the impressive pace of NLU methodology development. However, designing domain ontologies and NLU datasets is also critical for steering further progress in NLU, both from methodology and application perspective. Put simply, current publicly available NLU datasets do not keep up to date with current industry/application requirements for many reasons. **1)** They are usually crowdsourced by untrained annotators (thus typically optimised for quantity rather than quality), yielding examples with low lexical diversity and prone to annotation errors. **2)** They typically assume one intent per example, and thus enable only much simpler single-label ID experiments; such setups are not realistic in more complex industry settings (see Figure 1 again) and lead to unnecessarily large intent sets. **3)** Their ontologies are tied to specific domains, making it difficult to reuse already available annotated data in other domains. **4)** The complexity of the defined tasks and ontologies is limited; the undesired artefact is that current NLU datasets might overestimate the NLU models' abilities, and are not able to separate models any more performance-wise.[2]

In order to address all these gaps, we introduce NLU++, a novel NLU dataset which provides high-quality NLU data annotated by dialogue experts. NLU++ provides *multi-intent*, *slot-rich* and *semantically varied* NLU data, and is inspired by a number of NLU challenges which ToD systems typically face in production environments. Unlike previous ID datasets, examples are annotated with multiple labels, named *intent modules*[3] (see Table 1), with some examples naturally obtaining even up to 6-7 labels. These labels can be seen as sub-intent annotations, where their combinations yield full intents equivalent to "traditional" intents (Table 1). In addition, NLU++ defines a rich set of slots which are combined with the multi-intent sentences. NLU++ is divided into two domains (BANKING and HOTELS) where the two domain ontologies blend a set of *domain-specific* intents and slots with a set of *generic* (i.e., domain-universal) intents and slots. This design makes a crucial step towards generalisation and data reusability in NLU.

Finally, we run a series of experiments on NLU++ with current SotA ID and SL models, demonstrating the challenging nature of NLU++ and ample room for future improvement, especially in low-data setups. Our benchmark comparisons also demonstrate strong performance and shed new light on the (ability of) recently emerging QA-based NLU models (Namazifar et al., 2021; Fuisz et al., 2022), and warrant further research on ToD NLU. The NLU++ dataset is available at: `github.com/PolyAI-LDN/task-specific-datasets`.

2 Background and Motivation

A Brief History of NLU Datasets. As a core module of ToD systems, NLU has been researched since the early 1990s, when the Airline Travel Information System (ATIS) project was started (Hemphill

---

[2] For instance, for some standard and commonly used NLU datasets such as ATIS (Hemphill et al., 1990; Xu et al., 2020) and SNIPS (Coucke et al., 2018), the results of SotA models are all in the region of 97-98 F_1, with new models getting statistically insignificant gains which might be due to overfitting to the test set or even some remaining annotation errors.

[3] Henceforth, whenever *intents* are mentioned in the context of NLU++, we will be referring to *intent modules*.

		INTENTS			SLOTS		
Domain	**Number of examples**	**Total**	**Generic**	**Avg. per example**	**Total**	**Generic**	**Avg. per example**
BANKING	2,071	48	26	2.25	13	10	0.46
HOTELS	1,009	40	26	1.52	14	10	1.03
ALL	3,080	62	26	2.01	17	10	0.65

Table 2: Key statistics of the NLU++ dataset.

et al., 1990), consisting of spoken queries on flight-related information.[4] Over the next two decades, very few NLU resources were released.[5]

The lack of ToD NLU resources ended in 2013, with the beginning of the 'dialogue state tracking (DST) era' (Williams et al., 2013; Henderson et al., 2014; Kim et al., 2016). Instead of just classifying each turn of the user, DST deals with keeping track of the user's goal over the entire dialogue history, i.e., all the previous user and system turns. Several datasets where released during the DST challenges, all of them comprising simple intent sets (usually tagged as *dialogue acts*).

In order to adapt to the increasing data requirements of deep learning models, increasingly larger dialogue datasets have been released in recent years (Budzianowski et al., 2018; Wei et al., 2018; Rastogi et al., 2019; Peskov et al., 2019). However, the design of ToD datasets comes with some profound differences to datasets for e.g. machine translation or speech recognition, which affect current ToD datasets. **1)** The domain-specific nature of ToD datasets made the data tied to its ontologies, not allowing data reusability across different domains. **2)** The domain-specific ontologies required a lot of expertise for annotation, therefore many annotation mistakes were made (Eric et al., 2019; Zang et al., 2020). **3)** Collecting datasets of that size is unfeasible for development cycles in production, where new domains and models for them need to be very quickly developed and deployed.

Current NLU Trends, inspired by such production requirements, thus deviate from previous DST-oriented NLU research in two main aspects. First, the models went back to focusing on single-turn utterances, which **1)** simplifies the NLU design and **2)** renders the NLU tasks more tractable.[6] The requirement of fast development cycles also instigated more research on NLU (i.e., ID and SL tasks) in low-data scenarios. This way, systems can be developed and maintained faster by reducing the data collection and annotation effort. In addition, the NLU focus shifted from ontologies with only a handful of simple intents and slots (Coucke et al., 2018) to complex ontologies with much larger intent sets (Larson et al., 2019b; Liu et al., 2019b; Casanueva et al., 2020, *inter alia*).

Inspired by these NLU datasets and empowered by transfer learning with PLMs and sentence encoders (Devlin et al., 2019; Liu et al., 2019a; Henderson et al., 2020), there have been great improvements in single-turn NLU systems recently, especially in low-data scenarios (Coope et al., 2020; Mehri and Eric, 2021; Wu et al., 2020b,a; Krone et al., 2020; Henderson and Vulić, 2021; Namazifar et al., 2021; Dopierre et al., 2021; Zhang et al., 2021a,b).

Current Gaps in NLU Datasets. However, existing NLU datasets are still not up to the current industry requirements. **1)** They use crowdworkers for data collection and annotation, often through simple rephrasings; they thus suffer from low lexical diversity and annotation errors (Larson et al., 2019a). **2)** ID datasets always assume a single intent per sentence, which does not support modern production requirements. **3)** The ontologies of these datasets are very domain-specific (i.e., they thus do not allow data reusability) and narrow (i.e., they tend to overestimate abilities of the current SotA NLU models). **4)** Current NLU datasets do not combine a large set of fine-grained intents (again, with multi-intent examples) and a large set of fine-grained slots, which prevents proper and more insightful evaluations of joint NLU models (Chen et al., 2019; Gangadharaiah and Narayanaswamy, 2019).

---

[4] Remarkably, ATIS is still considered at present as one of the main go-to datasets in NLU reserach. This is also reflected in the fact that the recent most popular dataset for multilingual dialogue NLU was obtained by simply translating English ATIS to 8 more languages (Xu et al., 2020, MultiATIS++).

[5] We note that some Question Classification (Hovy et al., 2001), Paraphrasing (Dolan and Brockett, 2005) and Semantic Text Similarity(Agirre et al., 2012) datasets could be seen as the seed of modern ID datasets, but were not initially built for that purpose.

[6] While DST is theoretically more accurate, it requires amounts of data that grow exponentially with the number of turns; moreover, rule-based trackers have proven to be on par with the learned/statistical ones and require no data (Wang and Lemon, 2013).

Example	Intents	Domain
I want to change my room reservation	change, booking, room	HOTELS
I want to cancel a booking	cancel, booking	HOTELS
Why can't I amend my restaurant booking?	why, change, restaurant, booking, not_working	HOTELS
I am trying to make a transfer but it doesn't let me	make, transfer_payment, not_working	BANKING
I need to increase my overdraft	change, overdraft, higher	BANKING
Please close my savings account	cancel, account, savings	BANKING
The savings one	savings	BANKING
Make it higher	change, higher	GENERAL
Cancel it	cancel	GENERAL
Don't cancel it	deny, cancel	GENERAL

Table 3: NLU++ examples showing the combinatorial expressiveness of intent modules in the multi-intent setting.

We note that there has been some work on multi-label ID on ATIS, MultiWOZ and DSTC4 as multi-intent datasets; however, their multi-label examples remain very limited, simple, and span a small number of intents (Gangadharaiah and Narayanaswamy, 2019). Further, synthetic multi-intent datasets have been created by concatenating single-intent sentences, but such datasets also do not capture the complexity of true and natural multi-intent sentences (Qin et al., 2020).

3 NLU++ Dataset

The NLU++ dataset has been designed with the aim of addressing some of the major shortcomings of the current NLU datasets. In what follows, we describe the main improvements and new evaluation opportunities offered by NLU++.

3.1 Ontology

NLU++ comprises two domains: BANKING and HOTELS. The former represents a banking services task (e.g., making transfers, depositing cheques, reporting lost cards, requesting mortgage information) and the latter is a hotel 'bell desk' reception task (e.g., booking rooms, asking about pools or gyms, requesting room service). Both domains combine a large set of intents with a rich set of slots, with the ontologies inspired by requirements in production. A large number of intents and slots is shared between the two domains, in an attempt to increase data reusability/transferability. Table 2 provides the main statistics of the NLU++ dataset, while the full ontology is presented in Appendix A.

3.2 Multi-Intent Examples

One of the main contributions of this work is the novel design of the intent space, defined in a highly modular manner that natively supports intent recombinations and multi-intent annotations[7]. For instance, Table 3 shows several multi-intent examples based on the intent sets (termed *intent modules*) from Table 9 in Appendix A.

This design brings several benefits. **1)** The modular nature of the ontology allows for expressing a much more complex set of ideas through different combinations of intent modules (see Table 3), while reducing the overall size of the intent set compared to previous ID datasets[8] (see Table 1 and Table 5). **2)** It allows for the definition of *partial* intents (e.g., *"The savings one"*). This is crucial in multi-turn interactions, where the user often has to answer disambiguation questions (e.g., *"Which account would you like to close?"*). **3)** The modular approach allows the models to generalise to unseen combinations of intent modules. For instance, if (i) examples with the intents *change* and *booking*, and (ii) examples with the intents *cancel* and *account* exist in the training data, (iii) an unseen example with the intents *cancel* and *booking* could be properly predicted, as all the single intents/modules have already been seen by the ID model[9]. **4)** The design also allows us to distinguish between *domain-specific* versus *generic* intent modules. For example, the module *overdraft* is clearly related to BANKING, but the module *change* is much more generic, likely to occur in several different domains.

Finally, the modular design also allows us to

---

[7] Zhang et al. (2020) proposed a similar way of annotating existing intent detection datasets, showing performance improvements. However, this approach forced categorising the sub-intents in four predefined factors.

[8] Similar to how sub-word tokenization reduced the size of language model vocabularies while covering a larger set of words (Vaswani et al., 2018)

[9] Note that in single-label ID setups, all possible intent module combinations (i.e. "traditional" intents) must be covered (Bi and Kwok, 2013; Hou et al., 2021), which leads to unnecessarily large intent sets and larger data requirements.

study semantic variation of intent modules. Some intents (e.g., especially the domain-specific ones) can only be expressed in a few ways (e.g. *overdraft*, *direct_debit*, *swimming_pool*), while others can have much more varied surface semantic realisations, (e.g. *make, not_working*). Table 9 in Appendix A provides an estimation of the semantic variability of each intent (module).

3.3 Slots

NLU++ further includes a rich set of 17 slots, defined in Table 10 in Appendix A. Table 4 displays several NLU++ examples where complex combinations of intents and slots occur, showcasing how NLU++ might provide a much more challenging environment for the evaluation of joint ID and SL models in future research.

Following the design of previous standard SL datasets (Hemphill et al., 1990; Coucke et al., 2018; Coope et al., 2020), we provide *span annotations for slots*. On top of of this, to also support training and evaluation of SL models which are not span-based, we also provide *value annotations* (or *canonical values* as named by Rastogi et al. (2019)) for times, dates, and numeric values.

Similarly to intent modules, slots can also be divided into the *generic* ones (e.g. *time*, *date*) and the *domain-specific* ones (e.g *company_name*, *rooms*, *kids*), see Table 10. Again, this distinction allows for the cross-domain reusability of annotated data.

3.4 Data Collection and Annotation

Previous NLU datasets have usually relied on *crowdworkers*, aiming to collect a large number of examples, and typically optimising for quantity over quality. However, even with much simpler ontologies, workers are prone to make annotation mistakes, leading to very noisy datasets (Eric et al., 2019). In addition, when workers are asked to rephrase a sentence, they often change its semantic meaning or tend to provide rephrasings with extremely low lexical variability (Kang et al., 2018).

NLU++ reflects true production requirements and focuses on data quality. Instead of relying on crowdworkers, 4 highly skilled annotators with dialogue and NLP expertise, also familiar with production environments, collected, annotated, and corrected the data. The process started by defining the ontology for BANKING and HOTELS. Then, real user examples were fully anonymised and re-annotated following the defined ontology. Finally, new examples were created in order to cover less frequent intents and slots, aiming at creating realistic and semantically varied sentences with new combinations of intents and slots.

3.5 Comparison with Other NLU Datasets

Aiming to reflect the differences between NLU++ and the most popular ToD NLU datasets, Table 5 compares their general statistics. Since the focus of NLU++ is on curated high-quality data, NLU++ covers a fewer number of examples than the other datasets, but it is evident that NLU++ is the only real multi-intent dataset: it averages 2.01 intents per example with a high standard deviation. In addition, NLU++ is the only dataset that combines a large set of intents with a large set of slots.

In order to asses the quality and diversity of the NLU data, we include two additional metrics: 1) Type-Token Ratio (TTR) (Jurafsky and Martin, 2000) which measures lexical diversity) and *semantic diversity*. Both metrics are computed for the set of examples sharing an intent, weighted by the frequency of that intent[10] and finally averaged over intents. The semantic diversity per intent is computed as follows: (i) sentence encodings, obtained by the *ConveRT* sentence encoder (Henderson et al., 2020),[11] are computed for the set of sentences sharing the same intent; (ii) the centroid of these encodings is then computed; (iii) finally, the average cosine distance from each encoding to the centroid is computed. The overall scores clearly indicate that NLU++ offers a much higher lexical and semantic diversity than previous datasets, which should also render it more challenging for current SotA NLU models.[12]

4 Experiments and Results

In hope to establish NLU++ as a more challenging production-oriented testbed for dialogue NLU, especially in low-data scenarios, we evaluate a series of current cutting-edge models for both NLU tasks: intent detection (§4.1) and slot labeling (§4.2). Our aim is to assess and analyse their performance across different setups, and provide solid baseline reference points for future evaluations on NLU++.

Data Setups. Unless noted otherwise, for both tasks we adopt the standard K-fold cross-validation

---

[10] Note that ATIS has some intents with a single example: for these intents the TTR score would be 1. Weighting by the intent frequency avoids these intents dominating the metric.

[11] See Appendix B for a short description of ConveRT.

[12] SNIPS also shows high semantic diversity, but this is mostly due to the high frequency of named entities.

Table 5: Comparison of NLU++ with other popular NLU datasets; ATIS (Hemphill et al., 1990), SNIPS (Coucke et al., 2018), OOS (Larson et al., 2019b) and BANKING77 (Casanueva et al., 2020)
.

as done e.g. by Liu et al. (2019b). Through such *folding* evaluation, (i) we avoid overfitting to any particular test set and (ii) we ensure more stable results with smaller training and test data (i.e., when simulating low-data regimes typically met in production) through averaging over different folds.[13]

The experiments are run with $K = 20$ (**20-Fold**) and $K = 10$ (**10-Fold**), where we train on 1 fold and evalute on the remaining $K - 1$ folds. These setups simulate different degrees of data scarcity: e.g., the average training fold comprises ≈ 100 examples for BANKING and ≈ 50 for HOTELS for 20-Fold experiments, and twice as much for 10-Fold experiments. Besides these *low-data training setups*, we also run experiments in a **Large**-data setup, where we train the models on merged 9 folds, and evaluate on the single held-out fold.[14] The key questions we aim to answer with these data setups are: Which NLU models are better adapted to low-data scenarios? How much does NLU performance improve with the increase of annotated NLU data? How challenging is NLU++ in low-data versus large-data scenarios?

Domain Setups. Further, experiments are run in the following domain setups: (i) *single-domain* experiments where we only use the BANKING or the HOTELS portion of the entire dataset; (ii) *both-domain* experiments (termed ALL) where we use the entire dataset and combine the two domain ontologies (see Table 2); (iii) *cross-domain* experiments where we train on the examples associated with one domain and test on the examples from the other domain, keeping only *shared* intents and slots for evaluation. The key questions we aim to answer are: Are there major performance differences between the two domains and can they be merged into a single (and more complex) domain? Is it possible to use examples labeled with generic intents from one domain to boost another domain, effectively increasing reusability of data annotations and reducing data scarcity?

F_1 (micro) is the main evaluation measure in all ID and SL experiments.

4.1 Intent Detection: Experimental Setup

We evaluate two groups of SotA intent detection models: (i) *MLP-Based*, and (ii) *QA-Based* ones.

MLP-Based ID Baselines. Casanueva et al. (2020) and Gerz et al. (2021) have recently shown that, for the ID task, full and expensive fine-tuning of large pretrained models such as BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019a) is not needed to reach strong ID performance. As an alternative, they propose a much more efficient *MLP-based* approach to intent detection which works on par or

---

[13] Due to folding, variations in results with different random seeds were negligible, even in lowest-data setups.

[14] Effectively, Large-data experiments can be seen as 10-Fold experiments with swapped training and test data.

even outperforms full fine-tuning on the ID task.[15] In a nutshell, the idea is to use fixed/frozen "off-the-shelf" universal sentence encoders such as ConveRT (Henderson et al., 2020) or Sentence-BERT (Reimers and Gurevych, 2019) models to encode input sentences. A standard multi-layer perceptron (MLP) classifier is then learnt on top of the sentence encodings.

Two core differences to the previous work stem from the fact that we now deal with the multi-label ID task: **1)** to this end, we replace the output *softmax* layer with the *sigmoid* layer; and **2)** we define a threshold θ which determines the final classification: only intents with probability scores $\geq \theta$ are taken as positives. This way, the hyper-parameter θ effectively controls the trade-off between precision and recall of the multi-label classifier.

We comparatively evaluate several widely used state-of-the-art (SotA) sentence encoders, but remind the reader that this decoupling of the MLP classification layers from the fixed encoder allows for a much wider empirical comparison of sentence encoders in future work. The evalauted sentence encoders are: **1) CONVERT** (Henderson et al., 2020), which produces 1,024-dimensional sentence encodings; **2) LABSE** (Feng et al., 2020) (768-dim); **3) ROBL-1B** (1,024-dim) and **4) LM12-1B** (384-dim) (Reimers and Gurevych, 2019; Thakur et al., 2021). For completeness, we provide brief descriptions of each encoder in our evaluation, along with their public URLs, in Appendix B, and refer the reader to the original work for more details about each sentence encoder.

QA-Based ID Baselines. Another group of SotA ID baselines reformulates the ID task into the (extractive) question-answering (QA) problem (Namazifar et al., 2021; Fuisz et al., 2022). This QA-oriented reformatting then allows for additional specialised QA-tuning of large PLMs. In a nutshell, the idea is to (i) fine-tune the original PLM such as BERT/RoBERTa on readily available large general-purpose QA data such as SQuAD (Rajpurkar et al., 2016), and then (ii) further fine-tune this general QA model with in-domain ID data. This strategy has recently shown very strong performance on single-label ATIS data (Namazifar et al., 2021).

The main 'trick' is to reformat the input ID examples into the following format: *"yes. no. [SENTENCE]"* and pose a question such as: *"is the intent to ask about [INTENT]?"* (see Appendix A for the actual questions associated with each intent, also shared with the dataset). Here, *[SENTENCE]* is the placeholder for the actual input sentence, and *[INTENT]* is the placeholder for a short manually defined text (akin to language modeling prompts (Liu et al., 2021), see again Appendix A) which briefly describes the intent. The QA formulation lends itself naturally to the multi-label ID setup as each 'intent-related' question is posed separately. In other words, for each input example and for each of the L intents in the ontology the QA model must extract *yes* or *no* as the answer, where correct intent labels are the ones for which the answer is *yes*.[16] We note that our work is the first to apply and evaluate the QA approach on multi-label ID.

We experiment with two pretrained language models, both fine-tuned on the SQuAD2.0 dataset (Rajpurkar et al., 2018) before additional QA-tuning on NLU++ examples converted to the aforementioned QA format: **ROBB-QA** uses RoBERTa-Base as the underlying LM, while **ALB-QA** relies on the more compact ALBERT (Lan et al., 2020).

ID: Training and Evaluation. All MLP-based baselines rely on the same training protocol and hyper-parameters in all data and domain setups. The MLP classifier consists of 1 hidden layer of size 512, and is trained via binary cross-entropy loss for 500 epochs with the batch size of 32 and the dropout rate is 0.6. We use the standard AdamW optimizer (Loshchilov and Hutter, 2018) with the learning rate of 0.003 and linear decay; weight decay is 0.02. The threshold θ is set to 0.4.[17]

For QA models, we largely follow Namazifar et al. (2021) and fine-tune all models for 5 epochs, using AdamW; the learning rate of $2e{-}5$ with linear decay; weight decay is 0; batch size is 32.

---

[15] Our preliminary results on the NLU++ dataset corroborated these findings from prior work; due to a large number of experiments, we thus opt for this more efficient yet also very effective approach to ID.

[16] For instance, for the input sentence *"I need to increase my overdraft"* from the BANKING domain, we would pose all 48 questions associated with each of the $L = 48$ intents in BANKING, where the QA model should extract *yes* as the answer for intents *change*, *overdraft* and *more_higher_after*, and extract *no* for the remaining 45 intents in BANKING.

[17] These hyper-parameters were selected based on preliminary experiments with a single (most efficient) sentence encoder LM12-1B and training only on Fold 0 of the 10-Fold BANKING setup; they were then propagated without change to all other MLP-based experiments with other encoders and in other setups. We repeated the similar hyper-parameter search procedure for QA-based models, using ALB-QA..

	BANKING			HOTELS			ALL

4.2 Slot Labeling: Experimental Setup

For slot labeling, we benchmark two current SotA models: (i) *ConvEx* (Henderson and Vulić, 2021), as a SotA span-extraction SL model and (ii) the QA-based SL model (Namazifar et al., 2021) based on RobB-QA, which operates similarly to QA-based ID baselines discussed in §4.1, and relies on the same fine-tuning regime as our QA-based ID baselines. Again, we refer the reader to the original work for further details, and provide brief descriptions in Appendix D.

4.3 Results and Discussion

Main results with all the evaluated baselines are summarised in Table 6 (for ID) and Table 7 (SL).

ID: MLP versus QA Models. First, the comparisons among only MLP-based models reveal that **1)** all sentence encoders offer ID performance in similar, reasonably narrow score intervals (e.g., the variations in F_1 scores between all sentence encoders are typically below 4-6 F_1 points in all setups), and **2)** that ConveRT is the best-performing sentence encoder on average, which corroborates findings from prior work on other ID datasets (Casanueva et al., 2020; Wu and Xiong, 2020).

One very apparent and important indication in the reported results is the superiority of QA-based ID models over their MLP-based competitors. QA-based models largely outperform MLP-Based baselines in all domain setups, as well as in all data setups. The gains are visible even in Large-data setups, but the benefits of QA-based ID are immense in the lowest-data 20-Fold setups: e.g., 12 F_1 points over the strongest MLP ID model on HOTELS and 20 F_1 points on BANKING.

Moreover, the use of larger underlying LMs might push the scores with QA even further: using SQuAD-tuned Roberta-Large (RobL-QA) instead of Base (RobB) yields further gains – e.g., F_1 rises from 85.6 to 87.8 on 10-Fold BANKING, and similar trends are observed in other low-data setups.

Slot Labeling. In the SL task, the QA-based model also demonstrates its superiority, again with huge gains in low-data 20-Fold and 10-Fold setups, confirming that such QA-based or prompt-based methods (Liu et al., 2021; Gao et al., 2021) are especially well suited for low-data setups. The use of manually defined questions/prompts, which are typically easy to write by humans, combined with the expressive power of QA-based task formatting yields immense gains on low-resource dialogue NLU.

Given these very promising ID and SL results on NLU++, our work also calls for further and more intensive future research on QA-based models for dialogue NLU. However, we note that QA-based ID and SL methods do come with efficiency detriments, especially with larger intent and slot sets: the model must copy the input utterance and run a separate answer extraction for each intent/slot from the set, which is by several order of magnitudes more costly at both training and inference than MLP-based models. A promising future research avenue is thus to investigate combined approaches that could combine and trade off the performance benefits of QA-based models and the efficiency advantages of, e.g., MLP-based ID.

Low-Data vs. Large-Data. We also note that scores on both tasks, as reported in Tables 6-7, leave ample room for improvement in NLU methodology in future work, especially on SL (even in Large-data setups), and in low-data setups.

Cross-Domain Experiments. We also verify potential reusability of annotated data across domains with a simple ID experiment, where we train ID models on BANKING and evaluate on HOTELS, and vice versa. The results are summarised in Table 8. Besides (again) indicating that QA-based models outscore MLP-based ID, the results also suggest that for some *generic* intents it is possible to meet high ID performance without any in-domain annotations. For instance, we observe particularly high scores for highly generic and reusable intent modules such as *change*, *how*, *how_much*, *thank*, *when*, and *affirm*, all with per-intent F_1 scores of ≥ 90. We hope that these preliminary results might inspire similar ontology (re)designs in future work.

5 Conclusion

We have presented NLU++, a novel dataset for task-oriented dialogue (ToD) NLU that overcomes the shortcomings of previous NLU evaluation sets. NLU++ presents a multi-intent and slot-rich ontology, defines generic and domain-specific intents and slots to promote data reusability, and it focuses on the creation of high-quality complex examples and annotations collected by dialogue experts. Experimental results show that NLU++ raises the bar with respect to current NLU benchmarks, helping better discriminate and compare the performance of current state-of-the-art NLU models, particularly in low-data setups. We hope that NLU++ will be valuable in guiding future modeling efforts for ToD NLU, both in academia and in industry.

Limitations and Future Work. This work has shown that a better design of the intent set can improve data reusability. However, the current ontology does not cover generic sets of intents exhaustively, and we acknowledge a (sometimes) fine line between truly generic intents versus intents 'anecdotally' shared by two domains (e.g., *refund*). Further, the boundaries of some generic intents can sometimes be unclear and difficult to annotate, even for expert annotators.[18] Future work should try to ground the set of generic intents.

Further, we believe that span-based annotation might be sub-optimal for canonical values such as *times* and *dates*, where small differences in the span would lead to evaluation errors but would not suppose a problem for the value to be parsed. In addition, separating *time* and *date* intervals in different slots increases the difficulty of the annotations and models need to learn a more conflicting set of slots. Further, NLU++ currently provides fine-grained slots such as *date_from*, *date_to* and *date* to enable more complex scenarios, but such a design might slow down annotation process and make it cumbersome. Future work includes rethinking the SL task for these slots.

Finally, while single-turn NLU is more data-efficient and easier to model, some user utterances only make sense in the presence of context from the previous system utterance. While some previous datasets (Coope et al., 2020) deal with this issue with the help of extra annotations indicating if a slot has been requested, in this work we opt for using *non-contextualised* slots such as *number* and *time* and let the policy handle the contextualisation. However, future work should start looking into NLU datasets composed by *system* + *user* turns.

Acknowledgements

We are grateful to our colleagues in PolyAI for many fruitful discussions and suggestions. We also thank the anonymous reviewers for their helpful feedback and comments on the presentation.

Ethical Considerations

PolyAI Limited is ISO27k-certified and fully GDPR-compliant.

---

[18] For example, boundaries for intents like *greet*, *why* and *change* are clear, while others such as *make* or *not_working* are more prone to ambiguity and different interpretation.

Before data collection: all the data has been collected by workers of PolyAI Limited and all the annotators are also employees of PolyAI Limited.

During data collection: we did not include any personal information (e.g. personal names or addresses) and all the examples that included any had been fully anonymised or removed from the dataset. All the names in the dataset are created by randomly concatenating names and surnames from the list of the top 10K names from the US registry. Upon collection, the dataset has undergone an additional check by the internal Ethics committee of the company. NLU++ is licensed under CC-BY-4.0.

A Appendix: Ontology

The complete ontology of NLU++ is provided in Table 9 and Table 10.

B Appendix: Sentence Encoders in Intent Detection Experiments

ConveRT (Henderson et al., 2020) is trained with the conversational response selection objective (Henderson et al., 2019b) on large Reddit data (Al-Rfou et al., 2016; Henderson et al., 2019a), spanning more than 700M *(context, response)* sentence pairs. Thanks to its naturally conversational pretraining objective, it has been shown to be especially well-suited for conversational tasks such as intent detection (Casanueva et al., 2020) and slot labelling (Coope et al., 2020). It outputs 1,024-dim sentence encodings.

- `github.com/davidalami/ConveRT`

LaBSE. Language-agnostic BERT Sentence Embedding (LaBSE) (Feng et al., 2020) adapts pretrained multilingual BERT (mBERT) (Devlin et al., 2019) using a dual-encoder framework (Yang et al., 2019) with larger embedding capacity (i.e., a shared multilingual vocabulary of 500k subwords). While LaBSE is the current state-of-the-art multilingual encoder, it also displays very strong monolingual English performance (Feng et al., 2020). It produces 768-dim sentence encodings.

- `huggingface.co/sentence-transformers/LaBSE`

RobL-1B and **LM12-1B** (Reimers and Gurevych, 2019; Thakur et al., 2021) are sentence encoders which fine-tune the pretrained Roberta-Large (RobL) language model (Liu et al., 2019a) and the 12-layer MiniLM (Wang et al., 2020b), respectively, again using a contrastive dual-encoder framework (Reimers and Gurevych, 2019). The models are fine-tuned on a set of more than 1B sentence pairs: this set comprises various data such as Reddit 2015-2018 comments (Henderson et al., 2019a), Natural Questions (Kwiatkowski et al., 2019), PAQ (question, answer) pairs (Lewis et al., 2021), to name only a few.[19] RobL-1B outputs 1,024-dim encodings, while LM12-1B produces 384-dim encodings.

We opted for those two models in particular as one represents a class of large sentence encoders (RobL-1B), and the other is lightweight (LM12-1B), while both display very strong performance in a myriad of sentence similarity and semantic search tasks, see `www.sbert.net/docs/pretrained_models.html`.

- `huggingface.co/sentence-transformers/all-roberta-large-v1`
- `huggingface.co/sentence-transformers/all-MiniLM-L12-v1`

C Appendix: QA-Pretrained Models

We rely on the same SQuAD-tuned language models as Namazifar et al. (2021). **RobB-QA** can be found online at: `https://huggingface.co/deepset/roberta-base-squad2`; **ALB-QA** is available at: `https://huggingface.co/twmkn9/albert-base-v2-squad2`

D Appendix: Slot Labeling Baselines

ConVEx (Henderson and Vulić, 2021) demonstrates strong SL performance, especially in few-shot settings. It is pretrained on a pairwise cloze task extracted from the Reddit examples (Henderson et al., 2019a), and the majority of the pretrained model's parameters in ConVEx are kept frozen during fine-tuning, making it an extremely efficient model. We adopt the suggested hyper-parameters from Henderson and Vulić (2021).

QA-Based: Namazifar et al. (2021) train an extractive QA-based model to extract the spans of the slots from the input user utterance as answers to manually defined natural language questions (one per slot). It follows the same idea as QA-based ID models. We also provide such questions for each slot along with NLU++ for model training and inference: see the questions in Table 10.

---

[19] In a nutshell, the contrastive fine-tuning task which combines all the heterogeneous datasets is as follows: given a 'query' sentence from each sentence pair, and a set of R randomly sampled negatives plus 1 true positive (the sentence from the same pair), the model should predict which sentence from the set of $R + 1$ sentences is actually paired with the query sentence in the dataset. The full list of all datasets along with the exact model specifications is at: `huggingface.co/sentence-transformers/all-roberta-large-v1`.

Challenges in Generalization in Open Domain Question Answering

Linqing Liu[†] **Patrick Lewis**[‡†] **Sebastian Riedel**[‡†] **Pontus Stenetorp**[†]
[†]University College London [‡]Facebook AI Research
`{linqing.liu,patrick.lewis,s.riedel,p.stenetorp}@cs.ucl.ac.uk`

Abstract

Recent work on Open Domain Question Answering has shown that there is a large discrepancy in model performance between *novel* test questions and those that largely overlap with training questions. However, it is unclear which aspects of novel questions make them challenging. Drawing upon studies on systematic generalization, we introduce and annotate questions according to three categories that measure different levels and kinds of generalization: *training set overlap*, *compositional generalization (comp-gen)*, and *novel-entity generalization (novel-entity)*. When evaluating six popular parametric and non-parametric models, we find that for the established Natural Questions and TriviaQA datasets, even the strongest model performance for comp-gen/novel-entity is 13.1/5.4% and 9.6/1.5% lower compared to that for the full test set – indicating the challenge posed by these types of questions. Furthermore, we show that whilst non-parametric models can handle questions containing novel entities relatively well, they struggle with those requiring compositional generalization. Lastly, we find that key question difficulty factors are: cascading errors from the retrieval component, frequency of question pattern, and frequency of the entity.

1 Introduction

Over the last few years we have seen model innovations improving on standard natural language processing (NLP) benchmarks across the board (Devlin et al., 2019; Raffel et al., 2020; Lewis et al., 2020a). However, it is still clear that we are yet to obtain generalizable language understanding, as recent work has found that adversarial (Jia and Liang, 2017; Mudrakarta et al., 2018; Belinkov and Bisk, 2018) and out-of-distribution samples (Talmor and Berant, 2019; Elsahar and Gallé, 2019; McCoy et al., 2020) remain challenging for existing models across numerous tasks.

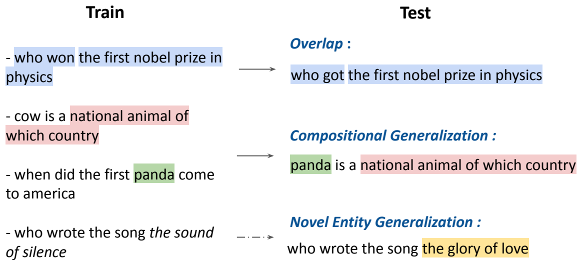

Figure 1: Questions categorized according to their relation to the training set: 1) *Overlap*: there exists a paraphrase of the question in the training set. 2) *Compositional*: all individual facts and the structure of the question has been observed across several questions in the training set – but not the given composition. 3) *Novel-entity*: the question contains at least one entity (marked here with yellow) not present in the training set.

Open-domain question answering (ODQA), which aims to answer factoid questions without any given context, is a task that has been receiving increasing attention in the community (Chen et al., 2017; Lee et al., 2019; Karpukhin et al., 2020; Izacard and Grave, 2021; Min et al., 2021). However, recent work has shown that there is a large discrepancy in model performance between questions and answers observed at train time and *novel* questions and answers – even if they are derived from the same distribution (Lewis et al., 2021a). This raises the question: "What are the aspects of these novel questions that make generalization challenging?" which we seek to explore in this paper.

In work on systematic generalization (Bahdanau et al., 2018; Lake and Baroni, 2018; Ruis et al., 2020), it is argued that even though a model has only observed a very small subset of all possible combinations of facts during training time, a good model should be able to generalize to all possible combinations of facts at test time. We draw upon these ideas to study generalization for ODQA and define the following three categories to support our investigation: *training set overlap*, *composi-*

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2014 - 2029
July 10-15, 2022 ©2022 Association for Computational Linguistics

tional generalization, and *novel-entity generalization*. See Figure 1 for definitions and examples. Our categorization breakdown is motivated by how they capture different levels of generalization: *overlap* requiring no generalization beyond recognizing paraphrases, *comp-gen* requiring generalization to novel compositions of previously observed entities and structures, and *novel-entity* requiring generalization to entities not present in the training set. It is worth noting that we explicitly study in-distribution generalization rather than out-of-distribution generalization (such as cross-domain generalization (Fisch et al., 2019)), as we will later demonstrate that even in-distribution generalization poses a major challenge for existing approaches.

We decompose and manually annotate three previously introduced ODQA datasets (Natural Questions (Lee et al., 2019), TriviaQA (Joshi et al., 2017), and WebQuestions (Berant et al., 2013)). Following this, we evaluate six recently proposed non-parametric and parametric ODQA models and analyze their performance, using both aggregate metrics and a breakdown according to our proposed categories. Non-parametric and parametric models differ in their access to information: the former has no access to any external context or knowledge, whereas the latter is provided relevant information alongside the question (Roberts et al., 2020).

One potential source of difficulty could be the question structure itself and as a byproduct of our decomposition approach we are able to derive a high-level *question pattern* for each question. We find a strong positive correlation between the pattern frequency in the training set and test accuracy. We then study how non-parametric models handle the comp-gen and novel-entity subsets respectively, since the performance on them is significantly worse than on the overlap subset. For *comp-gen* questions, perhaps surprisingly, we find that the frequency of entities mentioned in a question is strongly *negatively* correlated with test accuracy. For *novel-entity* questions, when we replace novel entities in the question and its support passages with entities seen in the training set the performance remains largely unchanged; we thus hypothesize that specific unseen entities are not the main bottleneck for model performance but rather a failure of the model to generalise compositionally. Aside from questions, we further analyze the retrieved passages and find the retrieval accuracy is equally lacking for the *comp-gen* and *novel-entity* subsets, at $\sim 75\%$ for top-20 accuracy. We also observe that many of the passages that do contain the correct answer lack sufficiently informative contexts for the question anchor words for the reader model to be able to locate it, indicating a need to either improve the reader models ability reason over multiple passages or the retriever model to provide passages with richer contexts.

To conclude, our key contributions are as follows: 1) We provide the first detailed study on generalization for ODQA, based on categories that measure different levels and kinds of generalization, that we use to annotate three previously proposed ODQA datasets [1]. 2) We show that for novel questions, non-parametric models handle novel question entities comparatively well, while they struggle to perform compositional generalization. 3) We demonstrate and quantify key factors that impact model generalization performance, which we believe will show the direction for future research towards more robust and generalizable ODQA models.

2 Dataset Construction

In this section, we describe how we process and annotate ODQA datasets to enable us to investigate generalization.

2.1 Question Decompostition

To study the compositional and novel-entity generalization of questions, we follow Keysers et al. (2019) and propose to view each question as being composed of primitive elements (atoms). Consider the question *"Who got the first Nobel Prize in Physics?"*. The atoms intuitively correspond to the modifier or adjunct of the predicate "who", predicate "got" and the entity "first nobel prize in physics". The combination of these atoms cover the main semantics of the question.

The way we measure generalization necessarily depends on how we break down the questions into atoms. Following manual analysis of questions from three popular ODQA datasets, we developed the following decomposition strategy to obtain atoms which cover all the desired question semantics. These are: question words, verbs, Wikipedia named entities (*wiki_entities*), and finally, other arguments (*other_args*) which correspond to other relevant aspects of the question. We explicitly ex-

---

[1] Our data and code are available at `https://github.com/likicode/QA-generalize`

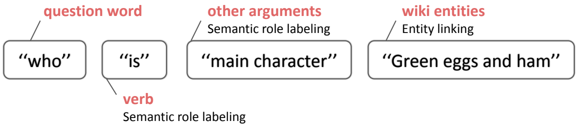

Figure 2: Example decomposition for the question *"Who is the main character in Green eggs and ham?"*

Group	Natural Questions	WebQ	TriviaQA
Overlap	837	501	458
Comp-gen	1,105	512	475
Novel-entity	597	640	456

Table 1: Number of questions for each generalization subset for the three datasets' test sets

tract wiki_entities since they leverage crucial semantics in factoid questions and other_args define essential details surrounding wiki_entities.

In order to automatically decompose questions, we first use an off-the-shelf semantic role labeling (SRL) model (Shi and Lin, 2019) to produce predicate-argument structures for each question. This provides us with the verb (i.e. the predicate), and semantic arguments. The question word is trivially obtained by identifying WH-words. We apply an off-the-shelf entity linking model (Li et al., 2020) to obtain the wiki_entities in the question. Finally, other_args are the SRL arguments which remain after we filter out arguments corresponding to wiki_entities. An example question decomposition is illustrated in Figure 2. More details are included in Appendix A.1.

2.2 Generalization Category Definitions

Based on the question decomposition, we define three generalization categories for ODQA datasets. We denote S_q as the set of the decomposed atoms of question q and C_Q as the complete set of decomposed atoms for all the questions in dataset Q. Our category subsets are then defined as:

- $Q_{\text{overlap}} \triangleq \{q \in Q_{\text{test}} \mid \exists\, q' \in Q_{\text{train}}, S_q \subseteq S_{q'}\}$
- $Q_{\text{comp\_gen}} \triangleq \{q \in Q_{\text{test}} \mid \exists\, q'_1, q'_2, ..., q'_k \in Q_{\text{train}},\ S_q \subseteq \bigcup_{i=1}^{k} S_{q'_i},\ S_q \nsubseteq S_{q'_i}\}$
- $Q_{\text{novel\_entity}} \triangleq \{q \in Q_{\text{test}} \mid \exists\, s \in S_q, s \notin C_{\text{train}}\}$

For overlap test question, there exists a training question where they have the same decomposed atoms or are subset of them; for comp_gen test question, its decomposed atoms are fully covered by the training set (a subset of the union of multiple training questions atoms), but not in one particular training question; and for novel-entity test question, there exist wiki_entities not present in the training set.

2.3 Question Categorization and Human Verification

With the decomposed atoms for all questions, we first categorize the test questions into overlap, comp-gen, and novel-entity categories based on the definitions of each generalization category. We optimize the selection criteria to cover as many eligible candidates for each category as possible. Further details can be found in Appendix A.2.

As our test set subsets are obtained automatically, we need to perform manual human verification to ensure that they are of high enough quality to draw empirical conclusions. To do this, we employ four expert annotators and use the following annotation process for each of the respective categories. *Overlap:* Annotators are shown q_{test} and the training questions with the highest degree of character-level overlap. If any of these questions are a paraphrase of q, the annotator will mark q_{test} as an *overlap* question. *Comp-gen:* q_{test} is presented to the annotators along with the training questions with the highest degree of word overlap. Annotators then verify that the test question is truly a compositional generalization and not a paraphrase of any of the given training questions. *Novel-entity:* Annotators need to: 1) Verify that the wiki_entities identified by the entity-linking model are indeed wiki entities. 2) Verify that the entities in q_{test} are not present among a set of questions from the training set whose entities have a high degree of character-level overlap with the entities in q_{test}. Statistics for the annotated category subsets are summarized in Table 1, examples are shown in Table 2, and additional details are covered in Appendix A.3.

3 Experiment

3.1 Datasets

We analyse three widely used ODQA datasets, each one is briefly introduced as follows:

Open Natural Questions (NQ) is an open-domain variant of Natural Questions (Kwiatkowski et al., 2019) introduced by Lee et al. (2019). This dataset consists of questions mined from Google

Group	Test question	Paired training question for annotator	Label
Overlap	who got the first nobel prize in physics	who won the first nobel prize in physics	T
	whens the last time the patriots played the eagles	when did the philadelphia eagles last win the super bowl	F
Comp-gen	when is the next scandal episode coming out	when is next fairy tail episode coming out	T
	what is the corporate tax rate in great britain	what is the rate of corporation tax in uk	F
Novel-entity	who wrote the song the *glory of love*	who sang *guilty of love* in the first degree	T
	who sings *too much time on my hands* lyrics	who sings *i've got too much time on my hands*	F

Table 2: Example of questions from Natural Questions (see Appendix A.8 for examples from the other two datasets) for human verification and their respective annotated labels (T for True and F for False).

search logs, with answers annotated as short spans of text in Wikipedia articles by crowd-workers. The NQ questions are generally simple, short, and *information-seeking*, as the questioner is unlikely to have known the question's answer when they formulated it. It consists of 79,168 train, 8,757 dev, and 3,610 test question answer pairs.

TriviaQA (Joshi et al., 2017) consists of questions and answers which were obtained by scraping trivia websites. TriviaQA questions are generally less information-seeking than those in NQ, and exhibit substantial syntactic and lexical variability. We use the open domain splits which contains 78,785 train, 8,837 dev, and 11,313 test question answer pairs (Lee et al., 2019). Answers in TriviaQA are Wikipedia entities, and any alias of the answer entity is considered a correct answer. We randomly sampled and annotated 2,000 questions from the test set for our analyses.

WebQuestions (Berant et al., 2013) consists of questions that were collected by performing a breadth-first search using the Google Suggest API. The questions in WebQuestions resemble those in NQ, but are generally shorter and simpler and demonstrate less variability. WebQuestions' answers are Freebase (Bollacker et al., 2008) entities, annotated by crowdworkers. It contains 3,778 train and 2,032 test questions.

3.2 Baseline Models

Non-parametric models mostly adopt a retrieve-and-read framework, retrieving relevant Wikipedia documents for the given question, and then produce the final answer conditioned on these documents. We consider two generative reader models: Retrieval-Augmented Generation (RAG, Lewis et al., 2020b), and Fusion-In-Decoder (FiD, Izacard and Grave, 2021). RAG combines a DPR (Karpukhin et al., 2020) dense retriever with a BART (Lewis et al., 2020a) generator, which are jointly fine-tuned end to end. FiD is a pipeline approach which uses DPR to retrieve a set of documents, and the decoder attends over all encoded document representations to generate the final answer. As an extractive reader model we use the reader component from DPR (Karpukhin et al., 2020). It extracts answer span from the highest-scoring document ranked from a passage selection model. We also include RePAQ (Lewis et al., 2021b), a QA-pair retriever which does *not* follow the retrieve-and-read paradigm. It retrieves QA-pairs from PAQ, a large resource of 65M automatically-generated QA-pairs, returning the answer of the most relevant QA-pair.

Parametric models are directly trained with QA pairs without access to an external corpus and thus store the required knowledge in its entirety in the model parameters. For our analyses, we include a BART-large model (Lewis et al., 2020a) and a more powerful T5-11B model (Roberts et al., 2020). They are both trained with questions as input and output question-answer pairs.

3.3 Model Category Analysis

Table 3 shows the Exact Match scores for models on our test set splits.

Non-parametric models on novel-entity questions For the non-parametric models, EM scores on *novel-entity* questions are relatively close to their overall total scores, with an average drop by 6.5% and 3.1% on NQ and TriviaQA respectively, with the exception of WebQuestions. The questions in WebQuestions only contain a single entity, which also tend to be high frequency entities. However, due to the very small size of the WebQuestions training set, many of these questions are considered to be in the novel-entity subset, despite containing relatively frequent entities, which, with a larger training set, would likely be classified as comp-gen questions, querying various relations regarding known entities.

Model		Natural Questions				TriviaQA				WebQuestions			
		Total	Overlap	Comp -gen	Novel -entity	Total	Overlap	Comp -gen	Novel -entity	Total	Overlap	Comp -gen	Novel -entity
Non-parametric	RAG	44.49	75.75	30.41	37.69	56.83	87.12	47.58	47.81	45.52	80.64	33.40	31.88
	FiD	**53.13**	78.85	**40.00**	**47.74**	**67.69**	**90.39**	**58.10**	**66.23**	-	-	-	-
	DPR	41.27	71.33	25.88	33.84	57.91	82.31	46.11	58.99	42.42	73.45	31.05	31.25
	RePAQ	47.26	78.61	34.21	36.85	52.06	89.08	42.95	38.38	-	-	-	-
Parametric	T5-11B+SSM	36.59	**81.48**	17.47	12.56	-	-	-	-	44.69	81.24	35.35	25.78
	BART	26.54	76.34	5.88	3.35	26.78	78.38	11.37	10.09	27.41	70.46	13.28	8.75

Table 3: Exact Match scores for each model. “Total” refers to the overall performance on the full test set. “Overlap”, “Comp-gen”, and “Novel-entity” refers to the model performance on the respective subset.

Non-parametric models on comp-gen questions Surprisingly, the performance of all non-parametric models degrades significantly on the *comp-gen subset* (drop by 14.2% on NQ, 10.2% on TriviaQA and 11.7% on WebQuestions). This finding suggests that non-parametric models struggle to perform compositional generalization, whereas they handle novel question entities comparatively well. We investigate this finding in greater detail in Section 4.

Parametric models on novel-entity and comp-gen questions parametric model performance drops significantly on both comp-gen and novel-entity subsets, but they achieve relatively higher EM scores on comp-gen questions. This indicates that novel-entity questions are more challenging for parametric models. This makes intuitive sense, since, for entities not seen during training, parametric models will struggle to “know" enough about the entity to generate a correct answer. In such cases, we find evidence that parametric models often resort to generating answers from superficially similar training questions, with 63.2% and 53.3% of answer predictions also occurring in the training data for T5-11B+SSM on NQ for comp-gen and novel-entity questions respectively.

Implications for modeling Among the non-parametric models, FiD achieves the highest EM scores for both comp-gen and novel-entity questions. FiD aggregates multiple passages together when generating answers. In contrast, the extractive DPR reader only uses the highest-scoring passage to extract the final answer. Based on observations from the experiment in Appendix A.4, we hypothesize that the NQ FiD model adopts a strategy similar to a reranker, and extracts an answer from the highest latently-relevant document.

Although without access to external knowledge but only automatically-generated QA-pairs in advance when answering questions, RePAQ still achieves higher or comparable performance as retrieve-and-read model RAG and DPR. It indicates that generating, storing and retrieving questions is a valid path in terms of model generalization.

NQ	Total	Overlap	Comp-gen	Novel-entity
Top-20	80.1	89.5	74.7	75.4
Top-100	86.1	92.0	82.4	83.1

Table 4: Top 20 and Top 100 retrieval accuracy on NQ test set for the DPR retriever.

Parametric models perform significantly worse compared to non-parametric models. BART struggles to answer any novel questions correctly, while T5-11B+SSM performs better due to much larger capacity. Petroni et al. (2019) demonstrate that language models are able to recall factual knowledge without any fine-tuning and can somewhat function as an unsupervised ODQA system. However, our experiments suggest that, large-scale language models (when fine-tuned to directly answer questions using a set of training QA pairs) struggle to answer questions about low frequency entities and relations, similar to the findings of Kassner et al. (2020) and Dufter et al. (2021).

Additional observations All models perform significantly higher on overlap questions, consistent with the findings of Lewis et al. (2021a). Parametric models with more parameters are the most effective at rote-memorizing training questions, and T5-11B+SSM even outperforms the non-parametric models on NQ and WebQuestions.

4 How Do Non-parametric Models Generalize?

Experimental results show that the performance of non-parametric models degrades significantly on the comp-gen subsets across all datasets. In this section, we would like to examine what the under-

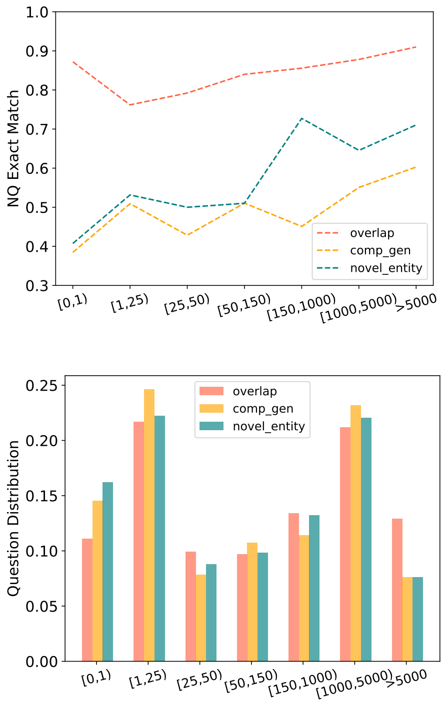

Figure 3: Influence of question pattern frequency, where test questions are binned based on the frequency of their question pattern in the *training set*.

lying challenge is for these questions. We focus on the NQ dataset as it has the largest annotated test set among three datasets.

Table 4 shows the top-k retrieval accuracy – which is the number of questions for which at least one passage of the top-k retrieved passages contains the gold answer. The difference in retrieval accuracy between comp-gen and novel-entity splits is relatively small ($< 1\%$), but is significantly lower than the overlap subset results. This indicates that the retriever performance is a confounding factor for the overall performance of comp-gen and novel-entity questions. Solely improving the retriever would benefit the model greatly for the subsets requiring generalization. Allowing us to study the reader model in isolation, for the remainder of our analysis we will only use the subset of questions for which there is at least one support passage that contains the gold answer.

4.1 Effects of Question Pattern Frequency

One might ask questions such as *"Who plays the doctor in Sons of Anarchy?"* and *"Who plays Stacey's mum in Gavin and Stacey?"*. Although semantically different, they share the structure "who plays [entity] in [entity]", which we refer to as a question pattern. To study if the frequency of these patterns affect model performance, we collect question patterns by replacing all wiki_entities in a question with the token *[entity]*, unifying the prepositions, and stemming each word.

We group test questions for each category by the frequency of their patterns in the training set. In Figure 3, we analyze FiD as an example since it achieves the highest EM score on unseen questions (results for other models can be found in Figure 6 in the Appendix). In the upper figure, the EM scores show that the model is more likely to make correct predictions for more common patterns. Given this observation, we would like to investigate if the significant performance edge of the overlap category is due to a larger percentage of more frequent patterns. According to the lower figure, which shows the proportion of questions for each frequency bin, the frequency distribution for each category is largely similar. Therefore the performance gap between overlap and the other two categories can not simply be explained by a difference in pattern distribution.

In Figure 3, we also note that as the pattern frequency increases, the performance between comp-gen and novel-entity diverges (for concrete question pattern examples see Figure 5). This gap has a significant effect on overall model performance, since common patterns make up a majority of the test set. Based on error analysis (see Appendix A.5 for details), we hypothesise that in the retrieved passages for comp-gen questions, answers do not always co-locate with the question anchor words. This indicates future research should encourage the retriever to fetch passages that cover all aspects of the question in order for it to be answerable. Under the assumption that the model could answer all patterns of questions equally well, regardless of frequency, the overall performance would be improved by $\sim 11\%$.

4.2 How do Non-parametric Models Handle Comp-gen Questions?

We use the decomposed atoms as the basis for our analyses on comp-gen questions. Following the previous subsection 2.1, we know that wiki_entities leverage crucial semantics for factoid questions and Wikipedia is the most widely used source of knowledge in current ODQA datasets (Yang et al., 2015; Hewlett et al., 2016; Rogers et al., 2021). Therefore, we would like to carefully study if the training set **wiki_entities** frequency affects model perfor-

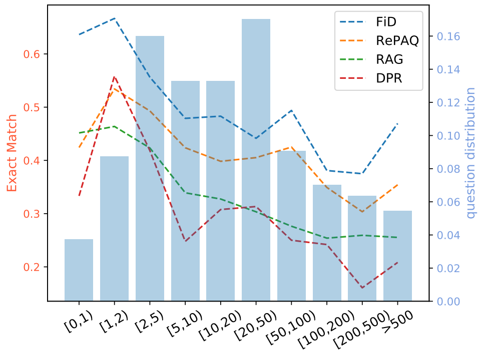

Figure 4: Plot showing the influence of the wiki_entities frequency in the question. The x-axis represents the wiki_entities frequency in the training set and we use the most frequent wiki_entities in each comp_gen question.

mance. Figure 4 plots the EM score as a function of how often a test question's wiki entity appears in a training question. We see that test accuracy is *anti-correlated* with the training-set frequency of test questions' entities. At first glance, this result seems surprising, and inconsistent with the well-known difficulty of modeling long-tail phenomena. However, the following interpretation helps to explain this apparent contradiction.

We manually inspect the questions with the most frequent wiki_entities, and find most of them are questions about countries, which is a frequent question topic in the NQ training set. For example, for the question *"How many farmers are there in the USA"*, almost all the retrieved passages are highly relevant. The gold answer is "3.2 million" with the context *"There were 3.2 million farmers"*. The model, however, generates the answer "2.2 million", taken from the context *"There were 2.2 million farms. . . "*. Both passages come from an article titled "Agriculture in the United States", and the model is failing to draw a distinction between *farms* and *farmers*. While it is easier to retrieve relevant documents for questions with more frequent wiki_entities (Chen et al., 2021), the passages retrieved for high-frequency entities are much more likely to contain type-consistent close-negatives and distractors, making it more difficult for the model to select the correct answer. In other cases, questions are highly ambiguous, such as, "*What is the average salary for a US congressman*", the gold answer *$174,000* applies for the year 2012, while predicted answer *$169,300* applies for the year 2008. For NQ, the existence of high-frequency entities could be indicative of an ambiguous question. If we conduct an analysis using the NQ dev set annotations provided by Min et al. (2020), we note that 50% of questions with the entity "*US*" and 64% of questions with the entity "*NBA*" are ambiguous. To quantify the impact, using FiD as an example, we note that if we match the performance of comp-gen questions with common wiki_entities to those with the unpopular wiki_entities, the accuracy could be improved with $\sim 4\%$ points.

Besides wiki_entities, it's prudent to consider the remaining atoms as well. The results are illustrated in Figure 7 and some findings are observed in the following: 1) For **question word**, all models achieve better performance for questions asking about WHO and WHICH, while performing worse on questions without any question word. Although EM scores drop significantly for WHY questions, it is hard to draw conclusions as there are only limited number of them in the test set. 2) There is no clear correlation between model performance and **verb** frequency. Some of the "best performing" verbs are: sing, sang, wrote, and play, which closely correlate with the most frequent question patterns such as "who sing song [ent]". 3) Since there is no clear correlation between model performance and other_args frequency either, we group test questions based on the number of **other_args** in each of the questions. It shows that models achieve higher EM scores on questions with fewer other_args. Interestingly, the most performing other_args are closely related to WHO and WHICH questions, such as "'s wife", "main character", and "tv show", while the "worse performed" other_args are mostly the comparative and superlative adjectives such as "biggest house" and "second largest" (also observed in Dua et al., 2019).

To summarize, the *remaining atoms* are codependent on each other, especially for limited-length factoid questions. They should preferably be treated as a single unit (e.g. question pattern) to arrive the meaning of the question. In essence, their compositionality cannot be ensured and isolated (Dankers et al., 2021). Wiki_entities on the other hands are independent of the context. The question is meaning-preserving even under wiki_entities substitution. The subpart for ODQA compositionality should focus on wiki_entities and question patterns. As discussed above, their individual frequency have different impacts on the various components of ODQA models.

4.3 How do Non-parametric Models Handle Novel-entity Questions?

Although we explicitly categorize unseen questions into comp-gen and novel-entity, broadly speaking, questions with novel entities also require the model to generalize to novel compositions and thus could be considered to belong to the comp-gen category. We seek to understand if the novel entities are the main bottleneck for ODQA models, or the model can handle them well enough to process the questions appropriately. To explore this issue further, we run an ablation study, where, at inference time, we replace the novel entities in the question *and* the support passages with an entity that has been seen from the training set. Our experimental setup is working under the following constraints: 1) There can be only one wiki_entity mentioned in the test question, so that replacing it will not risk altering the semantics of the original question. 2) The replacement entity must not be present in the original test question or its retrieved passages.

We run the inference for FiD model on 100 eligible questions, and find the model rarely changes its predicted answers, despite the modification, with 73% of the predicted answers remaining unchanged. We manually verified the remaining questions and observe that some differences are due to inherent limitations of our entity-swapping process, such as errors in entity-linking (see Appendix A.6 for examples). Interestingly, we find that three altered questions give the right answers, despite originally generating incorrect ones. Given these observations, we suggest that the model learns relatively good contextual embeddings for the novel entities by exploiting the context provided by the passages. Thus, specific unseen entities are not the main bottleneck for the model to locate the desired answers.

5 Related Work

5.1 Open Domain Question Answering

Early systems relied on surface text pattern matching methods to detect answers (Ravichandran and Hovy, 2002; Soubbotin and Soubbotin, 2001). For traditional ODQA systems, linguistic experts first identify a set of question types and expected answer types using rule-based mapping methods for each type of questions (Allam and Haggag, 2012). The input question needs to be classified into a certain type or taxonomy in order to be answered (Li and Roth, 2002; Suzuki et al., 2003). This approach is sub-optimal for most realistic use-cases, as it is not possible to enumerate all possible question types.

With the introduction of deep neural networks, recent ODQA system mostly adopt a "Retrieve-and-Read" architecture, popularized by Chen et al. (2017), retrieving relevant documents for a given question and inferring an answer from these documents. Recent retriever models learn to encode questions and documents into dense vectors to score their similarity (Lee et al., 2019; Karpukhin et al., 2020; Khattab et al., 2021). Reader models can be categorized into *extractive* models that predict an answer span within the document (Das et al., 2018; Lin et al., 2018; Yang et al., 2019) and *generative* that generate answers condition on the question and the retrieved passages (Lewis et al., 2020b; Izacard and Grave, 2021). Recent ODQA models provide substantial improvements over traditional systems (Zhu et al., 2021), but as shown in Section 4.1, they still struggle with complex and infrequent questions.

5.2 ODQA Model Analysis

Retrieving relevant passages is an essential component for open-book ODQA models. A broad spectrum of recent work apply transformer (Vaswani et al., 2017) models such as BERT (Devlin et al., 2019) for information retrieval (Yates et al., 2021). Following the success of using pretrained language models (Craswell et al., 2020), studies have been made regarding their properties. Luan et al. (2021) compare the lexical-matching abilities of these models to traditional methods such as BM25. Ma et al. (2021) and Wang et al. (2021) study reproducibility, and demonstrate improvements by combining lexical-matching and dense retrievers. Thakur et al. (2021) introduce the BEIR benchmark to study zero-shot generalization for multiple neural retrieval approaches. Their conclusion is consistent with our findings that there is considerable room for improving the generalization of dense-retrieval models.

To infer answers from retrieved documents, models generally use a *reader* component implemented as a neural Machine Reading Comprehension (MRC) model. Previous work has analyzed the MRC model by crafting adversarial attacks (Jia and Liang, 2017; Mudrakarta et al., 2018), studying the difficulty of popular benchmarks (Kaushik and Lipton, 2018), and demonstrating annotation bias (Gururangan et al., 2018; Sugawara et al., 2018; Chen and Durrett, 2019). Despite the success for various datasets, there is little work analyzing the whole pipeline of question answering systems. Lewis et al. (2021a) showed that models perform substantially worse on questions that cannot be memorized from training sets. Krishna et al. (2021) found that long-form question answering (LFQA) systems do not ground their answers in the retrieved passages. In contrast, for ODQA, we observe that when we replace retrieved passages with randomly-sampled passages at inference time, the model FiD (Izacard and Grave, 2021) largely fails to correctly answer any questions (see Appendix A.7 for experimental details). Gu et al. (2021) define similar generalization levels based on schemas for Knowledge Base Question Answering. However, our setting works without a schema and our generalization categories are derived from question decomposition atoms.

6 Conclusion

We study ODQA model generalization and categorize unseen questions into three subsets: *overlap*, *comp-gen*, *novel-entity*. Treating questions as being compositional, we decompose them into atomic elements based on their semantics. We believe that this decomposition strategy can help future work related to question structure and unification. We evaluated several recent ODQA models on these three subsets for three popular datasets. Our experimental findings both pinpoint the specific problems when handling different categories of novel questions and shed light on how to compositionally approach the factoid questions in ODQA task.

A Appendix

A.1 Question Decomposition

Below is a random selection of question decomposition examples from the NQ dataset. In each question, $\underline{\text{x}}_{qw}$ denotes the question_word, $\underline{\text{y}}_{verb}$ denotes the verb, and the spans of other_args and wiki_ents spans are denoted by brackets. Note that these structure slots are not always fully present in the question (e.g, Q3, Q4, Q6, Q7, Q10).

As we rely on automated systems as a part of our decomposition process, this leads to the following limitations. At times, the ELQ model fails to label wiki_ents, such as for Q8 where *every light in the house* is marked as other_args. Furthermore, as seen in Q9 there is the possibility of multiple question words being present although our approach only extracts a single question_word. Limitations such as these is one motivation for why we elected to perform manual verification for each question (Section 2.3).

1. $\underline{\text{Who}}_{qw}$ $\underline{\text{is}}_{verb}$ the [*other_args*: owner] of [*wiki_entities*: Reading Football Club]?
2. $\underline{\text{Who}}_{qw}$ $\underline{\text{died}}_{verb}$ in the [*other_args*: plane crash] [*wiki_entities*: Grey's Anatomy]?
3. [*other_args*: Cast] of [*wiki_entities*: Law & Order Special Victim Unit]?
4. $\underline{\text{When}}_{qw}$ did [*wiki_entities*: United States] $\underline{\text{enter}}_{verb}$ [*wiki_entities*: World War I]?
5. $\underline{\text{Where}}_{qw}$ are most [*wiki_entities*: nutrients] $\underline{\text{absorbed}}_{verb}$ in the [*wiki_entities*: human digestive tract]?
6. $\underline{\text{When}}_{qw}$ did the [*other_args*: government] $\underline{\text{change}}_{verb}$ the [*other_args*: retirement age]?
7. $\underline{\text{What}}_{qw}$ $\underline{\text{is}}_{verb}$ the [*other_args*: name] of the [*other_args*: gap] between [*other_args*: two front teeth]?
8. $\underline{\text{Who}}_{qw}$ $\underline{\text{sings}}_{verb}$ [*other_args*: every light in the house is on]?
9. $\underline{\text{Where}}_{qw}$ $\underline{\text{are}}_{verb}$ the [*wiki_entities*: Winter Olympics] and when do they start?
10. [*wiki_entities*: Swan Lake] [*wiki_entities*: the Sleeping Beauty] and [*wiki_entities*: the Nutcracker] $\underline{\text{are}}_{verb}$ [*other_args*: three famous ballets] by?

A.2 Question Collection for Human Verification

We use the following selection criteria to collect candidate questions for human verification. For the overlap subset, as a first step, each q is paired with each train question that shares the same answer or have answers which are a sub-sequence of q's answer. As a second step, we then require that the train question's similarity measurement score to q is over a pre-defined threshold and that they have the same wiki_entities as q. For the remaining test questions, we consider q as a candidate for comp-gen if all of its parsed elements are covered by the collection of all parsed elements in the training set. Lastly, if there exists any novel wiki_entities in q which are not present in the training set, q is considered as a novel-entity candidate.

A.3 Generalization Subset Details

As guidelines for the human annotators, we provide the following to resolve ambiguous or potentially problematic cases: 1) For overlap, we only consider questions that are superficial paraphrases and exclude those that require more complex forms of reasoning (e.g. *Who played Mark on the show The Rifleman? / Who played the boy on the show The Rifleman?*). 2) For comp-gen, all other_args in the test question must be covered in the collection of training set entities and all question_word atoms alongside with the verb must be present in the training set. However, there are questions where other_args are not covered in the training set (e.g. *Animation Resort*) or are highly specific due to the decomposition processing and thus not covered (e.g. *fourth movie* compared to *movie* or *three different types* compared to *types*) and are thus excluded from comp-gen. 3) For novel-entity, there are cases when ELQ fails to extract wiki_ents in questions because of words variation, such as *Who sang It Going to Take a Miracle?* compared to the correct wiki_ents *It's Gonna Take a Miracle*. 4) There are also intrinsic problems in the datasets, some test questions are exactly the same as train questions but paired with different answers: (*Where did Dolly Parton grow up?* with the answer *Tennessee* and *Where did Dolly Parton grew up* with the answer *Sevierville*). Following this manual verification, for Natural Questions, WebQuestions, and TriviaQA, 70.3%, 81.3%, and 69.5% of their test questions are covered in the generalization subsets respectively.

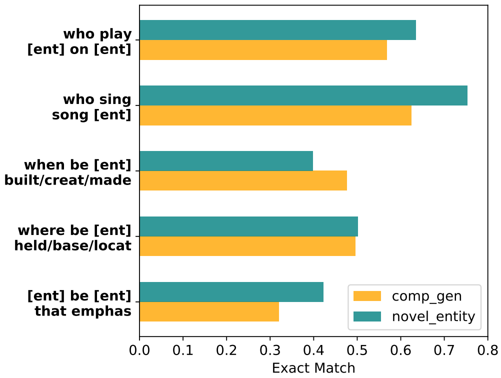

Figure 5: Examples of question patterns and EM scores for their corresponding questions. For each question pattern, we sample the same number of comp-gen and novel-entity questions. The two uppermost patterns are the most frequent (thousands of occurrences), the following two are of medium frequency (hundreds of occurrences), and the last is a novel pattern.

A.4 FiD Performance Analysis

Among the non-parametric models, FiD achieves the highest EM scores for both comp-gen and novel-entity questions. We are interested in understanding if FiD's improved performance is due to leveraging a greater amount of contextual evidence provided by multiple passages, or whether it simply generates the most frequently-mentioned plausible answer. We perform a simple experiment, by first collecting 544 questions answered incorrectly by FiD, where the gold answers occur less frequently than FiD's predicted answer in the retrieved passages. We then adjust the retrieved passages so that the original predicted answer and gold answer are mentioned an equal number of times, by masking out some of the original prediction mentions. After adjusting the frequencies, we regenerate the answer predictions, and observe that FiD only produces 44 correct answers out of 544. This suggests that answer mention frequency is not the governing feature for FiD when generating answers on NQ. It suggests the NQ FiD model adopts a strategy similar to a reranker, and extracts an answer from the highest latently-relevant document.

A.5 Additional Question Pattern Analyses

We sample the same number of comp-gen and novel-entity questions for each example pattern, and display the results in Figure 5. We checked several instances for the pattern "who play [ent] on [ent]", and find that the model fails more on comp-gen questions partially because the retrieved passages do not provide enough information to locate the answer. For example, for the question *"Who played Mary in Christmas with the Kranks?"* none of the retrieved passages contain both *Mary* and the movie name. The model produces the answer *Julie Gonzalo* from the passage *Julie Gonzalo Julieta [...] is an [...] actress. [She] is also known for her roles "Christmas with the Kranks"*, whereas the gold answer is *Felicity Huffman* from the passage *She also starred in [...] "Christmas with the Kranks"*. Since "Mary" is not mentioned in either passage, it is impossible to infer that the correct answer is *Felicity Huffman*. The support passages for novel-entity questions, on the contrary, more often cover both of the anchor entities (e.g. context *Little Boy Blue is an ITV drama series ... Stephen Graham was cast as Detective ...* for the question "*Who played the detective in Little Boy Blue*").

A.6 Additional Non-parametric Generalization Analysis

When analyzing the performance impact of the frequency of wiki_entities in questions, one will have to account for the fact that there might be more than one entity present in the same question. In our analysis in Section 4.2 we consciously only considered the most frequent entity in a question. Note that we also experiment with the least frequent entity and they show the same negative correlation between entity frequency and performance.

As we noted in Section 4.3, at times the novel entities in the original question may not match the corresponding mentions in the passage due to errors from the entity linking step. For instance, for the question *Who sings So Come and Dance with Me Jai Ho?* we swap the entity span "So Come and Dance with Me Jai Ho", however, this span is too wide as an entity as the correct entity would be "Jai Ho". Therefore the model is unable to match the correct song name in the passage; thus giving a different answer. Other error cases can be attributed to the granularity of the predicted answer: e.g. "624 CE" and "13 March 624 CE". We do however note that for the great majority of cases our entity-swapping procedure works as intended.

A.7 Answer Grounding in Retrieved Passages

We noted in Section 4 that we find evidence the FiD (Izacard and Grave, 2021) ODQA model does ground its answers in the retrieved passages. This observation can be contrasted to that of Krishna

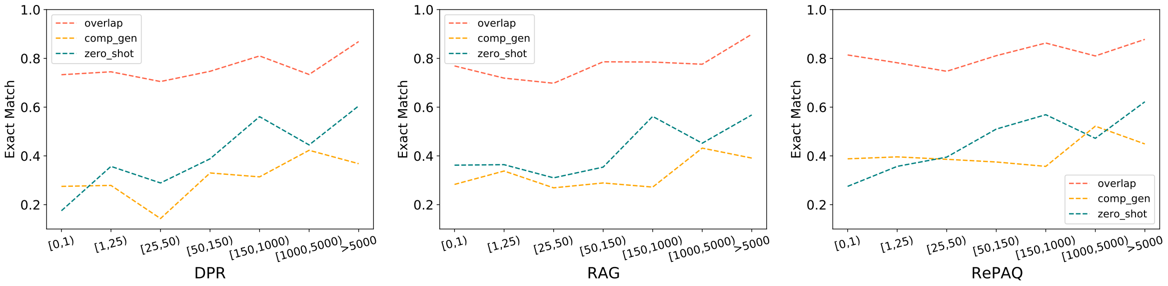

Figure 6: Influence of question pattern frequency. Each figure is associated with one non-parametric model, which is DPR, RAG and RePAQ from left to right. The test questions are binned based on the frequency of their question pattern in the training set. The y-axis shows the Exact Match score on the NQ test set.

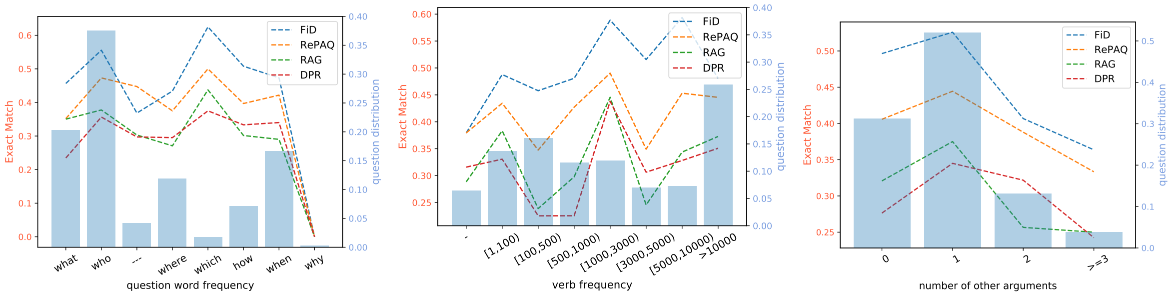

Figure 7: Influence of *question word*, *verb*, and *other_args* in the question (from left to right). For the two left-most figures, the test questions are binned based on the individual atom frequency in the training set, "-" indicates test questions whose question word or verb is not covered in the training set. For the right-most figure, the x-axis shows the number of other_args in each test question. All models are evaluated on the NQ test set.

Passage Processing	Total	Overlap	Comp-gen	Novel-entity
Original retrieved	53.1	78.9	40.0	47.7
50% random	53.2	78.3	39.9	48.3
99% random	55.5	74.3	46.1	54.0
100% random	3.6	5.1	2.0	3.0

Table 5: Comparison of FiD's predictions for the NQ test set, conditioned on the *originally retrieved* passages and a gradually increasing number of *randomly chosen* passages. x% means the percentage of retrieved passages are replaced with random ones. For *99% random*, the rest passage is gold passage which contains the gold answer span.

et al. (2021), who found that answers to long-form questions were not grounded in the passage, in that models would provide the same answer regardless of the context provided. A complete picture of the results from our experiment can be seen in Table 5. We note that when the models is fed solely random passages it fails to answer nearly all questions (3.6%). However, but provided with half gold and half random passages, it performs on par with its original performance. Lastly, we note that when presented with a single gold passage and otherwise only random passages, the model is still able to determine which passage is the gold passage and answer the question correctly – in fact, the performance even improves upon the original performance with more than more than 5% for comp-gen and novel-entity questions.

A.8 Additional Examples for three generalization subsets

Additional examples from Natural Questions are provided in Table 6, WebQuestions in Table 7, and TriviaQA datasets in Table 8.

Group	Test question	Train question

Beyond Distributional Hypothesis: Let Language Models Learn Meaning-Text Correspondence

Myeongjun Jang[1] **Frank Mtumbuka**[1] **Thomas Lukasiewicz**[2,1]

Abstract

The logical negation property (LNP), which implies generating different predictions for semantically opposite inputs (p is true iff $\neg p$ is false), is an important property that a trustworthy language model must satisfy. However, much recent evidence shows that large-size pre-trained language models (PLMs) do not satisfy this property. In this paper, we perform experiments using probing tasks to assess PLMs' LNP understanding. Unlike previous studies that only examined negation expressions, we expand the boundary of the investigation to lexical semantics. Through experiments, we observe that PLMs violate the LNP frequently. To alleviate the issue, we propose a novel intermediate training task, named *meaning-matching*, designed to directly learn a meaning-text correspondence, instead of relying on the distributional hypothesis. Through multiple experiments, we find that the task enables PLMs to learn lexical semantic information. Also, through fine-tuning experiments on 7 GLUE tasks, we confirm that it is a safe intermediate task that guarantees a similar or better performance of downstream tasks. Finally, we observe that our proposed approach[1] outperforms our previous counterparts despite its time and resource efficiency.

1 Introduction

Contemporary large-size PLMs, such as BERT (Devlin et al., 2019), ELECTRA (Clark et al., 2020), and GPT-2 and -3 (Radford et al., 2019; Brown et al., 2020), have shown excellent results in many downstream tasks, even performing better than humans in the GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019b) benchmark datasets.

However, their reliability is recently being challenged. Many studies have conducted various probing tasks and observed that PLMs exhibit faulty behaviours, such as insensitiveness to sentence ordering (Pham et al., 2021; Gupta et al., 2021; Sinha et al., 2021b), incomprehension on number-related representations (Wallace et al., 2019; Lin et al., 2020; Nogueira et al., 2021), and lack of semantic content understanding (Ravichander et al., 2020; Elazar et al., 2021). These issues raise concerns about PLMs' stability and reliability, precluding them from applications in practice, especially in risk-sensitive areas.

Another critical problem of PLMs is their inaccurate behaviour on *negation*, which is a principal property in many language understanding tasks. For tasks where the LNP holds (p is true iff $\neg p$ is false; see Aina et al. 2018), PLMs should make different answers for the original and negated inputs. However, several studies observed that PLMs violate this property. In masked knowledge retrieval tasks, PLMs frequently generate incorrect answers for negated input queries (Ettinger, 2020; Kassner and Schütze, 2020). In other studies, PLMs show a poor generalisation ability on negated natural language inference (NLI) datasets (Naik et al., 2018; Hossain et al., 2020).

Although the aforementioned studies produced promising analysis results, they limited the scope of the LNP only to adding negation expressions (e.g., "no" and "not"). However, other perturbations that generate the opposite meaning also can be applied to the property. Therefore, a consideration of such perturbation methods is necessary to fully assess whether PLMs satisfy the LNP.

Also, remedies to alleviate the problem have not been studied much yet. Hosseini et al. (2021) recently employed data augmentation and unlikelihood training (Welleck et al., 2020) to prevent models from generating unwanted words, given the augmented negated data during masked language modelling (MLM). However, this approach has several downsides. First, like previous works, Hosseini et al. (2021) only considered negation expressions. Second, the data augmentation method is contingent on many additional linguistic compo-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2030 - 2042
July 10-15, 2022 ©2022 Association for Computational Linguistics

nents, which causes the dependency of a model's performance on certain modules and precludes applying the method to other languages where such resources are unavailable. Finally, the model should be pre-trained from scratch with the unlikelihood objective, which consumes considerable time and resources.

In this paper, we expand the boundary of the LNP to lexical semantics, i.e., *synonyms* and *antonyms*, and ascertain that PLMs are prone to violate the LNP. Next, we propose a remedy, called **i**ntermediate-training on **m**eaning-**m**atching (IM^2), which hardly employs additional linguistic components. We hypothesise that a leading cause lies in the MLM training objective, which assumes the *distributional hypothesis* for learning the meaning of the text (Sinha et al., 2021a). Instead, we design a model that directly learns the correspondence between words and their semantic contents. Through experiments, we verify that our approach improves the model's comprehension of the LNP, while showing a stable performance on multiple downstream tasks.

Our main contributions are as follows: (i) We extend the investigation of the LNP from negation to lexical semantics (Section 2), (ii) we reveal that PLMs are prone to violate the LNP (Section 3), (iii) we propose a novel remedy, named IM^2, which is decoupled from the *distributional hypothesis* but learns meaning-text correspondence instead (Section 4), (iv) through experiments, we ascertain that the proposed approach improves the understanding of negation and lexical semantic information (Sections 5.1 and 5.2), and (v) we verify that meaning-matching is a stable and safe intermediate task that produces a similar or better performance in multiple downstream tasks (Sections 5.3 and 5.4).

2 Probing Tasks for Investigating the Logical Negation Property

We design three probing tasks to evaluate whether PLMs satisfy the LNP: masked knowledge retrieval on negated queries (MKR-NQ), masked word retrieval (MWR), and synonym/antonym recognition (SAR). Brief illustrations of each task are in Figure 1.

2.1 Masked Knowledge Retrieval on Negated Queries

The MKR-NQ task examines whether PLMs generate incorrect answers for negated queries. Following the work of Kassner and Schütze (2020), we constructed the evaluation dataset by negating the LAMA dataset (Petroni et al., 2019), which contains masked free-text forms of ConceptNet (Speer et al., 2017) triplets and their corresponding answers (e.g., (bird, CapableOf, fly) → ("A bird can [MASK]", fly)). The task aims to generate a correct word through MLM.

According to the LNP, a model must not generate the original answer if the query is negated. To measure how likely PLMs generate wrong predictions for negated queries, we collected pairs of (negated_query, wrong_predictions). We selected several relations in the LAMA dataset that ensure mutual exclusiveness between the original and negated queries.[2] For negating sentences, we selected LAMA data points that contain a single verb using the Spacy parts of speech (POS) tagger (Honnibal and Johnson, 2015). Next, we added negation expressions, such as "not" and "don't", or removed such expressions if they existed. Finally, we collected the wrong predictions from ConceptNet by using the head entity and relation. As a result, we collected 3,360 data points for this task. The list of the relations that we used and examples of the data are in Table 10 in Appendix A.

2.2 Masked Word Retrieval

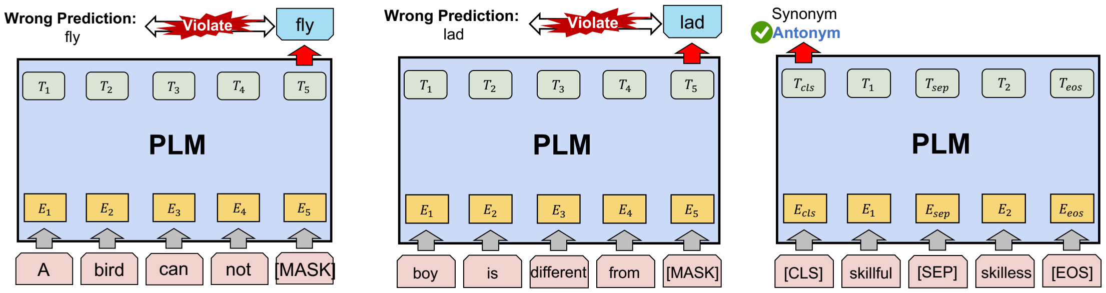
To expand the boundary of the LNP to lexical semantics, we design the MWR task, which generates an answer of a masked query, asking for the synonym/antonym of a target word through MLM (e.g., "happy is the synonym of [MASK]").

Let s_w and a_w denote masked queries that ask the synonym and antonym of the word w, respectively. Also, let A_s and A_a refer to the list of correct answers for s_w and a_w, respectively. Intuitively, A_a becomes the wrong predictions of s_w, because s_w and a_w have the opposite meaning. Therefore, we can evaluate the violation of the LNP by investigating whether a PLM generates wrong predictions.

To extract commonly-used words for our experiment, we first extracted nouns, adjectives, and adverbs that appear more than five times in the SNLI dataset (Bowman et al., 2015). Among the extracted candidates, we filtered words that have synonyms or antonyms in ConceptNet. Finally, we generated masked queries by employing templates used by Camburu et al. (2020). As a result, we collected about 27K data points for MWR. The

---

[2] For example, the *HasProperty* relation is not suitable to use, because sentences like "Some adults are immature" and "Some adults are not immature" are not mutually exclusive.



(a) MKR-NQ (b) MWR (c) SAR

Figure 1: Illustration of the MKR-NQ, MWR, and SAR tasks.

templates and examples of the data are in Table 11 in Appendix A.

2.3 Synonym/Antonym Recognition

SAR is a classification that distinguishes whether two given words are synonyms or antonyms. It aims to evaluate whether the contextualised representations of PLMs reflect the lexical meaning of words. Therefore, we use a parametric probing model (Adi et al., 2017; Liu et al., 2019a; Belinkov and Glass, 2019; Sinha et al., 2021a) for the experiment. Specifically, the experiment is performed on the final layer of each PLMs, i.e., we only train the classifier while keeping the encoder frozen. We use ConceptNet to build the dataset. ConceptNet has much more synonym triplets compared to antonyms. As a result, we randomly sample the synonym triplets to maintain a balance. To that end, we collect 33K, 1K, and 2K data points for the train, dev, and test datasets, respectively.

2.4 Evaluation Metrics

We use the top-k hit rate (HR@k) to evaluate the performance on the MKR-NQ and MWR tasks. Assume that $P = \{(p_1, c_1), (p_2, c_2), \ldots, (p_n, c_n)\}$ denotes the set of predictions for a data point x, where p_t and c_t refer to the predicted word and confidence score of the t-th prediction, respectively. Then, the top-k hit rate for a data point x is defined as follows:

$$HR@k(x) = \frac{\sum_{i=1}^{k} \mathbb{1}(p_i \in \mathcal{W}_x)}{k},$$

where $\mathcal{W}_x$ is the wrong prediction set of x. Intuitively, the metric measures the ratio of top-k predicted words that belong to the wrong prediction set.

To reflect the prediction confidence score to the evaluation metric, we additionally define the weighted top-k hit rate (WHR@k) that uses the confidence score as weights. It is worth to mention that lower metrics mean a better model performance in both cases as the metrics assess how likely the models make inaccurate answers that they must avoid. The weighted metric can be defined as follows:

$$WHR@k(x) = \frac{\sum_{i=1}^{k} c_i \times \mathbb{1}(p_i \in \mathcal{W}_x)}{\sum_{i=1}^{k} c_i}.$$

For the SAR task, we employ accuracy as an evaluation metric, because each data point has its own label, and the label distribution is not skewed.

3 PLMs Lack Information of Negation and Lexical Semantics

We select the following PLMs for the experiments: bidirectional encoder representations from transformers (BERT)-*base/large* (Devlin et al., 2019), RoBERTa-*base/large* (Liu et al., 2019b), and ALBERT-*base/large* (Lan et al., 2019). These PLMs are pre-trained with the MLM training objective. We added the ELECTRA-*small/base/large* models (Clark et al., 2020) for the SAR task, but it is not used for the MKR-NQ and MWR experiments, as the discriminator of the ELECTRA models are trained with the replaced token prediction (RTP) training objective and have no MLM classifier. No additional training is required for the MKR-NQ and MWR tasks. For the SAR task, we fine-tune each PLM for 10 epochs and apply the early stopping technique. We use the AdamW optimiser (Loshchilov and Hutter, 2019) for training with a learning rate of $5e^{-6}$ and a batch size of 32.

3.1 Results for MKR-NQ

The results for the MKR-NQ task are summarised in Table 1. In general, the results are consistent with previous works (Ettinger, 2020; Kassner and Schütze, 2020). We observe three important characteristics from the experimental results.

Model	MKR-NQ					MWR				
	HR@1	HR@3	WHR@3	HR@5	WHR@5	HR@1	HR@3	WHR@3	HR@5	WHR@5
BERT-*base*	9.57	6.38	8.42	5.00	7.81	35.03	18.83	28.71	13.26	26.03
BERT-*large*	13.33	7.70	11.17	6.03	10.51	36.66	20.45	29.68	14.60	26.56
RoBERTa-*base*	11.52	6.85	9.63	5.30	8.91	13.02	8.47	10.50	6.54	9.32
RoBERTa-*large*	15.72	9.25	13.31	6.86	12.24	27.92	17.07	23.06	12.84	20.82
ALBERT-*base*	4.24	3.75	4.24	3.26	4.09	26.37	14.95	22.10	10.75	20.32
ALBERT-*large*	9.22	6.38	7.96	4.94	7.30	50.77	25.05	42.67	17.03	39.09

Table 1: Overall results for the MKR-NQ and MWR experiments. We multiply 100 to each value to improve readability. Note that the lower the values the better.

	BERT		RoBERTa		ALBERT	
	base	*large*	*base*	*large*	*base*	*large*
$\mathcal{R}_{syn}$	37.79	36.58	17.13	46.01	11.37	76.10
$\mathcal{R}_{ant}$	41.44	41.79	13.57	30.21	33.26	62.65

Table 2: Ratios of instances that PLMs regenerate the word in the input sentence. $\mathcal{R}_{syn}$ and $\mathcal{R}_{ant}$ are the ratios of synonym and antonym-asking questions, respectively.

Model	Encoder-fixed		Fine-tune	
	$\mathcal{A}_{val}$	$\mathcal{A}_{test}$	$\mathcal{A}_{val}$	$\mathcal{A}_{test}$
BERT-*base* (108M)	53.1	55.0	84.0	85.6
BERT-*large* (333M)	54.4	53.5	92.1	92.5
RoBERTa-*base* (124M)	71.1	70.1	87.2	87.8
RoBERTa-*large* (355M)	69.7	69.1	93.7	94.2
ALBERT-*base* (11M)	56.6	58.1	81.5	84.0
ALBERT-*large* (17M)	54.7	56.6	86.9	88.0
ELECTRA-*small* (13M)	64.1	63.9	80.2	80.9
ELECTRA-*base* (109M)	67.9	70.6	93.3	92.9
ELECTRA-*large* (334M)	69.4	72.7	95.9	95.4

Table 3: Results of the SAR experiment. $\mathcal{A}_{val}$ and $\mathcal{A}_{test}$ are the accuracy of the *validation* and *test* dataset, respectively. We record the average of five repetitions.

First, large models produce a higher hit rate than their corresponding base-size models in all three PLMs, recording an average of about 1.5 times higher values. This implies that large-size models are more likely to generate wrong predictions for negated queries, even though they perform better than small-size models in many benchmark tests. The results suggest that evaluating a model's performance solely based on the accuracy metric is unwise.

Second, the hit rate decreases as k increases, which implies that the majority of PLMs' top predictions (e.g., k=1 or k=2) are incorrect. Finally, the weighted hit rate is much higher than the vanilla hit rate, suggesting that PLMs generate wrong predictions with high confidence.

3.2 Results for MWR

The results of the MWR task are summarised in Table 1. The three characteristics found in the MKR-NQ task are also observed in the MWR task. Also, we found the following additional patterns.

PLMs lack knowledge of antonyms. In general, the hit rates are extremely high compared to the MKR-NQ task in all the PLMs. Analysing their predictions, we find that PLMs generate incorrect predictions primarily in antonym-asking queries. Specifically, the average HR@1 of the antonym-asking queries is 41.9%, while that of the synonym-asking queries is only 1.4%. A leading cause is that PLMs simply replicate the word presented in the input query. Table 2 shows the ratio of instances where each PLM reproduces the same word in a question. While the values are quite high for both synonym-asking and antonym-asking queries, the problem is more severe in the latter case, because the generated predictions are definitely incorrect. Based on our results, we conclude that PLMs' contextualised representations lack lexical semantic information. Our conclusion is in line with the findings of Liu et al. (2019a) showing that encoder-fixed PLMs are not suitable to deal with tasks that require fine-grained linguistic knowledge.

Issues are more severe with nouns. We observe that the hit rates are higher when a word in a question is a noun. Specifically, the average HR@1 values of nouns, adjectives, and adverbs are 35.1%, 27.4%, and 11.8%, respectively. Interestingly, PLMs have a high error rate when dealing with nouns even though they are trained with a large written English corpus, where nouns form the greatest portion (at least 37%) of all POS tags (Hudson, 1994; Liang and Liu, 2013).

3.3 Results for SAR

As part of the comparison, we fine-tune each PLM on the SAR task, i.e., train the entire set of parameters. The results are summarised in Table 3. We observe a huge gap between the performance of fine-tuned models and that of encoder-fixed models.

In contrast to the fine-tuned models that produce a high accuracy, encoder-fixed models fall short of expectations, even recording almost a random guess performance in BERT models. Also, just as a common belief, large models' performance is greatly improved when fine-tuned. However, the difference between the large and small encoder-fixed models is insignificant, except for the ELECTRA models that exhibit only a marginal improvement. The two phenomenons suggest that PLMs' outstanding performance is predicated on updating many parameters to learn syntactic associations presented in training data (Niven and Kao, 2019; McCoy et al., 2019), but their contextualised representations do not carry abundant lexical meaning information.

4 Intermediate Training on Meaning Matching Task: IM^2

4.1 Issue of PLMs

Through the previous experiments, we observe that PLMs contain little information about negation and especially lexical semantics. We hypothesise a leading cause lies in the training objective of PLMs: the language modelling (LM) objective, which is a backbone pre-training task of almost all PLMs.

In the LM objective, words are generated based on given contexts. The *distributional hypothesis* (Harris, 1954), which assumes that semantically related or similar words will appear in similar contexts (Mrkšić et al., 2016), is the underpinning assumption of the LM objective (Sinha et al., 2021a). Under this assumption, a model learns the meaning of texts based on their correlation to others. This is a great benefit, because a model can learn the meaning of texts using only the text form, allowing unsupervised training. Based on this advantage, many unsupervised representations, such as Word2Vec (Mikolov et al., 2013), Glove (Pennington et al., 2014), and current PLMs, have been developed.

However, the problem is that the *distributional hypothesis* has limitations in reflecting a word's *semantic* meanings, because words having different or even opposite semantic meanings can appear in similar or the same contexts. For instance, consider the two words "boy" and "girl". We can readily imagine sentences in which the two words appear in the same context, e.g., "the little boy/girl cuddled the teddy bear closely". As a result, a model can learn their common functional meanings, i.e., young human beings, and the vector representations would be very similar if they were trained based on the *distributional hypothesis*. However, the representation hardly captures their semantic antonomy, e.g., gender. Similarly, negated sentences have almost identical contexts to their original forms. As a result, models cannot effectively learn the semantic meaning of words and negation expressions, provided they leverage only the text forms.

4.2 Meaning-Matching Task

In the light of meaning-text theory, there is a correspondence between linguistic expressions (*text*) and semantic contents (*meaning*) (Mel'čuk and Žolkovskij, 1970; Milićević, 2006). Instead of solely relying on the *distributional hypothesis*, we propose the new *meaning-matching* task, which can directly learn the correspondence. Specifically, meaning-matching is a classification that takes a word and a sentence as input and determines whether the sentence defines the word correctly. Through this task, a model can learn both meaning-text correspondences and correlations between a word and other words in a definition, which is rarely found in general corpora.

For training PLMs on our new task, we apply the *intermediate-training* technique (Phang et al., 2018; Wang et al., 2019a; Liu et al., 2019a; Pruksachatkun et al., 2020; Vu et al., 2020), which first fine-tunes PLMs on an intermediate task, and then fine-tunes the model again on target tasks. It has been shown that training on intermediate tasks that require high-level linguistic knowledge and inference ability could improve performance (Liu et al., 2019a; Pruksachatkun et al., 2020). Furthermore, it is more efficient in time and resources than pre-training models on large corpora (e.g., BERTNOT model (Hosseini et al., 2021)).

Dataset. We collect about 150K free-text definitions that depict the meaning of English words from **WordNet** (Miller, 1995) and the **English Word, Meaning, and Usage Examples** dataset.[3] In cases when a word appears in both datasets, we concatenate the word's definitions. Several examples of our data are presented in Table 12 in Appendix A. We use publicly available English datasets for convenience, but our approach is easily adaptable to other languages, since most of them have their own dictionaries.

Table 5: PLMs' accuracy change in the SAR task when we apply IM^2. We record the average across 5 runs. Our models show a statistically significant difference with p-value < 0.05 (*) compared to the baseline results in Table 3.

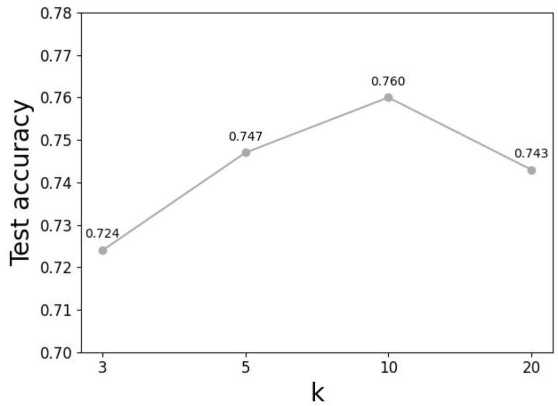

Figure 2: The performance of the RoBERTa-*base* (IM^2) model with different k values. We repeat each experiments for five times and record their average.

Training details. It is necessary to generate false word-definition pairs to train PLMs on the meaning-matching task. To achieve this, we use a negative sampling technique. We investigate the proper k in the range of 3, 5, 10, and 20. For a hyperparameter search, the performance of the RoBERTa-*base* model on the SAR task is used as a criterion. Figure 2 illustrates the SAR performance of the RoBERTa-*base* model with different k values. Intuitively, a large k value will lead the model to a better performance by investigating more word-meaning combinations. However, we observe that the model performs the best when k is 10, and the performance decreases if k is too large. We conjecture that a leading cause is that the dataset contains many words with similar meanings, mostly derived from the same *stem*. As a result, large k values can increase the possibility of recognising the meaning of such similar words as different.

To avoid the class-imbalance issue in a batch, we duplicate the correct word-definition pairs k times when we construct the training data. For training, the AdamW optimiser is used with a learning rate of $5e^{-6}$. We use 5% of data points for validation and train the models for 15 epochs with a batch size of 32. The early stopping technique is used to prevent overfitting.

Table 6: Examples of top-1 predictions on MWR queries. Unlike the original PLMs, our models do not reproduce a word in a query and make quite accurate predictions.

5 Experiments and Results

We conduct the same probing tasks after the intermediate training on the meaning-matching task.[4]

5.1 SAR Results

We first focus on the SAR task. After the intermediate training, all models are fine-tuned on the SAR task with the same hyperparameters described in Section 3. The results are summarised in Table 5.

---

[4] Our models trained with the meaning-match task can be downloaded from the following repositories: ELECTRA-large, BERT-large, RoBERTa-large.

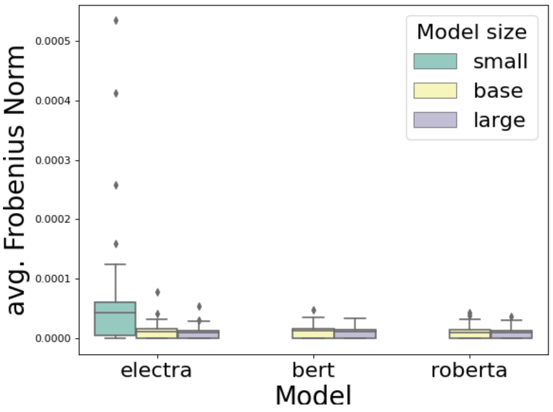

Figure 3: Frobenius norm box plots of PLMs' layer after intermediate training on the meaning-matching task.

Improved lexical semantic information. We generally observe marginal or no significant improvements when fine-tuning the whole parameters, especially for large-size PLMs. However, with fixed encoder, the performance is significantly improved for PLMs with more than 100M parameters, and the improvements are more significant for large PLMs. Our results show that the proposed approach assists PLMs to learn enhanced representations with more abundant lexical semantic information.

Catastrophic forgetting. We find that small PLMs, such as ELECTRA-*small* and ALBERT models, show no significant increase in performance or are negatively impacted. Because all PLMs achieve a comparable performance on the meaning-matching task, we hypothesise that a leading cause is *catastrophic forgetting* (Pruksachatkun et al., 2020; Wallat et al., 2020), where the model forgets previous knowledge learned through pre-training to accept new information from the intermediate task. To verify this, we measure the change of parameter values after IM^2. Concretely, let M_i and M_i^{mm} denote the parameter of i-th layer before and after IM^2. We calculate the average Frobenius norm for each layer:

$$\mathcal{F}_i = \frac{1}{|M_i|}|M_i - M_i^{mm}|_F.$$

Figure 3 shows the boxplots of $\mathcal{F}_i$ for each PLMs. We observe that the parameters of the ELECTRA-*small* model, which is negatively impacted, are changed considerably compared to other PLMs having parameters more than 100M. The results suggest that the size of PLMs is an important property to prevent the catastrophic forgetting issue.

5.2 MKR-NQ and MWR Results

Next, we perform the MKR-NQ and MWR tasks after applying the IM^2 method. Since our models are not trained with the MLM objective, we replace the encoder of original PLMs with that of the models after fine-tuning on the meaning-matching task and reuse the MLM classifier. For the experiments, we use BERT-*large* and RoBERTa-*large*, because they are pre-trained based on the MLM objective, and parameters are hardly changed after applying the IM^2 method. The results are summarised in Table 4.

We observe substantial decreases in the hit rates of incorrect predictions in both PLMs. For the MWR task, we find that the issue of regenerating a word in a given query is greatly relieved after applying the IM^2 method. Specifically, the percentage of such instances drops from 40.3% to 19.6% and from 33.8% to 25.2% for BERT-*large* and RoBERTa-*large*, respectively. Several examples of the predicted results are presented in Table 6. The results lend support to our claim that the IM^2 approach is of benefit to learning lexical semantic information and the meaning of negated expressions.

5.3 Fine-Tuning on the GLUE Benchmark

A critical drawback of intermediate training is that the target task performance could be negatively impacted if the intermediate task is not related to the target task (Liu et al., 2019a; Pruksachatkun et al., 2020). To confirm whether the issue occurs, we compare the performance of BERT, RoBERTa, and ELECTRA-*large* on 7 GLUE benchmark datasets (Wang et al., 2018) with their IM^2 counterparts. We train the models for 10 epochs for each dataset and apply the early stopping technique where the patience number is set to 3. It is observed that the training is generally finished within 8 epochs for all the models. The batch size per GPU and learning rates used for each dataset are described in Table 8. Datasets with large training set (e.g., MNLI, QNLI, and QQP) were not sensitive to the hyperparameters.

The results are presented in Table 7. We find no significant difference in performance for tasks with large datasets, such as MNLI, QNLI, QQP, and SST2. On the contrary, tasks with small datasets, like MRPC and RTE, are slightly improved. The

Model	COLA	MNLI-m	MNLI-mm	QNLI	RTE	QQP	MRPC	SST2

Model	SNLI		MNLI	
	dev	w/neg	dev	w/neg
BERTNOT	89.0±0.1	46.0±0.4	**84.3**±2.3	60.9±0.3
BERT-IM^2	**90.3**±0.2	**48.00**±0.5	83.1±0.3	**61.8**±0.6

Table 9: Accuracies on the original development dataset (dev) and the NegNLI (w/neg) dataset for SNLI and MNLI tasks. The results of our approach are averaged across 5 runs. The best values are in bold.

result is consistent with Pruksachatkun et al. (2020) and Vu et al. (2020), which showed that smaller tasks benefit much more from the intermediate training. Furthermore, unlike the previous studies that observed a negative transfer with the COLA dataset (Phang et al., 2018; Pruksachatkun et al., 2020), the performance is improved in our approach. The result suggests that meaning-matching is a safe intermediate task that ensures a positive transfer with target downstream tasks.

5.4 Experiments on the NegNLI Dataset

Finally, we conduct experiments on the NegNLI benchmark dataset (Hossain et al., 2020), where negation plays an important role for NLI tasks. As a baseline, we compare the reported performance of BERTNOT (Hosseini et al., 2021), which is a recently proposed remedy to improve PLMs' ability to understand negation. Since Hosseini et al. (2021) used BERT-*base* as a backbone model, we also apply the IM^2 method to BERT-*base*. The results are summarised in Table 9.

For both SNLI and MNLI, we observe that our approach outperforms BERTNOT in the NegNLI datasets, while yielding a comparable performance in the original development datasets. It is interesting that our approach improves the understanding of negation in both MKR-NQ and NegNLI tasks. We conjecture that a leading cause is that the definitions of the meaning-matching dataset contain many negation expressions, which enables a model to learn their proposed meaning (see Table 12). The results suggest that our proposed approach is more efficient than BERTNOT, because the IM^2 method leverages less time and resources for training.

6 Related Work

PLMs are at the core of many success stories in natural language processing (NLP). However, it remains unclear to what extent PLMs understand the syntactic and semantic properties of the human language. A series of probing tasks have been conducted on PLMs and have found them lacking or falling short on some language properties. Among the many findings of these probing tasks, PLMs have been found to be insensitive to the order of sentences when generating representations (Pham et al., 2021; Gupta et al., 2021; Sinha et al., 2021a), struggle to comprehend number-related representations (Wallace et al., 2019; Lin et al., 2020; Nogueira et al., 2021), and display a lack of semantic content understanding (Ravichander et al., 2020; Elazar et al., 2021).

In addition to the above faulty behaviours, Ettinger (2020) and Kassner and Schütze (2020) show that PLMs fail to comprehend *negation*, which is an important property of language in many natural language understanding (NLU) tasks. Ettinger (2020) check the ability of PLMs to understand the meaning of negation in given contexts. In their work, they check whether models are sensitive in their completions of sentences that either include *negation* or not. Under normal circumstances, the completions are expected to vary in truth depending on the presence or absence of negation in given sentences. Their results show that PLMs are insensitive to the impacts of negations when completing sentences. Kassner and Schütze (2020) construct the negated LAMA dataset by inserting negation elements (e.g., "not") in the LAMA cloze questions (Petroni et al., 2019). They use negated and original question pairs to query PLMs and establish that models are equally prone to make the same predictions for both the original and negated questions. In a well-informed setting, it is expected that PLMs should make different predictions for the original and negated questions. This shows that PLMs struggle to comprehend negation.

In light of the highlighted faulty behaviours of PLMs, especially their struggle to comprehend negation, Hosseini et al. (2021) propose a remedy to alleviate the problem. In their remedy, they augment the language modelling objective with an unlikelihood objective (Welleck et al., 2020) based on negated sentences from the training corpus. They use a syntactic augmentation method to generate negated sentences. In this method, the dependency parse of the sentences, POS tags, and morphological information of each word are taken as input, and the negation of sentences is done using sets of dependency tree regular expression patterns, such as Semgrex (Chambers et al., 2007). During training, they replace objects in negated sentences with [MASK] tokens and use unlikelihood training to make the masked-out tokens unlikely under the PLM distribution. To ensure that negated sentences are factually false, they use the corresponding positive sentences as context for the unlikelihood prediction task.

Previous studies (e.g., Kassner and Schütze (2020)) have mostly limited the scope of the logical negation property only to the negation expressions (e.g., "no" and "not"). However, the core spirit of this property is the *opposite meaning*, which is not only limited to the *negation*. Welleck et al. (2020) consider negating sentences using dependency tree regular expression patterns. This widens the scope of negation, as it is not only limited to the negation expressions "no" and "not". However, their approach relies on other components, such as Semgrex, and dependency and POS parsers, which could impact the quality of the data, hence impact the models' performance. In this work, we consider other perturbation methods to generate the opposite-meaning sentences to investigate whether PLMs satisfy the logical negation property, and we propose a remedy, called **i**ntermediate-training on **m**eaning-**m**atching (IM^2), which hardly employs additional linguistic components.

7 Summary and Outlook

In this work, we investigated PLMs' LNP. Compared to previous works that only examine negation expressions, we expanded the boundary of LNP to lexical semantics. We confirmed that PLMs are likely to violate LNP through extensive experiments.

We hypothesise that the distributional hypothesis is an insufficient basis for understanding the semantic meaning of texts. To alleviate the issue, we proposed a novel intermediate task: meaning-matching. Via experiments, we verified that meaning-matching is a stable intermediate task that substantially improves PLMs' understanding of negation and lexical semantic information while guaranteeing a positive transfer with multiple downstream tasks. Also, our approach produces a better performance on the negated NLI datasets compared to the unlikelihood training-based method, which leverages much more time and resources. Our work suggests that it is time to move beyond the distributional hypothesis to develop logically consistent and stable language models.

Por Qué Não Utiliser Alla Språk? Mixed Training with Gradient Optimization in Few-Shot Cross-Lingual Transfer

Haoran Xu, Kenton Murray

Johns Hopkins University
`{hxu64,kenton}@jhu.edu`

Abstract

The current state-of-the-art for few-shot cross-lingual transfer learning first trains on abundant labeled data in the source language and then fine-tunes with a few examples on the target language, termed *target-adapting*. Though this has been demonstrated to work on a variety of tasks, in this paper we show some deficiencies of this approach and propose a one-step mixed training method that trains on both source and target data with *stochastic gradient surgery*, a novel gradient-level optimization. Unlike the previous studies that focus on one language at a time when target-adapting, we use one model to handle *all target languages simultaneously* to avoid excessively language-specific models. Moreover, we discuss the unreality of utilizing large target development sets for model selection in previous literature. We further show that our method is both *development-free* for target languages, and is also able to escape from overfitting issues. We conduct a large-scale experiment on 4 diverse NLP tasks across up to 48 languages. Our proposed method achieves state-of-the-art performance on all tasks and outperforms target-adapting by a large margin[1], especially for languages that are linguistically distant from the source language, e.g., 7.36% F1 absolute gain on average for the NER task, up to 17.60% on Punjabi.

1 Introduction

The cost of linguistic data annotation and a plethora of differences across language resources and structures of natural language processing (NLP) tasks result in the problem that sufficient labeled data is only available for a handful of high-resource languages (Bender, 2011). The lack of data for low-resource languages leads to the need for effective cross-lingual transfer learning, which aims to leverage abundant labeled high-resource languages to improve model performance on low-resource ones. The majority of methods for cross-lingual transfer are mainly based on multilingual language models (LMs) (Devlin et al., 2019; Conneau et al., 2020; Xue et al., 2021) which are pre-trained on massive multilingual data. *Zero-shot cross-lingual transfer* is widely explored where a multilingual LM is trained on a large amount of labeled data in the source language without any target data, and then is directly evaluated on the target test set, frequently achieving surprisingly good performance (Wu and Dredze, 2019; Pires et al., 2019; Conneau et al., 2020). Recently, Lauscher et al. (2020) emphasize the effective mechanism of *few-shot cross-lingual transfer* for improving target-language performance, where only a few (such as 10) extra target examples can obtain substantial improvements. The current state-of-the-art methods for few-shot cross-lingual transfer learning (Lauscher et al., 2020; Hedderich et al., 2020; Maurya et al., 2021; Zhao et al., 2021) utilize the source-trained model (the same model training on the source data in zero-shot learning) to fine-tune on small target examples, which is termed *target-adapting*.

In this paper, we dissect the potential weaknesses of the ubiquitous target-adapting method and propose a one-step mixed training method that trains on both source and target data with a novel gradient-level optimization, **stochastic gradient surgery**. Specifically, we highlight 6 benefits (contributions) of our method in this paper as follows:

(1) State-of-The-Art Performance: Our proposed method achieves significant improvements compared to target-adapting on 4 diverse NLP tasks across up to 48 languages. For instance, averaged over all target languages, we demonstrate an absolute F1 improvement of 7.36% on NER using 5-shot learning, with our best performance gains on Punjabi where the gap is 17.60% (Section 4).

(2) One Model for All Languages: The target-adapting step generally focuses on only one target language. With the proposed method, we do not

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2043 - 2059
July 10-15, 2022 ©2022 Association for Computational Linguistics

need to fine-tune specialized models for every target language, which is of particular interest when scaling to dozens or even hundreds of languages. We discuss the benefits of mixed training one model on all target languages, even when their number of shots is extremely small (Section 3.2).

(3) Efficient Gradient De-Conflicting and Information De-Dilution: Two issues arise when mixed training uses data from all target languages in addition to the source language — conflicting gradients among languages and target information dilution. Stochastic gradient surgery efficiently de-conflicts gradients and de-dilutes the target information (Section 3.4 and 3.5).

(4) Single Language Friendly: Though our proposed method normally uses information from multiple target languages, in the simplest setting, where we only have a single target language, stochastic gradient surgery trained on source and target still substantially outperforms standard target-adapting. The improvement is especially pronounced for languages linguistically distant from the source language (Section 5.3).

(5) The Same Script Helps: For a specific language, the model is able to use information learned from other languages. In Section 5.4, we show that this gain is most pronounced in languages that use the same script.

(6) Development-Free for Target Languages: Target development (dev) set used by previous studies (Hsu et al., 2019; Zhao et al., 2021) significantly outnumber training examples in few-shot cross-lingual learning, which is not realistic in the true low-resource settings. However, target-adapting can be prone to overfit on small examples without target dev sets. In comparison, our proposed method is development-free for target languages and able to escape overfitting issues (Section 5.5).

2 Background and Related Works

2.1 Cross-Lingual Transfer Learning

Cross-lingual transfer learning enables systems to co-learn the meaning of words across languages and facilitates model transfer between languages, particularly from high-resource to low-resource languages (Ruder et al., 2019), even for languages that are linguistically distant (Xu et al., 2021; Yarmohammadi et al., 2021). Language transfer is based on finding a shared cross-lingual space for source and target languages. One of the most common methods is to align the source and target embedding spaces, termed cross-lingual word embeddings (CLWEs) (Mikolov et al., 2013; Artetxe et al., 2016; Conneau et al., 2018a; Vulić et al., 2019; Xu and Koehn, 2021a). Recently, multilingual pre-trained encoders have shown stronger effectiveness over CLWEs for cross-lingual transfer in various tasks (Artetxe and Schwenk, 2019; Wu and Dredze, 2019). While some studies utilize static pre-trained encoders for transfer learning (Wang et al., 2019; Xu and Koehn, 2021b), the majority of studies continuously train encoders for cross-lingual transfer (Conneau et al., 2020; Luo et al., 2021; Xue et al., 2021) based on the finding that source and target representations are still aligned after only fine-tuning on the source data (Hsu et al., 2019).

2.2 Few-Shot Learning

Few-shot learning was firstly investigated in computer vision (Fei-Fei et al., 2006). Currently, the majority of studies for NLP tasks are designed for one single language (usually English), e.g., model agnostic meta-learning (Finn et al., 2017) and prototypical networks (Snell et al., 2017). However, limited few-shot studies are explored in cross-lingual settings. Recent works mainly focus on zero-shot cross-lingual transfer to evaluate the cross-lingual generalization capabilities of multilingual representations, e.g., XTREME (Hu et al., 2020; Ruder et al., 2021) and XGLUE (Liang et al., 2020). Lauscher et al. (2020) further emphasize that additional fine-tuning on a few inexpensive labeled target-language instances is surprisingly effective across broad NLP tasks. Zhao et al. (2021) highlight the sensitivity of the selection of the few examples (shots) and suggest using the same shots for fair comparisons. State-of-the-art methods for few-shot cross-lingual learning follow the source-training + target-adapting paradigm. In this paper, we investigate deficiencies of this approach and propose more effective methods which significantly improve the transfer performance compared to target-adapting.

2.3 Gradient Surgery

Previous works on gradient optimization (Chen et al., 2018; Sener and Koltun, 2018; Yu et al., 2020) have successfully utilized gradient-level techniques to improve the performance of multi-task models. In fact, mixed training multilingual data can be categorized into multi-task learning (Zhang and Yang, 2018) but in a monolithic manner by using a single language-agnostic objective on the concatenated data from all languages. Recently, multilingual machine translation utilizes gradient-level regularization to improve the translation performance (Wang et al., 2020; Yang et al., 2021; Wang et al., 2021b). In this paper, our experiments mainly focus on training multiple target languages, so we propose **stochastic gradient surgery** (Section 3.5) which improves upon the original gradient surgery method (Yu et al., 2020) to improve the overall performance.

3 Methods

3.1 Ordinary Few-Shot Learning

The current state-of-the-art few-shot cross-lingual transfer learning method (Lauscher et al., 2020; Hedderich et al., 2020; Zhao et al., 2021) includes two stages, *source-training* and *target-adapting*. In the source-training stage, a pre-trained LM such as mBERT (Devlin et al., 2019) or XLM-R (Conneau et al., 2020) is fine-tuned with sufficient labeled data in the source language (which is usually English). In the target-adapting stage, the source-trained model is then fine-tuned only with a few examples in the target language. We abbreviate the name of this method to **ord-FS**.

3.2 Mixed Fine-Tuning on All Target Languages

The ord-FS method brings up a question: **is it necessary to fine-tune a language-specific model for each target language?** Can we use one model to handle all target languages to avoid excessively language-specific models? One straightforward method to have such a model is fine-tuning the source-trained model on concatenated examples of all target languages, instead of only one target. Here, we are interested in whether more few examples of other target languages will improve/degrade the overall performance. We abbreviate the name of this method to **mix-FT**.

3.3 Mixed Training on Source and Target Languages

Ord-FS and mix-FT follow the *transductive transfer*[2] learning method that first trains on the source domain and then fine-tunes on the target domain (Pan and Yang, 2009). However, recently, Xu et al. (2021) show that abruptly shifting the source domain to the target domain is not an optimized solution due to catastrophic forgetting (McCloskey and Cohen, 1989). Thus, we should be careful about the language domain gaps between the source and target languages, especially for distant languages. One naive but effective approach to preserve the source knowledge and escape catastrophic forgetting is simply training both the source and target data[3] (all target languages), where we simplify source-training and target-adapting into only one mixed training step. We abbreviate the name of this method to **naive-mix-train**.

3.4 Gradient Surgery in Mixed Training

One issue of naive-mix-train is conflicting gradients (Yu et al., 2020) among languages, which makes training more difficult because gradients point away from one another. We define that two gradients are conflicting if they have a negative cosine similarity. Another issue is that the information of the target domain will be diluted due to the overwhelming source data. Specifically, the gradient of source data is much larger in magnitude than the other languages in one batch training due to the small or even no target training instances in this batch. Hence, the source gradients will dominate the average gradient and result in information dilution of the target data and underestimation of the target language performance.

The main idea of using gradient surgery (Yu et al., 2020) to mitigate the two issues above is, in each backpropagation step, projecting the dominant gradient to the normal plane of a target gradient to de-conflict their gradients and '*remind*' the model of target instances. Specifically, we denote g_s as the gradient for the source language and g_t as the gradient for the target language. We first compute the cosine similarity between g_s and g_t and judge g_s and g_t are conflicting gradients if their similarity is negative. Next, we project g_s into the normal plane of g_t only if they are conflicting:

$$g_s' = g_s - \frac{g_s \cdot g_t}{\parallel g_t \parallel^2} g_t \tag{1}$$

The modified g_s' replace the original dominant source gradient to update the model parameters.

3.5 Stochastic Gradient Surgery

However, target data is usually not guaranteed to exist in the batch due to the small training size.

---

[2] The pre-training (source-training) and the fine-tuning (target-adapting) are the same task.

[3] Target data is randomly interpolated in the source data.

Even though we assume that we have target data for all target languages in each batch training, we should detect conflicting gradients not just between source and target languages, but also between every target language. However, this is extremely computationally expensive, especially when it comes to large-scale languages for training. Based on this, we propose **stochastic gradient surgery** approach, composed of two parts, **oracle dataset creation** and **stochastic training**.

Oracle Dataset Creation In the case of K-shot learning, the oracle dataset comprises K training instances[4] for each target language. To not use any external information, the oracle datasets of target languages are exactly the K target instances used in mixed training. Similar to Wang et al. (2020, 2021a); Yang et al. (2021), we create an oracle dataset to ensure that we can pair any one of the target languages with the source language to operate gradient surgery.

Stochastic Training In each batch training, we randomly pick oracle data of a random target language in a uniform distribution to conduct gradient surgery with the source batch data. Moreover, in order to avoid that small number of target examples constrain the source gradients into a sub-optimal place (especially for tasks which need higher-level semantic understanding), we also have a pre-set threshold α to control the probability of gradient surgery in each training step. The gradient surgery is conducted only if a sampled value $p \sim \text{uniform}[0, 1]$ is smaller than α.

The advantages of this method are that 1) we only focus on gradient de-conflicting between the source and one of the target languages, which only computes the gradient one additional time to avoid expensive computation, 2) and more importantly, the source language could be a pivot language which also helps gradients of target languages de-conflict between each other (more discussion in Section 5.2). The detailed workflow is shown in Algorithm 1. We abbreviate the name of this method to **gradient-mix-train**.

Algorithm 1: Stochastic Gradient Surgery

```
Input : Language Set $\mathcal{L}$; Pre-Trained Model $\theta$; Mixed Training Data $\mathcal{D}_{\text{train}}$;
        Oracle Data $\mathcal{D}^{l}_{\text{oracle}}, l \in \mathcal{L}$; Pre-Set Threshold $\alpha$.
Initialize $\theta_0 = \theta$, step $t = 0$
while not converged do
    ▷ Iterate batches $\mathcal{B}_{train}$ from data $\mathcal{D}_{train}$
    for $\mathcal{B}_{train}$ in $\mathcal{D}_{train}$ do
        $g_{\text{train}} = \nabla_{\theta_t} L(\theta_t, \mathcal{B}_{\text{train}})$
        Sample a language $l$ from set $\mathcal{L}$
        $g_{\text{oracle}} = \nabla_{\theta_t} L(\theta_t, \mathcal{D}^{l}_{\text{oracle}})$
        Sample a value $p \sim \text{uniform}[0, 1]$
        ▷ Gradient surgery
        if $g_{oracle} \cdot g_{train} < 0$ and $p < \alpha$ then
            $g_{\text{train}} = g_{\text{train}} - \frac{g_{\text{train}} \cdot g_{\text{oracle}}}{\|g_{\text{oracle}}\|^2} g_{\text{oracle}}$
        end
        Update $t \leftarrow t + 1$
        Update $\theta_t$ with gradient $g_{\text{train}}$
    end
end
```

4 Experiments

4.1 Development-Free Training

Importantly, Zhao et al. (2021) notice that few-shot learning easily tends to overfit quickly at a small number of shots, where the model performs best on the dev set at the beginning of training. One good solution to avoid overfitting is using target dev set for early stopping. Previous studies (Hedderich et al., 2020; Zhao et al., 2021) utilize a large amount of dev sets for each target language for model selection, e.g., even around 10K dev examples for Arabic in the NER task. However, it is unlikely that such a dev set would be available in reality, especially for the extreme low-resource training such as 1-shot and 5-shot learning, since it would be more effective to use it for training instead (Kann et al., 2019). The true standard setup of zero-shot cross-lingual learning only uses the source dev set (Zhao et al., 2021), and few-shot learning should also follow this setup, particularly at a small value of shots. Thus, we suggest **only using the source dev set for model selection**. However, for target-adapting, it does not makes sense to use the source dev for model selection due to the different languages in the training and dev steps. Hence, the two-step methods, ord-FS and mix-FT, use the last checkpoint for evaluation. Since naive-mix-train and gradient-mix-train train on both source and target data, they are suitable for using the source dev set for target model selection. We show that **our methods substantially outperform target-adapting whatever it uses unrealistic dev sets or**

---

[4] XNLI use K examples from every class followed by the "N-way K-shot" discussion in Section 4.3.

not in Section 4.4.

We consider all introduced methods in the experiment, including two-step methods (ord-FS, mix-FT), and one-step methods (naive-mix-train, gradient-mix-train). Moreover, in order to investigate the difference between using and not using dev sets, we add another baseline, **ord-FS+dev**, whis is ord-FS with unrealistically large dev sets[5] for model selection as Zhao et al. (2021) conduct.

4.2 Tasks and Datasets

We consider two lower-level (structured prediction) tasks, Wikiann Named-Entity Recognition (NER) task (Pan et al., 2017) and Part-of-Speech Tagging (POS) (Nivre et al., 2018) and two different types of higher-level tasks, Typologically Diverse Question Answering-Gold Passage[6] (TyDiQA-GoldP) (Clark et al., 2020) and Cross-lingual Natural Language Inference (XNLI) (Conneau et al., 2018b). We download datasets from the XTREME-R benchmark (Hu et al., 2020; Ruder et al., 2021). NER and POS cover 48 and 38 languages, respectively. Our experiments use 35 languages on POS because the remaining three languages, Thai(*th*), Tagalog(*tl*) and Yoruba(*yo*), do not have target training data in XTREME-R. TydiQA and XNLI cover 9 and 15 languages, respectively. We conduct aforementioned methods on all tasks for all languages. English is the source language and the others are targets. Statistics about languages are listed in Appendix B.

4.3 Settings

Two-step training methods, ord-FS(+dev) and mix-FT, have two different settings for source-training and target-adapting. For one-step methods, naive-mix-train and gradient-mix-train, their settings are the same as source-training in the two-step methods. We run 10 epochs for NER and POS, 60 for TyDiQA, and 10 for XNLI in both source-training and target-adapting. The batch size of all tasks is 32 for source-training and K for target-adapting with a 2e-5 learning rate. Pre-set threshold α is 1 for NER and POS and 0.1 for TyDiQA and XNLI unless otherwise noted. The values of α are empirically selected, which might not be optimal but strongly effective. The model architecture of NER and POS is based on pre-trained XLM-R$_{\texttt{large}}$ attached with a feed-forward token-level classifier. For TydiQA, the representations of all subwords in XLM-R$_{\texttt{base}}$ are input to a span classification head —- a linear layer computing the start and the end of the answer. For XNLI, the model architecture is XLM-R$_{\texttt{base}}$ with a simple softmax classifier on the vector of the start token. The number of examples we consider is $K \in \{1, 5, 10\}$. The sampling method is simply extracting random K shots. The only exception is XNLI, where we adopt the sampling method of conventional few-shot classification learning — "N-way K-shot" (Fei-Fei et al., 2006) — we sample K examples for N classes. Here, N is the total number of classes in XNLI. We repeat every experiment 5 times with 5 different random seeds[7] suggested by Lauscher et al. (2020). All methods use the same K shots for a fair comparison. We finally report the average accuracy (XNLI) or F1 scores (other tasks) and their standard deviation.

4.4 Results

The main results on each task, conditioned on the number of examples K and **averaged across all languages**, are presented in Table 1. The full results with each target language are shown in Appendix C. For all values of K and all tasks, **gradient-mix-train performs the best among all introduced few-shot learning methods**.

The zero-shot cross-lingual transfer results ($K = 0$) deliver similar results comparable to Ruder et al. (2021). Similar to the findings in Lauscher et al. (2020); Zhao et al. (2021), we notice substantial improvements with ord-FS(+dev) on lower-level tasks (NER and POS) and modest improvement on XNLI over zero-shot performance.

However, ord-FS significantly degrades the zero-shot performance on TyDiQA because it suffers from a tendency of overfitting on target training instances (more discussion in Section 5.5). On the other hand, with the help of dev sets in model selection, ord-FS+dev achieves higher performance than ord-FS on all tasks and particularly solve the overfitting issue.

Compared to ord-FS, NER and TyDiQA benefit most from mix-FT, e.g., from 65.91% to 70.60% with $K = 5$ in NER. However, it still suffers from the overfitting issue, but the impact decrease with more target examples. Training source sentences with target data (naive-mix-train) is a better solution. It consistently outperforms mix-FT on all

---

[5] Detail information of dev sets are shown in Appendix A

[6] We try to not use translated data such as XQuAD (Artetxe et al., 2020) to avoid unrealistic artifacts such as preserving source words (Clark et al., 2020).

[7] Shots are different with different seeds.

Table 2: Top-5 languages that achieve the highest improvement by using gradient-mix-train methods compared to ord-FS on all tasks in 5-shot learning. Most languages are distant from English.

tasks with various K, and importantly, overcomes the serious overfitting on the TyDiQA task and highly boosts the performance (e.g., from 48.73% of mix-FT to 57.03% of naive-mix-train in 1-shot learning). Furthermore, applying stochastic gradient surgery on mixed training (gradient-mix-train) achieves the best performance on all tasks with all settings of K and outperforms ord-FS by a significant margin, such as up to 7.36% averaged absolute improvement on NER in 5-shot learning. On the other hand, the gap between our methods and ord-FS in POS is smaller than in NER (the same type of task). The reason could be that the strong POS task baseline has already left less room for further improvement.

5 Analysis and Discussion

5.1 Which Language Benefits Most?

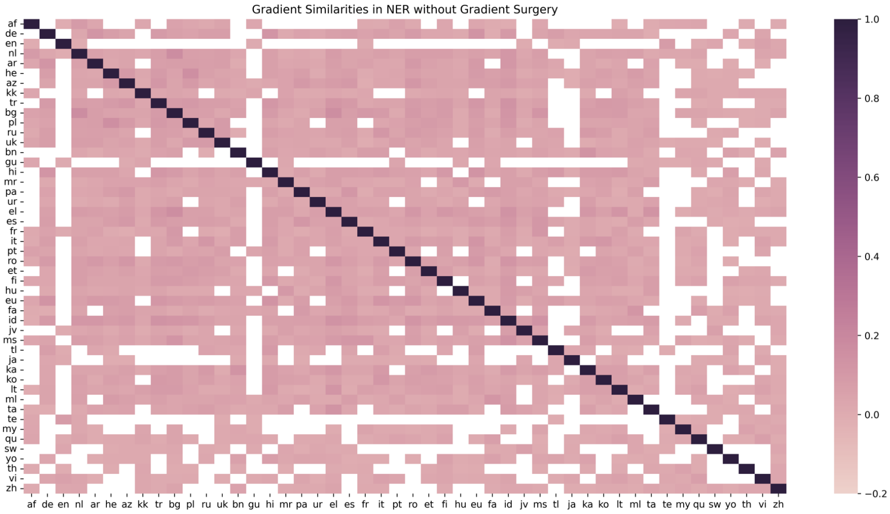
Table 1 shows the strong effectiveness of gradient-mix-train in improving the overall performance of each task. Here, we are interested in taking a closer look at the results of specific languages and investigating which language benefits most. Take 5-shot learning as an example. Table 2 illustrates the top-5 languages which boost most by using gradient-mix-train over ord-FS in all tasks[8], where the improvement is up to 17.60% absolute F1 scores for *pa* in the NER task. Most of the languages in the top-5 list are linguistically distant from English. We hypothesize that for such distant languages, the model has difficulty in learning the target training instances by abruptly shifting to the target domain. For closely related languages, the model is able to extrapolate the target-specific knowledge whose priors are close to English so that the model is less sensitive to these few target training examples than distant languages. However, gradient-mix-train is able to smoothly learn the distribution of source domain and extrapolate (distant) target domains by mixed training and gradient-level optimization.

5.2 Visualization of Gradient De-Conflicting

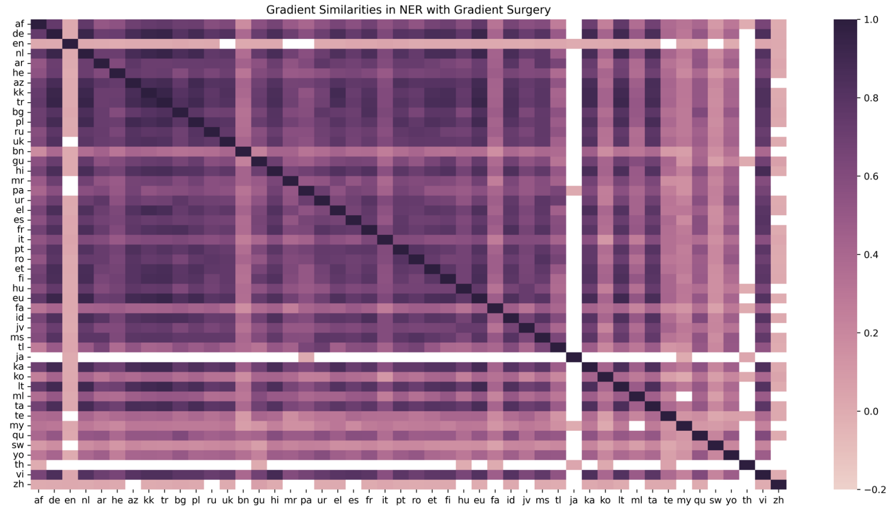
We take the NER task as an example to analyze the gradient de-conflicting of stochastic gradient surgery since it covers the most languages among all tasks. In Figure 1, we use a symmetric heatmap to visualize pair-wise gradient similarities, averaged by all 5 checkpoints in 5-shot learning. Note that languages in the figure are adjacent to other languages in the same linguistic language family. The gradient of English is calculated by the randomly picked 100 batches on average, and gradients of

---

[8] For the languages that benefit the least, gradient-mix-train still yields large gains over the baseline on NER and TyDiQA. We discuss this further in Appendix D.



(a) Gradient similarity across languages without gradient surgery

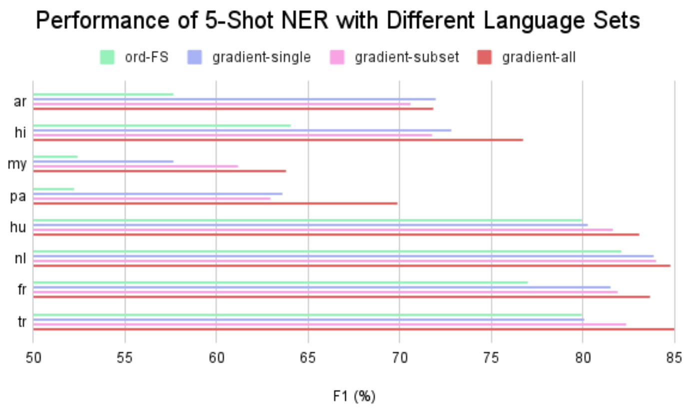


(b) Gradient similarity across languages with gradient surgery

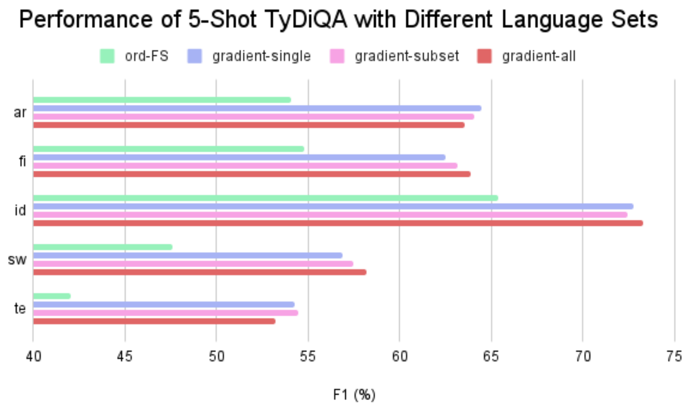
Figure 1: Gradient similarities across 48 languages in the NER task with 5 shots. Deeper colors represent higher cosine similarities. Conflicting gradients are directly marked as while cells in the heatmap. The similarities are highly improved after stochastic gradient surgery. The gradients are averaged from 5 checkpoints.

the other target languages are calculated by their 5 training instances. To highlight the conflicting gradients across languages, we directly mark the cells with negative similarities as pure white color.

Figure 1a shows the gradient similarities of the naive-mix-train model. As expected, gradient similarities of many language pairs are conflicting (white color cells), and gradients of most languages are approximately orthogonal, where their similarities are close to 0. It is worth mentioning that gradients similarities between English and most languages are conflicting. In comparison, in Figure 1b, we illustrates the gradient similarities of gradient-mix-train, and the gradient similarities between English and most of the target languages are positive. Moreover, gradients of most target language pairs have higher similarities (deeper colors), which also verifies the correctness of our statement that target languages utilize English as a pivot language to de-conflict and even improve their similarities. The only two exceptions are *th* and *ja*, the two hardest task in NER, whose F1 in zero-shot learning is only 1.02% and 18.31%. Their similarities with other languages are negative but positive between themselves. However, gradient-mix-train still achieve impressive improvement on *th* ($\Delta = 3.13\%$) and *ja* ($\Delta = 5.40\%$) compared to naive-mix-train (see the full results in Appendix C). We also notice the clustering by membership closeness in the linguistic family, along with the diago-



(a) Performance on various subsets of languages in NER



(b) Performance on various subsets of languages in TyDiQA

Figure 2: Performance of gradient-mix-train on different sets of languages compared to ord-FS for **(a)** NER and **(b)** TyDiQA. **gradient-{all,subset,single}** represents training on all/subset/single languages by using graident-mix-train.

nal of gradient similarity matrix, e.g., Indo-Aryan (*bn*, *gu*, *hi*, *mr*, *pa*, *ur*). Moreover, some language families are positive correlated, e.g., Slavic(*bg*, *pl*, *ru*, *uk*) and Austronesian(*id*, *jv*, *ms*).

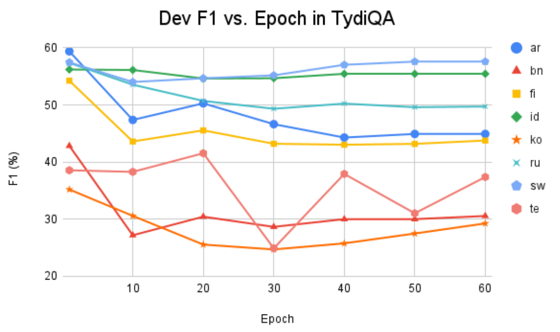


Figure 3: Dev F1 scores of ord-FS+dev in TyDiQA. 6 out of 8 target languages overfit quickly, where they achieve the best performance at the first epoch.

5.3 Mixed Training with One Single Language

In some cases, people are only interested in one target language and do not have resources for other languages. Hence, we further explore the effectiveness of gradient-mix-train in one target language case. We conduct experiments on the NER and TyDiQA tasks that show larger gaps among different methods than other two tasks. Considering the high expense of training the source data from scratch for every target language, we run experiments on subsets of languages for each task. For the NER task, we test on 8 languages: *ar*, *hi*, *my*, *pa*, which use different scripts from English, and *hu*, *nl*, *fr*, *tr*, which share the same script with English. Figure 2a shows the results for NER. Gradient-mix-train with only one single language is labeled as **gradient-single**[9] in the figure (blue, the second bar). We can focus on comparing ord-FS (green,

---

[9] We reduce α for NER to 0.1 due to only one language considered.

the first bar). We notice that gradient-single still outperforms ord-FS by a large margin for 4 non-Latin-script languages (e.g., 14.29% improvement for *ar*). In comparison, their gap becomes smaller when it comes to 4 Latin-script languages (e.g., 1.78% improvement for *nl*). Numeric results are shown in Appendix E. For the TyDiQA task, We pick 5 languages: *ar*, *fi*, *id*, *sw*, *te*. We note that gradient-single still highly boosts the performance compared to ord-FS.

5.4 Do the Same Scripts Help?

Continuing the previous discussions in Section 5.3, we add a new baseline, **gradient-all** (red, the last bar in Figure 2), which uses gradient-mix-train method with all languages (original settings). Interestingly, gradient-all outperforms gradient-single on all selected languages except for *ar* in NER, and a similar phenomenon also happens in TyDiQA. Note that *ar* is the only language that uses Arabic script in TyDiQA and only shares the same script with *yo* and *kk* among 48 languages in NER. It brings a question that **do small examples of other languages which use the same scripts help in few-shot learning?** Hence, we move our experiments further on using gradient-mix-train with subsets of languages. We still consider the languages used in Section 5.3. Note that these languages are carefully selected. In NER, only *my* and *pa* share the same script (Brahmic) among 4 distant languages, and *hu*, *nl*, *fr*, *tr* share the Latin script from different language families. In TyDiQA, only *fi*,*id* and *sw* use the same script (Latin). We train 4 similar languages and 4 distant languages in NER, respectively. For TyDiQA, we train all 5 languages. The results of mixed training on subset of languages is denoted as **gradient-subset**[10] (pink, the third bar) in Figure 2. As expected, gradient-subset achieves better performance than gradient-single on all similar languages and on *my* among distant languages in the NER task. As for other languages using distinct scripts, their performance slightly degenerates compared to gradient-single. A similar discussion also holds for the high-level TyDiQA task, but gaps between gradient-single and gradient-subset are smaller. In conclusion, to pursue the best performance, we recommend using gradient-mix-train with languages that share the same script or only a single language that uses a distinct script.

5.5 Escaping from Overfitting

The overfitting causes the significant degeneration of ord-FS performance in TydiQA. Figure 3 shows that 6 out of 8 target languages achieve the best dev score at the first epoch and decrease significantly afterwards. However, the phenomenon of degeneration is imperceptible in other tasks because only a few languages hit the same overfitting issue, e.g., 6.38% of languages achieve the best score at the first epoch in 1-shot learning for NER, and none of them has the issue in 10-shot learning. Different from two-step methods, one of the biggest benefits of gradient-mix-train is the perfect fit for only using the source dev set to avoid overfitting (for model selection) because training and dev steps use the same (dominant) language. Thus, although gradient-mix-train can also be further improved by using unrealistic target dev sets, the gaps are smaller compared to ord-FS (Appendix F).

6 Conclusion

We study the deficiencies of target-adapting in few-shot cross-lingual transfer and propose a mixed training method with gradient-level optimization. Our best model achieves state-of-the-art on four diverse NLP tasks with all values of K. Moreover, we are the first to use a single model to train all target languages and find that languages can benefit from others that share the same scripts. We also show the effectiveness of our method compared to target-adapting in a single target language case, and the gaps are still significant. Finally, we propose only using source dev set in few-shot settings and show that our method is development-free for targets and also able to escape from overfitting issues.

A Size of Dev Sets

In Figure 4, we show the size of dev sets that we used in our experiments, which are also the dev sets used by Zhao et al. (2021). Data of all tasks are downloaded from the XTREME-R benchmark (Hu et al., 2020; Ruder et al., 2021), where train/dev/test sets are already split. We can notice that the dev size of all languages in all tasks are tremendously higher than the largest number (10) of shots we pick in few-shot cross-lingual learning. However, in reality, if we only have access to a few training instance, we usually do not have a such large dev set. For tasks such as NER, POS and XNLI, we sample shots from the target training sets and directly use their supported dev sets. For TyDiQA which only supports train and dev sets in XTREME-R, we sample shots from the target training sets but use the remaining training data as dev sets, and we use dev sets for test.

B Language Statistics

In this paper, we cover a total of 49 languages in our whole experiments, including NER, POS, TyDiQA, and XNLI tasks. The list of full names of languages is shown in Table 3, with their ISO 639-1 code, script, and language families. We checkmark under the column of the task in the Table if the language is involved in the task.

C Full Results

The full results of NER, POS, TyDiQA and XNLI are shown in Table 4, Table 5, Table 6 and Table 7, respectively. In each task, we report F1 scores (or accuracy) of all covered languages in 1-,5-, or 10 shot learning by using all introduced methods. Best score among methods in each language is **bold**.

D Languages Benefits Least

In Table 8, we show the list of top-5 language which benefits least by using gradient-mix-train in 5-shot learning. In NER and XNLI, we can notice a reverse phenomenon in the top-5 languages which benefit most — most of the languages are linguistically closer to English, at least using the same (Latin) script. In NER and TyDiQA tasks, although the gap left by gradient-mix-train is much smaller than top-5 languages which benefits most, the improvements are still significant.

E Mixed Training with Subsets of Languages

Here, we show the numeric results of Figure 2a and Figure 2b in Table 9 and Table 10, respectively.

F Our Methods with Dev Sets

We take *ar* in the NER task as an example to show that gradient-mix-train can be further improved by utilizing large dev sets (around 10K). Figure 5 shows F1 scores of gradient-mix-train and ord-FS both with and without dev sets with increasing epoch numbers. Methods with the help of the dev set start showing its effectiveness in model selection when it comes to large enough epoch numbers. Importantly, the gap led by the dev set in gradient-mix-train is smaller than the one in ord-FS, which shows that gradient-mix-train is able to select approximately optimal model even without target dev sets by using the source dev set. It is also worth mentioning that gradient-mix-train even significantly outperforms the best performance of ord-FS with only 2 epoch of source (and target) data training. Still, ord-FS starts training based on 10-epoch source-trained model.

Gradient-mix-train shows less gap led by the dev set than ord-FS and can select approximately optimal model by only using the source dev set.

Learning to Execute Actions or Ask Clarification Questions

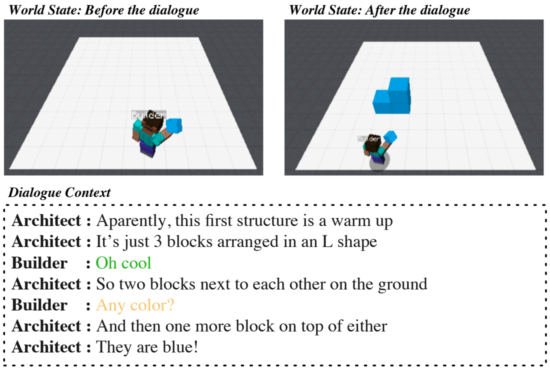
Abstract

Collaborative tasks are ubiquitous activities where a form of communication is required in order to reach a joint goal. Collaborative building is one of such tasks. We wish to develop an intelligent builder agent in a simulated building environment (Minecraft) that can build whatever users wish to build by just talking to the agent. In order to achieve this goal, such agents need to be able to take the initiative by asking clarification questions when further information is needed. Existing works on Minecraft Corpus Dataset only learn to execute instructions neglecting the importance of asking for clarifications. In this paper, we extend the Minecraft Corpus Dataset by annotating all builder utterances into eight types, including clarification questions, and propose a new builder agent model capable of determining when to ask or execute instructions. Experimental results show that our model achieves state-of-the-art performance on the collaborative building task with a substantial improvement. We also define two new tasks, the learning to ask task and the joint learning task. The latter consists of solving both collaborating building and learning to ask tasks jointly.

1 Introduction

Following instructions in natural language by intelligent agents to achieve a shared goal with the instructors in a pre-defined environment is a ubiquitous task in many scenarios, e.g., finding a target object in an environment (Nguyen and Daumé III, 2019; Roman et al., 2020), drawing a picture (Lachmy et al., 2021), or building a target structure (Narayan-Chen et al., 2019). A number of machine learning (ML) research projects about following instructions tasks have been initiated by making use of the video game Minecraft (Johnson et al., 2016; Shu et al., 2018; Narayan-Chen et al., 2019; Guss et al., 2019; Jayannavar et al., 2020). Building such agents requires to make progress in *grounded natural language understanding* – understanding complex instructions, for example, with spatial relations in natural language – *self-improvement* – studying how to flexibly learn from human interactions – *synergies of ML components* – exploring the integration of several ML and non-ML components to make them work together (Szlam et al., 2019).



Architect : Aparently, this first structure is a warm up
Architect : It's just 3 blocks arranged in an L shape
Builder : Oh cool
Architect : So two blocks next to each other on the ground
Builder : Any color?
Architect : And then one more block on top of either
Architect : They are blue!

Figure 1: A simple example of builder task: The builder can observe the world state and dialogue context. For the sake of space, only a part of the dialogue history is displayed. The utterance in green displays understanding and the utterance in yellow asks a clarification question.

The recently introduced Minecraft Corpus dataset (Narayan-Chen et al., 2019) proposes a collaborative building task, in which an architect and a builder can communicate via a textual chat. Architects are provided with a target structure they want to have built, and the builders are the only ones who can control the Minecraft avatar in the virtual environment. The task consists in building 3D structures in a block world-like scenario collaboratively, as shown in the Figure 1. Earlier works in Minecraft collaborative building tasks (Jayannavar et al., 2020) attempted to build an automated builder agent with a large action space but failed to allow the builder to take the initiative in the conversation. However, an intelligent agent should

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2060 - 2070
July 10-15, 2022

not only understand and execute the instructor's requests but also be able to take initiatives, e.g., asking clarification questions, in case the instructions are ambiguous. In the task defined by this dataset, builders may encounter ambiguous situations that are hard to interpret by just relying on the world state information and instructions. For example, in Figure 1, we provide a simple case where the architect fails to provide sufficient information to the builder, such as the color of the blocks. In this situation, it is clearly difficult for the builder to know exactly which action should be taken. If, however, the builder is able to clarify the situation with the architect, this ambiguity can be resolved. Therefore, builders, besides following architects' instructions, should take the initiative in the conversation and ask questions when necessary.

To this end, in this paper we annotate all builder utterances in the Minecraft Corpus dataset by categorizing them in the dataset into eight dialogue utterance types as shown in Table 2, allowing the intelligent agents to learn when and what to ask given the world state and dialogue context. Particularly, a builder would ask *task-level questions* or *instruction-level questions* for further clarifications. Experimental results in the Sec. 5.2 show that determining when to ask clarification questions remains a challenging task. However, it is worth noting that the clarification questions in the Minecraft Corpus dataset are more complex and diverse than those in navigation tasks (Roman et al., 2020; Nguyen and Daumé III, 2019; Thomason et al., 2020) whose questions are relatively simpler and mainly about where to go.

Also, we propose a new automated builder agent that learns to map instructions to actions and decide when to ask questions. Our model utilizes three dialogue slots, the action type slot, the location slot, and the color slot. This solution has the benefit of making the learning easier with respect to those models that work using a large action space (Jayannavar et al., 2020). To solve the collaborative building task, both the dialogue context and the world state need to be considered. Therefore, to endow our model with the ability to better learn the representations between the world state and language, our model implements a cross-modality module, which is based on the cross attention mechanism. Experimental results on our extended Minecraft Corpus dataset show that our model achieves state-of-the-art performance with a substantial improvement for the *collaborative building task*. We also provide new baselines for *learning to ask* task and the joint learning of these two tasks.

2 Related Work and Background

Dialogue Tasks. As virtual personal assistants have now penetrated the consumer market, with products such as Siri and Alexa, the research community has produced several works on *task-oriented dialogue tasks* such as: hotel booking, restaurant booking, movie recommendation, etc. (Budzianowski et al., 2018; Wei et al., 2018; Wu et al., 2019; Feng et al., 2021, 2022; Kim and Lipani, 2022). These task-oriented dialogues have been modelled as slot filling tasks. These tasks consist of correctly identifying and extracting information (slots) useful to solve the task. However, most of these slot filling tasks (Coope et al., 2020; Ni et al., 2020) are considered as semantic tagging or parsing of natural language and do not normally consider visual information. Moreover, these tasks focus only on two of the many components needed by conversational systems: the Natural Language Understanding (NLU) and Dialogue State Tracking (DST) ones (Budzianowski et al., 2018; Williams et al., 2014). Beside these task-oriented dialogue tasks, the research community has also focused on *instruction following dialogue tasks*, such as target completion tasks (de Vries et al., 2017), object finding tasks (Roman et al., 2020), and navigation tasks (Thomason et al., 2020). Narayan-Chen et al. (2019) proposed the Minecraft Corpus dataset, where the task consists in a cooperative asymmetric task involving an architect and a builder that have to build a target structure collaboratively. Jayannavar et al. (2020) then built a builder model to follow the sequential instructions from the architect.

Multi-Modal. Almost all instruction following dialogue tasks need to consider both contextual information and actions as well as the state of the world (Suhr and Artzi, 2018; Suhr et al., 2019; Chen et al., 2019; Lachmy et al., 2021), which remains a key challenge for instruction following dialogue tasks. In particular, the Vision-and-Dialog Navigation (VDN) task (Chen et al., 2019; Thomason et al., 2020; Roman et al., 2020; Zhu et al., 2021) where the question-answering dialogue and visual contexts are leveraged to facilitate navigation, has attracted increasing research attention. Other tasks, such as moving blocks tasks (Misra et al., 2017) and object finding tasks (Janner et al., 2018), also require the modelling of both contextual information in natural language as well as the world state representation to be solved.

Spatial Reasoning. Many instruction following dialogue tasks contain texts with spatial-temporal concepts (Chen et al., 2019; Yang et al., 2020). For instance, the Minecraft Corpus dataset contains utterances with spatial relations, e.g., "go to the middle and place an orange block two spaces to the left". Although pre-trained language models have been used successfully in a wide array of downstream tasks, interpreting and grounding abstractions stated in natural language, such as spatial relations, have not been systematically studied and remain still challenging. Therefore, another challenge for an agent is to follow instructions which require the learning and understanding of spatio-temporal linguistic concepts in natural language. To train models able to understand and reason about spatial references in natural language, Shi et al. (2022) proposed a benchmark for robust multi-hop spatial reasoning over texts.

Learning by Asking Questions. Determining whether to ask clarification questions and what to ask is critical for instruction followers to complete the tasks. Several recent studies have focused on learning a dialogue agent with the ability to interact with users by both responding to questions and by asking questions to accomplish their task interactively (Li et al., 2017; de Vries et al., 2017; Misra et al., 2018; Roman et al., 2020). For instance, de Vries et al. (2017) introduced a game to locate an unknown object via asking questions about objects in a given image. A decision-maker is introduced to learn when to ask questions by implicitly reasoning about the uncertainty of the agent. Different from earlier works (Kitaev and Klein, 2017; Suhr et al., 2019), recent works on VDN tasks propose agents that learn to ask a question when the certainty of the next action is low (Thomason et al., 2020; Roman et al., 2020; Chi et al., 2020). Roman et al. (2020) proposed a two models-based agent with a navigator model and a questioner model. The former model was responsible for moving towards the goal object, while the latter model was used to ask questions. Zhu et al. (2021) proposed an agent that learned to adaptively decide whether and what to communicate with users in order to acquire instructive information to help the navigation.

3 Dataset and Tasks

3.1 The Minecraft Dialogue Corpus

The Minecraft Dialogue Corpus (Narayan-Chen et al., 2019) is built upon a simulated block-world environment with dialogues between an architect and a builder. This consists of 509 human-human dialogues (15,926 utterances, 113,116 tokens) playing the role of an architect and a builder, and game logs for 150 target structures of varying complexity (min. 6 blocks, max. 68 blocks, avg. 23.5 blocks), For each target structure at least three dialogues are collected where each dialogue contains 30.7 utterances (22.5 architect utterances and 8.2 builder utterances) and 49.5 builder blocks movements on average.

The architect instructs about a target structure the builder to build it via a dialogue. Although the architect observes the builder operating in the world, only the builder can move blocks. The builder has access to an inventory of 120 blocks of six given colors that he or she can place or remove. The collaborative building task restricts the structures to a build region of size $11 \times 9 \times 11$, and contains 3709, 1331, and 1616 samples for training, validation, and test sets.

3.2 Builder Dialogue Annotation

Builders need to be able to decide their actions at any time point rather than only execute actions with the information about when to execute. Thus, we annotate all builders' utterances in the Minecraft Corpus dataset (Narayan-Chen et al., 2019) and categorize all 4,904 builder utterances into 8 utterance types. These types are partially inspired by the work of Lambert et al. (2019). Each utterance falls into exactly one category. These categories are defined as follows: ***(1) Instruction-level Questions:*** used to request that the architect clarifies previous instructions;***(2) Task-level Questions:*** used to request the architect to give a description about the whole picture of the building task, e.g., ask for the next instruction or ask to describe how the target structure should look like; ***(3) Verification Questions:*** used to request the architect to give feedback on previous actions; ***(4) Greetings:*** used to greet each other; ***(5) Suggestions:*** used to provide suggestions about building; ***(6) Display Understanding:*** used to express whether previous instructions have been understood; ***(7) Status Update:*** used to describe the current status, e.g., tell the architect where they are, their current block stock status, or

Table 1: The taxonomy of builder utterances: we categorize them into eight types where *instruction-level questions* and *task-level questions* are both a sub-type of clarification questions. There are 4,904 builder utterances in total.

Category	Example	Amount	Percentage
Instruction-level Questions	1. What color? 2. Is it flat?	914	18.64%
Task-level Questions	1. What are we building? 2. What's next?	252	5.14%
Verification Questions	1. Like that or othwr way? 2. Is this the cross you wanted?	1021	20.82%
Greeting	1. Ready? 2. Hello!	808	16.48%
Suggestions	1. In the future we can call these donuts or something 2. No problem, if it's hard to describe we can just go step by step	59	1.23%
Display Understanding	1. No problem. 2. Knew what you meant	1296	26.43%
Status Update	1. I don't have enough green to continue. 2. I'll stay with this perspective	101	2.06%
Others	1. I got my first job from Minecraft. 2. Oh, wwo, sorry!	453	9.24%

Table 2: Statistics of the extended Minecraft Dialogue Corpus: "Execution (Original)" represents that the builder should predict a sequence of building actions given the dialogue context and the world state in a sample; "Ask for clarifications" indicates that the builder should ask for more information in order to execute building actions; "Others" stands for remaining dialogue acts for the builder such as greetings, chit-chat, and display understanding.

	Train	Valid	Test
Execution (Original)	3709	1331	1616
Ask for clarifications	437	151	163
Others	837	267	366
Total	4983	1749	2145

whether they have finished a given instruction; ***(8) Others:*** not relevant to the task itself (e.g. chit-chat, expressing gratification, or apologies).

Among these 8 utterance types, the *instruction-level questions* and the *task-level questions* are a sub-type of clarification questions used to further clarify instructions or the task itself when the information from the architect is not clear or ambiguous. Based on these annotations, we extend the original dataset (the first row in Table 2) with two other dialogue acts, 'Ask for clarifications' and 'Others', as shown in the second and third rows of Table 2. Each 'Ask for clarifications' sample includes a world state and a dialogue context followed by a builder utterance labelled as *instruction-level questions* or *task-level questions*; each sample tagged as 'Others' includes a world state and a dialogue context followed by other builder utterance types.

3.3 Task Definition

Let $\mathcal{H}$ be the set of all dialogue contexts, $\mathcal{W}$ the set of all world states, and $\mathcal{A}$ the set of actions, including building actions (placing a block, removing a block, or a special stop action that terminates the task) and utterance actions (ask clarification questions or other utterance categories). Given a dialogue context $h \in \mathcal{H}$, an initial grid-based world state $w_0 \in \mathcal{W}$, the target is to predict the next action type as *Execution*, *Ask for clarifications* and *Others*. When the prediction of the action type is *Execution*, a sequence of actions $\{a_i\}_{i=1}^n$, where $a_i \in \mathcal{A}$ and a_n is the *Stop* action, is needed to be generated to reach the final target structure w_n. The action type *Execution* will update the world state via a deterministic transition function T such that $w_i = T(w_{i-1}, a_i)$ where $w_i \in \mathcal{W}$.

4 Method

In this section we introduce the proposed builder model, as shown in Figure 2. The model comprises four major components: the *utterance encoder*, the *world state encoder*, the *fusion module*, and the *slot decoder*. The utterance encoder (in Sec. 4.1) and world state encoder (in Sec. 4.2) learn to represent the dialogue context and the world state. These encoded representations are then fed into the fusion module (in Sec. 4.3) that learns contextualized embeddings for the grid world and textual tokens through the single and cross modality modules. Finally, the learned world and text representations are mapped into the pre-defined slot-values in the slot decoder (in Sec. 4.4).

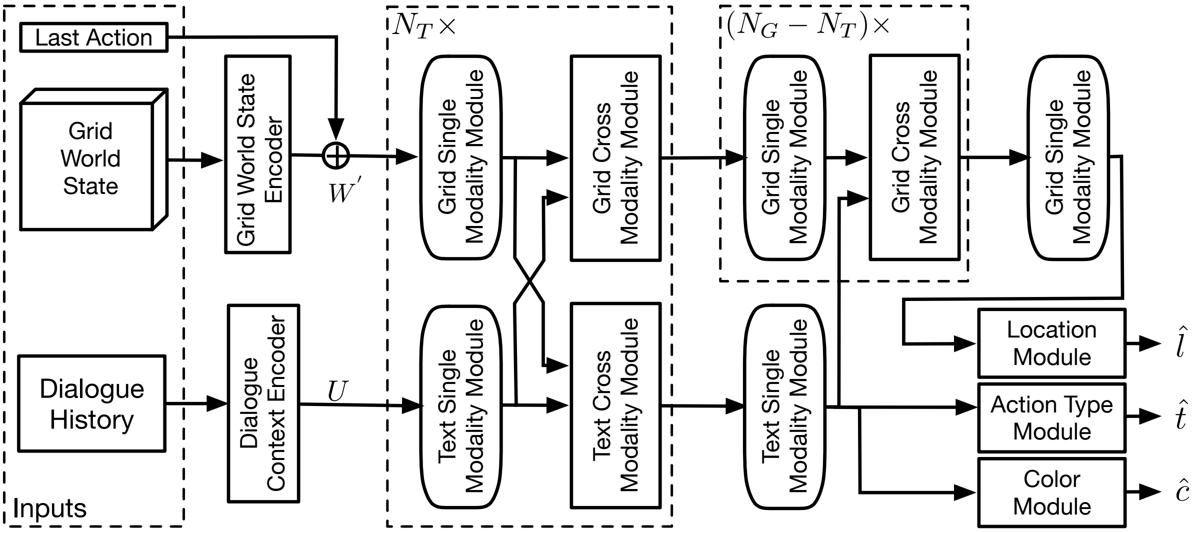


Figure 2: The model architecture. The $\oplus$ sign represents the concatenation operation. This illustration uses the plate notation. There are a total of N_T+1 text single modality modules, N_G+1 grid single modality modules, N_T text cross modality modules, and N_T grid cross modality modules. Arrows indicate the flow of information.

4.1 Dialogue Context Encoder

We add "architect" and "builder" annotations before each architect utterance A_t and each builder utterance B_t respectively. Then, the dialogue utterances are represented as

$$D_t = \text{“architect”}A_t \oplus \text{“builder”}B_t$$

at the turn t, where $\oplus$ is the operation of sequence concatenation.The entire dialogue context is defined as:

$$H = D_1 \oplus D_2 \oplus \cdots \oplus D_t \qquad (1)$$

Given the dialogue context H, we truncate the tokens from the end of the dialogue context or pad them to a fixed length as inputs and then use the dialogue context encoder to encode utterance history into $U \in \mathbb{R}^{s\times d_w}$, where d_w is the dimension of the word embedding and s is the maximum number of tokens for a dialogue context. The dialogue context encoder can be word embeddings like Glove Pennington et al. (2014) or contextual word embeddings Devlin et al. (2019), which are both widely used in the literature (Ni et al., 2021a,b; Wang et al., 2020, 2021).

4.2 Grid World State Encoder

The world state is represented by a voxel-based grid. We first represent each grid state as a 7-dimensional one-hot vector that stands for empty or a block having one of six colors, yielding a 7×11×9×11 world state representation. Additionally, we truncate the action history to the last five ones, assign an integer weight in $1,\ldots,5$ and then include these weights as a separate input feature in each grid, resulting in a raw world state input of $W_0 \in \mathbb{R}^{8\times 11\times 9\times 11}$. We also represent the last action as an 11-dimensional vector a where the first two dimensions represent the placement or removal actions, the next six dimensions represent the color, and the last three dimensions represent the location of the last action.

The structure of the world state encoder is similar to Jayannavar et al. (2020)'s, i.g., consisting of k 3D-convolutional layers (f_1) with kernel size 3, stride 1 and padding 1, followed by a ReLU activation function. Between every successive pair of these layers there is a 1×1×1 3D-convolutional layer (f_2) with stride 1 and no padding followed by ReLU:

$$W_i = \text{ReLU}(f_2^i(\text{ReLU}(f_1^i(W_{i-1})))), \qquad (2)$$
$$W_k = \text{ReLU}(f_1^i(W_{k-1})), \qquad (3)$$

where $i = 1, 2, \ldots, k-1$. $W_k \in \mathbb{R}^{d_c\times 11\times 9\times 11}$ is the learned world grid-based representation where d_c is the dimension of each grid representation. Then we concatenate the last action representation $a \in \mathbb{R}^{11}$ to each grid vectors in W_k and reshape them into $W' \in \mathbb{R}^{d_c'\times 1089}$, where $d_c' = d_c + 11$.

4.3 Fusion Module

The fusion module comprises four major components: two *single modality modules* and two *cross-modality modules*. The former modules are based on self-attention layers and the latter on cross-attention layers. These take as input the world state representation and dialogue history representation. Between every successive pair of grid single-modality modules or text single-modality modules there is a cross modality module. We take N_G and N_T layers for the grid cross modality module and the text cross modality module. We first revisit the definition and notations about the attention mechanism (Bahdanau et al., 2015) and then introduce how they are integrated into our single modality modules and cross-modality modules.

Attention Mechanism. Given a query vector x and a sequence of context vectors $\{y_j\}_{j=1}^{K}$, the attention mechanism first computes the matching score s_j between the query vector x and each context vector y_j. Then, the attention weights are calculated by normalizing the matching score: $a_j = \frac{exp(s_j)}{\sum_{j=1}^{K} exp(s_j)}$. The output of an attention layer is the attention weighted sum of the context vectors: $Attention(x, y_j) = \sum_j a_j \cdot y_j$. Particularly, the attention mechanism is called self-attention when the query vector itself is in the context vectors $\{y_j\}$. We use the multi-head attention following Devlin et al. (2019); Tan and Bansal (2019).

Single-Modality Module. Each layer in a single-modality module contains a self-attention sub-layer and a feed-forward sub-layer, where the feed-forward sub-layer is further composed of a linear transformation layer, a dropout layer and a normalization layer. We take $N_G + 1$ and $N_T + 1$ layers for the grid single-modality modules and the text single-modality modules respectively, interspersed with cross-modality module as shown in Figure 2. Since new blocks can only be feasibly placed if one of their faces touches the ground or another block in the Minecraft world, we add masks to all infeasible grids in the grid single-modality modules. For a set of text vectors $\{u_i^n\}_{i=1}^{s}$ and a set of grid vectors $\{w_j^m\}_{j=1}^{1089}$ as inputs of n-th text single-modality layer and m-th grid single-modality layer, where $n \in \{1, \ldots, N_T + 1\}$ and $m \in \{1, \ldots, N_G + 1\}$, we first feed them into two self attention sub-layers:

$$u_i^n = \text{SelfAttn}_u^n(u_i^n, \{u_i^n\}), \tag{4}$$

$$w_j^m = \text{SelfAttn}_w^m(w_j^m, \{w_j^m\}, mask) \tag{5}$$

Lastly, the outputs of self attention modules, u_i^n and w_j^m, are followed by feed-forward sub-layers to obtain $\hat{u_i}^n$ and $\hat{w_j}^m$.

Cross-Modality Module. Each layer in the cross-modality module consists of one cross-attention sub-layer and one feed-forward sub-layer, where the feed-forward sub-layers follow the same setting as the single-modality module. Given the outputs of n-th text single-modality layer, $\{\hat{u_i}^n\}_{i=1}^{s}$, and the m-th grid single-modality layer, $\{\hat{w_j}^m\}_{j=1}^{1089}$, as the query and context vectors, we pass them through cross-attention sub-layers, respectively:

$$\hat{u_i}^{n+1} = \text{CrossAttn}_u^n(\hat{u_i}^n, \{\hat{w_j}^m\}), \tag{6}$$

$$\hat{w_j}^{m+1} = \text{CrossAttn}_w^m(\hat{w_j}^m, \{\hat{u_i}^n\}), \tag{7}$$

The cross-attention sub-layer is used to exchange the information and align the entities between the two modalities in order to learn joint cross-modality representations. Then the output of the cross-attention sub-layer is processed by one feed-forward sub-layer to obtain $\{u_i^{n+1}\}_{i=1}^{s}$ and $\{w_j^{m+1}\}_{j=1}^{1089}$, which will be passed to the following singe-modality modules.

Finally, we obtain a set of word vectors, $\{\hat{u_i}^{N_T+1}\}_{i=1}^{s}$, and a set of grid vectors, $\{\hat{w_j}^{N_G+1}\}_{j=1}^{1089}$, that is, U^{N_T} and W^{N_G}. Since the value of N_G and N_T could be different, the modality with more layers would keep using the last single modality module's output of another modality as the input of its cross modality modules, as shown in the Figure 2.

4.4 Slot Decoder

The Slot Decoder contains three linear projection layers of trainable parameters, $M_L \in \mathbb{R}^{d_c^{'}}$, $M_C \in \mathbb{R}^{6 \times d_w}$, $M_T \in \mathbb{R}^{d_a \times d_w}$ where d_a is the number of action types to predict. We compute the average of $U^{N_T} \in \mathbb{R}^{s \times d_w}$ alongside the s-dimension to obtain $u \in \mathbb{R}^{d_w}$. Then we compute location logits, color logits, and action type logits:

$$\hat{l} = \text{softmax}(M_L \cdot W^{N_G}), \tag{8}$$

$$\hat{c} = \text{softmax}(M_C \cdot u), \tag{9}$$

$$\hat{t} = \text{softmax}(M_T \cdot u), \tag{10}$$

where softmax functions are used to map the extracted information into $\hat{l} \in \mathbb{R}^{1089}$, $\hat{c} \in \mathbb{R}^{6}$, and $\hat{t} \in \mathbb{R}^{d_a}$.

5 Experiments, Results and Discussion

In this section, we first compare our model against the baseline for the collaborative building task where models only need to learn the instruction following task (in Sec. 5.1). Then, we train our model to learn when to ask and evaluate on our extended Minecraft Dialogue Corpus (in Sec. 5.2). Finally, we evaluate our model's ability on the combination of the two above-mentioned tasks (in the Sec. 5.3). All training details are reported in the Appendix. The software and data are available at: `https://github.com/ZhengxiangShi/LearnToAsk`.

Table 3: Evaluation on the collaborative building task.

Model	Metric	Augmentation			
		None	2x	4x	6x
BAP model	F1	16.1	18.7	18.4	18.2
	Recall	12.6	15.2	14.3	15.0
	Precision	22.4	24.5	25.7	23.3
Ours (GloVe)	F1	**35.0**	**36.5**	**37.8**	**39.4**
	Recall	28.3	30.1	31.4	33.4
	Precision	45.8	46.2	47.6	48.1
Ours (BERT)	F1	34.5	30.1	30.4	35.4
	Recall	26.7	23.6	23.4	27.9
	Precision	48.7	42.6	43.5	48.5

5.1 Collaborative Building Task

Settings. In this task, the models are only trained to generate a sequence of actions without the need of considering *Ask for clarifications* and *Others*. We first compare our model against the only baseline[1] named BAP (Jayannavar et al., 2020) by only using the "Execution (Original)" dataset as in Table 2. Then, we conduct the experiments by using the augmented data from Jayannavar et al. (2020): the models are trained and evaluated with the augmented training data: 5,563 (indicated as 2x), 9,272 (4x), and 12,981 (6x) training samples. We provide the ground-truth previous actions and the world state for the next action prediction. For the sake of fairness, we retrain the BAP model under the same setting.

For our models, we present the performance of two different dialogue context encoders: we use the pre-trained GloVe word embeddings with 300 dimensions (Pennington et al., 2014) as the initial word embeddings followed by a GRU (Chung et al., 2014) and contextual word embeddings using the pre-trained BERT base model (Devlin et al., 2019). For the action type slot, we pre-define three potential values: *placement*, *removal*, and *stop*. The value of the location slot can be one of 1,089 candidate voxels and the value of the color slot can be one of six candidate colors. During training we minimize the sum of the cross entropy losses of the location slot, the color slot, and the action type slot. The F1-score metric on the test set is used to evaluate model performance by comparing the model predictions against the action sequence performed by the human builder.

Results. In Table 3 we present the results of our model and the baselines for the collaborative building task on the Minecraft Corpus Dataset. Experimental results show that our model outperforms the baseline model with a large margin. Results on the augmented dataset show that the advantage of the data augmentation is not obvious. The performance using contextualized word embeddings is poorer. This could be due to the size of the builder model with the BERT encoder which makes it more difficult to train.

5.2 Learning to Ask Task

Settings. In this task, all the models are trained only to predict one type of actions, *Execution*, *Ask for clarifications* and *Others*, without the need to generate a sequence of actions. All datasets in the Table 2 are used. In our model, for the action type slot, we define three potential slot values: *Execution*, *Ask*, and *Others*. In this experiment, the slots for location and color are not used. We use the pre-trained GloVe embeddings in the dialogue context encoder. During the training, the cross entropy loss of the action type is minimized.

Table 4: Test Accuracy of the learning to ask task.

Test Accuracy(%)		Prediction			Size
		Execute	Ask	Others	
Oracle	Execution	**93.81**	4.33	1.86	1616
	Ask	22.09	**63.80**	14.11	163
	Others	35.79	36.89	**27.32**	366
Overall Test Acc		80.05			2145

Results. In Table 4, we present the results of our model. Although our model achieves around 80% overall test accuracy, the correct answers mainly come from the execution type while the model struggles with the ask and other types. These two types have in fact a joint test accuracy of 38.6%. Experimental results demonstrate that the difficulty of the learning to ask task and that there is still a large room for improvement.

5.3 Joint Learning Task

Settings. In this task, the models are trained to not only predict one type of actions from *Execution*, *Ask for clarifications* and *Others* but also to generate a sequence of actions. All the datasets in Table 2 are used. In our model, for the action type slot, we pre-define five potential values: *Placement*, *Removal*, *Stop*, *Ask*, and *Others*. The value of the location slot can be one of 1,089 candidate grid and the value of the color slot is one of six candidate colors. We still use pre-train GloVe embedding in the dialogue context encoder. During the training we minimize the sum of the cross entropy losses of the location slot, the color slot, and the action type slot with weights equal to 0.1, 0.1, 0.8. We provide the ground-truth previous actions and the world state for the next action prediction.

Table 5: Test accuracy of the joint task.

Test Accuracy(%)		Prediction		
		Execution	Ask	Others
Oracle	Execution	**82.64**	8.64	8.72
	Ask	8.61	**60.93**	30.46
	Others	25.47	47.07	**31.46**
Overall Test Acc		72.26		

Table 6: The evaluation of the joint learning task.

	F1	Recall	Precison
Ours	28.4	20.9	43.9

Results. In Table 5, we present the results of our model's test accuracy for each action type. The model has an 72.3% test accuracy. However, if the execution of building actions is excluded, its joint test accuracy of ask and other action types is about 40.5%, indicating that deciding when to take the initiative remains challenging. In Table 6, we also report the results for the building task. Not surprisingly, the performance of our model drops slightly compared to those in Table 3, reflecting the difficulty of jointly learning.

5.4 Case Study

Although our model can predict the actions more accurately than the baseline, for example our model can usually predict the color of the blocks correctly with about 60% test accuracy rate, it is still non-trivial for our model to predict the whole action sequence correctly. In Figure 3, the architect instructed the builder to build a 3x3 square and then our model generated only parts of the structure successfully.

The dataset noise makes the learning process more challenging: the builder action sequences are noisy due to, for example, the builder miss-clicking in the construction process (Narayan-Chen, 2020). Also, builder action sequences are often fragmented between utterances due to the frequent interruptions of the architect. In order to solve these issues a good model should be capable to learn better representations for higher-level abstractions in natural language like spatial relation concepts and be more robust to noisy actions (Shi et al., 2022). However, existing models including pre-trained ones (Devlin et al., 2019) fail to learn such representations for spatial reasoning, which translates into poor performance in these instruction following tasks.

6 Conclusion

In this paper, we extend the Minecraft Corpus dataset by labelling builder utterances into eight types, in which two of them are relevant to clarification questions. This allows builder models to learn to take initiatives in the instruction following tasks. Also, we have proposed a new model that achieves state-of-the-art performance on the Minecraft collaborative building task with a large improvement. Besides these contributions, we introduce a new learning to ask task for clarification questions and a jointly learning task with the collaborative building task. We leave the generation of clarification questions to future work.

A Appendix

Training Details. We examine our model on the extend Minecraft Dialogue Corpus dataset. Our model's hyper-parameters are fixed for all three experiments in the Sec 5 as follows. The number of 3D-conv layers k is 3, the dimension of each grid representation d_c is 300, the number of layers of the grid cross-modality modules N_G is 4, and the number of layers of the text cross-modality modules N_T is 2. The max length of the dialogue context s is selected as 100 and the dropout rates are all set to 0.2. The number of heads for the attention mechanism in the text singe and cross modality modules is set to 2, while the number of heads is set to 1 for the attention mechanism in the grid singe and cross modality modules. The cross entropy loss from the location slot is not counted if the ground truth label of the action type is not 'placement' or 'removal', and the cross entropy loss from the color slot is not counted if the ground truth label of the action type is not 'placement'. The ground-truth of previous actions and the world state is provided to the models during the training and testing. For the experiment in the Sec 5.2 and 5.3, we randomly sample from 'Ask' and 'Others' sets in the training set to make training samples of different action types ('Execution', 'Ask', and 'Others') in the training set balanced. We train our model with cross entropy loss functions of all slots and a batch size of 50, using Adam optimizer (Kingma and Ba, 2015) with a learning rate of 1e-6, β_1 = 0.9 and β_2 = 0.99. We train our model with 50 epochs and select the model with the highest F1-score on the valid set.

Capturing Conversational Interaction for Question Answering via Global History Reasoning

Abstract

Conversational Question Answering (ConvQA) is required to answer the current question, conditioned on the observable paragraph-level context and conversation history. Previous works have intensively studied history-dependent reasoning. They perceive and absorb topic-related information of prior utterances in the interactive encoding stage. It yielded significant improvement compared to history-independent reasoning. This paper further strengthens the ConvQA encoder by establishing long-distance dependency among global utterances in multi-turn conversation. We use multi-layer transformers to resolve long-distance relationships, which potentially contribute to the reweighting of attentive information in historical utterances. Experiments on QuAC show that our method obtains a substantial improvement (1%), yielding the F1 score of 73.7%. All source codes are available at `https://github.com/jaytsien/GHR`.

1 Introduction

ConvQA is a task of answering questions conditioned on the conversation history as well as referential contexts. It heavily relies on the traceback of conversation history. For example, the pronoun "*it*" in Q_2 in Table 1 needs to be resolved first. It is indispensable to pursue its coreference "*alchemy index*" that appeared in the first-turn historical conversation (i.e., Q_0 and A_0). Therefore, the challenge of ConvQA is to detect the relevant evidence hidden in conversation history, and use it to strengthen the current round of question answering.

Section: Thrice: The Alchemy Index (2006-2008)
Context: In September 2006, the band announced plans for a new album (later titled The Alchemy Index) on their official website. The album was conceived as a series of 4 EPs, (...) I & II was released on October 16, 2007 and sold 28,000 copies in its first week. (...)
Q_0: What is the alchemy index? **A_0**: In September 2006, the band announced plans for a new album (later titled The Alchemy Index) on their official website. **Q_1**: What is notable about the album? **A_1**: The album was conceived as a series of 4 EPs (...)
Q_2: Was it well received? **A_2**: The Alchemy Index Vols. I & II was released on October 16, 2007 and sold 28,000 copies in its first week.

Table 1: An example from QuAC with the clues in conversation history (in blue) and context (in red).

Recently, utilizing global conversation history for enhancement is increasingly gaining interest, because it potentially contributes to capturing long-distance relevant evidence for answering. Both historical-answer-aware dynamic encoding of context (Qu et al., 2019b) and flow-based interaction modeling over shifting topics (Yeh and Chen, 2019) appear as successful solutions, where global conversation history is involved. However, some historical information fails to be maintained due to 1) the omission of historical questions and 2) disconnection from the earliest-stage conversation when topic frequently shifts.

In this paper, we develop a Global History Reasoning (GHR) model. GHR is not only capable of separately encoding different rounds of question-answering (QA) conversations, but sequentially fusing the encoded information of all QA pairs in visible conversations by a multi-layer attention network. It is designed to avoid the omission of available historical information and disconnection. We experiment on QuAC (Choi et al., 2018). The test results show that GHR yields substantial improvements when using BERT and ELECTRA as the baselines, and it achieves competitive performance compared to state-of-the-art methods.

2 Approach

The input of GHR comprises the referential context c, the current question in the t-th round, and all his-

July 10-15, 2022

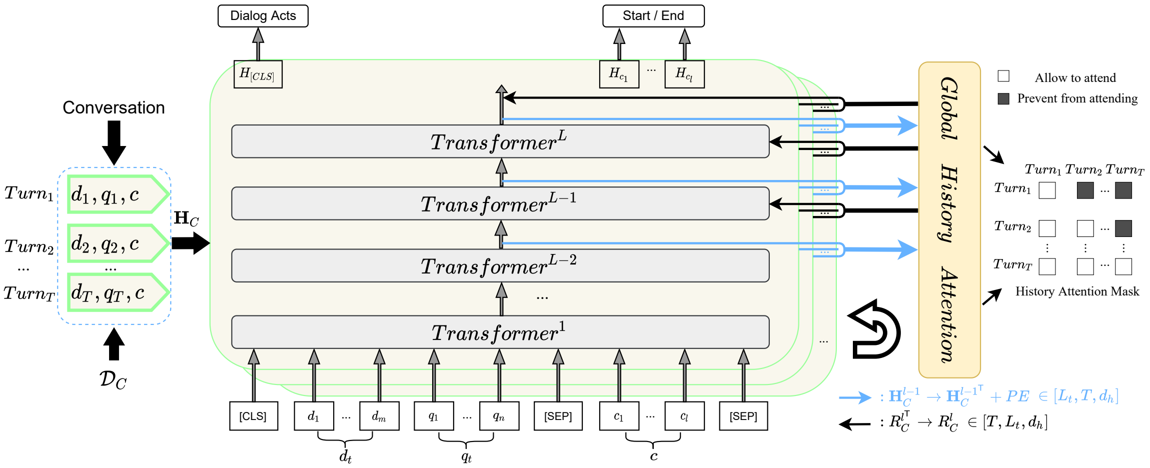

Figure 1: Architecture of global history reasoning (GHR) model.

torical QA pairs $\mathcal{H}_t = [(q_1, a_1), \ldots, (q_{t-1}, a_{t-1})]$, where q_i and a_i denote the question and answer in the i-th round in conversation, respectively. GHR models local history by learning utterance representation for the QA pair in every single round. Then, GHR fuses all visible local history and models their interaction with the referential context by global history attention. Finally, a linear layer with softmax is applied for answer prediction.

Figure 1 shows the overall architecture of GHR, where the sequentially stacked cards (drawn with light green rectangles) denote the encoding stages for the questions issued at different times. For example, the visible structure in the top card illustrates the encoding stage for the first question q_1, and at the time, both the local conversation history d_1 and the visible global history are NULL. The global attention mechanism is shown at the right side of the diagram, whose input is the representation encoded by each transformer layer (blue arrows), while the output is the refined representation by the masked global interaction (black arrows). The masking operation is used to temporally disable the subsequent QA conversations when the current question is being dealt with (as required in the task of ConvQA).

2.1 Local History Encoding

We follow the most commonly-used ConvQA scheme (Zhao et al., 2021) to form the input of our encoder. Given the current question q_t, we consider the historical QA pairs in the last two rounds $d_t = (q_{t-2}, a_{t-2}, q_{t-1}, a_{t-1})$ as the local history of q_t, and concatenate it with q_t and the context c as the input sequence. For the context whose length exceeds the maximum input length (usually 512 tokens) of the encoder, we divide them into multiple fragments and put them in a batch in order. Then we use a pre-trained language model (PLM) to encode the input sequence into contextualized representations:

$$\mathbf{h}_t = P_{LM}(d_t, q_t, c), \mathbf{h}_t \in \mathbb{R}^{L_t \times d_h} \quad (1)$$

where $P_{LM}(\cdot)$ denotes a transformer-based PLM encoder, L_t denotes the maximum length of input sequence and d_h is the hidden size.

2.2 Global History Reasoning

Most existing ConvQA studies suppose that the latest two-round conversation history has the most direct correlation to the current question. Therefore, they merely encode them into the input representation (Ohsugi et al., 2019; Ju et al., 2019) as mentioned in Eq.(1). This results in the omission of other essential information from the entire conversation, such as that signaling the long-distance reference and topic consistency. Some previous work extended the local encoding by absorbing attentive information from a larger range of QA pairs in history. However, the gradual attenuation for encoding (Yeh and Chen, 2019) causes the failure in giving more prominence to the long-distance related information. Besides, due to the limited and fixed size of the input sequence, the complete conversational interaction process actually has been divided into fragments. This makes it hard to ensure the coherence during encoding a series of conversation units (each unit is a QA pair occurring in the conversation history).

A sufficient flow of information among entire conversation units is warranted to compensate for these defects. Specifically, to enhance the interaction of multi-turn utterances, we design a global history attention mechanism to sequentially fuse contextualized representations of visible historical QA pairs $\mathcal{D}_C$. We denote the latent information representation of $\mathcal{D}_C$ as $\mathbf{H}_C = [\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_T]$, where $\mathbf{H}_C \in \mathbb{R}^{T \times L_t \times d_h}$, T is the number of rounds of the conversation. For example, $\mathbf{h}_i$ is the representation of the i-th round QA pair.

To obtain deep interactions between different rounds, we transpose the dimension of the input matrices $\mathbf{H}_C$ as $L_t \times T \times d_h$ and obtain $\mathbf{H}_C^\mathsf{T} = [\mathbf{h}_1^\mathsf{T}, \mathbf{h}_2^\mathsf{T}, \ldots, \mathbf{h}_T^\mathsf{T}]$. Then we add absolute positional embeddings $\mathbf{p}_i$ to $\mathbf{h}_i^\mathsf{T}$ to incorporate the position information of each token. The final input embeddings is:

$$\mathbf{H}_C^\mathsf{T} = [(\mathbf{h}_1^\mathsf{T}; \mathbf{p}_1), (\mathbf{h}_2^\mathsf{T}; \mathbf{p}_2), \ldots, (\mathbf{h}_T^\mathsf{T}; \mathbf{p}_T)], \quad (2)$$

where $\mathbf{H}_C^\mathsf{T} \in \mathbb{R}^{L_t \times T \times d_h}$.

During history reasoning, we apply a Global History Attention (GHA) layer to model the whole history and learn the history-aware representations for each token in the utterance:

$$\mathbf{R}_C^\mathsf{T} = [\mathbf{r}_1^\mathsf{T}, \mathbf{r}_2^\mathsf{T}, \ldots, \mathbf{r}_T^\mathsf{T}] = GHA(\mathbf{H}_C^\mathsf{T}), \quad (3)$$

where $\mathbf{r}_i^\mathsf{T} \in \mathbb{R}^{L_t \times d_h}$ denotes the history-aware representation of the i-th round, $GHA(*)$ is a transformer layer with history attention mask. In a real dialogue scene, a speaker is able to see all happened historical utterances before the current round, while subsequent utterances are unseen. Therefore, to avoid leaking the unseen utterances, we leverage the self-attention mask mechanism (Dong et al., 2019) (as shown in the right of Figure 1) to capture the visible historical information associated with token embeddings of each position. We then re-transpose $\mathbf{R}_C^\mathsf{T} \in \mathbb{R}^{L_t \times T \times d_h}$ to obtain $\mathbf{R}_C = [\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_T] \in \mathbb{R}^{T \times L_t \times d_h}$ for easily fusing the local and global history.

To integrate the contextualized representations $\mathbf{H}_C$ with the history-aware representations $\mathbf{R}_C$, we first adopt N GHA layers to obtain $\mathbf{R}_C^l$. In particular, the l-th GHA layer (Eq.(5))[1] is connected behind the (l-1)-th Transformer layer (Eq.(4)). N is a hyper-parameter that indicates that each of the last N Transformer layers is followed by a GHA layer. Then, we perform layer normalization (Ba et al., 2016) to update the final $\mathbf{H}_C$ (Eq.(6)).

$$\mathbf{H}_C^l = Transformer(\mathbf{H}_C^{l-1}) \quad (4)$$

$$\mathbf{R}_C^l \Leftarrow GHA(\mathbf{H}_C^{l-1}) \quad (5)$$

$$\mathbf{H}_C^l = LayerNorm(\mathbf{H}_C^l + \mathbf{R}_C^l) \quad (6)$$

Finally, we get the fusion representation $\mathbf{O}_C$ by concatenating $\mathbf{H}_C^L$ and $\mathbf{R}_C^{L+1}$ for the subsequent answer prediction.

$$\mathbf{O}_C = [\mathbf{H}_C^L; \mathbf{R}_C^{L+1}]. \quad (7)$$

2.3 Answer Prediction

Given the representations $\mathbf{O}_C = [\mathbf{o}_1, \mathbf{o}_2, \ldots, \mathbf{o}_T]$ from the global history reasoning module, an answer span is predicted by two linear layers with softmax that calculate the probability of each token being the start and end tokens over $\mathbf{o}_t$:

$$p_t^s, p_t^e = SoftMax(Linear(\mathbf{o}_t)), t \in [1, T] \quad (8)$$

where p_t^s, p_t^e are the probabilities of the start and end positions of the answer span in the t-th round, respectively.

In the training step, we utilize cross entropy to compute the loss of the start and end predictions.

$$\mathcal{L}_{span} = -\frac{1}{T}\sum_{t=1}^{T}(y_t^s logp_t^s + y_t^e logp_t^e) \quad (9)$$

Besides optimizing by the position loss of the answer span (Eq.(9)), we also apply multi-task optimization (Zhao et al., 2021) for training. Specifically, we apply three linear layers with softmax over the "[CLS]" vector of $\mathbf{o}_t$ to determine the current question's dialog acts, including answerability, affirmation, and continuation (Choi et al., 2018).

$$p_t^{na}, p_t^{af}, p_t^{ct} = SoftMax(Linear(\mathbf{o}_t^{cls})) \quad (10)$$

where p_t^{na} denotes the fractional vector of answerable probability of the question, p_t^{af} is the probability of affirmation, and p_t^{ct} is the probability of continuing to ask subsequent questions. We use cross entropy to compute losses of the acts.

$$\mathcal{L}_{na} = -\frac{1}{T}\sum_{t=1}^{T} y_t^{na} logp_t^{na} \quad (11)$$

$$\mathcal{L}_{af} = -\frac{1}{T}\sum_{t=1}^{T} y_t^{af} logp_t^{af} \quad (12)$$

$$\mathcal{L}_{ct} = -\frac{1}{T}\sum_{t=1}^{T} y_t^{ct} logp_t^{ct} \quad (13)$$

---

[1] For simplicity, we use $\Leftarrow$ in Eq.(5) to indicate the calculation process with the two transpose steps mentioned above.

where y_t^{na}, y_t^{af}, and y_t^{ct} are the ground-truths of answerability, affirmation, continuation, respectively. The final optimization goal is as follow.

$$\mathcal{L} = \alpha\mathcal{L}_{span} + \beta(\mathcal{L}_{ct} + \mathcal{L}_{af} + \mathcal{L}_{na}) \tag{14}$$

where α and β are coefficients for adjusting $\mathcal{L}_{span}$ and the combination of $\{\mathcal{L}_{ct}, \mathcal{L}_{af}, \mathcal{L}_{na}\}$.

3 Experiments

3.1 Settings

We conduct experiments on QuAC (Choi et al., 2018) consisting of 100K questions obtained from 14K information-seeking dialogues, which proposes unique challenges since these questions are open-ended, descriptive, highly contextual, and probably unanswerable. In particular, many questions require sufficient co-referencing and reasoning through interactions with conversation history.

We employ BERT$_{large}$[2] (Devlin et al., 2019) and ELECTRA$_{large}$[3] (Clark et al., 2020) as local history encoders. Meanwhile, we apply the voting strategy to implement comparable baseline models. The trade-off coefficients α and β in the loss function are set to 0.7 and 0.1 respectively (Zhao et al., 2021). The max query length and the stride of sliding window of GHR is set to 128. The batch size is set to 12. The answer length is set to 50 and learning rate is 2e-5. We rely on Pytorch and HuggingFace Transformer libraries (Wolf et al., 2020) for our experiments.

Following Choi et al. (2018), we adopt word-level macro-F1 and human equivalence score (HEQ) as evaluation metrics. HEQ-Q and HEQ-D measure the percentage of answers that the model accurately predicts but the human does not by given questions and dialogues.

We compare our GHR-based ConvQA model with the state-of-the-art models that are reported for performance on the QuAC leaderboard[4], including:

BiDAF++ (Choi et al., 2018) further augments BiDAF with self-attention and contextualized embeddings.

BiDAF++ w/2-ctx (Choi et al., 2018) additionally models conversation history from the previous two turns of QA pair by encoding their positions in conversation within the question embeddings and concatenating the marker embeddings to the passage embeddings.

Models	F1	HEQ-Q	HEQ-D
BiDAF++	51.8/50.2	45.3/43.3	2.0/2.2
BiDAF++ w/2-ctx	60.6/60.1	55.7/54.8	5.3/4.0
HAE	63.9/62.4	59.7/57.8	5.9/5.1
FlowQA	64.6/64.1	-/59.6	-/5.8
GraphFlow	-/64.9	-/60.3	-/5.1
FlowDelta	66.1/65.5	-/61.0	-/6.9
HAM	66.7/65.4	63.3/61.8	9.5/6.7
RoR	75.7/74.9	73.4/72.2	17.8/16.4
BERT (ours)	67.7/-	62.9/-	7.8/-
GHR (BERT)	69.0/-	64.6/-	8.0/-
ELECTRA (ours)	73.2/72.7	69.8/68.8	12.2/11.9
GHR (ELECTRA)	74.9/73.7	71.7/69.9	14.6/13.7

Table 2: Results on the dev/test set of QuAC.

HAE (Qu et al., 2019a) introduces a history answer embedding to incorporate the conversation history into BERT.

FlowQA (Huang et al., 2019) feeds the model with the hidden embeddings generated by reasoning in each new round of conversation.

GraphFlow (Chen et al., 2020) encodes conversation history into context graphs for context reasoning and analysis.

FlowDelta (Yeh and Chen, 2019) passes down the information gain between different turns to ensure that the model can focus on more informative cues in context.

HAM (Qu et al., 2019b) adopts position attention embeddings for history selection and optimizes the model from both answer span prediction and dialog act prediction via a multi-task learning framework.

RoR (Zhao et al., 2021) uses chunk reader to obtain chunk answers, which are aggregated for document reader to read again, and votes for the final answer.

3.2 Experimental Results

Table 2 shows the comparison of the existing published models with relatively high performance on the QuAC leaderboard with our GHR models on both the dev and test set. The test results show that all improvements of GHR are statistically significant (paired t-test (Dror et al., 2018), p-value < 0.01). We obtain the following observations.

1) Compared with the baseline models, the performances of the GHR models with BERT and ELECTRA are improved by 1.3 and 1.7 absolute F1 scores on the dev set, respectively. It indicates that GHR is effective for the ConvQA task, even based on the PLM with stronger representation capability (ELECTRA). This suggests that general PLM-dependent ConvQA models may have limita-

[4] https://quac.ai. Note that we only compare the proposed model to the methods with published papers.

Models	F1	HEQ-Q	HEQ-D
ELECTRA	73.2	69.8	12.2
w/ 1 GHA layer	74.3	71.2	14.5
w/ 2 GHA layers	74.4	71.3	14.1
w/ 3 GHA layers	**74.9**	**71.7**	14.6
w/ 4 GHA layers	74.7	71.5	14.4
w/ 5 GHA layers	73.7	70.3	**14.8**
w/ 6 GHA layers	73.3	69.8	14.0
w/ 7 GHA layers	72.6	69.3	12.7

Table 3: Effects of the number of GHA layers on the QuAC dev set.

tions without a step specifically targeting conversation history interactions.

2) GHR outperforms other models that utilize global conversation history, such as FlowQA, GraphFlow, and FlowDelta. We believe that these "flow"-based models tend to attenuate or ignore earlier conversation histories, which may prioritize recent utterances. Thus, when the current question is correlated to an earlier history or topic drifts, it is disadvantageous for the "flow"-based models. On the contrary, the GHR model still maintains a high focus on the early utterances through the GHA mechanism, so it can effectively utilize the global dialogue history.

3) Compared with the typical ConvQA model HAM, GHR outperforms it by a 2.3 absolute F1 score on the dev set with the same PLM settings (BERT). The reason might be that HAM only employs the answers of at most the first 4 rounds in conversations and pays more attention to the distribution of answer spans in the context, but does not model the question. Thus HAM is also difficult to solve the problem caused by the topic drifting. For GHR, we believe that modeling global history is the most effective factor leading to the benefits of GHR.

4) Compared with the best model on the QuAC leaderboard (RoR), our GHR is 1.2 absolute F1 scores lower than it on the test set. The reason is that RoR employs transfer learning to first finetune itself on the CoQA dataset, but such a method is meaningless for us since the target of this paper is quite different. Moreover, RoR focuses on modeling long contexts, but not modeling conversation history. It only utilizes the question in the current round. Also, GHR can be easily combined with RoR in implementation. Therefore, we suggest fusing the two models to further improve the performance of the ConvQA task.

We conduct an ablation experiment to investigate the effect of the number of the global history attention (GHA) layers on performance. Table 3 shows the results of the GHR (ELECTRA) models with from 1 to 7 of GHA layers. We can observe that the performance is improved when introducing the GHA layers, which verifies the effectiveness of our proposed approach. Moreover, GHR (ELECTRA) achieves the best performance when the number of GHA layers is 3. We also notice that when the number of layers is 1-4, the performance gaps between the models are not large, and all of them are close to the best performance. When the number of layers is greater than 4, the model performance begins to decline. We believe the reason is that the average round number of QuAC is 7, so a deeper structure may lead to overfitting.

Finally, we analyze the different results of the GHR model with its corresponding baseline, to directly observe the improvement brought by the global history attention mechanism (See Appendix A.3 for details).

4 Conclusion

In this paper, we propose a global history reasoning (GHR) approach to capture interactions between all utterances for conversational question answering. Experimental results conducted on QuAC show the effectiveness of the proposed model. In the future, we will explore how to implement interactions between conversation history and context by the position features of history answers. In addition, we will extend our conversation history modeling approach to the knowledge-grounded conversation generation task (see more related work in Appendix A.1).

A Appendix

A.1 Related Work

To model the history information in conversations, a kind of study focus on how to explicitly select important history question-answer pairs at the input step (Zhu et al., 2018; Reddy et al., 2019; Ju et al., 2019). Besides, a few studies argue that historical answer spans in context are more crucial, so they mark the answers when encoding the context (Choi et al., 2018; Qu et al., 2019a; Ohsugi et al., 2019; Qu et al., 2019b).

Another mainline of studies focus on conversation history reasoning. Huang et al. (2019) proposes a flow operation, feeding models entire hidden representation obtained by reasoning process when answering previous questions. The hidden states of each turn are passed back in turn by a unidirectional GRU. To avoid the changes of the captured representations during multi-turn reasoning, Yeh and Chen (2019) propose a flowdelta mechanism to explicitly capture the information gain in the conversation flow. Moreover, Chen et al. (2020) implement history reasoning by a flow operation on context graphs.

Recently, Vakulenko et al. (2021) propose to rewrite the current question using conversation history, with the goal to seek dependable clues to recover the default contents or resolve the coreferences. On the basis, Kim et al. (2021) resolve the conversational dependency via consistency regularization, and jointly use the original and rewritten questions to lead the supervised learning of QA models.

Modeling conversation history is a hot research area. It has also been widely studied in the direction of Knowledge-Grounded Conversation Generation (Kim et al., 2020; Zheng et al., 2020; Zhao et al., 2020). Such methods tend to model the full context and knowledge to generate responses, while GHR tends to model the context that is effective for answering the current question, and simultaneously learn the global history reasoning gain brought by different turns of history and the optimization of answer extraction.

A.2 Experiments on CoQA

CoQA (Reddy et al., 2019) is another typical ConvQA dataset. Table 4 lists the results of GHR model with from 1 to 7 of the GHA layers. It shows that the GHR model only improves 0.7% F1 over the baseline ELECTRA model on CoQA's dev

Models	F1
ELECTRA	89.0
w/ 1 GHA layer	89.3
w/ 2 GHA layers	89.5
w/ 3 GHA layers	**89.7**
w/ 4 GHA layers	89.5
w/ 5 GHA layers	89.3
w/ 6 GHA layers	88.8
w/ 7 GHA layers	88.6

Table 4: Effects of the number of GHA layers on the CoQA dev set.

Case #1
Section: Early political career: John Sherman Cooper (id: C_5caef3e3024c4f9294e1dacda1ff09b7_1)

Q$_0$: What was the first job he held?
A$_0$: After being urged into politics by his uncle, Judge Roscoe Tartar, Cooper ran unopposed for a seat in the Kentucky House of Representatives
Q$_1$: What was the first office he ran for?
A$_1$: Kentucky House of Representatives
Q$_2$: How long was he in office?
A$_2$: CANNOTANSWER

Current Question Q$_3$: Did he run for another political office after that?
Ground Truth: In 1929, Cooper declared his candidacy for county judge of Pulaski County.
ELECTRA: In 1939, he sought the Republican gubernatorial nomination.
GHR (ELECTRA): In 1929, Cooper declared his candidacy for county judge of Pulaski County.

Table 5: An example of the results predicted by GHR (ELECTRA) and ELECTRA on the dev set.

set. This is because CoQA's problems are quite straightforward, most of which can be predicted without conversation history (Yatskar, 2019). Thus CoQA is not suitable for our global history reasoning goals. Nevertheless, we still find that the effect of GHA layers on GHR was consistent in CoQA and QuAC, which means that GHR based on the same pretraining model performed relatively stable in different ConvQA tasks. As a result, GHR can play a role in modeling global history information in a variety of ConvQA tasks.

A.3 Case Study

The example in Table 5 compares the predictions between the model with ELECTRA and GHR (ELECTRA) model. On the dev set, we observe that GHR (ELECTRA) outperforms the ELECTRA model without the global history reasoning mechanism in almost all instances that contain similar long-distance referential relations. For example, we can see in Case #1, to correctly answer the current question Q$_3$, the model needs to infer that *he* refers to *Cooper* in A$_0$.

Learning Structural Information for Syntax-Controlled Paraphrase Generation

Abstract

Syntax-controlled paraphrase generation aims to produce paraphrase conform to given syntactic patterns. To address this task, recent works have started to use parse trees (or syntactic templates) to guide generation. A constituency parse tree contains abundant structural information, such as parent-child relation, sibling relation, and the alignment relation between words and nodes. Previous works have only utilized parent-child and alignment relations, which may affect the generation quality. To address this limitation, we propose a **S**tructural **I**nformation-augmented **S**yntax-**C**ontrolled **P**araphrasing (SI-SCP) model. Particularly, we design a syntax encoder based on tree-transformer to capture parent-child and sibling relations. To model the alignment relation between words and nodes, we propose an attention regularization objective, which makes the decoder accurately select corresponding syntax nodes to guide the generation of words. Experiments show that SI-SCP achieves state-of-the-art performances in terms of semantic and syntactic quality on two popular benchmark datasets. Additionally, we propose a **S**yntactic **T**emplate **R**etriever (STR) to retrieve compatible syntactic structures. We validate that STR is capable of retrieving compatible syntactic structures. We further demonstrate the effectiveness of SI-SCP to generate diverse paraphrases with retrieved syntactic structures.

1 Introduction

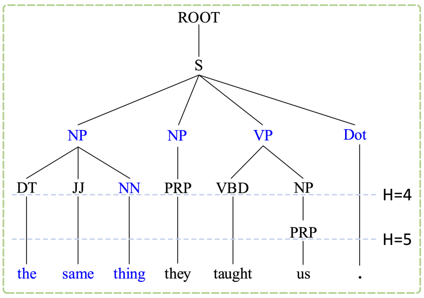

Figure 1: An example of a constituency tree structure. Parent-child relation: NP→NN, sibling relation: NP NP VP Dot, alignment relation between nodes and words: (NN thing), (NP the same thing).

Paraphrases are texts or passages conveying the same meaning but with different surface realization. Paraphrase generation (PG) is a key technology of automatically generating a restatement for a given text, which has the potential use in many downstream tasks, such as question answering (Gan and Ng, 2019), machine translation (Zhou et al., 2019), and sentence simplification (Zhao et al., 2018). However, a natural sentence can be paraphrased into various surface forms.

To obtain diverse paraphrases, controllable paraphrase generation (CPG) with specified styles has recently attracted growing interests e.g., satisfying particular sentiment (Hu et al., 2017; John et al., 2019; Dai et al., 2019; Lee et al., 2021) or syntactic structure (Iyyer et al., 2018; Chen et al., 2019; Liu et al., 2020; Kumar et al., 2020; Li et al., 2020; Yang et al., 2021). As CPG can produce diverse paraphrases by exposing syntactic control, it can be used in a wide range of application scenarios, such as dialogue generation (Niu and Bansal, 2018), data augmentation (Iyyer et al., 2018; Yang et al., 2021; Sun et al., 2021), and diverse question generation (Yu and Jiang, 2021), etc.

Generally, syntax-controlled paraphrase generation needs to tackle two major challenges. *The first challenge is how syntax-controlled generating is achieved?* For this challenge, Iyyer et al. (2018) use two encoders to encode input sentences and linearized parse trees to produce paraphrases. A constituency parse tree contains abundant structural information, such as parent-child relation, sibling relation, and the alignment relation between words and nodes, as shown in Figure 1. Linearizing parse trees, typically, result in loss of structural informa-

July 10-15, 2022

tion. Kumar et al. (2020) encode parse trees in a top-down manner, and then a queue-based decoding mechanism is proposed to incorporate syntax information. Li et al. (2020) employ a path attention mechanism to capture the tree structure of the syntax. However, these methods still have some limitations. The top-down encoding manner and path attention only consider parent-child relation. Additionally, due to the complexity of the queue-based decoding mechanism (Kumar et al., 2020), the predicted `pop` sequences cannot be guaranteed to be perfect, which may cause error propagation.

The second challenge is how compatible syntactic structures can be retrieved to guide generation in practice? Previous works (Iyyer et al., 2018; Li et al., 2020) use common syntactic templates that appear most frequently from the corpus, which means that these works generate syntactically diverse paraphrases using a fixed set of syntactic structures for all input sentences. The diversity in syntax is hence limited. Moreover, not all sentences can be paraphrased into the same set of syntactic structures.

In order to address these problems, we propose a **S**tructural **I**nformation-augmented **S**yntax-**C**ontrolled **P**araphrasing (SI-SCP) model based on attention network. Particularly, we design a tree transformer to capture parent-child and sibling relation. To learn the alignment relation between words and nodes, we propose an attention regularization objective. The basic motivation is that a syntactic template contains several syntax nodes which guide the generation of different words, respectively. As shown in Figure 1, the `NP` node guides the generation of noun phrase. Learning alignment relation makes the decoder accurately select corresponding syntax nodes to guide the generation of words. Additionally, to enhance diversity in syntax-controlled generation, we propose a **S**yntactic **T**emplate **R**etriever (STR) to retrieve compatible syntactic structures for any input sentence.

We evaluate our model on two popular benchmark datasets. Experiment results show that SI-SCP achieves the state-of-the-art performence in syntactic and semantic quality. The visualization results show the attention regularization makes the decoder accurately attend to corresponding syntactic nodes during decoding. Human evaluation also demonstrates that our method is able to generate semantically and syntactically better sentences than previous methods. We further show that STR can retrieve more compatible structures compared with the common syntactic templates method. SI-SCP can generate more syntactically diverse paraphrases with retrieved syntactic structures.

In summary, the major contributions of this paper are as follows:

- We build a novel syntax-controlled paraphrasing model that contains a tree-transformer and an attention regularization objective.
- To retrieve compatible syntactic structures in practice, we propose a syntactic template retriever.
- Experiments show that our SI-SCP achieves new state-of-the-art results in both semantic and syntactic evaluation on two popular benchmark datasets. We further demonstrate that STR is capable of retrieving compatible syntactic templates. The SI-SCP can produce more syntactically diverse paraphrases with retrieved syntactic structures.

2 Related Work

We focus primarily on the task of syntactically controlled paraphrase generation, which has recently attracted increasing attention (Iyyer et al., 2018; Chen et al., 2019; Liu et al., 2020; Kumar et al., 2020; Li et al., 2020). According to the control element, previous works can be divided into two categories. The first strand of research uses sentential exemplar as syntactic control. Chen et al. (2019) and Liu et al. (2020) design a latent variable to learn syntax by encoding the exemplar itself, and then use a syntactic latent variable to guide the generation of paraphrases. However, a latent based approach might not offer enough explicit syntactic information as guaranteed by actual constituency parse trees (Kumar et al., 2020). The second strand of research takes a parse tree as a syntactic input, controlling the syntax of generated text with the structure specified by the parse tree. Iyyer et al. (2018) use two encoders to encode input sentences and linearized parse trees to produce paraphrases. Due to the linearization of syntactic tree, a lot of structural information is generally lost. To capture the tree structure of the parse tree, Kumar et al. (2020) encode parse trees in a top-down manner, and then a queue-based decoding mechanism is proposed to incorporate syntactic information. Li

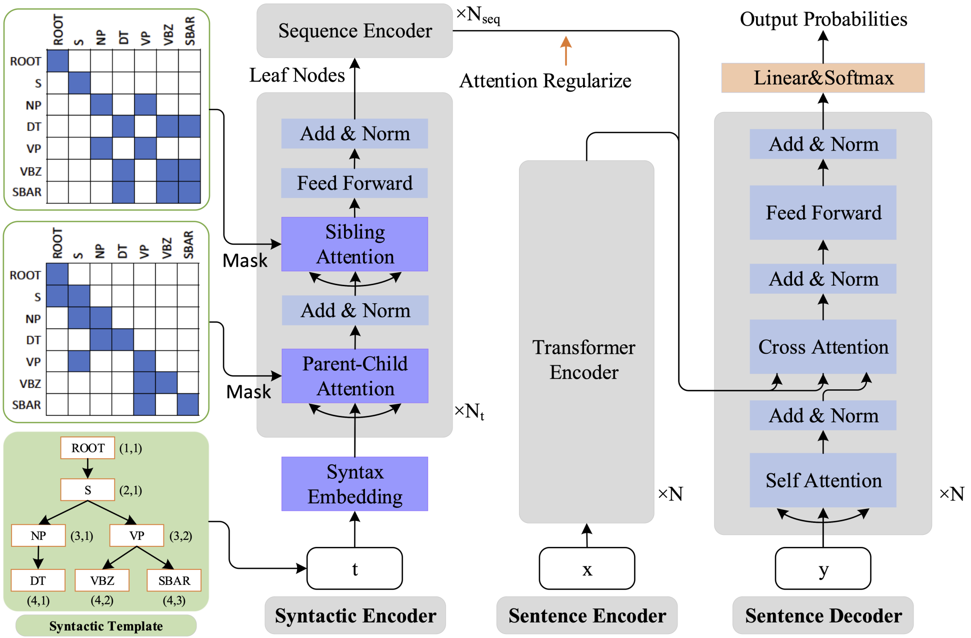

Figure 2: The architecture of syntax-controlled paraphrasing model. The sequence encoder is built with the transformer network, which is used to encode leaf nodes in the syntactic template. Please refer Section 3.3 for details.

et al. (2020) design a syntax encoder based on a path attention mechanism. However, these methods only consider parent-child relation in parse trees.

Differing from previous approaches, we propose a novel tree-transformer to model parent-child and sibling relation for better capturing the tree structure of the parse tree. To learn the alignment relation between words and nodes, we also propose an attention regularization objective, which makes the decoder accurately select corresponding syntax nodes to guide the generation of words. Additionally, we propose a syntactic template retriever that can help to retrieve compatible syntactic structures for any input sentences.

3 Syntax-Controlled Paraphrasing

3.1 Problem Formalization

We formulate the problem of syntax-controlled paraphrase generation as follows. Given a source sentence $\boldsymbol{x}$ and a syntactic template $\boldsymbol{t}$, the syntax-controlled text generation aims to generate target sentence $\boldsymbol{y}$ which conveys the meaning of $\boldsymbol{x}$ and conform to the syntactic structure of $\boldsymbol{t}$.

The syntactic template $\boldsymbol{t}$ is a partial constituency parse tree that provides a general syntax skeleton. Due to different levels of syntax trees contain different information, to compare fairly, we use the top-4 layers (in this work) of the full parse tree of $\boldsymbol{y}$ as the syntactic template for all baselines. Of course, our model can also use syntactic templates from other layers.

As shown in Figure 2, our model contains a sentence encoder and a syntactic encoder, which encodes the source sentence $\boldsymbol{x}$ and the template $\boldsymbol{t}$ separately. We deploy a target sentence decoder to generate the final text. The details of the proposed approach will be presented below.

3.2 Sentence Encoder

The sentence encoder contains N stacked transformer blocks. The hidden states of the sentence encoder are calculated by:

$$\boldsymbol{h}_x = \texttt{Transformer}(\boldsymbol{x}) \qquad (1)$$

where $\boldsymbol{h}_x$ is final hidden state of source sentence $\boldsymbol{x}$.

3.3 Syntactic Encoder

This encoder provides the necessary syntactic signal for the generation of paraphrases. A parse tree contains rich parent-child and sibling relations. To capture these information, we propose a tree-transformer with a syntax embedding layer, parent-child attention, and sibling attention modules.

Syntax Embedding Layer Given a syntactic template $\boldsymbol{t}$, we use (node, level, index) format sequences to represent it. Formally, let $\boldsymbol{t} = \{\boldsymbol{t}_1, \boldsymbol{t}_2, ..., \boldsymbol{t}_n\}$, where $\boldsymbol{t}_i = (p_i, l_i, s_i)$, p_i is a parse tree node, l_i is its level, s_i is the index of the node at a specific level. For example, the syntactic template in Figure 2 is represented by {(`ROOT`, 1, 1), (`S`, 2, 1), (`NP`, 3, 1), (`DT`, 4, 1), (`VP`, 3, 2), (`VBZ` 4, 2), (`SBAR`, 4, 3)}.

At the embedding layer, node tokens, level tokens, and index tokens are embedded respectively and then added together to produce the syntax embedding at position i:

$$\texttt{Emb}(\boldsymbol{t}_i) = \texttt{Emb}(p_i) + \texttt{Emb}(l_i) + \texttt{Emb}(s_i) \quad (2)$$

Parent-Child and Sibling Attention Then we calculate the hidden state of each node in a tree-structure manner. Specifically, we introduce an adjacency matrix to guide the calculation of the self-attention module:

$$\begin{aligned} \boldsymbol{A} &= \mathrm{Softmax}((\boldsymbol{Q}\boldsymbol{K}^T/\sqrt{d}) \odot \boldsymbol{M}) \\ \boldsymbol{h}_t &= \boldsymbol{A} \cdot \boldsymbol{V} \end{aligned} \quad (3)$$

where $\boldsymbol{Q}$ is a query matrix consisting of query vectors with dimension d, $\boldsymbol{K}$ is a key matrix consisting of key vectors with dimension d, $\boldsymbol{V}$ is a value matrix consisting of key vectors with dimension d. $\boldsymbol{M}$ is an adjacency matrix obtained from the syntactic template. $\odot$ denotes the element-wise product. For example, Figure 2 shows examples of the parent-child adjacency matrix and sibling adjacency matrix. We encode parent-child and sibling information by parent-child and sibling attention operations. We stack multiple tree transformer blocks to make the information of the ROOT node flow to leaf nodes.

After obtaining hidden states of all nodes, we use another encoder to encode all the leaf nodes in a sequential way:

$$\boldsymbol{h}_{leaf}^{seq} = \texttt{Transformer}(\boldsymbol{h}_{leaf}) \quad (4)$$

The reason we use this sequential encode is that parent-child and sibling attention modules would create a mismatch between the encoding and decoding process. Thus, it may be beneficial to introduce sequence information. We also demonstrate the effectiveness of the sequential encoder with experiments in Section 5.2.4.

3.4 Decoder

Based on the input sentence hidden states $\boldsymbol{h}_x$ and syntactic template hidden states $\boldsymbol{h}_{leaf}^{seq}$, the target transformer decoder uses two cross-attention modules to jointly exploit the input sentence and syntactic template information to generate the target text $\boldsymbol{y}$. Cross attentions are calculated as follows:

$$\begin{aligned} \boldsymbol{h}_{y,t}, \boldsymbol{A}_t &= \mathrm{Attn}(\boldsymbol{h}_y, \boldsymbol{h}_{leaf}^{seq}, \boldsymbol{h}_{leaf}^{seq}) \\ \boldsymbol{h}_{y,t,x}, \boldsymbol{A}_x &= \mathrm{Attn}(\boldsymbol{h}_{y,t}, \boldsymbol{h}_x, \boldsymbol{h}_x) \end{aligned} \quad (5)$$

where Attn is the multi-head attention module in transformer. $\boldsymbol{h}_y$ is hidden states of decoder, $\boldsymbol{A}_t$ and $\boldsymbol{A}_x$ are attention scores with the template and the input sentence, respectively. Through the feed-forward network sub-layer, $\boldsymbol{h}_{y,t,x}$ will be used as the input of the next layer or used to predict the next word.

Syntax Attention Regularization The attention weight $\boldsymbol{A}_t$ is essential for accurate syntactic control. We propose an regularization method to guide the learning of $\boldsymbol{A}_t$ using the alignment of nodes and words in a parse tree. Specifically, we propose a attention regularization loss as follows:

$$\mathcal{L}_{ar} = \mathrm{MSE}(\boldsymbol{A}_t, \hat{\boldsymbol{A}}_t) \quad (6)$$

where $\hat{\boldsymbol{A}}_t$ are oracle attention weights obtained from the alignment of nodes and words in a parse tree. `MSE` denotes the Mean Square Error loss function. By doing so, we can make learned $\boldsymbol{A}_t$ close to oracle attention distribution. We also introduce label smoothing (0.25) to reduce errors caused by parsing.

Because multi-layer transformer and multi-head attention mechanism produce multiple syntax attention matrices, we simply make each generated attention matrix close to the oracle attention. We leave alternatives to this simple method to our future work.

3.5 Training

To train the above model, we optimize the following objective function:

$$\mathcal{L} = \lambda_1 \mathcal{L}_{ce} + \lambda_2 \mathcal{L}_{ar} \quad (7)$$

where $\mathcal{L}_{ce} = -\sum_{t=1}^{N} \log p(y_t | \boldsymbol{x}, \boldsymbol{t}, y_{1:t-1})$ is the cross-entropy loss for ground-true y, λ_* are balancing hyper-parameters.

4 Syntactic Template Retriever

A sentence cannot be converted to any syntactic structures. Incompatible syntax will lead to imperfect paraphrase conversion and nonsensical sentences. In this work, we propose a **S**yntactic **T**emplate **R**etriever (STR) to find compatible syntax for a sentence in practice. The basic assumption is that syntactic templates expressing the same meaning are relatively close in semantic space. Specifically, given an input sentence and its parse tree, the retriever retrieves compatible syntactic templates based on similarity from a pre-collected template library.

4.1 Encoder

We use a template encoder to map any template $\boldsymbol{t}$ into a vector space. Meanwhile, for the input sentence $\boldsymbol{x}$ and its parse tree $\boldsymbol{p}_x$ (i.e., the query $\boldsymbol{q}$), we use a sentence encoder and parse tree encoder to map them to the same vector space, and then retrieves k syntactic templates whose vectors are closest to the query vector. We define the similarity between the query and the syntactic template using the dot product of their vectors:

$$\begin{aligned} \mathrm{sim}(\boldsymbol{q}, \boldsymbol{t}) &= \boldsymbol{v}_q \cdot \boldsymbol{v}_t^T \\ \boldsymbol{v}_t &= \mathrm{Enc}_t(\boldsymbol{t}) \\ \boldsymbol{v}_q &= \boldsymbol{W} \cdot [\mathrm{Enc}_x(\boldsymbol{x}); \mathrm{Enc}_p(\boldsymbol{p}_x)] \end{aligned} \tag{8}$$

where Enc_* denote three different encoders, $\boldsymbol{W}$ is a linear layer, ';' denotes concatenation operation.

The three encoders are built with the transformer encoder. We use linearized parse tree and syntactic template as input [1], prepend [CLS] token to each input, and then take the representation of the prepended token as the output of each encoder in a similar way to BERT (Devlin et al., 2019).

4.2 Training

The goal is to create a vector space such that relevant pairs of queries and templates will have a smaller distance (i.e., higher similarity) than the irrelevant pairs. We use paraphrase pairs to build training data, where positive templates are from reference sentences.

Let $(\boldsymbol{q}_i, \boldsymbol{t}_i^+, \boldsymbol{t}_{i,1}^-, ..., \boldsymbol{t}_{i,n}^-)$ be a training instance that consists of one relevant (positive) template $\boldsymbol{t}_i^+$, along with n irrelevant (negative) templates $\boldsymbol{t}_{i,j}^-$. To train the retriever, we optimize the negative log likelihood of the positive template:

$$\begin{aligned} &\mathcal{L}(\boldsymbol{q}_i, \boldsymbol{t}_i^+, \boldsymbol{t}_{i,1}^-, ..., \boldsymbol{t}_{i,n}^-) \\ &= -\log \frac{e^{sim(\boldsymbol{q}_i, \boldsymbol{t}_i^+)}}{e^{sim(\boldsymbol{q}_i, \boldsymbol{t}_i^+)} + \sum_{j=1}^{n} e^{sim(\boldsymbol{q}_i, \boldsymbol{t}_{i,j}^-)}} \end{aligned} \tag{9}$$

At the training stage, we use the trick of in-batch negatives to learn the retriever.

5 Experiments

In this section, we conducted experiments to answer the following questions:

- How does our model compare against previous models?
- Can our model produce diverse paraphrases with retrieved templates?

5.1 Controlled Paraphrase Generation

Implementation details are presented in Appendix A due to limited space.

5.2 Datasets

Following previous work (Kumar et al., 2020), we used ParaNMT-Small and QQP-Pos datasets to

---

[1] We compared linearized and structured approaches and both have comparable performance, the main reason may be that controlled paraphrase generation requires learning relation between text and syntax (words and nodes), while the retriever learns relation between syntax. Based on the principle of simplicity, we used the linearized approach.

evaluate model performance for controlled paraphrase generation. **ParaNMT-Small** (Chen et al., 2019) contains 500k paraphrase pairs for training, 500 and 800 manually labeled paraphrase pairs for development set and test set. The ParaNMT-small is a subset of the original ParaNMT-50M dataset (Wieting and Gimpel, 2018) which is constructed automatically through back-translation of original English sentences. **QQP-Pos** (Kumar et al., 2020) is selected from Quora Question Pairs (QQP) dataset. It contains about 140K training pairs and 3K/3K data pairs for testing/validation.

5.2.1 Baselines[2]

- Source as output: Simply output the source sentence as output.
- SCPN (Iyyer et al., 2018) & GuiG (Li et al., 2020): They adopt a two-stage generation process. Iyyer et al. (2018) use two Bi-LSTM (Hochreiter and Schmidhuber, 1997) encoders to encode input sentences and linearized parse trees respectively. An LSTM decoder with attention mechanism pays attention to both semantic and syntactic hidden states to generate paraphrases. Li et al. (2020) use transformer network and propose a syntactic encoder with a path attention mechanism. GuiG only provided trained model on the ParaNMT-Small dataset.
- SGCP (Kumar et al., 2020): SGCP encodes syntactic templates with GRU network in a top-down manner. We directly used released SGCP model[3] and top-4 layers of the full parse tree of the reference paraphrases as syntactic templates.
- SynTrans: The framework is similar to SCPN, and we replace LSTM with Transformer (Vaswani et al., 2017). In this experiment, we directly used linearized syntactic templates to guide generation.

5.2.2 Automatic Evaluation

1. Semantic Metrics: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005) scores between generated sentences and reference paraphrases in the test set were used as semantic metrics.
2. Syntactic Metrics: Following previous works (Chen et al., 2019; Kumar et al., 2020; Li et al., 2020), we used the tree edit distance (TED) against the parse tree of the reference.

Model	Semantic	Syntactic
SCPN	3.16	3.73
GuiG	3.67	3.77
SynTrans	3.05	3.51
SI-SCP	3.81	4.55

Table 2: Human evaluation results.

5.2.3 Human Evaluation

We conducted the human evaluation on 100 randomly selected instances from the test set of ParaNMT-Small in a blind fashion. Three annotators evaluated generated paraphrases in terms of semantic and syntactic similarity (generations vs references); each aspect was scored from 1 to 5.

5.2.4 Results

As can be observed in Table 1, firstly, SGCP gets the lowest results, we observe that SGCP often produces sentences that end abruptly, thereby harming syntax and semantics[4]. GuiG achieves better performance than SCPN model among two-stage approach. This is because GuiG adopts the more advanced transformer network and a path-attention mechanism which can capture partial structural information. For SynTrans which uses linerized syntactic templates directly, it obtains relatively lower performance. Conversely, SI-SCP achieves significant improvements in both semantic and syntactic metrics, which means that modeling structural information can improve the quality of generations.

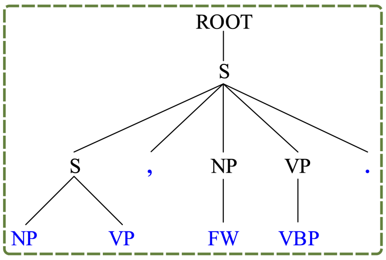
Among different variants of our model (ablation study), we see that removing any of the sequence encoder, attention regularization, and sibling attention module has a negative impact on performance, where attention regularization and sibling attention modules have a more significant impact.

---

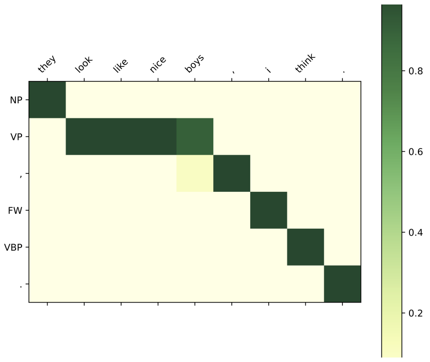
[2] Due to the different control types, we don't compared with the example-based methods (Chen et al., 2019; Liu et al., 2020)

[3] `https://github.com/malllabiisc/SGCP`

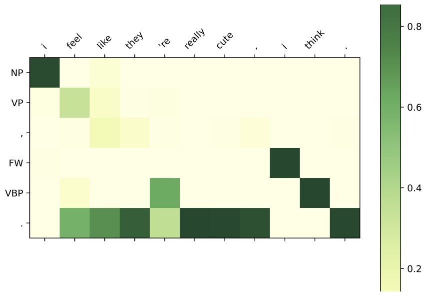
[4] The results of the SGCP baseline reported here are lower than in the original paper. This is because that original paper used very fine-grained syntactic information, which contains more hints about reference paraphrase. Additionally, compared with syntactic templates, fine-grained syntactic structures are more conducive to guiding models to generate natural sentences.



(a) Syntactic template



(b) Syntax Attention with Regularization



(c) Syntax Attention without Regularization

Figure 3: (a) shows the used syntactic template. (b) and (c) show visualization results of syntax attention with or without regularization.

Table 2 shows the results of human evaluation which are consistent with automatic evaluation results. Our model obtains the highest scores in both semantics and syntax, thereby highlighting the efficacy of our method.

Table 6 shows examples of paraphrases generated by different model. We can observe that our SI-SCP can produce better results than baseline models in terms of both semantics and syntax.

5.2.5 Visualization of Syntax Attention

We visualize the syntax attention when using the syntactic template as control in Figure 3. This is an instance from the test dataset: {***Source****: it looks to me like they are really sweet boys.* ***Reference****: they look like very nice boys, i think.*}. Figure 3 (a) is the syntactic tempalte used in the example.

We can see that most words can accurately align with corresponding nodes when using attention regularization. Without attention regularization, most words tend to pay attention to the punctuation. These results show that the proposed attention regularization can make the decoder accurately select corresponding nodes to guide the generation of words.

Dataset	Model	Top-1	Top-5	Top-10	Top-20

5.3 Diverse Paraphrase Generation

In this section, we further evaluated our model's ability to generate diverse paraphrases. We first examine whether STR can retrieve compatible templates. We generated 10 syntactically different paraphrases for each input sentence using 10 retrieved syntactic templates. Implementation details are presented in Appendix B.

5.3.1 Evaluation Metrics

We evaluated this task with the following metrics:

1. Retrieval Accuracy: We use Top-K retrieval accuracy on the test set, measured as the percentage of Top-K retrieved templates that contain the gold template. The gold template is

Template	Paraphrase
Source	you can choose between a movie or a pottery class.
(S (NP (PRP)) (VP (MD) (VP)) (.))	you can choose from the film or the pottery class.
(S (NP (NP) (CC) (NP)) (VP (MD) (VP)) (.))	the film or the pottery class can be selected.
(S (NP (NP) (,) (CC) (NP)) (VP (MD) (VP)) (.))	the film , or the pottery class can be selected.
(SQ (MD) (NP (PRP)) (VP (VP) (CC) (VP)) (.))	can you pick one of the film or the pottery class?
(S (NP (PRP)) (VP (VBZ) (UCP)) (.))	it 's possible to choose between film or the pottery class.
(S (NP (RB) (DT) (JJ) (NN)) (VP (MD) (VP)) (.))	perhaps a pottery class can choose between the movies and the film.

Table 5: Syntactic paraphrases generated by SI-SCP with retrieved templates. We show several successful and one failed (in blue) generations.

obtained from the reference sentence. This metric is used to evaluate the performance of the template retriever.

2. Semantics: Given 10 generated paraphrases $Y = \{y^1, y^2, ..., y^{10}\}$ for each input sentence in the test set. For 10 paraphrases, the one with the highest BLEU score to the reference sentence is selected as the final generation y^{best}. The BLEU score between (y^{best}, y) is calculated at the corpus level.

3. Rejection Rate: We use Sentence-BERT [5] (Reimers and Gurevych, 2019) to compute paraphrase scores for generated outputs with respect to the input. And then use this score[6] to filter out low-quality paraphrases. The percentage of filtered sentences is taken as a rejection rate.

4. Diversity: We compute BLEU between all pairs (y^i, y^j), then macro-average these values at the corpus-level.

5. Validity (Valid): To measure paraphrase quality, we perform human evaluation on 100 randomly selected paraphrases from the remaining paraphrases. Three annotators evaluate whether the generated sentences are true paraphrases, (the paraphrase is marked with 1, otherwise marked with 0). Then we compute the percentage of paraphrases marked as 1.

5.3.2 Results

As can be observed in Table 3, our STR significantly surpasses CT in retrieval accuracy. These results show that STR is capable of retrieving compatible syntactic templates.

In Table 4, we also show the results of the vanilla Seq2Seq based on transformer, where we use top-K (K=50) sampling to generate 10 paraphrases. Because this method tends to generate repeated sentences, it obtains lower valid scores on the QQP-Pos dataset. We see that syntax-controlled paraphrasing method significantly improve the diversity of generations.

Among different syntax-controlled models, compared with CT, STR significantly improves semantics, rejection rate, and validity metrics (Row 1/2/3/7/8 vs. Row 4/5/6/9/10). These results validate the advantages of the syntactic template retriever from the perspective of practical application. Using the same syntactic templates, GuiG can get a better rejection rate, but SI-SCP obtains better performance in terms of semantics, validity metrics. These results are consistent with automatic evaluation results in Table 1.

5.3.3 Case Study

Table 5 lists some paraphrases generated by SI-SCP with different syntactic templates. More generation results are presented in Appendix C. We see that the generated sentences always conform to the target templates. These examples are well-formed, semantically sensible, and grammatically correct sentences that also preserve semantics of the original sentences. However, our model also produces sentences with semantic deviation, like the failed cases in Table 5, when given template is incompatible with the input sentence.

6 Conclusion

We have presented a Structural Information-augmented Syntax-Controlled Paraphrasing (SI-SCP) model which can directly generate syntactic paraphrases with syntactic templates. Particularly,

---

[5] We used the paraphrase-distilroberta-base-v1, which is trained on large-scale paraphrase data. Available at: `https://public.ukp.informatik.tu-darmstadt.de/reimers/sentence-transformers/v0.2/`

[6] Similar to Iyyer et al. (2018), we set minimum paraphrase similarity to 0.7.

we propose a tree-transformer and an attention regularization. The tree transformer can model parent-child and sibling relation of the syntactic template. The attention regularization method makes the decoder accurately select corresponding syntax nodes to guide the generation of words. To retrieve compatible syntactic templates in practice, we further propose a Syntactic Template Retriever (STR). Experiments show that SI-SCP achieves substantial improvements over previous strong baselines. Furthermore, we also validate that STR is capable of retrieving compatible syntactic templates. SI-SCP can produce more syntactically paraphrases with retrieved syntactic templates.

A Controlled Paraphrase Generation

A.1 Implementation Details

We parsed all sentences in the training set, reference sentences in the validation and test set using Stanford CoreNLP (Manning et al., 2014). We used the scheduled Adam optimizer (Kingma and Ba, 2014) for optimization, and the learning rate was set to 2.0 for all experiments. We set hidden state size to 256 (i.e., d), filter size to 1024, head number to 4. The number of layers of the sentence encoder, sentence decoder, tree transformer and sequence encoder were set to 4, 4, 3, and 2, respectively. The batch size was set to 128. λ_1 was set to 5.0 while λ_2 1.0. We used BPE tokens pre-trained with $30,000$ iterations. All hyperparameter tuning was based on the BLEU score on the development set.

For the SynTrans baseline model, we set the number of syntactic encoder layers to 5 for fair comparison.

B Diverse Paraphrase Generation

B.1 Implementation Details

For the syntactic template retriever, we used 300 as hidden size, 512 as filter size and 4 heads in multi-head attention. The number of layers of sentence, syntax, and template encoders were all set to 4. The batch size was set to 512. We used the scheduled Adam optimizer (Kingma and Ba, 2014) for optimization, and the learning rate was set to 0.1. The word embedding layer was initialized by the publicly available GloVe (Pennington et al., 2014) 300-dimensional embeddings.[7]

C Generated Paraphrase Examples

Table 6 shows several paraphrases generated by each model. Table 7 lists some paraphrases generated by SI-SCP with different syntactic templates. Our model can generate more syntactically diverse paraphrases with retrieved syntactic templates.

Abstract

Different types of transformations have been used to model sentence simplification ranging from mainly local operations such as phrasal or lexical rewriting, deletion and re-ordering to the more global affecting the whole input sentence such as sentence rephrasing, copying and splitting. In this paper, we propose a novel approach to sentence simplification which encompasses four global operations: whether to rephrase or copy and whether to split based on syntactic or discourse structure. We create a novel dataset that can be used to train highly accurate classification systems for these four operations. We propose a controllable-simplification model that tailors simplifications to these operations and show that it outperforms both end-to-end, non-controllable approaches and previous controllable approaches.

1 Introduction

Sentence simplification is a text generation task where a sentence is transformed into a simpler version of itself while preserving its core meaning. Transformations can involve several different rewrite operations such as word substitutions (lexical paraphrasing), structural modifications (e.g. sentence splitting or syntactic paraphrasing), and deletion.

Sentence simplification has been shown to aid reader comprehension (Mason, 1978; Williams et al., 2003; Kajiwara et al., 2013) and be a useful preprocessing step for downstream NLP tasks such as relation extraction (Miwa et al., 2010; Niklaus et al., 2016) and machine translation (Chandrasekar et al., 1996; Mishra et al., 2014; Li and Nenkova, 2015; Mishra et al., 2014; Štajner and Popovic, 2016).

Modern systems are data-driven, learning to perform transformations from parallel corpora of complex-simple $\langle C, S \rangle$ pairs. Although many different approaches have been attempted in the past, including statistical machine translation (SMT)-based methods, nearly all systems proposed in recent years follow a neural sequence-to-sequence approach. As these systems are trained in an end-to-end manner they are able to perform lexical and syntactic operations in combination and produce outputs with very high fluency.

However, given the black-box nature of these end-to-end systems, they are forced to rely on imperfect training corpora to implicitly learn rewrite operations, many of which occur infrequently (Jiang et al., 2020). As a result, neural end-to-end systems have been found to be overly conservative, often making no changes to the original text or being limited to the paraphrasing of short word sequences (Alva-Manchego et al., 2017; Maddela et al., 2021). In addition, these systems provide limited capacity for controllability and are unable to express alternative variants of the simplified text (Alva-Manchego et al., 2017; Cripwell et al., 2021).

In response, attempts have been made to produce controllable simplification systems that can constrain either the shape (length, amount of paraphrasing, lexical and syntactic complexity) of the output (Martin et al., 2020) or the type of transformation to be applied (e.g., copy, split, merge, rewrite, etc.) (Scarton and Specia, 2018; Dong et al., 2019; Scarton et al., 2020; Garbacea et al., 2021; Maddela et al., 2021).

In this work we propose a novel approach to sentence simplification which encompasses four global operations: whether to copy the input sentence (no simplification needed), rephrase it, split it based on syntax, or split it based on discourse structure. We create a novel dataset that can be used to train highly accurate classification systems for these four operations and propose a controllable-simplification model that tailors simplification to them. We compare our model with various alternatives and previous work, using both quantitative metrics and human evaluation, and show that our

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2091 - 2103
July 10-15, 2022

model outperforms them. We also provide a qualitative analysis of the differences between the best models.

2 Related Work

2.1 Controllable Simplification

Scarton and Specia (2018), Nishihara et al. (2019) and Scarton et al. (2020) focus on tailoring outputs to specific reader groups based on the Newsela corpus (Xu et al., 2015), a popular simplification dataset which provides versions of news articles written for audiences of different reading levels. These works propose systems that adjust their simplifications to match one of these reading levels.

Martin et al. (2020) introduce a wider array of control attributes concerning grammatical features of the desired text such as compression level, amount of paraphrasing, and lexical and syntactic complexity.

Most recently, Maddela et al. (2021) propose a system that first uses a rule-based component (Niklaus et al., 2019) to generate candidates that have undergone splitting and deletion, before ranking them and sending the top n to a neural paraphasing model. Tunable settings in both components provide control over how much of the input is changed and whether to favour deletion or splitting. Their system received higher fluency and simplicity scores from human annotators compared to existing works.

However, at inference time, these methods all require the model to be explicitly informed about which reader level to cater to or which specific grammatical features or rewrite operations to prioritise. In constrast, we develop an approach that can not only be tuned manually, but can also operate in an end-to-end manner by inferring tunable parameters from the input.

2.2 Operation Classification

Alva-Manchego et al. (2017) and Dong et al. (2019) consider sentence simplification as a sequence-labeling problem, proposing systems that predict rewrite operations at the token-level before realising them downstream. Alva-Manchego et al. (2017) showed gains over previous approaches in terms of simplicity, but at the cost of fluency and meaning preservation. Dong et al. (2019) appears to resolve this trade off by introducing an enhanced interpreter that better constructs the resulting text.

Several existing works have attempted to use a classifer to determine which rewrite operation should be performed on an input at the sentence-level. Applying a sentence-level binary classifier as an initial step to predict whether simplification should be performed has been found to yield improved SARI results, reducing conservatism and spurious transformations (Scarton et al., 2020; Garbacea et al., 2021).

Multi-class systems have been explored with limited results. Scarton and Specia (2018) and Scarton et al. (2020) predict one of 4 operations (identical, elaboration, split, and merge) and feed this into an end-to-end model alongside the C as either a control token or one-hot vector. While Scarton and Specia (2018) fail to produce an accurate classifier or show any improvement over baselines, Scarton et al. (2020) show some gains in SARI when using predicted operation labels. However, their best classifier only yields an accuracy of 70%.

In the multi-class setting, models tend to struggle to accurately predict identity cases. We believe this is partially due to the training data used. All existing works use Cs from identical $\langle C, S\rangle$ pairs as training examples for this class, either alone or alongside standard Ss. The assumption here is that these pairs are identical because the C is already simplified. We will show that it is much more likely these items are unsimplified noise from the distribution of Cs and that excluding them from training data can dramatically improve accuracy.

We extend upon these sentence-level classification approaches by redefining the set of operations, creating comprehensive training and test data, and ultimately producing a classifier with much higher accuracy. We show that a pipeline approach which first predicts a rewrite operation outperforms existing end-to-end and controllable systems.

3 Operation Classification

We consider 4 operation types: *identity*, *rephrase*, *syntax-split*, and *discourse-split*. The *identity* and *rephrase* classes are equivalent to *identical* and *elaboration* from Scarton et al. (2020). In contrast, we split the *split* class into two distinct groups to capture further nuances of sentence splitting, as was explored in Cripwell et al. (2021).

Syntax-split indicates that a split should be performed based on a syntactic construct, whereas *discourse-split* indicates that a split should be performed based on a discourse relation. Examples of these can be found in Appendix A.

As we focus on single sentence simplification, we exclude the *merge* class used in (Scarton and Specia, 2018; Scarton et al., 2020).

3.1 Training Data

We construct training data for a simplification operation classifier by combining subsets of existing English datasets. We consider simplification datasets Wiki-auto, Newsela-auto [1] (Jiang et al., 2020), and MUSS (Martin et al., 2021) as well as dedicated splitting datasets WikiSplit (Botha et al., 2018) and D-CCNews (Cripwell et al., 2021).

Wiki-auto and Newsela-auto are automatically aligned $\langle C, S\rangle$ pairs extracted from Wikipedia and Newsela, respectively. MUSS contains 2.7M pairs mined from Common Crawl web data which are estimated paraphrases based on embedding distance. WikiSplit contains 1M split pairs mined from Wikipedia edit history, while D-CCNews contains discourse-split pairs mined from the CCNews corpus (Nagel, 2016). D-CCNews has two subsets: D-CCNews-C which contains single Cs, and D-CCNews-S which contains pairs of organic Ss and synthetic Cs. We include samples from both subsets. Table 1 provides a breakdown of the inclusions from each source.

We heuristically assign silver operation labels to sentences from these datasets as follows:

identity: Ss from the Wiki-auto and Newsela-auto *rephrase* and *syntax-split* sets. We can be fairly confident that Ss from known simplification datasets are sufficiently simplified.

rephrase: Cs from MUSS, Wiki-auto and Newsela-auto where there is no split in the output S and Levenshtein similarity between the C and S is less than 1 standard deviation above the mean (< 0.92). This is to exclude near-identical pairs.

syntax-split: Cs from WikiSplit, MUSS, Wiki-auto and Newsela-auto whose S exhibits a split and does not contain an identifiable discourse marker.

discourse-split: Cs from all datasets whose S contains a split and a discourse adverbial. [2]

We call the resulting dataset **IRSD**$_4^C$. [3] We also consider a 3-class subset which excludes the *identity* class (**IRSD**$_3^C$) to explore how results change when models are trained to always simplify.

3.2 Test Data

We use two datasets for evaluation. A random sample of 1% of the training data is set aside as a large (34K examples) silver test set. We also create a smaller gold test set by randomly sampling 100 items from each of the 4 classes in our silver test set and presenting them to 3 annotators instructed to select the most appropriate operation with which to simplify the text. Further details of the annotation process are in Appendix B.

We approved all annotations that received a majority label agreement and manually adjudicated cases where all annotators disagreed (11%). The mean Cohen's Kappa agreement score between annotators is 0.246, illustrating the difficulty of this task. In many cases, several operations could feasibly apply, and so assigning a single correct label is not always a perfect solution. Appendix C lists some examples of this.

3.3 Classification Model

We fine-tune pretrained RoBERTa models (Liu et al., 2019) with classification heads on IRSD$_4^C$ and IRSD$_3^C$. [4] Further training details are provided in Appendix D.

Results on Silver Test Data. Results can be seen in Figure 1. Accuracy on the silver test set (98%) is much higher than previous works: Scarton and Specia (2018) and Scarton et al. (2020) achieve mean accuracies of 51% and 70% for a similar 4-class task. Garbacea et al. (2021), who only train a binary (*simp*, *no-simp*) classifier achieve 81% accuracy.

Notably, the accuracy for the *identity* class is much higher than the 59% achieved by Scarton et al. (2020). This is perhaps in part due to our exclusion of Cs from identical $\langle C, S\rangle$ pairs in the *identity* training subset. We explored this hypothesis by using a test set containing Cs from identical pairs alongside the existing *identity* examples.

Figure 2 shows that doing so reduces performance on the *identity* class dramatically; the model only classifies 9.8% of these Cs as *identity* and 82.4% of them as *rephrase*. This suggests that

---

[1] We specifically use the aligned pairs used for simplification experiments in Jiang et al. (2020), which excludes identical pairs and those of readability levels 0-1, 1-2, and 2-3.

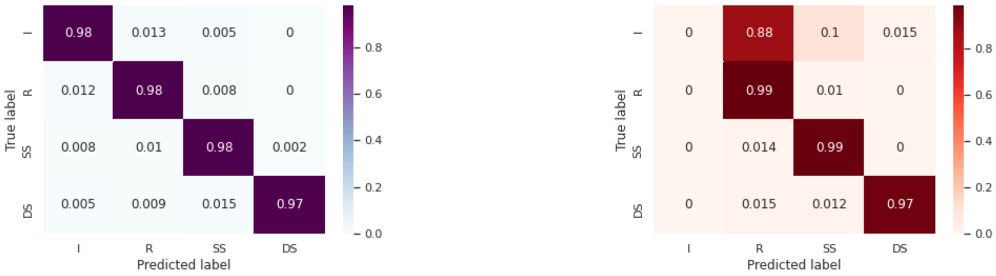
[2] D-CCNews is down-sampled to keep classes similar in size.

[3] Our data and code is available at `https://github.com/liamcripwell/control_simp`. Newsela data is excluded, subject to their terms of use, but can be provided upon request after receiving a licence.

[4] We use the pretrained *roberta-base* model available at `https://huggingface.co/roberta-base`.

Class	Source WikiSplit	MUSS	Wiki-auto	Newsela-auto	D-CCNews-C	D-CCNews-S	Total
Identity (0)	-	-	513,436	338,798	-	-	**852,234**
Rephrase (1)	-	461,702	366,382	171,508	-	-	**999,592**
Syntax-Split (2)	633,900	53,008	68,357	88,669	-	-	**843,934**
Discourse-Split (3)	269,666	1,002	5,277	2,060	250,062	249,958	**778,025**
Total	**903,566**	**515,712**	**953,452**	**601,035**	**250,062**	**249,958**	**3,473,785**

Table 1: Data source distributions for each operation class in IRSD$_4^C$.



(a) 4-class

(b) 3class

Figure 1: Normalised confusion matrix of (a) the four-class classifier and (b) the three-class classifier, evaluated on the silver-label test set.

these examples are from a distribution more similar to the *rephrase* examples and are possibly complex sentences themselves that have not been fully simplified in the source data. This observation validates our decision to exclude them.

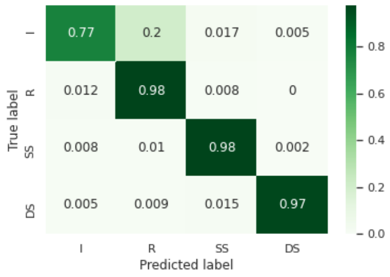


Figure 2: Normalised confusion matrix for the 4-class operation classifier, evaluated on the silver-label test set containing Cs from identical $\langle C, S\rangle$ pairs in the *identity* class.

Results on Gold Test Data. As shown in Figure 3, classification accuracy on the gold test set is considerably lower than on the silver data. *Identity* examples are often predicted as *rephrase*; *syntax-split* often as *discourse-split*; and *rephrase* examples regularly receive predictions across all four classes.

However, this aligns with our observations with respect to manual labelling difficulties. Often it is not immediately clear whether a particular example should be ignored or slightly rephrased. Similarly, it often seems plausible for either type of split to be performed. *Rephrase* is the broadest of the four classes, and so cases where any one of the other three classes could also apply should be expected.

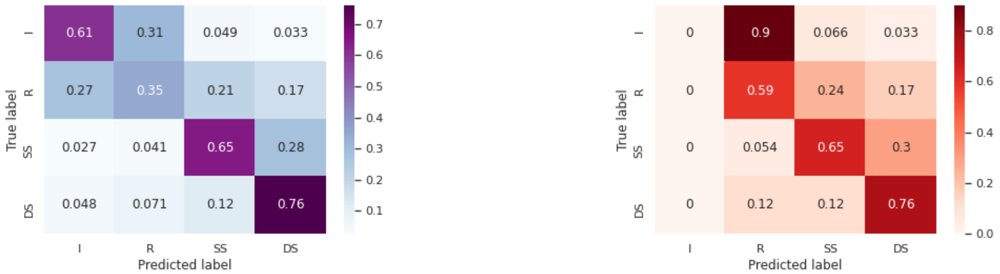
Despite being lower than on the silver examples, we believe these results show a strong signal of performance, with common mistakes being analogous to difficulties encountered by human annotators.

4 Sentence Simplification

4.1 Data

Training Data. For the sentence simplification task we use a modified version of IRSD^C which additionally includes target simplifications, i.e. $\langle C, o, S\rangle$ triples. We refer to this as **IRSD$_4^S$** and its 3-class subset as **IRSD$_3^S$**.

For the *identity* class, we take all inputs from **IRSD$_4^S$** labelled as *identity* and map them to themselves. For *rephrase* and *syntax-split*, we take the *rephrase* and *syntax-split* inputs and map them to their simplifications in the source datasets. We do the same for *discourse-split*, but, as D-CCNews-C instances do not contain simplifications, we replace them with additional $\langle C, S\rangle$ pairs from D-CCNews-S.



(a) 4-class

(b) 3-class

Figure 3: Normalised confusion matrix of (a) the four-class classifier and (b) the three-class classifier, evaluated on the human-annotated test set.

Test Data. We first train and test our systems on IRSD$^S_{3/4}$ and Newsela-auto.

Next, in order to compare with past works, we perform evaluation on the Newsela-auto test set introduced by Maddela et al. (2021). It contains 24,035 *rephrases*, 9,208 *syntax-splits*, and 148 *discourse-splits*. We refer to this as **Newsela-M** and also include results on the subset with split in their reference S (Newsela-M (Split)). We use this test set so we can leverage pre-existing system outputs from past works for comparison.

Additionally, we evaluate on the ASSET corpus (Alva-Manchego et al., 2020) which is a much smaller test set (359 examples) containing 10 human-written references per input. All test examples have at least one *rephrase* reference, 248 have at least one *syntax-split* reference, 12 have at least one *discourse-split* reference, and 0 have an *identity* reference.

4.2 Models

Existing Systems We consider a number of past works for comparison: (i) **Hybrid** (Narayan and Gardent, 2014), an older system with a probabilistic splitting component combined with an MT-based lexical paraphraser; (ii) **BERT**, pretrained encoder-decoder transformer (BERT$_{base}$) finetuned on simplification which achieved state-of-the-art performance (Jiang et al., 2020); (iii) **EditNTS** (Dong et al., 2019), a recent model using operation prediction; and (iv) **MadExP** (Maddela et al., 2021), current state-of-the-art controllable system. [5] We exclude other systems which require conditioning on specific reading levels.

Baseline End-to-End Model. We include end-to-end baselines that are trained to perform $C \rightarrow S$ with no additional information. These are used to gauge whether our controllable models are competitive with a black-box approach. We use the BART architecture (Lewis et al., 2020) and fine-tune a pretrained model with a language-modelling head on $\langle C, S\rangle$ pairs from 4 distinct datasets: IRSD$^S_4$ (**BART**$_4$), IRSD$^S_3$ (**BART**$_3$), Wiki-auto (**BART**$_W$) and Newsela-auto (**BART**$_N$). [6]

Controllable Model. Next, we train an end-to-end generative model to perform $\langle C, o\rangle \rightarrow S$, where o is an operation label. The o is used as a control token prepended to the input sequence for C. We use the same BART architecture as our end-to-end baselines.

From this model, we construct several systems: (i) an oracle baseline (**Ctrl**$_{Oracle}$) taking the silver operation label and performing generation as an end-to-end task; (ii) a pipeline system using a classifier to predict o before running the generative model.

We refer to different configurations as **Ctrl**$_{i,j}$, where i is the number of classes the classifier is trained on and j is the number of classes the generator is trained on. E.g. Ctrl$_{3,4}$ uses a classifier trained on IRSD$^C_3$ and a generator trained on IRSD$^S_4$. [7] We expect that using the 4-class classifier will result in more conservative outputs. Using the 3-class generator could allow more model capacity to focus on simplification. Conversely, the extra training data used by the 4-class generator could improve general performance.

---

[5] We use system outputs from versions of all of these models that have been trained on Newsela-Auto.

[6] We use the pretrained *facebook/bart-base* model available at https://huggingface.co/facebook/bart-base.

[7] For Ctrl$_{4,3}$ any inputs classified as *ignore* are returned without being passed to the generator.

Table 2: Automatic sentence simplification results on the IRSD_4^S, IRSD_3^S and Newsela-auto test sets.

5 Experimental Setup

5.1 Automatic Evaluation

The most common evaluation metrics used in text simplification are BLEU and SARI, with SARI being viewed as the more effective at describing simplicity. Both focus primarily on lexical similarities between the reference and system output without consideration for structural simplification.

A recent meta-analysis (Alva-Manchego et al., 2021) of automated text simplification evaluation shows that the precision-based BERTScore (P_{BERT}) (Zhang et al., 2019) is most highly correlated with human judgements. As P_{BERT} is very effective at identifying low quality simplifications, the authors recommend using it as a primary test of quality before referring to other metrics like SARI.

We report P_{BERT} and SARI as our primary metrics [8] and also use the split recall (R_{Split}) to evaluate how often the model performs splitting in known cases. We value recall over precision as it gives a better indication of whether a model regularly performs splits, but have also included the precision (P_{Split}) for clarity.

5.2 Human Evaluation

We perform a human evaluation of simplification systems by having 3 annotators evaluate outputs. In order to consider a range of structurally diverse examples we use our classifier to label the Newela-M test set with predicted operations and randomly select 25 from each of the 4 classes (further details in Appendix B). We presented the annotators with the input C from each $\langle C, S\rangle$ pair alongside the reference S and outputs from selected systems. Judgements are made with respect to 3 criteria: fluency, adequacy, and simplicity.

Fluency refers to the grammaticality of the output; adequacy measures meaning preservation with respect to the input; and simplicity measures the overall simplicity of the result. We followed standard practice by having these criteria judged on a 1-5 Likert scale and averaging the results. For simplicity, we advised workers that a high score can be given to an output identical to the input if there is little to no obvious changes that would make the sentence simpler.

We consider the following systems for comparison: EditNTS, MadExp, BART_N, BART_4, and $\text{Ctrl}_{4,4}$. This allows us to compare our systems to strong recent works and examine the effect of (i) using IRSD^S vs Newsela training data and (ii) using our controllable model vs an end-to-end approach.

6 Results and Discussion

Automatic evaluation results are shown in Table 2.

IRSD^S vs Other Data Models trained with IRSD^S ($\text{BART}_{3/4}$ and $\text{Ctrl}_{*,*}$) greatly outperform those trained on other datasets ($\text{BART}_{N/W}$) across every metric on the IRSD^S test sets. On the Newsela test set, IRSD^S models perform at least as well as BART_N. This is unsurprising as IRSD^S is much larger than Newsela and contains many of

Table 3: Comparison with existing systems and baselines. Oracle labels are acquired by applying the same heuristics used in the creation of IRSD^S. Note that the oracle labels for these test sets do not contain *identity* cases.

System	Fluency	Adequacy	Simplicity	Mean
Ref.	4.65^{**}	3.95^{**}	4.37^{*}	4.32
EditNTS	3.81^{**}	3.83^{**}	3.91^{**}	3.85
MadExP	3.74^{**}	3.52^{**}	3.97^{**}	3.75
BART_N	4.68	4.26^{**}	**4.38***	4.44
BART_4	4.71	**4.74**	4.14	4.53
$\text{Ctrl}_{4,4}$	**4.77**	**4.74**	4.20	**4.57**

Table 4: Human evaluation results for selected simplification systems and baselines. Ratings significantly different from $\text{Ctrl}_{4,4}$ are denoted with $*$ ($p < 0.05$) and $**$ ($p < 0.01$). Significance was determined with a Student's t-test.

the same examples. However, it shows the diversity of IRSD^S does not reduce Newsela-specific performance.

On Newsela test data, using the 3-class classifier ($\text{Ctrl}_{3,*}$) yields higher SARI and R_{Split} than the 4-class case. This is likely because *identity* is never predicted thereby encouraging less conservative simplification on a test set where most examples are simplified (Maddela et al. (2021) excludes all examples with high or low similarity between the input and the reference from the test set).

End-to-End vs Controllable Controllable systems outperform their end-to-end counterpart on all metrics and datasets. In particular, they show a large increase in R_{Split}, suggesting that explictly triggering splits via control tokens greatly improves a model's ability to correctly administer splits where needed. Using silver operation labels in Ctrl_{Oracle} shows universally higher scores than classifier-based pipelines, indicating that there is still room for improvement in terms of classification performance.

Existing Systems Comparative results with existing systems are summarised in Table 3. All of our systems achieve much higher P_{BERT} scores than any existing system. This suggests that merely using the BART architecture yields much more fluent outputs than other models. MadExP, which receives the highest SARI scores, actually receives much lower P_{BERT} than almost any other system, indicating that although it may be simplifying the text well, outputs might be less fluent.

$\text{Ctrl}_{3,4}$ achieves the highest scores on Newsela-M, except for being slightly beaten by MadExP on SARI. It is expected to be better than $\text{Ctrl}_{4,4}$ here as Newsela-M does not include any identical $\langle C, S \rangle$ pairs and therefore penalises copying inputs. Ctrl_{Oracle} universally outperforms other systems.

On ASSET, BART_N actually achieves the highest SARI, closely followed by MadExP. We hypothesise that models trained on IRSD^S might achieve lower SARI as the training data includes examples from splitting datasets that do not exhibit any further simplification, leading to more conservative lexical changes when splitting is performed.

Human Evaluation Human evaluation results are shown in Table 4. $\text{Ctrl}_{4,4}$ scores highest in fluency and overall. Both $\text{Ctrl}_{4,4}$ and BART_4 score highest in adequacy. BART_N scores highest in simplicity.

All of our systems are rated highly accross all criteria and receive better average scores than even the reference. This clearly highlights the capability of pretrained generative models like BART to produce highly fluent texts. Further, we see that using a classifier trained on our data to predict operation-specific control-tokens further enhances

	Output
(1) Complex	*An acidic goo from the stomach dissolves the snail's flesh so the worm can re-swallow both stomach and prey.*
Simple	*An acidic goo from the stomach dissolves the snail's flesh, and the flatworm can then re-swallow both stomach and snail.*
BART$_N$	*[del] The goo dissolves the snail's flesh so the worm can re-swallow both stomach and prey.*
BART$_4$	*An acidic goo from the stomach dissolves the snail's flesh so the worm can re-swallow both stomach and prey.*
Ctrl$_{4,4}$	*An acidic goo from the stomach dissolves the snail's flesh. **[split] This allows** the worm to re-swallow both stomach and prey.*
(2) Complex	*Archer's parents were Catholic in Protestant England, which became illegal.*
Simple	*Archer's parents were Catholic. Being Catholic was against the law in England at the time.*
BART$_N$	*Archer's parents were Catholic. They did not want the government to interfere with their religion.*
BART$_4$	*Archer's parents were Catholic in Protestant England. [del]*
Ctrl$_{4,4}$	*Archer's parents were Catholic in Protestant England, which became illegal.*
(3) Complex	*Many people around the world are now furious at an American dentist who paid to go lion hunting in Zimbabwe.*
Simple	*Palmer paid to go lion hunting in Zimbabwe, which is in Africa.*
BART$_N$	*People around the world are **mad** at a dentist. He was paid to go lion hunting in Africa.*
BART$_4$	*Many people around the world are now furious at an American dentist who paid to go lion hunting in Zimbabwe.*
Ctrl$_{4,4}$	*Many people around the world are now furious at an American dentist who paid to go lion hunting in Zimbabwe.*
(4) Complex	*The Senegalese capital, on the far western edge of Africa, looks nothing like the sleepy port city that Amadou Sy remembers from his youth.*
Simple	*Amadou Sy remembers Dakar as a quiet city.*
BART$_N$	*The Senegalese capital **[del]** does not look like the sleepy port city that Amadou Sy remembers from his youth.*
BART$_4$	*The Senegalese capital **[del]** looks nothing like the sleepy port city that Amadou Sy remembers from his youth.*
Ctrl$_{4,4}$	*The Senegalese capital is on the far western edge of Africa. [split] It looks nothing like the sleepy port city that Amadou Sy remembers from his youth.*

Table 5: Example system outputs illustrating commonly seen patterns. Blue/**bold** marks positive changes while red/underlined marks negative changes or errors.

performance in both fluency and simplicity. However, we also believe our training data limits simplicity at times due to examples from pure splitting datasets exhibiting no simplification but for a split.

We believe the relatively low adequacy rating given to the reference can partly be attributed to sentence alignment failures and cases where the S makes reference to terms mentioned earlier in their article that are not explicit in the C.

Qualitative Analysis We perform a qualitative analysis of system outputs from the human evaluation to get a better idea of differences between our models. Table 5 illustrates common patterns.

BART$_N$ regularly produces the most simple output, but often over-simplifies to the point of removing important contextual information (e.g. item 1). It also sometimes fails to maintain the correct meaning of the input (e.g. items 2 and 3).

BART$_4$ often produces outputs very similar to Ctrl$_{4,4}$, but performs splitting much less regularly (e.g. items 1 and 4) which can uphold structural complexity.

Ctrl$_{4,4}$ outputs best retain the original meaning of the input. The benefit of having a classifier predict *identity* cases can be seen in item 2 where the other models end up rephrasing poorly or deleting important information. However, when performing splits, it fails to sufficiently rephrase, often keeping obviously complicated words (e.g. item 4).

7 Conclusion

In this work we present a new dataset for simplification operation classification and show that it can be used to produce classifiers of much higher accuracy than what has been proposed in existing studies. We show that a controllable system using such a classifier to predict control tokens outperfoms end-to-end baselines and existing systems on a range of datasets and receives extremely high ratings in fluency, adequacy and simplicity from human evaluators. However, this system does result in slightly lower simplicity ratings compared to reference texts and a Newsela baseline, suggesting that further improvements can be made to the system or dataset in order to achieve the best possible results across all criteria.

A Splitting Types

In the paper we distinguish two types of sentence splits, based on the findings of Cripwell et al. (2021). A syntax-split is when the split is licensed by syntactic constructs such as relative clauses, VP or sentence coordinations, gerund or appositive constructions. On the other hand, discourse-splits are licensed by the presence of a discourse relation between two discourse units. Often discourse-splits require additional rewriting in order to fully preserve the discourse semantics which would otherwise be broken by a minimal split operation. Furthermore, they can usually be represented via many equivalent variants.

Table 6 shows an example of these differences. [9] The text in C1 contains a temporal discourse relation marked by ***and after this*** which is made explicit in the discourse-split output (S1a) by the adverbial ***Afterwards***. A possible variant exists (S1b) where an inverse adverbial connective (***Before this***) is used. The seconds tier of the table shows two syntax-split examples, where minimal rephrasing is required.

B Human Annotation

In order to compile the gold-label test set for the classification task we instructed 3 human annotators to assign the labels they considered most appropriate for 400 examples. These annotators were students enrolled in a local NLP master's program and were paid slightly above the minimum wage for their work. Nine items were identified as malformed and thus removed.

Annotations were completed through a web form interface (e.g. in Figure 4). For each of the 400 items, they were presented with the input sentence and required to select one of the four class labels. They were also given the option to flag examples as being malformed or incomprehensible (which we removed from the final set). Prior to their completion of the task, they were given a detailed description of each class along with a range of examples.

For the simplification output evaluation we instructed the same 3 annotators to give their judgements on outputs from 6 systems for 100 inputs randomly sampled from the silver-label test set. Again, this was done via a web form where each input text is provided followed by the outputs from each system (e.g. in Figure 5). Below this, the annotators select 1-5 for each of the outputs on the three quality criteria: fluency, adequacy, and simplicity.

Full text instructions for both human annotation tasks are provided in the supplementary materials.

C Difficult Labelling Examples

The main paper mentions cases where it is difficult to determine a single best rewrite operation. Table 7 shows some common examples of this.

D Training Details

During training of the RoBERTa classification models, we used a learning rate of $2e^{-5}$. The network has 12 hidden layers, a hidden size of 768, and was pretrained with the masked language modeling objective on 160GB of books and web content.

During training of the BART generative models, we used a learning rate of $3e^{-5}$. The network has 6 layers in each of the encoder and decoder, a hidden size of 768, and was pretrained to perform reconstruction of corrupted documents on a combination of books and Wikipedia data.

All of our finetuning experiments used a batch size of 32, performed dropout with a rate of 0.1 and early stopping as regularisation measures. All models were trained on a computing grid using 4 Nvidia RTX 2080 Ti GPUs (11GB memory) for an average of 24 hours. For each experiment we set aside 1% of the training set for validation.

For the generative models, at test time we generate output sequences by performing beam search with a beam size of 5 and restrict output to a maximum length of 128 tokens.

The use of the Newsela corpus is subject to a data sharing agreement from Newsela, Inc. This licence permits the data to be used for non-commercial research purposes.

E System Outputs

Table 8 contains example system outputs not included in the main paper which illustrate commonly seen patterns across systems.

Abstract

Open-domain conversational systems are assumed to generate equally good responses on multiple domains. Previous work achieved good performance on the single corpus, but training and evaluating on multiple corpora from different domains are less studied. This paper explores methods of generating relevant responses for each of multiple multi-domain corpora. We first examine interleaved learning which intermingles multiple corpora as the baseline. We then investigate two multi-domain learning methods, labeled learning and multi-task labeled learning, which encode each corpus through a unique corpus embedding. Furthermore, we propose Domain-specific Frequency (DF), a novel word-level importance weight that measures the relative importance of a word for a specific corpus compared to other corpora. Based on DF, we propose weighted learning, a method that integrates DF to the loss function. We also adopt DF as a new evaluation metric. Extensive experiments show that our methods gain significant improvements on both automatic and human evaluation. We share our code and data for reproducibility.[1]

1 Introduction

Recent work has achieved improvements in general performance for open-domain response generation (Vinyals and Le, 2015; Serban et al., 2017; Li et al., 2016; Xu et al., 2018). However, most studies are restricted to single-corpus training and evaluating, while there lacks studies for training and evaluating with multiple corpora from different domains. Single-corpus training has intrinsic limitations. For example, a corpus of everyday chats, e.g., the PersonaChat corpus (Dinan et al., 2019), does not cover technical topics discussed in Ubuntu chatlogs (Lowe et al., 2015). A conversational system that learns only from PersonaChat or from multiple corpora without an appropriate technique is not likely to generate relevant responses for certain topics (see Table 1). Therefore, it is necessary for an open-domain conversational system to learn from multiple corpora, and to learn with good techniques.

Context	What are you going to do on the remote system exactly?
PersonaChat	I am going to be a pilot. I am going to fly planes.
4 corpora (concatenated)	I am going to go to the beach.

Table 1: Irrelevant responses generated from fine-tuned GPT-2. The GPT-2 model is fine-tuned respectively on PersonaChat / concatenated 4 corpora (OpenSubtitles, Twitter, Ubuntu, PersonaChat)

	Test set			
Fine-tune corpus	OSDB	Twitter	Ubuntu	PersonaChat
PersonaChat	478.8	159.6	264.7	19.6
4 corpora (concatenated)	392.8	110.7	199.2	19.0

Table 2: Imbalanced perplexity performance of fine-tuned GPT-2. The GPT-2 model is fine-tuned on PersonaChat / concatenated 4 corpora (OpenSubtitles, Twitter, Ubuntu, PersonaChat)

Furthermore, the case of using a single small-scale open-domain corpus has apparent weaknesses. A common way of dealing with a small-scale corpus is through fine-tuning (Li et al., 2016; Akama et al., 2017; Chu et al., 2017). Fine-tuning on a single corpus tends to make the model overfit on that specific corpus while performing worse on other corpora. Table 2 shows the result of a GPT-2 model gaining good performance on PersonaChat while performing poorly on other corpora.

This paper explores how to train and evaluate on multiple corpora from different domains for the open-domain response generation task. We propose

several methods to make a model generate relevant responses for each of the multiple corpora.

Since simply training multiple corpora one by one does not solve the imbalanced performance (as shown in Table 1 and 2), we first investigate *interleaved learning*, a method that intermingles the training data instead of simply concatenating, which ensures a model learns from all corpora evenly. We use this method as a baseline. Additionally, we explore two multi-domain learning methods: *labeled learning* and *multi-task labeled learning*. Labeled learning comes from a control technique in response generation (Li et al., 2016; Johnson et al., 2017; Yang et al., 2017). Previous works focus on controlling persona and style, while our method controls corpus's information with the corpus embedding. Multi-task labeled learning is inspired by works of domain adaption (Luan et al., 2017; Niu and Bansal, 2018; Chu and Wang, 2018), where multiple losses from both the corpus classifier and response generator are minimized. To the best of our knowledge, this paper is the first that uses corpus embeddings on the open-domain response generation task for multiple corpora.

Furthermore, we propose a novel *weighted learning* with Domain-specific Frequency (DF). DF is a word-level importance weight (Leopold and Kindermann, 2002) that assigns different weights (importance) to the same words from different corpora. In the training process, we weight the loss of a model with DF, so that the model focuses on the most important words for a specific corpus.

For automatic evaluation metrics, we eliminate the stop words and use ROUGE-1 (precision, recall, F1) (Lin, 2004) to measure the **relevance** of the generated responses. In addition, we adopt DF to see how relevant the generated response of a model is to a specific corpus. We will explain DF as an evaluation metric in Section 4.4. Results show that for overall performance, the best method (weighted learning) improves 27.4% on precision, 45.5% on recall, and 34.1% on F1. Further, it has at least 20.0% higher DF, stating that it uses more important words from the "correct" corpus. We also conduct an extensive human evaluation on 2400 generated responses. The human evaluation shows a highly significant ($p < 0.001$) improvement on all of our proposed methods, especially the weighted learning method.

We summarize our work as follows:

- We explore the problem of training and evaluating on multiple corpora from different domains for open-domain response generation. The task is to make the conversational models generate relevant responses for **each** corpus.
- We examine several multi-domain corpora learning methods for their ability to solve the proposed task.
- We propose Domain-specific Frequency (DF) as in weighted learning and as an evaluation metric. DF distinguishes important words for each corpus and helps a model to focus on these important words in the training process.

2 Related Work

Open-Domain Response Generation Recent work of open-domain response generation generally follows the work of Ritter et al. (2011) where the task is treated as a machine translation task, and many of them use a Seq2Seq structure (Sutskever et al., 2014) following previous work (Vinyals and Le, 2015; Shang et al., 2015; Sordoni et al., 2015). In recent years, substantial improvements have been made (Serban et al., 2017; Li et al., 2016; Wolf et al., 2019), and embeddings are used to control response generation on extra information such as persona (Li et al., 2016), profiles (Yang et al., 2017), coherence (Xu et al., 2018), emotions (Huang et al., 2018), and dialogue attributes like response-relatedness (See et al., 2019). However, there is a lack of work that uses embeddings to control response generation over multiple corpora. Our work follows the common models of open-domain conversational systems, while we study the problem of multiple corpora of different domains.

Multi-Domain Learning and Domain Adaption Multi-domain learning aims at making a conversational model learn from multiple domains to prevent the performance from degrading due to domain differences (Ben-David et al., 2007). There are two categories of solutions for multi-domain learning (Joshi et al., 2012): (i) capturing domain-specific characteristics in the parameters (Daumé III, 2007); (ii) capturing the relationship among different domains (Saha et al., 2011).

Some work of natural language generation and machine translation is related to multi-domain learning. Luan et al. (2017) and Niu and Bansal (2018) use multi-task learning for domain adaption respectively on speaker-role and politeness. Wen et al. (2016) and Akama et al. (2017) utilizes fine-tuning as a common way of domain adaption for language generator and style transferer. For machine translation, in order to deal with the mixed-domain parallel corpus, Zeng et al. (2018) adjust the weights of target words in the training objective based on their relevance to different domains. We differ in that we propose DF and we deal with the response generation task. Chu et al. (2017) propose mixed fine-tuning, which adds the out-of-domain pre-training data to the fine-tuning dataset, and they observe an improvement of performance. In this paper, we also mix small-scale fine-tuning datasets with out-of-domain training data, while the data we add is not necessarily used during pre-training. Shi et al. (2015) state that fine-tuning can be done by placing the corpus to be fine-tuned at the end of the entire corpus, which is an extension of curriculum learning proposed by Bengio et al. (2009). We also explore how the order of multiple corpora influences the result, but our focus is on balancing performance. Recently, Smith et al. (2020) investigated blending conversational skills with knowledge and empathy skills, where they mix 3 corpora. They focus on selecting appropriate skills and they propose a blended corpus with labels, while we focus on generating responses that are most relevant to a specific corpus.

3 Base Models

We use two base models: an LSTM Seq2Seq model with attention (Hochreiter and Schmidhuber, 1997; Sutskever et al., 2014; Bahdanau et al., 2015) and a pre-trained GPT-2 model (Radford et al., 2019). The LSTM Seq2Seq model with attention is a common model for conversational systems (Li et al., 2016; See et al., 2019), and the GPT2 model is a state-of-the-art model for the response generation task (Zhang et al., 2020; Zhao et al., 2020).

The basic task of response generation is to predict the next word given the past and current words of the context and response, and to make the generated response as similar to the original response as possible. The task can be described as follows. Probability of response Y given context X is predicted as:

$$P(Y|X) = \prod_{t=1}^{n} P(y_t|y_1, \ldots, y_{t-1}, X), \quad (1)$$

where $X = x_1, \ldots, x_m$ and $Y = y_1, \ldots, y_n$ is a context-response pair.

3.1 LSTM Seq2Seq Model with Attention

We simplify an LSTM with attention unit as $LSTM^*$ since it is well introduced in previous work (Li et al., 2016). We calculate the hidden vector h_t at step t as:

$$h_t = LSTM^*(h_{t-1}, E(z_t)), \quad (2)$$

where $h_{t-1} \in \mathbb{R}^{dim}$ is the hidden vector at step $t-1$, dim is the dimension of hidden vectors, and $E(z_t)$ is the word embedding for word $z_t \in (x_1, \ldots, x_m, y_1, \ldots, y_{n-1})$. We apply dot multiple in the attention mechanism when calculating the context vector c_t:

$$c_t = H \cdot (softmax(H^\top \cdot h_t))$$

where $H \in \mathbb{R}^{d \times m}$ is the concatenation of hidden vectors from the encoder. c_t is input to the next step $t+1$ in the decoder. Each token's hidden vector h_t in the decoder is combined with c_t through a linear layer and an activation to predict the next token.

3.2 GPT-2

As for GPT-2, we follow the adaption of Wolf et al. (2019). The transformer block of GPT-2 captures the relation of multiple words in one sentence, which largely follows Vaswani et al. (2017). The hidden vector to be input to the transformer block is calculated as:

$$h_{0[t]} = E(X, Y_{[1:t]}) + (E_0, E_1) + W_p, \quad (3)$$

where $Y_{[1:t]}$ is $(y_1, \ldots, y_t)$, $E(X, Y_{[1:t]})$ is the subword embedding for context X and response $Y_{[1:t]}$. E_0 and E_1 are dialogue-state embeddings, which tutor the model to distinguish between contexts and responses. W_p is a pre-trained position embedding. The probability of the subword to generate is then calculated as:

$$h_{[t]} = transformer\_block(h_{0[t]}) \quad (4)$$

$$P(y)_{t+1} = softmax(E^\top(h_{[t]})), \quad (5)$$

where $y \in V$, and V stands for the sub-word vocabulary. We simplify the structure of transformer block as $transformer\_block$. In the block, a mask is filled in the attention matrix, which bans past words from attending to future words. This ensures that the model follows the traditional language modeling. The hidden vector of t_{th} sub-word is used to generate the probability distribution for the vocabulary ($P(y),\ y \in V$) for $(t+1)_{\text{th}}$ sub-word. $E^\top$ means that the model uses the sub-word embeddings in calculating sub-word probabilities for generation (Press and Wolf, 2017).

4 Proposed Methods

4.1 Interleaved Learning

Interleaving is a concept in cognitive psychology proven to be efficient for learning (Kornell and Bjork, 2008): intermingling learning material of different topics helps students to gain better learning results than learning the material topic by topic. Previous work from machine learning also shows that training order greatly influences the performance (Bengio et al., 2009). When the training is conducted on a simple concatenation of multiple corpora, the model tends to concentrate on the last corpus (Shi et al., 2015). To address this issue, we propose interleaved learning as an alternative: each time we collect one context-response pair from each of the corpora, and we randomly shuffle them. For example, if there are 3 corpora $(a_1, a_2, ...), (b_1, b_2, ...), (c_1, c_2, ...)$ where a_i, b_i and c_i are context-response pairs, the resulting mixed corpus might be $(b_1, a_1, c_1, c_2, b_2, a_2, ...)$. Interleaved learning guarantees that the combined corpus is evenly distributed, which helps the model learn from multiple corpora evenly.

4.2 Labeled Learning

We propose our labeled learning as follows: each corpus is assigned a randomly initialized unique embedding, and the conversational model learns these embeddings together with conversations during the training period. We denote these embeddings as “corpus embedding”, or E_c. A model captures each corpus’s characteristics through the corpus embedding and uses it to control the generated responses. To know which corpus embedding to use, each context is labeled with which corpus it comes from, and these labels are provided to the model both in the training and generation period. We propose an approach for each of our base models for encoding corpus embeddings.

For the LSTM model, following Li et al. (2016), we input the corpus embedding E_c into the first layer of the decoder LSTM at every step, together with the response words. Calculation of a hidden vector h_t in the decoder LSTM is then adapted to:

$$h_t = LSTM^*(h_{t-1}, E(y_t), E_c). \tag{6}$$

The structure is illustrated in the dashed red rectangle of Figure 1a.

For the GPT-2 model, our method is based on Wolf et al. (2019). Instead of two kinds of dialogue-state embeddings (context embedding E_0 and response embedding E_1), we replace the response embedding with corpus embeddings E_c. As a result, the model is aware of which corpus the response belongs. Calculation of a hidden vector to be input to the transformer block is adapted to:

$$h_{0[t]} = E(X, Y_{[1:t]}) + (E_0, E_c) + W_p. \tag{7}$$

The structure is illustrated in Figure 1b.

4.3 Multi-Task Labeled Learning

Labeled learning needs corpus labels for both training and generation processes. To avoid providing labels in the generation process, we combine multi-task learning with labeled learning on multiple corpora. Here, the conversational model has to predict by itself which corpus a context belongs to, which is expected to result in worse performance, but less information is required. In the encoder, we have a classifier layer that uses the sum of hidden vectors from the encoder ($\sum H$) to predict the corpus of a context. The loss of the classifier is calculated as:

$$\mathcal{L}_c = -\log\left(softmax\left(\left(\sum H\right) \cdot W_{[c]}\right)\right), \tag{8}$$

where $W_{[c]} \in \mathbb{R}^{dim}$ is the part from the classifier layer for target corpus c. $\mathcal{L}_c$ is summed up with the loss from the response generator. The predicted corpus embedding is input into the decoder like labeled learning (see Section 4.2). The simplified structure is illustrated in Figure 1a.

4.4 Document-specific Frequency (DF)

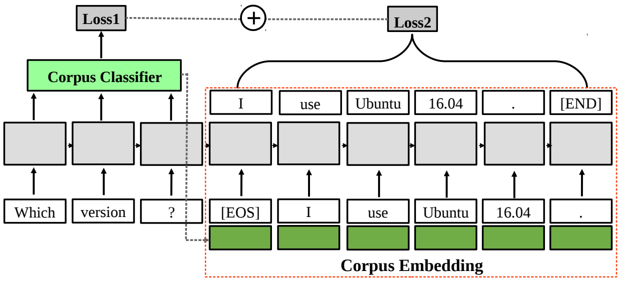
We propose Domain-specific Frequency (DF) to measure how important a word is with respect to a different corpus under a collection of corpora. DF is used for weighted learning and evaluation. It is calculated as follows:

$$f(w)_d = \text{freq}(w)_d - \text{min}_v\{\text{freq}(v)_d\} \tag{9}$$

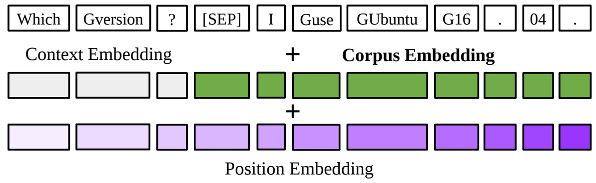
$$\text{df}(w)_d = \begin{cases} 0 & f(w)_d = 0 \\ \frac{f(w)_d}{\sum_{d \in D} f(w)_d} & f(w)_d \neq 0 \end{cases} \tag{10}$$

$$\text{DF}(w)_d = \frac{\text{df}(w)_d}{\text{max}_v\{\text{df}(v)_d\}}, \tag{11}$$

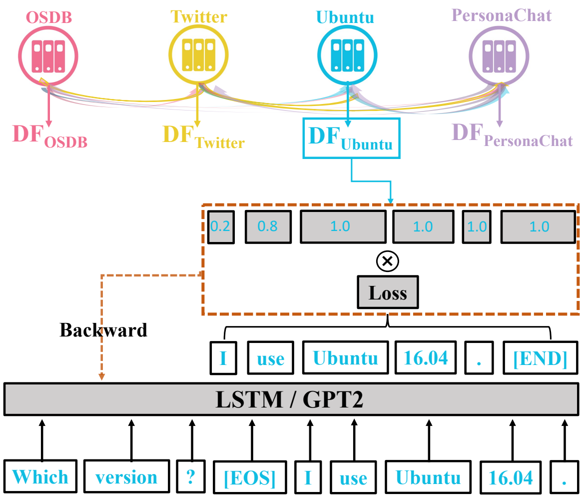
where $\text{freq}(w)_d$ is the relative frequency of a word w in a corpus d, and D represents the set of all corpora. It is easy to see from Equation 10 that $\text{DF}(w)_d$ represents the importance of word w for corpus d compared to other corpora. For a word w that frequently appears in corpus d but seldom



(a) Structure of multi-task labeled learning on LSTM model



(b) Corpus embeddings with sub-word embeddings on GPT-2



(c) Structure of weighted learning

Figure 1: Adapted models with labeled learning, multi-task labeled learning and weighted learning

in other corpora (e.g., "upgrade" from Ubuntu corpus), $\sum_{d \in D} f(w)_d$ is close to $f(w)_d$, making $\mathrm{DF}(w)_d$ approach 1. A word that frequently appears in all corpora (e.g., "I", "you") is punished, resulting in a lower $\mathrm{DF}(w)_d$. A word that seldom appears in corpus d but frequently appears in other corpora (e.g., "music" seldom appears in Ubuntu corpus, but is common in other corpora) has the lowest $\mathrm{DF}(w)_d$. Words that appear minimal times (e.g., once) in a corpus are ignored with Equation 9. Words that appear few times (e.g., twice or three times) are not dealt with, yet they are not of great influence in our experiments. We apply a normalization in the final step (Equation 11) to make $\mathrm{DF}(w)_d$ of each corpus d range from 0 to 1.

We show $\mathrm{DF}(w)_{\text{Ubuntu}}$ and $\mathrm{DF}(w)_{\text{PersonaChat}}$ of some words in Table 3. We also show the results of TF-IDF (log normalization variant), a commonly used word importance weight, as a comparison. As expected, for the corpus Ubuntu and PersonaChat, most unique words w have very different $\mathrm{DF}(w)_{\text{Ubuntu}}$ and $\mathrm{DF}(w)_{\text{PersonaChat}}$. Unique words of each corpus get the highest values for the corresponding corpus, like "upgrade" for the Ubuntu corpus and "music" for the PersonaChat corpus; these words receive the lowest values for *incorrect* corpora, like "upgrade" for PersonaChat and "music" for Ubuntu. The stress on unique words makes DF more suitable for our task.

Word	TF-IDF(%)		DF(%)		αDF$_{(\alpha=100)}$	
	Ubuntu	PersonaChat	Ubuntu	PersonaChat	Ubuntu	PersonaChat
i	100.0	62.6	20.8	42.1	2.6	7.3

teacher	0.1	2.2	0.7	77.8	1.0	53.5
music	1.5	7.6	4.8	82.9	1.2	49.1
travel	0.1	3.1	0.3	88.9	1.0	57.1
hobby	0.1	1.6	0.6	94.3	1.1	81.7
hiking	0	1.5	0	97.6	0	91.8

Table 3: Normalized TF-IDF (%), DF (%) and αDF of some words for Ubuntu and PersonaChat (more examples on other corpora can be found in Section A)

Weighted Learning with DF Weighted learning weights the loss of the predication y' for each target word w using $\mathrm{DF}(w)_d$. In the training period, each context is labeled with the corpus d it belongs to, so that the model can use the $\mathrm{DF}(w)_d$ of the corresponding corpus. Here DF is calculated only on the training sets. In the generation step, corpus labels are not provided, so DF is not used. The loss is weighted as follows :

$$\mathcal{L}_{\text{weighted}} = \mathrm{DF}(w)_d \cdot \left(-\log\left(softmax(y'_w)\right)\right), \tag{12}$$

where y'_w represents the model's predicted score for the target word w. With the weighted loss, the model concentrates on words that are important to the corpus of the current context, and focuses less on frequent words or words that are not important to the current corpus. The structure is illustrated in Figure 1c.

Evaluation with DF For the generated responses to be relevant to a specific corpus, they have to be similar to that corpus, which includes using important words of that corpus (e.g., responses generated for the Ubuntu corpus should have more technical words than other corpora). Thus, we propose DF as an evaluation metric that shows to what extent the generated responses use important words of the corresponding corpus. We want to decrease the influence of common words like "i", "to", etc., and thus address the important words. So we adopt exponential DF with α as the base (αDF):

$$\alpha\text{DF}(w)_d = \begin{cases} 0 & \text{DF}(w)_d = 0 \\ \alpha^{\text{DF}(w)_d} & \text{DF}(w)_d \neq 0, \end{cases} \tag{13}$$

where α is a constant. $\alpha\text{DF}(w)_d$ rescales $\text{DF}(w)_d$ by exponent with α as a base. In our experiments, we set α to be 100, which transforms the range of the metric from $(0, 1)$ to $(0, 100)$. This makes the difference between high and low αDF more significant than DF and gives a 100-scale score. For each corpus $d \in D$, we average $\alpha\text{DF}(w)_d$ on word w from the generated responses of each test set, which gives us αDF_d scores ($d \in D$) for each test set. Ideally, the generated responses of a specific corpus d should have a higher αDF_d score and lower $\alpha\text{DF}_{\overline{d}}$ score ($\overline{d} \in \{d' \in D \mid d' \neq d\}$). For example, generated responses of the Ubuntu test set should have a higher $\alpha\text{DF}_{\text{Ubuntu}}$ score, while a lower $\alpha\text{DF}_{\overline{\text{Ubuntu}}}$ score ($\overline{\text{Ubuntu}} \in \{d' \in D \mid d' \neq \text{Ubuntu}\}$). αDF_d scores for responses from the original test sets are the standard scores.

We show $\alpha\text{DF}(w)_{\text{Ubuntu}}$ and $\alpha\text{DF}(w)_{\text{PersonaChat}}$ (calculated purely on test set) in Table 3. As expected, αDF has a more significant difference between important words and common words.

Is DF a Legal Evaluation Metric? Although DF is used for both weighted learning and evaluation, we see DF as a suitable evaluation metric for our task and not biased in favor of weighted learning due to: 1) A word receives multiple DF values in the training process given the corpus that a context belongs to; 2) in the generation process, DF is never used. 3) In the evaluation process, DF can be calculated purely on the test sets. Note that since a word receives multiple DF values in the training step, it is equivalently likely for the model trained with weighted learning to be influenced by DF weights of **incorrect** corpus. Above all, in the evaluation step, if the trained model is influenced more by DF weights from the correct corpus, it already means that the model is good at distinguishing which corpus a given context is from, thus is suitable for our task.

5 Experiment Setup

5.1 Datasets

Data Collection We collected 4 commonly used English corpora of different domains from the ParlAI platform (Miller et al., 2017): OpenSubtitles corpus (OSDB)[2] (Lison et al., 2018), Twitter corpus[3] (Miller et al., 2017), Ubuntu chatlogs corpus (Lowe et al., 2015)[4] , and PersonaChat corpus (Zhang et al., 2018) from the NeurIPS 2018 ConvAI2 Challenge (Dinan et al., 2019). Each corpus contains 250K context-response pairs, as much as the size of the original PersonaChat used in ConvAI2 competition. This gives us 1M context-response pairs in total. The corpus for training is a combination of these 4 corpora. For comparison, we have a single corpus–PersonaChat–trained on both base models. For testing, each of the 4 corpora has a test set of 30K context-response pairs, which is the same size of the test set of PersonaChat.

The OpenSubtitles corpus (OSDB) is a noisy dataset of film subtitles. We removed films that belonged to genres that usually had few conversations, such as musical and documentary films. We regarded two neighboring sentences as a context-response pair following Vinyals and Le (2015). The Twitter corpus contains one-turn dialogues extracted from Twitter. The original author has already cleaned it, so we only removed special symbols such as hashtags, Emojis, and @. The Ubuntu corpus contains dialogues about solving technical problems of Ubuntu. The PersonaChat corpus contains dialogues between two workers acting as specific personas; we focused on the dialogue part and ignored the persona part. This corpus allows us to compare our base models with state-of-the-art performance. These 4 corpora have very different characteristics, confirmed by the imbalanced performance of GPT-2 fine-tuned on a single corpus (see Table 2).

5.2 Training and Decoding

We used Pytorch (Paszke et al., 2017) to implement the LSTM Seq2Seq model with attention and the pre-trained GPT-2 models. For GPT-2, we adapted

Table 5: $\alpha\mathrm{DF}_d$ scores for generated responses from multiple corpora. The columns "train" indicate train-set-$\alpha\mathrm{DF}_d$. The columns "test" indicate test-set-$\alpha\mathrm{DF}_d$.

our model from the implementation of the HuggingFace team[5]. The LSTM model has 4 layers and the dimension is 512. The training procedure was with a batch size of 256, learning rate of 1.0, dropout rate of 0.2, and gradient clip threshold of 5. The vocabulary size is 50000. GPT-2 has 12 layers, 12 heads, and the dimension is 768, the same as the pre-trained model. The training procedure was with Adam and we adopted a similar setup as Wolf et al. (2019): the batch size was 32, learning rate was 6×10^{-5}, $\beta_1 = 0.9$, $\beta_2 = 0.999$, L2 weight decay set to 0.01, learning rate linearly decreased to zero at the end. We followed these hyper-parameters to ensure state-of-the-art performance for the base models. We use the same hyper-parameters for both base models and models with our proposed methods, so the proposed methods work slightly (but not much) worse than it should be. This is to avoid the extra improvement caused by hyper-parameters. We pre-trained the LSTM model on 3 large-scale corpora (OSDB, Twitter and Ubuntu) with interleaved learning until converging. GPT-2 is already pre-trained, so we directly used it for fine-tuning (details about pre-training convergence can be found in Section B). For decoding, we adopted greedy decoding for all the models to ensure an equal condition.

5.3 Evaluation

For automatic metrics, to measure the **relevance** of the generated responses, we eliminated punctuation and stop words, and adopted Rouge-1[6] (precision, recall, F1) as multi-grams become meaningless

---

[5] `https://huggingface.co/`.

[6] We used implementation from `https://github.com/google-research/google-research/tree/master/rouge`.

without stop words. However, Rouge-1 compares the generated responses with the golden ones, while there is never a standard response for any context, so in addition to Rouge, we use αDF score that shows to what extent the generated responses use important words of the corresponding corpus, as stated in Section 4.4. Due to the limitation of automatic evaluation methods (Liu et al., 2016), we also conduct an extensive human evaluation on the relevance of generated responses to contexts (see Section 6.1 for details).

6 Results

Our base models achieve perplexity scores of 28.9 (LSTM model) and 19.6 (GPT-2) on the test set of the PersonaChat dataset from the ConvAI2 competition when fine-tuned with the single PersonaChat corpus (more details can be found in Section C). These results would likely advance the models to the second round in the competition.

Table 4 shows that models trained with our proposed methods gain better performance on Rouge than baselines. Baselines concentrate on the last trained corpus (PersonaChat), while with the proposed methods, performance is more balanced on multiple corpora. Weighted learning has the best overall performance on all metrics, and it performs especially well on the Ubuntu corpus, indicating that it might be good at distinguishing the unique technical words from the Ubuntu corpus. Labeled learning is the second best with stable improvement from interleaved learning, indicating that the corpus embeddings function as expected. Multi-task labeled learning has slightly worse performance than interleaved learning, indicating that predicting the corpus of a contexts is not easy, and wrong predictions result in worse performance.

Table 5 shows αDF_d scores for generated responses of each corpus. Full results can be found in Section E. We use both αDF_d calculated purely on the train set (train-set-αDF) and αDF_d calculated purely on the test set (test-set-αDF). The black scores are scores for the corresponding corpus (we expect high scores for these parts), while the grey scores are scores for non-related corpus–PersonaChat (we expect low scores for these parts). Note that scores for different corpora are in different scales. From the table, we can see that train-set-DF scores and test-set-DF scores are similar, and weighted learning always has the highest score, indicating that weighted learning distinguishes well which corpus a context comes from. Labeled learning is the second best, indicating that the learned corpus embeddings help the model to use more important words of the corresponding corpus. Compared to the concatenated corpus, the improvement is at least 20%, while the decrease in PersonaChat is just 9% at most.

6.1 Human Evaluation

We conducted a human evaluation on all GPT-2 models: base models and models adapted with our proposed methods. We randomly picked 2400 responses: 400 different contexts evenly from 4 corpora with 6 responses generated by each of our models. 3 judges[7] are asked to pick the most and the least relevant response(s) for the given context. The most relevant response(s) are given score 3, the least relevant response(s) are given score 1, and the other(s) are given score 2. Table 6 shows the overall scores of all GPT-2 based models. Table 7 shows the p-value for the t-test conducted between every two models. The overall scores of our proposed methods are all highly significantly ($p < 0.001$) higher than the concatenated models, especially the weighted learning method.

6.2 Response Examples

The generated responses from better methods are more relevant to the corresponding corpus, while worse methods cannot distinguish contexts from different corpora (e.g., they may answer any questions in a "PersonaChat" way). To show an intuition of the difference among our proposed methods, we present some response examples generated by GPT-2 in Section G.

6.3 Possible Limitations

Our proposed methods are meant to be able to work in most models, which is why we choose the most common conversational models as our base models. However, there are many variants of conversational models focusing on different aspects, such as integrating knowledge, avoiding dull responses, keeping the speech style, etc. We cannot ensure that our methods work for all of these variant models. Also, dialogues are always multi-turn, while we focus on a simpler task: single-turn response generation.

---

[7] Similar to previous work like Zhang et al. (2020), we have 3 judges. We have one random worker from `https://www.mturk.com/worker`, one bachelor student, and one graduate student. An example of the mTurk interface can be found in Section F.

Model \ Corpus	OSDB	Twitter	Ubuntu	PersonaChat	Overall
PersonaChat (single)	1.53	1.43	1.21	2.09	1.56
Concatenated	1.67	1.71	1.60	2.16	1.78
Interleaved	2.04	1.89	2.18	2.24	2.09
Labeled	2.10	2.10	2.32	2.24	2.19

Concatenated	$2.54 \times 10^{-7**}$	1.00	\	\	\	\
Interleaved	$4.71 \times 10^{-34**}$	$2.09 \times 10^{-12**}$	1.00	\	\	\
Labeled	$1.08 \times 10^{-46**}$	$9.41 \times 10^{-21**}$	$1.18 \times 10^{-2*}$	1.00	\	\
Multi-task Labeled	$6.65 \times 10^{-35**}$	$6.96 \times 10^{-13**}$	8.86×10^{-1}	1.17×10	1.00	\
Weighted	$1.65 \times 10^{-103**}$	$2.86 \times 10^{-63**}$	$6.54 \times 10^{-26**}$	$1.59 \times 10^{-15**}$	$2.01 \times 10^{-25**}$	1.00

Table 7: P-value for t-test on overall human evaluation scores of GPT-2 based models, ** $p < 0.001$

Furthermore, the methods are trained and evaluated on English corpora. There can be a limitation on applying the methods to other languages.

7 Conclusions

We have experimented with 4 methods–interleaved learning (baseline), labeled learning, multi-task labeled learning, and weighted learning–to help common open-domain conversational systems generate relevant responses for multiple corpora of different domains. We adopted Rouge (precision, recall, F1) for auto evaluation. In addition, we used DF to evaluate how well a model uses relevant words for a corresponding corpus. We also did an extensive human evaluation. Our results show significant improvement in performance for our proposed methods, especially weighted learning. Future work of multi-turn response generation is potential. We have focused on one-turn response generation, while dialogue is naturally multi-turn so further research is needed.

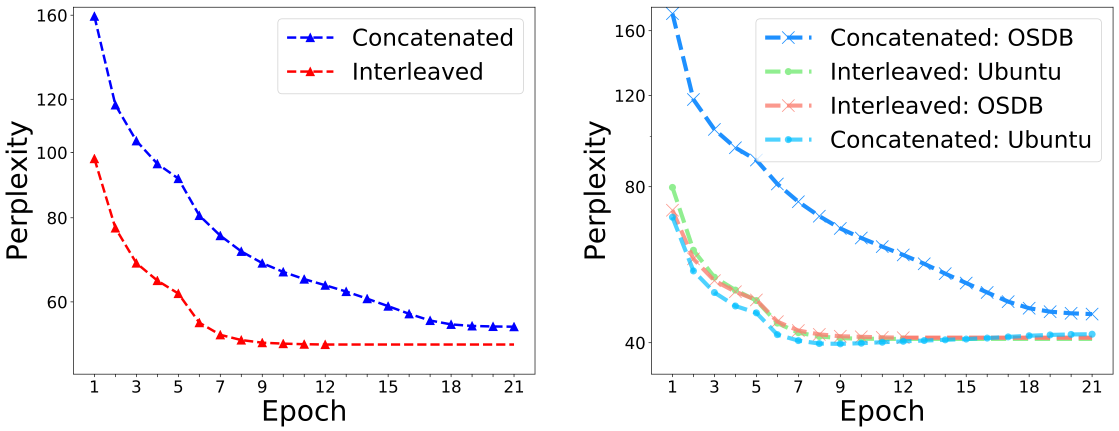
Table 8: Normalized TF-IDF (%), DF (%) and αDF of more example words for 4 corpora

Example words are divided into five blocks. The first block has frequent words in all corpora, the second block has unique words from OSDB, the third block has unique words from Twitter, the fourth block has unique words from Ubuntu, and the fifth block has unique words from PersonaChat. The values of the corresponding corpus are marked with different colors.

From this table, it is clear that the commonly used word importance weight, TF-IDF, is not suitable for our task. This is due to the vast range of frequency, which leads to a relatively small penalty for IDF (Inversed Document Frequency) over words with too large TF (Term Frequency).

B Convergence time of pre-training LSTM model on large-scale corpora



(a) Overall perplexity of 3 corpora (OpenSubtitles, Twitter, Ubuntu) per epoch

(b) Perplexity of OSDB corpus and Ubuntu corpus per epoch

Figure 2: Convergence time of pre-training LSTM on large-scale corpora

In the pre-training period, it takes 21 epochs for the concatenated corpus to converge on the base LSTM model, while only 12 epochs with interleaved learning, which is 43% shorter. When trained on the concatenated corpus in the order of OSDB → Twitter → Ubuntu, it takes 20 epochs for the perplexity on OSDB and Ubuntu to be balanced, while with interleaved learning, it takes less than one epoch. For concatenated corpus, the performance of the Ubuntu corpus is sacrificed in order to balance the performance of the two corpora, which results in worse overall performance.

C Results of automatic evaluation with stop words

Table 9: Perplexity, BLEU (%) and F1 (%) scores for baselines and proposed methods fine-tuned on 4 corpora (**with** stop words). BLEU is from NLTK sentence BLEU

Models of labeled, multi-task labeled and weighted learning do not have the best hyper-parameters, but the same hyper-parameters as the base models. Their perplexity is slightly worse than it should be.

The results of the single corpus PersonaChat trained with the LSTM model confirm our concern on a small fine-tuning corpus. The LSTM model is pre-trained on OSDB, Twitter and Ubuntu; however, the performance for the 3 corpora greatly decreases after fine-tuning.

The automatic evaluation with stop words is not good for measuring relevance, since stop words are taken too much into account. See BLEU and F1 scores of PersonChat (single) and weighted learning as an example. Models trained on PersonaChat (single) cannot answer Ubuntu technical questions **at all**, yet they receive better scores than weighted learning. But once the stop words are removed, the scores of weighted learning surplus PersonaChat (single) a lot.

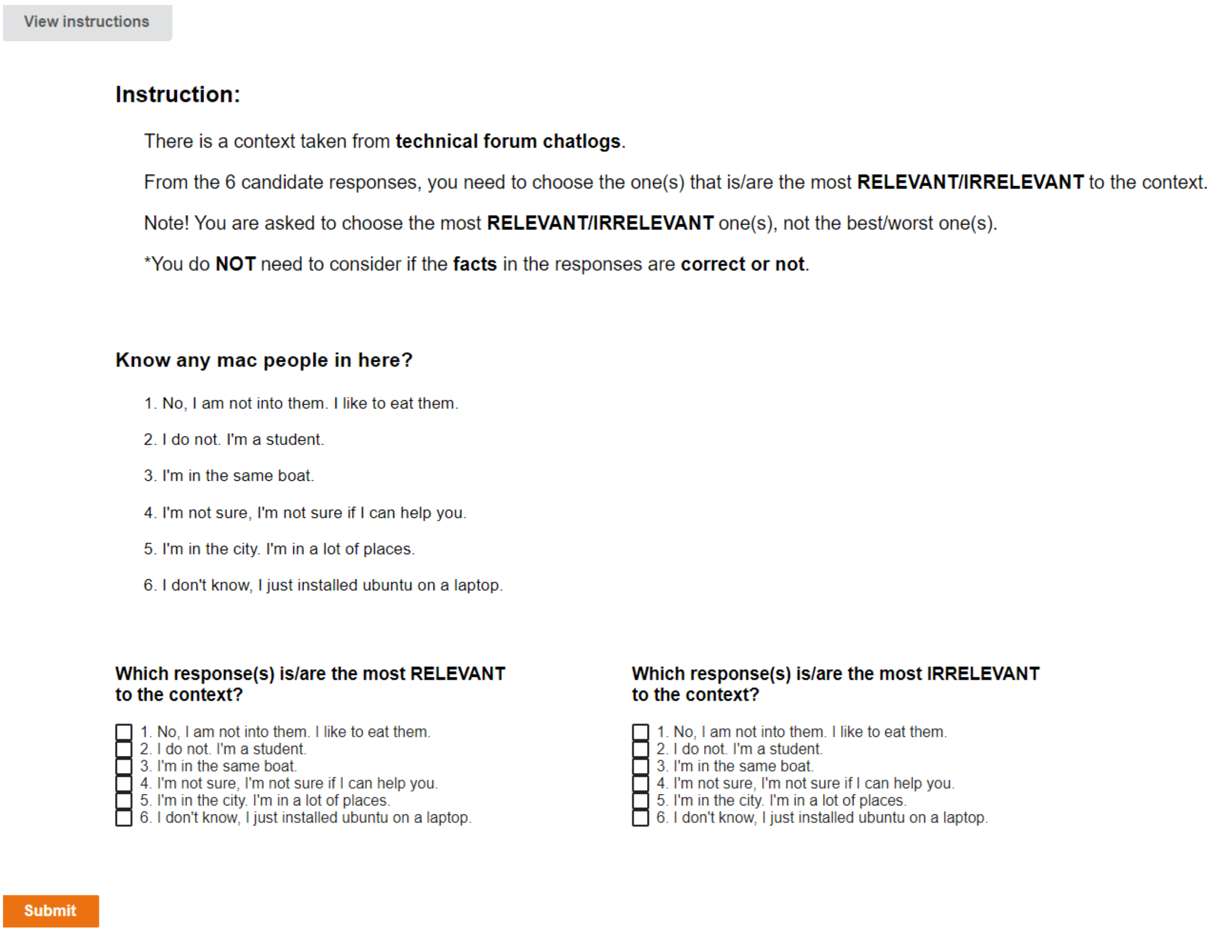
(d) αDF_d scores for generated responses from PersonaChat

Table 11: Full results of αDF_d scores for generated responses from multiple corpora

F Example of human evaluation system



Instruction:

There is a context taken from **technical forum chatlogs**.

From the 6 candidate responses, you need to choose the one(s) that is/are the most **RELEVANT/IRRELEVANT** to the context.

Note! You are asked to choose the most **RELEVANT/IRRELEVANT** one(s), not the best/worst one(s).

*You do **NOT** need to consider if the **facts** in the responses are **correct or not**.

Know any mac people in here?

1. No, I am not into them. I like to eat them.
2. I do not. I'm a student.
3. I'm in the same boat.
4. I'm not sure, I'm not sure if I can help you.
5. I'm in the city. I'm in a lot of places.
6. I don't know, I just installed ubuntu on a laptop.

Which response(s) is/are the most RELEVANT to the context?

☐ 1. No, I am not into them. I like to eat them.
☐ 2. I do not. I'm a student.
☐ 3. I'm in the same boat.
☐ 4. I'm not sure, I'm not sure if I can help you.
☐ 5. I'm in the city. I'm in a lot of places.
☐ 6. I don't know, I just installed ubuntu on a laptop.

Which response(s) is/are the most IRRELEVANT to the context?

☐ 1. No, I am not into them. I like to eat them.
☐ 2. I do not. I'm a student.
☐ 3. I'm in the same boat.
☐ 4. I'm not sure, I'm not sure if I can help you.
☐ 5. I'm in the city. I'm in a lot of places.
☐ 6. I don't know, I just installed ubuntu on a laptop.

Figure 3: Human evaluation system for Ubuntu contexts

G Examples of generated responses

OSDB Context: You know the main reason parents kill kids?

PersonaChat (single): I am not sure. I am a vegan.
Concatenated: I know. I've a daughter that just turned 18.
Interleaved: Because they're afraid of what they're gonna do.
Labeled: Because they're not going to be able to handle it.
Multi-Task Labeled: Because they're afraid of what they're gonna do.
Weighted: Because they're afraid of the consequences.

OSDB Context: The big banks will fail, triggering a domino effect.

PersonaChat (single): I am not sure yet. I am sure they will fail.
Concatenated: I'm not sure. I'm not sure what the big banks are doing.
Interleaved: What?
Labeled: I'm not sure what you're talking about.
Multi-Task Labeled:I'm not sure what you mean.
Weighted: What's going on?

OSDB Context: Rigor mortis has yet to set in. His core body temperature remains at 98 degrees. His skin color, lividity is healthy.

PersonaChat (single):I'm not sure if I like him or not. I like to eat meat.
Concatenated: That is good. I like to cook. I am a chef.
Interleaved: He is a very good doctor.
Labeled: He's a good guy.
Multi-Task Labeled: He is a man of great character.
Weighted: He's been in the hospital for two weeks.

Twitter Context: Hillary ran away from rain today. Trump is back on stage minutes after assassination attempt.

PersonaChat (single): I'm not sure what that means.
Concatenated: That is so sad. I hope she gets better soon.
Interleaved: I'm so sorry. I'm so sorry.
Labeled: I'm so sorry.
Multi-Task Labeled: I'm not sure what happened to her.
Weighted: She's a liar.

Twitter Context: It was gruesome & extremely rare to have two witnesses. It was linked to epstein. Media didn't report it.

PersonaChat (single): I'm sorry to hear that. I'm a nurse.
Concatenated: I'm not sure what that means. I'm a big fan of the show.
Interleaved: I'm not sure what happened to the epstein case.
Labeled: I'm not sure what the link was, but it was a link to a video.
Multi-Task Labeled: I'm not sure what happened to the epstein case.
Weighted: The media is biased and biased.

Twitter Context: This is 100% true, but can we talk about it tomorrow and make argentina the focus today? Something needs to stick.

PersonaChat (single): Yes, I think so. I'm going to go to the gym tomorrow.
Concatenated: I'm going to go see a movie.
Interleaved: I'm not sure what that's. I'm not sure what that's.
Labeled: I'm not sure what that means. I'm not sure what that means.
Multi-Task Labeled: I'm not sure what you mean by that. I'm not sure what you mean by that.
Weighted: I'm not sure if I can talk about it tomorrow.

Ubuntu Context: What are you going to do on the remote system exactly?

PersonaChat (single): I am going to be a pilot. I am going to fly planes.
Concatenated: I am going to go to the beach.
Interleaved: I'm going to install the latest version of Ubuntu.
Labeled: I'm going to install a new kernel.
Multi-Task Labeled: I'm going to install the latest version of Ubuntu.
Weighted: I'm trying to connect to the server.

Ubuntu Context: Know any mac people in here?

PersonaChat (single): No, I am not into them. I like to eat them.
Concatenated: I do not. I'm a student.
Interleaved: I'm in the same boat.
Labeled: I'm not sure, I'm not sure if I can help you.
Multi-Task Labeled: I'm in the city. I'm in a lot of places.
Weighted: I don't know, I just installed ubuntu on a laptop.

Ubuntu Context: Type sudo name of application (in short)

PersonaChat (single): I like to play games on my computer.
Concatenated: I did not see that. I am a programmer.
Interleaved: I have a root shell, but I can't login.
Labeled: I have a root shell.
Multi-Task Labeled: I don't know what that is.
Weighted: It is Sudo apt-get install xubuntu-desktop.

PersonaChat Context: That must be hard. I like a beer after driving my nissan pathfinder.

PersonaChat (single): I like to go to the movies. I have been to a few.
Concatenated: I am a huge gamer, I play dungeons and dragons on my computer.
Interleaved: I like to drive my nissan camry.
Labeled: I like to go to the movies with my friends.
Multi-Task Labeled: I like to drive my prius.
Weighted: I love beer too. I love to drink it while I am driving.

PersonaChat Context: A food bank near my house. Do you ever volunteer?

PersonaChat (single): I do, I love to volunteer at the soup kitchen.
Concatenated: Yes I do. I love to help people.
Interleaved: I do. I have a lot of friends.
Labeled: I do. I am a volunteer at the local soup kitchen.
Multi-Task Labeled: I do. I love it. I volunteer at the animal shelter.
Weighted: I do. I love volunteering at the food pantry.

PersonaChat Context: Yes! My son is in junior high and I just started letting him watch them too.

PersonaChat (single): I am a mom of two boys. I have a son.
Concatenated: I am a mom, I have three kids.
Interleaved: I love kids, I have a son who is in high school.
Labeled: I bet he is a good kid. I am a teacher.
Multi-Task Labeled: I am sorry to hear that. I am a teacher.
Weighted: I bet you are a good mom.

Abstract

We propose a novel siamese generative adversarial net for abstractive text summarization (SSPGAN), which can preserve the main semantics of the source text. Different from previous generative adversarial net based methods, SSPGAN is equipped with a siamese semantic-preserving discriminator, which can not only be trained to discriminate the machine-generated summaries from the human-summarized ones, but also ensure the semantic consistency between the source text and target summary. As a consequence of the min-max game between the generator and the siamese semantic-preserving discriminator, the generator can generate a summary that conveys the key content of the source text more accurately. Extensive experiments on several text summarization benchmarks in different languages demonstrate the effectiveness of the proposed method.

Figure 1: The case of lacking saliency in abstractive text summarization. Bold text represents the key content, while the underlined parts represent the unimportant content.

1 Introduction

Abstractive text summarization endeavors to produce a concise and fluent summary for a given text, while maintaining the key content and overall meaning. Previous attempts tackle this problem with either rule-based or statistical-based methods. Recently, with the successes obtained on the machine translation task (Sutskever et al., 2014; Sheng et al., 2020), the neural network based sequence-to-sequence framework is also applied to the abstractive text summarization task. Specifically, the sequence-to-sequence architecture consists of an encoder responsible for transforming the source sequence $\mathbf{x} = \{x_1, x_2, \ldots, x_{Tx}\}$ into an intermediate representation, and a decoder to generate a target sequence $\mathbf{y} = \{y_1, y_2, \ldots, y_{Ty}\}$ using the previously generated intermediate representation. Furthermore, to dynamically generate a context vector for a target word being generated, the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015) is proposed to strengthen the sequence-to-sequence models, which enables the model to focus on the relevant parts of the source-side sequence. Based on the encoder-decoder framework, many variants of model structures, such as convolutional neural network (CNN) and recurrent neural network (RNN) are proposed (Bahdanau et al., 2014; Gehring et al., 2017). With the emergence of Transformer (Vaswani et al., 2017), which is based entirely on the attention mechanism, state-of-the-art performance is achieved on many sequence-to-sequence tasks. Nevertheless, for the task of abstractive text summarization, one of the dominant challenges is to maintain saliency, which requires the generated summary to convey the important information accurately. As shown in Figure 1, the key content of the source text “Chengdu become the ‘Silicon Valley’ in the west of our country” is

accurately summarized in the reference, while the generated summary expresses the unimportant content “Chengdu releases software and information technology service industry development report”.

Intuitively, the lack of saliency in summarization is usually caused by attending to wrong parts of the source text, inspiring many attention optimization methods for more accurate attention mechanism. Among them, (Lin et al., 2018) proposes a global encoding framework, which controls the attention information flow from the encoder to the decoder based on the global information of the source context. (Gui et al., 2019) proposes an effective method to regularize the attention weights from both global and local aspects. (Duan et al., 2019) introduces a novel attention mechanism, where the attention weights on relevant parts of the source side are encouraged while the attention weights on less relevant or irrelevant parts are discouraged with a softmax and a softmin function respectively. However, for these methods, the underlying nature of saliency, which is actually the sentence-level semantic consistency between the source text and the generated summary, is generally overlooked.

To explicitly maintain the semantic consistency, we propose a novel Siamese Semantic-Preserving Generative Adversarial Net (SSPGAN) for abstractive text summarization. In SSPGAN, different from conventional adversarial training (Goodfellow et al., 2014) which mainly focuses on how to generate more realistic data, a novel training paradigm is introduced to generate a summary that is more semantically consistent with the source text. Specifically, the proposed model consists of two adversarial modules which play a min-max game:

- A conventional neural encoder-decoder based generator, which aims to generate the summary sequence based on the input text.
- A siamese semantic-preserving discriminator. Different from the conventional discriminator in a generative adversarial net (GAN), in addition to distinguishing the real summary from the generated summary, it is also required to capture the semantic consistency between the source text and the target summary. And we adopt a pseudo siamese net to achieve that. Specifically, we aim to maximize the semantic similarity for a real sentence pair (text, real summary), while minimizing it for a generated sentence pair (text, generated summary).

During the training process, in terms of the authenticity and semantic consistency with the input source text, the generator aims to fool the discriminator into believing that its output is a human-generated summary, and the discriminator makes efforts not to be fooled by improving its ability to distinguish the machine-generated summary from the human-generated one. This kind of adversarial training achieves a win-win situation when the generator and the discriminator reach a Nash Equilibrium (Zhao et al., 2016; Arora et al., 2017; Guimaraes et al., 2017).

Different from conventional GANs, which assume the existence of a generator in a continuous space, in our proposed framework, the text summarization model is in fact not a typical generative model, but instead a probabilistic transformation that maps a source text to a target summary, both in a discrete space. To this end, we turn to a policy gradient method named REINFORCE (Williams, 1992), which can guarantee that both the two sub models are effectively optimized in an adversarial manner. In addition to the conventional reward, which is the estimated probability of the generated summary being discriminated as the real one, we also adopt the semantic similarity between the source text and the generated summary as a supplementary reward signal. Besides, we employ Transformer (Vaswani et al., 2017) as the basis of our discriminator to capture both the global and local features of the sentence.

The contributions of this work are three-fold:

- We propose a siamese net based discriminator to ensure the semantic consistency between the generated summary and the source text.
- A generative adversarial net based entirely on Transformer is proposed. As far as we know, this work is the first attempt to apply such framework into the text summarization task.
- Experimental results on both English and Chinese text summarization datasets show that the proposed model outperforms conventional GAN-based methods. And we also demonstrate that the proposed method can maintain semantic consistency from multiple perspectives.

2 Related Work

Automatic text summarization can be broadly divided into extractive and abstractive summarization.

The extractive methods simply extract important parts of the source text and reorganize them in a certain order (Jing and McKeown, 2000; Knight and Marcu, 2000; Neto et al., 2002). In comparison, abstractive text summarization is closer in principle to the process of manual summarization, which extracts the essential information of the source text and describes it in a shorter version as the abstractive summary. In this paper, we focus on abstractive text summarization.

Previous works on abstractive text summarization are mainly designed with statistical methods and rule-based methods (Banko et al., 2000; Dorr et al., 2003; Zajic et al., 2004; Cohn and Lapata, 2008). Recently, the sequence-to-sequence neural framework becomes predominant on the task of abstractive text summarization (Chopra et al., 2016; Nallapati et al., 2016; Li et al., 2017b). Later on, with the advent of Transformer (Vaswani et al., 2017), more and more works choose it as the base model in their frameworks.

For the abstractive text summarization task, out-of-vocabulary (OOV), repetitions and lack of saliency are three dominant challenges. To tackle the problem of OOV, some works introduce the pointer network and copy mechanism (Nallapati et al., 2016; See et al., 2017; Gu et al., 2016; Paulus et al., 2017). On the issue of repetitions, (See et al., 2017) adopts a coverage mechanism, which is inspired by the coverage vector from neural machine translation (Tu et al., 2016). Regarding saliency, some works (Duan et al., 2019; Gui et al., 2019) focus on how to optimize the attention mechanism, while (Zhu et al., 2021) tries to enhance the factual consistency with a fact corrector. Meanwhile, (Narayan et al., 2021) adopts the content planning to improve the performance of abstractive summarization model. However, the essence of saliency, which is the sentence-level semantic consistency between the source text and the generated summary, is intuitive yet usually overlooked.

The proposed training principle is based on adversarial learning (Goodfellow et al., 2014). In conventional adversarial training, a generator and a discriminator compete with each other, forcing the generator to produce high quality samples that can fool the discriminator. Adversarial training typically excels in image generation (Goodfellow et al., 2014), with less applications in natural language processing tasks (Yu et al., 2017; Li et al., 2017a), mainly due to the difficulty of propagating the signals from the discriminator to the generator through the discretely generated tokens. (Yu et al., 2017) addresses this issue with a reinforcement learning approach for sequence generation. Thus, the adversarial training paradigm can improve the model on the sentence-level instead of the vanilla token-level (e.g., maximum likelihood estimation).

To address the semantic inconsistency problem mentioned above, we introduce the paradigm of siamese net into GANs. Siamese net is a class of neural network architectures that contain more than one identical or different sub networks, which depends on whether the inputs are similar or not. Siamese net is generally used to measure the similarity between the inputs by comparing their corresponding output feature vectors, and can be broadly divided into two types: true siamese net and pseudo siamese net. The true siamese net contains identical sub networks which share the same architecture and network parameters, while the pseudo siamese net contains sub networks which have different parameters and even different architectures. Among the existing works, (Kenter et al., 2016) is the first to adopt siamese net into unsupervised sentence embedding learning. (Mueller and Thyagarajan, 2016) proposes MaLSTM to learn sentence similarities with Manhattan distance. (Neculoiu et al., 2016) considers similarity matching of a sentence pair as a binary classification task and replaces the Manhattan distance with cosine similarity. Recently, (Reimers and Gurevych, 2019) introduces the principle of siamese net to fine-tune BERT (Devlin et al., 2019) for better sentence embedding.

Different from previous GAN-based abstractive text summarization model in the work of (Liu et al., 2018), by incorporating siamese net into GANs, the generator can generate summaries which are more semantically consistent with the source texts. As far as we know, this work is the first attempt to apply siamese net to the GAN-based sequence-to-sequence generation task.

3 Siamese Semantic-Preserving Generative Adversarial Net

In this section, we introduce the architecture of the proposed Siamese Semantic-Preserving Generative Adversarial Net (SSPGAN) in detail. The model consists of two main components. The first component is a standard Transformer-based summary generator G (Figure 2). During adversarial training, the generator G is treated as an agent tak-

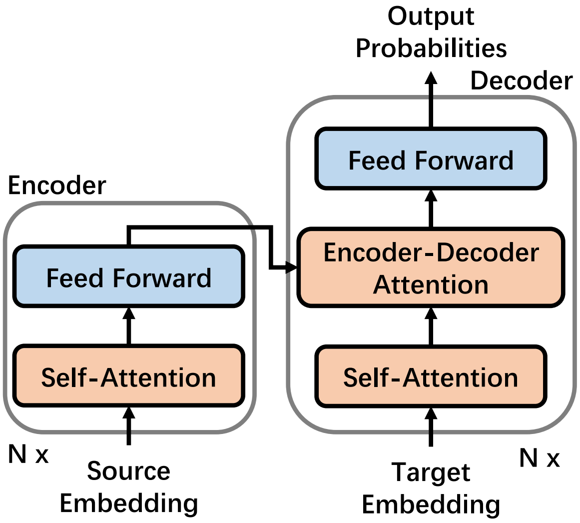

Figure 2: The summary generator, taking a conventional Transformer based encoder-decoder architecture (Vaswani et al., 2017), where the predicted word from the previous step serves as the input of the current step during inference. We omit some layers for brevity.

ing sequential actions (i.e., generating words) and trained using policy gradient given the reward of each generated word. The second component is a siamese network based discriminator D, which is also implemented based on the Transformer. On the one hand, the discriminator D is required to distinguish the generated summary from the real one. On the other hand, it aims to capture the semantic similarity between the source text and the target summary. Specifically, it is expected to maximize the semantic similarity for the real sentence pair (text, real summary), while minimizing the semantic similarity of the generated pair (text, generated summary). From these two perspectives, we compute a composite reward for each generated summary. Both the generator G and the discriminator D are iteratively trained. Figure 3 shows the overview of the adversarial training framework. In the following, we describe the generator G and the siamese semantic-preserving discriminator D in detail.

3.1 Generator

At time step t, the generator G takes an action (i.e., a word y_t) according to a stochastic policy $\pi_\theta(y_t|\mathbf{x}, \mathbf{y}_{t-1})$, where $\mathbf{x}$ is the input source text, $\mathbf{y}_{t-1} = [y_1, \ldots, y_{t-1}]$ is the previously generated partial summary, and θ is the parameter of the policy. We utilize the conventional Transformer based encoder-decoder framework (Vaswani et al., 2017) as the model of the policy. By sequentially generating each word y_t using the policy $\pi_\theta(.)$ until the end, a complete sentence $\mathbf{y}$ is generated. In conventional sequence-to-sequence learning, the model is trained to minimize the cross-entropy loss:

$$\mathcal{J}(\theta) = -\sum_{n=1}^{N}\sum_{t=1}^{T_n} \log \pi_\theta(\hat{y}_t^n|\mathbf{x}^n, \hat{\mathbf{y}}_{t-1}^n) \tag{1}$$

where N is the number of text-summary pairs, T_n is the length of the ground-truth summary $\hat{\mathbf{y}}^n$, Loss is the cross-entropy loss, $\hat{\mathbf{y}}_{t-1}^n$ and $\hat{y}_t^n$ are the ground-truth partial summary and word, respectively. Nevertheless, in adversarial training, these is no explicit supervised information for computing the cross-entropy loss. Hence, we adopt our discriminator D to assess the quality of the generated complete summary $\mathbf{y}^n$. Specifically, the discriminator D is responsible for calculating a reward using the generated summary $\mathbf{y}^n$ and the source text $\mathbf{x}^n$ (See Section 3.3 for details).

3.2 Siamese Semantic-Preserving Discriminator

Our discriminator D aims to not only distinguish the real summary from the generated one, but also capture the semantic similarity between the source text and the target summary. Here, the discriminator D is implemented based on the Transformer, as Transformer is capable of capturing both local and global sentence features. In the meantime, to capture the semantic similarity, the whole framework of the discriminator D is designed based on the siamese net (right panel in Figure 3).

Given the source text $\mathbf{x} = \{x_1, x_2, \ldots, x_{Tx}\}$ and the target summary $\mathbf{y} = \{y_1, y_2, \ldots, y_{Ty}\}$ (here $\mathbf{y}$ represents both the real and generated summary for simplicity), where x_t and y_t are the t-th words in the corresponding sequences. For the source text sequence $\mathbf{x}$, we take it as input of the Transformer encoder. After the processing of Transformer blocks, a hidden state sequence $h_\mathbf{x}$ will be produced:

$$h_\mathbf{x} = \{h_{x_1}, h_{x_2}, \ldots, h_{x_{T_x}}\} \tag{2}$$

where h_{x_t} is the hidden state corresponding to x_t in the input sequence. Thus, h_{x_t} contains not only the positional information, but also the global and local correlation information. To get the final feature representation $f_\mathbf{x}$ for the input sequence, a mean-pooling operation is leveraged over the output hidden state sequence $h_\mathbf{x}$. Since there exists difference between the textual structures of the source text

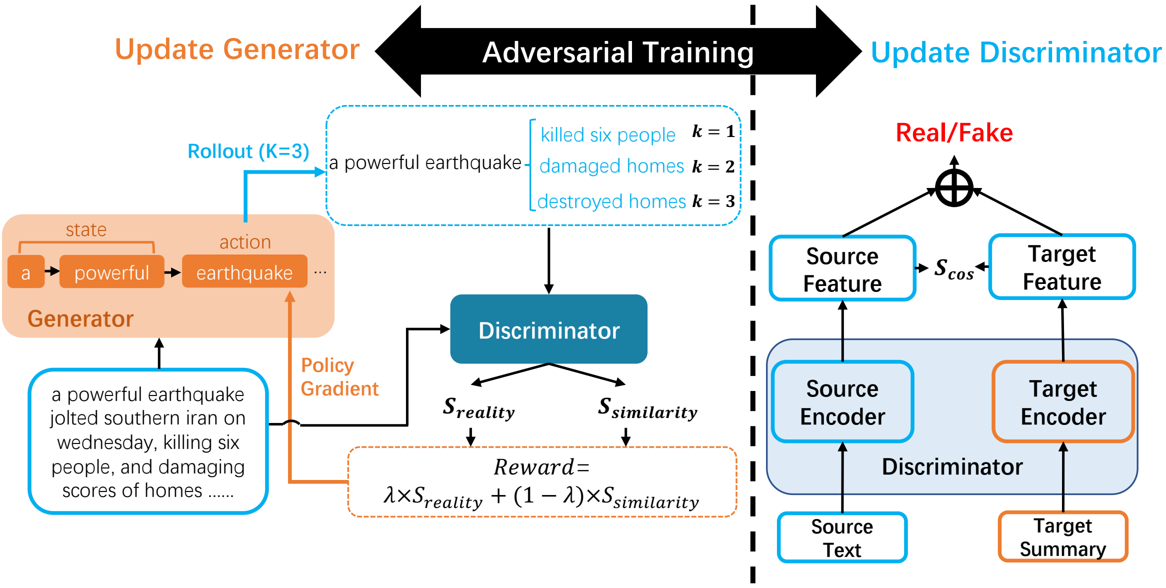

Figure 3: Overview of the model. Left panel: our generator G produces a summary conditioned on the source text. At each time step, the expected reward of a newly generated word ("earthquake" in the presented example) is computed from the siamese semantic-preserving discriminator D using Monte Carlo rollout. We use policy gradient to update the generator G toward generating summaries with higher rewards. Right panel: the discriminator D observes the generated summary and aims at distinguishing it from the real one. Besides, the discriminator D is responsible for capturing the semantic consistency between the source text and the target summary. During adversarial training, both the generator G (left) and the discriminator D (right) are iteratively updated to improve.

and the target summary, for the target summary, we adopt the same encoder framework as the one for the source text, but share no parameters (i.e., pseudo siamese net). And the corresponding final feature representation $f_{\mathbf{y}}$ is also obtained using the mean-pooling operation. Finally, given both the source text and the target summary, the probability that the target summary is classified as real can be calculated as:

$$p = \sigma(V[f_{\mathbf{x}}, f_{\mathbf{y}}]) \tag{3}$$

where V is the weight matrix to transform the concatenation of $f_{\mathbf{x}}$ and $f_{\mathbf{y}}$ into a 2-dimensional embedding and σ is the logistic function. Finally, the training objective for discriminating the real summary from the generated one can be formulated as a supervised classification objective:

$$\mathcal{L}_{real}(\phi) = -\sum_{n=1}^{N} \log p(l^n | \mathbf{x}^n, \mathbf{y}^n; \phi) \tag{4}$$

where N is the number of text-summary pairs, ϕ is the model parameters of the discriminator D, and l^n is the corresponding label (i.e., 0 for the generated summary and 1 for the real summary).

To capture the semantic similarity between the source text and the target summary, we further utilize the final features of the pseudo siamese net. Specifically, we aim to maximize the semantic similarity between the source text and the real summary, while minimizing it for the pair of the source text and the generated summary. To this end, we adopt the cosine function to evaluate the similarity of the sentence pair:

$$\mathcal{S}_{cos} = \frac{\langle f_{\mathbf{x}}, f_{\mathbf{y}} \rangle}{||f_{\mathbf{y}}||\ ||f_{\mathbf{y}}||} \tag{5}$$

and the value of $\mathcal{S}_{cos}$ ranges from -1 to 1. Next, we can obtain the contrastive loss $\mathcal{L}_{sim}$ for siamese semantic similarity learning:

$$\begin{aligned}\mathcal{L}_{sim} = \frac{1}{N} \sum_{n=1}^{N} & l^n \mathcal{L}_{+}(f_{\mathbf{x}}^n, f_{\mathbf{y}}^n) \\ & + (1 - l^n) \mathcal{L}_{-}(f_{\mathbf{x}}^n, f_{\mathbf{y}}^n)\end{aligned} \tag{6}$$

where N is the number of text-summary pairs, l^n is the corresponding summary label (i.e., 1 for the real sentence pair and 0 for the generated sentence pair), $\mathcal{L}_{+}$ and $\mathcal{L}_{-}$ are the corresponding loss functions for the real and generated sentence pair, respectively. The two sub loss functions are given by:

$$\begin{aligned}\mathcal{L}_{+}(f_{\mathbf{x}}^n, f_{\mathbf{y}}^n) &= (1 - \mathcal{S}_{cos})^2 \\ \mathcal{L}_{-}(f_{\mathbf{x}}^n, f_{\mathbf{y}}^n) &= \begin{cases} \mathcal{S}_{cos}^2 & \text{if } \mathcal{S}_{cos} > 0 \\ 0 & \text{otherwise} \end{cases}\end{aligned} \tag{7}$$

Thus, we can obtain the final objective of the siamese semantic-preserving discriminator D:

$$\mathcal{L}_d = \eta \mathcal{L}_{real} + (1-\eta)\mathcal{L}_{sim} \tag{8}$$

where η is a hyper-parameter to balance the two sub training objectives.

3.3 Policy Gradient Training

Following (Yu et al., 2017), during adversarial training, the goal of the generator G is defined as to generate a summary sequence from the start state to maximize its expected overall reward. Formally, the objective function is calculated as:

$$\mathcal{J}_{adv}(\theta) = \sum_{\mathbf{y}_{1:T}} G_\theta(\mathbf{y}_{1:T}|\mathbf{x}) \cdot R_{D_\phi}^{G_\theta}(\mathbf{y}_{1:T-1}, \mathbf{x}, y_T) \tag{9}$$

where θ denotes the parameters of G, $\mathbf{y}_{1:T} = \{y_1, \ldots, y_T\}$ indicates the generated target summary, $\mathbf{x}$ is the source text. Here we denote T_y as T for simplicity. $R_{D_\phi}^{G_\theta}$ is the action-value function of the generated summary given the source text $\mathbf{x}$ (i.e., the expected accumulative reward starting from the state $(\mathbf{y}_{1:T-1}, \mathbf{x})$, taking action y_T, and adopting the policy G_θ). To estimate the action-value function, we combine the probability of being classified as real by the discriminator D with the cosine similarity as the total reward:

$$\begin{aligned} R_{D_\phi}^{G_\theta}(\mathbf{y}_{1:T-1}, \mathbf{x}, y_T) =& \lambda \cdot s_{reality} \\ &+ (1-\lambda) \cdot s_{similarity} \\ s_{reality} =& D_\phi(\mathbf{x}, \mathbf{y}_{1:T}) - b(\mathbf{x}, \mathbf{y}_{1:T}) \\ s_{similarity} =& \mathcal{S}_{cos}(\mathbf{x}, \mathbf{y}_{1:T}) \end{aligned} \tag{10}$$

where $b(\mathbf{x}, \mathbf{y}_{1:T})$ denotes the baseline value to reduce the variance of the reward. In practice, we set it to 0.5 during training. And λ is a hyper-parameter for balance. It is worth noting that, (10) only defines a reward value for a completely generated summary. If $\mathbf{y}_{1:T}$ is partially generated, the values of $D_\phi(\mathbf{x}, \mathbf{y}_{1:T})$ and $\mathcal{S}_{cos}(\mathbf{x}, \mathbf{y}_{1:T})$ are meaningless. To evaluate the action-value for an intermediate state, we apply Monte Carlo (MC) tree search under the policy G_θ to sample the following unknown tokens. Each search lasts until the end of summary token is sampled or the sampled summary reaches the maximum length. For more stable reward and lower variance, we conduct a K-time roll-out as follow:

$$\{\mathbf{y}_{1:T_1}^1, \ldots, \mathbf{y}_{1:T_K}^K\} = MC^{G_\theta}((\mathbf{y}_{1:t}, \mathbf{x}), K) \tag{11}$$

where T_i denotes the length of the summary sampled by the i-th Monte Carlo search. $(\mathbf{y}_{1:t}, \mathbf{x})$ is the current state and $\mathbf{y}_{t+1:T_i}^i$ is sampled based on the policy G_θ. Accordingly, the discriminator provides K rewards for the sampled K summaries respectively. The final reward for the intermediate state is computed as the average of K rewards. Thus, for the generated summary with length T, we compute the final reward for y_t at the sentence level as:

$$R_{D_\phi}^{G_\theta}(\mathbf{y}_{1:t-1}, \mathbf{x}, y_t) = \begin{cases} \frac{1}{K}\sum_{k=1}^{K} \lambda(D_\phi(\mathbf{x}, \mathbf{y}_{1:T}^k) - b(\mathbf{x}, \mathbf{y}_{1:T}^k)) + \\ (1-\lambda)\mathcal{S}_{cos}(\mathbf{x}, \mathbf{y}_{1:T}^k) & t < T \\ \lambda(D_\phi(\mathbf{x}, \mathbf{y}_{1:t}) - b(\mathbf{x}, \mathbf{y}_{1:t})) + \\ (1-\lambda)\mathcal{S}_{cos}(\mathbf{x}, \mathbf{y}_{1:t}) & t = T \end{cases} \tag{12}$$

Using the discriminator D as a reward function can further improve the generator iteratively by dynamically updating D. Once we have a set of more realistic generated summaries, we shall re-train the discriminator model by minimizing (8). Each time when a new discriminator model is obtained, we can re-train the generator. The gradient of the objective $\mathcal{J}_{adv}(\theta)$ w.r.t. the generator's parameters θ can be formulated as:

$$\begin{aligned} \nabla \mathcal{J}_{adv}(\theta) =& \frac{1}{T}\sum_{t=1}^{T}\sum_{y_t} R_{D_\phi}^{G_\theta}(\mathbf{y}_{1:t-1}, \mathbf{x}, y_t) \\ &\cdot \nabla_\theta(G_\theta(y_t|\mathbf{y}_{1:t-1}, \mathbf{x})) \\ =& \frac{1}{T}\sum_{t=1}^{T} \mathbb{E}_{y_t \in G_\theta}[R_{D_\phi}^{G_\theta}(\mathbf{y}_{1:t-1}, \mathbf{x}, y_t) \\ &\cdot \nabla_\theta \log p(y_t|\mathbf{y}_{1:t-1}, \mathbf{x})] \end{aligned} \tag{13}$$

3.4 Adversarial Training

The overall training flow of SSPGAN is shown in Figure 3. Both the generator G and the siamese semantic-preserving discriminator D learn together by pursuing competing goals. Given $\mathbf{x}$, the generator G generates a summary $\mathbf{y}$. It would prefer summaries with bigger rewards, which implies larger values of $s_{reality}$ and $s_{similarity}$. In contrast, the discriminator D would encourage smaller values of $s_{reality}$ and $s_{similarity}$. Thus, the generator G and the siamese semantic-preserving discriminator D play a min-max game (see Algorithm 1 in the Appendix A.2 for more details).

4 Experiments

4.1 Datasets

We conduct extensive experiments on both Chinese and English text summarization datasets. The Chinese dataset we adopt is a large corpus of Chinese short text summarization (LCSTS) (Hu et al., 2015), which is collected from Sina Weibo, a famous Chinese social media website. Following the data split of previous works, we get around 2.4M text-summary pairs for training, 10K pairs for validation and 725 pairs with annotation score no less than 3 for testing. For English text summarization, we use the Gigaword dataset based on Annotated Gigaword (Napoles et al., 2012), and preprocess it identically to (Rush et al., 2015), which results in 3.8M sentence pairs for training, 190K for validation and around 1.9K for testing.

4.2 Evaluation Metrics

For a fair comparison with previous works, we adopt ROUGE (Lin, 2004) as the automatic evaluation metric. ROUGE measures the degree of overlap between the generated summary and the reference, with respect to the number of n-grams. We report ROUGE-1 (uni-gram), ROUGE-2 (bi-gram), ROUGE-L (longest common subsequence - LCS) on the testing set for our quantitative experiments. Since the official ROUGE evaluation package is only available for English summarization, to evaluate the models on the Chinese summarization task, we follow (Hu et al., 2015) and map all characters including punctuation and numbers to numerical IDs, and then conduct evaluation on them. In experiments, we denote ROUGE as RG for simplicity.

4.3 Compared Models

Baselines for the Chinese text summarization task include the followings. RNN and RNN-context are two RNN-based models adopted in (Hu et al., 2015), without and with the attention mechanism respectively. CopyNet leverages the copy mechanism to alleviate the OOV problem (Gu et al., 2016). RNN-MRT (Shen et al., 2016) and Actor-Critic (Li et al., 2018) are two sentence-level training methods to address the problem of teacher forcing which use the maximum likelihood estimation. DRGD (Li et al., 2017b) uses a recurrent latent random model to strengthen the abstractive text summarization model. GlobalEncoding (Lin et al., 2018) controls the information flow from the encoder to the decoder based on the source-side global information.

System	RG-1	RG-2	RG-L
ABS	29.55	11.32	26.42
ABS+	29.76	11.88	26.96
Concept-pointer+DS	37.01	17.10	34.87
DRGD	36.27	17.57	33.62
Actor-Critic	36.05	17.35	33.49
Transformer	37.57	18.90	34.69
SSPGAN	**38.31**	**19.89**	**35.60**

Table 1: The full-length F-1 based ROUGE scores on the testing set of the English benchmark Gigaword. Here we bold the best results.

As for the English dataset, besides DRGD and Actor-Critic, we choose the following baselines. ABS and ABS+ are two pioneer methods using neural networks for abstractive text summarization (Rush et al., 2015). Concept-pointer+DS engages abstractive summarization models to generate new conceptual words (Wang et al., 2019).

Our model is complemented based on Tensor2Tensor [1]. For all experiments, SSPGAN is run with 5 random seeds on 2 NVIDIA V100 GPUs and the final automatic results are presented with means (see the Appendix A.1 for more details).

4.4 Quantitative Results

4.4.1 English Results

Table 1 shows the results on the English dataset Gigaword. The results of the baselines are reported in the upper rows, while the bottom row summarizes the results of the proposed SSPGAN. When we introduce the SSPGAN framework to Transformer, it significantly improves the performance, proving the effectiveness of our method.

4.4.2 Chinese Results

The experimental results on the Chinese dataset LCSTS are presented in Table 2. As can be observed from the comparison between the baselines in the upper rows and SSPGAN in the bottom row, the proposed method achieves the best performance. In addition, the proposed SSPGAN brings significant improvements to the classical baseline Transformer. Precisely, Transformer is greatly improved in ROUGE-1/2/L with gains of +1.88/+1.09/+1.20.

System	RG-1	RG-2	RG-3
Transformer	37.57	18.90	34.69
+SSPGAN (η, λ=1.0)	38.00	19.41	35.18
+SSPGAN (η, λ=0.7)	**38.31**	**19.89**	**35.60**
+SSPGAN (η, λ=0)	37.78	19.19	34.99

Table 3: Ablation study regarding the sub training objectives proposed in (8) and (10). We bold the best results.

4.5 Analysis

In this section, we analyze the effectiveness of the proposed method from multiple perspectives. All the experiments are conducted on Gigaword.

4.5.1 Ablation Study

As shown in Table 3, we analyze the contributions of different sub training objectives proposed in (8) and (10). On the Transformer model, the basic GAN (i.e., the second row with η=1.0 and λ=1.0) achieves improvement with gains of +0.43/+0.51/+0.49 in ROUGE scores. We also test the results when Transformer is only guided by the semantic similarity objective (i.e., the fourth row with η=0 and λ=0), resulting gains of +0.21/+0.29/+0.30. Armed with the proposed SSPGAN (i.e., the third row with η=0.7 and λ=0.7), the performance can be more significantly improved with gains of +0.74/+0.99/+0.91 in ROUGE scores.

4.5.2 Human Evaluation

System	R	C
Transformer	6.39	6.65
+SSPGAN (η, λ=1.0)	**7.09**	6.82
+SSPGAN (η, λ=0.7)	7.06	**7.33**
+SSPGAN (η, λ=0)	6.64	6.78

Table 4: Comparison of human evaluation on a random subset of the Gigaword testing set. We denote the readability and consistency as R and C, respectively. The best results are bold.

Source: malaysia's national car maker proton **expects to export its cars to russia** by early next year to boost its overseas sales, a company official said tuesday
Reference: malaysian carmaker proton **seeks inroads into russia** by early next year
GAN: malaysia's car maker to boost overseas sales
SSPGAN: malaysia's proton **to export cars to russia**

Source: chinese vice-premier wu yi said tuesday that the country should step up efforts to **develop its service trade** in a bid to alter the growth pattern of foreign trade and increase employment and domestic consumption.
Reference: chinese vice-premier calls for fast **development of service trade**
GAN: chinese vice-premier urges to increase domestic consumption
SSPGAN: chinese vice-premier urges **development of service trade**

Figure 4: Comparison of the summaries generated by the basic GAN and the proposed SSPGAN. Bold text represents that the correct contents are extracted, while the underlined parts correspond to the wrong ones.

To further evaluate the quality of the generated summaries, we randomly select 50 test examples from the Gigaword testing set for human evaluation. For each example, we show the source text, the ground truth summary as well as the summaries generated by different models. The human evaluators do not know which summary comes from which model or which one is the ground truth. Two scores from 1 to 10 are assigned to each summary (1 and 10 indicate the worst and the best respectively), one for readability (how well-written the summary is) and one for consistency (how well the summary conveys the key content of the source text). Each summary is rated by 10 invited human evaluators who are capable of reading English proficiently. And the results are averaged across all selected examples and evaluators. As shown in Table 4, equipped with the basic GAN objective, the readability is improved significantly with comparable results (i.e., the second row with η=1.0 and λ=1.0 and the third row with η=0.7 and λ=0.7). As for the consistency, our proposed model (i.e., the third row with η=0.7 and λ=0.7) achieves the highest score, which justifies that the proposed method can preserve the key content of the source text more accurately. It is worth noting that the improvements of the fourth row are limited, which is only equipped with siamese similarity objective. Due to the lack of basic GAN objective, the improvement of readability is limited, resulting in incomplete sentence semantic expression and damage to the improvement of consistency.

4.5.3 Case Study

Figure 4 shows some examples of the generated summaries on the English dataset, in which both the basic GAN and the proposed SSPGAN produce readable results. However, as shown in the highlights of the SSPGAN examples, the proposed method is able to convey the key content of the source text more accurately, resulting in more salient summaries as expected. Specifically, in the upper example, the key content "expects to export its car to russia" in the source text is only expressed by SSPGAN, while the basic GAN generates "boost overseas sales", ignoring the most relevant information. Similar behaviors can also be observed in the bottom example.

5 Conclusion

This paper presents a novel siamese generative adversarial net (SSPGAN) which can preserve the semantic consistency between the source text and the target summary for abstractive text summarization. In SSPGAN, a novel semantic similarity based reward is introduced to further augment the GAN-based abstractive text summarization to preserve the semantic consistency and convey the key content in the source text. It is worth noting that SSPGAN addresses the problem of saliency for text summarization from a totally different perspective of semantic consistency, therefore it is orthogonal to some state-of-the-art methods which focus on attention mechanism, and can be applied to them for further improvements.

A Appendix

A.1 Experimental Setup

We build both the generator and the siamese semantic-preserving discriminator on the basis of Transformer. For the generator, in both the encoder and the decoder, 6 layers are stacked with dimensions of embedding layers and hidden layers set to 512. The dimension of feed-forward layers is set to 2048. And we set 8 heads for multi-head attention. In the discriminator, both the text encoder and the summary encoder have the same framework as the encoder in the generator, except that the number of layers is set to 2. For the generator, we adopt the joined source-target vocabulary for both English and Chinese experiments. The encoder input embeddings, the decoder input embeddings and the decoder output embeddings are all shared. For the discriminator, the two encoders share the input embeddings.

For the Chinese dataset, we tokenize the sequences into character-level text-summary pairs and evaluate the performance based on the reference tokens. For the English dataset, to improve the computational efficiency and avoid problems with closed vocabularies, we segment the data using byte-pair encoding (BPE) (Sennrich et al., 2016), which results in a vocabulary of 32K tokens.

During pre-training, for the generator, Adam optimizer is used with the learning rate set as 0.0005.

The inverse square root learning rate decay is applied for initial warm up and annealing with 4000 steps. For the discriminator, we adopt RMSProp optimizer with the learning rate of 0.0005 and $\eta = 0.7$. The dropout rate is set to 0.3 for both models. During adversarial training, for both models, the learning rate is set to 0.00001 without changing the optimizer. K in Monte Carlo rollout is set as 20 and λ is 0.7.

In the proposed architecture, there are 2 hyper-parameters η and λ need to be jointly tuned during training. Here we conduct a grid search to find a proper combination of these hyper-parameters. For both η and λ, the value is selected in set $[0.1, 0.3, 0.5, 0.7, 0.9]$ and we experimentally find that the η of 0.7 and the λ of 0.7 give the best results on validation sets.

Towards Job-Transition-Tag Graph for a Better Job Title Representation Learning

Jun Zhu, Céline Hudelot

`{jun.zhu, celine.hudelot}@centralesupelec.fr`

Abstract

Works on learning job title representation are mainly based on *Job-Transition Graph*, built from the working history of talents. However, since these records are usually messy, this graph is very sparse, which affects the quality of the learned representation and hinders further analysis. To address this specific issue, we propose to enrich the graph with additional nodes that improve the quality of job title representation. Specifically, we construct *Job-Transition-Tag Graph*, a heterogeneous graph containing two types of nodes, i.e., job titles and tags (i.e., words related to job responsibilities or functionalities). Along this line, we reformulate job title representation learning as the task of learning node embedding on the *Job-Transition-Tag Graph*. Experiments on two datasets show the interest of our approach.

1 Introduction

The learning of job title (referred to as job for short) [1] representation has received much attention in the recruitment field because the learned representation is beneficial to various tasks, such as job recommendation (Dave et al., 2018; Liu et al., 2019b), job title benchmarking (Zhang et al., 2019), and job mobility prediction (Zhang et al., 2021; Zhu et al., 2021). However, in practice, learning a good representation is challenging for the following reasons: (i) **Noisy data**: job title data is noisy due to personal subjective reasons (i.e., spelling errors) or objective reasons (i.e., resume parsers are not perfect). (ii) **Messy data**: job titles are messy because people have different ways of thinking, and naming conventions vary by company and industry. For example, there are many alternative job titles for the same position, e.g., "purchasing clerk" and "buyer". Another problem is that due to the ambiguity of certain terms, they can refer to different positions in different contexts, e.g., "registered nurses sandwich rehab" and "sandwich maker". For these reasons, standard semantic-based approaches that aggregate (e.g., mean or sum) word representations to get job title semantic representation may lead to mismatches. Moreover, these methods ignore hidden relationships between job titles, e.g., titles in the same resume may be similar. (Dave et al., 2018; Zhang et al., 2019) learn representations from graphs. They create graphs from career trajectories, where nodes represent job titles and edges represent job transitions. Then they design different loss functions to embed the nodes into a low-dimensional space. However, the generated graphs are usually sparse due to the above reasons, limiting the performance of graph-based methods. Standardizing job titles before generating graphs can alleviate the sparsity issue to a certain extent, but at the cost of losing some information. To tackle these challenges, we propose to enrich graphs with structured contextual information and learn job title representations through network embedding methods. More specifically, inspired by domain-specific Named Entity tags (i.e., *RES*ponsibility and *FUN*ction) proposed in (Liu et al., 2019a), we treat the job title as a combination of responsibilities, functionalities, and other additional information. Words related to *responsibility* and *functionality* are defined as tags. We assume that job titles with the same tag describe similar job responsibilities or functionalities, making them more likely to have similar representations. Along this line, we construct *Job-Transition-Tag Graph*, a heterogeneous graph containing two types of nodes, i.e., job titles and tags, which carries more information, thereby alleviating the sparsity problem.

2 Methodology

2.1 Preliminaries

A graph/network is represented as $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, with node set $\mathcal{V}$ and edge set $\mathcal{E}$. Nodes and edges

---

[1] In this paper, we use *job title* and *job* interchangeably.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2133 - 2140
July 10-15, 2022

can optionally have a type, so a graph can be homogeneous or heterogeneous. In the recruitment field, the career trajectory of talents can be represented by graphs. Formally, consider a job seeker set $\mathcal{U}$ and their working history set $\mathcal{H} = \{H^u\}_{u \in \mathcal{U}}$, where the working history of each u is represented as a sequence of n work records ordered by time $H^u = \{J_1, \ldots, J_n\}$. The i-th record J_i is denoted by (j_i, p_i), indicating that u is engaged in a position (titled j_i) during the p_i period. The set of job titles j_i that occurred in $\mathcal{H}$ is denoted as $\mathcal{J}$. Based on $\mathcal{H}$, *Job-Transition Graph* (Figure 1a) can be constructed, which is formally defined as:

Definition 1 (Job-Transition Graph) *is defined as a directed homogeneous graph* $\mathcal{G}^{jj} = (\mathcal{J}, \mathcal{E}^{jj})$ *generated from* $\mathcal{H}$*, where* $\mathcal{J}$ *is a set of job titles, and the edge* $e^{jj}_{xy} \in \mathcal{E}^{jj}$ *represents the job transition from the former job* j_x *to the next job* j_y*.*

2.1.1 Learning from Job-Transition Graph: An Overview

$\mathcal{G}^{jj}$ is often used for job title representation learning tasks. The current procedure is first to build a $\mathcal{G}^{jj}$, and then learn job title representation from it. More specifically, (Dave et al., 2018) first builds $\mathcal{G}^{jj}$ and the other two graphs. Then, the Bayesian personalized ranking and margin-based loss functions are used to learn job title representations from graphs. Job2Vec (Zhang et al., 2019) constructs a $\mathcal{G}^{jj}$, where the node denotes a job title affiliated with the specific company, and a multi-view representation learning method is proposed. (Zhang et al., 2021) adds company nodes in $\mathcal{G}^{jj}$ to build a heterogeneous graph. Then they use a graph neural network to represent the nodes. As mentioned in Section 1, the job title and job transition data are messy. Therefore, $\mathcal{G}^{jj}$ may be sparse (Zhang et al., 2019), which we will further prove in Section 3.1. In order to alleviate this issue, a simple method is to standardize job titles and then construct a normalized and denser graph based on the standardized job titles. For example, (Dave et al., 2018) normalizes titles by using Carotene (Javed et al., 2015), (Zhang et al., 2019) aggregates titles by filtering out low frequency words, and (Zhang et al., 2021) unifies titles according to IPOD (Liu et al., 2019a). However, the standardization of job titles may lose some specific information. Furthermore, these methods either ignore the semantic information contained in job titles (Dave et al., 2018; Zhang et al., 2021) or separate the semantic information from the graph topology (Zhang et al., 2019).

2.1.2 Job Title Composition

Generally, a job title consists of three parts (Liu et al., 2019a; Zhang et al., 2019): (i) **Responsibility**: describes the role and responsibility of a position from different levels (e.g., director, assistant, and engineer). (ii) **Functionality**: describes the business function of a position from various dimensions (e.g., sales, national and security). (iii) **Additional Information**: contains personal-specific information. We denote the words related to *responsibility* and *functionality* as tags, and they form a tag set $\mathcal{T}$. These tags are the essence of the job title and provide important information about the position. However, few works directly include this information in the representation learning scheme. In this paper, we consider these tags when generating graphs. These tags can alleviate the graph sparsity problem of $\mathcal{G}^{jj}$ and provide additional information for the learning of job title representations.

2.2 Proposed Graphs

In order to address the sparsity issue of $\mathcal{G}^{jj}$, we consider adding more information when generating graphs, i.e., tags related to job responsibilities or functionalities, driven by the job title composition. Along this line, we define various types of graphs:

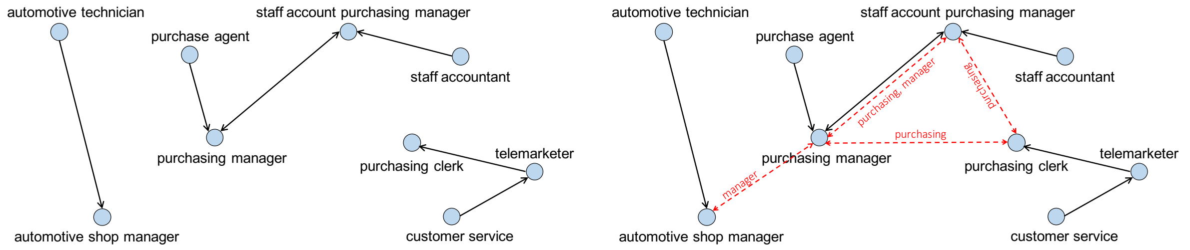
Definition 2 (Enhanced Job-Transition Graph) *is based on* $\mathcal{G}^{jj}$ *with additional enhanced edges. It is defined as* $\mathcal{G}^{jj}_E = (\mathcal{J}, \mathcal{E}^{jj} \cup \mathcal{E}^{jj}_E)$*, where* $\mathcal{E}^{jj}_E$ *is a set of enhanced edges. More specifically, if* j_x *and* j_y *share a tag* w*, then we add a bi-directional edge between them, i.e.,* e^{jj}_{xy} *and* e^{jj}_{yx}*.*

As shown in Figure 1b, red dashed lines represent additional enhanced edges, e.g., “purchasing manager” shares the tag “purchasing” with “purchasing clerk”, so we add edges between them.

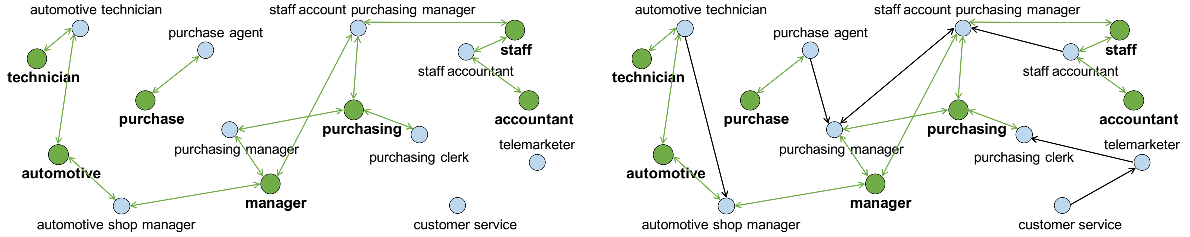
Definition 3 (Job-Tag Graph) *is defined as a heterogeneous graph* $\mathcal{G}^{jt} = (\mathcal{J} \cup \mathcal{T}, \mathcal{E}^{jt})$*, with job titles and tags, two node types.* $\mathcal{E}^{jt}$ *is a set of bi-directional edges between a job title and a tag, representing the “has/in” relationship.*

An example of the “has/in” relationship is given in Figure 1c (i.e., the green line), where the job title “automotive technician” *has* a tag “automotive”, and “automotive” is *in* “automotive technician”. In order to aggregate more information, we further combine *Job-Transition Graph* and *Job-Tag Graph* to build *Job-Transition-Tag Graph*:

Definition 4 (Job-Transition-Tag Graph) *is defined as a heterogeneous graph* $\mathcal{G}^{jtj} = (\mathcal{J} \cup$



(a) Job-Transition graph. (b) Enhanced Job-Transition graph.



(c) Job-Tag graph. (d) Job-Transition-Tag graph.

Figure 1: Examples of four types of graphs with blue/green circles representing job titles/tags. Black lines represent job transitions, red dotted lines represent additional enhanced edges, and green lines represent “has/in” relationships.

$\mathcal{T}, \mathcal{E}^{jj} \cup \mathcal{E}^{jt}$) with job titles and tags, two node types, and transition and “has/in”, two edge types.

Inspired by the achievements of network embedding models in the node representation learning problem (Hamilton et al., 2017), we apply different network embedding models to learn job title representation from the graphs defined above.

3 Experiments

We evaluate the proposed job title representation learning scheme through (i) a node classification task (i.e., *job title classification*) and (ii) a link prediction task (i.e., *next-job prediction*). This section will first describe the two datasets used and experimental settings, followed by discussing the results.

3.1 Datasets

CareerBuilder12 (CB12): an open dataset from a Kaggle competition. [2] It contains a collection of working experiences represented by sequences of job titles. For the node classification task, we use *AutoCoder* [3] to assign a SOC 2018 to each job title. The labeling details are given in Appendix A.1.
Randstad: a private French resume dataset provided by Randstad company, where each resume is parsed into multiple sections, e.g., *PersonalInformation*, *EducationHistory* and *EmploymentHistory*. An example is given in Figure 3 of Appendix. Graphs are built from *EmploymentHistory* section.

Both datasets use a tree-like taxonomy, as described in Appendix A.1 and A.2. For example, from root class to leaf class, the *CB12* taxonomy is organized as *MajorGroup* → *MinorGroup* → *BroadGroup* → *DetailedOccupation*. Consistent with the reality of the recruitment market, some occupations rarely appear in both datasets. To balance the data, we filter out occupations with fewer than 200 occurrences, i.e., *MinorGroup* for *CB12* and *JobGroup* for *Randstad*. Also, for graph construction, we remove working histories with less than two work records, i.e., $|H^u| < 2$.

	#C	#W	$\lvert\mathcal{J}\rvert$	$\lvert\mathcal{E}^{jj}\rvert$	$\lvert\mathcal{E}_E^{jj}\rvert$	$\lvert\mathcal{E}^{jt}\rvert$
CB12	16	1,682	9,216	20,640	6,477,819	22,149
Randstad	18	2,303	12,864	36,722	6,663,267	22,897

Table 1: Statistics of datasets and corresponding graphs, #C represents the number of categories, and #W represents the vocabulary size for node one-hot encoding.

In order to generate tags, we first tokenize titles into tokens and remove stopwords, numbers, and punctuation. Then, we use the Top-200 tokens that appear most frequently in job titles and belong to IPOD (Liu et al., 2019a) as tags. The details of tag generation are given in Appendix A.3. We assign the one-hot encoding of the corresponding title for each title node as the node feature. The vocabulary set is obtained by filtering words with a frequency of 1 from the tokenized job titles. Statistics for

Table 2: Job title classification results (Macro-F1/Micro-F1). The score in bold is the best among all methods applied to all graphs, and the scores underlined are the best in all graphs of each method. For *M2V*, we report the best results obtained by the meta-path *Job-Tag-Job*.

datasets and graphs are summarized in Table 1. We can observe that $\mathcal{G}^{jj}$ (i.e., $|\mathcal{J}|$ and $|\mathcal{E}^{jj}|$) are sparse.

3.2 Experimental Settings

For *job title classification* task: we classify job titles into root categories in this work, i.e., *Major-Group* for *CB12* and *JobClass* for *Randstad*. We randomly split the data into training/validation/test sets with a ratio of 60%/20%/20%.

For *next-job prediction* task: we treat it as a link prediction task on *Job-Transition Graph* to predict whether there exists an edge (transition) between two nodes (job titles). We keep the same split ratio on positive/negative edges, where negative edges are randomly picked from unconnected node pairs (i.e., the same size as positive edges).

We evaluate the performance of our proposed learning scheme against the following baselines. A detailed description of these baselines is provided in Appendix A.4.

- **Homogeneous**: *Node2Vec (N2V)* (Grover and Leskovec, 2016), *GCN* (Kipf and Welling, 2017) and *GAT* (Velickovic et al., 2018).
- **Heterogeneous**: *Metapath2Vec (M2V)* (Dong et al., 2017), *RGCN* (Schlichtkrull et al., 2018) and *HAN* (Wang et al., 2019b).
- **Semantic-based**: *Word2Vec (W2V)* (Le and Mikolov, 2014) and *BERT* (Devlin et al., 2019).

Our implementation is based on the DGL package (Wang et al., 2019a). [4] In both tasks, for unsupervised methods, node representations are learned from the entire dataset. Then train the logistic regression classifier on both the training and validation sets. Each semi-supervised model is trained on the training set, and the parameters are optimized on the validation set. The final performance is evaluated on the test set. To ensure fairness, we keep the same data split for both methods, repeat each prediction experiment ten times, and report the average performance scores (i.e., Macro-F1 and Micro-F1 for *job title classification* and AUC for *next-job prediction*). For details of other parameter settings, see Appendix A.5.

3.3 Results

3.3.1 Job Title Classification

Table 2 summarizes the best results of all methods on different graphs. We have the following observations: (i) Among all graphs, all models generally have the lowest scores on $\mathcal{G}^{jj}$ because this graph is often sparse and can only provide limited information. (ii) All models perform better on $\mathcal{G}_E^{jj}$ (except Macro-F1 of *GCN*) than $\mathcal{G}^{jj}$, which shows that the enhanced edges provide additional information. One interpretation for enhanced edges is adding semantic information, i.e., two job titles are more likely to be similar if they share the same word, represented by edges from the graph perspective. (iii) The heterogeneous models perform well on our proposed $\mathcal{G}^{jtj}$, which indicates that the added tag nodes can effectively improve the quality of representation. Note that we did not apply homogeneous methods to $\mathcal{G}^{jtj}$, but the results on $\mathcal{G}_E^{jj}$ prove that the information given by tags is useful. (iv) The models with attention mechanisms outperform the models without attention, demonstrating that the attention mechanism is good at capturing important information from noisy graphs.

3.3.2 Next-Job Prediction

We further evaluate the learning scheme using *next-job prediction*, which can be viewed as a link prediction task to predict whether a position will be recommended as the next-job. For unsupervised methods, edge features are represented by applying binary operators (Grover and Leskovec, 2016)

---

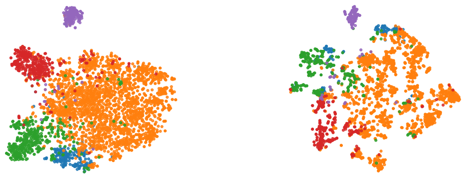
	N2V	GAN	M2V	HAN (Dot)	W2V (Dot)	BERT (Dot)	W2V (Hadamard)	BERT (Hadamard)
$\mathcal{G}^{jj}$	0.564	0.704	0.548	0.685	0.763	0.477	0.777	**0.840**
$\mathcal{G}_E^{jj}$	0.692	0.789	0.593	0.792				
$\mathcal{G}^{jt}$	-	-	0.604	0.768				
$\mathcal{G}^{jtj}$	-	-	0.604	0.833				

Table 3: Next-job prediction results (AUC) on *CB12*. The bold score is the best among all methods, and the underlined score is the second-best.

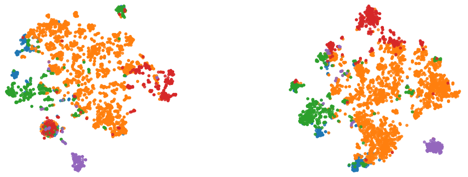
on node pairs, and then the best binary operator is selected based on the validation set, while the dot product is used for semi-supervised methods. The results on *CB12* given in Table 3 show the promising results of our proposed graphs. Like *job title classification*, the scores of all network embedding methods, i.e., *N2V*, *GAN*, *M2V* and *HAN* better on $\mathcal{G}_E^{jj}$ compared to $\mathcal{G}^{jj}$, and the heterogeneous models perform best on $\mathcal{G}^{jtj}$. Such results further demonstrate the effectiveness of our proposed method for constructing graphs, whether adding additional information based on tags (i.e., $\mathcal{G}_E^{jj}$) or directly adding tags to the graph (i.e., $\mathcal{G}^{jt}$ and $\mathcal{G}^{jtj}$). *BERT* using Hadamard operator performs best, followed by *HAN* on $\mathcal{G}^{jtj}$ with a slight difference of 0.007. However, when we use the dot product used in *HAN* to obtain edge features for *BERT*, the AUC of *BERT* drops sharply to 0.477, while *W2V* only drops a little to 0.763. We will discuss such results in future work. Overall, the results of link prediction also demonstrate the effectiveness of our proposed graphs.

3.3.3 Visualization

For a more intuitive comparison, we select five occupations and then visualize the job title representations learned by *HAN* in Figure 2, with each color corresponding to an occupation category. Overall, the representations learned by *HAN* on all graphs are clustered into groups. However, when considering tags, representations are easier to be subdivided further in each category. For example, in Figure 2d, the orange occupation can be further divided into three sub-clusters, which proves that adding tag nodes can help capture more detailed information and make the learned representation more informative. This detailed information helps further categorize occupations, as we only classify job titles into the root category (i.e., *MajorGroup*) in this work.



(a) HAN ($\mathcal{G}^{jj}$). (b) HAN ($\mathcal{G}_E^{jj}$).



(c) HAN ($\mathcal{G}^{jt}$). (d) HAN ($\mathcal{G}^{jtj}$).

Figure 2: Visualization of representations (CB12). *Healthcare support* (green), *Healthcare practitioners and technical* (blue), *Architecture and engineering* (purple), *Office and administrative support* (orange) and *Transportation and material handling* (red).

4 Conclusion

This paper first proposes to enrich *Job-Transition Graph* commonly used in job title representation learning tasks by adding tag-related information or directly adding tag nodes, and then learn job title representations through network embedding methods. This enhancing method can alleviate the sparsity problem in *Job-Transition Graph*, thereby improving the quality of learned representations, as demonstrated in the experimental results of *job title classification* and *job title classification*. In future work, we would like to explore why the Hadamard operator and dot product lead to such different link prediction results for *BERT*. Furthermore, other research lines are (i) considering edge weights when learning from graphs, (ii) classifying job titles into different occupational levels, and (iii) improving the tag generation approach.

Acknowledgment

This work is supported by the Randstad research chair in collaboration with MICS Lab, CentraleSupélec, Université Paris-Saclay. We would like to thank the *Mésocentre* [5] computing center of CentraleSupélec and École Normale Supérieure Paris-Saclay for providing computing resources.

A Appendix

A.1 Job Title Label Assignment

Job titles are not pre-labeled in the original working experience dataset provided by CareerBuilder12. Therefore, for the job title classification task, we use an online third-party API O*Net-SOC AutoCoder [6] to assign a Standard Occupation Classification code (SOC) 2018 to each job title, as well as a match score (i.e., scores above 70 means that the correct code is accurately predicted at least 70% of the time). SOC 2018 is a four-level taxonomy structure, including *MajorGroup* (23), *MinorGroup* (98), *BroadGroup* (459) and *DetailedOccupation* (867). For example, *O*Net-SOC AutoCoder* assigns the code 11-2022 (Sales Managers) for the title "sales director", which belongs to the level of *DetailedOccupation*. 11-2020 (Marketing and Sales Managers) is *BroadGroup* level, 11-2000 (Advertising, Marketing, Promotions, Public Relations, and Sales Managers) is *MinorGroup* level, and 11-0000 (Management Occupations) is *MajorGroup* level. In this work, we categorize job titles into *MajorGroup*. We have annotated a total of 30,000 job titles. The developer guarantees that the code assigned to the title plus description has an accuracy rate of 85%. However, only the job title is provided in our experiments, so the SOC 2018 code may be incorrectly assigned. For this reason, we filtered out job titles with scores below 70. Therefore, 12,908 unique job titles remain.

A.2 Randstad Data Description

Figure 3 shows an example of parsed resume in *Randstad* dataset. We build graphs from *EmploymentHistory*, which contains a *JobTitle*, and its corresponding occupation labels (i.e., *JobCode*, *JobGroup* and *JobClass*). The hierarchical taxonomy structure used in the Randstad dataset has a three-level hierarchy, where *JobCode*s are leaf classes, and each internal class (i.e., *JobGroup*) or root class (i.e., *JobClass*) is the aggregation of all its descendant classes. There are 25 *JobClass*s, 295 *JobGroup*s and 4,443 *JobCode*s, respectively. In this work, we categorize job titles into *JobClass*.

Figure 3: An example of parsed resume in Randstad.

A.3 Tag Generation

For both datasets, we first tokenize titles into tokens and remove stopwords, numbers, and punctuation. The word frequency distribution of words in two datasets are shown respectively in Figure 4, which are subject to the long-tail distribution, similar to the observation in (Zhang et al., 2019). Most words appear only once, i.e., 53.55% of words only appear one time in *CB12* dataset, and this ratio is 56.55% in *Randstad* dataset. Figure 4 further shows the top ten and last ten frequent words in each dataset. Obviously, high-frequency words like "manager" and "sales" describe the responsibility or functionality of the job title, while low-frequency words are usually noise or person-specific words. Based on the domain-specific NE tags (i.e., *RES*ponsibility, *FUN*ction) proposed in IPOD (Liu et al., 2019a), we then select the Top-200 tokens that appear most frequently and appear in the IPOD NE tag set as tags for each dataset.

Figure 4: Word frequency distribution, where the red line represents the average value. *Top-10* words are sorted by frequency, and *Last-10* are randomly selected from the words with a frequency of 2.

A.4 Baseline Description

We explore the following network embedding methods on our proposed graphs to learn job title representation. According to the type of graph, the network embedding methods are naturally divided into *Homogeneous* and *Heterogeneous*. Then, we further categorize each category into *Unsupervised* and *Semi-Supervised* according to whether node

---

[6] http://www.onetsocautocoder.com/plus/onetmatch

labels are provided for learning.

Homogeneous&Unsupervised

- *Node2Vec (N2V)* (Grover and Leskovec, 2016): is an extension of DeepWalk with a biased random walk process for neighborhood exploration.

Homogeneous&Semi-supervised:

- *GCN* (Kipf and Welling, 2017): is a semi-supervised Graph Neural Network (GNN) that generalizes the convolutional operation to homogeneous graphs.
- *GAT* (Velickovic et al., 2018): uses a self-attention strategy to learn the importance between a node and its neighbors.

Heterogeneous&Unsupervised:

- *Metapath2Vec (M2V)* (Dong et al., 2017): performs meta-path-guided walks and utilizes Skip-Gram to embed heterogeneous graphs.

Heterogeneous & Semi-supervised:

- *RGCN* (Schlichtkrull et al., 2018): is an extension of *GCN* on heterogeneous graphs, introducing relation-specific transformations based on the type of edges.
- *HAN* (Wang et al., 2019b): proposes a hierarchical attention mechanism, i.e., node-level and semantic-level for heterogeneous graphs.

In addition to the comparison between network embedding methods, we will also compare the representation learned through graphs with the representation obtained by semantic-based methods.

Semantic-based:

- *Word2Vec (W2V)* (Le and Mikolov, 2014): the representation of a job title is obtained by averaging word vectors in it. We use word vectors trained on Google News [7] for *CB12*, and a pre-trained French embedding model (Fauconnier, 2015) for *Randstad*.
- *BERT* (Devlin et al., 2019): the job title representations are obtained by using the bert-as-service package (Xiao, 2018), a sentence encoding service for mapping variable-length sentences to fixed-length vectors. We default to using the pre-trained BERT models provided by the package, i.e., BERT-Base-Uncased is used for *CB12*, and BERT-Base-Multilingual-Cased (New) for *Randstad*.

A.5 Parameter Settings

Our implementation is based on the PyTorch version of the DGL package (Wang et al., 2019a). For *job title classification*, we randomly split the data into training/validation/test sets with a ratio of 60%/20%/20%. We keep the same split ratio on positive/negative edges for *next-job prediction*, where negative edges are randomly picked from unconnected node pairs (i.e., the same size as positive edges). To ensure fairness, we keep the same data split for all methods, and we set the node embedding to 128 for all methods, except for *W2V*.

In the *job title classification* and *next-job prediction* tasks, for unsupervised methods, node representations are learned from the entire dataset. The logistic regression classifier is then trained on both the training and validation sets. Each semi-supervised model is trained on the training set, and the parameters are optimized on the validation set. The final performance is evaluated on the test set. Models are optimized with the Adam (Kingma and Ba, 2015) with a learning rate of 1e-3, and we apply L_2 regularization with value 5e-4. We use an early stop with a patience of 100, i.e., if the validation loss does not decrease in 100 consecutive epochs, we stop training. For models applying the attention mechanism, the dropout rate of attention is set to 0.2. For random-walk-based methods, including *N2V* and *M2V*, we set the window size to 5, walk length to 10, walks per node to 50, the number of negative samples to 5. For *M2V*, we test all meta-paths and report the best performance. For *next-job prediction* task, edge features are represented by applying binary operators (Grover and Leskovec, 2016) on pairs of nodes, and then the best operator is chosen based on the validation set, while the dot product is used for all semi-supervised methods.

We repeat each prediction experiment ten times and report the average performance scores (i.e., Macro-F1 and Micro-F1 for *job title classification* and AUC for *next-job prediction*).

Abstract

Cross-Lingual Retrieval Question Answering (CL-ReQA) is concerned with retrieving answer documents or passages to a question written in a different language. A common approach to CL-ReQA is to create a multilingual sentence embedding space such that question-answer pairs across different languages are close to each other. In this paper, we propose a novel CL-ReQA method utilizing the concept of language knowledge transfer and a new cross-lingual consistency training technique to create a multilingual embedding space for ReQA. To assess the effectiveness of our work, we conducted comprehensive experiments on CL-ReQA and a downstream task, machine reading QA. We compared our proposed method with the current state-of-the-art solutions across three public CL-ReQA corpora. Our method outperforms competitors in 19 out of 21 settings of CL-ReQA. When used with a downstream machine reading QA task, our method outperforms the best existing language-model-based method by 10% in F1 while being 10 times faster in sentence embedding computation. The code and models are available at `https://github.com/mrpeerat/CL-ReLKT`.

1 Introduction

Cross-lingual question answering allows a question posed in one language to be answered using materials written in a different language. As exemplified in Figure 1, one may ask, "Who was the first king of Hongsawadee?" and have their answer retrieved from a collection of historical documents in Burmese or other languages. To support the given example application, we require a retrieval system that can handle documents and questions in multiple languages at the same time. That is, we want to map questions and answers from multiple languages into the same space for easy retrieval. This functionality is also known as *Cross-Lingual Retrieval Question Answering* (CL-ReQA).

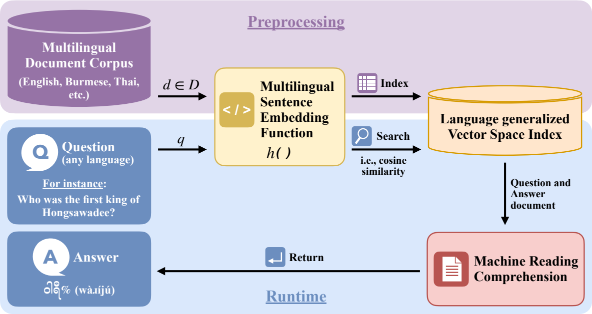

Figure 1: Overview of CL-ReQA. A user wishes to retrieve the answer to the question “Who was the first king of Hongsawadee?” from a collection of multilingual documents.

1.1 Existing Methods

One prominent approach to CL-ReQA is *multilingual sentence embedding*, i.e., creating an embedding space that can handle questions and answers from different languages. This approach can be further categorized into (i) *LM-Based:* finetuning a language model (LM), e.g., mBERT and XLM-R; (ii) *USE-Based:* finetuning the Universal Sentence Encoder (USE) for QA.

LM-based. Devlin et al. (2019) and Conneau et al. (2020) proposed a pretrained large-scale language model (LM) with multiple languages (100+ languages) called mBERT and XLM-R, respectively. Both solutions rely on finetuning the LM part to the target task. Reimers and Gurevych (2020) showed an accuracy improvement from 11.6% to 88.6% after finetuning with a bilingual text mining task. Finetuning LMs has been explored by many recent works, e.g., triplet loss with various supervised learning tasks (Reimers and Gurevych, 2019), knowledge distillation (Reimers and Gurevych, 2020), dense network QA encoder (Karpukhin et al., 2020), and providing initial word embeddings for the translation task (Feng et al., 2020). Nonetheless, finetuning these models requires a large number of training samples (more than 100,000 sentences in some cases (Reimers and Gurevych, 2020; Zhang et al., 2021; Wang et al.,

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2141 - 2155
July 10-15, 2022 ©2022 Association for Computational Linguistics

2021)) to give the best performance in multilingual settings. On the other hand, cross-lingual QA training corpora are usually smaller with only 1,000 to 1,500 questions per language. We need a method that can operate with a limited amount of data.

Multilingual Universal Sentence Encoding (mUSE). Based on the Universal Sentence Encoder (USE) architecture (Cer et al., 2018), Yang et al. (2020) proposed a training method utilizing a multilingual corpus with 16 different languages and multiple training objectives. They call their pre-trained network multilingual USE or mUSE.

Experimental results from Trijakwanich et al. (2021) show that mUSE provides superior performance over the LM-based methods. However, this method performs poorly on languages outside the mUSE training corpus, i.e., *unsupported languages*. This limitation hinders the adoption of mUSE on limited-resource languages.

1.2 Our Work

Proposed Method. In this paper, our goal is to improve the robustness of multilingual sentence embedding that works with a wide range of languages, including those with a limited amount of training data. Leveraging the generalizability of language knowledge transfer (LKT), we propose a *Cross-Lingual Retrieval Language Knowledge Transfer* (CL-ReLKT) framework. Figure 1 illustrates how cross-lingual retrieval can be conducted through a multilingual embedding function $h()$. Given a question-document pair (q, d) in any language, $h(d)$ is closer to $h(q)$ than any other documents using any similarity measure, e.g., cosine similarity.

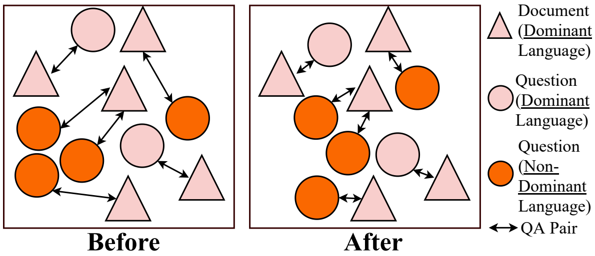

Figure 2: QA vector representations before and after performing the CL-ReLKT framework. The main goal of our framework is to improve the consistencies between document-question pairs from different languages in the embedding space so that they can be correctly retrieved.

Learning Objective. As shown in Figure 2, the proposed CL-ReLKT framework is designed to improve the embedding space by making cross-lingual question-answer pairs closer to each other. The crux of our proposed framework lies in the following two parts. First, we formulate a LKT process to create a language-generalized student. In particular, we leverage the fact that there is likely to be one language in a large multilingual corpus that dominates all others. We use that language to help improve the embedding quality of other languages. Second, we formulate a new loss function designed to improve the cross-lingual consistency between question-answer pairs in a multilingual environment. We aim to improve the consistencies between the teacher (dominant language) and student (other languages) for the following teacher-student output pairs: question-question, document-document, and document-question.

Experimental Studies. To determine the effectiveness of our approach, we compared the proposed methods with the current best practices (discussed in Section 1.1) on the CL-ReQA task across three datasets in 15 languages. Experimental results show that the CL-ReLKT framework outperformed all competitive methods on languages supported by mUSE in all cases. The results on unsupported languages, i.e., languages outside of the mUSE training corpus, show that the CL-ReLKT framework improved the performance of the mUSE encoder significantly $(p < 0.05)$ in all cases. Moreover, on a downstream task of machine reading QA (MR-QA), our method obtained better F1 and exact match scores than those of the best existing LM-based method in seven out of eight cases. Last but not least, our method is also 10 times faster than the state-of-the-art LM-based competitor in sentence embedding computational cost.

Summary of Contributions.

- We propose a new language knowledge transfer method called *Cross-Lingual Retrieval Language Knowledge Transfer (CL-ReLKT)* to transfer knowledge from the dominant language to non-dominant languages and build a language-generalized encoder.
- We design a new loss function to enforce cross-lingual consistency between dominant and non-dominant language vector representations.
- To assess the performance and efficiency of the models, we conducted an extensive set of experimental studies involving 2 tasks, 15 languages, and 8 competitors. Experimental results show the benefits of our proposed CL-ReLKT framework. Moreover, we found that retrieving answers at the document level yields a significant improvement over the passage-level methods.

2 Background

2.1 Dominant Language

In a multilingual dataset, the distribution of languages tends to be imbalanced. As shown in Figure 3, the number of sentences in English is approximately 50% of all sentences in the corpus used to construct mUSE (Yang et al., 2020).

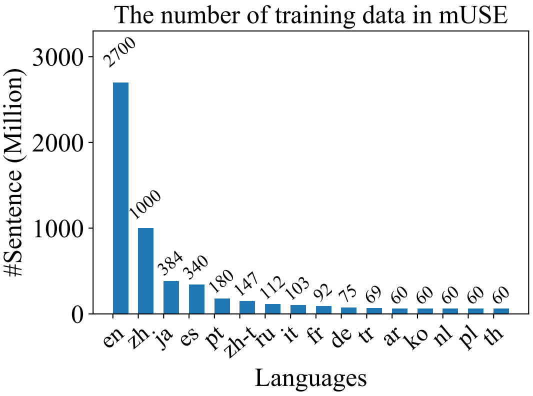

Figure 3: The distribution of QA training data used by mUSE (Yang et al., 2020)[1].

Due to the stated language imbalance, the model performance in languages with a large amount of data tend to be substantially better than that in other languages (Arivazhagan et al., 2019; Wang et al., 2020). This issue can be problematic when we want the model performance to be consistent across multiple languages.

For the case of mUSE, as shown in Figure 3, we can see that English is the *dominant language* in terms of training data available. Hence, the English-to-English retrieval performance tends to be better than all other language pairs. To verify this performance gap, we conducted a CL-ReQA experimental study using questions in non-English and answer documents in English; mUSE was used to encode the questions and documents. Experimental results show a significant performance improvement when the questions are translated into English instead of using the original non-English questions, i.e., translated questions from Russian to English improving the precision-at-1 from 43.3% to 52.8%. For the full results, see Appendix A.3.

2.2 Language Knowledge Transfer (LKT)

There are many techniques to boost a model performance on low-resource languages using the structure obtained from rich-resource ones. Transfer and multitask learning have been popular paradigms for leveraging rich-resource languages. These methods usually rely on the shared-encoder strategy so that the language pattern learned in one language can be shared across all other languages using the same model (Lin et al., 2019; Nooralahzadeh et al., 2020; Zoph et al., 2016; Schwenk and Douze, 2017; Neubig and Hu, 2018; Yang et al., 2020; Feng et al., 2020). These classes of techniques are commonly known as *Language Knowledge Transfer (LKT).*

With a shared encoder, improvements on one language tend to benefit other languages as well. Let us consider a scenario where we have a large number of question-answer pairs in English and a significantly smaller number of pairs in other languages, e.g., Russian, French, and German. By letting other languages share the same encoder as we update the encoder weights while training with English data, we can also improve the general encoding performance of the model in other languages.

3 Proposed Method

In this section, we formulate our proposed methods by leveraging the two concepts discussed in the previous section, *dominant language* and *language knowledge transfer*. In particular, we perform language knowledge transfer to transfer the knowledge from the dominant languages to other languages. Our proposed method consists of two stages: teacher model preparation and Cross-Lingual Retrieval Language Knowledge Transfer (CL-ReLKT), which are described as follows.

3.1 Stage 1: Teacher Model Preparation

The purpose of this stage is to create a strong teacher for language knowledge transfer in the next stage. For a base model, we use $\text{mUSE}_{\text{small}}$ for efficiency and performance reasons [2].

There are several techniques that can be used to create the teacher model,$\text{mUSE}_{\text{teacher}}$. The results from our ablation study (Appendix A.5) suggest that triplet loss is a reasonable choice. As shown in Equation 1, triplet loss $\mathcal{L}_{\text{tp}}$ is a training objective that maximizes the cosine similarity $\cos(\cdot)$ between anchor-positive pairs (a, p) and makes similarity between anchor-negative pairs (a, n) smaller than a given threshold α for all the training data M.

$$\mathcal{L}_{\text{tp}} = \sum_{i=0}^{|M|} [\max((1 - \cos(h(a_i), h(p_i))) - (1 - \cos(h(a_i), h(n_i))) + \alpha, 0)] \quad (1)$$

---

[1] For brevity, we use the ISO-639 standard to refer to the languages used in this paper.

[2] See Sections 5.2 and 5.4 for further details.

While the anchors a can be randomly sampled from the questions, we need the CL-ReQA model to help select positives p and negatives n. For negative sample categorization, we consider two options. First, we can directly use the original mUSE$_{\text{small}}$ model to categorize the negative samples according to the current embedding space (online fashion) (Kaya and Bilge, 2019). Second, we can apply the method proposed by Karpukhin et al. (2020), which utilizes BM25 (Trotman et al., 2014) to produce textual similarity scores. From the ablation study given in Appendix A.5.1, the results show that the first three epochs use the initial strategy for triplet mining (Kaya and Bilge, 2019) before proceeding to online mining (Kaya and Bilge, 2019) for five epochs yield the best performance.

3.2 Stage 2: CL-ReLKT

We now describe our method to improve the general CL-ReQA performance using the concept of language knowledge transfer (LKT). As we mentioned in Section 2.2, LKT is a technique that the language pattern learned in one language can be shared across all other languages using the same model. Applying the same concept to our problem, we can set the LKT process to improve the embedding consistency between the dominant language and other languages. In particular, we setup the LKT environment as follows: (i) the teacher operates in the dominant language, i.e., English; (ii) the student operates in non-dominant languages; (iii) the student tries to mimic the embedding outputs of the teacher. In what follows, we describe the teacher and student models, inputs, and the loss function for the training process.

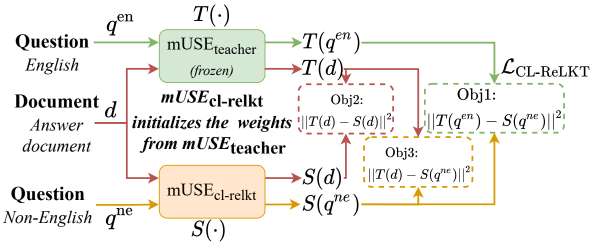

Figure 4: The training process of Cross-lingual Retrieval Language Knowledge Transfer (CL-ReLKT) comprising (i) a teacher model (T), mUSE$_{\text{teacher}}$; (ii) a student model (S), mUSE$_{\text{cl-relkt}}$; and (iii) three training objectives, *Obj 1-Obj 3*

Teacher and Student Models. As illustrated in Figure 4, the *Cross-Lingual Retrieval Language Knowledge Transfer (CL-ReLKT)* process consists of a teacher, student, and loss function. Initially, the student's parameters are initialized to the same values as those of the teacher trained in Stage 1. During the training process, the teacher's parameters are fixed; we only adjust the student's parameters according to the loss function.[3]

Inputs. Let us now consider input questions and answer documents of the training process. As illustrated in Figure 4, both teacher and student models accept the same document input d. However, there are two different versions for each question, *English* q^{en} and *non-English* q^{ne}. The English question q^{en} is a translation of the original one q^{ne}. This gives us a question pair $(q^{\text{ne}}, q^{\text{en}})$ for language knowledge transfer between different languages. For simplicity, we use Google Neural Machine Translation (GNMT) to translate q^{ne} into q^{en}. Note that if available, one may also use human-translated parallel questions.

The teacher model $T()$ accepts q^{en} as input, while the student model $S()$ accepts q^{ne} as input. In other words, q^{en} functions as the "reference" of the LKT process. According to our assessment (Appendix A.5.3), English provides the best performance and hence is chosen as the dominant language for the training process. Note that this finding also conforms with the data distribution shown in Figure 3.

Loss Function. The goal of our CL-ReLKT loss function $\mathcal{L}_{\text{CL-ReLKT}}$ is to let the student mimic the teacher's knowledge from the dominant language to the student's target language. As shown in Figure 5, our loss function $\mathcal{L}_{\text{CL-ReLKT}}$ has three consistency objectives, namely, question-question, document-document, and document-question. We describe them as follows.

- *Obj 1: Question-Question.* The first objective is to enforce the consistency between $S()$ and $T()$ when encoding the same question expressed in English q^{en} and non-English q^{ne}, respectively.
- *Obj 2: Document-Document.* While adjusting the student $S()$ for the first objective, we also want to keep its answer document encoding unchanged. Hence, we want to maintain the consistency between $T(d)$ and $S(d)$.
- *Obj 3: Document-Question.* To accommodate the lookup process, the embedding space should also keep question-answer pairs consistent with each other. As our third objective, we minimize

---

[3] Note that the student model can be of any architecture and can be initialized using any method. In this work, we choose the self-model for simplicity. See Section 5.5 and Appendix A.4 for more information.

the discrepancy between the student's question vector $S(q^{\text{ne}})$ and the teacher's document vector $T(d)$.

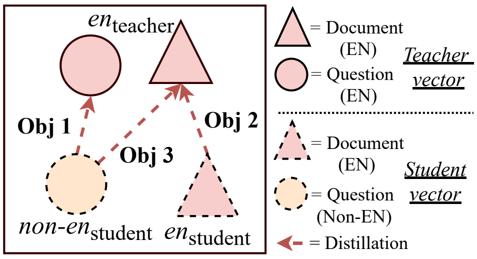

Figure 5: Illustration three objectives of Cross-Lingual Language Knowledge Transfer (CL-ReLKT) loss function.

We formulate the loss function $\mathcal{L}_{\text{CL-ReLKT}}$ as a linear combination of these three consistency objectives. Using the squared L2 norm as the discrepancy measure, we obtain the following loss function:

$$\mathcal{L}_{\text{CL-ReLKT}} = \frac{\gamma}{|M|}\sum_{i=0}^{|M|}[\beta||T(q_i^{\text{en}}) - S(q_i^{\text{ne}})||^2 + \lambda||T(d_i) - S(d_i)||^2 + \omega||T(d_i) - S(q_i^{\text{ne}})||^2], \tag{2}$$

where M is the set of training samples used in a given batch, and β, λ, and ω are the weighting coefficients.

Discussion. As stated earlier, the goal of the loss function is to transfer the teacher's knowledge to the student operating in target languages. Since the performance of the teacher's dominant language is generalized, after the LKT process, other languages will have the same properties. The experimental results show that the student can better handle unsupported languages and improve the performance of supported languages than the teacher model. This improvement comes from the cross-lingual consistency objectives, Obj 1 and Obj 3, in the loss function, while Obj 2 maintains the monolingual consistency. Moreover, $\mathcal{L}_{\text{CL-ReLKT}}$ does not require the teacher and student models to be of the same architecture; it can be applied to any pre-trained models. (For more information, see Appendix A.4)

4 Experimental Setup

4.1 Datasets

To evaluate the effectiveness of our method, we conduct our experiments on three well-known CL-ReQA corpora: XORQA, XQuAD, and MLQA. All experiments were done by XX→EN where XX is the question language (15 languages), and EN is answer passages or documents.

XORQA (Asai et al., 2021a) is a benchmark dataset for multilingual open-retrieval question answering. The dataset contains questions in a diverse set of seven non-English languages and answer documents in English. We use the *Gold Paragraph* part of the corpus, which contains 12,895 documents and 8,949 question-answer pairs. The authors, however, did not provide a public test dataset. Thus, we divide the samples into train/dev/test (0.7/0.1/0.2).

XQuAD (Artetxe et al., 2020) is a dataset for evaluating cross-lingual question answering performance. XQuAD comprises 48 documents and 13,090 question-answer pairs obtained from the development set of SQuAD v1.1 (Rajpurkar et al., 2016) with 11 languages. Since XQuAD is too small for model training, we used it for testing only. Translated questions from SQuAD v1.1 (training set) were used instead for training the models (the same setup as XQuAD (Artetxe et al., 2020)).

MLQA (Lewis et al., 2020) is also a dataset for evaluating cross-lingual question answering performance. The dataset contains 15,806 documents and 33,706 question-answer pairs in seven different languages. However, the authors did not provide any training dataset. As a result, we combined the development and test datasets and divided them into train/dev/test (0.7/0.1/0.2).

4.2 Competitive Methods

We compare the performance of our method with two groups of competitive methods as follows:

LM-based. As discussed in Section 1, one approach to CL-ReQA is to use an embedding space based on some language model. In the experimental studies, we compare our methods to the following LM-based competitors.

- *XLM-R-nli-stsb*: A RoBERTa-based cross-lingual model trained using the NLI and STS benchmark datasets (Reimers and Gurevych, 2019).
- *mBERT-triplet*: A BERT-based multilingual model finetuned with a QA dataset using triplet loss (Reimers and Gurevych, 2019).
- *XLM-R←SBERT*: A XLM-RoBERTa model trained by distilling from the sentence BERT model (Reimers and Gurevych, 2020).
- *DPR*: A dense-network solution using the multilingual BERT model to provide the cross-lingual QA capability (Karpukhin et al., 2020).
- *CORA*: An adaptation of DPR on multilingual Wikipedia QA data (Asai et al., 2021b).

- *LaBSE*: A multilingual sentence encoder using mBERT to provide initial word embedding vectors (Feng et al., 2020).

We retrained mBERT-triplet, XLM-R←SBERT and DPR with the CL-ReQA training set following previous work (Reimers and Gurevych, 2019; Asai et al., 2021b; Zhang et al., 2021).

Multilingual Universal Sentence Encoding (mUSE). As an alternative to LM, we can also construct a QA embedding space from a well-known multilingual sentence encoder, mUSE. In particular, we consider the following mUSE variants.

- *mUSE$_{small}$*: The mUSE$_{\text{small}}$ encoder was based on Convolution Neural Network (Kim, 2014).
- *mUSE$_{large}$*: The mUSE$_{\text{large}}$ encoder was on the transformer architecture (Vaswani et al., 2017).

Note that although there exists a QA variant of mUSE, mUSE$_{\text{qa}}$, we found that this QA variant does not provide any performance improvement over mUSE$_{\text{large}}$. As a result, we omit mUSE$_{\text{qa}}$ from our study.

Our proposed methods. As previously discussed, we construct our proposed methods based on mUSE$_{\text{small}}$. The first method, mUSE$_{\text{teacher}}$, is constructed from triplet loss where each triplet consists of a question, its corresponding answer document, and a non-answer document. The second method, mUSE$_{\text{cl-relkt}}$, is constructed from the process of Cross-Lingual Retrieval Language Knowledge Transfer (with all languages in the training datasets).

4.3 Hyperparameter and Evaluation Settings

Hyperparameter. In these experiments, we use grid search on the following hyperparameters: learning rates, triplet loss margin (α), $\mathcal{L}_{\text{CL-ReLKT}}$'s coefficients ($\gamma$,$\beta$,$\omega$), and the number of negative samples for triplet loss. The hyper-parameter configurations are given in Table 1.

Hyperparameters	Values for grid search
Learning Rates	1e-3,5e-4, 1e-4, 1e-5, 1e-6
α	0.1-1 (0.01/steps)
γ	[100, 1000, 10000]
β	1,1e-1, 1e-2, 1e-3, 1e-4
ω	1,1e-1, 1e-2, 1e-3, 1e-4
#negative samples	[1, 2, 3, 5, 10]

Table 1: Hyperparameter configurations.

For the Cross-Lingual Retrieval Language Knowledge Transfer settings, we use a batch size of 8 with a total number of 10 epochs. Since the student model receives the initial weights from the teacher, the CL-ReLKT's loss value ranges between $[10^{-3}, 10^{-5}]$ and the loss value of Obj 3 is lower than those of other objectives. To prevent the CL-ReLKT's loss value from being too small, we multiply the value by γ and set the coefficient of Obj 2, λ, to 1. In addition, we evaluate the precision score on the development set every 100 steps. If the precision score does not improve, the learning rate is halved.

Evaluation. We use precision at k where we set k to 1 (P@1) which is a common practice for the CL-ReQA task (Ahmad et al., 2019; Yang et al., 2020; Guo et al., 2021) and cross-lingual retrieval tasks (Reimers and Gurevych, 2020; Feng et al., 2020). We also provide precision at 5 and 10 results in Appendix A.2. Furthermore, we used McNemar's test as the significant statistical measurement ($p < 0.05$) for all experiments.

5 Experimental Results

5.1 Passage- vs Document-bases on Machine Reading QA (MR-QA)

To determine the best answer retrieval unit for MR-QA, we compare two scenarios. (i) *Passage-based*: Retrieving answers as passages; (ii) *document-based*: Retrieving answers as documents. For conciseness, we chose DPR, which is the state-of-the-art LM-based competitor, for comparison. For testing, we chose XORQA, which is the newest MR-QA benchmark. For all test cases, we used the same machine reading comprehension model constructed from XLM-R. In particular, we finetuned XLM-R using the same training portion of XORQA described in Section 4.1.

Model	XORQA									
	RU		KO		JA		FI		AVG	
	F1	EM	F1	EM	F1	EM	F1	EM	F1	EM

Table 3: Precision at 1 (P@1) on the CL-ReQA task in *supported languages*

icantly outperformed DPR for both input options on average.

Discussion. The document-based representation has advantages and drawbacks in comparison to the passage-based one. In particular, by grouping passages associated with the same document together, the retrieval unit becomes larger, making it harder to miss an answer. However, operating at the document level also means that we have to handle a larger input. That is, for the three corpora used in the experimental studies, the model has to handle 128 tokens on average when the input is a passage, while the input size can be up to 1,996 tokens when the input is a document. The results provide empirical evidence that the benefits outweigh the drawback. We believe that as machine reading models improve over time, longer input passages will provide even better results. For more information about the retriever's performance, see Appendix A.1.

5.2 CL-ReQA: Supported Languages

Previously, we have shown that document-based yield the best MR-QA results. Thus, we will use this setting for the rest of the embeddings experiments. In this experiment, we report the effectiveness of our proposed methods on mUSE's supported languages where the answer retrieval unit is document-based. We evaluated our methods against the competitors discussed in Section 4.2.

Results. As shown in Table 3, our proposed models $\mathit{mUSE}_{\mathit{teacher}}$ and $\mathit{mUSE}_{\mathit{cl\text{-}relkt}}$ provide significant improvements from the base model, $\text{mUSE}_{\text{small}}$. Moreover, our models also outperformed the largest pre-trained variant of mUSE, $\text{mUSE}_{\text{large}}$. All of our proposed models also significantly performed better than the LM-based competitors. The results also show that our consistency enhancement method, CL-ReLKT, were effective in all cases except AR for the MLQA dataset.

Discussion. Experimental results verify that for languages supported by mUSE, our approach based on the language knowledge transfer concept (Section 2.2) can provide significant improvements over the teacher model. However, the improvements were less significant than ours when the language knowledge transfer concept is applied to an LM to create mBERT-triplet and XLM-R-nli-stsb from mBERT and XLM-R, respectively.

Notice that methods based on mBERT performed poorly in Thai (TH). We can also see that finetuning mBERT with triplet loss (mBERT-triplet) and multilingual dense retrieval (CORA) did not provide any improvements on Thai. This is because Thai was not included in the construction process of mBERT (uncased-version), and the amount of the training data is insufficient to improve the model.

5.3 CL-ReQA: Unsupported Languages

Let us consider how well our proposed models performed when used with languages not supported by the base model, $\text{mUSE}_{\text{small}}$, i.e., FI, RO, EL, HI, and VI. Similar to the study presented in the previous subsection, we used XORQA, XQuAD, and MLQA as our test corpora.

Results. Table 4 presents the P@1 scores of our methods and the competitors. We can see that the original mUSE models, $\text{mUSE}_{\text{small}}$ and $\text{mUSE}_{\text{large}}$, did not perform well in these languages. As expected, $\text{mUSE}_{\text{teacher}}$ had a tendency to provide some improvements over $\text{mUSE}_{\text{small}}$. This is because these languages were not included in the original training process, and the amount of data is insufficient to improve the performance of these languages. In contrast, we obtained significant improvements through the CL-ReLKT methods, $\text{mUSE}_{\text{cl-relkt}}$. For five out of seven cases, $\text{mUSE}_{\text{cl-relkt}}$ were the best performer compared to other models. Two LM-based methods, XLM-R←SBERT and LaBSE, were the best performer in HI with the test corpora of XQuAD and MLQA, respectively.

As an alternative to cross-lingual retrieval, one can convert the problem to a monolingual retrieval one using a machine translation (MT) model. We found that using an MT model (i.e., GNMT, MBART) with DPR following Asai et al. (2021a) helps improve the performance of LM-based models. However, the performance decreases in some languages, i.e., in Finish (XORQA), DPR's performance is dropped from 39.1 to 32.0 and dropped to 36.4 when GNMT and MBart were applied to the DPR, respectively. For the full discussion and results see Appendix A.3.

Model	**XORQA**	**XQuAD**				**MLQA**	
	FI	**RO**	**EL**	**HI**	**VI**	**HI**	**VI**
LM-based							
mBERT-triplet	18.7	48.3	30.3	23.9	39.9	7.1	24.1
XLM-R-nli-stsb	30.7	45.4	44.5	39.1	40.3	31.4	28.6
XLM-R←SBERT	25.3	42.4	42.9	**40.3**	40.3	29.4	28.4
DPR	39.1	52.9	36.1	15.5	10.1	26.2	32.1
CORA	15.1	27.7	26.9	18.5	28.6	15.8	23.9
LaBSE	40.6	42.0	42.9	37.8	39.9	**31.8**	27.2
Multilingual Universal Sentence Encoding (mUSE)							
$\text{mUSE}_{\text{small}}$	18.3	41.6	10.9	4.2	25.6	2.0	25.4
$\text{mUSE}_{\text{large}}$	27.2	49.6	13.0	3.4	25.6	1.4	16.8
Our proposed methods							
$\text{mUSE}_{\text{teacher}}$	25.0	42.4	13.4	4.2	29.4	2.0	27.4
$\text{mUSE}_{\text{cl-relkt}}$	**48.2**	**76.9**	**64.3**	34.0	**71.8**	3.2	**44.2**

Table 4: Precision at 1 (P@1) on the CL-ReQA task in *unsupported languages*.

Discussion. The performance gap between $\text{mUSE}_{\text{small}}$ and $\text{mUSE}_{\text{cl-relkt}}$ demonstrates the effectiveness of the proposed CL-ReLKT framework. In particular, we can use CL-ReLKT to generalize a base sentence embedding model to handle languages that were not originally included in the training process.

Regarding the CL-ReLKT performance on Hindi (HI), one important observation is that Hindi is the only language in this study whose family is not represented in the original training data, which results in a lot of OOV tokens from unknown characters. We provide more explanation in Appendix A.6.

5.4 Run-time Efficiency on Query Encoding

Let us now consider the efficiency of the methods. Since this investigation focuses on the embedding methods, we consider only the sentence embedding computational time. We used a DGX-1 machine using one Intel Xeon E5-2698 and one NVIDIA Tesla V100 GPU to benchmark the models.

Results. As shown in Table 5, the experimental result shows that $\text{mUSE}_{\text{small}}$ is the fastest. The result shows that $\text{mUSE}_{\text{small}}$ took only ∼7.9 ms on average to encode one query at a time. Since our method is based on the $\text{mUSE}_{\text{small}}$ architecture, we also obtain a similar run time. For the LM-based methods, we found that LaBSE is the quickest one. However, the method is still slower than $\text{mUSE}_{\text{teacher}}$ and $\text{mUSE}_{\text{cl-relkt}}$ by at least 80%. We can also find that MT-assisted, i.e., GNMT and MBart, are significantly slower than our methods. For the MT-assisted results, GNMT used 258.3 ms for one query while MBart used 9,132 ms.

Model	**XORQA**	**XQuAD**	**MLQA**
MT-assisted			
DPR+GNMT	258.3±37.9	339.3±54.2	395.0±58.1
DPR+MBart	9,132±8,111	6,527±5,838	5,382±274
LM-based			
mBERT-triplet	20.2±1.0	30.6±1.5	30.2±1.7
XLM-R-nli-stsb	20.5±1.1	22.1±2.7	23.4±4.6
XLM-R←SBERT	22.2±3.7	31.6±1.9	31.3±2.4
DPR	58.3±28.5	110.3±47.6	103.0±52.5
CORA	197.7±9.9	369.7±16.4	274.7±145.3
LaBSE	15.2±2.6	14.3±2.2	14.6±2.3
Multilingual Universal Sentence Encoding (mUSE)			
$\text{mUSE}_{\text{small}}$	**8.4±1.0**	**7.9±1.1**	**7.6±1.2**
$\text{mUSE}_{\text{large}}$	23.8±2.5	30.3±5.0	27.0±4.7
Our proposed methods			
$\text{mUSE}_{\text{teacher}}$	8.6±1.0	8.3±1.1	8.1±1.0
$\text{mUSE}_{\text{cl-relkt}}$	8.5±1.5	8.3±1.5	8.5±1.4

Table 5: The average computational sentence encoding time and standard division in *ms*.

Discussion. Since $\text{mUSE}_{\text{small}}$ is a much smaller model than BERT-base and XLM-R-base, it is advantageous to use our proposed methods when efficiency is a concern, e.g., edge deployment. While GNMT and MBart were effective in improving the performance of LM-based models (Appendix A.3), the additional machine translation cost renders the approach less desirable.

5.5 Ablation Studies on the Training Objective for LKT

This study compares our Cross-Lingual Retrieval Language Knowledge Transfer method with other

LKT techniques using the same baseline model. To directly assess the effect of the LKT method, we use the original $\text{mUSE}_{\text{small}}$ instead of the $\text{mUSE}_{\text{teacher}}$ as the starting model in this study. We compare four training objectives:

- We apply the training objective following Reimers and Gurevych (2020)'s work denoted mUSE_{mse} where the training objective contains the first CL-ReLKT's objective with an additional loss term that minimizes the difference between English and English embeddings from the previous iteration;
- As mentioned in Section 5.3 the CL-ReLKT loss has three objectives. $\text{mUSE}^{\text{q}}_{\text{cl-relkt}}$ uses only the first objective;
- $\text{mUSE}^{\text{qd}}_{\text{cl-relkt}}$ uses the first and the second objective; and
- Lastly, $\text{mUSE}_{\text{cl-relkt}}$ uses the full version of the CL-ReLKT loss function.

Results. The experiment results are given in Table 6. As expected, our training objective outperformed competitive training objectives. The performance of $\text{mUSE}_{\text{cl-relkt}}$ outperformed other training objectives from six out of seven cases. Especially Reimers and Gurevych (2020)'s training objective, our method outperformed with significant results on six out of seven cases except for HI→EN in MLQA.

Model	XORQA	XQuAD				MLQA	
	FI	RO	EL	HI	VI	HI	VI
$\text{mUSE}_{\text{small}}$	18.3	41.6	10.9	4.2	25.6	2.0	25.4
mUSE_{mse}	31.0	65.5	17.6	8.0	35.3	1.4	26.0
$\text{mUSE}^{\text{q}}_{\text{cl-relkt}}$	33.7	67.2	16.8	5.5	34.5	2.2	37.0
$\text{mUSE}^{\text{qd}}_{\text{cl-relkt}}$	38.5	62.6	18.9	8.4	34.5	**3.7**	38.0
$\text{mUSE}_{\text{cl-relkt}}$	**39.4**	**73.9**	**58.0**	**27.0**	**71.4**	**3.7**	**38.7**

Table 6: Comparison of different LKT training objectives. Precision at 1 (P@1) on the CL-ReQA task in unsupported languages.

6 Conclusion

In this paper, we propose a novel Cross-Lingual Retrieval Language Knowledge Transfer framework for CL-ReQA. Our framework is designed to improve the general performance and enable the baseline model to handle unsupported languages by exploiting the concepts of *Dominant Language* and *Language Knowledge Transfer*. Our method outperformed competitive methods in all cases of supported languages and five out of seven cases of unsupported languages. Furthermore, we demonstrated that grouping passages associated with the same document together could benefit machine reading QA.

7 Responsible NLP Research Checklist

Did you discuss the limitations of your work? The limitation of our work is out-of-domain problems. We strongly advise against using our model with out-of-domain data.

Did you discuss any potential risks of your work? There is a risk of retrieving incorrect documents causing the machine reading comprehension part to produce wrong answers.

Did you discuss the license or terms for use and/or distribution of any artifacts? The XORQA dataset is under the MIT License, while XQuAD and MLQA are under CC-BY-SA 4.0.

Did you discuss if your use of existing artifact(s) was consistent with their intended use, provided that it was specified? For the artifacts you create, do you specify intended use and whether that is compatible with the original access conditions (in particular, derivatives of data accessed for research purposes should not be used outside of research contexts)? XORQA, XQuAD, and MLQA were created for retrieval QA assessments; we use them for this exact purpose.

Did you discuss the steps taken to check whether the data that was collected/used contains any information that names or uniquely identifies individual people or offensive content, and the steps taken to protect / anonymize it? From our careful inspection, there is no offensive content or sensitive data included in the three datasets: XORQA, XQuAD, and MLQA.

Did you report descriptive statistics about your results (e.g., error bars around results, summary statistics from sets of experiments), and is it transparent whether you are reporting the max, mean, etc. or just a single run? We reported the mean average score for all experiments, which is a common practice for reporting the performance.

If you used existing packages (e.g., for preprocessing, for normalization, or for evaluation), did you report the implementation, model, and parameter settings used (e.g., NLTK, Spacy, ROUGE, etc.)? All experiments were done by Tensorflow because mUSE is only available on Tensorflow.

A Appendix

A.1 CL-ReQA: Passage- vs Document-bases

This study reports the effect of the passage-based and document-based input on retrieval performance. The experiment was conducted in supported and unsupported languages of three datasets: XORQA, XQuAD, and MLQA.

Results. As shown in Table 7, the document-based input substantially outperform the passage-based one in all languages and all datasets. The performance of mUSE$_{\text{cl-relkt}}$ on passage-based for supported and unsupported languages is lower than document-based significant on every unsupported language. These results conform with those of the downstream task presented in Table 2.

Model	**XORQA**			**XQuAD**			**MLQA**		
	RU	**JA**	**FI**	**DE**	**ES**	**VI**	**DE**	**ES**	**VI**
Passage-base									
mUSE$_{\text{cl-relkt}}$	56.4	45.9	45.6	51.7	51.3	23.5	61.9	62.4	32.3
Document-base									
mUSE$_{\text{cl-relkt}}$	**58.2**	**49.5**	**48.2**	**83.2**	**84.0**	**72.3**	**64.8**	**62.8**	**44.2**

Table 7: Comparison of different retrieval inputs such as passage- and document-bases on the CL-ReQA task in *supported* and *unsupported languages*.

Discussion. This experiment shows that the efficiency of document-based is more robust than passage-based significant. Moreover, when we applied both inputs to a downstream task, MR-QA, the experiment results showed that changing the input from passage-based to document-based is more robust.

A.2 CL-ReQA: Precision at 5,10

In this experiment, we study the effectiveness of our method on mUSE's supported languages. We report the precision score at 5 and 10 on the XORQA dataset.

Results. As shown in Table 8, our proposed model, mUSE$_{\text{cl-relkt}}$, on P@5 and P@10 have the same narrative as P@1 (Table 3). That is, the cross-lingual retrieval language knowledge transfer model improved the performance from the teacher model, mUSE$_{\text{teacher}}$, and it outperformed every LM-based model.

Discussion. Experimental results verify that precision at other k's values does not change any conclusion from our work. The results show that our model outperformed other models in precision at 1, 5, and 10 settings.

Model	**XORQA**

Our proposed methods						
mUSE$_{\text{teacher}}$	78.2	69.6	69.2	82.8	78.1	78.5
mUSE$_{\text{cl-relkt}}$	**79.7**	**70.7**	**72.0**	**85.4**	**78.3**	**78.8**

Table 8: Comparison of different Precision at k (P@k) where k values are equal to 5 and 10 on the CL-ReQA task in *supported languages* on XORQA.

A.3 CL-ReQA: Monolingual vs Cross-lingual Retrievals

In this study, we compare the CL-ReQA approach against the MT-assisted monolingual retrieval one. For CL-ReQA methods, we chose DPR and mUSE$_{\text{cl-relkt}}$. For the MT-assisted methods, we used two translators, GNMT and MBart (Liu et al., 2020), to translate all questions into English which is the documents' language. These two translators were then applied to assist DPR in the same manner as the XORQA investigation (Asai et al., 2021a).

Results. Table 9 shows that the two translators provide substantial improvements to DPR and mUSE-based. The GNMT-assisted tended to perform better than the MBart-assisted in almost all cases. As state in Section 3.2, our language knowledge transfer comprise of GNMT in the training data process. Thus, the performance of our method with/without MT-assisted is similar. Our method was the best performer in six out of nine cases. Moreover, in seven out of nine cases, the performance of our method is decreased when MBart is applied. Since the performance of MBart is lower than GNMT, the performance of mUSE$_{\text{cl-relkt}}$+MBart is dropped significantly.

Discussion. Machine translators can provide a quick solution to improve the performance of cross-lingual retrieval. In this way, the problem of cross-lingual retrieval is converted into a monolingual one. This approach can be useful when the language pair has a reliable translator, but there is insufficient QA data to create a cross-lingual retrieval

model. However, we consider the multilingual sentence embedding approach to be superior to the MT-assisted one due to the following reasons: (i) the computational cost benefits of skipping the MT process; (ii) the MT-assisted approach can be negatively affected by a poor MT performance; (iii) the reliance of MT models can be a limitation for some language pairs. See Appendix A.7 for a further analysis.

A.4 CL-ReLKT on Other Architectures

This study demonstrates our cross-lingual retrieval language knowledge transfer method on LM-based models. For diversity, we select BERT-based (mBERT-triplet) and RoBERTa-based (XLM-R-nli-stsb) because these models trained only on the dominant language, English, same as mUSE$_{\text{teacher}}$.

Results. As shown in Table 10, we applied the CL-ReLKT framework on other architectures, i.e., BERT and RoBERTa, on supported languages of XORQA. The experimental results show that CL-ReLKT on LM-based models significantly improves XLM-R-nli-stsb. Furthermore, when we use mBERT-triplet as the teacher instead of XLM-R-nli-stsb. The result shows a small improvement over the student instead of using XLM-R as the teacher model.

Discussion. Our CL-ReLKT can be applied to any pre-trained model not limited to only in mUSE's architecture. However, to give the best results, let the student initialize the weight from the teacher. In addition, the results from both models are not over mUSE's performance.

Model		XORQA		
		RU	KO	JA
LM-based				
mBERT-triplet (1)		41.0	19.0	46.4
XLM-R-nli-stsb (2)		28.7	26.6	28.0
LM-based + CL-ReLKT				
T=(1)	XLM-R-nli-stsb$_{\text{cl-relkt}}$	29.0	27.1	28.3
T=(2)	XLM-R-nli-stsb$_{\text{cl-relkt}}$	33.2	30.8	31.9

A.5 Ablation Studies

This study presents the effect of each design decision in the triplet loss and cross-lingual retrieval language knowledge transfer proposed. Here, we investigate the following components: (i) training strategies; (ii) training data settings; (iii) reference languages for cross-lingual retrieval language knowledge transfer (CL-ReLKT); and (iv) distance functions for CL-ReLKT. In each investigation, we use the best setting from the previous steps. All experimental results were obtained from XX→EN retrieval on the XORQA test set across four languages, where XX can be one of these languages Russian (RU), Korean (KO), Japanese (JA), and Finnish (FI).

A.5.1 Training strategies

As shown in Table 11, we compare training strategies with/without each of the following components: initialization, online updates, and other deep metric learning techniques. As expected, the result shows that online negative sampling and initializing with BM25 helps improve the performance of triplet loss. Furthermore, we also study the effect of replacing triplet loss with contrastive learning as presented in the current state-of-the-art work (Karpukhin et al., 2020). We found that contrastive loss consistently provides a performance improvement over the original mUSE$_{\text{small}}$ model but still lags behind the triplet loss.

A.5.2 Training data settings

In terms of training data for the teacher training, there are two decisions we need to consider: (i) the answer representation unit: whether to use one passage or one document as the retrieval unit in the training process; (ii) the question language: whether to use the original questions (in multiple languages) or translate them all to English. In the case of English, all English questions were translated using GNMT. As shown in Table 11, the *passage* and *English* combination provides the best performance.

A.5.3 Teacher's language for CL-ReLKT

In this study, we explore the choice of language to function as the reference (teacher) in the CL-ReLKT process. Intuitively, we want a language that is well-represented in the training corpora when constructing the original model. Consequently, we compare English, Spanish, and German. As expected, English, which is the dominant language in the training corpora of mUSE, provides the best performance. These results also conform with the discussion on the dominant language provided in Section 2.1.

A.5.4 Distance functions for CL-ReLKT

The distance function is critical to the CL-ReLKT performance. While there exists many distance functions we can apply to the LKT process, we consider two of the most widely used ones, cosine and squared L2. As we can see, squared L2 provides the best performance.

A.5.5 Discussion

From the results, we conclude that the default settings of our proposed methods are (i) triplet loss as the training objective (ii) English question + passages as the answer representation unit (iii) English as the teacher language, and (iv) square L2 distance as the distance function for CL-ReLKT.

Component		**XORQA**			
		RU	**KO**	**JA**	**FI**

A.6 Language Analysis

In this section, we discuss Hindi, which our method performs worse than other competitive methods, and examines other languages that we have not shown in the tables, such as Telugu and Bengali.

As shown in Table 4, the mUSE$_{\text{cl-relkt}}$'s performance is the best in every language except Hindi. This is due to the mUSE encoder's tokenizer (sentencepiece), which cannot handle Hindi well compared to other unsupported languages (i.e., FI, RO, EL, VI). For instance, we measured the tokenizer's out-of-vocabulary (OOV) rate of the mUSE's tokenizer on Hindi (XQuAD) and found that the OOV rate of Hindi is $\sim$14.5%. On the other hand, the OOV rate on Greek on the same dataset is only 2.2% which is $\sim$12.3% lower than Hindi. Since the language families of the languages used in mUSE are not Indo-Aryan (Hindi and Bengali) nor Dravidian (Telugu) [4], the mUSE's sentencepiece cannot handle Indo-Aryan and Dravidian language families well. To make the mUSE encoder handle these language families better, we might need to retrain the mUSE sentencepiece tokenizer by using other tokenizers (i.e., sentencepiece in mBERT). Since mBERT's tokenizer is trained on more than 100 languages, mBERT and XLM-R perform better than the mUSE$_{\text{cl-relkt}}$ on Indo-Aryan languages. Another solution would be to use the universal tokenizer (Gillick et al., 2016) which represents the input as bytes instead of characters.

A.7 Error Analysis: MT-assisted vs Ours

We provide some sample questions that our model and the MT-assisted model (DPR+GNMT) answer differently in Table 12. We notice that our method does better than MT-assisted when the questions are very specific, such as the question relating to Brothers Grimm. In general, we find that our model generally performs better when the question contains names. This is because machine translation can sometimes fail to translate names properly.

On the other hand, when the questions are not specific, it is a toss-up whether the prediction is correct for both models. Rows 2 and 3 show examples of such vague questions. Lastly, we found that our model performed particularly worse than MT-

assisted on contents related to numbers, as shown in the last two examples. Embedding numerical information is generally hard when the data is scarce. The model in our method has to map questions from multiple languages and numbers close together. This makes learning numerical concepts such as in example number four challenging. We believe this is a good avenue for further research.

BORT: Back and Denoising Reconstruction for End-to-End Task-Oriented Dialog

Haipeng Sun, Junwei Bao,* Youzheng Wu, Xiaodong He
JD AI Research, Beijing, China
`{sunhaipeng6, baojunwei, wuyouzheng1, hexiaodong}@jd.com`

Abstract

A typical end-to-end task-oriented dialog system transfers context into dialog state, and upon which generates a response, which usually faces the problem of error propagation from both previously generated inaccurate dialog states and responses, especially in low-resource scenarios. To alleviate these issues, we propose BORT, a **b**ack and den**o**ising **r**econs**t**ruction approach for end-to-end task-oriented dialog system. Squarely, to improve the accuracy of dialog states, *back reconstruction* is used to reconstruct the original input context from the generated dialog states since inaccurate dialog states cannot recover the corresponding input context. To enhance the denoising capability of the model to reduce the impact of error propagation, *denoising reconstruction* is used to reconstruct the corrupted dialog state and response. Extensive experiments conducted on MultiWOZ 2.0 and CamRest676 show the effectiveness of BORT. Furthermore, BORT demonstrates its advanced capabilities in the zero-shot domain and low-resource scenarios[1].

1 Introduction

Recently, task-oriented dialog systems, which aim to assist users to complete some booking tasks, have attracted great interest in the research community and the industry (Zhang et al., 2020c). Task-oriented dialog systems have been usually established via a pipeline system, including several modules such as natural language understanding, dialog state tracking, dialog policy, and natural language generation. The natural language understanding module converts user utterance into the structured semantic representation. The dialog state generated by the dialog state tracking module is used to query the database to achieve matched entities. The natural language generation module converts the action state estimated by the dialog policy module to the natural language response. This modular-based architecture is highly interpretable and easy to implement, used in most practical task-oriented dialog systems in the industry. However, every module is optimized individually and doesn't consider the entire dialog history, which affects the performance of the dialog system. Therefore, many researchers focus on end-to-end task-oriented dialog systems to train an overall mapping from user natural language input to system natural language output (Lei et al., 2018; Zhang et al., 2020b; Hosseini-Asl et al., 2020; Lin et al., 2020; Yang et al., 2021).

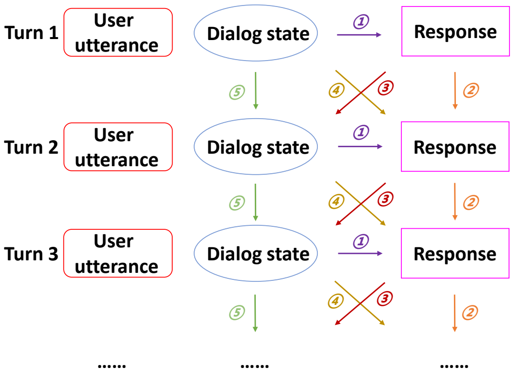

Figure 1: Illustration of different error propagation problem types, denoted by arrows in different colors, along the multi-turn task-oriented dialog flow. For example, the orange arrow indicates that the error in the previously generated response would affect the response generation in the current dialog turn.

However, all existing task-oriented dialog systems still suffer from one or more types of error propagation problems from both previously generated inaccurate dialog states and responses, as is illustrated in Figure 1. Firstly, the generated dialog state, which is crucial for task completion of task-oriented dialog systems, is usually inaccurate across the end-to-end task-oriented dialog system training. Secondly, the previously generated dialog state and response are encoded to create the current

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2156 - 2170
July 10-15, 2022

dialog state and response during inference, while the oracle previous dialog state and response are encoded during training. There exists a discrepancy between training and inference, affecting the quality of generated system responses.

We propose BORT, a back and denoising reconstruction approach for end-to-end task-oriented dialog systems to alleviate these issues. To improve dialog state learning ability, back reconstruction is used to reconstruct the generated dialog state back to the original input context to ensure that the information in the input side is completely transformed to the output side. In addition, to enhance the denoising capability of the task-oriented dialog system to reduce the impact of error propagation, denoising reconstruction is used to reconstruct the corrupted dialog state and response. It guarantees that the system learns enough internal information of the dialog context to recover the original version. Experimental results on MultiWOZ 2.0 and CamRest676 show that our proposed BORT substantially outperforms baseline systems. This paper primarily makes the following contributions:

- We propose two effective reconstruction strategies, i.e., back and denoising reconstruction strategies, to improve the performance of end-to-end task-oriented dialog systems.
- Extensive experiments and analysis on MultiWOZ 2.0 and CamRest676 show the effectiveness of BORT.
- BORT achieves promising performance in zero-shot domain scenarios and alleviates poor performance in low-resource scenarios.

2 Task-Oriented Dialog Framework

As illustrated in Figure 2(a), we construct an encoder-decoder framework for an end-to-end task-oriented dialog system via dialog state tracking and response generation tasks. One shared encoder encodes dialog context, and two different decoders decode dialog state and system response, respectively. The objective function $\mathcal{L}_{all}$ of the entire training process is optimized as:

$$\mathcal{L}_{all} = \mathcal{L}_B + \mathcal{L}_R, \tag{1}$$

where $\mathcal{L}_B$ is the objective function for dialog state tracking, and $\mathcal{L}_R$ is the objective function for response generation.

2.1 Dialog State Tracking

Motivated by Lin et al. (2020), we model the Levenshtein dialog state, which means the difference between the current dialog state and the previous dialog state, for dialog state tracking task to generate minimal dialog state and reduce the inference latency. The Levenshtein dialog state ΔB_t of dialog turn t, is generated based on the previous dialog state B_{t-1}, the previous system response R_{t-1}, and the current user utterance U_t via the encoder-decoder framework:

$$H_{eb} = encoder(B_{t-1}, R_{t-1}, U_t), \tag{2}$$

$$\Delta B_t = decoder_b(H_{eb}), \tag{3}$$

where H_{eb} denotes the hidden representation of the encoder for dialog state tracking. Therefore, the dialog state tracking objective function can be optimized by minimizing:

$$\mathcal{L}_B = \sum_{i=1}^{N} \sum_{t=1}^{n_i} -logP(\Delta B_t | B_{t-1}, R_{t-1}, U_t), \tag{4}$$

where N denotes the number of dialog sessions, n_i denotes the number of dialog turns in the dialog session i.

For inference, a predefined function $\Omega(\cdot)$ is used to generate the dialog state B_t as

$$B_t = \Omega(\Delta B_t, B_{t-1}). \tag{5}$$

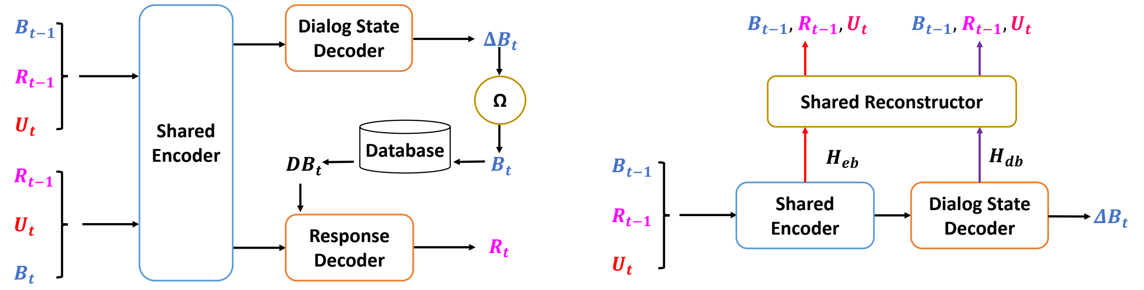
The predefined function $\Omega(\cdot)$ deletes the slot-value pair in B_{t-1} when the `NULL` symbol appears in the ΔB_t, and it updates the B_{t-1} when new slot-value pair or new value for one slot appears in the ΔB_t. Refer to Lin et al. (2020) for more details. The generated dialog state B_t is used to query the corresponding database. The database state embedding DB_t represents the number of matched entities and whether the booking is available or not. The embedding DB_t is used as the start token embedding of the response decoder for response generation.

2.2 Response Generation

The response R_t of dialog turn t is generated based on the previous system response R_{t-1}, the current user utterance U_t, the current dialog state B_t, and the database state embedding DB_t, which is formulated as:

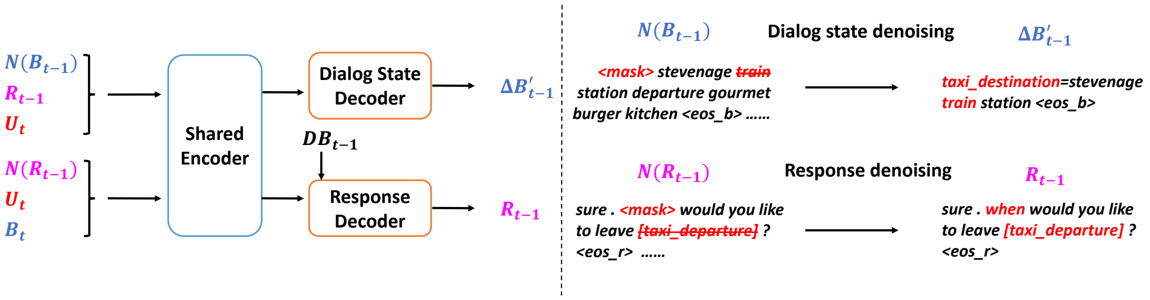
$$H_{er} = encoder(R_{t-1}, U_t, B_t), \tag{6}$$

$$R_t = decoder_r(H_{er}, DB_t), \tag{7}$$



(a) Base architecture

(b) Back reconstruction



(c) Denoising reconstruction

Figure 2: Illustration of the task-oriented dialog training process. We take turn *t* of a dialog session as an example.

where H_{er} denotes the hidden representation of the encoder for response generation. Therefore, the response generation objective function can be optimized by minimizing:

$$\mathcal{L}_R = \sum_{i=1}^{N} \sum_{t=1}^{n_i} -logP(R_t|R_{t-1}, U_t, B_t, DB_t). \quad (8)$$

3 Methodology

In this section, we proposes two reconstruction strategies, i.e., back reconstruction and denoising reconstruction, respectively. Generally, during task-oriented dialog training, objective functions $\mathcal{L}_{BR}$ and $\mathcal{L}_{DR}$ are added to enhance model learning ability. The general objective function of a task-oriented dialog system can be reformulated as follows:

$$\mathcal{L}_{all} = \mathcal{L}_B + \mathcal{L}_R + \lambda_1 \mathcal{L}_{BR} + \lambda_2 \mathcal{L}_{DR}, \quad (9)$$

where $\mathcal{L}_{BR}$ and $\mathcal{L}_{DR}$ denote the objective functions for back reconstruction and denoising reconstruction. λ_1 and λ_2 are hyper-parameters that adjust the weights of the objective functions.

3.1 Back Reconstruction

Dialog state is essential for the task completion of a task-oriented dialog system (Wang et al., 2022). As illustrated in Figure 2(b), we propose a back reconstruction strategy to mitigate the generation of inaccurate dialog states, including encoder-reconstructor and encoder-decoder-reconstructor modules. For the encoder-reconstructor module, the dialog context $C(t) = (B_{t-1}, R_{t-1}, U_t)$ could be reconstructed to enhance encoder information representation by the encoder hidden representation H_{eb}. For the encoder-decoder-reconstructor module, the decoder hidden representation H_{db} could be used to reconstruct the dialog context $C(t)$ to encourage the dialog state decoder to achieve complete information of dialog context.

The dialog state would be reconstructed back to the source input and the corresponding reconstruction score would be calculated to measure the adequacy of the dialog state. The objective function $\mathcal{L}_{BR}$ for the back reconstruction is optimized by minimizing:

$$\begin{aligned} \mathcal{L}_{BR} = & \sum_{i=1}^{N} \sum_{t=1}^{n_i} -logP(C(t)|H_{eb}) \\ & + \sum_{i=1}^{N} \sum_{t=1}^{n_i} -logP(C(t)|H_{db}). \end{aligned} \quad (10)$$

3.2 Denoising Reconstruction

To enhance the denoising capability of the task-oriented dialog system, we propose denoising reconstruction to guarantee that the system learns enough dialog context representation to recover the original version, as illustrated in Figure 2(c). Motivated by denoising auto-encoder strategy that maps a corrupted input back to the original version (Vincent et al., 2010), we introduce noise in the form of random token deleting and masking in the source input to improve the dialog model learning ability. Specifically, we delete or mask every token in the previous dialog state and system response with a probability α. More concretely, we propose two denoising reconstruction modules, i.e., dialog state denoising and response denoising modules.

For the dialog state denoising module, we reconstruct the new Levenshtein dialog state, which means the corrupted part of the dialog state rather than the complete dialog state in the original denoising auto-encoder. The Levenshtein dialog state $\Delta B'_{t-1}$ of dialog turn t, is generated based on the noisy dialog context $N_B(t) = (N(B_{t-1}), R_{t-1}, U_t)$. $N(B_{t-1})$ is the previous corrupted dialog state. For example, the Levenshtein dialog state '*taxi_destination=stevenage train station*' is reconstructed from the corrupted dialog state where '*taxi_destination*' is masked and '*train*' is deleted, as shown in Figure 2(c). For response denoising module, the previous system response R_{t-1} of dialog turn t is reconstructed based on the noisy dialog context $N_R(t) = (N(R_{t-1}), U_t, B_t, DB_{t-1})$. $N(R_{t-1})$ is the previous noisy system response. Therefore, the objective function $\mathcal{L}_{DR}$ for the denoising reconstruction is optimized by minimizing:

$$\begin{aligned}\mathcal{L}_{DR} = &\sum_{i=1}^{N}\sum_{t=1}^{n_i} -logP(\Delta B'_{t-1}|N_B(t)) \\ &+ \sum_{i=1}^{N}\sum_{t=1}^{n_i} -logP(R_{t-1}|N_R(t)).\end{aligned} \tag{11}$$

3.3 Training and Inference Details

There exists inconsistency between the lexicalized user utterance and delexicalized system response, which is used to reduce the influence of different slot values on evaluation (Zhang et al., 2020b). This adds an extra burden for the system to generate a delexicalized system response. To alleviate this issue, we introduce delexicalized user utterances for response generation while lexicalized user utterances are still used for dialog state tracking. For example, '*02:15*' is converted into delexicalized form '*[taxi_arriveby]*' for response generation, as shown in Figure 2(a). Different forms of user utterances take better training of both tasks, ultimately improving task completion.

For inference of dialog state tracking, generated previous dialog state, oracle previous system response, and current user utterance are used as dialog context to generate the current Levenshtein dialog state. For inference of response generation, motivated by Yang et al. (2021), we use generated previous system response instead of oracle previous system response to generate the current system response to maintain coherence throughout the whole dialog session.

4 Experiments

4.1 Datasets and Evaluation Metrics

To establish our proposed end-to-end task-oriented dialog system, we consider two task-oriented dialog datasets, MultiWOZ 2.0 (Budzianowski et al., 2018) and CamRest676 (Wen et al., 2017).

MultiWOZ 2.0 is a large-scale human-to-human multi-domain task-oriented dialog dataset. The dataset consists of seven domains: attraction, hospital, police, hotel, restaurant, taxi, and train. It contains 8438, 1000, and 1000 dialog sessions for training, validation, and testing datasets. Each dialog session covers 1 to 3 domains, and multiple different domains might be mentioned in a single dialog turn. Particularly, there are no hospital and police domains in the validation and testing dataset. To make our experiments comparable with previous work (Zhang et al., 2020b; Lin et al., 2020; Yang et al., 2021), we use the pre-processing script released by Zhang et al. (2020b) and follow the automatic evaluation metrics to evaluate the response quality for the task-oriented dialog system. **Inform** rate measures if a dialog system has provided a correct entity; **Success** rate measures if a dialog system has provided a correct entity and answered all the requested information; **BLEU** score (Papineni et al., 2002) measures the fluency of the generated response; the **combined score**, which is computed by $(Inform + Success) \times 0.5 + BLEU$, measures the overall quality of the dialog system. To evaluate the performance of dialog state tracking, we use the **joint goal accuracy** to measure the accuracy of generated dialog states.

CamRest676 is a small-scale restaurant-domain dataset. It contains 408, 136, 132 dialog sessions for training, validation, and testing datasets. To make our experiments comparable with previous work (Lei et al., 2018; Wu et al., 2021), we use the same delexicalization strategy and use **BLEU** score and **Success F1** to evaluate the response qual-

BORT	T5-small	**93.8++**	**85.8++**	18.5	**108.3++**

Table 1: Comparison of end-to-end models evaluated on MultiWOZ 2.0. "++" after a score indicates that the proposed BORT is significantly better than Baseline (mask=0) at significance level p <0.01. * denotes the re-evaluated result by the author-released model since the result reported in this original paper (Yang et al., 2021) was evaluated using the ground truth dialog state instead of generated dialog state to query the database entities.

ity for the task-oriented dialog system. The success rate measures if the system answered all the requested information to assess recall while Success F1 balances recall and precision.

4.2 Settings

In the training process for the task-oriented dialog system, we select two backbone models. BORT is a transformer-based system initialized by a pre-trained model. BORT_G is a GRU-based system without a pre-trained model. The detailed training settings and results of the BORT_G backbone are provided in Appendix A.1.

For the BORT backbone, we use pre-trained T5-small (Raffel et al., 2020) to initialize the dialog system, based on the HuggingFace Transformers library (Wolf et al., 2020) and follow the settings of Lin et al. (2020). There are six layers for the encoder and the decoder. The dimension of hidden layers is set to 512, and the head of attention is 8. The batch size is set to 96. The AdamW optimizer (Loshchilov and Hutter, 2019) is used to optimize the model parameters. The learning rate is 0.0025, and the learning rate decay is 0.8. The hyper-parameters λ_1 and λ_2 are set to 0.05 and 0.03, respectively. For the denoising reconstruction strategy, the noise probability α is 0.15. The hyper-parameter analysis is provided in Appendix A.2. Training early stops when no improvement on the combined score of the validation set for five epochs. All results in the low-resource scenario are the average scores of three runs. One P40 GPU is used to train all dialog systems.

4.3 Baselines

Compared with other previous work, our proposed BORT is evaluated in two context-to-response settings: end-to-end modeling to generate dialog state and system response, and policy optimization to generate system response based on ground truth dialog state. Policy optimization results are provided in Appendix A.3.

Sequicity (Lei et al., 2018) and DAMD (Zhang et al., 2020b) are GRU-based end-to-end task-oriented dialog systems with a copy mechanism. Decoder based pre-trained model GPT-2 (Radford et al., 2019) is used in SimpleTOD (Hosseini-Asl et al., 2020), SOLOIST (Peng et al., 2020), and UBAR (Yang et al., 2021). Encoder-decoder based pre-trained model T5 (Raffel et al., 2020) and BART (Lewis et al., 2020) is used in MinTL (Lin et al., 2020). Reinforcement learning is used in LAVA (Lubis et al., 2020) and SUMBT+LaRL (Lee et al., 2020). Especially, SUMBT+LaRL merges a dialog state tracking model SUMBT (Lee et al., 2019) and a dialog policy model LaRL (Zhao et al., 2019) and fine-tune them via reinforcement learning, achieving the state-of-the-art performance.

In addition, we implement two baseline systems. One baseline is the base architecture of a task-oriented dialog system, as illustrated in Figure 2(a). The other is a noise-based baseline system, just masking 15% tokens in the dialog context for dialog training.

4.4 Main Results

Table 1 presents the detailed inform rates, success rates, BLEU scores, and combined scores of end-to-end dialog models on the MultiWOZ 2.0. Our re-implemented baseline system performs better than MinTL (Lin et al., 2020), using the same pre-trained T5-small model. This indicates that the baseline is a strong system. Our proposed BORT significantly outperforms our re-implemented baseline system by 6.5 combined scores, while the simple noise-based method (Baseline (mask=0.15)) doesn't achieve better performance. Moreover, BORT outperforms the previous state-of-the-art SUMBT+LaRL by 1.6 combined scores, achieving the best performance in terms of inform rate, success rate, and combined score. This demonstrates the effectiveness of our proposed BORT.

Model	Success F1	BLEU
Sequicity (Lei et al., 2018)	85.4	25.3
ARDM (Wu et al., 2021)	86.2	25.4
SOLOIST (Peng et al., 2020)	87.1	25.5
BORT	**89.7**	**25.9**

Table 2: Comparison of end-to-end task-oriented dialog systems on CamRest676.

To better assess the generalization capability of BORT, we fine-tune BORT on the CamRest676. The detailed Success F1 and BLEU scores on the CamRest676 are presented in Table 2. Our proposed BORT outperforms the previous state-of-the-art SOLOIST by 2.6 Success F1, achieving the best performance in terms of Success F1. This demonstrates the generalization capability of our proposed BORT.

4.5 Further Evaluation Analysis

Nekvinda and Dušek (2021) identify inconsistencies between previous task-oriented dialog methods in data preprocessing and evaluation metrics and introduce a standalone standardized evaluation script. BLEU score is computed with references, which have been obtained from the delexicalized MultiWOZ 2.2 span annotations.

Model	Inform	Success	BLEU	Combined
DAMD (Zhang et al., 2020b)	57.9	47.6	16.4	69.2
LABES (Zhang et al., 2020a)	68.5	58.1	18.9	82.2
AuGPT (Kulhánek et al., 2021)	76.6	60.5	16.8	85.4
MinTL-T5-small (Lin et al., 2020)	73.7	65.4	**19.4**	89.0
SOLOIST (Peng et al., 2020)	82.3	72.4	13.6	91.0
DoTS (Jeon and Lee, 2021)	80.4	68.7	16.8	91.4
UBAR (Yang et al., 2021)	83.4	70.3	17.6	94.5
BORT	**85.5**	**77.4**	17.9	**99.4**

Table 3: Comparison of end-to-end task-oriented dialog systems evaluated on the standardized setting (Nekvinda and Dušek, 2021).

To get a more complete picture of the effectiveness of reconstruction strategies, we also use this evaluation script to evaluate our proposed BORT which is trained on MultiWOZ 2.0. As shown in Table 3, BORT also substantially outperforms the previous state-of-the-art UBAR by a large margin (4.9 combined scores), achieving the best performance in terms of inform rate, success rate, and combined score. This further demonstrates the effectiveness of our proposed BORT.

4.6 Ablation Study

We empirically investigate the performance of the different components of BORT as shown in Table 4. Our introduced user utterance delexicalization strategy gains 1.9 combined scores, indicating the effectiveness of the user utterance delexicalization strategy. Back reconstruction performs slightly better than denoising reconstruction by 1 combined score regarding the two proposed reconstruction strategies. Moreover, the combination of both reconstruction strategies can complement each other to further improve the performance of the dialog system. The detailed analysis on different modules of every reconstruction strategy is provided in Appendix A.4.

Model	Inform	Success	BLEU	Combined
BORT	93.8	85.8	18.5	108.3
w/o DR	92.9	84.0	18.8	107.3
w/o BR	92.0	84.4	18.1	106.3
w/o BR & DR	90.4	81.4	17.8	103.7
w/o BR & DR& UD	89.0	78.8	17.9	101.8

Table 4: The performance of the different components of our proposed BORT on MultiWOZ 2.0. BR denotes back reconstruction, DR denotes denoising reconstruction, UD denotes user utterance delexicalization.

4.7 Dialog State Tracking

Table 5 reports the dialog state tracking performance of the end-to-end task-oriented dialog systems on MultiWOZ 2.0. BORT substantially outperforms MinTL (Lin et al., 2020) using the same pre-trained T5-small model by 2.8 points, achieving 54.0 joint goal accuracy. Moreover, BORT achieves the highest joint goal accuracy among the end-to-end task-oriented dialog systems. This indicates that our proposed reconstruction strategies could improve dialog state learning ability.

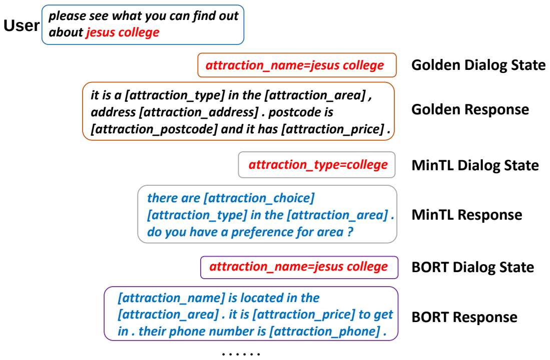
4.8 Case Study and Human Evaluation

Moreover, we analyze translation examples and conduct a human evaluation to further explore the

Model	Joint Accuracy
MinTL-T5-small (Lin et al., 2020)	51.2
SUMBT+LaRL (Lee et al., 2020)	51.5
MinTL-BART (Lin et al., 2020)	52.1
UBAR (Yang et al., 2021)	52.6
SOLOIST (Peng et al., 2020)	53.2
BORT	**54.0**

Table 5: The dialog state tracking performance of end-to-end task-oriented dialog systems on MultiWOZ 2.0.

effectiveness of BORT. Figure 3 shows an example generated by MinTL and BORT, respectively. More examples are provided in Appendix A.5. MinTL generates the response to request for the preferred area about college since it generates an inaccurate dialog state '*attraction_type=college*' rather than correct dialog state '*attraction_name=jesus college*'. In contrast, BORT generates an accurate dialog state, achieving the appropriate response that provides the information of *jesus college*. These further demonstrate the effectiveness of our proposed reconstruction strategies.



please see what you can find out about jesus college

attraction_name=jesus college

it is a [attraction_type] in the [attraction_area] , address [attraction_address] . postcode is [attraction_postcode] and it has [attraction_price] .

attraction_type=college

there are [attraction_choice] [attraction_type] in the [attraction_area] . do you have a preference for area ?

attraction_name=jesus college

[attraction_name] is located in the [attraction_area] . it is [attraction_price] to get in . their phone number is [attraction_phone] .

Figure 3: An example of the task-oriented dialog systems in dialog session PMUL4025.

For human evaluation, we manually evaluate the quality of generated responses on 50 dialog sessions, which are randomly extracted from the MultiWOZ 2.0 testing set. We consider the fluency and appropriateness of the generated response based on scores ranging from 1 to 5. The fluency metric measures whether the generated response is fluent. The appropriateness metric measures whether the generated response is appropriate and the system understands the user's goal. Three fluent English speakers are asked to evaluate these generated responses. The average scores evaluated by them are shown in Table 6. The results are consistent with the automatic evaluation, indicating that BORT could improve the quality of generated response.

Model	Fluency	Appropriateness
MinTL-T5-small	4.50	3.88
UBAR	4.50	3.81
BORT	**4.55**	**3.98**

Table 6: The human evaluation of the end-to-end task-oriented dialog systems on MultiWOZ 2.0.

4.9 Domain Adaptation Analysis

To investigate the domain adaptation ability of BORT to generalize to some unseen domains, we simulate zero-shot experiments by excluding one domain and training BORT on other domains. As shown in Table 7, the train and taxi domains achieve the highest combined scores because they have a high overlap in ontology with other domains. In addition, BORT and MinTL with an encoder-decoder-based pre-trained model achieve significantly better domain adaptation performance than DAMD without a pre-trained model and UBAR with a decoder-based pre-trained model, which demonstrates the encoder-decoder based pre-trained model have better domain transferability. Moreover, our proposed reconstruction strategy could further improve combined scores in the zero-shot domain scenario.

Model	Attraction	Hotel	Restaurant	Taxi	Train
DAMD	28.7	26.9	24.4	52.3	51.4
UBAR	28.3	29.5	23.5	59.5	53.9
MinTL	33.4	37.3	31.5	60.4	77.1
BORT	**33.6**	**38.7**	**32.0**	**62.7**	**85.6**

Table 7: Comparison of combined scores on the MultiWOZ 2.0 in the zero-shot domain scenario.

4.10 Low Resource Scenario Analysis

To better assess the robustness of our proposed BORT, we choose 5%, 10%, 20%, and 30% of training dialog sessions to investigate the performance of task-oriented dialog systems in the low resource scenario. As shown in Table 8, BORT substantially outperforms other methods in these low-resource scenarios. This is because the error propagation problem in the low resource scenario is more serious, while BORT could effectively alleviate the error propagation problem. Moreover, our proposed BORT trained on the 30% dataset performs comparably to some baseline systems trained on all datasets as shown in Table 1. These further demonstrate that our proposed BORT is robust, alleviating poor performance in the low-resource

Model	**5%**				**10%**				**20%**				**30%**			
	Inform	**Success**	**BLEU**	**Combined**	**Inform**	**Success**	**BLEU**	**Combined**	**Inform**	**Success**	**BLEU**	**Combined**	**Inform**	**Success**	**BLEU**	**Combined**
DAMD	49.1	23.7	11.3	47.7	57.6	32.6	12.0	57.1	64.7	45.0	15.3	70.2	64.5	47.3	15.5	71.4
UBAR	35.7	21.2	11.0	39.5	62.4	43.6	12.7	65.7	76.2	58.3	14.1	81.4	81.2	65.4	14.7	88.0
MinTL	55.2	40.9	**13.9**	62.0	67.7	55.7	15.3	77.0	66.7	57.9	**17.3**	79.6	74.9	66.5	**17.3**	88.0
BORT	**69.8**	**45.9**	11.0	**68.9**	**74.5**	**60.6**	**15.5**	**83.1**	**82.1**	**65.5**	14.3	**88.1**	**83.8**	**69.9**	17.2	**94.1**

Table 8: Comparison of task-oriented dialog systems on the MultiWOZ 2.0 in the low resource scenarios.

scenario.

4.11 Error Propagation Analysis

To investigate the denoising capability of our proposed BORT, we perform the simulated experiments, where noise is added in the oracle dialog state for the policy optimization evaluation. In detail, we replace every token in the oracle dialog state with the masked token with a probability to generate synthetic noise. As shown in Figure 4, BORT performs substantially better than the baseline system in the noisy scenario. In particular, as the noise ratio in the oracle dialog state increases, the performance gap between the baseline system and BORT increases. When noise proportion is 0, BORT still performs better than the baseline system because BORT generates more appropriate response via the denoising reconstruction strategy. These demonstrate that our proposed BORT is robust and effective.

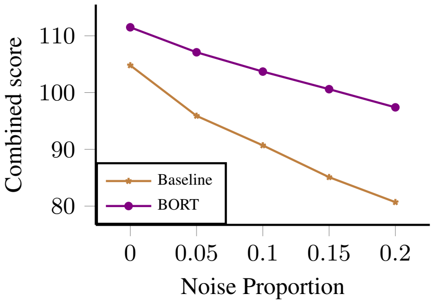


Figure 4: The policy optimization performance (combined score) of baseline and BORT as the noise in the oracle dialog state increases on the MultiWOZ 2.0.

5 Related Work

End-to-end task-oriented dialog system has attracted much attention in the dialog community. A two-stage copynet framework was proposed to establish an end-to-end task-oriented dialog system based on a single sequence-to-sequence model (Lei et al., 2018). Zhang et al. (2020b) proposed a multi-action data augmentation framework to improve the diversity of dialog responses. Recently, large-scale language model pre-training has been effective for enhancing many natural language processing tasks (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019). Decoder-based pre-trained language model such as GPT-2 (Radford et al., 2019) was used to improve the performance of end-to-end task-oriented dialog system (Budzianowski and Vulić, 2019; Hosseini-Asl et al., 2020; Peng et al., 2020; Yang et al., 2021). The Levenshtein dialog state instead of the dialog state was generated to reduce the inference latency (Lin et al., 2020). In addition, they used encoder-decoder-based pre-trained model such as T5 (Raffel et al., 2020) and BART (Lewis et al., 2020) to establish a dialog system. In contrast with previous work, in which system response was generated, Wu et al. (2020) used encoder-based pre-trained model such as BERT (Devlin et al., 2019) for task-oriented dialog system, aiming to retrieve the most relative system response from a candidate pool. Reinforcement learning could also be used to enable task-oriented dialog systems to achieve more successful task completion (Lubis et al., 2020; Lee et al., 2020).

Tu et al. (2017) proposed an encoder-decoder-reconstructor framework for neural machine translation to alleviate over-translation and under-translation problems. Reconstruction strategy was used to moderate dropped pronoun translation problems (Wang et al., 2018). In contrast, we considered the adequacy of semantic representations rather than natural language sentences to build the reconstruction model. Vincent et al. (2010) proposed a denoising autoencoder, in which random noise is added to enhance the robustness of the model, alleviating the overfitting problem of traditional auto-encoder. The denoising auto-encoder strategy was used as the language model to generate more fluent translation candidates for the unsupervised neural machine translation (Artetxe et al., 2018; Lample et al., 2018; Sun et al., 2019). In addition, a denoising auto-encoder was used to pre-train sequence-to-sequence models on the large scale corpus (Lewis et al., 2020; Liu et al., 2020). In contrast, we proposed a denoising reconstruction mechanism to alleviate the error propagation problem along the multi-turn conversation flow.

6 Conclusion

This paper proposes back and denoising reconstruction strategies for the end-to-end task-oriented dialog system. Back reconstruction strategy is proposed to mitigate the generation of inaccurate dialog states, achieving better task completion of the task-oriented dialog system. Denoising reconstruction is used to train a robust task-oriented dialog system, further alleviating the error propagation problem. Our extensive experiments and analysis on MultiWOZ 2.0 and CamRest676 demonstrate the effectiveness of our proposed reconstruction strategies.

A Appendix

A.1 BORT_G Settings and Results

For the BORT_G backbone, we follow the settings of Zhang et al. (2020b). We use one layer bi-directional GRU for the encoder and the decoder. The dimension of hidden layers is set to 100. The batch size is 128. The AdamW optimizer (Loshchilov and Hutter, 2019) is used to optimize the model parameters, and the learning rate is 0.005.

Model	Inform	Success	BLEU	Combined
DAMD	76.3	60.4	16.6	85.0
MinTL-T5-small	80.0	72.7	19.1	95.5
BORT_G	87.3	75.8	18.4	100.0

Table 9: Comparison of end-to-end models evaluated on MultiWOZ 2.0.

As shown in Table 9, BORT_G performs better than DAMD without a pre-trained model, achieving the improvement of 15.0 combined scores, even though multi-action data augmentation is not used in BORT_G. Moreover, BORT_G outperforms MinTL (Lin et al., 2020), using the pre-trained model. This demonstrates the effectiveness and applicability of our proposed reconstruction strategies.

A.2 Hyper-parameter Analysis

In Figure 5, we empirically investigate how the hyper-parameters in Eq. 9 affects the dialog performance on the MultiWOZ 2.0 validation set. The selection of hyper-parameters λ_1 and λ_2 influence the role of the $\mathcal{L}_{BR}$ and $\mathcal{L}_{DR}$ across the entire end-to-end task-oriented dialog training process. Larger values of λ_1 or λ_2 cause the $\mathcal{L}_{BR}$ or $\mathcal{L}_{DR}$ to play a more important role than the original task-oriented dialog loss terms. The smaller the value of λ_1 or λ_2, the less important is the $\mathcal{L}_{BR}$ or $\mathcal{L}_{DR}$. As Figure 5 shows, λ_1 ranging from 0.01 to 0.5 nearly all enhances task-oriented dialog performance, and when λ_2 is larger than 0.3, the performance underperforms the baseline system. When $\lambda_1 = 0.05$ and $\lambda_2 = 0.03$, our proposed BORT achieves the best performance on the validation set.

In addition, the influence of noise type and noise proportion on the performance of our proposed BORT on the MultiWOZ 2.0 validation set is empirically investigated, as shown in Figure 6. Both deletion and masking noise strategies could improve the dialog performance. In particular, their combination is further better than both of them. This demonstrates that both noise strategies can complement each other to further improve the dialog performance. As shown in Figure 6, when the noise proportion is 0.15, our proposed BORT achieves the best performance on the validation set.

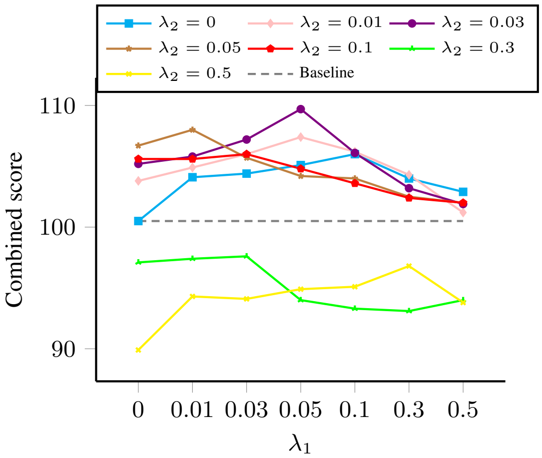

Figure 5: BORT performance (combined score) with different levels of hyper-parameters on the MultiWOZ 2.0 validation set.

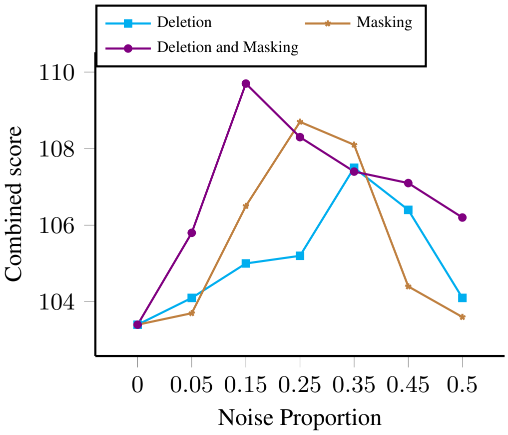

Figure 6: BORT performance (combined score) with different levels of noise type and noise proportion on the MultiWOZ 2.0 validation set.

A.3 Policy Optimization Evaluation

The detailed inform rates, success rates, BLEU scores, and combined scores of policy optimization dialog models on the MultiWOZ 2.0 are presented in Table 10. The ground truth dialog state is used for the policy optimization setting to query the database entities and generate system responses. Our proposed BORT achieves performance comparable to the state-of-the-art LAVA in terms of inform rate. In addition, compared with previous policy optimization methods, BORT achieves bet-

Model	Pre-trained	Inform	Success	BLEU	Combined
LaRL (Zhao et al., 2019)	n/a	82.8	79.2	12.8	93.8

ter performance in terms of the combined score even though BORT has not modeled action learning.

Compared with previous works, BORT achieves much more significant improvement in the end-to-end setting rather than policy optimization setting because our proposed reconstruction strategies pay more attention to improving the quality of dialog state while the golden dialog state is used in the policy optimization setting.

A.4 Ablation Study

Moreover, we further investigate the performance of the different components of the two proposed reconstruction strategies, respectively. As shown in Table 11, encoder-decoder-reconstructor module for back reconstruction strategy significantly outperforms encoder-reconstructor module by 2.2 combined scores because dialog state decoder could achieve more dialog context information for encoder-decoder-reconstructor. In addition, regarding two denoising reconstruction modules, dialog state denoising and response denoising have achieved similar performance. These two modules could improve the denoising capability of the task-oriented dialog system.

Model	Inform	Success	BLEU	Combined
Back reconstruction	92.9	84.0	18.8	107.3
w/o enc-rec	92.2	83.5	19.0	106.9
w/o enc-dec-rec	92.1	81.2	18.0	104.7
Denoising reconstruction	92.0	84.4	18.1	106.3
w/o dialog state denoising	91.7	83.0	17.9	105.3
w/o response denoising	92.8	81.2	18.6	105.6

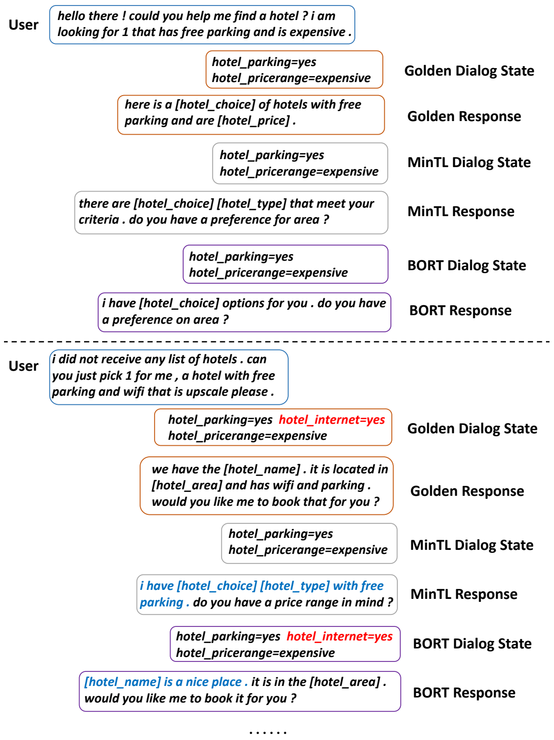
A.5 More examples

Figures 7 - 11 show several examples generated by MinTL and BORT, respectively. As shown in Figure 7, MinTL generates the inadequate dialog state, which may provide the hotel without internet. Our proposed BORT reconstructs the generated dialog state back to the original input context to ensure the information in the input side is completely transformed to the output side to achieve an adequate dialog state via a back reconstruction strategy. Figure 8 shows that our proposed BORT generated the correct slot value '*european*' rather than the corrupted one '*europeon*' from the corrupted dialog context, indicating the robustness of the denoising reconstruction strategy. As shown in Figures 9 - 11, MinTL generates the inaccurate dialog state, leading to the inaccurate response. The results are consistent with our opinion that the generated dialog state, which is crucial for task completion of a task-oriented dialog system, has always been inaccurate across the end-to-end task-oriented dialog system training. Moreover, Figure 11 shows that MinTL faces the problem of error propagation from both previously generated inaccurate dialog states and responses. Our proposed BORT can alleviate these issues via reconstruction strategies, further demonstrating the effectiveness of BORT.



User
hello there ! could you help me find a hotel ? i am looking for 1 that has free parking and is expensive .

Golden Dialog State
hotel_parking=yes hotel_pricerange=expensive

Golden Response
here is a [hotel_choice] of hotels with free parking and are [hotel_price] .

MinTL Dialog State
hotel_parking=yes hotel_pricerange=expensive

MinTL Response
there are [hotel_choice] [hotel_type] that meet your criteria . do you have a preference for area ?

BORT Dialog State
hotel_parking=yes hotel_pricerange=expensive

BORT Response
i have [hotel_choice] options for you . do you have a preference on area ?

User
i did not receive any list of hotels . can you just pick 1 for me , a hotel with free parking and wifi that is upscale please .

Golden Dialog State
hotel_parking=yes hotel_internet=yes hotel_pricerange=expensive

Golden Response
we have the [hotel_name] . it is located in [hotel_area] and has wifi and parking . would you like me to book that for you ?

MinTL Dialog State
hotel_parking=yes hotel_pricerange=expensive

MinTL Response
i have [hotel_choice] [hotel_type] with free parking . do you have a price range in mind ?

BORT Dialog State
hotel_parking=yes hotel_internet=yes hotel_pricerange=expensive

Abstract

Previous studies have proved that cross-lingual knowledge distillation can significantly improve the performance of pre-trained models for cross-lingual similarity matching tasks. However, the student model needs to be large in this operation. Otherwise, its performance will drop sharply, thus making it impractical to be deployed to memory-limited devices. To address this issue, we delve into cross-lingual knowledge distillation and propose a multi-stage distillation framework for constructing a small-size but high-performance cross-lingual model. In our framework, contrastive learning, bottleneck, and parameter recurrent strategies are combined to prevent performance from being compromised during the compression process. The experimental results demonstrate that our method can compress the size of XLM-R and MiniLM by more than 50%, while the performance is only reduced by about 1%.

1 Introduction

On the internet, it is widespread to store texts in dozens of languages in one system. Cross-lingual similar text matching in multilingual systems is a great challenge for many scenarios, e.g., search engines, recommendation systems, question-answer robots, etc. (Cer et al., 2017; Hardalov et al., 2020; Asai et al., 2021).

In the monolingual scenario, benefiting from the robust performance of the pre-trained language models (PLMs) (e.g., BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), T5 (Raffel et al., 2020), etc.), significant success has been achieved in text-similarity matching tasks. For example, Reimers and Gurevych (2019) proposed the SBERT model trained with similar text pairs and achieved the state-of-the-art performance in the supervised similarity matching. In unsupervised scenarios, Gao et al. (2021) proposed the SimCSE model, which was trained on Wiki corpus through contrastive learning task.

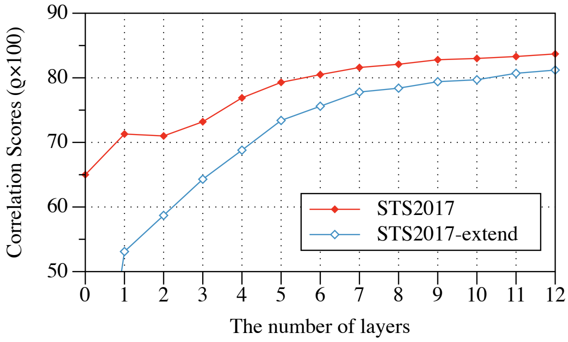

Figure 1: Evaluation results of XLM-R with different number of encoder layers on the STS2017 **monolingual** task and the STS2017-extend **cross-lingual** task, using SBERT-paraphrases for knowledge distillation.

Drawing on the success in the monolingual scenario, researchers began to introduce pre-training technology into cross-lingual scenarios and proposed a series of multilingual pre-trained models, e.g., mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019), XLM-R (Conneau et al., 2020), etc. Due to the vector collapse issue (Li et al., 2020), the performances of these cross-lingual models on similarity matching tasks are still not satisfactory. Reimers and Gurevych (2020) injected the similarity matching ability of SBERT into the cross-lingual model through knowledge distillation, which alleviated the collapse issue and improved the performance of cross-lingual matching tasks.

Although the cross-lingual matching tasks have achieved positive results, the existing cross-lingual models are huge and challenging to be deployed in devices with limited memory. We try to distill the SBERT model into an XLM-R with fewer layers following Reimers and Gurevych (2020). However, as shown in Figure 1, the performance will be significantly reduced as the number of layers decreases. This phenomenon indicates that cross-lingual capabilities are highly dependent on the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2171 - 2181
July 10-15, 2022

model size, and simply compressing the number of layers will bring a serious performance loss.

In this work, we propose a multi-stage distillation compression framework to build a small-size but high-performance model for cross-lingual similarity matching tasks. In this framework, we design three strategies to avoid semantic loss during compression, i.e., multilingual contrastive learning, parameter recurrent, and embedding bottleneck. We further investigate the effectiveness of the three strategies through ablation studies. Besides, we respectively explore the performance impact of reducing the embedding size and encoder size. Experimental results demonstrate that our method effectively reduces the size of the multilingual model with minimal semantic loss. Finally, our code is publicly available[1].

The main contributions of this paper can be summarized as follows:

- We validate that cross-lingual capability requires a larger model size and explore the semantic performance impact of shrinking the embedding or encoder size.
- A multi-stage distillation framework is proposed to compress the size of cross-lingual models, where three strategies are combined to reduce semantic loss.
- Extensive experiments examine the effectiveness of these three strategies and multi-stages used in our framework.

2 Related work

2.1 Multilingual models

Existing multilingual models can be divided into two categories, namely Multilingual general model and Cross-lingual representation model.

In the first category, transformer-based pre-trained models have been massively adopted in multilingual NLP tasks (Huang et al., 2019; Chi et al., 2021; Luo et al., 2021; Ouyang et al., 2021). mBERT (Devlin et al., 2019) was pre-trained on Wikipedia corpus in 104 languages, achieved significant performance in the downstream task. XLM (Conneau and Lample, 2019) presented the translation language modeling (TLM) objective to improve the cross-lingual transferability by leveraging parallel data. XLM-R (Conneau et al., 2020) was built on RoBERTa (Liu et al., 2019) using CommonCrawl Corpus.

In the second category, LASER (Artetxe and Schwenk, 2019) used an encoder-decoder architecture based on a Bi-LSTM network and was trained on the parallel corpus obtained by neural machine translation. Multilingual Universal Sentence Encoder (mUSE) (Chidambaram et al., 2019; Yang et al., 2020) adopted a bi-encoder architecture and was trained with an additional translation ranking task. LaBSE (Feng et al., 2020) turned the pre-trained BERT into a bi-encoder mode and was optimized with the objectives of mask language model (MLM) and TLM. Recently, Mao et al. (2021) presented a lightweight bilingual sentence representation method based on the dual-transformer architecture.

2.2 Knowledge distillation

However, Multilingual models do not necessarily have cross-lingual capabilities, especially in the first category, in which vector spaces of different languages are not aligned. Knowledge distillation (Hinton et al., 2015) used knowledge from a teacher model to guide the training of a student model, which can be used to compress the model and align its vector space at the same time.

For model compression, knowledge distillation aimed to transfer knowledge from a large model to a small model. BERT-PKD (Sun et al., 2019) extracted knowledge from both last layer and intermediate layers at fine-tuning stage. DistilBERT (Sanh et al., 2019) performed distillation at pre-training stage to halve the depth of BERT. TinyBERT (Jiao et al., 2020) distilled knowledge from BERT at both pre-training and fine-tuning stages. MobileBERT (Sun et al., 2020) distilled bert into a model with smaller dimensions at each layer. MiniLM (Wang et al., 2021) conducted deep self-attention distillation.

Unlike previous works presenting general distillation frameworks, we focus on compressing multilingual pre-trained models while aligning their cross-lingual vector spaces. In addition, we take inspiration from Reimers and Gurevych (2020), which successfully aligned the vector space of the multilingual model through cross-lingual knowledge distillation (X-KD). Our framework combines the advantages of X-KD for aligning vectors and introduces three strategies and an assistant model to prevent performance from being compromised

Stage 1: Teaching assistant

Stage 3: Teaching student

Stage 2: Align student embedding

Stage 4: Multilingual contrastive learning

Figure 2: The overview of the model architecture and the multi-stage distillation. It consists of four stages and aims to obtain a small multilingual student model. For convenience, we take the English SBERT as the teacher model, XLM-R as the assistant model. $< s_i, t_i >$ is a pair of parallel sentences in two different language. N is the batch size. MSE is the mean squared error loss function.

during compression.

3 Method

In this section, we will introduce our method in detail. First, we exhibit the model architecture, and then introduce the multi-stage distillation strategy for the model training. An overview of our approach is shown in Figure 2.

3.1 Model architecture

Given a large-size monolingual model as teacher T and a small-size multilingual model as student S, our goal is to transfer semantic similarity knowledge from T to S and simultaneously compress the size of S with m parallel sentences $P = \{< s_1, t_1 >, < s_2, t_2 >, \cdots < s_m, t_m >\}$.

3.1.1 Teacher model

In this work, we use SBERT (Reimers and Gurevych, 2019) as the teacher model, which has been proven to perform well on monolingual semantic similarity tasks. SBERT adopts a siamese network structure to fine-tune a BERT (Devlin et al., 2019) encoder, and applies a mean pooling operation to its output to derive sentence embedding.

3.1.2 Assistant model

Mirzadeh et al. (2020) proved that when the gap between the student and teacher is large, the performance of the student model will decrease. We hope to get a small student model with cross-lingual capabilities, while the teacher is a large monolingual model. To alleviate the gaps, we introduce an assistant model A (Mirzadeh et al., 2020), which is a large multilingual model with cross-lingual ability.

3.1.3 Student model

Inspired by ALBERT (Lan et al., 2020), we design the student model with Parameter Recurrent and Embedding Bottleneck strategy. Since there is no available multilingual ALBERT, we need to design from scratch.

Parameter recurrent. We choose the first M layers of the assistant model as a recurring unit (RU). The role of RU is to initialize the student model with layers from the assistant model. Concretely, the RU is defined as,

$$RU = \{L_i | i \in [1, M]\}, \qquad (1)$$

where L_i is the i^{th} transformer layer.

Embedding bottleneck. Multilingual pre-trained models usually require a large vocabulary V to support more languages, which leads to large embedding layer parameters. We add a bottleneck layer (He et al., 2016; Lan et al., 2020; Sun et al., 2020) of size B between embedding layer and hidden layer H. In this way, the embedding layer is reduced from $O(V \times H)$ to $O(V \times B + B \times H)$.

3.2 Multi-stage distillation

Multi-stage Distillation is the key for enabling the small-size student model with cross-lingual matching ability.

Stage 1. Teaching assistant

As the **Stage 1** in Figure 2, we use the teacher model and parallel corpus to align vector space between different languages through the loss function in (2), enabling its cross-lingual ability (Reimers and Gurevych, 2020).

$$\ell_{stage1} = \frac{1}{|N|}\sum_{i}^{N}\left[(h_T^{si} - h_A^{si})^2 + (h_T^{si} - h_A^{ti})^2\right], \tag{2}$$

where N is the batch size, and s_i and t_i denotes the parallel sentences in a mini batch.

Stage 2. Align student embedding

As the **Stage 2** in Figure 2, we align the embedding bottleneck layer with the assistant embedding space through the loss function in (3),

$$\ell_{stage2} = \frac{1}{|N|}\sum_{i}^{N}\left[(h_{Ae}^{si} - h_{Be}^{si})^2 + (h_{Be}^{ti} - h_{Ae}^{ti})^2\right], \tag{3}$$

where h_{Ae}^{si}, h_{Ae}^{ti} denotes the output of assistant embedding layer, h_{Be}^{si}, h_{Be}^{ti} denotes the output of embedding bottleneck layer.

Stage 3. Teaching student

In the **Stage 3**, the student model is trained to imitate the output of the assistant model with loss function in (4),

$$\ell_{stage3} = \frac{1}{|N|}\sum_{i}^{N}\left[(h_A^{si} - h_S^{si})^2 + (h_S^{ti} - h_A^{ti})^2\right], \tag{4}$$

where h_A^{si}, h_A^{ti} denotes the output of assistant model, h_S^{si}, h_S^{ti} denotes the output of student model.

Stage 4. Multilingual contrastive learning

After the above three stages, we can get a small multilingual sentence embedding model. However, as shown in Figure 1, when the model size decrease, its cross-lingual performance decreases sharply. Therefore, in this stage, we propose multilingual contrastive learning (MCL) task further to improve the performance of the small student model.

Assuming the batch size is N, for a specific translation sentence pair (s_i, t_i) in one batch, the mean-pooled sentence embedding of the student model is (h_S^{si}, h_S^{ti}). The MCL task takes parallel sentence pair (h_S^{si}, h_S^{ti}) as positive one, and other sentences in the same batch $\left\{(h_S^{si}, h_S^{tj})|j \in [1, N], j \neq i\right\}$as negative samples. Considering that the MCL task needs to be combined with knowledge distillation. Unlike the previous work (Yang et al., 2019; Feng et al., 2020; Mao et al., 2021), the MCL task does not directly apply the temperature-scaled cross-entropy loss function.

Here, we introduce the implementation of the MCL task. For each pair of negative examples (s_i, t_j) in the parallel corpus, the MCL task first unifies (s_i, t_j) into the source language (s_i, s_j), then uses the fine-grained distance between h_T^{si} and h_T^{sj} in the teacher model to push away the semantic different pair (h_S^{si}, h_S^{tj}) in the student model. For positive examples, the MCL task pull semantically similar pair (h_S^{si}, h_S^{ti}) together. The MCL task loss is (5),

$$\ell_1 = \frac{1}{N^2}\sum_{i}^{N}\sum_{j}^{N}\left(\phi(h_T^{si}, h_T^{sj}) - \phi(h_S^{si}, h_S^{tj})\right)^2, \tag{5}$$

where ϕ is the distance function. Following prior work (Yang et al., 2019; Feng et al., 2020), we set $\phi(x, y) = cosine(x, y)$. we also add the knowledge distillation task for multilingual sentence representation learning. The knowledge distillation loss is defined as,

$$\ell_2 = \frac{1}{|N|}\sum_{i}^{N}\left[(h_T^{si} - h_S^{si})^2 + (h_T^{si} - h_S^{ti})^2\right], \tag{6}$$

In stage 4, the total loss function is added by ℓ_1 and ℓ_2.

$$\ell_{stage4} = \ell_1 + \ell_2. \tag{7}$$

Table 1: Spearman rank correlation ($\rho \times 100$) between the cosine similarity of sentence representations and the gold labels for STS 2017 **monolingual** dataset. b indicates whether to use the Embedding Bottleneck strategy, bs indicates the hidden size of Bottleneck layer. $|RU|$ indicates the first $|RU|$ layers from the basic model are taken as Recurrent Unit, the recurrent times = basic model layers/$|RU|$.

4 Experimental results

4.1 Evaluation setup

Dataset. The semantic text similarity (STS) task requires models to assign a semantic similarity score between 0 and 5 to a pair of sentences. Following Reimers and Gurevych (2020), we evaluate our method on two multilingual STS tasks, i.e., STS2017 (Cer et al., 2017) and STS2017-extend (Reimers and Gurevych, 2020), which contain three monolingual tasks (EN-EN, AR-AR, ES-ES) and six cross-lingual tasks (EN-AR, EN-ES, EN-TR, EN-FR, EN-IT, EN-NL).

Parallel corpus. In stage 1, stage 2 and stage 3, we use TED2020 (Reimers and Gurevych, 2020), WikiMatrix (Schwenk et al., 2021), Europarl (Koehn, 2005) and NewsCommentary (Tiedemann, 2012) as parallel corpus for training. In stage 4, TED2020 is used for contrastive learning. In this way, the student model first learns generalized multilingual knowledge and then possesses semantic similarity capabilities.

Metric. Spearman's rank correlation ρ is reported in our experiments. Specifically, we first compute the cosine similarity score between two sentence embeddings, then calculate the Spearman rank correlation ρ between the cosine score and the golden score.

4.2 Implementation details

Mean pooling is applied to obtain sentence embeddings, and the max sequence length is set to 128. We use AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of 2e-5 and a warm-up of 0.1. In stage1, stage2, and stage3, the models are trained for 20 epochs with a batch size of 64, while in stage 4, the student model is trained for 60 epochs. The mBERT, XLM-R used in this work are base-size model obtained from Huggingface's *transformers* package (Wolf et al., 2020), and the MiniLM refers to *MiniLM-L12-H384*[2]. Our implementation is based on *UER*(Zhao et al., 2019).

4.3 Performance comparison

We compare the model obtained from our multi-stage distillation with the previous state-of-the-art models, and results are shown in Table 1 and Table 2. In *Pre-trained Model*, `mBERT(mean)` and `XLM-R(mean)` are mean pooled mBERT and XLM-R models. `mBERT-nli-stsb` and `XLM-R-nli-stsb` are mBERT and XLM-R fine-tuned on the NLI and STS training sets. LASER and LaBSE are obtained from Artetxe and Schwenk (2019) and Feng et al. (2020). In *Knowledge Distillation*, we use the paradigm of `Student`←`Teacher` to represent the `Student` model distilled from the `Teacher` model. There

Table 2: Spearman rank correlation ($\rho \times 100$) between the cosine similarity of sentence representations and the gold labels for STS 2017-extend **cross-lingual** dataset. b indicates whether to use Embedding Bottleneck strategy, bs indicates the hidden size of Bottleneck layer. $|RU|$ indicates the first $|RU|$ layers from the basic model are taken as Recurrent Unit, the recurrent times = basic model layers/$|RU|$.

are two teacher models, i.e., `SBERT-nli-stsb` and `SBERT-paraphrases`, which are released by UKPLab[3]. The former is fine-tuned on the English NLI and STS training sets, and the latter is trained on more than 50 million English paraphrase pairs. The student models include mBERT, XLM-R, DistilmBERT (Sanh et al., 2019) and MiniLM (Wang et al., 2021).

Table 1 and Table 2 show the evaluation results on monolingual and multilingual STS task, respectively. For the XLM-R, our method compresses the embedding size by 83.2% with 0.3% worse monolingual performance and 0.9% worse cross-lingual performance, compresses the encoder size by 75% with slightly higher (0.4%) monolingual performance and 0.5% worse cross-lingual performance. When compressing the embedding layer and the encoder simultaneously, the model size is reduced by 80.6%, its monolingual performance drop by 2% and cross-lingual performance drop by 4%, but it still outperforms the pre-trained models.

For comparison with other distillation methods, MiniLM← SBERT-paraphrases is taken as a strong baseline. Our framework can further compress its embedding size by 66.7% with 0.6% worse in monolingual performance and 1.1% worse in cross-lingual performance. Its encoder size is further compressed by 75% with slightly higher monolingual (0.1%) and cross-lingual (0.4%) performance. In addition, our compressed XLM-R($b = True$, $bs = 128$, $|RU| = 12$) achieves higher monolingual(0.8%) and cross-lingual(1.9%) performance with the same model size.

4.4 Ablation study

Among the three key strategies, multilingual contrastive learning (**MCL**) and parameter recurrent (**Rec.**) are two crucial mechanisms to improve model performance. The bottleneck is used to compress the model. In this section, ablation studies is performed to investigate the effects of **MCL** and **Rec.**. The effects of the bottleneck will be dis-

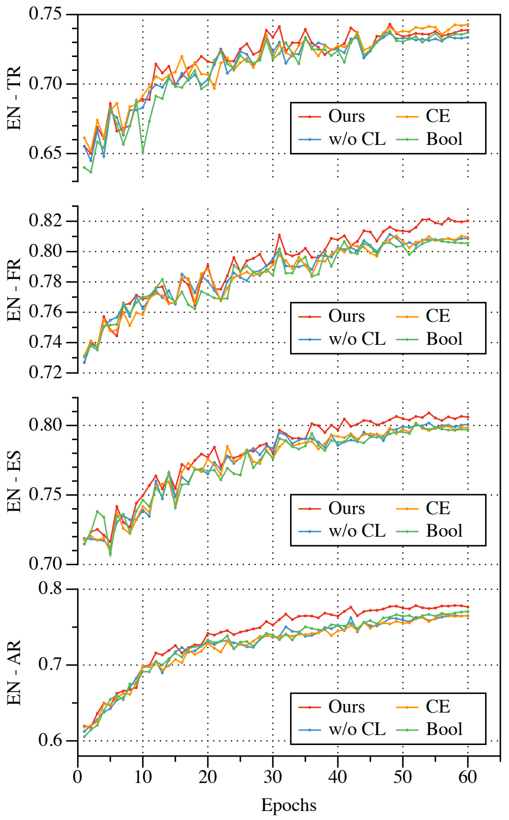

Figure 3: Performance of XLM-R (b=True, bs=128, $|RU|$ = 3) after each training epoch on EN-AR, EN-ES, EN-FR, EN-TR tasks with different contrastive learning settings.

cussed in section 4.7.

XLM-R(b=True, bs=128, $|RU|$ = 3) is selected as the basic model. We consider three different settings: 1) training without MCL task. 2) training without parameter recurrent. 3) training without both. The monolingual results and multilingual results are presented in Table 3 and Table 4.

It can be observed that: 1) without MCL task, the model performs poorer on the cross-lingual tasks. 2) without parameter sharing, the model performs poorer on all datasets. 3) MCL task can significantly improve the cross-lingual performance on EN-AR, EN-ES, EN-FR, EN-NL. It can be concluded that both MCL task and parameter recurrent play a key role in our method.

4.5 Effect of contrastive learning

To investigate the effects of contrastive learning in stage 4, we select XLM-R(b=True, bs=128, $|RU|$ = 3), modify the original objective in (5) into three different settings, namely, *Bool*, *CE* and *w/o CL*.

In the *Bool* setting, the soft label in (5) is replaced with hard label (0 or 1), as (8),

Settings	**EN-AR**	**EN-DE**	**EN-TR**	**EN-ES**	**EN-FR**	**EN-IT**	**EN-NL**	**Avg.**
`Ours`	78.0	79.8	73.9	80.5	82.1	80.3	81.2	79.4
Bool	77.0↓	80.5↑	73.5↓	79.8↓	80.3↓	80.7↑	81.2	79.0↓
CE	76.6↓	79.9↑	74.3↑	80.0↓	80.8↓	80.6↑	80.7↓	78.9↓
w/o CL	75.9↓	79.7↓	73.2↓	79.9↓	80.4↓	80.4↑	80.5↓	78.5↓

Table 5: Evaluation results of XLM-R ($b = True, bs = 128, |RU| = 3$) on the STS2017-extend cross-lingual task with different contrastive learning settings.

Settings	**Avg. (Monolingual)**	**Avg. (Cross-lingual)**
Single-stage		
Random Initialize	78.1	71.1
+ Pre-Distillation	79.0	73.8
Multi-stage		
stage 1 + 2	48.4	20.8
stage 1 + 2 + 3	75.2	70.6
stage 1 + 2 + 3 + 4	**82.6**	**79.4**

Table 6: Comparison of using different stage settings on monolingual and multilingual STS task. XLM-R is the basic model. The first three layers from XLM-R are taken as a Recurrent Unit, bottleneck hidden size is 128.

$$\ell_{Bool} = \frac{1}{N^2}\sum_{i}^{N}\sum_{j}^{N}\left(\delta(h_T^{si}, h_T^{sj}) - \phi(h_S^{si}, h_S^{tj})\right)^2, \tag{8}$$

where $\delta(x, y) = 1$, if $x = y$, otherwise 0.

In the *CE* setting, the objective in (5) is replaced with temperature-scaled cross-entropy, as (9),

$$\ell_{CE} = -\sum_{i}^{N}\sum_{j}^{N}\phi_T \log\frac{e^{\phi_S/\tau}}{\sum_{k=1}^{N} e^{\phi_S/\tau}}, \tag{9}$$

where $\phi_T = cos(h_T^{si}, h_T^{sj})$, $\phi_S = cos(h_S^{si}, h_S^{tj})$, $\tau = 0.05$ is a hyperparameter called temperature.

In the *w/o CL* setting, the contrastive learning is removed in Stage 4.

Table 5 presents the model performance of cross-lingual semantic similarity task with different settings. It can be observed that all the above training objectives can improve the model performance on the cross-lingual task, compared with the *w/o CL* settings. Model trained with (8) and (9) underperform that trained with (5), especially on EN-AR, EN-ES, EN-FR, EN-NL task.

We plot the convergence process of different settings in Figure 3. On EN-AR, EN-ES, EN-FR tasks, our setting outperform other settings. It is worth mentioning that on the EN-TR task, our setting underperform the *CE* setting according to Table 5. However, our setting reaches the same level as *CE* setting during the 30 to 40 epoch.

4.6 Effect of multi-stages

To verify the effectiveness of multi-stages, we shows the performance comparison of using different stage settings in Table 6. In the *Single-stage* setting, we first initialize the shrunk student model in two ways: (1) Random Initialize: Adding the untrained embedding bottleneck layers to the student model. (2) Pre-Distillation: The student model with bottleneck layer is initialized by distillation using XLM-R and the same corpus as section 4.1. Then we follow Reimers and Gurevych (2020) to align vector space between different languages. In the *Multi-stage* setting, the performance of the student model is reported after each stage.

As shown in Table 6, the *Multi-stage* setting outperforms the single-stage one, indicating that our multi-stage framework with an assistant model is effective. Adding stage3 and stage4 further improves the student model performance, suggesting that multi-stage training are necessary.

4.7 Effect of bottleneck and recurrent unit

In this section, we study the impact of embedding bottleneck and recurrent unit strategies on multilingual semantic learning. We consider three settings for each strategy, as shown in Table 7 and Table 8.

First, we found that both XLM-R and MiniLM perform better as the bottleneck hidden size bs increases. The performance is best when the entire embedding layer is retained, The MiniLM(b=False) can outperform its original model in Table 1 and Table 2. But the benefit of increasing bs is not obvious unless the entire embedding layer is retained.

Second, by increasing the number of recurrent unit layers $|RU|$, XLM-R and MiniLM have been steadily improved on these two tasks. The increase in model size caused by the $|RU|$ is less than the bs. For example, the performance of MiniLM on cross-lingual tasks increased by 8%, while its size only increased by 15.9M.

Finally, it can be observed that when using the bottleneck layer (b=True), the model performance will increase steadily as $|RU|$ increases. The smaller the encoder hidden size, the more significant effect caused by $|RU|$ increasing (ΔMiniLM>ΔXLM-R). However, the increase of bs can not improve performance significantly but make the embedding size larger. Therefore, an effective way to compress the multilingual model is reducing bs while increasing $|RU|$. In this way, we shrink XLM-R by 58%, MiniLM by 55%, with less than 1.1% performance degradation.

5 Conclusion

In this work, we realize that the cross-lingual similarity matching task requires a large model size. To obtain a small-size model with cross-lingual matching ability, we propose a multi-stage distillation framework. Knowledge distillation and contrastive learning are combined in order to compress model with less semantic performance loss.

Our experiments demonstrate promising STS results with three monolingual and six cross-lingual pairs, covering eight languages. The empirical results show that our framework can shrink XLM-R or MiniLM by more than 50%. In contrast, the performance is only reduced by less than 0.6% on monolingual and 1.1% on cross-lingual tasks. If we slack the tolerated loss performance in 4%, the size of XLM-R can be reduced by 80%.

On the Limitations of Dataset Balancing:
The Lost Battle Against Spurious Correlations

Roy Schwartz **Gabriel Stanovsky**
School of Computer Science, The Hebrew University of Jerusalem
`{roy.schwartz1,gabriel.stanovsky}@mail.huji.ac.il`

Abstract

Recent work has shown that deep learning models in NLP are highly sensitive to low-level correlations between simple features and specific output labels, leading to overfitting and lack of generalization. To mitigate this problem, a common practice is to balance datasets by adding new instances or by filtering out "easy" instances (Sakaguchi et al., 2020), culminating in a recent proposal to eliminate single-word correlations altogether (Gardner et al., 2021). In this opinion paper, we identify that despite these efforts, increasingly-powerful models keep exploiting ever-smaller spurious correlations, and as a result even balancing all single-word features is insufficient for mitigating all of these correlations. In parallel, a truly balanced dataset may be bound to "throw the baby out with the bathwater" and miss important signal encoding common sense and world knowledge. We highlight several alternatives to dataset balancing, focusing on enhancing datasets with richer contexts, allowing models to abstain and interact with users, and turning from large-scale fine-tuning to zero- or few-shot setups.

1 Introduction

Effective human communication relies on our ability to understand extra-textual context based on common sense, world knowledge or shared cultural experiences, a property often cited as Grice's second maxim of quantity: "Do not make your contribution more informative than is required" (Grice, 1975, 1989). Studies have estimated that only 12% of the information conveyed by text is mentioned explicitly (Graesser, 2013; Tandon et al., 2020). To illustrate this, consider the question "*who is the president of the U.S.*?". To answer it, a human reader is likely to presume many unstated propositions, as exemplified in Tab. 1.

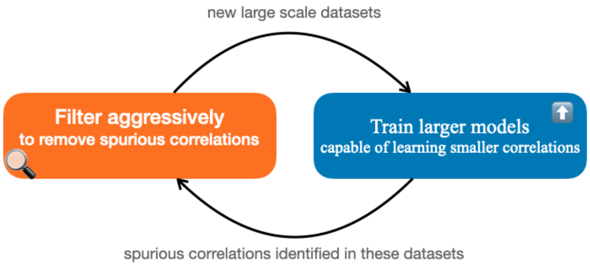

Figure 1: A high-level overview of the current state of supervised NLP research. Dataset developers create more aggressive filtering techniques (left), leading to larger models that are able to solve them by finding more elusive spurious correlations (right).

Who is the president of the U.S.?

Context	**Answer**
∅	Joe Biden
The year 2019	Donald Trump
The West Wing, season 1	Josiah "Jed" Bartlet

Table 1: Context, whether explicit or implicit, matters in textual understanding, as exemplified by the question "*who is the president of the U.S.*?". E.g., in the first line, given no other context, a QA system should provide the most sensible fallback answer (*Joe Biden*, at the time of writing).

In contrast to humans, supervised models often fail to generalize and understand implicit context, instead resorting to low-level correlations in the data, leading to amplified bias (Zhao et al., 2017; Stanovsky et al., 2019) and brittle performance (Schwartz et al., 2017; Gururangan et al., 2018). To address this, recent approaches have suggested mitigating such correlations by *balancing* the dataset via either adding or removing certain instances (Goyal et al., 2017; Hudson and Manning, 2019; Zellers et al., 2018; Sakaguchi et al., 2020). In parallel, developers keep building larger and larger pretrained models (Devlin et al., 2019; Liu et al., 2019; Raffel et al., 2020), which, when *fine-tuned* on these datasets, consistently manage to reach human performance. Taken together, these trends lead to an arms-race between data curation

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2182 - 2194
July 10-15, 2022

and model development (Fig. 1).

In this position paper, we question the value of mitigating spurious correlations via dataset balancing, by showing that their existence in large training sets is both inevitable and to some extent even desired, as they are an inherent property of natural language understanding. We build on a recent result by Gardner et al. (2021), who assumed that every single-word feature correlation is *spurious*, i.e., can be used to mislead a model. We extend their argument, showing that balancing single-word features is insufficient for eliminating all spurious correlations, and that balancing feature combination is needed for that purpose. On the other hand, we show that balancing too much leads to datasets that contain no learnable signal either. We conclude by questioning whether mitigating all spurious correlations via dataset balancing is *practical*.

Following, we show that this practice is also *undesired*. We show that ignoring these correlations will hinder the learning of fallback options for both world knowledge facts (*Joe Biden is the president of the U.S.*) and common sense knowledge (*a person is happy when receiving a gift*), thus preventing models from using this knowledge in cases of uncertainty. We conclude that the existence of spurious correlations in training sets should not be solved by creating more balanced datasets.[1]

We then discuss alternatives to mitigating spurious correlations. We argue that models should be trained to understand constructions emanating from an apriori theory of language, such as negation, sarcasm, humor, and metaphors. We also suggest adopting modeling approaches that identify when the context is insufficient. We argue that in such cases, the model should *not* fallback to default assumptions, but rather abstain or interact with the user to clear ambiguities. Finally, we question the basic procedure of large-scale fine-tuning, and suggest focusing on zero- and few-shot learning instead (Liu et al., 2021b).

2 Dataset-Model Arms Race

This section provides a view of recent research in NLP as an *arms race* between models and datasets. Below we describe the conditions leading to this arms race, and present our main research question, challenging its value for making progress in NLP.

Figure 2: An example of dataset balancing (adapted from Goyal et al., 2017). For each (question, image) pair in the VQA dataset (left), VQA2.0 adds another image, for which the answer is different (right).

Models exploit spurious correlations While pretrained models consistently perform well across multiple tasks, various studies have pointed out that this is often achieved by exploiting spurious correlations in datasets, rather than improving on the underlying task (Glockner et al., 2018; Gururangan et al., 2018; Elazar et al., 2021), and that this phenomenon becomes more prominent as the models grow in size (Li et al., 2021).

Mitigating spurious correlations via balancing Various dataset curators have tried to prevent models from learning spurious correlations by modifying their training data via a careful control for the training label distribution, effectively striving for a *balanced* dataset. One approach is to *add* examples in order to balance the dataset (Goyal et al., 2017; Sharma et al., 2018; Hudson and Manning, 2019). For instance, the VQA2.0 dataset (Goyal et al., 2017) is built by taking every (question q, image i, answer a) triplet in the VQA dataset (Antol et al., 2015), and adding another triplet with the same question q, but a different image i', guaranteed to lead to a different answer a'. See Fig. 2 for an example.

Filtering as balancing A complementary balancing approach to augmentation is *filtering* examples out from datasets such that spurious correlations are minimized. This approach was taken in the creation of the SWAG dataset (Zellers et al., 2018), using “adversarial filtering” (AF). In AF, dataset instances that are easily solved by an adversarial model are filtered out. The AF approach and similar approaches were picked up by many datasets such as ReCoRD (Zhang et al., 2018), DROP (Dua et al., 2019), HellaSWAG (Zellers et al., 2019), αNLI (Bhagavatula et al., 2020), and

---

[1] We emphasize that balancing methods are still useful as they can lead to mitigation of *some* spurious correlations, and therefore better generalization (Le Bras et al., 2020; Swayamdipta et al., 2020), as well as potentially more efficient training. We argue that these methods are inherently limited in their ability to mitigate *all* spurious correlations.

WinoGrande (Sakaguchi et al., 2020).

Here we argue that approaches like AF converge to removing all low-level correlations,[2] and therefore a fully balanced dataset. As this approach relies on an external model, applying it with ever stronger models with higher capacity, will allow these models to pick up on subtler correlations (Li et al., 2021). At the extreme, the remaining instances that could not be solved by a fully capable model will have no statistical signal that can be exploited by that model, i.e., a balanced dataset. We henceforth refer to both augmentation and filtering as *balancing* methods.

Large models solve the new datasets In parallel to the efforts in dataset balancing, the leading *modeling* approach in recent years in NLP is pretraining large language models on raw text corpora, followed by fine-tuning them on supervised downstream applications. These models continue to grow in size (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019; Radford et al., 2019; Raffel et al., 2020), and their fine-tuning performance improves accordingly. This in turn leads to more aggressive balancing, setting in motion a kind of *arms race* between datasets and models (Fig. 1).

Evidently, a similar trend emerges for the previously mentioned datasets: (1) the first baselines, reflecting the state of the art at the time of dataset creation, perform relatively poorly, e.g., 59% on SWAG, 47% on ReCoRD, 47 F1 on DROP, 47% on HellaSWAG, 69% on αNLI, and 79% on WinoGrande; (2) model developers introduce increasingly larger and heavily-parameterized models, hill-climbing on these datasets; and eventually (3) models essentially solve the dataset within a year or two, often outperforming humans: 86% on SWAG (Devlin et al., 2019), 94% on ReCoRD (He et al., 2021b), 88 F1 on DROP (Chen et al., 2020), 93% on HellaSWAG (He et al., 2021b), 92% on αNLI (He et al., 2021a), and 90% on WinoGrande (Raffel et al., 2020). (4) new large-scale datasets are collected with more aggressive pruning techniques, thus repeating the cycle.

Based on these findings, our main research question is whether dataset balancing is the most promising method for mitigating spurious correlations. We note that an arms race between models and datasets might spur advances. Here we question a specific aspect of this arms race: the improvement of datasets by using more aggressive filtering techniques. Next we turn to present practical and conceptual limitations of this practice.

Name	Description
`ingenuine`	Correlations between features and output labels for no reason.
`ungeneralizable`	Correlations that do not generalize to new contexts.
`every-word`	Correlations between every single-word feature and output label.

Table 2: Different definitions of *spurious correlations*.

3 The Lost Battle Against Spurious Correlations

So far we have identified dataset balancing as a common way to mitigate spurious correlations. Next, we outline how different works define spurious correlations (Sec. 3.1), and then question whether dataset balancing is a viable way for mitigating them; we note that balancing too little is bound to leave spurious correlations in the data (Sec. 3.2), while balancing too much discards meaningful signal (Sec. 3.3). We finish by questioning whether this practice is even desired (Sec. 3.4).

3.1 What are Spurious Correlations?

Mitigating spurious correlations is frequently used as motivation for developing new balancing approaches. However, the term *spurious correlations* is often not clearly and consistently defined. The basic definition is a set of features that are correlated but not causally related.[3]

In NLP, several definitions of spurious correlations are typically used. One conceptual definition, denoted here `ingenuine` (e.g., Wang and Culotta, 2020; Rogers, 2021) is a feature correlated with some output label for no apparent reason. Such features often result from the annotation process (referred to as *annotation artifacts*; Gururangan et al., 2018). For instance, Gururangan et al. (2018) have shown that the words “cat” and “sleeping” are correlated with contradictions in the SNLI dataset (Bowman et al., 2015).

This definition is appealing: we want our models to learn real information about the world, and not properties of a given dataset. However, it is also

---

[2] Indeed, AFLite, an extension of AF, was designed to “systematically discover and filter *any* dataset artifact in crowdsourced commonsense problems” (Le Bras et al., 2020, emphasis in the original).

[3] `https://en.wikipedia.org/wiki/Spurious_relationship`

somewhat subjective, and could include features that might be referred to as genuine, such as the word "not" indicating NLI contradictions. Further, genuine features, i.e., those representing a real phenomenon in the world (e.g., "amazing" as a feature for positive sentiment), are also likely to lead models make to erroneous predictions in some contexts (e.g., negation or sarcasm; Gardner et al., 2021). Such features could thus harm generalization, so some might consider them spurious as well.[4]

In an alternative definition, denoted `ungeneralizable`, a spurious feature is one that works well for specific examples but does not hold in general (Chang et al., 2021; Yaghoobzadeh et al., 2021). This definition does not address the nature of the feature (genuine or not), but does make an implicit assumption that such features are of high importance (e.g., high pointwise mutual information values with the corresponding label; Gururangan et al., 2018). This definition is no longer subjective in terms of the genuineness of the feature, but is still subjective in the level of effect on generalizability (i.e., what is a *high* value of PMI?).

Gardner et al. (2021) relaxed the last constraint, and assumed that *every* simple correlation between single word features and output labels is spurious (henceforth `every-word`). They then defined a class of *competent* datasets, where the marginal probability for every feature is uniform over the class label, i.e., for any feature x_i and label $y \in Y$, $p(y|x_i) = \frac{1}{|Y|}$, thus limiting models from picking up any correlation between single features and output labels.

We next extend the `every-word` approach beyond single words, showing that models that can exploit single word features can also exploit some feature interactions, and therefore these should also be considered spurious. Tab. 2 summarizes the different definitions of spurious correlations.

3.2 Balancing too Little Leaves some Spurious Features

Gardner et al. (2021) assumed that as each word can appear in certain contexts that change its semantic meaning (e.g., negation, sarcasm), each word is potentially spurious. Here we note that the same argument can be applied to feature interactions, such as word n-grams. We start with a toy example to illustrate our argument for bigrams, and then extend it for larger values of n.

Split	**Text**	**Label**
Train	very good	$+$
	very bad	$-$
	not good	$-$
	not bad	$+$
Test	not very good	$-$
	good	$+$

Table 3: A toy example of a training set (*Train*), which is balanced for unigrams, but not for bigrams. Relying on the bigram correlations (e.g., memorizing that "very good" leads to a positive sentiment) will lead to mispredictions on the test set (*Test*).

Consider the toy dataset for the task of sentiment analysis shown in Tab. 3, with vocabulary V={*good, bad, not, very*}, and label set $Y = \{ +, - \}$. The *Train* split is balanced with respect to single-word features, i.e., it is a *balanced* or *competent* dataset:

$$\forall w \in V, y \in Y \ : \ p(y|w) = \frac{1}{|Y|}$$

Assume the semantics of this dataset is that of English, while '$+$' means positive sentiment and '$-$' means negative.

A model trained on *Train* can achieve perfect training accuracy by learning the correct semantics. However, achieving perfect training accuracy can also be done by learning correlations between *two-word* features and the target label (i.e., memorizing all the training examples). In this case, the model would make the wrong prediction for the first test example in *Test* (as it has learned that *very good* is a feature that indicates positive sentiment), and similarly, will make a random prediction for the second test example, which does not contain any two-word feature seen during training.

This example highlights that balancing single-word features does not guarantee resiliency to spurious correlations, and therefore in order to mitigate all spurious correlations, balancing pairs of features is also required. One can construct similar examples for larger values of n, by similarly considering multi-word expressions and common co-occurrences (e.g., "jaw dropping", "worst day ever"). These could serve as spurious correlations in the same way single words do.

Another example is sarcasm. A model that fails to understand sarcastic contexts will misinterpret

---

[4] See Eisenstein (2022) for discussion of different feature types.

Original Train Set		Augmented Samples	
Input	**Label**	**Input**	**Label**
0 0	0	*0 0	1
0 1	1	*0 1	0
1 0	1	*1 0	0
1 1	0	*1 1	1

Table 4: Left: a training set for the XOR function, balanced for unigrams. Right: requiring that bigrams are also balanced would prevent models from learning.

statements that appear in such contexts, even if it perfectly understands the base meaning of these statements. Thus, the entire reasoning process of such a model, whether relying on simple features, feature interactions, or other types of understanding, will result in mispredictions of certain inputs, and thus can be considered spurious.

As a result, to truly mitigate all spurious correlations in a dataset, balancing feature combinations is required as well. Accordingly, balancing too little will leave some spurious correlations in the dataset.

3.3 Too much Balancing Prevents Learning Valuable Semantic Knowledge

We observed that balancing too little does not allow models to fully eliminate spurious correlations. Here we show that too much balancing can prevent models from learning valuable knowledge.

Consider the training data for learning the XOR function presented in Tab. 4 (left). This dataset contains enough learnable signal when considering feature interactions despite being balanced for single words. Nonetheless, balancing this dataset for *pairs of features* would result in no information, and thus prevent any model from learning this function (Tab. 4, right).

Now consider a given natural language dataset D. Define n to be the length of the longest document in D. By definition, balancing every combination of up to n features leaves no learnable signal in D.[5] We conclude that balancing too much can prevent models from learning semantic knowledge.

Combining the two observations, we are left with the question of the potential intersection between balancing too much and balancing too little: does a sweet spot exist for which no spurious correlations are found in the dataset, but enough learnable signal is left? And even if so, would a balancing algorithm, whether by augmentation or filtering, be able to find it? We leave these questions for future work, but note that addressing them is a prerequisite for the theoretical and practical application of dataset balancing for mitigating spurious correlations.

3.4 Dataset Balancing is *Undesired*

Even if a sweet spot exists between balancing too little and too much, do we really want to find it? Here we argue that perhaps not.

The practice of dataset balancing is designed to prevent models from learning that some words or expressions have a common fallback meaning that can stem from dataset artifacts (e.g., “cat” as an indicator of contradiction) but also from cultural and historical contexts (e.g., Biden is the U.S. president in 2022). Fallback meanings are crucial for understanding language, as contexts are often underspecified (Graesser, 2013). Indeed, relying on fallback meanings might make models fail to process some inputs correctly, and might not generalize to other domains where the fallback meaning is different. We argue that the ability to use them is a central ability of language understanding.

For example, substantial efforts are made to teach models *world knowledge*, such as that the president of the U.S. is Joe Biden, the capital of Brazil is Brasília, and France is the soccer world champion. These efforts include building world knowledge datasets (Wang et al., 2021), developing methods for enhancing models with this information (Zhang et al., 2019; Peters et al., 2019), and evaluating how well models capture it (Rubinstein et al., 2015; Roberts et al., 2020). But many of these world-knowledge facts are context dependent: the capital of the Brazil has changed in 1960, the president of the U.S., as well as soccer world champions potentially change every 4 years, etc.

Another example is *common sense knowledge*, such as “people are happy when they receive a gift”, “an elephant is taller than a zebra”, and “a statue that doesn’t fit into a suitcase is too large”. A large body of work has been carried out to create benchmarks that measure the common sense abilities of models (Liu and Singh, 2004; Levesque et al., 2012; Zellers et al., 2018; Sakaguchi et al., 2020; Bisk et al., 2020), as well as augmenting models with such abilities (Qin et al., 2020; Bosselut et al., 2021).

Common sense reasoning is, by definition, stochastic and reliant on understanding presup-

---

[5] We assume the standard data collection process when using AF, in which the last step is balancing (Zellers et al., 2018; Dua et al., 2019), and longer instances cannot be added.

posed, underspecified context. One could imagine a person unhappy to receive a gift (e.g., because it is not what they wanted), a fantastically large zebra compared to a tiny elephant, and a suitcase with multiple compartments which prevent a small statue from fitting in it.

These examples illustrate that a model that learns these correlations and relies exclusively on them to make predictions is limited and is bound to make mistakes in some contexts. One way to avoid these mistakes is to balance these correlations out, and prevent models from knowing these assertions to begin with. We argue that this solution is not a *desired* solution. In essence, an interpreter's task (be it human or machine) is to infer the most probable context in which a statement is made, and as a result, it *should* have a fallback option for such world knowledge and common sense assertions.

Discussion We recognize that a balanced dataset may not be balanced with respect to the appearance of common-sense or world-knowledge assertions *in a given context*. E.g., a model might balance-out the general fact that Joe Biden is the U.S. president, but *not* that he is the president in 2022. As in many cases much of the context is unobserved (Graesser, 2013), the question is whether we want models to make a prediction in cases of uncertainty based on the fallback option. We argue that doing so is a desired strategy in many cases (though a preferred strategy might be to interact of abstain from making a decisive prediction, see Sec. 4.2).

We also acknowledge that correlations in the real world can be misleading. For instance, people often mistake the biggest commercial city in some countries for their capital (e.g., Istanbul in Turkey), potentially due to the high correlation between the two. In such cases, relying on the fallback option might lead to prediction error. However, we argue that following the human strategy of relying on a fallback option in cases of uncertainty will promote models' communication abilities.[6]

We want to stress that balancing methods can result in mitigating *some* of the spurious correlations, and therefore lead to increased generalization (Le Bras et al., 2020; Swayamdipta et al., 2020). Moreover, the process of filtering the data naturally results in smaller datasets, which leads to lower training costs (Swayamdipta et al., 2020). While such contribution is meaningful in terms of, e.g., environmental concerns (Strubell et al., 2019; Schwartz et al., 2020), it is orthogonal to our research question. Overall, despite the important contributions of balancing techniques, this paper shows that even the perfect balancing method might not mitigate all spurious correlations in a satisfying way.

So how can we make models more resilient to spurious correlations without balancing the data? Below we discuss several ideas for doing this.

Current Practice	**Proposal**
Dataset balancing	Richer contexts (§4.1)
A closed label set	Abstain/interact (§4.2)
Large-scale fine-tuning	Few-shot learning (§4.3)

Table 5: Our suggestions for mitigating the effects of spurious correlations, listing three current practices, each with an alternative proposal.

4 Ways to Move Forward

So far, we presented limitations of dataset balancing as a means to mitigate spurious correlations. In this section we discuss several alternatives to this practice, summarized in Tab. 5. We note that none of these proposals is particularly novel. Rather, we intend to survey alternatives proposed in literature and argue that these may be promising for addressing the drawbacks of spurious correlations, and that more efforts should be put into studying them.

4.1 Augmenting Datasets with Rich Contexts

The implicit assumption of dataset balancing is that in order to mitigate spurious correlations the model has to *unlearn* them, that is, they should be removed altogether from the training set. We argue that instead we should be focusing on learning and modeling richer contexts.

As an example, consider negation. A model that generalizes well, should learn the meaning of words such as *not*, and should be able to negate new words, even those that were seen only in positive contexts at training time. For example, if a model only sees during training words like "amazing" or "happy" with positive sentiment, and thus learns that these words bear positive meaning, we would still expect it to interpret their negated appearance (e.g., *not amazing*) as an indicator of *negative* sentiment. Such generalization is crucial for language learning, and should ideally allow models to not rely exclusively on spurious correlations. Despite

---

[6] A counter example is social biases, where we want to explicitly discourage models from having a fallback option (see Sec. 4.4 for discussion).

the immense progress in the field in the past decade, negation still poses a challenge to modern NLP tools (Hossain et al., 2020, 2022).[7]

We suggest taking into account different types of contexts during dataset design. In particular, collecting training examples with contexts such as negation (Morante and Blanco, 2012), humor (Weller and Seppi, 2019; Annamoradnejad and Zoghi, 2020), sarcasm (Davidov et al., 2010; Oprea and Magdy, 2020), or metaphors (Tsvetkov et al., 2014; Mohammad et al., 2016). This recommendation applies to both supervised tasks, and perhaps more so to pretrained data. We suggest adding documents with such contexts throughout the pretraining corpus, or as a continued pretraining step to existing large-scale models.[8]

To incorporate contexts from a wide range of phenomena, we can leverage the vast literature on broad-coverage semantics (Baker et al., 1998; Steedman and Baldridge, 2006; Banarescu et al., 2013; Abend and Rappoport, 2013).[9] This line of work proposes theories of language, composing inventories of linguistic constructions with an algebraic formulation of their inter-relations in terms of truth value, factuality, and more. These inventories often include the phenomena discussed above, such as negation, sarcasm, and presupposition.

4.2 Interaction and Abstention to Cope with Underspecified Contexts

Most NLP tasks are designed with a closed label set that forces models to make a concrete prediction for each test instance, without an option to abstain or interact with the user to get more information. Even for tasks with a large label set (e.g., language modeling), models still have to output a valid vocabulary item. Here we argue that this practice creates an *inductive bias* towards using spurious correlations in cases of uncertainty, as the model has "nothing to lose" in case of low certainty, and is encouraged to always make some prediction, potentially relying on spurious correlations.[10]

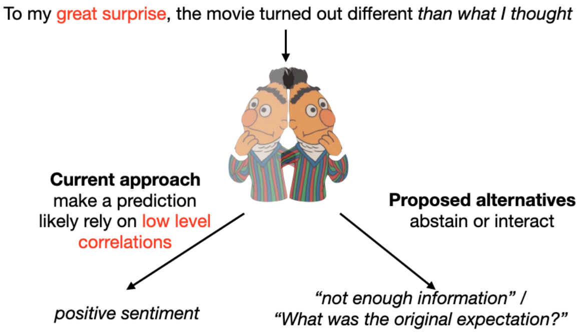

Figure 3: An example of abstention/interaction in cases of uncertainty. For the task of sentiment analysis, models currently assign a label to each input, even for ambiguous or underspecified ones (top). This may lead the model to over-rely on spurious correlations (marked in red, bottom left). Models that abstain or interact (bottom right) might learn to rely less on such correlations.

To further illustrate this point, consider the ambiguous sentence "*To my great surprise, the movie turned out different than what I thought*.", in the context of sentiment analysis. The reader cannot infer whether the writer is pleasantly surprised (a positive review) or disappointed (a negative review). We argue that in such cases models might lean towards a positive sentiment based on the words "great" and "surprise", which are typically correlated with a positive sentiment.

To test this, we ran a RoBERTa-large model (Liu et al., 2019) fine-tuned on SST-2 (Socher et al., 2013) on that example.[11] As expected, the model returns a *positive* label, with 99.99% confidence. Interestingly, three different interpretation methods (simple gradient visualization, Simonyan et al., 2014; integrated gradient visualization, Sundararajan et al., 2017; and SmoothGrad, Smilkov et al., 2017) all find the word "great" or "surprise" to be one of the three most influential words on the model's prediction. While this example does not prove the prevalence of this problem, it does demonstrate its existence.

To address this problem, we suggest adopting approaches that allow models to abstain and interact when they cannot make a decision with high confidence (Chow, 1957; Hellman, 1970; Laidlaw and Feizi, 2019; Balcan et al., 2020). See Fig. 3. This can be achieved by building datasets with unanswerable questions (Ray et al., 2016; Rajpurkar et al., 2018; Sulem et al., 2021), but also by designing models that abstain in cases of low certainty for

---

[7] Though we should continually assess the challenge negation poses on the most recent models (Bowman, 2022).

[8] We recognize that editing pretrained corpora poses significant challenges due to their immense size, as demonstrated by recent efforts such as corpus analysis (Dodge et al., 2021) and deduplication (Lee et al., 2022).

[9] See Abend and Rappoport (2017) for a survey.

[10] We recognize that in some cases we do want the model to make a prediction under cases of uncertainty (see Sec. 3.4). The ability to detect when is it reasonable to make an educated guess is an important property of an intelligent agent, and an exciting research question.

[11] We used the AllenNLP demo (`https://demo.allennlp.org/sentiment-analysis/`).

all inputs, even those with an unambiguous gold label.[12] We hypothesize that encouraging the model to provide this output when it is unsure, rather than making a semi-educated guess, potentially based on spurious correlations, could reduce its dependency on such correlations.

4.3 The End of Large-Scale Fine-Tuning?

This paper has demonstrated the limitations of mitigating spurious correlations via dataset balancing. A naive way to mitigate spurious correlations is to stop using large-scale datasets altogether. We echo recent calls (Liu et al., 2021b) and argue that for supervised learning (i.e., large-scale fine-tuning), recent advances in zero- and few-shot learning might make this option possible.

Large pretrained models such as T5 (Raffel et al., 2020) or GPT-3 (Brown et al., 2020), trained on vast amounts of data, arguably learn enough about the world to acquire many of the skills currently learned through supervised learning. Indeed, the large increase in the size and capacity of pretrained language models has led to a new wave of few-shot and zero-shot methods (Schick and Schütze, 2021; Shin et al., 2020; Gu et al., 2022), which are able to reach human-level performance on certain tasks using only a few dozens of training examples (Schick and Schütze, 2021). Given these impressive results, it is not clear whether there is still value in fine-tuning models on large-scale datasets for all tasks. In the context of this work, focusing on few-shot learning might allow models to not learn some of the correlations that result from manual annotation (Schwartz et al., 2017; Gururangan et al., 2018; Poliak et al., 2018), as they will not be exposed to many of them to begin with.

We note that this proposal is not a perfect solution. First, some spurious correlations may be picked up by the small number of examples. This is less of a problem in the zero-shot setting, or in cases where the model parameters are not updated in few-shot settings (Brown et al., 2020), but studying the extent to which spurious correlations are picked up in other few-shot settings is an important avenue for future research. Second, some spurious correlations might be picked up during the pretraining stage (Gehman et al., 2020; Birhane et al., 2021; Dodge et al., 2021). Continuing to quantify this phenomenon and finding ways to mitigate it is another important line of research.

An important question in this context is the tasks for which supervised learning is still needed. It seems plausible that excelling in language modeling tasks requires mastering the skills that stand in the base of many NLP tasks, such as sentiment analysis, syntactic parsing, and NER. However, it is similarly plausible that this is not the case for other tasks, e.g., summarization, simplification and dialogue. We are cautious in making concrete recommendations for which tasks to apply this principle, but suggest the following intuitive rule of thumb: for datasets or tasks for which the state of the art is close to or surpasses the human baseline, we should consider moving to few-shot setups.

Finally, dataset creation is still a valuable and important line of research. Our recommendation to stop building large scale training sets does not make this task redundant, to both spur the design of better models, and to better test their capabilities. We suggest that instead of building large training sets and small validation and test sets, authors should consider building large test sets, as a means for achieving improved statistical power (Card et al., 2020).

4.4 A Note on Social-Bias Correlations

So far, we discussed the problems with unlearning spurious correlations, and advocated instead for more elaborate context modeling. One exception might be the case of social biases. Textual data often reflects human stereotypes such as spurious correlations between labels and protected group attributes, e.g., alignments between professions and gender or race. Unlike other types of knowledge discussed in Sec. 3.4, in this case there is an incentive to prevent models from learning this type of correlation as means for actively reducing the harms of such biases, especially in commercial and public-facing applications, such as machine translation (Stanovsky et al., 2019) or automated financial decision-making (Bartlett et al., 2021). As a result, methods for dataset balancing are no longer *undesired* for mitigating such spurious correlations.

Nonetheless, as demonstrated in Sec. 3, methods for dataset balancing are a limited solution for mitigating spurious correlations, including social-bias ones. In contrast, the methods proposed in this section for mitigating spurious correlations might also

---

[12] Model calibration techniques (DeGroot and Fienberg, 1983; Guo et al., 2017; Card and Smith, 2018) are often used both for allowing models to abstain (Cortes et al., 2016; Shrikumar et al., 2019) and identifying unanswerable questions (Kamath et al., 2020; Zhang et al., 2021).

assist in mitigating social biases, or at least slow down their amplification (Zhao et al., 2017).

5 Related Work

This paper discusses the arms-race between models and datasets. Previous works criticized one side of this arms race—the increasing size of pretrained models—due to ethical and environmental concerns (Schwartz et al., 2020; Bender et al., 2021), or questioning its ability to learn meaningful abstractions from raw text (Bender and Koller, 2020; Merrill et al., 2021). This work studies the second part of this arms race, regarding the efforts to mitigate spurious correlations through dataset balancing. The release of such datasets is often motivated by their potential to spur progress in modeling, and to help tease apart qualitative differences between models. Liu et al. (2021a) showed that this is not necessarily the case, by observing that the ranking of reading comprehension models on small and synthetic benchmarks is similar to that of the (large) SQuAD dataset (Rajpurkar et al., 2016).

Raji et al. (2021) recently criticized the concept of benchmarks as a whole, arguing that they are only capturing specific skills and not "general" capabilities. Our paper raises related concerns about training sets implicitly containing spurious correlations, and suggests reconsidering the practice of building large-scale training sets.

Finally, concurrent to this work, Eisenstein (2022) discussed several types of spurious correlations in the context of causality theory (Pearl, 2009), and used a toy example to demonstrate their different effects on models. They concluded that domain knowledge is required to identify the correlations that are indeed spurious, i.e., those that might challenge the generalization ability of models.

6 Conclusion

Spurious correlations in large textual corpora can result in model brittleness, lack of generalization, and an inflated sense of the state of the art. Mitigating their negative side-effects is an important research goal of the NLP community. In this paper we presented practical and conceptual limitations of dataset balancing as a means for doing so. We proposed alternative ways for mitigating spurious correlations, including adding richer contexts to textual corpora, and allowing models to abstain or interact in cases of uncertainty. We concluded by suggesting to reconsider the practice of fine-tuning pretrained models on large-scale training sets.

7 Broader Impact and Ethical Consideration

Our work did not involve any new data or annotation collection, and as such did not require crowdsourced or in-house workers, or introduces any new models and related risks. Instead, we examine existing resources and common data balancing approaches. In Section 4.4 we specifically discuss the relation between these practices and implications on social bias in models.

Specializing Pre-trained Language Models for Better Relational Reasoning via Network Pruning

Siyu Ren **Kenny Q. Zhu**[*]

Abstract

Pretrained masked language models (PLMs) were shown to be inheriting a considerable amount of relational knowledge from the source corpora. In this paper, we present an in-depth and comprehensive study concerning specializing PLMs into relational models from the perspective of network pruning. We show that it is possible to find subnetworks capable of representing grounded commonsense relations at non-trivial sparsity while being more generalizable than original PLMs in scenarios requiring knowledge of single or multiple commonsense relations.

1 Introduction

The past few years have witnessed the revolution of NLP methods with the advent of pretrained language models (PLMs) such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019a). They are first pretrained on vast amount of unlabeled text corpora using masked language modeling (MLM) objective and then fine-tuned on task-specific data, offering a surge of improvements on a wealth of NLP tasks. However, we know very little about *what* and *how much* knowledge embedded in PLMs actually contributes to the success. Notable endeavors (Peters et al., 2018; Goldberg, 2019; Tenney et al., 2019) toward this understanding focus on probing linguistic knowledge therein. They demonstrated that pretraining did impart useful linguistic abstraction about syntax and semantics into PLMs.

More recently, several works presented intriguing results examining relational knowledge within PLMs. Relational knowledge (Speer and Havasi, 2012; Vrandečić and Krötzsch, 2014) is typically defined as describing the abstractive relationship between a pair of concepts or entities, which is crucial for facilitating language understanding. Petroni et al. (2020) first posed the LAMA probe, an English benchmark comprising multiple sets of prompts. Each prompt is a cloze-like sentence transformed from a relational knowledge triple:

Knowledge Triple: <*bus, HasA, ?*>
Object Label: seats.
Prompt: you are likely to find _ in a bus.

By substituting _ with a special [MASK] token and reusing the MLM head, prompt-based relational knowledge probing provides an estimated lower bound of what PLMs know without training an additional layer which was used in the previous linguistic probes. They showed that, even without grounded supervision, PLMs capture such relational knowledge at a level competitive to supervised alternatives. Subsequent works further showed that some specific prompts, acquired either through heuristical mining (Jiang et al., 2020) or gradient-guided search (Shin et al., 2020), can better trigger the models to correctly predict the missing object.

Despite the mounting evidence for the existence of relational knowledge in PLMs, it remains unclear how such knowledge is represented internally. In light of this, we raise the core question in this paper: *Given the general language representation space modeled by a PLM, can we extract its latent representation subspaces for different relations and specialize the PLM into relation-specific knowledge models?* These subspaces exclusively represent knowledge inherited from different subset of MLM data, expressing different relations between masked word and remaining context, thus can potentially benefit applications where knowledge of certain relations are explicitly required.

We study this question by first drawing inspiration from recent findings (Saunshi et al., 2020; Lee et al., 2020; Zhang and Hashimoto, 2021): *the more MLM pretraining simulates downstream task, the more successful the transfer will be.* For example, filling *like* or *hate* into a cloze like "*I [MASK] this film, it's great.*" provide a clear way in which

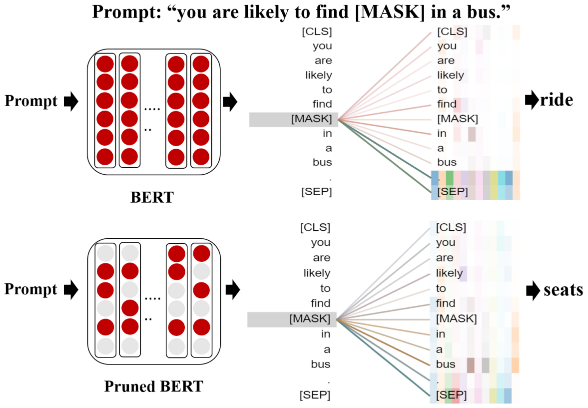

Figure 1: Querying original/pruned BERT-BASE with prompts of relation *HasA*. The color spectrum indicates the 12 attention heads in the last layer (Vig, 2019).

the model can implicitly learn to perform sentiment classification. Similarly, we hypothesize that training on MLM data expressing certain relation r between masked word and remaining context would lead to effective transfer on knowledge probing that targets relation r.

By exploiting this correlation conversely, we offer a new way for extracting representation subspaces responsible for different relational knowledge based on their transfer performance on knowledge probing task. Instead of introducing additional parametric transformation upon the original space, we restrict these subspaces to have correspondence with subnetworks of PLMs and propose an end-to-end differentiable weights pruning framework. Our experiments show that it is possible to find subnetworks capable of representing grounded commonsense relations at non-trivial sparsity while also exhibiting evident disentanglement. Figure 1 exemplifies a cloze prompt where the identified subnetwork produces the valid answer *seats* by attending to relevant context, i.e., bus, while the original BERT fails. We then examine the knowledge transfer ability of these subnetworks in scenarios requiring knowledge of single or multiple commonsense relations for reasoning. Experiment on commonsense knowledge base completion show that the identified subnetworks even outperform strong supervised knowledge base completion methods. These subnetworks also outperform the original PLMs in both many-shot and zero-shot commonsense question answering tasks, when combined properly.

Code and all pruned subnetworks are opensourced at `https://github.com/DRSY/LAMP`.

2 Methodology

We first provide background on pretrained masked language models and the formulation of cloze prompt for querying these models, then we proceed to elaborate our proposed pruning procedure.

2.1 Pretrained Masked Language Models

Given a sequence of tokens $\boldsymbol{w} = [w_1, w_2, ..., w_n]$ with length n, the model outputs a sequence of hidden states $\boldsymbol{h} = [h_1, h_2, ..., h_n]$ corresponding to each token. In standard MLM pretraining, h_i is fed into a MLM head for computing the reconstruction probability $P(w_i|\boldsymbol{w}_{-i})$ of the masked i-th token w_i, where $\boldsymbol{w}_{-i}$ are all other unmasked tokens. We denote the pretrained masked language model $\mathcal{LM}$ with parameter θ as $\mathcal{LM}_\theta$ in the following sections.

2.2 Knowledge Probing with Cloze Prompts

The natural language cloze prompts, such as "*you are likely to find a basement in below your [MASK]*", offer a straightforward means of querying pretrained masked language models that conform to their interfaces.

We follow the formulation of Petroni et al. (2020), where relational knowledge is in the form of triplets $\langle subj, r, obj \rangle$. Here $subj$ refers to the subject, obj refers to the object, and r indicates their corresponding relation. To query a model $\mathcal{LM}_\theta$, each relation r is associated with a set of cloze template prompts T_r, each of which consists of a sequence of tokens, and two of which are place-holders for $subj$ and obj (e.g., "*you are likely to find* $[subj]$ *in* $[obj]$"). We can check the existence of the knowledge in $\mathcal{LM}_\theta$ by substituting the $[subj]$ place-holder with the real subject and asking the model to predict the missing object:

$$\hat{obj} = \arg\max_{w \in \mathcal{V}} P_{\mathcal{LM}_\theta}([obj] = w | subj, T_r)$$

where $\mathcal{V}$ is the vocabulary of $\mathcal{LM}_\theta$. We say that $\mathcal{LM}_\theta$ carries the knowledge if $\hat{obj} = obj$.

2.3 Extracting Representation Subspaces by Weights Pruning

Extracting representation subspaces for different roles/functionalities has been explored by prior works, such as attaining disentangled subspaces of style and semantic content in text style transfer task (John et al., 2019). The typical approach is to apply parametric transformation function upon the original space and optimize through end-to-end downstream fine-tuning. However, it induces additional parameters and cannot faithfully reveal the relational knowledge originally present in PLMs since such knowledge can be stored in the newly introduced parameters outside of PLMs. We circumvent this issue by focusing on the representation spaces modeled by subnetworks of $\mathcal{LM}_\theta$. A subnetwork $\mathcal{LM}_{\theta_r}$ of relation r is obtained by setting certain dimensions of θ to zero.

The next step is to identify $\mathcal{LM}_{\theta_r}$ such that the representation space it corresponds to inherits its knowledge from the MLM data expressing relation r. Based on the previous evidence (Zhang and Hashimoto, 2021) that shows positive correlation between downstream performance and task similarity with MLM data, we propose to estimate representation space for relation r by searching for the $\mathcal{LM}_{\theta_r}$ that is the most predictive of the prompts expressing relation r. Specifically, for each weight matrix W^l from the set of all weight matrices $\boldsymbol{W}^l$ in the l-th transformer layer, we assign a learnable pruning mask generator G^l_r that is element-wise initialized from a prior distribution $\phi(\cdot)$. Each entry $g^l_{i,j} \in G^l_r$ is a real-valued scalar that determines whether its corresponding weight $w^l_{i,j} \in W^l$ should be pruned. We explore two different schemes of converting G^l_r into a masking matrix M^l_r from a probabilistic view.

2.3.1 Stochastic Pruning

The first variant is to establish a probabilistic formulation for determining the importance of individual weights. Formally, $g^l_{i,j}$ is taken as the input to a sigmoid function for parametrizing a Bernoulli distribution $B(\sigma(g^l_{i,j}))$, from which a binary masking random variable $m^l_{i,j}$ is sampled:

$$m^l_{i,j} \sim B(\sigma(g^l_{i,j})) \tag{1}$$

where $m^l_{i,j} \in M^l_r$. The resulting masking matrix M^l_r can then be used to select weights within original linear layer W^l by a Hadamard product:

$$W^l_r = W^l \odot M^l_r \tag{2}$$

Due to the non-differentiability introduced by sampling, the gradient w.r.t. loss function (described in Section 2.3.3) cannot be back-propagated to $g^l_{i,j}$. As a remedy, we use the re-parametrization technique by Li et al. (2018) to approximate $m^l_{i,j}$ with another differentiable variable $\tilde{m}^l_{i,j}$:

$$\tilde{m}^l_{i,j} = \sigma(\frac{g^l_{i,j} + \log U - \log(1-U)}{\tau}) \tag{3}$$

where $U \sim Uniform(0,1)$ and τ is a small positive temperature parameter. As τ approaches zero, $\tilde{m}^l_{i,j}$ will match sampled $m^l_{i,j}$ more accurately (detailed proof can be found in Appendix A).

Consequently, Eq. (2) becomes:

$$W^l_r = W^l \odot \tilde{M}^l_r \tag{4}$$

2.3.2 Deterministic Pruning

While our first probabilistic pruning formulation considers flexible weights combination, the second proposed variant utilizes a hard thresholding function to directly generate the masking matrix.

Let t denote the predefined thresholding hyperparameter ranging from 0 to 1, then we have:

$$\hat{m}^l_{i,j} = \begin{cases} 1, & \sigma(g^l_{i,j}) \geq t \\ 0, & otherwise, \end{cases} \tag{5}$$

where σ is the sigmoid function. Similar to Section 2.3.1, the resulting binary masking matrix $\hat{M}^l_r$ is then used to select weights relevant to relation r by a Hadamard product:

$$W^l_r = W^l \odot \hat{M}^l_r \tag{6}$$

Note that the hard thresholding operation in Eq. (5) also blocks the gradient propagation to $g^l_{i,j}$. Here we employ the Straight-Through gradient estimator (Hubara et al., 2016; Zhao et al., 2020) and use $\frac{\partial \mathcal{L}_r}{\partial \hat{m}^l_{i,j}}$ as a proxy of $\frac{\partial \mathcal{L}_r}{\partial g^l_{i,j}}$. We elucidate the loss function $\mathcal{L}_r$ w.r.t. relation r in the next section.

2.3.3 Training and Inference

The resultant subnetwork $\mathcal{LM}_{\theta_r}$ is expected to behave like a specialized neural knowledge base. That is, given a prompt requiring knowledge about relation r, $\mathcal{LM}_{\theta_r}$ should be able to fill in the missing object more accurately than $\mathcal{LM}_\theta$. Hence the learning objective for pruning mask generator $\{\boldsymbol{G}^l_r\}_{l_b \leq l \leq l_t}$, where l_b and l_t indicate the range of transformer layers, is to find the subnetwork $\mathcal{LM}_{\theta_r}$ that minimizes:

$$\mathcal{L}_r = -\mathbb{E}_{(subj,T_r,obj)\in D_r}[\log P_{\mathcal{LM}_{\theta_r}}(obj|subj, T_r)] \tag{7}$$

where D_r is the collection of prompts under relation r. The training procedure is conducted for each relation $r \in \mathcal{R}$ of interest. Finally, we obtain a set of trained $\{\boldsymbol{G}_r\}_{r \in \mathcal{R}}$ for the designated pretrained model $\mathcal{LM}_\theta$.

During inference, for deterministic pruning, M_r is obtained from G_r by Eq. (5). For stochastic pruning, M_r is obtained by taking the expectation value (i.e., $\sigma(G_r)$) of Bernoulli variables.

3 Experiments

We present our pruning setup and detailed analysis in Section 3.1. Then we compare the knowledge transfer ability of pruned subnetworks against original PLMs in scenarios requiring knowledge of single or multiple relations for reasoning in Section 3.2 and Section 3.3 respectively.

3.1 Pruning & Analysis

Data Split	# Relations	# Prompts
Train	16	20,841
Validation	16	5,955
Test	16	2,978

Table 1: Statistics of C-LAMA.

Dataset. We use the ConceptNet (Speer and Havasi, 2012) subset of LAMA benchmark for both pruning and evaluation, denoted as C-LAMA. C-LAMA contains commonsense facts from the English part of ConceptNet that has single-token objects covering 16 relations. These facts are extracted from Open Mind Common Sense (OMCS). Since C-LAMA has no official data splits, we construct the train/validation/test splits with a ratio of 7:2:1. Detailed statistics are listed in Table 1.

Models. We experiment with the DistilBERT-base (Sanh, 2019), BERT-base, RoBERTa-base (Liu et al., 2019a), and the more recent MPNet-base (Song et al., 2020) as the choices of $\mathcal{LM}$. After pruning, each $\mathcal{LM}$ will have 16 pruned subnetworks corresponding to the 16 commonsense relations. As a straightforward comparison, for each $\mathcal{LM}$ we also obtain 16 fine-tuned models corresponding to the same 16 relations. Precision P@K averaged across all relations is used to evaluate the prompt filling performance.

Setup. The prior distribution $\phi(\cdot)$ is a Gaussian $\mathcal{N}(\mu, 1)$ where μ is the mean that controls the initial sparsity of the pruned model (e.g., $\mu = 0$ indicates 50% initial sparsity). We set l_t to be the top layer of a given model and choose l_b from $\{3, 4\}$ for DistilBERT, $\{6, 7, 8, 9\}$ for BERT, RoBERTa, and MPNet. The temperature τ is fixed as 0.1. The threshold t is fixed as 0.5. We use Adam (Kingma and Ba, 2015) with a batch size of 32 and a linear warm-up scheduler with 0.1 warm-up ratio for training the mask up to 6 epochs. The learning rate is fixed as 3×10^{-4}. We run all experiments with three different random seeds and report the averaged results. All experiments are conducted on a GTX 1080 Ti GPU with 11GB RAM.

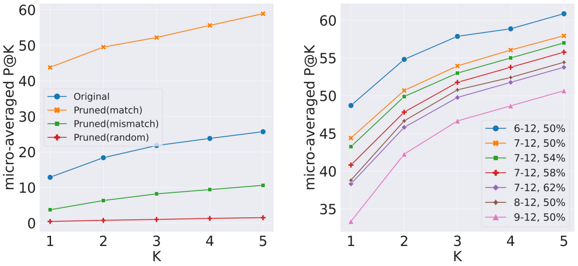

Figure 2: Ablation on the pruning masks (left) and effect of initial sparsity and pruned layers (right).

Factors impacting performance. To investigate how μ and l_b affect the performance, we perform a preliminary experiment by applying deterministic pruning on BERT-base with l_b in $\{6, 7, 8, 9\}$ and the initial sparsity in $\{50\%, 54\%, 58\%, 62\%\}$. Figure 2 (right) shows that (i) increasing the number of pruned layers helps distill more knowledge; and (ii) larger initial sparsity is more likely to prune away weights that are important to certain knowledge and cannot be recovered in the later training process. In general, we find an initial sparsity around 50% yields a decent performance both in probing and downstream applications. We adopt this setting in the rest of this paper unless otherwise stated.

How specialized are these subnetworks? Ideally, specialized subnetworks are expected to perform poorly on relations other than their associated ones. We verify this by instantiating the pruning mask upon BERT-base with a set of mismatched masks. Specifically, we corrupt the correspondence of relation between masks and prompts by shuffling the masks 15 times, as there are 16 relations in total. Then we calculate the micro-averaged P@K for each shift and average the results. As indicated by the green curve in the left part of Figure 2, if we apply the mismatched masks from other relations, the P@1 score significantly drops to 3.8 from 43.8, a performance even worse than the original model. It suggests that the representation spaces for different commonsense relations modeled by these subnetworks are highly disentangled.

Model	P@1 (%)	P@2 (%)	P@3 (%)	Sparsity	l_b-l_t	# Param.
DistilBERT-base	11.4	16.6	19.9	0%	-	66M
DistilBERT-base w/ fine-tuning	27.9	36.3	41.4	0%	-	66M
DistilBERT-base w/ stochastic pruning	14.8	21.5	26.3	~30%	4-6	66M

MPNet-base w/ fine-tuning	23.8	30.9	36.3	0%	-	110M
MPNet-base w/ stochastic pruning	19.8	27.9	33.2	~30%	7-12	110M
MPNet-base w/ deterministic pruning	**47.9**	**52.8**	**55.6**	~50%	7-12	88M

Table 2: Relational knowledge probing results on C-LAMA test set.

Non-triviality of subnetworks. We also examine the non-triviality of subnetworks by initializing the masks with a Bernoulli distribution $B(0.5)$ and averaging the results from 5 different random seeds. If we apply such random masks with sparsity comparable to the learned ones, the P@1 drops drastically to 0.4 (red curve in the left part of Figure 2). This notable difference proves that the effective subnetworks cannot be trivially identified through random weights pruning.

Test set results. Table 10 summarizes the test set results. Among all original PLMs, RoBERTa achieves the highest P@1 score of 15.4 while DistilBERT gets the lowest 11.4. It indicates that while PLMs are shown to be helpful for downstream learning, they cannot accurately complete cloze-like prompts that require commonsense relation knowledge. This observation also coincides with previous finding (Zhang and Hashimoto, 2021) that the uniform masking adopted by PLMs is biased towards extracting statistical dependencies. Comparing the results for each pair of original and pruned models, we consistently observe a significant increase in pruned models, especially for deterministically pruned ones (27.4% on average). The pruned models also surpass their fine-tuned counterparts, which is likely due to that fine-tuning makes aggressive updates to parameters and overfits to the training set by memorizing spurious features.

To sum up, the substantial performance gains provide new evidences for the existence of sparse latent relational knowledge structures in PLMs. These structures are previously weakened by other pretrained weights *reserved* for more general-purpose use and are *exposed* by the proposed pruning method. It is worth noting that deterministic pruning excels by a big margin compared to stochastic one. It implies that successful extraction of relation-specific representation space relies on ignoring the information in the input that is irrelavant to the relation. Therefore, we focus our analysis on deterministically pruned PLMs and denote them by `pruned` in the rest of this paper.

Visualization of attention and representations. To explain how the subnetworks accommodate more accurate commonsense knowledge despite having far fewer weights than the full-scale models, we randomly sample several prompts that the subnetworks correctly answered but the full-scale model (BERT-base) failed to, and visualize the attention patterns in the last layer.

Figure 3: Attention weight visualization. *AtLocation*/*PartOf* is required in the left/right column.

Specifically, we focus on the attention weights between [MASK] and other tokens in the prompt. A first glance of change of attention pattern was given earlier in Figure 1, and now we show more examples of other ConcetpNet relations in Figure 3.

Table 3: One-hop link prediction results. Best results are marked with **bold** font and second best with underline.

We observe that while the original pretrained model tends to attend to special tokens like period and [SEP], the subnetwork successfully grasps the relevant concepts (i.e., apple, worms, and basement) in the prompt hence produces the correct object. We also use t-SNE (van der Maaten and Hinton, 2008) to visualize the last layer's representation of [CLS] for each prompt. From Figure 4, the representations computed by original pretrained model are hardly separable as different types of knowledge are mixed together. In contrast, the pruned subnetwork can extract meaningful and disentangled representations for different commonsense relations.

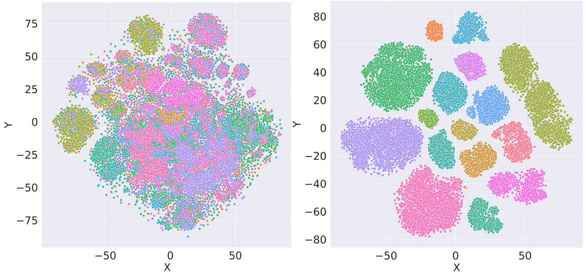

Figure 4: t-SNE visualization of [CLS] representation from original (left) and pruned (right) BERT-base.

3.2 Single-Relation Scenario

In this section, we compare the transfer ability of pruned subnetworks against original PLMs in a scenario that explicitly requires knowledge of single commonsense relation, i.e., commonsense knowledge base completion (CKBC), which aims at populating a CKB with valid relational triples. We use the ConceptNet-100K benchmark provided by Li et al. (2016). To ensure a fair evaluation, we manually create a subset of ConceptNet-100K consisting of triples with single-token subject/object. We also ensure that its dev/test set has **no overlap** with C-LAMA. Each relation is associated with a sentence template (provided in Appendix B) of which the wording is distinct from those in C-LAMA. The resulting dataset contains 17,891 training instances, 349 development instances, and 446 test instances.

One-hop link prediction. We first formulate CKBC as a link prediction task, i.e., predicting the missing object given the subject and relation. We regard the pruned subnetworks and the original PLMs as the unsupervised off-the-shelf neural knowledge base and include the results of several strong KB completion methods for reference.

Table 3 shows most of the supervised models outperform full-scale PLMs by a large margin, which suggests the inefficacy of directly using PLMs to perform link prediction. However, the subnetworks identified by our pruning procedure can acquire performance on par with or better than the state-of-the-art supervised models, which shows the potential of language models as neural knowledge base that is underestimated by previous studies. Surprisingly, pruned DistilBERT get the highest MRR, outperforming other larger and more advanced PLMs. RoBERTa struggles to predict correct objects, perhaps due to its larger vocabulary size compared to WordPiece (50,265 vs 30,522) and less lexicon overlap (53% vs. 59%) with the dataset.

Two-hop extrapolation. Sometimes, a pair of commonsense relations can be combined to derive a new relational knowledge triple. For example, the two triples $\langle s1, IsA, o1\rangle$ and $\langle s2, HasProperty, o2\rangle$, where o1 equals to s2, can be combined into a new test triple $\langle s1, HasProperty, o2\rangle$. Based on this rule, we construct 5,151 new test triples (absent in

ConceptNet-100K) with *HasProperty* relation, which allows us to compare the two-hop extrapolation ability of pruned subnetworks with original PLMs. Table 4 shows that pruned subnetworks exhibit significantly better ability of extrapolating from known relational knowledge to novel knowledge, with an average improvement of 23.2/24.8/24.0 in terms of P@1/P@2/P@3.

Model	**P@1**	**P@2**	**P@3**
DistilBERT-base	10.6	17.8	23.0
DistilBERT-base (pruned)	**28.2**	**36.5**	**44.6**
BERT-base	11.9	18.5	21.9
BERT-base (pruned)	**42.9**	**52.1**	**58.4**
RoBERTa-base	16.8	24.1	28.0
RoBERTa-base (pruned)	**21.5**	**28.7**	**31.0**
MPNet-base	16.6	24.8	29.3
MPNet-base (pruned)	**56.2**	**64.2**	**67.7**

Table 4: Two-hop extrapolation results (%).

Model	< linen, IsA, ? >	< sing, Causes, ? >
DistilBERT	surname commodity profession	death disease trouble
DistilBERT(pruned)	cloth fabric garment	happiness joy peace

Table 5: Top-3 predictions of two triples sampled from CKBC dev set. The predictions are ranked by probability in descending order with ground-truth marked in green and other plausible answers underlined.

Case Study. We present a case study of link prediction examples from both pre-trained and pruned DistilBERT in Table 5. In both examples, the pre-trained DistilBERT makes completely unrelated predictions (e.g.,*surname*, *profession*, and *death*) and only two predictions (i.e., *commodity* and *trouble*) can be hardly considered as plausible. In contrast, the model pruned for IsA/Causes are specialized in accurately representing these relations and can even produce reasonable answers in addition to the ground-truth.

3.3 Multi-relation Scenario

In this section, we compare the transfer ability of pruned subnetworks against original PLMs in a scenario that implicitly requires knowledge of multiple commonsense relations, i.e., commonsense question answering (CQA).

Stand-alone fine-tuning. We conduct stand-alone fine-tuning using BERT/DistilBERT and their pruned subnetworks on 6 widely adopted CQA tasks: RTE (Dagan et al., 2009), COPA (Roemmele et al., 2011), CommonsenseQA (Talmor et al.), SWAG (Zellers et al., 2018), aNLI (Bhagavatula et al., 2020) and CosmosQA (Huang et al., 2019). For each task, we identify the commonsense knowledge that might be required with a simple yet effective heuristic: we obtain the five most frequent relations measured by how many times the subject and object holding certain relation in ConceptNet appear in the context or the answer. Then we take the union of masks for each relation and apply the resultant mask to BERT/DistilBERT as the initialization for fine-tuning. Intuitively, such union operation would preserve all relational knowledge of interest. We repeat training three times with different random seeds for each task using hyperparameters suggested in the original papers. The detail of mask combination for each task is in Appendix B.

Task	BERT	DistilBERT
RTE	69.2±2.3⇒**69.8**±2.0	61.2±1.2⇒**62.1**±1.2
COPA	62.4±5.0⇒**63.1**±4.7	54.0±2.0⇒**56.0**±2.0
CommonsenseQA	53.1±0.6⇒**54.1**±0.7	47.9±0.7⇒**48.6**±0.7
SWAG	73.9±0.3⇒**74.2**±0.1	70.1±0.3⇒**70.4**±0.1
aNLI	63.7±0.4⇒**64.0**±0.4	60.1±0.4⇒**60.4**±0.4
CosmosQA	61.3±1.0⇒**61.8**±0.2	56.4±0.8⇒**57.2**±0.4

Table 6: Stand-alone fine-tuning accuracy (original ⇒ pruned) of BERT and DistilBERT.

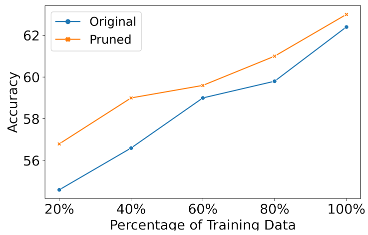

Figure 5: Results on COPA with varying portion of data.

Table 8 shows that, when initialized with proper subnetworks, the model can better transfer to commonsense question answering tasks via more relevant *prior* knowledge. We further analyze the change of performance under the low-resource regime. Figure 5 shows that the pruned BERT exhibits a notable advantage when training data is extremely scarce. As more training data is seen, the benefit of the pruned model is reduced but still significant.

Integrated fine-tuning. We also integrate the pruned subnetworks to QA-GNN (Yasunaga et al.,

Model	COPA-Tra.	COPA-Val.	CSQA	CA	WSC	SM	ARCT1	ARCT2	Avg.	Δ
DistilBERT-base	58.3	60.0	29.6	84.6	53.3	71.6	48.6	50.4	57.0	-
DistilBERT-base (pruned)	**61.5**	**69.0**	**31.5**	**89.6**	**56.9**	**72.1**	**53.4**	**51.6**	**60.7**	+3.7
BERT-base	60.2	54.0	26.5	89.0	57.3	69.7	46.8	50.3	56.7	-
BERT-base (pruned)	**63.0**	**64.0**	**28.5**	**91.8**	**59.0**	**71.7**	**50.0**	**52.0**	**60.0**	+3.3
RoBERTa-base	60.7	59.0	39.9	90.1	61.8	73.1	48.6	53.1	60.7	-
RoBERTa-base (pruned)	**65.3**	**72.0**	**40.4**	**93.4**	**62.9**	**74.4**	**53.2**	**55.1**	**64.6**	+3.9
MPNet-base	66.5	69.0	40.0	94.5	64.3	75.8	52.9	56.7	64.9	-
MPNet-base (pruned)	**71.0**	**74.0**	**41.7**	**97.3**	**66.4**	**77.5**	**56.1**	**57.7**	**67.7**	+3.2

Table 7: Zero-shot accuracy (%) for commonsense question answering. Better results of each pair is in **bold**.

2021), a state-of-the-art hybrid question answering system in which a PLM and GNN are employed for joint reasoning over text and knowledge graph. We follow their official implementation with the only modification on the PLM part. With the same set of masks as in the stand-alone fine-tuning on CommonsenseQA, the pruned BERT achieves an accuracy of 60.9% versus 60.1% of original model, suggesting a generally stronger knowledge transfer ability not only in stand-alone but also in the integrated settings.

Zero-shot learning. We then assess the ability of pruned subnetworks to perform zero-shot commonsense reasoning, a setting where the knowledge relied on to complete the task is solely determined by the model itself. We focus on the following 8 multiple-choice CQA datasets: training set of COPA (COPA-Tra.), validation set of COPA (COPA-Val.), CommonsneseQA, Conjunction Acceptability (CA) (Zhou et al., 2020), Winograd Schema Challenge (WSC) (Levesque et al., 2012), SenseMaking (SM) (Wang et al., 2019), ARCT1 (Habernal et al., 2018) and ARCT2 (Niven and Kao, 2019). Each sample in the above datasets can be formulated as $\{[CLS]\ context\ [SEP]\ choice_i\ [SEP]\}_{i=1}^{N}$, where N is the number of choices. We compute the plausibility score of each choice using the MLM head. The choice of the maximum plausibility score is chosen as the answer.

Since multiple types of knowledge are typically required for effective commonsense reasoning, We employ the same heuristic used in many-shot learning setting for determining the set of the most important relations for each task as well as the same mask union operation to obtain parameter initialization. It can be observed from Table 7 that the pruned models can actually surpass their full-size counterparts in all tasks considered in our experiments. Our explanation is that knowledge irrelevant to the specific task in the original PLMs hurt the in-domain zero-shot reasoning capability. It also demonstrates that the most important relational knowledge vary from task to task.

4 Related Work

Since the emergence of large pre-trained language models, much work has focused on understanding their internal contextual representations. Most prior work (Shi et al., 2016; Belinkov et al., 2017) pays attention to either using extraneous probing tasks to examine whether certain linguistic properties can be identified from those representations, or ablating the models to observe how behavior changes. More recently, some studies (Goldberg, 2019; Tenney et al., 2019) have shown the existence of linguistic knowledge (e.g., syntax) in various but generally lower layers of pre-trained transformers.

To shed more light on how PLMs memorize abstract knowledge rather than statistical co-occurrence patterns, we extend previous probe (Petroni et al., 2020) on relational knowledge. Specifically, we are concerned with commonsense knowledge that is grounded on ConceptNet relations. Our work differs in that we focus on not only probing but also bringing latent relational knowledge to the surface and unleashing more potential for better relation reasoning.

Another relevant line of research is network pruning (Liu et al., 2019b; Lin et al., 2020) and lottery ticket hypothesis (Frankle and Carbin, 2019; Prasanna et al., 2020; Chen et al., 2020). The former aims at reducing the size of model parameters without compromising accuracy and the latter reveals subnetworks whose initializations made them capable of being trained effectively comparable to the original model. In contrast, we seek to uncover subnetworks in over-parametrized PLMs that specializes on commonsense knowledge tailored for downstream tasks rather than focusing on good global initialization, and achieve good results.

5 Conclusion

This study investigated specializing PLMs for better relational reasoning via network pruning. In the pilot experiment we find evidence of latent sparse subnetworks capable of representing grounded commonsense relations in various PLMs. Further experiments revealed that such subnetworks possess stronger relational reasoning capability than original PLMs. Our work provides a new vantage point about the internal mechanism as well as practical utilization of relational knowledge in PLMs, opening up avenues to better understanding and adapting pretrained language representations.

A Derivation for Stochastic Pruning

To re-parametrize the discrete binary Bernoulli variable $m^l_{i,j} \sim B(\sigma(g^l_{i,j}))$, denote the approaximate differentiable variable as $\tilde{m}^l_{i,j} = \sigma(\frac{g^l_{i,j}+\log U-\log(1-U)}{\tau})$ where τ is a real-valued temperature value, we have the following derivation holds for arbitrary $\epsilon \in (0, 0.5)$:

$$P(m^l_{i,j}=1) - P(\tilde{m}^l_{i,j} \geq 1-\epsilon) \leq (\frac{\tau}{4}) \log\frac{1}{\epsilon}$$

Specifically, when temperature τ approaches 0, $\tilde{m}^l_{i,j} = m^l_{i,j}$.

Lemma 1: $\sigma^{-1}(x) = \log\frac{x}{1-x}$.

Lemma 2: $\frac{\sigma(x)-\sigma(y)}{x-y} \leq \frac{1}{4}$.

Proof:

$$\begin{aligned}
&P(\tilde{m}^l_{i,j} \geq 1-\epsilon) \\
=&P(\sigma(\frac{g^l_{i,j}+\log U-\log(1-U)}{\tau}) \geq 1-\epsilon) \\
=&P(\frac{g^l_{i,j}+\log U-\log(1-U)}{\tau} \geq \log(\frac{1}{\epsilon}-1)) \\
=&P(g^l_{i,j} - \tau\log(\frac{1}{\epsilon}-1) \geq \log(\frac{1}{U}-1)) \\
=&P(e^{g^l_{i,j}-\tau\log(\frac{1}{\epsilon}-1)} \geq \frac{1}{U}-1) \\
=&P(U \geq \frac{1}{1+e^{g^l_{i,j}-\tau\log(\frac{1}{\epsilon}-1)}}) \\
=&\sigma(g^l_{i,j} - \tau\log(\frac{1}{\epsilon}-1))
\end{aligned}$$

Then:

$$\begin{aligned}
&P(m^l_{i,j}=1) - P(\tilde{m}^l_{i,j} \geq 1-\epsilon) \\
=&\sigma(g^l_{i,j}) - \sigma(g^l_{i,j} - \tau\log\frac{1}{\epsilon}-1) \\
\leq&\frac{\tau}{4}\log(\frac{1}{\epsilon}-1) \\
\leq&\frac{\tau}{4}\log\frac{1}{\epsilon}
\end{aligned}$$

The process for deriving $P(m^l_{i,j}=0) - P(\tilde{m}^l_{i,j} \leq \epsilon) \leq (\frac{\tau}{4})\log\frac{1}{\epsilon}$ can be analogously obtained. □

B Implementaiton Details

B.1 Templates

The templates we used in single-relation scenario for different commonsense relations are defined as follows:

AtLocation: Something you find at ⟨*obj*⟩ is ⟨*subj*⟩.
CapableOf: ⟨$subj$⟩ can ⟨*obj*⟩.
Causes: ⟨$subj$⟩ causes ⟨*obj*⟩.
CausesDesire: ⟨$subj$⟩ would make you want to ⟨*obj*⟩.
Desires: ⟨$subj$⟩ wants to ⟨*obj*⟩.
HasPrerequisite: ⟨$subj$⟩ requires ⟨*obj*⟩.
HasProperty: ⟨$subj$⟩ can be ⟨*obj*⟩.
HasSubevent: when ⟨$subj$⟩, ⟨*obj*⟩.
HasA: ⟨$subj$⟩ contains ⟨*obj*⟩.
IsA: ⟨$subj$⟩ is a ⟨*obj*⟩.
MadeOf: ⟨$subj$⟩ can be made of ⟨*obj*⟩.
MotivatedByGoal: you would ⟨$subj$⟩ because ⟨*obj*⟩.
NotDesires: ⟨$subj$⟩ does not want ⟨*obj*⟩.
PartOf: ⟨$subj$⟩ is part of ⟨*obj*⟩.
ReceivesAction: ⟨$subj$⟩ can be ⟨*obj*⟩.
UsedFor: ⟨$subj$⟩ may be used for ⟨*obj*⟩.

When performing CKBC task, we first fetch the template based on the relation of the triple to be complete and fill in the ⟨$subj$⟩ and let the model predict the missing ⟨*obj*⟩. Concretely, the ⟨*obj*⟩ placeholder is replaced by the mask token corresponding to different pre-trained language models.

B.3 Stand-alone Fine-tuning

For fine-tuning on commonsense reasonging tasks, we only experiments with BERT-base due and perform hyper-parameter search only in terms of batch size in the range of $\{8, 16, 32\}$ and learning rate in the range of $\{3e^{-5}, 4e^{-5}, 5e^{-5}\}$ due to computational budget. We also adopt early stopping based

BERT-large w/ stochastic pruning	22.1	30.1	35.4	∼30%	17-24	336M
BERT-large w/ deterministic pruning	69.2	74.1	76.3	∼50%	17-24	284M

Table 10: Macro-averaged precision metrics of BERT-large on C-LAMA test set

on accuracy on the devlopment set. The combination achieving highest accuracy is shown in Table 8.

B.4 Zero-shot Learning

In constrast with fine-tuning, zero-shot evaluation is deterministic as long as the model does not involve any stochastic module, thereby averting extensive hyperparameter tuning. Instead we perform exaustive search over knowledge combinations for each pretrained language model with number of knowledge types in $\{3, 4, 5\}$. The ConceptNet-grounded knowledge type combination achieving highest accuracy is listed in Table 9.

C Extracted Commonsense Triples

Here we present the additional experiment result of extracting novel relaitonal triples based on our specialized relation-specific knowledge models. Applying the pruned DistilBERT-base model to predict missing objects for triples in ConceptNet-100K test set, we obtain commonsense triples deemed to be novel by three human annotators with Flessi's Kappa score κ of 0.65. We further filtered out triples that are included in the training or development set of ConceptNet-100K. Here we show some representative cases categorized by their relations:

CapableOf:

$(computer, crash)$, $(computer, communicate)$

IsA:

$(sex, relationship)$, $(submarine, weapon)$, $(submarine, vessel)$

AtLocation:

$(knife, war)$, $(knife, dinner)$, $(crab, dinner)$

UsedFor:

$(stage, fun)$, $(stage, performance)$, $(literature, education)$, $(literature, research)$

HasA:

$(book, index)$, $(book, information)$

HasProperty:

$(music, loud)$

Future work involves using seed triples beyond ConceptNet-100K dataset, e.g., the whole ConceptNet knowledge graph , and mining more novel and plausible commonsense knowledge.

D Limitations

The major limitations of our work lie in how do we choose and combine the representation subspaces/subnetworks in multi-relation scenario. We proposed a simple heuristic (i.e., based on statistics of dataset and union operation upon masks) in the paper and it empirically works well, but more principled and optimal method should be further studied. Another potential limitation is that we limit our scope to commonsense relations only in this paper. We leave other binary relations (e.g., factual relations defined in WikiData) as future work.

D2GCLF: Document-to-Graph Classifier for Legal Document Classification

Abstract

Legal document classification is an essential task in law intelligence to automate the labor-intensive law case filing process. Unlike traditional document classification problems, legal documents should be classified by reasons and facts instead of topics. We propose a Document-to-Graph Classifier (D2GCLF), which extracts facts as relations between key participants in the law case and represents a legal document with four relation graphs. Each graph is responsible for capturing different relations between the litigation participants. We further develop a graph attention network on top of the four relation graphs to classify the legal documents. Experiments on a real-world legal document dataset show that D2GCLF outperforms the state-of-the-art methods in terms of accuracy.

1 Introduction

Legal Artificial Intelligence (LegalAI) (Zhong et al., 2020; Rissland et al., 2003) is a specific subject to apply the artificial intelligence technology into legal tasks including legal judgement prediction (Rosca et al., 2020; Gan et al., 2021), similar case matching (Tran et al., 2019) and law case classification (Noguti et al., 2020; Lin et al., 2012; Li et al., 2019a). In this paper, we focus on law case classification. The traditional case filing process requires experts to categorize the civil complaints manually, which is labor-intensive. For example, a court in a small town has more than 10,000 civil complaint cases per year in China. This calls for accurate machine learning techniques to improve the efficiency of the case filing process.

Recently, deep learning approaches (Wang et al., 2018a; Johnson and Zhang, 2017; Wang, 2018; Shen et al., 2018; Zhang et al., 2018; Lin et al., 2017) have significantly improved the accuracy of text classification on well-known datasets, e.g., Amazon reviews. Existing methods learn a latent representations for each document by considering the semantics and themes of the documents. In this way, documents are classified into high-level topics such as "Sport" and "Medical". Unlike traditional datasets, legal documents of different types exhibit high semantic similarity. For example, Table 1 shows two semantically similar cases in different Chinese civil categories.

Given the nature of legal classification tasks, there are two limitations of applying existing text classification models. First, document structure is a key to accurate classification, but it is ignored in most existing methods. Legal documents in different categories may only differ in some particular parts. Some previous research proposed to utilize the graph with sentence relations to address the problem (Hu et al., 2019). But not all sentences are relevant to the document class. Second, the facts and reasons in the legal cases are essential for distinguishing different dispute types, but they are not considered in existing methods. Existing word co-occurrence graphs (Zhang and Zhang, 2020; Ragesh et al., 2021; Zhang et al., 2020) are not only hard to represent the key facts but also include words that are irrelevant to the document class.

We argue that the key to accurate legal document classification is to understand the facts, which are expressed as relations between entities. For example, the debtor-creditor relationship denotes the fact that someone borrows other entities' money. Motivated by this, we designed a Document-to-Graph Classifier (D2GCLF) to address the two limitations above. D2GCLF extracts four graphs from *each* legal document to represent the facts about the key entities, i.e., plaintiffs and defendants. The four graphs are (1) *Entity-Matter* graph to describe the matters (e.g., money) associated with the entities; (2) *Entity-Action* graph to describe the actions of entities; (3) *Entity-Keyword* graph to model the general topic of the facts about

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2208 - 2221
July 10-15, 2022

Table 1: Examples of translated legal documents of two different types in Chinese law. See Appendix A for the original Chinese documents. The class "Dispute Over Contract of Sale of Commercial Residential Housing Property" (DOCSCRH) covers extremely similar words as the other class "Dispute Over Contract for Sale and Purchase of Housing Property" (DOCSPHP). The only evidence to distinguish the two classes is the seller's identity – only real estate companies sell commercial residential house. For ethical concerns, we hide the parties' names for both cases.

Class	Documents
DOCS CRH	**Plaintiff:** LF **Defendant:** GDYZ co.,ltd **Fact and Reason:** On June 3, 2016, the plaintiff and the defendant signed a contract to purchase a house located in D City with a construction area of 19.36 square meters and a purchase amount of 367,724 yuan. The defendant promised to deliver the relevant documents of the commercial housing transfer registration to the plaintiff before May 15, 2018, which was overdue Liquidated damages were paid according to one ten thousandth of the total purchase price per day; after the signing of the contract, the plaintiff paid the defendant all the purchase price, but the defendant has not yet delivered to the plaintiff the relevant documents for the transfer of commercial housing. The defendant' s delay in handling the housing ownership certificate breached the contract, which harmed the interests of the plaintiff. Therefore, a lawsuit was filed in the court.
DOCS PHP	**Plaintiff:** ZB **Defendant:** YJ **Defendant:** WS **Fact and Reason:** The two defendants are relatives, and WS was YJ's mother-in-law. On November 24, 2015, the plaintiff and the defendant reached an agreement to purchase a house. On November 27, 2015, the plaintiff and the defendant signed a house purchase contract. On December 3, 2015, the plaintiff paid the purchase price and has been living until now. At the beginning of 2019, the plaintiff failed to urge the defendant to go through the house transfer procedures, so he sued to the court.

the two entities; and (4) *Semantic Role Labeling* (SRL) graph to model broader relations including those among third-party persons and facts. We will elaborate on each graph in Section 3.2. To learn the document representation, D2GCLF combines the four graphs and passes them to a graph representation learning module, based on the idea of graph attention networks (Velickovic et al., 2018). Then, D2GCLF uses the document representation for classification. Our main contributions include:

- We propose a new idea of leveraging facts, i.e., the relations between entities, for legal document classification.
- We propose a novel document-to-graph model for legal document classification.
- We conduct extensive experiments on a real-world legal document dataset. The proposed model outperforms the state-of-the-art text classifiers.

2 Related Work

2.1 Traditional Classification Methods

Traditional text classifiers are based on machine learning models, including Naïve Bayes, Logistic regression, etc. Naïve Bayes assumes the words in a document are independent given the class and estimates the class label with Maximum a Posteriori (Zhang and Hawkins, 2018; Fang et al., 2020). Logistic regression (Genkin et al., 2005; Ifrim et al., 2008; Pranckevičius and Marcinkevičius, 2016) and Support Vector Machine (SVM) (Sathe and Aggarwal, 2019; Pranckevičius and Marcinkevičius, 2016) find decision boundaries for the document classes in the feature space. Bagging (Li et al., 2011) and AdaBoost (Bloehdorn and Hotho, 2004) classifiers ensemble multiple classification models. The bagging model chooses the best result of multiple subclassifiers as the final decision. AdaBoost uses the sub-classifiers to focus on the fallible classification cases when training. In the legal domain, some early studies utilize these models to classify judgments (Lin et al., 2012; Li et al., 2019a).

2.2 Deep Neural Networks

Deep neural network classifiers learn latent semantic representations of the input documents, which are then used for classification. Convolutional Neural Networks (CNNs) perform convolution operations for capturing the local context in the latent representation (Li et al., 2019b; Wang et al., 2018b). Recurrent Neural Networks (RNNs) consider the sequential information of a sentence (Das et al., 2019). Long-Short Term Memory (LSTM), Gated Recurrent Unit (GRU), and other modified RNNs (Liu et al., 2016) address the gradient vanishing problem of RNN with well-designed gates in a recurrent unit. Hybrid models, such as Recurrent Convolutional Neural Networks (RCNN), combine RNN and CNN. RCNN is more robust to noise when encoding the sequential information (Lin et al., 2018).

Bidirectional Encoder Representations from Transformers (BERT) series are widely utilized in

NLP tasks. BERT is proven effective in many LegalAI tasks, such as judgment prediction. Previous studies of BERT in legal domain include the legal BERT(Cui et al., 2021; Chalkidis et al., 2020), RoBERTa(Cui et al., 2020), Chinese legal Longformer (Xiao et al., 2021), etc.

2.3 Graph-based Classifications

All the methods above focus on the semantics of documents. However, the document structure, especially for long documents, is also vital for text classification. Recent studies (Kipf and Welling, 2016; Yao et al., 2019; **?**; Liu et al., 2020) propose to represent the documents in a homogeneous or heterogeneous graph. The homogeneous graph consists of all coherent words as nodes (Ragesh et al., 2021; Zhang et al., 2020) – two words are connected if they co-occur. The heterogeneous graph utilizes the entities-sentence co-occurrence (Hu et al., 2019). Given the representative graph, a graph neural network is used to classify the documents (Veličković et al., 2017; Pal et al., 2020; **?**).

To the best of our knowledge, all existing methods classify the documents by topics, reflected by either word frequency or word co-occurrence. None of the existing methods leverage the facts described in the documents. Different from existing methods, we propose to explore the facts in the legal documents for accurate classification.

3 Document-to-Graph Classifier

3.1 Motivation

Referring back to the previous example in Table 1, we observe that a civil complaint case often contains four main components: (1) **Entity information sections** that cover the information of litigation participants; (2) **Facts** between the entities, which are essential for identifying the type of dispute; (3) **Reason** why the plaintiff sued; (4) **Miscellaneous items** that include discussions on the relevant law, procedure, evidence. Miscellaneous items are less relevant to document types, because the same law may be used in different types of disputes. Figure 1 shows the common structures for civil complaints.

The relations among the key participants are often implied in the sentences in the fact and reason sections. These relations vary across different types. Table 2 shows four example sentences relevant to different types of lending disputes. The first three examples belong to “Dispute Over Contract for Private Lending” (DOCPL). Example 1 discusses a lending action, while Example 2 and 3 mention the purpose and reason for the lending action. In Example 4 of a “Dispute Over Contract of Suretyship” (DOCS) document, the “guarantor” is pivotal to identifying the type. However, this keyword may be overlooked by a classifier unless it understands the relations among participants from the sentences.

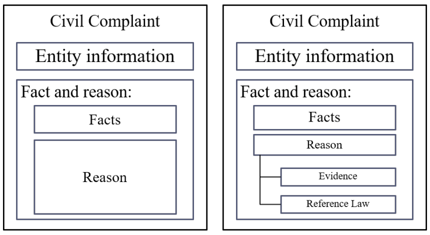

Figure 1: The common structure of Chinese Civil Complaints (Left) and a specific type (Right).

Table 2: Example of different lending disputes.

No.	Example sentence	Class
1	A borrowed B 5,000 dollars.	DOCPL
2	A borrowed B 5,000 dollars to buy C’s house.	DOCPL
3	A failed in business and borrowed money from B.	DOCPL
4	A borrowed B’s money, C is the guarantor. Because A did not return the money, B ask C to return.	DOCS

Motivated by the observations above, we propose a **Document-to-Graph Classifier (D2GCLF)**. D2GCLF represents a legal document by relation graphs constructed from the facts. Figure 2 shows the architecture of the D2GCLF. Our method extracts four relation graphs, each graph represents the facts associated with the main participants from different aspects (Section 3.2). Once we obtain the graphs, we learn a latent representation of each document by aggregating the information from all graphs, based on the idea of graph attention networks (Section 3.3). The document representation is then passed to a log-softmax layer to generate the class label.

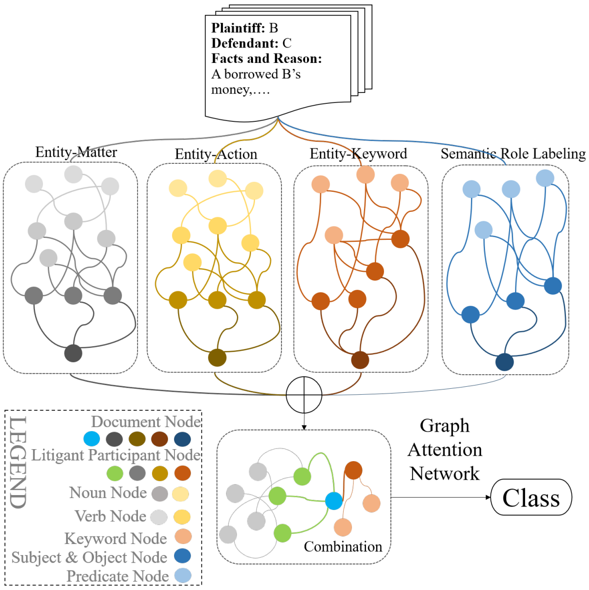

Figure 2: The architecture of D2GCLF.

3.2 Graph Extraction

Entity-Matter Graph The Entity-Matter graph is motivated by the observation that each dispute case should correspond to some matters between the plaintiffs and defendants. For example, the first case in Table 1 discusses the matter of commercial housing transfer and housing ownership. We consider the ”matters” as the key evidence for identifying the class of a dispute case. Observing that ”matters” are often nouns that appear in the same sentence of the plaintiffs and defendants, we extract the nouns from every sentence that contains both plaintiffs and defendants using a part-of-speech parser[1]. To understand the actions that have been taken on the ”matters”, we also extract the verb that describes each extracted noun. For example in Table 2, the verb ”borrowed” will be extracted together with the noun ”dollar”. Then, we construct the Entity-Matter graph as follows: (1) create a document node, a plaintiff node (denoted by A) and a defendant node (denoted by B); (2) connect both A and B to the document node; and (3) connect the nouns extracted to both A and B, and to the verbs describing them. Figure 3 shows an example of Entity-Matter graph.

Entity-Action Graph The Entity-Action graph is motivated by the observation that each dispute case should correspond to some actions between the plaintiffs and defendants. For example, the first case in Table 1 indicates that the plaintiff has “paid” the defendant money to purchase the house. The verb “paid” is an action that has been taken by the plaintiff. Motivated by this, we extract the verb from every sentence that contains both plaintiffs and defendants as actions. To understand the actions, we also extract the object of each action. For example in Table 2, the noun “dollar” will be extracted together with the verb “borrowed”. Similar to the construction of Entity-Matter graph, we connect the plaintiff and defendant to a document node. The difference is to connect the plaintiff and defendant with each “action”. In addition, we attach the corresponding object to each “action” node. Figure 4 shows an example of Entity-Action graph.

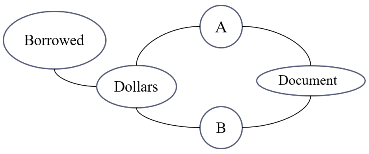

Figure 3: An example of Entity-Matter graph extracted from text: “A borrowed B dollars”.

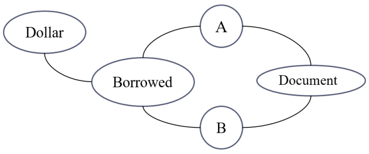

Figure 4: An example of Entity-Action graph extracted from text: “A borrowed B dollars”.

Entity-Keyword Graph The Entity-Keyword graph is designed to capture the topics related to the plaintiffs and defendants. For example, the first case in Table 1 includes keywords such as “house”, “transfer” and “buy”, which describe the general topics of the dispute. We extract keywords from every sentence that contains all litigation participants using Textrank (Mihalcea and Tarau, 2004). For example in Table 2, “dollar” and “borrowed” are the keywords relevant to the key stakeholders. To construct the Entity-Keyword graph, we create the document node and participant nodes in the same way as the previous two graphs. Then, we connect the keywords extracted to the litigation participants. Figure 5 shows an example of the Entity-Keyword graph.

SRL Graph The above graphs only focus on the noun or verb related to the litigation participants. However, besides the main participants, other peo-

---

[1] `https://pypi.org/project/pkuseg/`

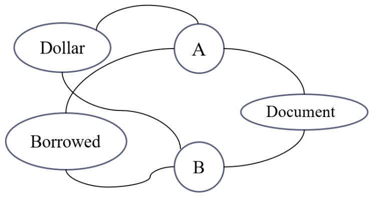

Figure 5: An example of Entity-Keyword graph extracted from text: "A borrowed B dollars".

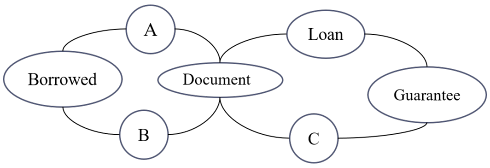

Figure 6: An example of SRL graph extracted from text: "A borrowed B dollars. C provide guarantee for the loan". In the example, "borrowed" is the predicate associated with A and B.

ple and facts may be involved in a law case. For instance, in Example 4 of Table 2, C is a third party individual, who is not the direct participant in the case but acts as a guarantor. Therefore, we construct a Semantic Role Lableing (SRL) graph to extract relations in the form of (subject, predicate, object) from every sentence in the document using the LTP tool[2]. For example in Table 2, (A, borrowed, B) and (C, guarantee, "loan") will be extracted. Then, we construct the SRL graph by: (1) connecting the extracted subjects and objects to the document node; and (2) connecting subjects and objects through the predicates. Figure 6 shows an example of the SRL graph.

Combined graph The four graphs extracted above represent the facts in the documents from different aspects, and thus they have limited presentation power if applied individually. As such, we combine the four graphs by merging the nodes that denote the same concepts from the four graphs into one, e.g., the document nodes, the plaintiff and defendant nodes, and other noun or verb nodes. The edges from the four graphs are preserved in the combined graph. Figure 7 shows an example of the combined graph.

3.3 Graph-based Document Representation Learning

Given the combined graph that represents the facts in a document, we aim to learn a latent representation for the document that encodes information

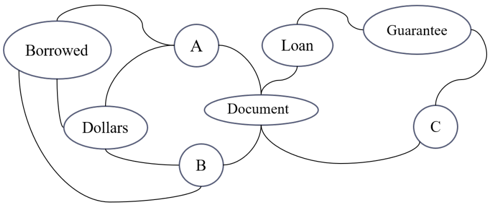

Figure 7: An example of the combined graph.

of the graph. In this work, we apply a graph attention network (Veličković et al., 2017) to aggregate the information from all nodes to the "document" node for learning document representations. Note that, our method is flexible to apply any existing graph neural networks for document representation learning. We will leave the comparison of different graph neural networks as future work.

The input of the graph attention network is a set of node features:

$$h = \{\vec{h}_1, \vec{h}_2, \ldots, \vec{h}_N\}, \vec{h}_i \in \mathbb{R}^F, \tag{1}$$

where N is the number of nodes and F is the number of features for each node. We use pre-trained word embeddings (detailed in Section 4.3) as the input feature h for all nodes.

The outputs are the F'-dimension latent representations of all nodes:

$$h' = \{\vec{h'}_1, \vec{h'}_2, \ldots, \vec{h'}_N\}, \vec{h'}_i \in \mathbb{R}^{F'}. \tag{2}$$

For each node, the graph attention network performs self-attention and the cross-correlation attention with neighbor nodes:

$$\begin{gathered} a : \mathbb{R}^{F'} \times \mathbb{R}^{F'} \rightarrow \mathbb{R} \\ e_{ij} = a(\mathbf{W}\vec{h}_i, \mathbf{W}\vec{h}_j), \end{gathered} \tag{3}$$

where $\mathbf{W}$ represents the weight, a is a single-layer feedforward neural network, e_{ij} means the importance of node j to node i, vector h is the feature vector and subscripts i, j denote the i-th node and the j-th node, respectively. Then, a softmax function is applied to regularize the attention scores α_{ij} for the adjacent nodes such that they sum to one.

$$\alpha_{ij} = softmax_j(e_{ij}) = \frac{exp(e_{if})}{\sum_{k \in \mathcal{N}_i} exp(e_{ik})}. \tag{4}$$

Then, the latent representation of a node is computed as an aggregation of its neighbors:

$$\vec{h}'_i = \sigma\Big(\sum_{j \in \mathcal{N}_i} \alpha_{ij} \mathbf{W}\vec{h}_j\Big), \tag{5}$$

---

[2] http://ltp.ai/docs/quickstart.html

where the $\sigma(\cdot)$ is an activation function and $\mathbf{W}$ is a learnable weight matrix. In this work, we use the Rectified Linear Unit $RELU(\cdot)$ as the activation function. In order to be able to focus on the information from the scattered nodes to Document node, we apply multi-head attention, which calculate K different attention scores $\alpha_{i,j}^{k}$ and weights $\mathbf{W}^k$:

$$\vec{h}_i' = \sigma(\frac{1}{K}\sum_{k=1}^{K}\sum_{j\in\mathcal{N}_i}\alpha_{i,j}^{k}\mathbf{W}^k\vec{h}_j). \tag{6}$$

By the above formulation, the "document" node will aggregate information from its neighbors, which in turn, aggregate information from their neighbors.

Let the latent vector representation of the document be $\vec{h}_{doc}'$, which is obtained by Eq. 6. We feed the document representation $\vec{h}_{doc}'$ to a log-softmax layer to compute the probability for a document to be a particular type by:

$$p(class|doc) = log\text{-}softmax(\vec{h}_{doc}'). \tag{7}$$

To learn the parameters of the model, we minimise the Negative Log Likelihood Loss:

$$\mathcal{L} = -\sum_{(d,l_d)\in\mathcal{D}_{train}} \log p(l_d|d), \tag{8}$$

where (d, l_d) is a pair of document d and its class label l_d in the training set $\mathcal{D}_{train}$.

4 Experiments

4.1 Dataset

Chinese civil law contains more than 400 classes. Among those 400 classes, we asked legal experts to pick up 20 classes, which are the most semantically close to each other. Table 5 shows the name and the label of each of the 20 selected classes. We then collected the 4,000 judgments from China Judgments Online[3] by choosing the latest published 200 cases in the searching result for each of the 20 classes. Following the format of the Chinese judgment, we selected the parties' information paragraph and the plaintiff's allegation paragraph from each judgment to create the statement of claim. The resulting dataset contains 4,000 civil cases, 200 cases per class. Ethic issues are discussed in Section 6.

We randomly split the dataset into 70% training set and 30% test set. For the anaphora and co-references in the indictments, we replace them with the actual name of the litigation participants.

4.2 Compared Models

We compare the proposed method with several baselines. As described in Section 2, multiple word representation methods can be used, such as TF-IDF and word embeddings. For word embedding, We use the pre-trained word embedding on People's Daily News[4]. Because, the linguistic style of the newspaper is very similar to the Chinese legal document. The comparison of different word representations, initialization, and TF-IDF, for baselines are presented in Appendix C. For neural network-based model, we keep the same parameter as the original papers and we selected the 10 best checkpoints based on performance on the validation set and report averaged results on the test set.

Machine learning methods. We compare our model with Naïve Bayes, SVM, Logistic Regression, Boosting model, Bagging model in legal document classification. The best embedding result for these models is Char-level TF-IDF representation. We utilize the suitable pre-trained Chinese word embeddings[4].

Deep learning. We compare D2GCLF with deep learning techniques including CNN, RNN, RNN-Bidirectional (BiRNN), BiLSTM, RCNN, HN-ATT (**?**)) using pre-train word embeddings[4] as input.

BERT series. We utilize the pre-trained BERT (Devlin et al., 2018)[5], RoBERTa (Cui et al., 2021)[6], and Chinese Legal Longformer (Xiao et al., 2021)[7] to compare with the proposed model. After encoding the document by the pre-trained model, we add a fully-connected layer to predict the label. Based on the pre-trained language model, BERT, we also select the Task-Scaling mechanisms (TaSc) (Chrysostomou and Aletras,

---

[3] All indictments used in this paper were collected on China Judgment Online`https://wenshu.court.gov.cn/`. For ethical concern, we only release the Reference Number and url for the cases we used. The index file is available on: `https://drive.google.com/file/d/1bZVv0TPSjIRsRj0OP67v8Y-K-tb-o7IE/view?usp=sharing`.

[7] https://github.com/thunlp/LegalPLMs

2021)[8] as baseline. TaSc allows us to learn non-contextualised information from category text.

Graph-Based series. We also include graph-based models, such as Graph Convolutional Networks (GCN) (Yao et al., 2019), GrapSAGE (**?**) and Graph Attention Networks (GAT) (Pal et al., 2020), TextING (Zhang et al., 2020). For GCN, GAT, and GrapSAGE following Yao et al. (Yao et al., 2019), we construct a document-word graph from the dataset. Specifically, we create a graph node for each document and each word. Then, a word node connects to a document node if the word is in the document. Word nodes are connected if they are in the same document. Then, we also strictly follow TextING instructions[9].

4.3 Configuration

We utilize the same pre-trained Chinese word embeddings[4] as the baseline methods. For the parameters of D2GCLF, we set the size of node representation $F' = 25$ in Eq. 2 and the number of attention heads $K = 8$ in Eq. 6, and utilize the Adam optimizer with the learning rate $5 * 10^{-5}$, and weight decay $5 * 10^{-4}$. In the experiments, the parameters of all methods are obtained by cross-validation on the training data. To validate the performance of the classifiers, we use AUC as the evaluation metric. Experiments are repeated five times and take the average on a workstation with an Nvidia GeForce RTX 3090 GPU with 24 GB memory.

4.4 Result and Discussion

Overall Comparison: The overall comparison among all methods is shown in Table 3. We observe that D2GCLF outperforms all methods and gains a 4% AUC improvement over the best baseline method. Among the traditional classification methods, the boosting model achieves the best AUC because it ensembles multiple models, each of which focus on different features. Naïve Bayes performs the worst. This is because it heavily relies on the class distribution in the training data, which could be different in the test set.

For deep neural networks, CNN performs the best while RNN performs the worst (70% of AUC). This is because RNN embeds sentences and words that may not be relevant to the class. Conversely, CNN aggregates information in a local context, which is less sensitive to noise. Among the deep learning methods, BERT performs the best, because the transformer can capture the impact from key sentences, paragraphs, or sections to some extent. As we have mentioned, the key factors for determining the class of a legal document often lies in particular sentences, paragraphs, or sections. The graph neural networks with a document-word graph perform the worst, because the graph contains irrelevant words. TextING constructs a word graph by connecting co-coherence words to represent structure information for message passing. However, it does not work well for the legal data because the graph does not capture the key facts.

Table 3: Classification performance

Model Name		AUC
Machine Learning	Naive Bayes	81.93%
	Logistic Regression	85.81%
	SVM	85.15%
	Bagging Model	85.35%
	Boosting Model	87.17%
Deep Learning	CNN	85.75%
	RNN	79.08%
	BiRNN	83.07%
	BiLSTM	84.67%
	RCNN	83.55%
	HN-ATT	85.14%
BERT Series	BERT	85.75%
	TaSc	85.27%
	RoBERTa	81.00%
	Legal Longformer	82.25%
Graph based	GCN	79.08%
	GAT	83.07%
	GraphSAGE	83.55%
	TextING	83.71%
Ours	D2GCLF	**91.33%**

Besides, deep learning methods such as CNN and RNN are less effective in legal document classification than in other domains. This is because legal documents imply complex relations among the participants, while the size of real-world legal document datasets, especially the indictment documents, is relatively small for learning a complex and deep model from plain texts. D2GCLF outperforms existing methods by representing the facts in a document as a graph.

[9] https://github.com/CRIPAC-DIG/TextING

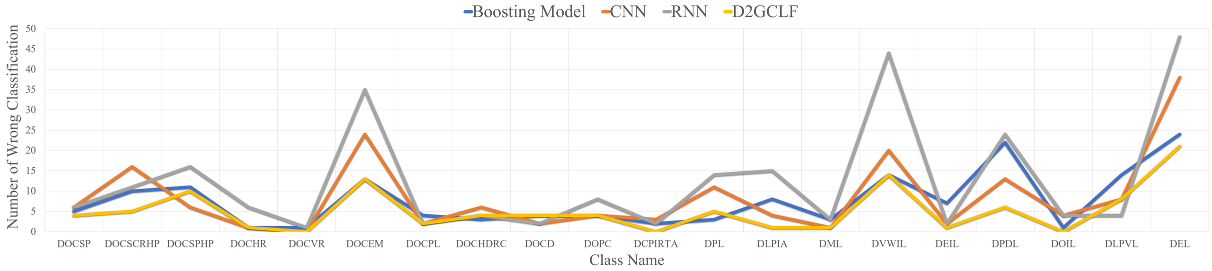

Figure 8: Number of wrong classification cases in different types.

Table 4: Ablation study for the four graphs. $\ominus$ denotes the variant that removes one of the four graphs from D2GCLF.

Model Name	AUC
$D2GCLF_{Entity-Matter}$	84.83%
$D2GCLF_{Entity-Action}$	83.42%
$D2GCLF_{SRL}$	82.25%
$D2GCLF_{Entity-Keyword}$	82.25%
$D2GCLF_{\ominus Entity-Matter}$	87.08%
$D2GCLF_{\ominus Entity-Action}$	87.67%
$D2GCLF_{\ominus SRL}$	87.75%
$D2GCLF_{\ominus Entity-Keyword}$	88.08%
D2GCLF	**91.33%**

Ablation Study: Next, we test the impact of different relation graphs. We first compare the performance of each graph, denoted by $D2GCLF_{graph}$, where $graph \in$ {Entity-Matter, Entity-Action, SRL, Entity-Keyword}. Then, we compare the full model with its variants by removing each graph, denoted by $D2GCLF_{\ominus graph}$.

Table 4 shows the AUC of all variants. The Entity-Matter graph performs the best among individual graphs. Besides, when the Entity-Matter graph is removed from the full model, the performance decreases the most. The result justifies that matters involving both participants are the most important factors for classifications. The performance drop of $D2GCLF_{\ominus Entity-Action}$ implies the actions of the participants provides additional information for classification. $D2GLF_{\ominus Entity-Keyword}$ results in the least performance drop. This justifies that the topics represented by keywords may have little impact on the task. The significant difference between the full and ablation models shows that the four graphs complement each other.

Case Study: We report the numbers of wrong classification cases for each model in Figure 8. Due to the space limit, we only report the results of Boosting, CNN, RNN and D2GCLF. Overall, D2GCLF generates the least wrong classifications in most classes (e.g., DPDL, DOCD and DOCSP). Specifically, the two classes *Disputes of employer liability (DEL)* and *Dispute of voluntary workers injured liability (DVWIL)* are the most difficult to identify, because they are highly related to other types. The difference between the two is whether work is paid or volunteered. Besides, the injured liability includes traffic accidents, medical liability, etc., which are similar to other dispute classes. D2GCLF performs the best, even for difficult classes because it considers the facts, e.g. traffic accidents.

5 Conclusion

This study explores a novel idea of classifying legal documents based on the facts discussed in the documents. We propose a Document-to-Graph Classifier (D2GCLF) to implement our idea by modeling the facts as four relation graphs, and applying graph attention network to learn the document representation for classification. Experiments on a real-world legal document dataset show the effectiveness of the four relation graphs and the superior performance (91.33% AUC) of D2GCLF.

6 Ethics Statement

The 4,000 Chinese cases that this research is based upon are drawn from the China Judgements Online (`https://wenshu.court.gov.cn/`), which is available for everyone to search cases' judgments once logged in. We notice that previous researches (Tsarapatsanis and Aletras, 2021; Leins et al., 2020) are worried about the ethical concerns raised in terms of applying the NLP technique into the legal domain. Some researchers believe that processed datasets cause people to harm the relevant parties as such datasets enable a more straightforward retrieval process than searching through the original datasets published by government agencies. We would like to point out that the judgments published on China Judgment Online already redacted most of the important personal information. Nevertheless, to mitigate against any remaining concerns, in our dataset, we only publish the case reference number and URL instead of the full text which is available. Besides, we only allow the index dataset to be used in research, not for any other purpose. To download or any other way to use judgments in China Judgment Online, please follow the website's terms and conditions.

A Example of Legal Documents

Table 6 shows two examples of real cases with similar topics but categories in different types.

B Classes in Dataset

There are twenty classes in our experiment, such as Dispute over contract for sale and purchase, etc. Table 5 shows the full name and abbreviation of these classes.

C Baselines

Except for the baselines, which are introduced in Section 4, we also utilize the other word embedding methods to test the baselines. The full result is shown in Table 7.

Table 5: Classes in dataset

No.	**Class**
1	Dispute over contract for sale and purchase (DOCSP)
2	Dispute over contract of sale of commercial residential housing property (DOCSCRHP)
3	Dispute over contract for sale and purchase of housing property (DOCSPHP)
4	Disputes over contract for housing rental (DOCHR)
5	Disputes over contract for vehicle rental (DOCVR)
6	Dispute over contract of earnest money (DOCEM)
7	Dispute over contract for private lending (DOCPL)
8	Dispute over contract for housing demolition, relocation and compensation (DOCHDRC)
9	Dispute over contract for decoration (DOCD)
10	Dispute over partnership contract (DOPC)
11	Dispute over compensation for personal injury resulting from traffic accidents (DCPIRTA)
12	Disputes of product liability (DPL)
13	Disputes over liability for personal injury from animals (DLPIA)
14	Dispute of medical liability (DML)
15	Dispute of voluntary workers injured liability (DVWIL)
16	Disputes of educational institutions liability (DEIL)
17	Disputes of property damage liability (DPDL)
18	Dispute of online infringement liability (DOIL)
19	Disputes of labor providers victimization liability (DLPVL)
20	Disputes of employer liability (DEL)

Word representation techniques Most existing methods take word representations as input. As such, we apply different word representation techniques: (1) Word-level TF-IDF that calculates each word's TF-IDF in the document; (2) N-grams TF-IDF that calculates the word frequency on the n-gram basis; (3) Char-level TF-IDF that calculates the frequency of n consecutive characters; (4) Pre-trained word embedding[10] that represents the semantics of each word with a low-dimensional vector.

Machine learning methods We choose the Naive Bayes, SVM, Logistic Regression, Boosting model, Bagging model to classifier the legal documents. Given that these methods will not update the word representation vector, We run these classifers on Word-level, N-grams and Char-level TF-IDF representations.

Deep learning We compare our method to deep learning techniques including CNN, RNN, RNN-Bidirectional (BiRNN), BiLSTM, RCNN. We compare the classification performance of this category of methods with both random initialized and pre-train word embeddings.

Abstract

Cross-domain named entity recognition (NER) aims to borrow the entity information from the source domain to help the entity recognition in the target domain with limited labeled data. Despite the promising performance of existing approaches, most of them focus on reducing the discrepancy of token representation between source and target domains, while the transfer of the valuable label information is often not explicitly considered or even ignored. Therefore, we propose a novel autoregressive framework to advance cross-domain NER by first enhancing the relationship between labels and tokens and then further improving the transferability of label information. Specifically, we associate each label with an embedding vector, and for each token, we utilize a bidirectional LSTM (Bi-LSTM) to encode the labels of its previous tokens for modeling internal context information and label dependence. Afterward, we propose a Bi-Attention module that merges the token representation from a pre-trained model and the label features from the Bi-LSTM as the label-aware information, which is concatenated to the token representation to facilitate cross-domain NER. In doing so, label information contained in the embedding vectors can be effectively transferred to the target domain, and Bi-LSTM can further model the label relationship among different domains by pre-train and then fine-tune setting. Experimental results on several datasets confirm the effectiveness of our model, where our model achieves significant improvements over existing methods.[1]

1 Introduction

Named entity recognition (NER) is a fundamental task in natural language processing (NLP), aiming to identify salient information from raw texts, such as persons, locations, and so on. NER can be viewed as a specific sequence labeling problem, where models built upon pre-trained language models have recently achieved significant improvements. However, most conventional approaches trained on specific domains (source domains) are hard to generalize to new domains (target domains) due to the differences in text genre and limitation of labeled data. Thus, cross-domain NER has been proposed for alleviating this problem, which aims to learn information from the source domain to enhance NER in the target domain.

For example, Jia et al. (2019) utilized a parameter generation network to combine cross-domain language modeling and NER, thereby enhancing the model to extract knowledge of domain differences from raw texts. Furthermore, Liu et al. (2020b); Gururangan et al. (2020) proposed to continue pre-training the language models on the target domain-related corpus. Despite the outstanding performance, existing approaches mainly focus on handling the text discrepancy between different domains and apply Conditional Random Fields (CRF) (Lafferty et al., 2001) to capture label-label dependence in neighbor tags. Several issues cannot be appropriately solved. First, most of them rely heavily on the powerful encoder to implicitly extract token-label relationships due to the limitation of the sequence labeling framework, which is insufficient, especially for the limited data in a new domain, where the encoder is hard to be fully trained. In cross-domain NER, token-label relationships are more critical since better token-label interaction can help the model distinguish the differences and similarities between the two domains. For example, in the general domain, "Bayes" usually is a "*person*" entity, while in the artificial intelligence (AI) domain, for "supervised learning are Naive Bayes classifier", "Bayes" is an "*algorithm*" entity. Clearly, if a model is aware that the NE label of the previous phrase "supervised learning" is an "*AI field*" entity and thus pays more attention to this

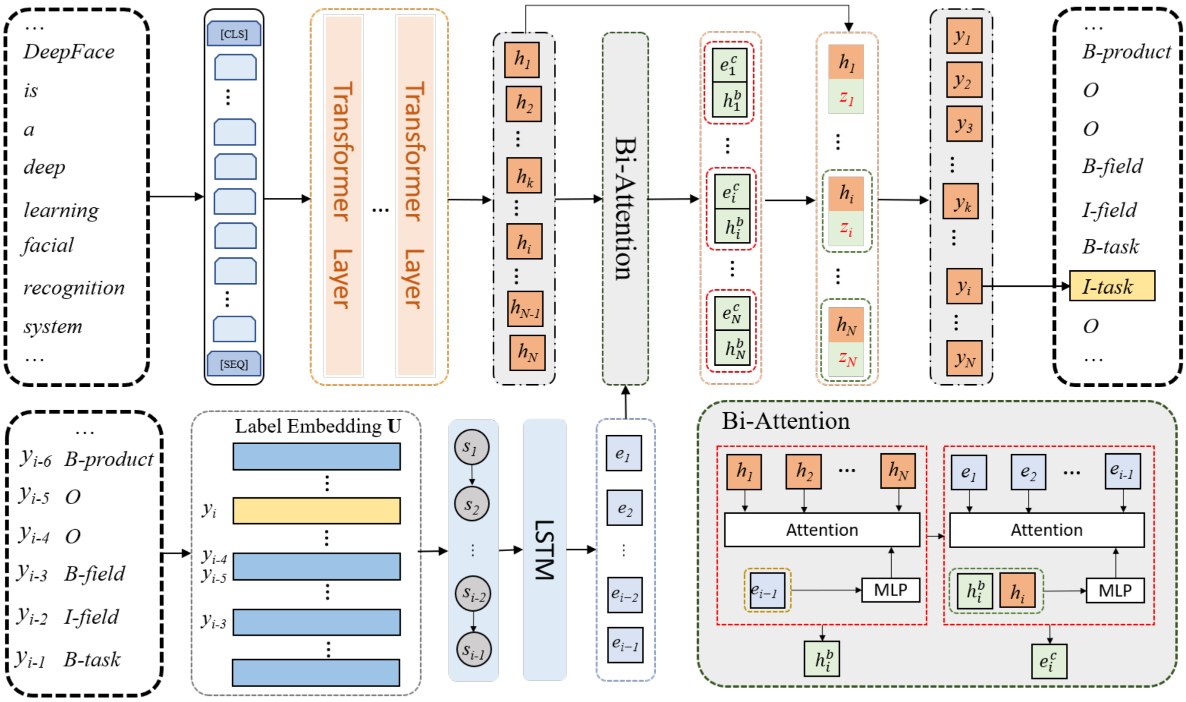

Figure 1: The overall architecture of our proposed model. The upper part is the general sequence labeling model paradigm, and the left bottom part is used to extract label-aware information (i.e., $\mathbf{z}_i$) and the right bottom part reveals the Bi-Attention structure.

phrase, predicting “Bayes” as an “*algorithm*” entity shall be an easier task. Such previous label information (e.g., labels of “supervised learning”) can be explicitly used to help the model enhance the relationship between tokens and labels instead of purely depending on the encoder itself. Second, remote label-label relationships and label semantic information are also important for cross-domain NER instead of only modeling the interdependency among adjacent labels as CRF does. For example, for “Like a Girl which is from the Scenery and Fish”, “Like a Girl” is an “*album*” entity and “Scenery and Fish” is a “*song*” entity. Although they are not adjacent, since entity type ‘*album*” is semantically close to “*song*”, they tend to exist in the same sentence. When the model has predicted an “*album*” entity, it will pay more attention to the “*song*” entity during predicting other words in the sentence, which is a type of helpful supplementary information. Third, when two domains share the same NE types, these shared labels usually represent similar meanings such that they are easily adapted to the target domain, which is paid less attention in previous studies. Therefore, fully using shared NE labels and further appropriately modeling the correlations between the shared labels and target domain-related ones are also beneficial to advance cross-domain NER.

In this paper, we propose a novel autoregressive cross-domain NER framework to help the model facilitate domain adaptation by improving the relationship between the source text and its named entity (NE) labels and enhancing label information transfer. In detail, we associate each label with an embedding vector (randomly initialized and learned later), and for each token in the original text, we input the embeddings of the label sequence generated from previous steps into a bidirectional LSTM (Bi-LSTM), whose hidden states model label sequence information. Next, we propose a Bi-Attention module to perform two attention between token representations from a pre-trained model and label features from the Bi-LSTM to calculate label background and context information and then concatenate them as the label-aware information. We then fuse label-related knowledge into current token representation for promoting cross-domain NER. In doing so, our model can learn label embeddings and the potential relationship between tokens and labels by pre-training on the source domain, especially for shared entity labels, and then adapt them to the target domain by fine-tuning. Experimental results on several datasets show that our approach outperforms existing studies.

2 Method

2.1 Problem Definition

NER can be conventionally performed as a sequence labeling problem (Lample et al., 2016; Luo et al., 2020), where named entities can be viewed as labels of tokens. Specifically, given an input sequence $\mathcal{X} = \{x_1, x_2, \cdots, x_N\}$ with N tokens, the goal of NER is to output the corresponding label sequence $\mathcal{Y} = \{y_1, y_2, \cdots, y_N\}$ with the same length, i.e., modeling $p(\mathcal{Y} \mid \mathcal{X})$. In the cross-domain NER task, we are given two datasets from the source and target domains, denoted as $\mathcal{D}_{src}$ and $\mathcal{D}_{tgt}$, respectively. The aim is to learn valuable knowledge from $\mathcal{D}_{src}$ and transfer it to the target domain $\mathcal{D}_{tgt}$.

Many existing (cross-domain) NER models (Liu et al., 2020b; Jia and Zhang, 2020; Lin and Lu, 2018) predict a token's entity purely based on the context of the sequence, and they formulate $p(\mathcal{Y} \mid \mathcal{X}) = \prod_{i=1}^{N} p(y_i \mid \mathcal{X})$. However, these approaches pay less attention to the label information and the relationship between labels and tokens. To explicitly enhance such relationship and capture label information, we propose a novel framework to predict NE labels by utilizing both previous labels and token representation, which can be formulated as an autoregressive model:

$$p(\mathcal{Y} \mid \mathcal{X}) = \prod_{i=1}^{N} p(y_i \mid y_1, \ldots, y_{i-1}, \mathcal{X}). \quad (1)$$

In the cross-domain setting, such information can be extended between the labels in the source and target domains, which is an effective way of transferring knowledge to the target domain.

2.2 Proposed Model

As mentioned above, our proposed model consists of three main parts: the input sequence encoder that encodes the input sequence $\mathcal{X}$, the label encoder that encodes the previous tokens' labels $y_1, \cdots, y_{i-1}$, and the label predictor that predicts NER labels of tokens. An overview of our proposed model is shown in Figure 1, whose details are introduced as follows.

2.2.1 Input Sequence Encoder

Following many other cross-domain NER methods (e.g., Liu et al. (2020b)), we use a pre-trained BERT (Devlin et al., 2019) model denoted as $f_{\text{dte}}(\cdot)$ to encode the input sequence:

$$[\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_N] = f_{\text{dte}}(x_1, x_2, \cdots, x_N), \quad (2)$$

where $\mathbf{h}_i$ is a d_1-dimensional vector for each token x_i, which is expected to capture the contextual information of the corresponding token.

2.2.2 Label Encoder

To model the relations between the token sequence and label sequence, we propose a novel label encoder to extract the contextual information from the label sequence. An important distinction of our work from most previous approaches is that we predict the NE labels based on both commonly-used current token representation (i.e., $\mathbf{h}_i$) and *label-aware information* extracted from the previous labels (i.e., $y_{1:i-1}$[2]). Intuitively, the process of generating labels has a flavor of the sequence-to-sequence decoders. In detail, we first construct a randomly initialized label lookup table $\mathbf{U} \in \mathrm{R}^{K*d_2}$, where K denotes the number of unique labels in source or target domains, and d_2 is the size of label embedding. For a label y_k with $k \in \{1 : K\}$, we can embed it to $\mathbf{s}_k \in \mathrm{R}^{d_2}$ by using $\mathbf{U}$. To fully utilize the label-related knowledge for the current token x_i, we employ a Bi-LSTM (Hochreiter et al., 1997) to encode the label sequence (i.e., $y_{1:i-1}$) , expressed as:

$$[\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_{i-1}] = f_{\text{re}}(\mathbf{s}_1, \mathbf{s}_2, \cdots, \mathbf{s}_{i-1}), \quad (3)$$

where $f_{\text{re}}(\cdot)$ is the label sequence encoder (i.e., Bi-LSTM) and $\mathbf{e}_k \in \mathrm{R}^{2d_2}$ is the output of the Bi-LSTM for $k \in \{1 : i-1\}$, which is expected to capture the contextual information of previous labels.

2.2.3 Label Predictor

The label predictor is to leverage the contextual information of both the input sequence and previous label sequence to predict the NER labels. To merge the two kinds of information, we introduce a simple yet effective Bi-Attention module. Specifically, following (Wang et al., 2016), we regard the last hidden state of Bi-LSTM in the label encoder (i.e., $\mathbf{e}_{i-1}$ in Equation (3)) as the representation of label sequence, which severs as the query vector, while all token representations from the input sequence encoder (i.e., $\mathbf{h}_{1:N}$ in Equation (2)) are viewed as the key and value matrices. Before performing the matrix product, we apply a fully connected layer to project the $\mathbf{e}_{i-1}$ into the same dimension as the $\mathbf{h}_i$:

$$\mathbf{e}'_{i-1} = \mathbf{W}_2 \cdot \mathbf{e}_{i-1} + \mathbf{b}_2, \quad (4)$$

---

[2] In the training stage, the previous labels are from the ground truth while they are predicted by our model in the test stage.

where $\mathbf{e}'_{i-1}$ is a d_1-dimensional vector. We then compute the attention weight with the softmax function:

$$\mathbf{a}_i^b = \text{Softmax}(\mathbf{e}'_{i-1}\mathbf{h}^{\text{T}}). \tag{5}$$

Herein, $\mathbf{a}_i^b$ can be viewed as a probability distribution and used to produce a weighted sum over the input token representations (i.e., $[\mathbf{h}_{1:N}]$):

$$\mathbf{h}_i^b = \sum_k^N a_{i,k}^b \mathbf{h}_k. \tag{6}$$

Since label background information $\mathbf{h}_i^b$ is guided by $\mathbf{e}_{i-1}$, it is naturally to represent the relationship between the label of current token (i.e., y_i) and the whole input sequence. In addition, it is also necessary to capture the relationship between the current token x_i and previously predicted labels (i.e., $y_{1:i-1}$), which can improve the sensitivity of x_i to previous NE tags. We first concatenate token representation $\mathbf{h}_i$ and label background information $\mathbf{h}_i^b$ as a comprehensive intermediate state, which is further mapped to a $2d_2$-dimensional vector:

$$\mathbf{h}'_i = \mathbf{W}_3 \cdot \mathbf{h}_i \oplus \mathbf{h}_i^b + \mathbf{b}_3. \tag{7}$$

Below, we still adopt a simple attention module to compute the label context information:

$$\mathbf{e}_i^c = \sum_k^{i-1} a_{i,k}^c \mathbf{e}_k, \mathbf{a}_i^c = \text{Softmax}(\mathbf{h}'_i\mathbf{e}^{\text{T}}). \tag{8}$$

where $\mathbf{a}_i^c$ indicates the weight vector of token i over $\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_{i-1}$. Finally, we concatenate label background information over input sequence and context information over predicted NE labels as the final label-aware information $\mathbf{z}_i$:

$$\mathbf{z}_i = \mathbf{h}_i^b \oplus \mathbf{e}_i^c. \tag{9}$$

Note that, $\mathbf{W}_2$, $\mathbf{W}_3$, $\mathbf{b}_2$ and $\mathbf{b}_3$ are learnable parameters.

To further fuse label-related knowledge into token x_i, we concatenate h_i and corresponding *label-aware information* $\mathbf{z}_i$, formulated as:

$$\mathbf{u} = [\mathbf{h}_1 \oplus \mathbf{z}_1, \mathbf{h}_2 \oplus \mathbf{z}_2, \cdots, \mathbf{h}_n \oplus \mathbf{z}_N], \tag{10}$$

where $\mathbf{u}$ is the final sequence representation. Finally, we apply a trainable matrix $\mathbf{W}_o$ and bias $\mathbf{b}_o$ to map the $\mathbf{u}_i$ to the output space by $\mathbf{o}_i = \mathbf{W}_o \cdot \mathbf{u}_i + \mathbf{b}_o$ and utilize a softmax function to obtain the distribution with respect to all NE labels.

2.3 Pre-training and Fine-tuning in the Cross-domain Setting

To enhance text feature extraction in the target domain, we follow Liu et al. (2020b) to continue pre-training the input sequence encoder on the domain-related corpus to narrow the difference between source and target domain in terms of domain background and text distribution (Gururangan et al., 2020) and further capture more productive features from the target domain, which refers as domain-adaptive pre-training (DAPT). Moreover, to effectively transfer information to the target domain, we train our model in two stages: pre-training and fine-tuning. In detail, in the first stage, we train our model on $\mathcal{D}_{src}$ to learn text knowledge and enhance feature extractor. More importantly, this process can learn valuable label embeddings before accessing the target domain, especially for shared NE labels. At the second stage, we fine-tune our model on the target domain to adopt it to $\mathcal{D}_{tgt}$. Since we utilize a Bi-LSTM to encode label sequences with the help of the pre-trained shared label embeddings from the first stage, our model can further learn relations between the shared NE labels and target domain-specific NE labels (i.e., the labels that only exist in the target domain) as well as the intrinsic label dependency information. This can further help the model to leverage the knowledge of the source domain to better understand these unseen labels in the target domain.

Results of our model are averaged over three runs with different seeds.

(Liu et al., 2013b) and MIT Restaurant (Restaurant) (Liu et al., 2013a), where the first one is regarded as the source domain dataset and the others are performed as the target domain datasets. Specifically, Conll2003 is a popular NER dataset collected from the Reuters Corpus and is tagged with four NE types, including PER, LOC, ORG and MISC. CrossNER is drawn from Wikipedia and contains five different domain datasets: politics, natural science, music, literature, and AI. Movie and Restaurant corpus consist of user utterances for movie and restaurant domains with 12 and 8 classes. For all datasets, we follow their official splits of training, validation, and test sets, and their statistics are summarized in Table 1. Note that in this paper, we employ the standard BIO scheme to represent each NE label.

3.2 Baselines and Evaluation Metrics

To explore the performance of our proposed model, we compare it to following main baselines:

- **BERT-TAGGER** (Devlin et al., 2019): This fine-tunes the BERT model with a label classifier.
- **DAPT-TAGGER** (Liu et al., 2020b): This first applies DAPT and then is directly fine-tuned on the cross-domain NER task.
- **BERT-CRF**, **DAPT-CRF** (Liu et al., 2020b): These have the same main architecture as **BERT-TAGGER** and **DAPT-TAGGER**, and the difference is that they incorporate a CRF layer.

We also compare our model to existing studies:

- **LSTM-CRF** (Lample et al., 2016): This proposes to combine character- and word-level features and utilize a bidirectional LSTM with a sequential CRF layer to perform NER.
- **FLAIR** (Akbik et al., 2018): This leverages the internal states of a character language model to produce contextual string embedding and then integrate them into the NER model.
- **COACH** (Liu et al., 2020a): This learns the slot entity pattern and combines the features for each slot entity to enhance entity types prediction.
- **CROSS-DOMAIN LM** (Jia et al., 2019): This employs a parameter generation network to combine cross-domain language modeling and NER, thereby enhancing The model performance.
- **MULTI-CELL LSTM** (Jia and Zhang, 2020): This utilizes a multi-cell compositional LSTM structure for enhancing NER domain adaptation.
- **BARTNER** (Yan et al., 2021): This formulates NER tasks as an entity span sequence generation problem and incorporates BART as their backbone (Lewis et al., 2020).

To make a fair comparison, we exploit F1 scores as the evaluation metric.

3.3 Implementation Details

In our experiments, our model is implemented based on transformers[3] and Liu et al. (2020b)[4]. We choose BERT-base-cased[5] as our input sequence encoder to extract the features from the source sequence and follow its default model setting where we use 12 layers of self-attention with 768-dimensional embeddings. The dimension of the label embedding (i.e., d_2) is set to 100, and the hidden size of LSTM is the same as the d_2, which is also set to 100. Other hyperparameters, including the learning rate, batch size, and the number of epochs, are reported in Appendix A.1. During the training process, we utilize Adam (Kingma and Ba, 2015) to optimize all the trainable parameters, including the ones in the pre-trained model. The

4 Results

4.1 Comparison with Previous Studies

To illustrate the effectiveness of our proposed model, we compare it to previous studies and report the results in Table 2. There are several observations. First, we can observe that our model significantly outperforms all previous works, which illustrates the effectiveness of the proposed framework. Second, the comparison between our model and BARTNER-base confirms the validity of incorporating label information in cross-domain NER. Although both methods utilize generative approaches to perform NER, our model can grasp label-related knowledge by directly encoding NE tags with the help of a label embedding table. However, BARTNER-base needs to covert NE labels to original tokens, which may hurt the label information extraction and transfer. Third, our model demonstrates its superiority of simplicity when compared with those works that either incorporate external resources or introduce complicated training designs. For example, Multi-Cell LSTM combines two auxiliary tasks, entity type prediction and attention score guidance, with the NER task, and applies multi-task learning. In contrast, our model can achieve better results with a simpler method, where we only need to train our model on the source domain and then fine-tune it to the target domain. This indicates that an appropriate design can alleviate the need for additional resources.

When DAPT is introduced to Ours and Multi-Cell LSTM, Ours+DAPT and Multi-Cell LSTM+DAPT further improve the performance (with 3.71% and 2.16% improvements on averaged F1-score on CrossNER dataset), which illustrates that DAPT can narrow the gap between the source and target domains. Since domain-related corpus contains abundant domain-specialized background information, it can help the model better understand the text in the target domain. Besides, both Ours and Ours+DAPT outperform Multi-Cell LSTM+DAPT, regardless of DAPT, further demonstrating the potential of our proposed model in cross-domain NER.

4.2 Effect of Label-Aware Information

The main results are shown in Table 3. First, models incorporating label information outperform those ignoring such information (i.e., BERT and DAPT w/o LB+LC), which further confirms the validity of label information in this task. We can attribute that such information can provide valuable label-related knowledge to enhance the entity prediction. Second, on these datasets, the performance gains from our full model (i.e., BERT with LB+LC) over BERT-tagger on the CrossNER are larger than that of Movie and Restaurant. This observation owes to the fact that Movie and Restaurant do not share the same entity types with Conll2003, leading to a larger gap between label information from the source domain and target domain, which makes it more difficult for label features transfer. Third, our proposed framework shows its effectiveness when compared with those models that introduce the CRF layer. The reason behind this might be that our model can learn better label-related information from the source domain (including token-label and label-label relationships) and transfer it to the target domain, especially for two domains that share the same NE labels, while CRF can only recognize correlations between tags in the neighborhoods.

Moreover, we also conduct ablation studies: (1) without label context information (i.e., w/o LC), (2) without label background information (i.e., w/o LB), (3) without label context and background in-

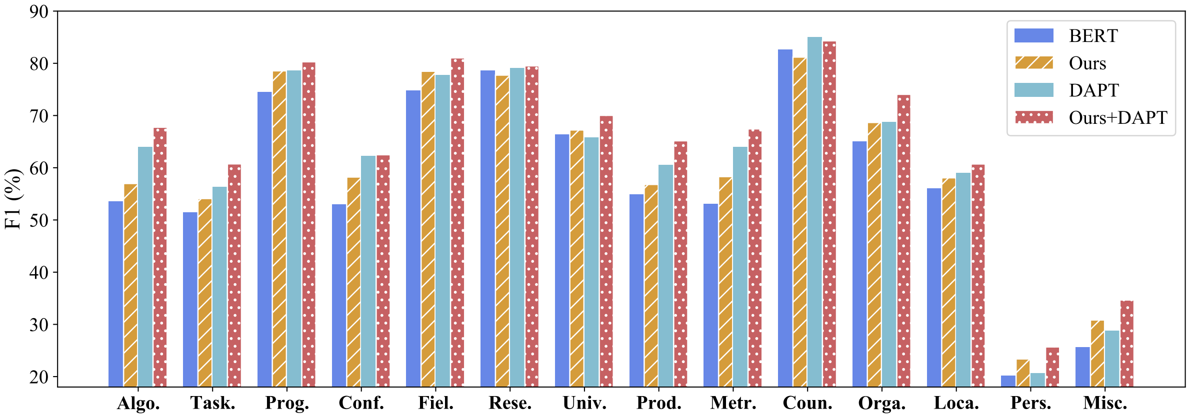

Figure 2: F1 scores of fine-grained comparisons on AI datasets. Results are averaged over three runs. The last four entity types are shared between the source and target domains.

formation (i.e., w/o LB+LC). The comparison between the base model (i.e., w/o LB+LC) and ones with LB or LC shows the effectiveness of each component in promoting cross-domain entity identification. Besides, it is observed that our full models (i.e., LB+LC) outperform w/o LB and w/o LC, which illustrates that combining label background and context information can further enhance information transfer and bring more improvements. The main reason might be that these two vectors are weighted sum over token features and label representation, respectively, with different focuses. Therefore, their combination can generate a better understanding of the label knowledge.

5 Analyses

5.1 In-domain Performance

To test the in-domain performance of our model, we utilize the single domain dataset to train our model and evaluate it on the corresponding test set, with results reported in Table 4. We can observe that our innovation in terms of incorporating label information is also productive for the in-domain NER task, where our model achieves better performance than the corresponding baselines. It can be attributed that our model can grasp a more comprehensive understanding between text and their labels and thus boost in-domain NER. However, the improvement gains from our model over baselines on the in-domain NER task are not as significant as that on cross-domain NER. An explanation for this observation may be that, in cross-domain NER, our model can better comprehend shared NE types. Therefore, it could help the model recognize differences and find more reasonable similarities between different domains, while this advantage may not be helpful for in-domain NER.

Model	Politics	Science	Music	Literature	AI
BERT†	66.56	63.73	66.59	59.95	50.37
Ours	**68.13**	**66.21**	**68.75**	**61.37**	**53.09**
DAPT†	70.45	67.59	73.39	64.96	56.36
Ours+DAPT	**71.83**	**69.23**	**74.79**	**66.35**	**58.12**

Table 4: F1 scores with respect to in-domain NER.

5.2 Fine-grained Comparison

We further investigate the fine-grained comparison on the AI dataset and visualize the results in Figure 2. We can see that our model obtains better performance in most entity types, regardless of whether DAPT is used, which indicates that the improvements gained from label-aware information are consistent across various entity classes. All shared entity types (i.e., the last four entity types) achieve increased performance by our models, indicating that our model can grasp more useful label information from the source domain and effectively transfer them to the target domain. However, for all non-shared entity types, our model leads to a slight decrease on a few entity types (e.g., **Country**). We find that **Country** is similar with **Location** and Conll2003 annotates some countries as the **Location** while CrossNER tends to label them as the **Country**. For example, *"Netherlands"* in Conll2003 is the **Location**, whereas, in the AI dataset, it is marked as the **Country**. Hence, the label information learned from the source domain may contribute to mis-classification about **Country** in the target domain. It can also explain performance drop in entity category **Researcher** since it is easily confused with **Person**.

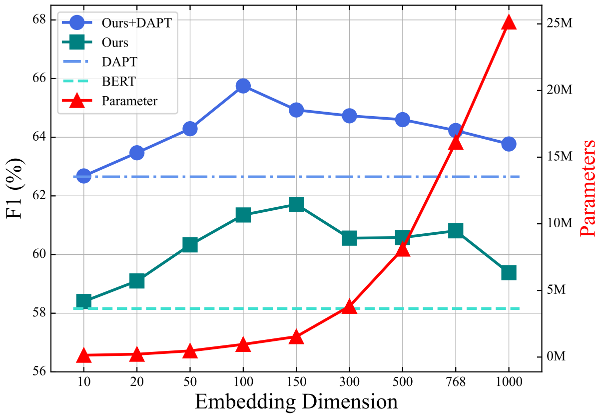

Figure 3: The F1 scores from Ours and Ours+DAPT against the label embedding dimension, where the model is tested on the AI dataset.

5.3 Effect of Label Embedding Dimension

To demonstrate the impacts of label embedding size, we train our model by varying the embedding dimension d_2 from 10 to 1000, as shown in Figure 3. It is observed that increasing the embedding size performs a better performance when the dimension is relatively small (i.e., $d_2 \leq 100$ for Ours+DAPT and $d_2 \leq 150$ for Ours). It indicates that, within this range, larger embedding can bring more valuable label information. However, when the dimension becomes too large, the performance gradually drops. It can be explained that a too large embedding matrix is difficult to be trained, resulting in redundant noise and degraded model performance. In addition, our model only introduces relatively small parameters when incorporating label-aware information. Especially when our models obtain the best results at $d_2 = 100$ and 150, their introduced extra parameters are 0.88% and 1.41% compared to the base model.

5.4 Effect of Data Size

To explore the impact of the target domain data size, we conduct experiments on different amounts of target training data (i.e., increasing from 10 to 100 samples) based on best-performing settings. The results are shown in Figure 4. With the data size increasing, all models gradually obtain better F1 scores, which illustrates that data scale plays an important role in the NER task. Besides, it is observed that both Ours and Ours+DAPT outperform corresponding baselines (i.e., BERT and DAPT) no matter how many samples we select, which further confirms the effectiveness of incorporating label information into cross-domain NER.

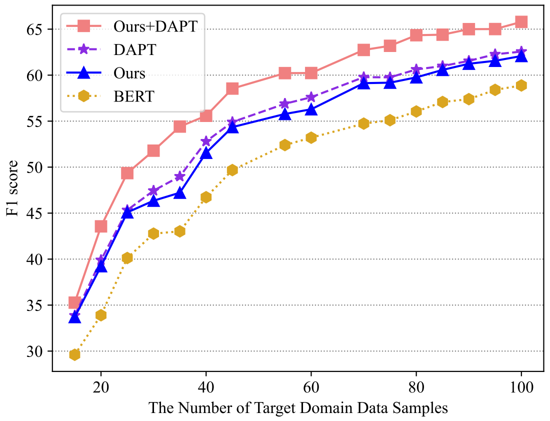

Figure 4: F1 scores of BERT, Ours, DAPT, and Ours+DAPT with different amounts of AI data in the target domain.

6 Related Work

In NLP, NER aims to identify entities from unstructured text, which has been studied widely over the past decades. Recently, neural networks have significantly improved the performance of NER, owing to their strong ability in feature extraction (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016; Yan et al., 2019; Devlin et al., 2019; Luo et al., 2020; Wang et al., 2021; Yamada et al., 2020; Yan et al., 2021). For example, Huang et al. (2015); Lample et al. (2016) combined Bi-LSTM with a CRF layer to enhance NER. Devlin et al. (2019); Yamada et al. (2020); Yan et al. (2019) further introduced the Transformer-based (Vaswani et al., 2017) encoders to extract more effective information from the sequence, which is then used to facilitate NER. However, although these models achieved great performance, they required large-scale labeled training data to adapt to different domains. Therefore, cross-domain NER has drawn substantial attention in recent years and gradually become one of the hot research topics in NLP. Many approaches have been proposed to enhance cross-domain NER (Pan et al., 2013; Jia et al., 2019; Jia and Zhang, 2020; Liu et al., 2020b; Chen and Moschitti, 2019). For example, Jia et al. (2019) utilized a parameter generation network to perform cross-domain and cross-task knowledge transfer and employed multi-task learning to combine NER and language modeling tasks. Furthermore, Jia and Zhang (2020) presented a multi-cell compositional LSTM structure that incorporated the entity type by a separate cell state to enhance the cross-domain NER. Compared with these studies, our model provides a simple but effective solution for addressing cross-domain NER by improving label information transfer and predicting current labels through corresponding tokens and previous labels together.

7 Conclusion

In this paper, we have proposed a novel framework for cross-domain NER to enhance the relationship between the source text and labels and improve label information transfer, where each NE label is jointly predicted by corresponding token and previous NE labels. We not only adopt a commonly-used pre-trained model to extract token representation, but also introduce a random initialized embedding matrix and Bi-LSTM-based label encoder to model the label sequence generated from previous steps. After that, we construct two different attention between hidden states of Bi-LSTM and token representations to produce label background and context information, which are then concatenated as label-aware information and applied to predict labels. Thanks to this design, the label information can be effectively transferred from the source to the target domain. Comprehensive experimental results on several benchmark datasets illustrate the effectiveness of our model, which achieves significant improvements over existing methods.

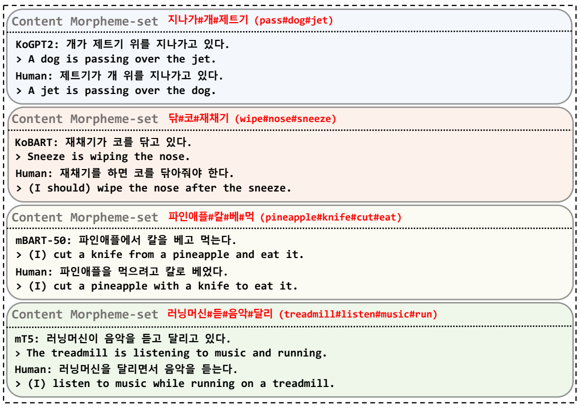
Abstract

Recent natural language understanding (NLU) research on the Korean language has been vigorously maturing with the advancements of pretrained language models and datasets. However, Korean pretrained language models still struggle to generate a short sentence with a given condition based on compositionality and commonsense reasoning (i.e., generative commonsense reasoning). The two major challenges are inadequate data resources to develop generative commonsense reasoning regarding Korean linguistic features and to evaluate language models which are necessary for natural language generation (NLG). To solve these problems, we propose a text-generation dataset for Korean generative commonsense reasoning and language model evaluation. In this work, a semi-automatic dataset construction approach filters out contents inexplicable to commonsense, ascertains quality, and reduces the cost of building the dataset. We also present an in-depth analysis of the generation results of language models with various evaluation metrics along with human-annotated scores. The whole dataset is publicly available at (`https://aihub.or.kr/opendata/korea-university`).



Content Morpheme-set 지나가#개#제트기 (pass#dog#jet)

KoGPT2: 개가 제트기 위를 지나가고 있다.
> A dog is passing over the jet.
Human: 제트기가 개 위를 지나가고 있다.
> A jet is passing over the dog.

Content Morpheme-set 닦#코#재채기 (wipe#nose#sneeze)

KoBART: 재채기가 코를 닦고 있다.
> Sneeze is wiping the nose.
Human: 재채기를 하면 코를 닦아줘야 한다.
> (I should) wipe the nose after the sneeze.

Content Morpheme-set 파인애플#칼#베#먹 (pineapple#knife#cut#eat)

mBART-50: 파인애플에서 칼을 베고 먹는다.
> (I) cut a knife from a pineapple and eat it.
Human: 파인애플을 먹으려고 칼로 베었다.
> (I) cut a pineapple with a knife to eat it.

Content Morpheme-set 러닝머신#듣#음악#달리 (treadmill#listen#music#run)

mT5: 러닝머신이 음악을 듣고 달리고 있다.
> The treadmill is listening to music and running.
Human: 러닝머신을 달리면서 음악을 듣는다.
> (I) listen to music while running on a treadmill.

Figure 1: Example results of the KoGPT2, KoBART, mBART-50, mT5, and humans on Korean generative commonsense reasoning task. The results are sentences that combine the given content morphemes (in **red boldface**).

1 Introduction

With the advent of Transformer (Vaswani et al., 2017) model, the importance of language resources and language modeling in natural language processing (NLP) has been heightened. Indeed, various studies on Korean language resources, such as Korean morpheme analysis (Matteson et al., 2018; Kim and Colineau, 2020; Moon and Okazaki, 2020), natural language understanding (NLU) tasks including KorNLI and KorSTS (Ham et al., 2020), KMRE (Lee et al., 2020), and KLUE (Park et al., 2021) are being conducted alongside the studies on off-the-shelf pretrained language models in Korean (Devlin et al., 2019; Radford et al., 2019; Lewis et al., 2020).

Despite the prosperity of Korean NLP research, two critical problems remain: (i) an absence of a research base for natural language generation (NLG) and (ii) a deficient ability for models to generate commonsense knowledge. In other words, (i) there exists neither a dataset (Gehrmann et al., 2021) nor standards for evaluating (Celikyilmaz et al., 2020) the results generated by language models in Korean because most Korean language resources are focused on NLU tasks thereby making it difficult to accelerate the development of NLG research.

(ii) Korean language models encounter difficulties even in generating sentences using simple commonsense knowledge. Commonsense knowledge is a sociocultural knowledge shared by humans (Liu and Singh, 2004). It is not visible but it is melted in their words (Tandon et al., 2018). To make natural sentences using commonsense knowledge like those made by humans, comprehensive abilities

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2233 - 2249
July 10-15, 2022

of generative commonsense reasoning (Lin et al., 2020) are needed. This requires holistic understanding of commonsense reasoning (Lake and Baroni, 2018; Keysers et al., 2020) and sentence compositionality (Hahm et al., 2020).

Though people acquire commonsense knowledge and effortlessly use it in their daily lives, it is challenging for language models to imitate this ability. As shown in Figure 1, off-the-shelf Korean and multilingual language models seem to lack the competence for generative commonsense reasoning. Some model-generated sentences *do not make sense* (e.g., "`개가 제트기 위를 지나고 있다. A dog is passing over the jet.`", "`재채기가 코를 닦고 있다. Sneeze is wiping the nose.`"), *use inappropriate prepositions* (e.g., "`파인애플에서 칼을 베고 먹는다. I cut a knife from a pineapple and eat it.`"), or *misplace parts of speech* (e.g., "`러닝머신이 음악을 듣고 달리고 있다. The treadmill is listening to music and running.`").

To address these issues and inspired by CommonGen (Lin et al., 2020), we develop a Korean CommonGen dataset for generative commonsense reasoning. The dataset is composed of commonly used daily-life concepts and sentences made by combining those concepts. Our dataset differs from the CommonGen dataset as follows: (i) We collect Korean corpus and label it to cover Korean sociocultural commonsense knowledge. For example, the sentence of the corpus contains the unique Korean sociocultural terms "`귀농(return to the farm)`" and "`곶감(dried persimmons)`". (ii) Although we adopt the image caption data from CommonGen, we add the summary data of daily conversations into our dataset thereby obtaining diverse sentences. (iii) Because Korean language models use segmented morphemes as vocabulary (Lee et al., 2020; Kim and Colineau, 2020), we construct the concept set with content morphemes that have linguistic features and lexical meanings. (iv) We analyze the evaluation metrics including the human-annotated score to demonstrate the validity of the evaluation criteria.

We reduce the cost of data construction significantly through an automated method and inspect the quality and unethical issue of Korean CommonGen by crowd-sourcing[1]. In addition, we conduct an in-depth study of our proposed dataset with various ablation experiments on morpheme segmentation and training methods. Furthermore, the model-generated sentences are compared and analyzed by quantitative, qualitative, and human scores. We disclose the dataset used in this paper to contribute to the development of Korean NLG research.

2 Related Works

Commonsense Knowledge Commonsense knowledge is knowledge about everyday life that all people possess, and it is arguably the most general and widely applicable knowledge (Liu and Singh, 2004). Compared to encyclopedic knowledge, which returns specific details about named entities on a modern search engine, commonsense knowledge includes elusiveness and context dependence (Tandon et al., 2018).

Compositionality Compositionality is an essential element that AI systems have to solve for given conditions. For example, the MS-COCO (Lake and Baroni, 2018) dataset is utilized for image caption task generating the description from an image data as an input data. The task demands the compositionality of the model as the model composes the natural description. Moreover, SCAN (Lake and Baroni, 2018) demonstrates mapping instructions to sequence an RNN model's ability to generate continuous behavior. However, these studies have shown that AI systems still struggle to generate complete results.

Commonsense Reasoning Commonsense reasoning is the ability to infer unrecognized commonsense knowledge or relations among given concepts. In a recent NLP research, various commonsense reasoning datasets have been disclosed. CommonsenseQA (Talmor et al., 2019) organizes the dataset with closed questions to commonsense based on the concept of ConceptNet and analyzes the skills of commonsense reasoning required for each question by categorizing them. Cosmos QA dataset (Huang et al., 2019) introduces a question answering dataset based on the fact that is not externally revealed in the context. CoS-E dataset (Rajani et al., 2019) attempts to strengthen the commonsense training of the model by adding a person's description of the commonsense QA. The XCOPA dataset (Ponti et al., 2020) mitigates the gaps in commonsense that could arise from linguistic and cultural differences, while building a dataset.

We construct a test set to generate sentences by reasoning unseen content morphemes in training. **# Additional morphemes** is the number of unseen single morphemes counted through extra 4,080 human references. **#Caption-based rate** and **#Dialogue-based rates** mean the ratio of each data among the total dataset.

Generative Commonsense Reasoning Based on compositionality and commonsense reasoning, we concentrate on generative commonsense reasoning, the ability required to generate sentences that conform to commonsense knowledge for given conditions. In the case of English-based language models, various studies have improved the ability of generative commonsense reasoning based on the CommonGen (Lin et al., 2020) dataset. KG-BART (Liu et al., 2021b) enhances the model allowing to capture the relationship between nodes in the graph, while including the ConceptNet knowledge graph in the attention calculation process for text input. RE-T5 (Wang et al., 2021) reinforces the input value by using a retriever to import sentences related to the concepts from external knowledge. KFCNet (Li et al., 2021) presents the state-of-the-art performance in CommonGen by removing low-quality sentences in external knowledge and applying contrastive learning, respectively.

However, there does not exist Korean dataset for generative commonsense reasoning and advanced research as well. Therefore, in this paper, we aim to create a new text-generation dataset inspired by CommonGen (Lin et al., 2020) and grant a direction for the future Korean NLG research.

3 Korean CommonGen

Korean CommonGen is a text-generation dataset for Korean commonsense reasoning and evaluation. As depicted in Figure 2, Korean CommonGen consists of concept sets typically used in daily life and sentences depicting those concepts. Language models are trained to generate a sentence by reasoning and combining the concepts based on human-generated sentences. The model-generated result should include all the given concepts, be grammatically correct and make sense.

Korean CommonGen includes 43,188 training examples and 2,040 testing examples as presented in Table 1. Corresponding to one concept set of content morphemes, the training example comprises one sentence, and the testing example contains three sentences. In the case of the training set, 45.58% of examples are English-Korean translated MS-COCO[2] (Lin et al., 2014) image caption data, and 52.42% are Korean dialogue summary data of AI-HUB[3]. To make the models learn the semantic role and relation of unseen content morphemes through commonsense reasoning, the test set has 748 single content morphemes unseen during training. Additionally, more than one pair of unseen content morphemes is included in each testing example. The test set has additional two reference sentences for every 2,040 content morpheme set annotated by crowd-sourcing. These additional references enable the consideration of the diverse possibilities in model-generated sentences (Chomsky, 1965). We allow additional references to include 4,682 newly annotated content morphemes that do not appear in the concept set. As a result, the model can obtain a higher score when the generated sentence has additional morpheme fitted on commonsense. The dataset is constructed through semi-automatic approach, and the details are described in §3.1 Automatic Dataset Construction and §3.2 Annotate and Refine by Crowd-sourcing.

3.1 Automatic Dataset Construction

We implement the automatic construction approach with a part-of-speech (POS) tagger, a named entity recognition (NER) tagger, a sentence level filtering, and Korean Hate Speech classifier. They extract the content morphemes, and screen out the sentences that include unethical expressions, violate commonsense or have unnatural sentence structures. With these automated modules, we reduce the cost for human annotation by $7,766.

[2] `https://aihub.or.kr/keti_data_board/visual_intelligence`

[3] `https://aihub.or.kr/aidata/30714`

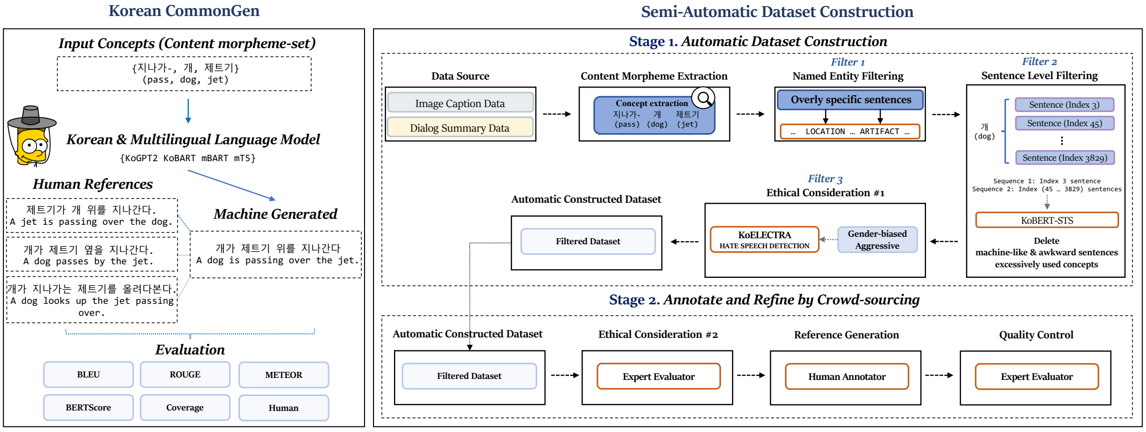

Figure 2: Overview of Korean CommonGen and pipeline of semi-automatic dataset construction.

Data Sources In this study, we organize the dataset with the image caption and dialogue summary sentences describing daily life based on commonsense knowledge that does not correspond to the specific or professional domains.

For data construction, we utilize the Korean image caption dataset released by AI-HUB visual intelligence, which is translated from the original English MS-COCO dataset. The caption sentences in this dataset describe the scenes that occur in everyday life. It implies that universal commonsense knowledge implicitly lies in those sentences. As they are the combinations of objects, and relations exist in the corresponding (ground-truth) image, it is appropriate for models to learn how to compose sentences by considering all the given concepts.

The Korean dialogue summary dataset of AI-HUB is also adopted for data construction. These data contain conversations on everyday topics and include commonsense knowledge that has implicit Korean sociocultural content. We secure the diversity of sentences and commonsense knowledge by adding non-visual conversation contents not solely using image caption sentences based on visual information, such as conventional CommonGen.

We delete the sentences involving the unexpected foreign words and special symbol tokens in the phase of preprocessing. Both datasets consist of sentences that take the form of declarative statements. In this process, we unify the structure of sentences to be ended with '다.' (i.e., an ending word in Korean declarative statement) for minimizing the variances in performance evaluation according to the decoding hyperparameters or strategies.

Content Morpheme Extraction POS tagging is the task that assigns the grammatical group tag to the text based on the language's perspective and definition (Kanakaraddi and Nandyal, 2018). We utilize POS tagging to extract the content morphemes essential for making concept sets. We apply the morpheme segmentation of ko-mecab (KUDO, 2005) using the Korean morpheme analysis package KoNLPy (Park and Cho, 2014).

Korean is a highly inflected language with many inflectional morphemes and has multiple POS tag patterns. In addition, Korean is an agglutinative language. If the Korean language is tokenized with *eojeol* segmentation by white spaces, the number of vocabulary units increases exponentially, and the accuracy of correct tagging decreases. Korean embedded models also operate morpheme segmentation to avoid expensive computational costs caused by the exponential increase in new vocabularies with *eojeol* segmentation (Lee et al., 2020; Kim and Colineau, 2020). Therefore, we adopt the morpheme segmentation method to improve efficiency and suitability.

When creating the concept set, we employ the content morphemes. The content morphemes include the definite actions, states, or semantic information of the sentence. They involve the verb and adjective stems, and some adjectives are grammatically similar to the verbs in Korean. Therefore, it is possible to create a sentence with the content morphemes, considering both the semantic relations between them and their grammatical usage.

Based on the criteria of the content morpheme tagging, we classify the nouns (`NNG`, `NNP`, `NNB`, `NNBC`, `NR`, `NP`), determiners (`MM`), adverbs (`MAG`, `MAJ`), verbs (`VV`, `VA`, `VX`, `VCP`, `VCN`), radixes (`XR`), and interjections (`IC`) as the content morpheme[4]. However, the proper noun (`NNP`), numeral (`NR`), pronoun (`NP`) are only understandable in certain situations and perspectives among the content morpheme. Thus, we delete the sentences including `NNP`, `NR`, and `NP` in the process of morpheme segmentation. The detailed differences according to the segmentation are described in §6.

Named Entity Filtering NER is a subtask of Information Extraction, which attempts to recognize the named entities such as a person, location, and quantity from the unstructured text (Nadeau and Sekine, 2007). We utilize the NER to remove the sentences including the non-commonsense knowledge from the data sources.

As mentioned above, the Korean dialogue summary dataset of AI-HUB carries the daily conversations, which means it contains commonsense knowledge in abundance. However, there is a possibility that the sentences consist of specific domain knowledge that is shared only by the particular group or time. Named entities, such as specific names of persons, organizations, and locations, are not commonsense entities because most people do not comprehend them. For instance, "`윤호는 착해 보이지만 연예인 기질은 아닌 것 같다. (Yoonho looks kind, but he is not talented for the entertainment.)`", name of person ‘`윤호(Yoonho)`’ is vague to be categorized as commonsense knowledge.

We vacate the sentences containing the non-commonsense knowledge with NER tagging in the phase of dataset construction. In the NER tagging, we adopt the neural network model in Pororo library[5] and remove the 119,355 sentences containing the non-commonsense named entities.

Sentence Level Filtering Through NER and POS tagging, a substantial number of sentences with non-commonsense knowledge can be filtered out. However, there remain several sentences that contain awkward translations or do not properly reflect commonsense knowledge. To filter out these residues, we selectively extract sentences that follow common Korean sentence structure and contain rich commonsense knowledge at the sentence level.

These are proceeded by the comparison between sentences within the same morpheme. For the selection process, we apply inverted index to every $s \in S$ that contains unique content morpheme $x \in X$. A set of inverted indexed sentences for each context morpheme x is denoted as $s^x = \{s_i^x\}_{i=1}^{N_s}$, where the maximum size of N_s is set to 100.

Then, based on the contextual representation embedding of the language model, we estimate the similarity score between every two diverse sentences in s^x using the KoBERT[6] fine-tuned with the KorSTS (Ham et al., 2020) dataset. More specifically, the similarity score $\hat{y}_{i,j}$ between two sequences s_i^x, s_j^x is estimated as shown in Equation 1.

$$\hat{y}_{i,j} = \sigma(W(h_{ij}) + b) \tag{1}$$

h_{ij} indicates the KoBERT encoded representation of the concatenated sequence s_i^x, s_j^x. σ denotes activation unit and W, b are trainable parameters of a linear pooling layer. To figure out descent sentences that fluently follow the common Korean sentence form and contain rich commonsense knowledge within the same content morpheme, we set up $score_i^x$ for each sentence s_i^x. $score_i^x$ is estimated by summing up all the similarity score $\hat{y}_{i,j}$ between s_i^x and other sentences, as shown in Equation 2.

$$score_i^x = \left(\sum_{j=1}^{N_s} \hat{y}_{i,j} \right) - \hat{y}_{i,i} \tag{2}$$

We evaluate $score_i^x$ for each sentence s_i^x and sort all the sentences in a descending order. According to their scores, the top-2 sentences are selected for each unique content morpheme.

Ethical Consideration Machine-translated MS-COCO can deviate from the intended purpose or have aggressive terms because of cultural differences. Also, a dialogue summary of daily conversations can include socially inappropriate or discriminatory content. Thus, we filter out these expressions so that models cannot unintentionally return inappropriate responses to some triggers.

To detect unethical expressions, we use the Korean Hate Speech Detection (Moon et al., 2020) dataset. As a model, KoELECTRA[7] is pretrained with the ELECTRA (Clark et al., 2019) structure and Korean corpora. KoELECTRA is trained to classify whether input sequences contain gender biased or aggressive representation. The classifier's predicted 1,083 results are potentially unethical

---

[4] https://www.korean.go.kr/front/onlineQna/onlineQnaView.do?mn_id=216&qna_seq=209597

[5] https://github.com/kakaobrain/pororo

[6] https://github.com/SKTBrain/KoBERT

[7] https://github.com/monologg/KoELECTRA

risk statements, including either gender bias or offensive. Among them, 172 sentences contain both gender biased and offensive problems.

However, we note that the classifier is not complete (Roller et al., 2021); thus, we reschedule those results with a secondary inspection through two expert annotators. The classifier tends to be overly sensitive to words that refer to a particular gender (e.g., male, female) or words that can be used aggressively (e.g., cut, bound, etc.). In addition, the published source data: MSCOCO and AI-HUB Dialogue Summary, have completed pre-validation and data curation. We find the problem that most of the predicted sentences are false-positive. Therefore, we conduct a second round evaluation to consider whether the sentences conform to the definition of commonsense knowledge and do not deviate from social norms. In the second round, two human annotators majoring in linguistics and computer science remove 124 sentences with criminal, drug, and excessive biased among predicted 1,083 results.

3.2 Annotate and Refine by Crowd-sourcing

We generate additional reference sentences using the extracted content morphemes via crowdsourcing. Employing the expert human annotators, we also check the quality of the references and implement secondary inspection on the dataset to filter out sentences that contain ethical issues.

Reference Generation To evaluate the diversity of model-generated sentences, we produce additional 4,080 references based on the 2,040 concept set designated as test data. We employ 22 human annotators with bachelor's degrees through crowdsourcing[8]. The working guidelines are as follows: First, we ensure the additional references are not similar or do not merely change the position of the subject/verb/object. Second, the given content morphemes are preserved, and the annotators can append extra modifiers conforming to commonsense. Third, references do not incorporate overly specific named entities or numerical expressions.

Quality Control 17 expert annotators holding bachelor's degrees in Korean language or linguistic secure the quality of the automatic constructed data via secondary inspection and assessment[9]. Since the references determine the model's performance, human correction is performed on the references to maintain high quality leading to 303 inappropriate sentences being removed.

4 Experiments Settings

4.1 Evaluation Metrics

The evaluation metrics consist of n-gram overlapping, semantic similarity, content morpheme coverage, and human score. We use automatic evaluation metrics based on n-gram overlapping such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005). These metrics compute the token level similarity between model-generated candidate and reference sentences. Next, we utilize BERTScore (Zhang et al., 2019) as semantic similarity and evaluate the outputs using mBERT and KoBERT to identify differences between multilingual and monolingual models. We also indicate the concept coverage which is the average percentage of given concepts that exist in model-generated sentences.

To estimate human evaluation, we employ 17 expert annotators as per the conditions specified in §3.2 to evaluate four criteria as follows: (i) Grammar Correction: Is it a valid sentence for Korean grammar?; (ii) Factuality: Does it contain the given content morphemes as much as possible?; (iii) Commonsense: Is it following commonsense knowledge?; (iv) Fluency: Is it a natural sentence for a mother tongue speaker? The human annotators score each measure with 2 points for excellent, 1 point for regular, and 0 points for insufficient. Moreover, we estimate human annotator performance by considering their reference sentences in the test set. We develop a system of prediction by comparing each annotator's references to calculate inter-annotator agreement. We measure the inter-annotator agreement of 3 evaluators with Fleiss' Kapa (Fleiss, 1971). Overall Fleiss' Kapa coefficient correlations for each human evaluation are Commonsense 0.426, Factuality 0.478, Fluency 0.401, and Grammar Correction 0.344; therefore have moderate reliability among evaluators[10].

4.2 Baselines

The baselines include GPT2 (Radford et al., 2019) using only the decoder structure of Transformer (Vaswani et al., 2017) and BART (Lewis et al., 2020) using the encoder-decoder. Among

Table 2: Experimental results of various baselines on the Korean CommonGen test set.

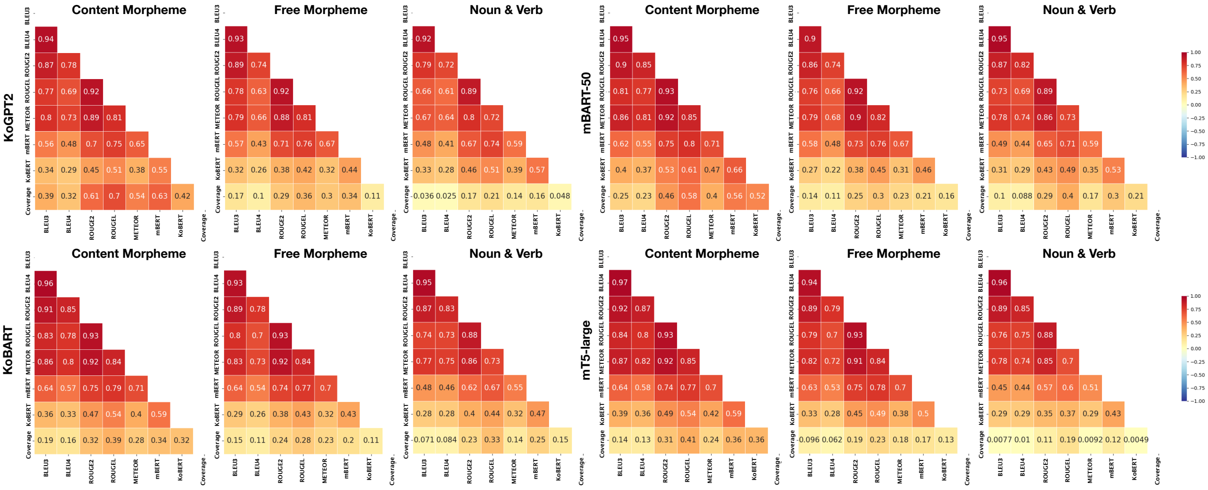

Figure 3: Correlation of automatic evaluation metrics among Korean and multilingual language models. The box's color is deep with reddish, and the score is the more extensive the white boldface, the higher correlation.

the models with the mentioned structure, we use KoGPT2[11] and KoBART[12] pretrained with Korean corpora. We also conduct experiments on mBART (Liu et al., 2020), mBART-50 (Tang et al., 2020), and mT5 (Xue et al., 2021) based on encoder-decoder as multilingual language models.

5 Quantitative Evaluation

We conduct a quantitative analysis of our dataset as shown in Table 2. First, encoder-decoder models exhibit higher performance than the decoder-only model. The decoder-only model is limited in reconstructing input content morphemes into acceptable quality sentences based on generative commonsense reasoning only with uni-directional prompt engineering (Liu et al., 2021a). Moreover, the encoder-decoder models with an encoder can formulate sentences based on bi-directive embedding information for given content morphemes.

Second, KoBART has a model parameter of 124M which is smaller than that of the mBART and mBART-50 models (whose model parameters are 610M) but exhibits partially competent performance. This result shows that if the models are of identical structure, the multilingual model with a high proportion of machine-translated data in the pre-training process may encounter difficulties in generating high-quality sentences based on generative commonsense reasoning.

Third, mBART, and mBART-50 show similar performance. In the case of mBART-50, low-resource languages have the effect of improving, but high-resource languages present partial degradation because of the curse of dimension. Korean is a medium-resource language, but its performance decreases like other high-resource languages.

Forth, mT5-large model has the most model parameters of 1.3B, and the pre-training method using sequence-to-sequence task form with prompt engineering appears to impact it positively. Additionally, the mT5-large shows the most comparable execution to human performance and higher coverage and semantic scores than BARTs. However, most of small size baselines still have tribulation generating sentences containing all of the given content morphemes, and overall performance is lower than humans.

6 Ablation Study

We attempt to demonstrate the validity of concept extraction and data sources. Thus, we perform ablation studies with respect to the concept set and data source configuration method.

6.1 Other Than The Content Morphemes

The first ablation study is conducted by tokenizing the set of concepts into noun and verb as suggested in CommonGen and free morphemes that can be used alone depending on the presence or absence of independence. According to the configuration method of the concept set, Figure 3 shows the correlation between automatic evaluation metrics and Table 3 exhibits the performance of the baselines.

The p-value for the correlation of all evaluation metrics is less than 0.05 (statistical significance). As depicted in Figure 3, content morpheme concepts have the highest overall correlation with other evaluation metrics. Table 3 also shows that this approach has the highest performance in most evaluation indicators. Through these results, we find that constructing concepts based on content morpheme has minimized the loss of information required for complete Korean sentences.

When it comes to free morpheme concepts, the concept set does not include the vocabulary of verbs and adjectives. As described in Figure 3, difficulty in constituting sentences increases dramatically, and correlations with the evaluation metrics are lowered by omitting information on verbs and adjectives, which are core components of a sentence. Consequently, free morpheme concepts overlook most of the valuable information, making it challenging to infer essential semantic components to compose sentences and exhibit inferior performance, as shown in Table 3.

Next, in the case of noun and verb concepts, Figure 3 shows the lowest overall correlation with other evaluation metrics. Table 3 also presents the performance gap between evaluation metrics which is considerable on account of omitting information on adjectives and adverbs according to the combination of concepts. In addition, it is tough to reproduce the relationship between the word root and ending according to the conjugation of Korean in forming sentences. Therefore, all baselines have difficulty with sentence composition considering inflectional units and indicate the lowest coverage on average.

Among the configuration methods of the concept set, content morpheme concepts have the highest overall correlation with other evaluation metrics. This method also shows that the loss of information required for complete Korean sentences is minimized and that sentence composition considering the Korean linguistic features is also possible.

Table 4: Ablation study for the data source. Baselines train with **IC**: Image caption data, **DS**: Dialogue summary data, and **IC & DS**: Image caption and dialogue summary data.

6.2 Image Caption or Dialogue Summary

Table 4 shows the results of baselines by dividing data source into image caption and Korean dialogue summary. The evaluation data includes both image captions and dialogue summarized sentences.

The image caption is straightforward but still contains awkward expressions owing to machine-translated results. Moreover, the Korean dialogue summary is relatively elaborated and incorporates a natural expression of mother-tongues to a wide range of everyday conversation topics.

As described in Table 4, the entire data combining the attributes of the two sources demonstrate the highest performance. These results show that our dataset requires more diverse sentence composition and commonsense reasoning processes than solely using image caption sources offered by CommonGen (Lin et al., 2020). Additionally, the dialogue summary includes various sociocultural commonsense knowledge of mother-tongues. It is challenging to feed all contexts with only a small amount of data. Thus, models trained only with dialogue summary show lower performance than those trained only with image caption. Considering experimental results of Table 4, we organize the training such that the model first learns image captions and then highly complicated dialogue summarized sentences.

7 Human Evaluation

We further conduct a human evaluation for model-generated sentences, as shown in Table 5. The experimental results show that the mT5 model achieves the highest score and tendency of the score distribution parallel to the automatic evaluations. This point indicates that the estimation results with automatic metrics obtained from earlier experiments are comparable to human agreements. Closely examining the four evaluation criteria of human scores reveals that the baselines show the lowest score on average in fluency compared to other evaluation criteria and the highest score on average in factuality. This means that the models are relatively well-trained to use content morphemes in complete sentences, but their ability to generate spontaneous sentences is insufficient.

The correlation score between each evaluation criteria of human evaluation and automatic evaluation metrics is described in Figure 4. The heatmap shows that recall-based metrics have high correlations with human scores. This result corresponds to the demonstrations in (Lin, 2004) and (Banerjee and Lavie, 2005). In the case of coverage, a different trend showing low correlations with other human scores except for factuality is observed. It can be predicted that the criteria we have suggested and the basis for human judgment are somewhat consistent. The lower correlation in factuality with automatic evaluation metrics shows that containing all the given concepts does not necessarily constitute a well-crafted sentence.

Moreover, human-annotated scores have statistical significance in correlation with automatic evaluation metrics (p.value < 0.05), and show considerably similar values to Figure 3 in BERT-based semantic scores. However, there are weak positive correlations with other automatic evaluation metrics. These results show that it is difficult to evaluate the model's generative commonsense reasoning in the traditional estimation approach, and advanced research is needed to improve it.

Human evaluation	**GC**	**CS**	**FC**	**FL**	**TT**
KoGPT2	0.85	0.74	1.27	0.64	3.50

8 Conclusion

In this paper, we propose a Korean CommonGen dataset including Korean sociocultural commonsense knowledge and morpheme-based linguistic features. The dataset heeds the semi-automatic dataset construction method based on automatic construction and crowd-sourcing annotation with quality assessment. We perform a comparative analysis and an ablation study to demonstrate the validity of the dataset and evaluation metrics for generative commonsense reasoning. Moreover, we conduct a Korean and multilingual language models' standard performance experiment to investigate the dataset's problems and competencies. In future work, the dataset will enhance evaluation metrics regarding syntax and diversity of sentences to improve the interpretation of the model-generated results. We believe that our proposed dataset will serve as a fundamental resource to Korean NLG and commonsense reasoning research.

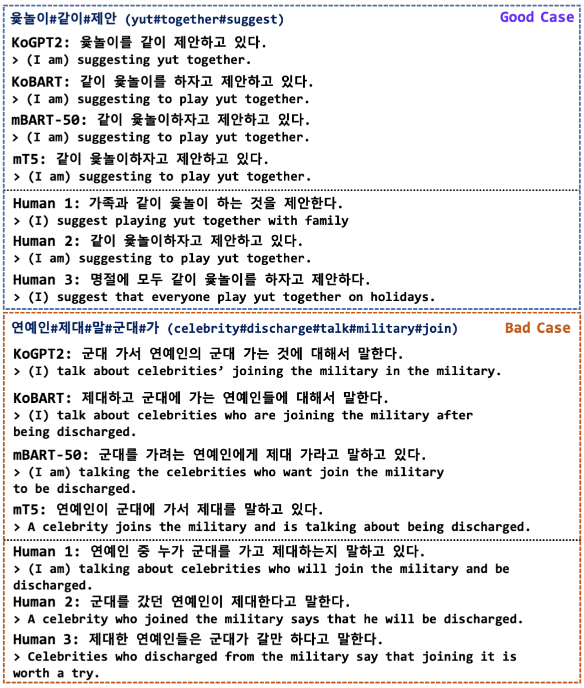
A Qualitative Evaluation

We conduct a qualitative analysis on the machine-generated sentences as illustrated in Figure 5. Qualitative evaluation is executed by composing the content morphemes of the test set to generate sentences based on commonsense. In the analysis, we separate the model-generated results embracing the Korean commonsense knowledge into the good case and the bad case.

Good Case In the case that requires low complicated compositionality and simple commonsense reasoning, the models tend to generate identical sentences. When KoGPT2 generates the sentences, the result shows prominent differences with the outputs of other models, and it has an inconsistent grammatical correction. On the contrary, KoBART, mBART-50, and mT5 yield brief sentences that adopt relatively stable grammar rules and postpositional expressions.

Bad Case In the case that requires complicated compositionality and struggling commonsense reasoning, the gap of qualities between the model-generated sentences is more significant than the opposite case. KoGPT2 generates incoherent sentences that exploit the given content morphemes repetitively or contain many errors in commonsense reasoning. KoBART induces more natural Korean sentences than the other models, but the results are still harsh to understand owing to their ambiguous expressions. From the multilingual language models, mBART-50 yields unnatural sentences like machine-translated sentences. In addition, the models show semantically incorrect results as if the models misunderstand the meaning of some words like '제대(discharge).' The mT5 employs more manageable words and brief sentences, including all given content morphemes as much as possible.

Although the ability of the Korean monolingual language model's compositionality still seems insufficient, the results show that the models partially understand the content morpheme with a cultural specialty such as the conscription system. In contrast, the multi-language model shows substantial compositionality and abnormal usage of the content morpheme with cultural specialty as its limitation.



윷놀이#같이#제안 (yut#together#suggest) Good Case

KoGPT2: 윷놀이를 같이 제안하고 있다.
> (I am) suggesting yut together.

KoBART: 같이 윷놀이를 하자고 제안하고 있다.
> (I am) suggesting to play yut together.

mBART-50: 같이 윷놀이하자고 제안하고 있다.
> (I am) suggesting to play yut together.

mT5: 같이 윷놀이하자고 제안하고 있다.
> (I am) suggesting to play yut together.

Human 1: 가족과 같이 윷놀이 하는 것을 제안한다.
> (I) suggest playing yut together with family

Human 2: 같이 윷놀이하자고 제안하고 있다.
> (I am) suggesting to play yut together.

Human 3: 명절에 모두 같이 윷놀이를 하자고 제안하다.
> (I) suggest that everyone play yut together on holidays.

연예인#제대#말#군대#가 (celebrity#discharge#talk#military#join) Bad Case

KoGPT2: 군대 가서 연예인의 군대 가는 것에 대해서 말한다.
> (I) talk about celebrities' joining the military in the military.

KoBART: 제대하고 군대에 가는 연예인들에 대해서 말한다.
> (I) talk about celebrities who are joining the military after being discharged.

mBART-50: 군대를 가려는 연예인에게 제대 가라고 말하고 있다.
> (I am) talking the celebrities who want join the military to be discharged.

mT5: 연예인이 군대에 가서 제대를 말하고 있다.
> A celebrity joins the military and is talking about being discharged.

Human 1: 연예인 중 누가 군대를 가고 제대하는지 말하고 있다.
> (I am) talking about celebrities who will join the military and be discharged.

Human 2: 군대를 갔던 연예인이 제대한다고 말한다.
> A celebrity who joined the military says that he will be discharged.

Human 3: 제대한 연예인들은 군대가 갈만 하다고 말한다.
> Celebrities who discharged from the military say that joining it is worth a try.

Figure 5: A case study comparing commonsense generation in the test set. We categorize the good and bad cases based on the model-generated sentences' quantitative evaluation. The two cases include Korean commonsense knowledge, 'Yut' is related to traditional Korean games, and 'military' and 'discharge' are related to the conscription, which expresses Korean sociocultural characteristics.

B Further Experiments

We conduct experiments to verify the training method of commonsense reasoning, assessment on the data dependency, and expandability within the commonsense domain.

B.1 High-Level Commonsense Reasoning

Table 6 shows the evaluation results on the models trained by randomly deleting one concept to evaluate the high-level commonsense reasoning. The seeds for the random deletion are set to $\{42, 52, 62, 72, 82\}$. Because of the random deletion, the training data get more challenging as if the model composed the sentence reasoning with at least one content morphemes not given. The performance of the models decreases compared with the model trained with the entire concept set. Deleted content morphemes affect the disappearance of the commonsense knowledge rather than the enhancement of the commonsense reasoning during the training phase. In the case of mBARTs, the extent of the performance decline is the most substantial, and mBARTs show inferior performance than KoBART on average. In addition, compared with the other models, mT5-base is sensitive to a given situation of the source input. This result means that a BART model pretrained with monolingual corpora is significantly robust, regardless of its small model size. The models trained with the identical architecture and corpora show a considerably different extent of optimization according to the model size in text generation.

B.2 Reformulated CommonGen Test set

In the following process, we introduce a new evaluation dataset that utilizes the raw data sources that are of little relevance to the training dataset.

First, based on the knowledge graph, we extract the concepts at the one-hop links ConceptNet (Liu and Singh, 2004). The top 20 ranked concepts with high weights are selected among the 25 according to the categories suggested in CommonGen. Second, the concepts are broadened based on the ConceptNet knowledge graph tagged with the grammatical role and translated as vocabulary units through NAVER dictionary[13] crawling. Third, we employ two professional annotators who possess high comprehension of the task and are proficient in Korean as a native language[14]. The annotators create a new Korean evaluation dataset combining the broadened concepts based on the CommonGen test set and ConceptNet knowledge graph. Fourth, we construct the dataset with the created sentences using the reverse extraction method used in §3.1. Therefore, the new evaluation dataset consists of 1,083 sentences embracing Korean commonsense knowledge with flawless syntax. Furthermore, utilizing the concepts of the knowledge graph ConcepNet representative in the commonsense domain, we evaluate the dataset's dependency on the raw data source of the training dataset.

The performance of the models evaluate with the reformulated test set, in which two annotators create the sentences using the ConceptNet and CommonGen test set, are shown in Table 7. We train the models involving the same data and hyperparameters used in the experiment of Table 2. The models show the maintained performance with the new dataset constructed by a human using the other data source within the commonsense domain. Therefore, this result demonstrates that the models are not substantially dependent on the specific

---

data source. Moreover, KoBART is robust on the domain transfer, and the performances of mBARTs are decreased to a great extent in the case of experiment setting transition, revealing similar consequences with the experiment in Table 6. On the contrary, the performance of KoBART and mT5 models is enhanced indicating the expandability of the downstream task within the commonsense domain utilizing our dataset.

B.3 Human Evaluation

We perform human evaluation on the sentences generated via the model using the new test dataset irrelevant to the training dataset, as exhibited in Table 8. Compared to the results of the human evaluation using the test dataset relevant to the training dataset depicted in Table 5, each model has proximate results in the expected distribution and tendency, in which mT5-large achieves the best score. Despite the results in Table 8 evaluated with the low relevance in test dataset, models achieve an only marginal lower score than Table 5. This implies that the models not only learn with the semantic and syntactic role of the content morpheme in the concept set but also their ability to acquire unseen commonsense. Moreover, factuality shows the slightest gap between Table 8 and Table 5. This result indicates that factuality is more independent of the training dataset than the other evaluation metrics.

C Implementation Details

C.1 Training

Generative language models are trained to generate a reference sentence containing m tokens $s_{ref} = \{r_1, r_2, ..., r_m\}$ by referring a content morpheme-set containing l morphemes $x_{set} = \{x_1, x_2, ..., x_l\}$. Training is implemented by optimizing the objective conditional probability of given tokens in an

auto-regressive generation. As formulated in Equation 3, the conditional probability is configured with model parameters for maximizing the likelihood. The pretrained model parameter is initialized to θ by training with dataset D.

$$\max_{\theta} \frac{1}{|D|} \sum_{(s_{ref}, x_{set}) \in D} \log \left[\prod_{t=1}^{m} p_\theta(r_t \mid r_{<t}; x_{set}) \right] \tag{3}$$

C.2 Hyperparameter Settings

We implement Huggingface[15] framework for language modeling in a single NVIDIA Quadro RTX 8000 GPU with 48GB and 18-core Intel Xeon Gold 6230 CPU. For KoGPT2 training, parameters are trained by batch size 4 with gradient accumulation, seed 42, learning rate 5×10^{-5}, warmup steps 400, AdamW optimizer (Loshchilov and Hutter, 2019) ($\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-8$), and block size 128. In the case of encoder-decoder models, key hyper-parameters are also initialized by default settings suitable for the model architectures. We set the hyper-parameters in training stage as batch size 16 with gradient accumulation, seed 42, initial learning rate 5×10^{-5}, warmup steps 400, AdamW optimizer ($\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-8$), max source length 64, max target length 256, and source prefix *"summarize"* (only for mT5-large).

C.3 Decoding Strategy

The decoding strategy is restricted to identical conditions in text generation. We set the beam size to 10, max sequence length to 30, min sequence length to 10, and no-repeat n-gram size to 3 for the imposition of a penalty on duplicate token generation. We re-rank the generated sentences sorted in descending order based on five candidate sentences that cover the number of the corresponding morphemes as the given content morpheme-set and select the highest rank as a concluding outcome.

D Error Analysis

This section investigates several errors found in our semi-automatic construction method.

The NER system has difficulty filtering out non-commonsense knowledge considering every person's perspectives. In this paper, we define commonsense knowledge as most people in the same society understand implicitly. However, it is challenging for commonsense knowledge to be defined with concrete scope and explanation. Therefore, some named entities can be viewed as commonsense knowledge to certain people. In our dataset construction method, the sentences holding the possibility of non-commonsense knowledge are safely deleted to maintain the rate of commonsense knowledge. Nevertheless, as the raw data sources pass through the automatic method, a proportion of sentences among the deleted sentences have the potential of reusability owing to the flexible definition of commonsense knowledge.

In the content morpheme extraction process, we solely use one POS tagger, ko-mecab, as a pilot study. Rather than discussing the performance of the various POS tagger, we mention the issues on the adoption process of the tagger. The process should include the sub-process of verification on the candidates of taggers or comparative study on the multiple datasets constructed with multiple taggers, respectively. The latter sub-process can cause

---

[15] `https://github.com/huggingface/transformers`

costly issues and require a lot of time to implement because new datasets for taggers should be reconstructed.

The usage of content morphemes can bring out uncertainty about whether the concept in the concept set should play a role as a verb or a noun. This feature embraces both pros and cons. The advantage is that the concept is granted unrestrained parts to endow the generated sentences diversity. The disadvantage is that the generation model may struggle to choose the semantic role of the concept. For example, the concept '이야기(`story`)', which plays a role as a noun, holds the probability of a role as a verb by combining with the verb derivative suffix. As a consequence, the generated sentence mismatches with the answer, conversely, increasing the diversity of the outputs.

To evaluate high-level commonsense reasoning, we set the seed and randomly delete one concept of the concept set. However, this deletion method is not the best way to assess commonsense reasoning. In selecting a concept to be removed, it is necessary to delete the concept deeply related to the remaining concepts so that the model can infer the meaning of deleted concept using the remaining concepts. For example, suppose the knowledge graph with more numerous data based on Korean commonsense knowledge such as ConceptNet is established. In that case, we would delete the more proper concept from the commonsense knowledge perspective.

Abstract

Recent works show that discourse analysis benefits from modeling intra- and inter-sentential levels separately, where proper representations for text units of different granularities are desired to capture both the meaning of text units and their relations to the context. In this paper, we propose to take advantage of transformers to encode contextualized representations of units of different levels to dynamically capture the information required for discourse dependency analysis on intra- and inter-sentential levels. Motivated by the observation of writing patterns commonly shared across articles, we propose a novel method that treats discourse relation identification as a sequence labelling task, which takes advantage of structural information from the context of extracted discourse trees, and substantially outperforms traditional direct-classification methods. Experiments show that our model achieves state-of-the-art results on both English and Chinese datasets. Our code is publicly available[1].

1 Introduction

Discourse dependency parsing (DDP) is the task of identifying the structure and relationship between Elementary Discourse Units (EDUs) in a document. It is a fundamental task of natural language understanding and can benefit many downstream applications, such as dialogue understanding (Perret et al., 2016; Takanobu et al., 2018) and question answering (Ferrucci et al., 2010; Verberne et al., 2007).

Although existing works have achieved much progress using transition-based systems (Jia et al., 2018b,a; Hung et al., 2020) or graph-based models (Li et al., 2014a; Shi and Huang, 2018; Afantenos et al., 2015), this task still remains a challenge. Different from syntactic parsing, the basic components in a discourse are EDUs, sequences of words, which are not trivial to represent in a straightforward way like word embeddings. Predicting the dependency and relationship between EDUs sometimes necessitates the help of a global understanding of the context so that contextualized EDU representations in the discourse are needed. Furthermore, previous studies have shown the benefit of breaking discourse analysis into intra- and inter-sentential levels (Wang et al., 2017), building sub-trees for each sentence first and then assembling sub-trees to form a complete discourse tree. In this Sentence-First (Sent-First) framework, it is even more crucial to produce appropriate contextualized representations for text units when analyzing in intra- or inter-sentential levels.

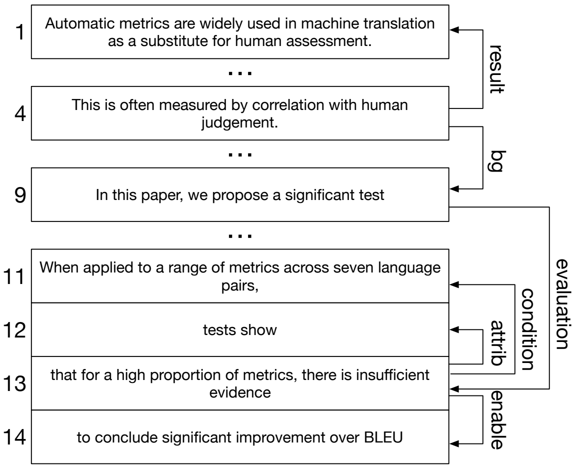

Figure 1: An excerpt discourse dependency tree in SciDTB. Each indexed block is an EDU, and the origin of the arrow pointing to a particular EDU is its head.

Figure 1 shows an excerpt discourse dependency structure for a scientific abstract from SciDTB (Yang and Li, 2018). The lengths of EDUs vary a lot, from more than 10 words to 2 words only (EDU 12: *tests show*), making it especially hard to encode by themselves alone. Sometimes it is sufficient to consider the contextual information in a small range as in the case of EDU 13 and 14, other times we need to see a larger context as in the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2250 - 2261

case of EDU 1 and 4, crossing several sentences. This again motivates us to consider encoding contextual representations of EDUs separately on intra- and inter-sentential levels to dynamically capture specific features needed for discourse analysis on different levels.

Another motivation from this example is the discovery that the distribution of discourse relations between EDUs seems to follow certain patterns shared across different articles. Writing patterns are document structures people commonly use to organize their arguments. For example, in scientific abstracts like the instance in Figure 1, people usually first talk about background information, then introduce the topic sentence, and conclude with elaborations or evaluations. Here, the example first states the background of widely used automatic metrics, introduces the topic sentence about their contribution of a significance test followed by evaluation and conclusion. Taking advantage of those writing patterns should enable us to better capture the interplay between individual EDUs with the context.

In this paper, we explore different contextualized representations for DDP in a Sent-First parsing framework, where a complete discourse tree is built up sentence by sentence. We seek to dynamically capture what is crucial for DDP at different text granularity levels. We further propose a novel discourse relation identification method that addresses the task in a sequence labeling paradigm to exploit common conventions people usually adopt to develop their arguments. We evaluate our models on both English and Chinese datasets, and experiments show our models achieve the state-of-the-art results by explicitly exploiting structural information in the context and capturing writing patterns that people use to organize discourses.

In summary, our contributions are mainly twofold: (1) We incorporate the Pre-training and Fine-tuning framework into our design of a Sent-First model and develop better contextualized EDU representations to dynamically capture different information needed for DDP at different text granularity levels. Experiments show that our model outperforms all existing models by a large margin. (2) We formulate discourse relation identification in a novel sequence labeling paradigm to take advantage of the inherent structural information in the discourse. Building upon a stacked BiLSTM architecture, our model brings a new state-of-the-art performance on two benchmarks, showing the advantage of sequence labeling over the common practice of direct classification for discourse relation identification.

2 Related Works

A key finding in previous studies in discourse analysis is that most sentences have an independent well-formed sub-tree in the full document-level discourse tree (Joty et al., 2012). Researchers have taken advantage of this finding to build parsers that utilize different granularity levels of the document to achieve the state-of-the-art results (Kobayashi et al., 2020). This design has been empirically verified to be a generally advantageous framework, improving not only works using traditional feature engineering (Joty et al., 2013; Wang et al., 2017), but also deep learning models (Jia et al., 2018b; Kobayashi et al., 2020). We, therefore, introduce this design to our dependency parsing framework. Specifically, sub-trees for each sentence in a discourse are first built separately, then assembled to form a complete discourse tree.

However, our model differs from prior works in that we make a clear distinction to derive better contextualized representations of EDUs from fine-tuning BERT separately for intra- and inter-sentential levels to dynamically capture different information needed for discourse analysis at different levels. We are also the first to design stacked sequence labeling models for discourse relation identification so that its hierarchical structure can explicitly capture both intra-sentential and inter-sentential writing patterns.

In the case of implicit relations between EDUs without clear connectives, it is crucial to introduce sequential information from the context to resolve ambiguity. Feng and Hirst (2014) rely on linear-chain CRF with traditional feature engineering to make use of the sequential characteristics of the context for discourse constituent parsing. However, they greedily build up the discourse structure and relations from bottom up. At each timestep, they apply the CRF to obtain the locally optimized structure and relation. In this way, the model assigns relation gradually along with the construction of the parsing tree from bottom up, but only limited contextual information from the top level of the partially constructed tree can be used to predict relations. Besides, at each timestep, they sequentially assign relations to top nodes of the partial tree, without being aware that those nodes might represent different levels of discourse units (e.g. EDUs, sentences, or even paragraphs). In contrast, we explicitly train our sequence labeling models on both intra- and inter-sentential levels after a complete discourse tree is constructed so that we can infer from the whole context with a clear intention of capturing different writing patterns occurring at intra- and inter-sentential levels.

3 Task Definition

We define the task of discourse dependency parsing as following: given a sequence of EDUs of length l, $(e_1, e_2, ..., e_l)$ and a set of possible relations between EDUs Re, the goal is to predict another sequence of EDUs $(h_1, h_2, ..., h_l)$ such that $\forall h_i, h_i \in (e_1, e_2, ..., e_l)$ is the head of e_i and a sequence of relations $(r_1, r_2, ..., r_l)$ such that $\forall r_i, r_i$ is the relation between tuple (e_i, h_i).

4 Our Model

We follow previous works (Wang et al., 2017) to cast the task of discourse dependency parsing as a composition of two separate yet related subtasks: dependency tree construction and relation identification. We design our model primarily in a two-step pipeline. We incorporate Sent-First design as our backbone (i.e. building sub-trees for each sentence and then assembling them into a complete discourse tree), and formulate discourse relation identification as a sequence labeling task on both intra- and inter-sentential levels to take advantage of the structure information in the discourse. Figure 1 shows the overview of our model.

4.1 Discourse Dependency Tree Constructor

To take advantage of the property of well-formed sentence sub-trees inside a full discourse tree, we break the task of dependency parsing into two different levels, discovering intra-sentential sub-tree structures first and then aseembling them into a full discourse tree by identifying the inter-sentential structure of the discourse.

Arc-Eager Transition System Since discourse dependency trees are primarily annotated as projective trees (Yang and Li, 2018), we design our tree constructor as a transition system, which converts the structure prediction process into a sequence of predicted actions. At each timestep, we derive a state feature to represent the state, which is fed into an output layer to get the predicted action. Our model follows the standard Arc-Eager system, with the action set: $O = \{Shift, Left-Arc, Right-Arc, Reduce\}$.

Specifically, our discourse tree constructor maintains a stack *S*, a queue *I*, and a set of assigned arcs *A* during parsing. The stack *S* and the set of assigned arcs *A* are initialized to be empty, while the queue *I* contains all the EDUs in the input sequence. At each timestep, an action in the action set *O* is performed with the following definition: *Shift* pushes the first EDU in queue *I* to the top of stack *S*; *Left-Arc* adds an arc from the first EDU in queue *I* to the top EDU in stack *S* (i.e. assigns the first EDU in *I* to be the head of the top EDU in *S*) and removes the top EDU in *S*; *Right-Arc* adds an arc from the top EDU in stack *S* to the first EDU in queue *I* (i.e. assigns the top EDU in *S* to be the head) and pushes the first EDU in *I* to stack *S*; *Reduce* removes the top EDU in *S*. Parsing terminates when *I* becomes empty and the only EDU left in *S* is selected to be the head of the input sequence. More details of Arc-Eager transition system can be referred from Nivre (2003).

We first construct a dependency sub-tree for each sentence, and then treat each sub-tree as a leaf node to form a complete discourse tree across sentences. In this way, we can break a long discourse into smaller sub-structures to reduce the search space. A mathematical bound for the reduction of search space of our Sent-First framework for DDP and discourse constituent parsing is also provided in Appendix.

Contextualized State Representation Ideally, we would like the feature representation to contain both the information of the EDUs directly involved in the action to be executed and rich clues from the context from both the tree-structure and the text, e.g. the parsing history and the interactions between individual EDUs in the context with an appropriate scope of text. In order to capture the structural clues from the context, we incorporate the parsing history in the form of identified dependencies in addition to traditional state representations to represent the current state. At each timestep, we select 6 EDUs from the current state as our feature template, including the first and the second EDU at the top of stack *S*, the first and the second EDU in queue *I*, and the head EDUs for the first and the second EDU at the top of stack *S*, respectively. A feature vector of all zeros is used if there is no EDU at a certain position.

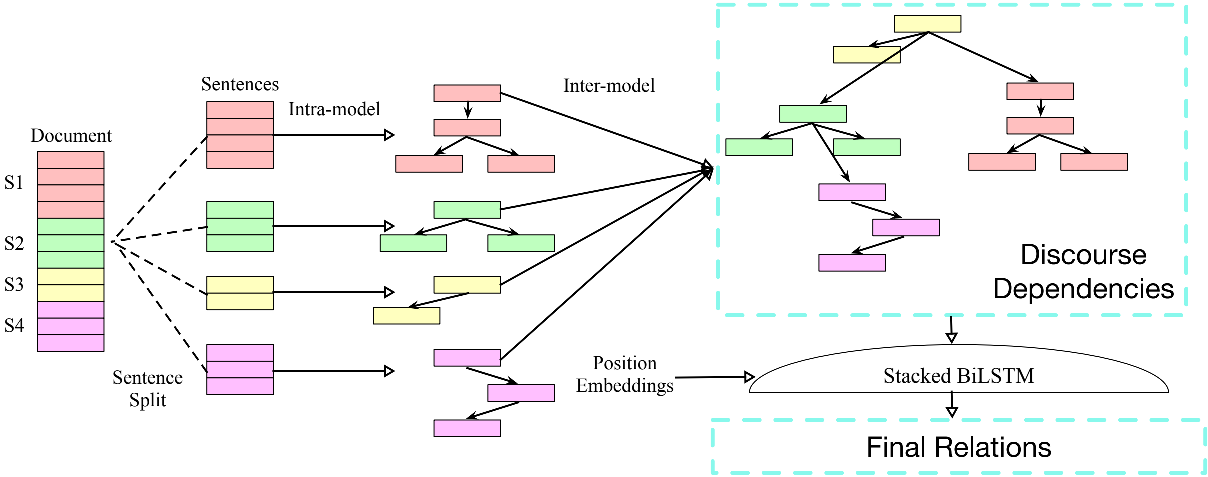

Figure 2: An overview of our model. Intra-sentential dependencies are discovered first and inter-sentential dependencies are constructed after that to form a complete dependency tree.

EDU Representations To better capture an EDU in our Sent-First framework, we use pre-trained BERT (Devlin et al., 2018) to obtain representations for each EDU according to different context. We argue that an EDU should have different representations when it is considered in different parsing levels, and thus requires level-specific contextual representations. For intra-sentential tree constructor, we feed the entire sentence to BERT and represent each EDU by averaging the last hidden states of all tokens in that EDU. The reason behind is that sentences are often self-contained sub-units of the discourse, and it is sufficient to consider interactions among EDUs within a sentence for intra-sentential analysis. On the other hand, for inter-sentential tree constructor, we concatenate all the root EDUs of different sentences in the discourse to form a pseudo sentence, feed it to BERT, and similarly, represent each root EDU by averaging the last hidden states of all tokens in each root EDU. In this way, we aim to encourage EDUs across different sentences to directly interact with each other, in order to reflect the global properties of a discourse. Figure 2 shows the architecture for our two-stage discourse dependency tree constructor.

4.2 Discourse Relation Identification

After the tree constructor is trained, we train separate sequence labeling models for relation identification. Although discourse relation identification in discourse dependency parsing is traditionally treated as a classification task, where the common practice is to use feature engineering or neural language models to directly compare two EDUs involved isolated from the rest of the context (Li et al., 2014a; Shi and Huang, 2018; Yi et al., 2021), sometimes relations between EDU pairs can be hard to be classified in isolation, as global information from the context like how EDUs are organized to support the claim in the discourse is sometimes required to infer the implicit discourse relations without explicit connectives. Therefore, we propose to identify discourse relation identification as a sequence labeling task.

Structure-aware Representations For sequence labeling, we need proper representations for EDU pairs to reflect the structure of the dependency tree. Therefore, we first tile each EDU in the input sequence $(e_1, e_2, ..., e_l)$ with their predicted heads to form a sequence of EDU pairs $((e_1, h_1), (e_2, h_2), ..., (e_l, h_l))$. Each EDU pair is reordered so that two arguments appear in the same order as they appear in the discourse. We derive a relation representation for each EDU pair with a BERT fine-tuned on the task of direct relation classification of EDU pairs with the [CLS] representation of the concatenation of two sentences.

Position Embeddings We further introduce position embeddings for each EDU pair (e_i, h_i), where we consider the position of e_i in its corresponding sentence, and the position of its sentence in the discourse. Specifically, we use cosine and sine functions of different frequencies (Vaswani et al., 2017) to include position information as:

$$PE_j = sin(No/10000^{j/d}) + cos(ID/10000^{j/d})$$

where PE is the position embeddings, No is the position of the sentence containing e_i in the discourse, ID is the position of e_i in the sentence, j is the dimension of the position embeddings, d is the dimension of the relation representation. The position embeddings have the same dimension as relation representations, so that they can be added directly to get the integrated representation for each EDU pair.

Stacked BiLSTM We propose a stacked BiLSTM neural network architecture to capture both intra-sentential and inter-sentential interplay of EDUs. After labeling the entire sequence of EDU pairs $((e_1, h_1), (e_2, h_2), ..., (e_l, h_l))$ with the first layer of BiLSTM, we select the root EDU for each sentence (namely the root EDU selected from our intra-sentential tree constructor for each setence) to form another inter-sentential sequence. Another separately trained BiLSTM is then applied to label those relations that span across sentences. Note that we will overwrite predictions of inter-sentential relations of the previous layer if there is a conflict of predictions.

4.3 Training

Our models are trained with offline learning. We train the tree constructor and the relation labeling models separately. We attain the static oracle to train tree constructors and use the gold dependency structure to train our discourse relation labelling models. Intra- and inter-sentential tree constructors are trained separately. To label discourse relations, we fine-tune the BERT used to encode the EDU pair with an additional output layer for direct relation classification. Sequence labeling models for relation identification are trained on top of the fine-tuned BERT. We use cross entropy loss for training.

5 Experiments

Our experiments are designed to investigate how we can better explore contextual representations to improve discourse dependency parsing.

We evaluate our models on two manually labeled discourse treebanks of different language, i.e., Discourse Dependency Treebank for Scientific Abstracts (SciDTB) (Yang and Li, 2018) in English and Chinese Discourse Treebank (CDTB) (Li et al., 2014b). SciDTB contains 1,355 English scientific abstracts collected from ACL Anthology. Averagely, an abstract includes 5.3 sentences, 14.1 EDUs, where an EDU has 10.3 tokens in average. On the other hand, CDTB was originally annotated as connective-driven constituent trees, and manually converted into a dependency style by Yi et al. (2021). CDTB contains 2,332 news documents. The average length of a paragraph is 2.1 sentences, 4.5 EDUs. And an EDU contains 23.3 tokens in average.

We evaluate model performance using Unlabeled Attachment Score (UAS) and Labeled Attachment Score (LAS) for dependency prediction and discourse relation identification. UAS is defined as the percentage of nodes with correctly predicted heads, while LAS is defined as the percentage of nodes with both correctly predicted heads and correctly predicted relations to their heads. We report LAS against both gold dependencies and model predicted dependencies. We adopt the fine-granularity discourse relation annotations in the original datasets, 26 relations for SciDTB and 17 relations for CDTB.

For both datasets, we trained our dependency tree constructors with an Adam optimizer with learning rate 2e-5 for 3 epochs. Our relation labeling models are all trained with an Adam optimizer until convergence. Learning rate is set to one of {1e-5, 2e-5, 4e-5}.

5.1 Baselines

Structure Prediction We compare with the following competitive methods for structure prediction. (1) **Graph** adopts the Eisner's algorithm to predict the most probable dependency tree structure (Li et al., 2014a; Yang and Li, 2018; Yi et al., 2021). (2) **Two-stage**, which is the state-of-the-art model on CDTB and SciDTB, uses an SVM to construct a dependency tree (Yang and Li, 2018; Yi et al., 2021). (3) **Sent-First LSTM** is our implmentation of the state-of-the-art transition-based discourse constituent parser on RST (Kobayashi et al., 2020), where we use a vanilla transition system with pretrained BiLSTM as the EDU encoder within the Sent-First framework to construct dependency trees. (4) **Complete Parser** is modified from a state-of-the-art constituent discourse parser on CDTB (Hung et al., 2020), using a transition system with BERT as the EDU encoder to construct a dependency tree. Because of the inherent difference between constituency parsing and dependency parsing, we only adopt the encoding strategy of (4) and (5) into our arc-eager transition system.

We also implement several model variants for

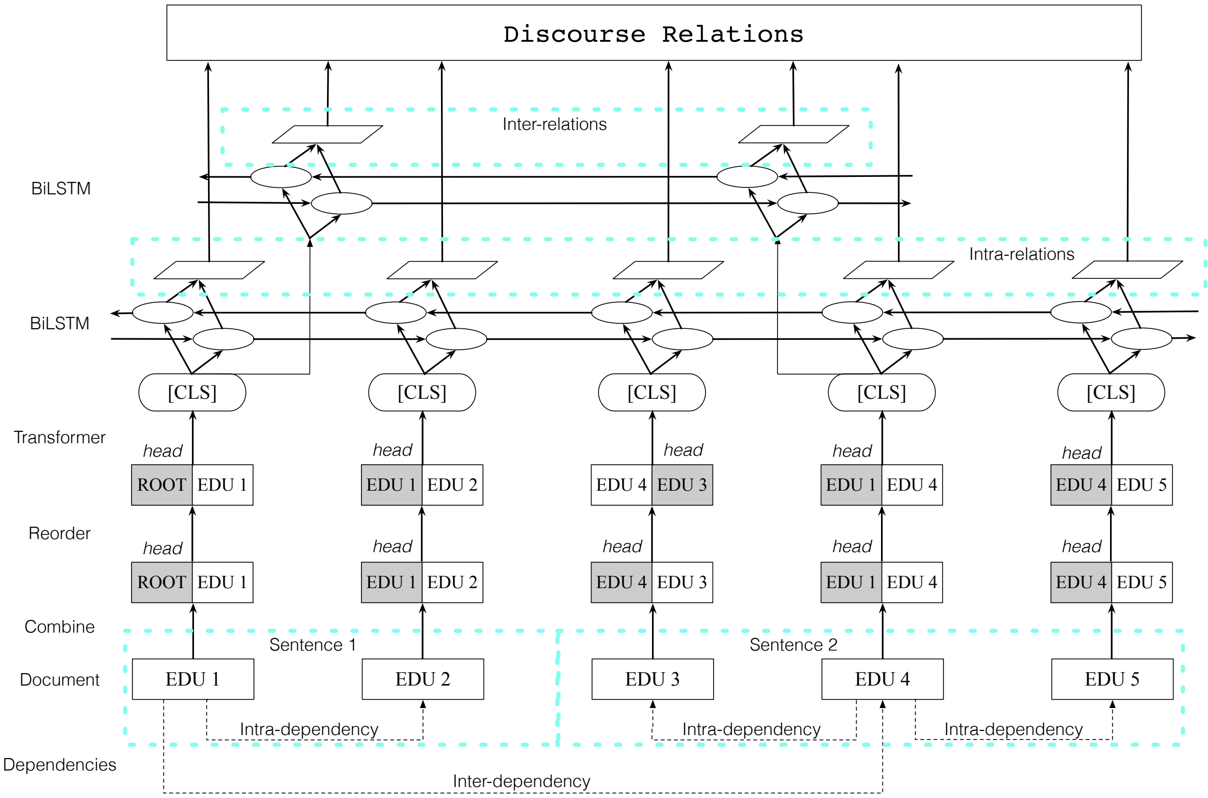

Figure 3: The architecture of our relation labeling stacked BiLSTM model. Hierarchical sequence labeling is used for labeling relations on intra-sentential and inter-sentential levels.

comparison and ablation study. (5) **Complete Parser (contextualized)** is our modified version of Complete Parser where, instead of encoding each EDU separately, we obtain the EDU representations by encoding the whole sentence with BERT and average the corresponding token representations for the EDU. (6) **BERT + Sent-First (shared)** incorporate different contextualized embeddings from BERT into the Sent-First framework for parsing at intra- and inter-sentential levels, with the same BERT layer shared across intra-sentential and inter-sentential parsing. (7) **BERT + Sent-First** fine-tunes separate BERT layers for intra-sentential and inter-sentential parsing independently.

	SciDTB	CDTB
Model	UAS	
Graph (Cheng21)	57.6	58.5
Two-stage (Cheng21)	70.2	80.3
Sent-First LSTM (Kobayashi20)	63.9	/

Relation Identification (1) **Graph** uses an averaged perceptron to classify relations by direct classification (Yi et al., 2021; Yang and Li, 2018). (2) **Two-stage** exploits careful feature engineering and trains an SVM to classify the relations for pairs of EDUs (Yi et al., 2021; Yang and Li, 2018). (3) **Sent-First LSTM** uses biLSTM to encode each EDU separately and a feed forward neural network for direct relation classification. (4) **BERT** is our implementation of the state-of-the-art model from Yi et al. (2021) and Hung et al. (2020), which fine-tunes a BERT model with an additional output layer to directly classify both intra-sentential and inter-sentential relations. (5) **BERT + BiL** formulates dependency discourse relation identification as a sequence labeling task, training an additional layer of BiLSTM on top of the BERT layer finetuned on direct classification. (6) **BERT SBiL** trains another BiLSTM to label inter-sentential relations on top of the original model BERT + BiL.

5.2 Main Results

Dependency Prediction Table 1 summarizes the performances of different models on both datasets in terms of UAS. For traditional feature engineering models, Two-stage has already achieved satisfactory performance, even beating several neural models like Sent-First LSTM and Complete Parser. This is probably because traditional feature engineering methods design delicate structural features in addition to representations of EDUs so that they can include contextual clues to facilitate parsing. Complete Parser leverages the benefit of better representations from pre-trained transformers to encode the information of individual EDUs, achieving a significant improvement over Sent-First LSTM model with LSTM as primary encoders. However, we show that our model BERT + Sent-First that exploits the potential of Sent-First framework with proper contextualized representations to capture the interactions between individual EDUs and the context surpasses all the existing baselines. The performance of our model can be further improved if we encode contextualized embeddings separately for intra-sentential and inter-sentential parsing to dynamically capture different information required to parsing at different text granularity levels.

Relation Identification Although previous methods like Graph, Two-stage, and Sent-First LSTM achieve decent results on both datasets, their performances are not comparable to transformer methods developed in recent years. BERT (Cheng21) is our implementation of the state-of-the-art method for relation classification in discourse dependency parsing, which improves the baseline by a large margin. Although BERT is still a very strong baseline in many NLP tasks, direct classification with BERT neglects the contextual clues in the discourse that can be exploited to aid discourse relation identification, as have been discussed in section 1. We show that the results can be further improved by making use of the sequential structure of the discourse. We design multiple novel sequence labeling models on top of the fine-tuned BERT and all of them achieve a considerable improvement (more than 1%) over BERT in terms of accuracy both on the gold dependencies and the predicted dependencies from our Sent-First (separate), showing the benefit of enhancing the interactions between individual EDUs with the context. It yields another large gain when we introduce another layer of inter-sentential level BiLSTM, showing again that it is crucial to capture the interactions between EDUs and their context in both intra- and inter-sentential levels.

5.3 Detailed Analysis

Contextualized Representations for Tree Construction Intuitively, a model should take different views of context when analyzing intra- and inter-sentential structures. As we can see in Table 1, BERT + Sent-First (shared) improves Complete Parser (contextualized) by 1.2% and 2.4% on SciTDB and CDTB, respectively. The only difference is BERT + Sent-First makes explicit predictions on two different levels, while Complete Parser (contextualized) treats them equally. When we force BERT + Sent-First to use different BERTs for intra- and inter-sentenntential analysis, we observe further improvement, around 3% on both datasets.

If we take a closer look at their performance in intra- and inter-sentential views in Table 3, we can see that BERT + Sent-First (shared) performs better than single BERT model, Complete Parser (contextualized), on both intra- and inter- levels of SciDTB and CDTB, though in some cases we only observe marginal improvement like inter-sentential level of SciDTB. However, when we enhance BERT + Sent-First with different encoders for intra- and inter-sentential analysis, we can observe significant improvement in all cases. That again shows the

importance of anaylzing with different but more focused contextual representations for the two parsing levels.

Classification or Sequence Labeling? Most previous works treat discourse relation identification as a straightforward classification task, where given two EDUs, a system should identify which relationship the EDU pair hold. As can be seen from Table 2, all sequence labeling models (our main model as well as the variants) achieve a considerable gain over direct classification models on both datasets, especially in terms of accuracy on gold dependencies. This result verifies our hypothesis about the structural patterns of discourse relations shared across different articles. It is noticed that BERT + SBiL performs the best because its hierarchical structure can better capture different structured representations occuring at intra- and inter-sentential levels.

In Table 4, we include the performances of different models on intra- and inter-sentential relations on SciDTB with gold dependency structure. We observe that although our BERT+BiL model improves accuracies on both levels compared to the traditional classification model, the more significant improvement is on the inter-sentential level (by 2.1%). We show that it can even be promoted by another 2.4% if we stack an additional BiLSTM layer on top to explicitly capture the interplay between EDUs on the inter-sentential level. That's probably because writing patterns are more likely to appear in a global view so that discourse relations on the inter-sentential level tend to be more structurally organized than that on the intra-sentential level.

To test the effectiveness of our model for implicit discourse relation identification, We delete some freely omissible connectives identified by Ma et al. (2019) to automatically generate implicit discourse relations. This results in 564 implicit instances in the test discourses. We run our model on the modified test data without retraining and compare the accuracies on those generated implicit relations. Table 5 shows the accuracies for those 564 instances before and after the modification. After the modification, although accuracies of all three models drop significantly, our sequence labeling model BERT+BiL and BERT+SBiL outperform the traditional direct classification model BERT by 1.4% and 2.5% respectively, showing that our sequence labeling models can make use of clues from the context to help identify relations in the case of implicit relations.

In addition, we experiment with other empirical implementations of contextualized representations instead of averaging tokens like using [CLS] for aggregate representations of sentences for inter-sentential dependency parsing, but we did not observe a significant difference. Averaging token representations turns out to have better generalizability and more straightforward for implementation.

5.4 Case Study

For the example shown in Figure 1, the relation between EDU 9 and EDU 13 is hard to classify using traditional direct classification because both of them contain only partial information of the sentences but their relation spans across sentences. Therefore, traditional direct classification model gets confused on this EDU pair and predicts the relation to be "elab-addition", which is plausible if we only look at those two EDUs isolated from the context. However, given the gold dependency structure, our sequence labeling model fits the EDU pair into the context and infers from common writing patterns to successfully yield the right prediction "evaluation". This shows that our model can refer to the structural information in the context to help make better predictions of relation labels.

6 Conclusion

In this paper, we incorporate contextualized representations to our Sent-First general design of the model to dynamically capture different information required for discourse analysis on intra- and inter-sentential levels. We raise the awareness of taking advantage of writing patterns in discourse parsing and contrive a paradigm shift from direct classification to sequence labeling for discourse relation identification. We come up with a stacked biLSTM architecture to exploit its hierarchical design to capture structural information occurring at both intra- and inter-sentential levels. Future work will involve making better use of the structural information instead of applying simple sequence labeling.

A Proof of Theorems

Theorem 1: For a document D with m sentences $(s_1, s_2, ..., s_m)$ and n of the sentences have length(in terms of the number of EDUs) greater or equal to 2 satisfying $|s_i| \geq 2$. Let T be the set of all projective dependency trees obtainable from D, and let T' be the set of all projective dependency trees obtainable from D in a *Sent-First* fashion. Then the following inequality holds:

$$|T'| \leq \frac{2}{n+1}|T|$$

Proof of Theorem 1: By the definition of our *Sent-First* method, trees in T' satisfy the property that there is exactly one EDU in each sentence whose head or children lies outside the sentence. It is clear that $T' \subset T$. We consider a document D with m sentences $(s_1, s_2, ..., s_m)$ and n of the sentences have length(in terms of the number of EDUs) greater or equal to 2 satisfying $|s_i| \geq 2$.

$\forall \sigma' \in T'$, σ' is a valid projective dependency tree obtainable from D in a *Sent-First* fashion. We define a t-transformation to a sentence s_i, $|s_i| > 1$ with its local root of the sentence e_{ia} not being the root of the document in σ' with the following rules:

1. If e_{ia} has no child outside s_i, e_{ib} is its furthest (in terms of distance to e_{ia}) child or one of its furthest children inside s_i, then delete the edge between e_{ia}) and e_{ib} and set the head of e_{ib} to be the head of e_{ia}.

2. Else if e_{ia} has at least one child before e_{ia} inside s_i, and e_{ib} is its furthest child before e_{ia} inside s_i. Delete the edge between e_{ia} and e_{ib}. If $i > 1$, set the head of e_{ib} to be the local root of sentence s_{i-1}, else $i = 1$, set the head of e_{ib} to be the local root of sentence s_{i+1}.

3. Else, e_{ia} has at least one child after e_{ia} inside s_i, and e_{ib} is its furthest child after e_{ia} inside s_i. Delete the edge between e_{ia}) and e_{ib}. If $i < m$, set the head of e_{ib} to be the local root of sentence s_{i+1}, else $i = m$, set the head of e_{ib} to be the local root of sentence s_{m-1}.

Suppose σ_i is obtained by applying t-transformation to the sentence s_i, it is obvious to show that $\sigma_i \in T/T'$. $n-1$ valid t-transformations can be applied to σ'. A reverse transformation t^{-1} can be applied to σ_i with the following rule: if a sentence has two local roots, change the head of one of the roots to the other root. In this way, at most two possibly valid trees $\in T'$ can be obtained because we are not sure which one is the original local root of the sentence. Therefore, at most 2 different $\sigma' \in T'$ can be found to share the same tree structure after a t-transformation. See Figure 5 for illustration. Therefore,

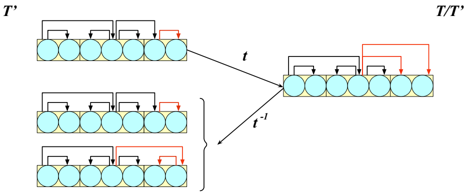

Figure 4: An illustration of transformation t for ***Theorem 1***.

$$|T/T'| \geq \frac{n-1}{2}|T'|$$

$$|T'| \leq \frac{2}{n+1}|T|$$

Theorem 1 shows that the search space shrinks with the number of sentences. Therefore, *Sent-First* approach is especially effective at the reduction of search space so that the parser has a better chance to find the correct result, no matter what kind of parser is used specifically. Since the effectiveness has been proved, this approach can even be confidently generalized to other cases where similar sentence-like boundaries can be identified.

Besides, an even stronger bound regarding the use of *Sent-First* method can also be proved for constituent parsing.

Theorem 2: For a document D with $m > 1$ sentences $(s_1, s_2, ..., s_m)$ and n of the sentences have length(in terms of the number of EDUs) greater or equal to 2 satisfying $|s_i| \geq 2$. Let T be the set of all binary constituency trees obtainable from D, and let T' be the set of all binary constituency trees obtainable from D in a *Sent-First* fashion. Then the following inequality holds:

$$|T'| \leq (\frac{1}{2})^n|T|$$

Proof of Theorem 2: By the definition of our *Sent-First* method, trees in T' satisfy the property that EDUs in a sentence forms a complete subtree. It is clear that $T' \subset T$. We define a tree transformation t, for a tree u_1 with child u_2 and u_3, u_3 being a complete discourse tree of a sentence with more than 2 EDUs. u_3 must also have 2 children named u_4 and u_5 where u_4 is adjacent to u_2 in the sentence. After transformation t, a new tree u_1' is derived whose children are u_5 and a subtree u_6 with children u_2 and u_4. $u_1 \in T'$, while $u_1' \in T/T'$. Illustration see Figure 6. Note that t is one-to-one so that different u_1 will be transformed to different u_1' after t-transformation and u_1 can be applied t-transformation twice if both children of u_1 are complete DTs for a sentence (more possible trees u_1' can be transformed into if the order of transformation is also considered). Transformation t is a local transformation and does not affect sub-trees u_2, u_4, and u_5.

$\forall \sigma' \in T'$, σ' is a valid projective dependency tree obtainable from D in a *Sent-First* fashion. Since all sub-trees representing a sentence must merge into one complete discourse tree representing the whole document, there must be n independent t transformations applicable to some subtrees in σ', so that at least $2^n - 1$ trees can be obtained after $i \geq 1$ t transformations $\in T/T'$. Since t-transformation is one-to-one, $\forall \sigma_1, \sigma_2 \in T', \sigma_1 \neq \sigma_2$, σ_1' is a tree obtained after some t-transformations on σ_1, σ_2' is a tree obtained after some t-transformations on σ_2, $\sigma_1' \neq \sigma_2'$.

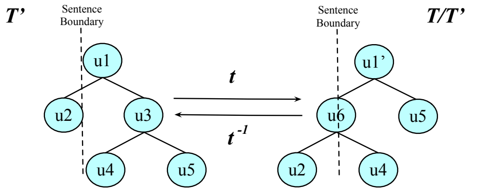

Figure 5: An illustration of transformation t for ***Theorem 2***.

Therefore,

$$|T/T'| \geq (2^n - 1)|T'|$$

$$|T'| \leq (\frac{1}{2})^n|T|$$

Abstract

We present a new method `LiST`[1] for parameter-efficient fine-tuning of large pre-trained language models (PLMs) for few-shot learning. `LiST` improves over recent methods that adopt prompt-based fine-tuning (FN) using two key techniques. The first is the use of self-training to leverage large amounts of unlabeled data for prompt-based FN in few-shot settings. We use self-training in conjunction with meta-learning for re-weighting noisy pseudo-prompt labels. Self-training is expensive as it requires updating all the model parameters repetitively. Therefore, we use a second technique for light-weight fine-tuning where we introduce a small number of task-specific parameters that are fine-tuned during self-training while keeping the PLM encoder frozen. Our experiments show that `LiST` can effectively leverage unlabeled data to improve the model performance for few-shot learning. Additionally, the fine-tuning is efficient as it only updates a small percentage of parameters and the overall model footprint is reduced since several tasks can share a common PLM encoder as backbone. A comprehensive study on six NLU tasks demonstrate `LiST` to improve by 35% over classic fine-tuning and 6% over prompt-based FN with 96% reduction in number of trainable parameters when fine-tuned with no more than 30 labeled examples from each task. With only $14M$ tunable parameters, `LiST` outperforms GPT-3 in-context learning by 33% on few-shot NLU tasks[2].

1 Introduction

Large pre-trained language models (PLMs) have obtained state-of-the-art performance in several natural language understanding tasks (Devlin et al., 2019a; Clark et al., 2020; Liu et al., 2019a). Despite their remarkable success in fully supervised settings, their performance is still not satisfactory when fine-tuning with only a handful of labeled examples. While models like GPT-3 (Brown et al., 2020) have obtained impressive few-shot performance with in-context task adaptation, they have a significant performance gap relative to fully supervised SoTA models. For instance, few-shot GPT-3 performance is 20 points worse than fully-tuned DeBERTa (He et al., 2021) on SuperGLUE. This

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2262 - 2281
July 10-15, 2022 ©2022 Association for Computational Linguistics

poses significant challenges for many real-world tasks where large labeled data is difficult to obtain.

In this work, we present a new fine-tuning method `LiST` that aims to improve few-shot learning ability over existing fine-tuning strategies using two techniques as follows.

The first one is to leverage self-training with large amounts of unlabeled data from the target domain to improve model adaptation in few-shot settings. Prompt-based fine-tuning (Gao et al., 2021) have recently shown significant improvements over classic fine-tuning in the few-shot learning setting. In this paper, we demonstrate that self-training with unlabeled data is able to significantly improve prompt-based fine-tuning (Gao et al., 2021) where we iteratively update a pair of teacher and student models given *natural language prompts* and *very few labeled examples for the task*. Since the uncertain teacher in few-shot setting produces noisy pseudo-labels, we further use meta-learning to re-weight the pseudo-prompt labels.

Traditional self-training can be expensive if we have to update all model parameters iteratively. To improve the efficiency of self-training, the second key technique introduces a small number of task-specific adapter parameters in the PLM that are updated with the above technique, while keeping the large PLM encoder fixed. We demonstrate such light-weight tuning with self-training to match the model performance where all parameters are tuned. This enables *parameter-efficient use of self-training* and *reduces the storage cost* of the fine-tuned model since multiple fine-tuned models can now share the same PLM as backbone during inference. Note that the computational cost of inference is out of the scope of this paper and previous work has studied several ways to address it including techniques like model distillation (Hinton et al., 2015) and pruning (LeCun et al., 1990).

We perform extensive experiments in six natural language understanding tasks to demonstrate the effectiveness of `LiST`. We devise a comprehensive evaluation framework considering the variance in few-shot performance of PLMs with different shots, random seeds and splits[3]. Results show that `LiST` improves over traditional and more recent prompt-based FN methods by 35% and 6%, respectively, with 96% reduction in number of trainable parameters given only 30 labeled examples for each downstream task. Figure 1 shows the results on MNLI (Williams et al., 2018a) as an example. We compare `LiST` with GPT-3 in-context learning outperforming it by 33% as well as several SoTA few-shot semi-supervised learning approaches with `LiST` outperforming the strongest baseline by 6% given only 30 labeled examples for each task.

Problem statement. Each downstream task in our framework consists of very few labeled training examples $\mathcal{D}_K^{Train}$ for different shots $K \in \{10, 20, 30\}$ where $|\mathcal{D}_K^{Train}| = K$, unlabeled data $\mathcal{D}^U$ where $\mathcal{D}^U \gg \mathcal{D}_K^{Train}$, and a test set $\mathcal{D}^{Test}$.

Given above dataset $\mathcal{D}_K = \mathcal{D}_K^{Train} \cup \mathcal{D}^U$ for a task with shots K, a PLM with parameters Θ_{PLM} and loss function $\mathcal{L}$, we want to adapt the model for the few-shot learning task by introducing a small number of tunable model parameters $\psi \ll \Theta_{\text{PLM}}$.

2 Background on Model Fine-tuning

Given a text sequence x or a pair of sequences $\{x_1, x_2\}$ separated by special operators (e.g., [CLS] and [SEP]) and a language model encoder $enc(\theta)$ parameterized by θ – classic fine-tuning popularized by (Devlin et al., 2019b) leverages hidden state representation $h_{[CLS]}$ of the sequence(s) obtained from $enc([\text{[CLS]}\ x_1\ \text{[SEP]}\ x_2\ \text{[SEP]}])$ as input to a task-specific head $softmax(W^T \cdot h_{[CLS]})$ for classification, where $W \in \mathbb{R}^{d \times L}$ with d and L representing the hidden state dimension and number of classes, are randomly initialized tunable parameters. In the process it updates both task-specific head W and encoder θ parameters jointly.

However, this introduces a gap between pre-training and fine-tuning objective with disparate label spaces and additional randomly initiated parameters W introduced for task-specific fine-tuning. This is particularly challenging for few-shot classic fine-tuning, where the limited labeled data is inadequate for adapting the task-specific head and PLM weights effectively. Prompt-based FN (Schick and Schütze, 2021b; Gao et al., 2021) addresses this gap, by re-formulating the objective as a cloze-style auto-complete task. This is done by adding a phrase (also called *prompt*) to a sentence like $x_1 =$ "`contains no wit, only labored gags`" in the form of $\tilde{x} = x_1 \oplus$ "`It was [MASK]`", where $\oplus$ denotes concatenation of two strings; and output mappings (also called *verbalizers*) from vocabulary $\mathcal{V}$ to the label space $\mathcal{Y}$ like "`{great, terrible}`" corresponding to positive and negative classes (refer to Figure 3 for an example). The probability of

---

[3] LiST repository contains the dataset partitions for different shots, seeds and splits for every task for reproducibility and benchmarking of efficient few-shot language models.

predicting class $y \in \mathcal{Y}$ is equal to calculating the probability of corresponding label word $v \in \mathcal{V}$:

$$p([\text{MASK}] = v|\tilde{x}) = \frac{\exp(W_v^T \cdot h_{[\text{MASK}]})}{\sum_{v' \in V} \exp(W_{v'}^T \cdot h_{[\text{MASK}]})} \quad (1)$$

where W_v indicates the tunable parameters. Since it is identical to masked language modeling (MLM), W_v is initialized by pre-trained weights of PLMs.

In this work, we demonstrate lite self-training with unlabeled data to significantly improve prompt fine-tuning of PLMs in few-shot settings.

3 Related Works

Few-shot and Semi-supervised Learning. Recent works have explored semi-supervised methods for few-shot learning with task-specific unlabeled data, including data augmentation (Xie et al., 2019; Vu et al., 2021), self-training (He et al., 2019; Mukherjee and Awadallah, 2020; Wang et al., 2021c) and contrastive learning (Gunel et al., 2020). GPT-3 (Brown et al., 2020) leverages massive scale with 175 billion parameters to obtain remarkable few-shot performance on several NLU tasks given *natural language prompts* and a few *demonstrations* for the task. Recent works (Schick and Schütze, 2021a; Gao et al., 2021) extend this idea of *prompting* to language models like BERT (Devlin et al., 2019b) and RoBERTa (Liu et al., 2019b). The most related work to ours is iPET (Schick and Schütze, 2021a), which combines prompt-based FN with semi-supervised learning. While iPET ensembles multiple fully-tuned models, we develop a lightweight prompted self-training framework to achieve both data and parameter efficiency.

Few-shot adaptation works (Finn et al., 2017; Li et al., 2019; Zhong et al., 2021; Wang et al., 2021b,a; Beck et al., 2021) train models on *massive labeled data on source tasks* and develop techniques to adapt them to *a target task with few-shot labels*. For instance, (Beck et al., 2021) first trains on miniImagenet with *38,400 labeled examples* (64 classes and 600 samples per class). Similarly, (Zhong et al., 2021; Beck et al., 2021) first train their models on thousands of labels from the source task to study few-shot target adaptation. In contrast, we focus on ***single-task true few-shot learning*** with only **10 to 30** labeled examples available overall and **no auxiliary supervision labels**. Refer to (Perez et al., 2021) for an overview of true few-shot learning for NLU. The objective of few-shot adaptation and true few-shot learning is also quite different. The objective of true few-shot learning is to learn a new task with limited labeled data while the objective of few-shot adaptation is to efficiently transfer to a new task/domain with limited labeled data. Thus, few-shot adaptation leverages multi-task setting with auxiliary labeled data from the source tasks that are not available in our setting. The most relevant works to our setup (Gao et al., 2021; Wang et al., 2021c; Schick and Schütze, 2021a; Mukherjee and Awadallah, 2020) are used as baselines in our paper.

Light-weight tuning. Standard fine-tuning methods tune all trainable model parameters for every task. Recent efforts have focused on lightweight tuning of large PLMs by updating a small set of parameters while keeping most of parameters in PLMs frozen, including prefix tuning (Li and Liang, 2021), prompt token tuning (Lester et al., 2021a) and Adapter tuning (Houlsby et al., 2019; Pfeiffer et al., 2020). All of the above works focus on fully supervised settings with thousands of labeled examples using classic fine-tuning. In contrast, we focus on few-shot learning settings leveraging prompts for model tuning, where we make several observations regarding the design and placement of adapters in few-shot settings in contrast to its resource-rich counterpart. Some recent works (Beck et al., 2021; Zhong et al., 2021) pre-train adapters with full supervision with thousands of labeled examples from source tasks for few-shot target adaptation. Different from this, we explore adapter tuning for single-task few-shot learning without any auxiliary supervision labels.

4 Methodology

4.1 Overview

We adopt a PLM (e.g., RoBERTa (Liu et al., 2019b)) as the *shared encoder* for both the student and teacher for self-training. The shared PLM encoder is frozen and not updated during training. We introduce *tunable adapter parameters* in both teacher and student (discussed in Section 4.2) that are iteratively tuned during self-training. Refer to Figure 2 for steps in the following discussion.

We first use prompt-based fine-tuning to update the teacher adapter (*Step 1*) with few-shot labeled examples and leverage the teacher model to assign pseudo-prompt labels (*Step 2*) on unlabeled data $\mathcal{D}^u$. The teacher is often uncertain in few-shot learning and produces noisy pseudo-labels. Therefore, we adopt meta-learning (discussed in Section 4.3) to re-weight the noisy pseudo-labeled samples (*Step 3*). The re-weighted data is used to train the student adapter (*Step 4*). Since adapter training with noisy pseudo labels is quite unstable, we introduce knowledge distillation warmup (discussed in Section 4.3.1). Finally, we assign the trained student adapter to be the new teacher adapter (*Step 5*). Following *true* few-shot learning settings, we do not use any held-out development or validation set. Therefore, we repeat the above steps for a pre-defined number of times ($M = 6$). The overall training procedure is summarized in Algorithm 1 (Appendix B). Throughout the training, we keep the shared student and teacher encoder parameters frozen and update the corresponding adapter parameters along with their language model heads.

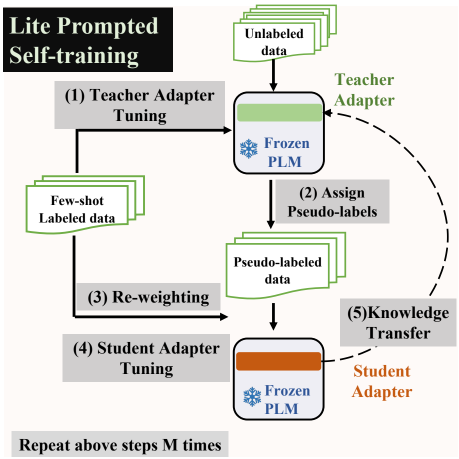

Figure 2: Lite prompted self-training on unlabeled data with prompts and adapters make parameter-efficient few-shot learners with `LiST`.

4.2 Lightweight Prompt Adapter Tuning

The predominant methodology for task adaptation is to tune all of the trainable parameters of the PLMs for every task. This raises significant resource challenges both during training and deployment. A recent study (Aghajanyan et al., 2021) show that PLMs have a low instrinsic dimension that can match the performance of the full parameter space. To adapt PLMs for downstream tasks with a small number of parameters, adapters (Houlsby et al., 2019) have recently been introduced as an alternative approach for lightweight tuning. Consider the following scenario for demonstration, where we want to use RoBERTa-large with $\mathcal{M} = 355M$ parameters as the PLM for $\mathcal{T} = 100$ tasks. Full fine-tuning for this scenario requires updating and storing $\mathcal{M} \times \mathcal{T} = 35.5B$ parameters. Now, consider fine-tuning with `LiST` that requires $\mathcal{A} = 14M$ (tunable) adapter parameters for every task while keeping the PLM fixed. This results in overall $\mathcal{M} + \mathcal{A} \times \mathcal{T} = 1.8B$ parameters, thereby, reducing the overall storage cost by 20x. Adapters have been shown to match the PLM performance in fully supervised settings with thousands of training labels in classic fine-tuning. In contrast, this is the first work to study the role of adapters in few-shot prompt-based FN. We explore different design and placement choices of adapters in few-shot settings and investigate the performance gap with fully supervised as well as fully tunable parameter space.

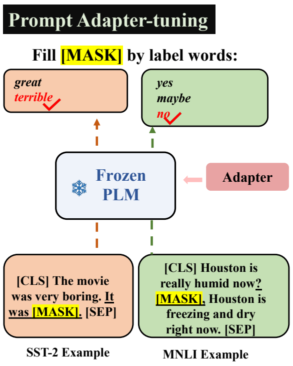

Figure 3: The underlined text depicts task prompt to transform classification into Fill-in-MASK task. Label words are used as proxy for original task labels.

The adapter tuning strategy judiciously introduces new parameters into the original PLMs. In contrast to standard prompt-based FN that updates all the PLM parameters Θ_{PLM}, prompt-adapter tuning only updates the newly introduced adapter parameters as well as the (masked) language model head of the PLM (jointly denoted as ψ), while keeping the remaining parameters of the original network frozen. The adapter used in `LiST` consists of two fully connected layers as shown in Figure 4, where a feedforward layer down projects input representations to a low dimensional space d (referred as the bottleneck dimension), and another feedforward layer up projects the low-dimensional features back to the original dimension. However, these newly-inserted parameters can cause divergence resulting in up to 20% performance degradation in few-shot settings (discussed in Section 5.3). To handle this issue, we adopt a skip-connection design where the adapter parameters are initialized with zero-mean small Gaussian noise.

Adapter placement. Prior works on lightweight adaptation tune bias (Cai et al., 2020b) or embeddings (Lester et al., 2021a) of Transformers in

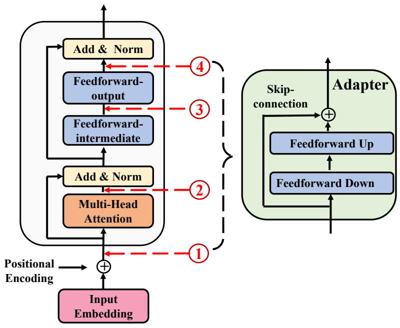

Figure 4: `LiST` explores several adapter placement choices (numbered positions in left) in standard Transformer architecture, with adapter design shown in right.

fully-supervised settings for improving parameter-efficiency with minimal performance loss. However, for few-shot settings, we note that adapter placement is critical to bridge the performance gap with that of a fully tunable model and the choices of tuning bias or embedding can result in upto 10% performance degradation (discussed in Section 5.3). To this end, we explore several choices of adapter placement (refer to Figure 4) corresponding to the most important transformer modules, namely, embedding, intermediate feedforward, output feedforward and attention module in *every layer* of the Transformer. Based on empirical experiments (refer to Section 5.3) across six diverse NLU tasks, we observe the feedforward output and attention modules to be the most important components for parameter-efficient adaption in few-shot settings.

Formally, consider $\widetilde{\mathcal{D}}_K^{Train} = \{\widetilde{x}^l, \widetilde{y}^l\}$ to be the few-shot labeled data and $\widetilde{\mathcal{D}}^U = \{\widetilde{x}_u\}$ to be the unlabeled data, where we transform the input sequences x to cloze-style input $\widetilde{x}$ containing a single mask following the prompting strategy outlined in Section 2. We use the same pattern templates and verbalizers (output mapping from the task-specific labels $\mathcal{Y}$ to single tokens in the vocabulary $\mathcal{V}$) from traditional prompt-based FN works (Gao et al., 2021). Given the above adapter design and placement of choice with parameters ψ, a dataset $\widetilde{\mathcal{D}}_K^{Train}$ with shots K, a PLM encoder *enc* with parameters Θ_{PLM}, where $\Theta_{\text{PLM}} \gg \psi$, we want to perform the following optimization for efficient model adaptation:

$$\psi \leftarrow \arg\min_{\psi} \; \mathcal{L}(\widetilde{\mathcal{D}}_K^{Train}; \Theta_{\text{PLM}}, \psi) \tag{2}$$

4.3 Re-weighting Noisy Prompt Labels

Consider $\{\hat{y}_n^{(t)}\}_{n=1}^N$ to be the pseudo prompt-labels (for the masked tokens in $\widetilde{x}_n^u \in \widetilde{X}$) from the teacher $(\Theta_{\text{PLM}}, \hat{\psi}_{\text{tea}})$ in the t-th iteration where N is the number of unlabeled instances and $\hat{\psi}_{\text{tea}}$ represent the teacher adapter parameters. In self-training, the student model is trained to mimic the teacher predictions on the transfer set. Consider $\mathcal{L}(\hat{y}_n^{(t)}, \text{enc}(\widetilde{x}_n^u; \Theta_{\text{PLM}}, \psi_{\text{stu}}^{(t)}))$ to be the loss of the student model with parameters $(\Theta_{\text{PLM}}, \psi_{\text{stu}}^{(t)})$ on the pseudo-labeled data in the t-th iteration, where Θ_{PLM} and ψ_{stu} represent the PLM and the student adapter parameters respectively. In order to reduce error propagation from noisy pseudo-labels, we leverage meta-learning to re-weight them based on the student model loss on the validation set as our meta-objective. The intuition of meta re-weighting is to measure the impact or weight of a pseudo-labeled example given by its performance on the **validation set**. Since we do not have access to a separate validation set in the spirit of true few-shot learning, we leverage the labeled training set $\widetilde{\mathcal{D}}_K^{Train}$ judiciously for re-weighting. To this end, we leverage the idea of weight perturbation (Ren et al., 2018) to set the weight of pseudo-labeled example $(\widetilde{x}_i^u, \hat{y}_i^{(t)})$ to $\epsilon_i^{(t)}$ at iteration t as:

$$\mathcal{L}_r^{(t)}(\epsilon, \psi) = \frac{\sum_{i=1}^{N} [\epsilon_i^{(t)} \cdot \mathcal{L}(\hat{y}_i^{(t)}, \text{enc}(\widetilde{x}_i^u; \Theta_{\text{PLM}}, \hat{\psi}_{\text{stu}}^{(t-1)}))]}{N}. \tag{3}$$

$$\hat{\psi}_{\text{stu}}^{(t)}(\epsilon) = \hat{\psi}_{\text{stu}}^{(t-1)} - \alpha \nabla \mathcal{L}_r^{(t)}(\epsilon, \psi). \tag{4}$$

where α is the step size. Weight perturbation is used to discover data points that are most important to improve performance on the validation set. Optimal value for the perturbation $\epsilon_i^{(t)*}$ can be obtained via minimizing student model loss on the validation set at iteration t as:

$$\epsilon_i^{(t)*} = \arg\min_{\epsilon_i} \frac{\sum_{i=1}^{|\widetilde{\mathcal{D}}_K^{Train}|} \mathcal{L}(y_i, \text{enc}(x_i; \Theta_{\text{PLM}}, \hat{\psi}_{stu}^{(t)}(\epsilon_i))}{|\widetilde{\mathcal{D}}_K^{Train}|} \tag{5}$$

To obtain a cheap estimate of the meta-weight at step t, we take a single gradient descent step on a mini-batch $\widetilde{\mathcal{D}}^{(t)} \in \widetilde{\mathcal{D}}_K^{Train}$ as:

$$u_i^{(t)} = -\frac{\partial}{\partial \epsilon_i} \left(\frac{\sum_{i=1}^{|\widetilde{\mathcal{D}}^{(t)}|} \mathcal{L}(y_i, \text{enc}(\widetilde{x}_i; \Theta_{\text{PLM}}, \hat{\psi}_{stu}^{(t)}(\epsilon)))}{|\widetilde{\mathcal{D}}^{(t)}|} \right) \tag{6}$$

The weight $w_i^{(t)}$ of $(\widetilde{x}_i^u, \hat{y}_i^{(t)})$ at iteration t is set to be proportional to the negative gradient $u_i^{(t)}$ to reflect the importance of pseudo-labeled samples. Samples with negative weights are filtered out since they could potentially degrade the student performance. Finally, we update student adapter parameters ψ_{stu} while accounting for re-weighting as:

$$\mathcal{L}^{(t)} = \frac{1}{N}\sum_{i=1}^{N}[w_i^{(t)} \cdot \mathcal{L}(\hat{y}_i^{(t)}, \mathrm{enc}(\widetilde{x}_i^u; \Theta_{\mathrm{PLM}}, \hat{\psi}_{\mathrm{stu}}^{(t-1)}))]). \tag{7}$$

4.3.1 Knowledge Distillation For Student Warmup

Meta re-weighting leverages gradient as a proxy to estimate the weight of noisy pseudo labels. However, the gradients of adapter parameters ψ are not stable in the early stages of training due to random initialization and noises in pseudo labels. This instability issue is further exacerbated with adapter tuning that usually requires a larger learning rate (Pfeiffer et al., 2020). Therefore, to stabilize adapter tuning, we propose a warmup training stage via knowledge distillation (Hinton et al., 2015) to first tune adapter parameters via knowledge distillation loss for T_{warm} steps and then we continue self-training with re-weighted updates via Eq. 7. Since the re-weighting procedure has access to our training labels, we do not use labeled data in knowledge distillation while using only the unsupervised consistency loss between teacher model $(\Theta_{\mathrm{PLM}}, \hat{\psi}_{\mathrm{tea}})$ and student model $(\Theta_{\mathrm{PLM}}, \hat{\psi}_{\mathrm{stu}})$ on unlabeled data as.

$$\underset{\hat{\psi}_{stu}}{\arg\min}\, \mathrm{KL}(f(\widetilde{x}^u; \Theta_{\mathrm{PLM}}, \hat{\psi}_{\mathrm{tea}}) \parallel f(\widetilde{x}^u; \Theta_{\mathrm{PLM}}, \hat{\psi}_{\mathrm{stu}})). \tag{8}$$

We further validate the effectiveness of knowledge distillation for warmup with ablation analysis.

4.3.2 Student Adapter Re-initialization

A typical challenge in few-shot settings is the lack of a separate validation set. In the spirit of *true* few-shot learning, we use only the available few-shot labeled examples $\widetilde{\mathcal{D}}_K^{Train}$ as the validation set for meta-learning of the student model. This poses an interesting challenge of preventing label leakage. To address this issue, we *re-initialize the student adapter parameters* every time at the start of each self-training iteration to mitigate interference with labeled data. Note that the student and teacher model share the encoder parameters Θ_{PLM} that are always kept frozen and not updated during training.

5 Experiments

5.1 Experimental Setup

Dataset. We perform large-scale experiments with six natural language understanding tasks as summarized in Table 6. We use four tasks from GLUE (Wang et al., 2019), including MNLI (Williams et al., 2018b) for natural language inference, RTE (Dagan et al., 2005; Bar Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009) for textual entailment, QQP[4] for semantic equivalence and SST-2 (Socher et al.) for sentiment classification. The results are reported on their development set following (Zhang et al., 2021). MPQA (Wiebe et al., 2005) and Subj (Pang and Lee, 2004) are used for polarity and subjectivity detection, where we follow (Gao et al., 2021) to keep $2,000$ examples for testing and use remaining examples for semi-supervised learning.

For each dataset, we randomly sample $|\mathcal{K}| \in \{10, 20, 30\}$ manually labeled samples from the training data, and add the remaining to the unlabeled set while ignoring their labels – following standard setups for semi-supervised learning. We repeatedly sample K labeled instances five times, run each model with 5 different seeds and report average performance with standard deviation across the runs. For the average accuracy over 6 tasks, we did not include standard deviation across tasks. Furthermore, for every split and shot, we sample the labeled data such that $\mathcal{D}_{10}^{Train} \subset \mathcal{D}_{20}^{Train} \subset \mathcal{D}_{30}^{Train}$ to evaluate the impact of incremental sample injection.

Following *true few-shot learning* setting (Perez et al., 2021), we do not use additional *development set* beyond $|\mathcal{K}|$ labeled samples for any hyper-parameter tuning or early stopping. The performance of each model is reported after fixed training epochs (see Appendix for details).

Baselines. In addition to classic-tuning (Classic FN), we adopt prompt-based fine-tuning (Prompt FN) from (Gao et al., 2021) as labeled-only baselines. We also adopt several state-of-the-art semi-supervised baselines including UST (Mukherjee and Awadallah, 2020), MetaST (Wang et al., 2021c) and iPET (Schick and Schütze, 2021a). UST and MetaST are two self-training methods which are based on classic fine-tuning strategies. iPET is a semi-supervised method leveraging prompt-based fine-tuning and prompt ensembles to obtain state-of-the-art performance. While iPET ensembles multiple fully-tuned models, we develop a lite self-training framework to achieve both data and parameter efficiency. As the strongest semi-supervised baseline, we implement a new method *PromptST based on self-training using prompts and adapters*

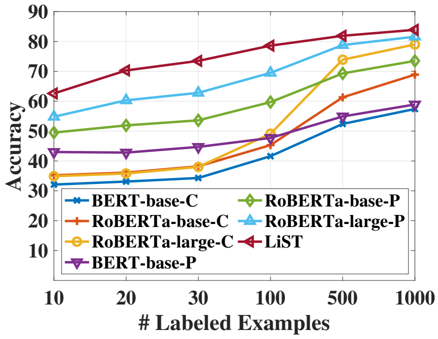
Table 1: Performance comparison of different tuning strategies on different NLU tasks with RoBERTa-large as the encoder with standard deviation in parantheses. UST, MetaST, PromptST and iPET are semi-supervised methods using unlabeled data, whereas Classic and Prompt FN only use labeled data.

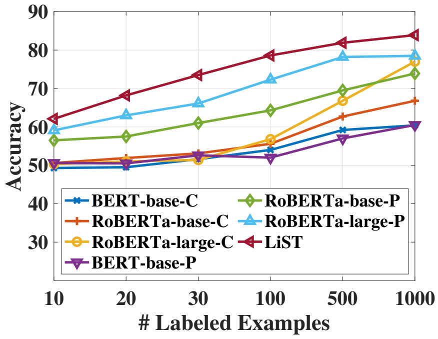
(as a subset of the methods used in LiST), but without any re-weighting, or KD warmup that are additionally used in LiST. The methods Prompt FN, PromptST and LiST adopt same prompts and label words as in (Gao et al., 2021). We implement our framework in Pytorch and use Tesla V100 gpus for experiments. Prompts used in experiments and hyper-parameter configurations are presented in Appendix.

5.2 Key Results

Table 1 shows the performance comparison among different models with $|\mathcal{K}| = 30$ labeled examples with fixing RoBERTa-large as the encoder. Fully-supervised RoBERTa-large trained on thousands of labeled examples provides the ceiling performance for the few-shot setting. We observe LiST to significantly outperform other state-of-the-art baselines along with 96% reduction in tunable parameters, achieving both labeled data- and parameter-efficiency. More specifically, LiST improves over Classic FN, Prompt FN, iPET and PromptST by 34.6%, 5.7%, 8.6% and 6.2% respectively in terms of average performance on six tasks. This demonstrates the impact of self-training with unlabeled data and prompt-based FN. Additionally, iPET and LiST both leverage prompt-based FN to significantly improve over UST and MetaST that use classic fine-tuning strategies, confirming the effectiveness of prompt-based FN in the low data regime. iPET ensembles multiple prompts with diverse qualities and under-performs Prompt FN on average in our few-shot setting without using any development set.



(a) MNLI



(b) RTE

Figure 5: Performance comparison of Classic-tuning (denoted as "C") and prompt-based fine-tuning (denoted as "P") with LiST on MNLI and RTE using language model encoders of different sizes.

Figure 5 compares the performance of tuning methods with varying number of training labels and encoders of different sizes. We observe that large models are more data-efficient compared to smaller models. However, large fully-tunable models are expensive to use in practise. We observe that LiST with small number of tunable parameters consistently outperforms fully-tunable classic and prompt-based FN strategies in all labeled data settings, demonstrating both data and parameter ef-

`LiST` Adapter (128)	14M	**77.7**
Full tuning	355M	77.6

Table 4: Average accuracy of several lightweight parameter-efficient tuning strategies with $|\mathcal{K}| = 30$ labels without unlabeled data on **six tasks** along with the number (#) of tunable parameters. Each task is run with 5 different seeds. `LiST` Adapter performance with different bottleneck dimension d of its adapters is shown in parantheses.

ficiency. Additional results with different backbone encoders and varying number of shots and fine-tuning strategies are presented in the Appendix in Tables 13, 14, 15 and 19 that demonstrate similar trends as we observe in Table 1 and Figure 5.

Comparison with GPT-3 in-context Learning. We perform a comparison between GPT-3 in-context learning, RoBERTa-large Prompt-based fine-tuning and LiST methods with varying number of training labels in Table 2. For a fair comparison, the prompt and label words are same for the three approaches. We observe that `LiST` outperforms GPT-3 In-context learning and Prompt-based FN consistently with different number of labels.

5.3 Adapter Analysis

In this section, we explore adapter design choices for prompt-based FN with RoBERTa-large as encoder *using only few-shot labeled data.*

Where to insert an adapter in Transformers? In order to answer this question, we conduct an experiment to study the role of various Transformer modules in few-shot prompt-based FN. To this end, we tune a given module along with the language model head while keeping all other parameters frozen. Table 3 shows the performance comparison of tuning specific modules on six tasks with varying number of labeled examples. The main modules of RoBERTa include *Embedding*, *Attention*, *Feedforward Output* and *Feedforward Intermediate* layers. We observe that tuning only the *Feedforward Output* or the *Attention* module delivers the best performance across most tasks with few-shot labels. Correspondingly, this motivated us to insert our adapter parameters into these two modules. More detailed results are presented in Appendix Table 11.

Comparison with other lightweight parameter efficient model tuning strategies. To validate the effectiveness of `LiST` adapters, we compare it against several baselines in Table 4. For a fair comparison, we present two variations of our `LiST` adapters with bottleneck dimensions $d = \{2, 128\}$ corresponding to $1M$ and $14M$ parameters to match other adapter capacities; all the approaches in Table 4 are *trained with 30 labels only without* *unlabeled data* for a fair comparison. (1) Bias-only is a simple but effective lightweight method, which tunes bias terms of PLMs while keeping other parameters frozen. (2) Tuning head layers is widely used as a strong baseline for lightweight studies (Houlsby et al., 2019), where we tune last two layers including language model head while freezing other parameters. (3) prompt-tuning is a lightweight method which only updates task prompt embedding while keeping entire model frozen. (4) Houlsby Adapter tunes inserted adapter parameters keeping the encoder frozen by adopting classic tuning strategy. Besides these lightweight methods, we also present a performance comparison with full model tuning as a strong baseline. More detailed results are presented in Appendix in Tables 12 and 20 that demonstrate similar trends.

Table 4 shows that LiST is able to match the performance of full model prompt-based FN with bottleneck dimension $d = 128$ and outperforms all other baselines with similar capacities. While lightweight model tuning choices like tuning the bias or inserting adapters into classic tuning models are shown to be effective in fully-supervised settings (Cai et al., 2020b; Houlsby et al., 2019), we observe them to under-perform for few-shot learning. We observe that simpler tuning choices like Head-only and Bias-only results in upto 10% performance degradation. Houlsby adapter and Prompt-only results in upto 20% performance degradation. In constrast, LiST adapter is able to match the performance of full tuning in few-shot setting, demonstrating the importance of adapter placement choices and parameter initialization.

5.4 Ablation Analysis

Table 5 demonstrates the impact of different components and design choices of LiST.

- **Adapter training stability.** Training with very few labels and noisy pseudo labeled data results in instability for adapter tuning. To demonstrate training stability, we include the average accuracy and standard deviation across several runs and splits as metrics. We observe that hard pseudo-labels hurt the model performance compared to soft pseudo-labels and exacerbate the instability issue. This is in contrast to observations from classic fine-tuning (Wang et al., 2021c). A potential reason could be that the well pre-trained language model head for prompt-based FN is able to capture better associations among different prompt labels.
- **Knowledge Distillation Warmup.** In this ablation study, we remove the warmup phase with knowledge distillation from LiST (denoted as "LiST w/o KD Warmup"). Removing this component results in 4% performance drop in terms of average accuracy and 300% larger standard deviation – demonstrating the importance of KD Warmup in stabilizing LiST training.

Method	**Avg Acc**	**Avg Std**	**Datasets**	
			MNLI (m/mm)	RTE
LiST ($14M$)	72.6	2.8	73.5 (2.8) / 75.0 (3.7)	71.0 (2.4)
w/o re-init	68.3	4.2	66.7 (2.8) / 68.3 (4.3)	69.0 (4.9)
w/o KD Warmup	68.8	8.8	67.9 (12.9) / 69.0 (13.1)	69.2 (4.5)
w/o Re-weighting	71.6	4.0	72.9 (3.4) / 74.2 (4.5)	69.7 (4.1)
w/ Hard Pseudo-Labels	70.9	4.4	71.7 (3.8) / 73.0 (5.4)	69.5 (4.2)
LiST w/o Adapter ($355M$)	72.6	2.5	73.6 (2.7) / 74.8 (2.7)	71.2 (2.3)

Table 5: Ablation analysis of LiST with 30 labels on MNLI and RTE with tunable parameters in parantheses.

- **LiST versus LiST w/o Adapter.** In LiST, we only fine-tune the adapter and language model head while keeping other encoder parameters frozen to achieve parameter efficiency. Table 5 shows that LiST using only 4% tunable parameters is able to match the performance of fully tunable LiST (that is without using any adapters and tuning all encoder parameters) on MNLI and RTE – demonstrating the effectiveness of our lightweight design. More ablation results with varying shots are presented in Appendix in Tables 16, 17 and 18 that demonstrate similar trends as in Table 5.

6 Conclusions and Future Work

We develop a new method LiST for lightweight tuning of large language models in few-shot settings. LiST uses prompted self-training to learn from large amounts of unlabeled data from target domains. In order to reduce the storage and training cost, LiST tunes only a small number of adapter parameters with few-shot labels while keeping the large encoder frozen. With only 30 labels for every task, LiST improves by upto 35% over classic fine-tuning and 6% over prompt-tuning while reducing 96% of the tunable parameters. With significant reduction in the cost of (data) annotation and overall model footprint, LiST provides an efficient framework towards life-long learning of AI agents (Biesialska et al., 2020). While adapters reduce storage cost, LiST does not reduce inference latency given the PLM backbone. A future work is to consider combining model compression techniques (Han et al., 2015; Cai et al., 2020a) with adapters to reduce FLOPS and latency.

7 Ethical Considerations

In this work, we introduce a lightweight framework for self-training of language models with only a few labeled examples. We expect that progress and findings presented in this paper could further benefit NLP applications with limited labeled data. In the real-world setting, it is usually not only expensive to obtain large-scale labeled data for each task but also brings privacy and compliance concerns when large-scale data labeling is needed. The privacy concerns could be further exacerbated when dealing with sensitive user data for peronslization tasks. Our framework which only needs few-shot labeled data could help in this to obtain state-of-the-art-performance while alleviating privacy concerns. The proposed framework is tested across different tasks and could be used for applications in various areas including finance, legal, healthcare, retail and other domains where adoption of deep neural network may have been hindered due to lack of large-scale manual annotations on sensitive user data.

While our framework advance the progress of NLP, it also suffers from associated societal implications of automation ranging from job losses for workers who provide annotations as a service as well as for other industries relying on human labor. Moreover, it may bring additional concerns when NLP models are used by malicious agents for propagating bias, misinformation and indulging in other nefarious activities. However, many of these concerns can also be alleviated with our framework to develop better detection models and mitigation strategies with only a few representative examples of such intents.

The proposed method is somewhat compute-intensive as it involves large-scale language model. This might impose negative impact on carbon footprint from training the described models. In order to reduce the storage and training cost, the proposed design tunes only a small number of adapter parameters with few-shot labels while keeping the large encoder frozen.

A Datasets

A.1 Dataset information

Table 6 summarize dataset statistics and task descriptions. All the datasets are in English Language. The licence information is as follows.

MNLI: The majority of the corpus is released under the OANC's license, which allows all content to be freely used, modified, and shared under permissive terms. The data in the FICTION section falls under several permissive licenses; Seven Swords is available under a Creative Commons Share-Alike 3.0 Unported License, and with the explicit permission of the author, Living History and Password Incorrect are available under Creative Commons Attribution 3.0 Unported Licenses; the remaining works of fiction are in the public domain in the United States (but may be licensed differently elsewhere).

RTE: The dataset is public release but the corresponding licence information is not found in the source website [5].

QQP: We did not find the responding license. The source website [6] is not accessible.

SST-2 dataset: CC0: Public Domain

Subj: The dataset is public release but the Licence information is not presented in the source website [7].

MPQA: The dataset[8] is public release. Made available under the terms of GNU General Public License. They are distributed without any warranty.

We follow the licence of datasets for research use. We manually check no offensive content in our few-shot training dataset.

A.2 Prompts

Table 7 summarizes manually-designed prompts and label words for each dataset in our experiments. These prompts and label words were adopted from (Gao et al., 2021).

B Algorithm Flow

Algorithm 1 summarizes overall flow of `LiST`. We adopt a light self-training mechanism which keeps the shared student and teacher encoder parameters frozen and only updates the adapter parameters along with the corresponding language model heads. Beside the lightweight tuning design, another key step in our self-training framework is to utilize the few-shot labeled data to fine-tune the student model $\psi_{\text{stu}}^{(T)}$) in every self-training session. Such a step is different with conventional self-training framework, which either leverages labeled data for initial teacher fine-tuning or combine labeled data with unlabeled data for joint training of student model. The iterative usage of unlabeled data and labeled data helps in better teacher initialization before next round of adapter prompt-tuning on $\widetilde{\mathcal{D}}_K^{Train}$ which further helps in improving model tuning and the quality of pseudo labels.

Algorithm 1: `LiST` Algorithm.

```
Input: Labeled samples $\widetilde{\mathcal{D}}_K^{Train} = \{\widetilde{x}^l, \widetilde{y}^l\}$; Unlabeled samples
      $\widetilde{\mathcal{D}}^U = \{\widetilde{x}_u\}$; a pre-trained language model with parameters
      $\Theta_{\text{PLM}}$; randomly initialized Adapter with parameters $\psi$;
      Number of student training iterations $T$, KD warmup steps
      $T_{warm}$ and self-training sessions $M$.
Initialize teacher adapter $\psi_{\text{tea}} = \psi^{(0)}$
Tune teacher adapter $\psi_{\text{tea}}$ on small labeled data $\widetilde{\mathcal{D}}_K^{Train}$;
for $m \leftarrow 1$ to $M$ do
    Initialize the student adapter $\psi_{\text{stu}} = \psi^{(0)}$ ;
    for $t \leftarrow 1$ to $T$ do
        Infer pseudo prompt labels $\{\hat{y}_n^{(t)}\}_{n=1}^N$ for unlabeled
          data $\widetilde{\mathcal{D}}^U = \{\widetilde{x}_u\}$ with teacher model
          $(\Theta_{\text{PLM}}, \psi_{\text{tea}})$;
        Randomly sample a batch of pseudo-labeled samples
          from $(\widetilde{x}_u, \hat{y}^{(t)})$;
        if $t < T_{warm}$ then
            Train student adapter $\psi_{\text{stu}}$ according to Eq. 8
        else
            Sample a mini-batch from $\widetilde{\mathcal{D}}^{(t)} \in \widetilde{\mathcal{D}}_K^{Train}$
            as validation mini-batc for re-weighting;
            Train student adapter $\psi_{\text{stu}}$ on re-weighted
              pseudo-labeled samples according to Eq. 7;
        end
    end
    Tune student adapter $\psi_{\text{stu}}^{(T)}$ on small labeled data $\widetilde{\mathcal{D}}_K^{Train}$;
    Update the teacher adapter: $\psi_{\text{tea}} = \psi_{\text{stu}}^{(T)}$
end
```

C Experimental Details

C.1 Hyper-parameters

Following the true few-shot learning spirit, we do not have any additional development set for hyper-parameter tuning. Instead we keep all the hyper-parameter same for different tasks, different model families and sizes as well as different shots K. We retain most of the default hyper-parameter configurations from related work. For each task, we run the model five times with different data splits and different random seeds in $\{1, 2, 3, 4, 5\}$. Our experiments are conducted in few-shot supervision setting and few-shot semi-supervised setting. In

single-sentence	SST-2	2	6,920	872	sentiment	positive, negative
	Subj	2	8,000	2,000	subjectivity	subjective, objective
	MPQA	2	8,606	2,000	opinion polarity	positive, negative

Table 6: Dataset summary and task descriptions. For each task, we sample $\mathcal{K} \in \{10, 20, 30\}$ labeled examples to form five different splits with different random seeds from the original training set, and add the remaining to the unlabeled set while ignoring their labels.

Task	Prompt	Label words
SST-2	$<S_1>$ It was `[MASK]` .	positive: great, negative: terrible
MR	$<S_1>$ It was `[MASK]` .	positive: great, negative: terrible
Subj	$<S_1>$ This is `[MASK]` .	subjective: subjective, objective: objective
MNLI	$<S_1>$? `[MASK]` , $<S_2>$	entailment: Yes, netural: Maybe, contradiction: No
RTE	$<S_1>$? `[MASK]` , $<S_2>$	entailment: Yes, not_entailment: No
QQP	$<S_1>$ `[MASK]` , $<S_2>$	equivalent: Yes, not_equivalent: No

Table 7: Task prompt and label words summary. $<S_1>$ and $<S_2>$ indicate input sentences.

the following, we introduce the hyper-parameters for each setting respectively.

Few-shot supervision setting. We set learning rate as 5e-6, training epochs as 400 and batch size as 4. The bottleneck dimension d of Adapter is set to 128. The optimizer is AdamW (Loshchilov and Hutter, 2017) with default settings besides learning rate. We use variance for adapter as 0.002 and observe that the performance is not sensitive to variance values when the scale of variance values are equal or less than 0.002. Since experiments are run with different number of labeled examples, the GPU hours range from 5 minutes to 1 hour per task.

Few-shot semi-supervised setting. For initial teacher fine-tuning, we adopt the same hyper-parameter configuration as in few-shot supervision setting. To facilitate training on a large amounts of unlabeled data, the learning rate in self-training is set to 1e-4 following fully supervised adapter work (Pfeiffer et al., 2020). The batch size of unlabeled data for student adapter training is 16 and the size of minibatch $\widetilde{\mathcal{D}} \in \widetilde{\mathcal{D}}_K^{Train}$ for meta re-weighting in Eq. 6 is 4. For each self-training session, we train student adapter for $T = 1000$ steps and further fine-tune 50 epochs on given labeled data. The student KD warmup ratio is set to 60%, i.e., $T_{warm} = 600$ steps, without extra hyper-parameter tuning. We repeat all the steps in self-training training $M = 6$ times. Since experiments are run with different number of labeled examples and datasets, the GPU hours of all approaches are different, ranging from 1 hour to 10 hours per task.

Models	#Params	Avg Acc
BERT-base	110M	67.4
BERT-large	336M	68.0
RoBERTa-base	125M	73.7
RoBERTa-large	355M	**77.6**
T5-small	60M	66.5
T5-base	220M	71.9
T5-large	770M	77.3

Table 8: Average accuracy of prompt FN with different encoders using $|\mathcal{K}| = 30$ labels on six tasks.

C.2 Few-shot Supervision with Varying Model Sizes and Labels

To better understand the role of different model families in few-shot prompt-based FN, we evaluate the performance of representative state-of-the-art PLMs like BERT (Devlin et al., 2019b), RoBERTa (Liu et al., 2019b) and T5 (Raffel et al., 2020) of different sizes (parameters) using varying amounts of labeled data. We report macro-averaged results over six tasks where each has five different splits for easy comparison.

Effect of model choices. Table 8 shows the performance comparison of three representative PLMs with different parameters using prompt-based FN on 30 labeled samples. We observe that average performance increases with increase in model size within each model family. Overall, we observe

RoBERTa models to perform much better than BERT, and marginally outperform T5 models of much bigger size. Accordingly, we use RoBERTa-large as the base encoder for both `LiST` and other baseline methods.

Effect of varying the number of labels $|\mathcal{K}|$. From Figure 5, we observe prompt-based FN to consistently outperform classic-tuning under all labeled data settings when using the same encoder. With increase in the amount of labeled examples, prompt-based FN and classic-tuning both improve in performance, although with reduced performance gap. This demonstrates prompt-based FN to be the most impactful for low-resource settings with few training labels. `LiST` improves over both classic and prompt-based FN in all settings with massive reduction in number of tunable parameters.

C.3 Experimental result details

Fine-tuning strategies with varying number of shots. Table 9 shows the performance comparison of RoBERTa-large with two fine-tuning strategies and varying number of labeled samples including zero-shot supervision, few-shot supervision from 10 to 30 and full supervision. Prompt fine-tuning shows competitive performance in zero-shot learning, outperforming classic fine-tuning strategy with 30 labeled examples on several tasks like MNLI and SST-2. As the size of labeled examples increases, the average performance of classic and prompt fine-tuning strategy improves significantly and prompt fine-tuning strategy consistently improves classic fine-tuning with a big gap in the few-shot setting. With full supervision, Prompt fine-tuning strategy and classic fine-tuning strategy achieve similar performance, demonstrating that Prompt fine-tuning is most impactful for low-resource settings with few training labels.

Task performance of varying number of shots and models. We show performance changes regarding varying number of shots and varying model choices in Figure 5 and include more detailed results including average accuracy over 5 runs and corresponding standard deviation on MNLI and RTE in Table 10.

Task performance of different modules with varying number of shots. We show the average accuracy on tuning different modules of RoBERTa-large with $|K| = 30$ on six tasks in Table 3. In Table 11, we show average accuracy with standard deviation of RoBERTa-large on each task using varying shots of labeled data. We can observe that Feedforward-output performs best in average while Attention module achieves best performance on some tasks. The conclusion is consistent across different shots of labeled data. Such observations motivate us to insert Adapter into *Feedforward Output* and *Attention* modules to handle diverse tasks.

Task performance of lightweight model tuning strategies. We show the average accuracy of serveral lightweight strategies with $|K| = 30$ labeled examples on six tasks in Table 4. In Table 12, we show average accuracy with standard deviation of lightweight tuning strategies on each task with $|K| = 30$ labeled examples. We can observe that `LiST` Adapter outperforms all the lightweight tuning strategies for all six tasks, demonstrating the effective design in adapter placement and parameter initialization.

Comparisons over different PLMs. Table 13, 14 and 15 show the performance comparison of two representative PLMs with different parameters using prompt-based FN on 10, 20 and 30 labeled samples. We observe that average performance increases with increase in model size within each model family. Overall, we observe RoBERTa models to perform much better than BERT. This observation is consistent with the observation in Table 8.

More ablation Analysis. Tables 16, 17 and 18 show the performance of LiST (14 MM parameters) by removing different components as well as LiST without (w/o) adapter (355 MM parameters). It can be observed that the trend is consistent over different shots. “w/o re-init“ leads to performance drop consistently in various shots and different data sets. Adapter with 4% tunable parameters obtains similar performance to full model tuning for shots of 10, 20 and 30 as shown in Table 8.

Adapters w/ different number of training labels. We compare the performance of LiST Adapter (14 MM parameters) against full model tuning (355 MM parameters) where we obtain 96% tunable parameter reduction with almost matching performance across 10, 20 and 30 shots in Table 20.

CLMLF:A Contrastive Learning and Multi-Layer Fusion Method for Multimodal Sentiment Detection

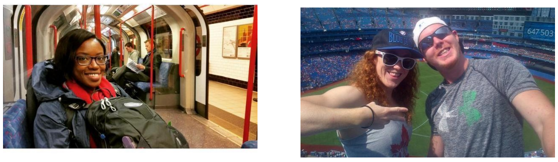
Zhen Li, Bing Xu[*], Conghui Zhu, Tiejun Zhao
Harbin Institute of Technology, Harbin, China
linklizhen@163.com, {hitxb,conghui,tjzhao}@hit.edu.cn

Abstract

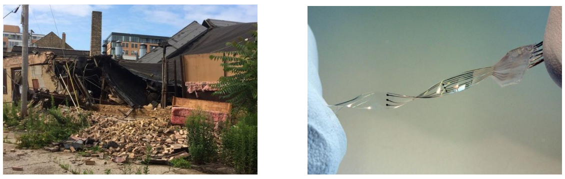
Compared with unimodal data, multimodal data can provide more features to help the model analyze the sentiment of data. Previous research works rarely consider token-level feature fusion, and few works explore learning the common features related to sentiment in multimodal data to help the model fuse multimodal features. In this paper, we propose a Contrastive Learning and Multi-Layer Fusion (CLMLF) method for multimodal sentiment detection. Specifically, we first encode text and image to obtain hidden representations, and then use a multi-layer fusion module to align and fuse the token-level features of text and image. In addition to the sentiment analysis task, we also designed two contrastive learning tasks, label based contrastive learning and data based contrastive learning tasks, which will help the model learn common features related to sentiment in multimodal data. Extensive experiments conducted on three publicly available multimodal datasets demonstrate the effectiveness of our approach for multimodal sentiment detection compared with existing methods. The codes are available for use at `https://github.com/Link-Li/CLMLF`

1 Introduction

With the development of social networking platforms which have become the main platform for people to share their personal opinions. How to extract and analyze sentiments in social media data efficiently and correctly has broad applications. Therefore, it has attracted attention from both academic and industrial communities (Zhang et al., 2018a; Yue et al., 2019). At the same time, with the increasing use of mobile internet and smartphones, more and more users are willing to post multimodal data (e.g., text, image, and video) about different topics to convey their feelings and sentiments. So multimodal sentiment analysis has become a popular research topic (Kaur and Kautish, 2019).



(a) Heathrow. Fly early tomorrow morning. (positive) (b) Blue Jays game with the fam! Let's go! (positive)



(c) Ridge Avenue is closed after a partial building collapse and electrical fire Saturday night. (negative) (d) Flexible spinal cord implants will let paralyzed people walk. (neutral)

Figure 1: Examples of multimodal sentiment tweets

As for multimodal data, the complementarity between text and image can help the model analyze the real sentiment of the multimodal data. As shown in Figure 1, detecting sentiment with only text modality or image modality may not be certain of the true intention of the tweet. Such as Figure 1a, if we only analyze the text modality, we will find that this is a declarative sentence that does not express sentiment. In fact, the girl's smile in the image shows that the sentiment of this tweet is positive. At the same time, in Figure 1c, we can find that the ruins in the image which deepen the expression of negative sentiment in the text.

For multimodal sentiment analysis, we focus on text-image sentiment analysis in social media data. In existing works, some models try to concatenate different modal feature vectors to fuse the multimodal features, such as MultiSentiNet (Xu and Mao, 2017) and HSAN (Xu, 2017). Kumar and Vepa (2020) proposes to use gating mechanism and attention to obtain deep multimodal contextual feature vectors. Multi-view Attentional Network (MVAN) is proposed by Yang et al. (2020) which

July 10-15, 2022

introduces memory networks to realize the interaction between modalities. Although the above mentioned models are relatively better than unimodal models, the inputs with different modalities are in different vector spaces. Therefore, it is difficult to fuse multimodal data with a simple concatenation strategy, so the improvement is also limited. Furthermore, the gating mechanism and memory network are essentially not designed for multimodal fusion. Although they can help the model analyzes the sentiment in the multimodal data by storing and filtering the features in the data, it is obvious that these methods are difficult to align and fuse the features of text and image. Since Transformers have achieved great success in many fields, such as natural language processing and computer vision (Lin et al., 2021; Khan et al., 2021), we propose **M**ulti-**L**ayer **F**usion (**MLF**) module based on Transformer-Encoder. Benefiting from the multi-headed self-attention in Transformer, which can capture the internal correlation of data vectors. Therefore, text tokens and image patches with explicit and implicit relationships will have higher attention weight allocation to each other which means the MLF module can help align and fuse the token-level text and image features better. And MLF is a multi-layer encoder, which can help improve the abstraction ability of the model and obtain deep features in multimodal data.

Some previous work has explored the application of contrastive learning in the multimodal field. Huang et al. (2021) proposes the application of contrastive learning in multilingual text-to-video search, and Yuan et al. (2021) applies contrastive learning to learn visual representations that embraces multimodal data. However, there is little work to study the application of contrastive learning in multimodal sentiment analysis, so we propose two contrastive learning tasks, **L**abel **B**ased **C**ontrastive **L**earning (**LBCL**) and **D**ata **B**ased **C**ontrastive **L**earning (**DBCL**), which will help the model learn common features related to sentiment in multimodal data. For example, as shown in Figure 1a and Figure 1b. We can find that both tweets show positive sentiment. And we also can find there are smiling expressions in the image of the two tweets which is a common feature of those tweets. If the model can learn common features related to sentiment, it will greatly improve the performance of the model.

In this paper, we propose a **C**ontrastive **L**earning and **M**ulti-**L**ayer **F**usion (**CLMLF**) method for multimodal sentiment analysis based on text and image modalities. For evaluation, CLMLF is verified on three multimodal sentiment datasets, namely MVSA-Single, MVSA-Multiple (Niu et al., 2016) and HFM (Cai et al., 2019). CLMLF achieves better performance compared to several baseline models in all three datasets. Through a comprehensive set of ablation experiments, case study, and visualizations, we demonstrate the advantages of CLMLF for multimodal fusion[1]. Our main contributions are summarized as follows:

- We propose a multi-layer fusion module based on Transformer-Encoder that multi-headed self-attention can help align and fuse token-level features of text and image, and it can also benefit from the depth of MLF which improves model abstraction ability. Experiments show that the proposed architecture of MLF is simple but effective.
- We propose two contrastive learning tasks based on label and data, which leverages sentiment label features and data augmentation. Those two contrastive learning tasks can help the model learn common features related to sentiment in multimodal data, which improve the performance of the model.

2 Approach

2.1 Overview

In this section, we will introduce CLMLF. Figure 2 illustrates the overall architecture of CLMLF model for multimodal sentiment detection that consists of two modules: multi-layer fusion module and multi-task learning module. Specifically, the multi-layer fusion module is on the right in Figure 2, it includes a text-image encoder, image Transformer layer, and text-image Transformer fusion layer modules. The multi-task learning module is on the left in Figure 2, it includes three tasks, sentiment classification, label based contrastive learning and data based contrastive learning tasks.

2.2 Multi-Layer Fusion Module

We use Multi-Layer Fusion module to align and fuse the token-level features of text and image. As shown on the right of Figure 2. First, we

---

[1] There are also the experimental results and analysis of CLMLF in aspect based multimodal sentiment analysis task, which can refer to Appendix B

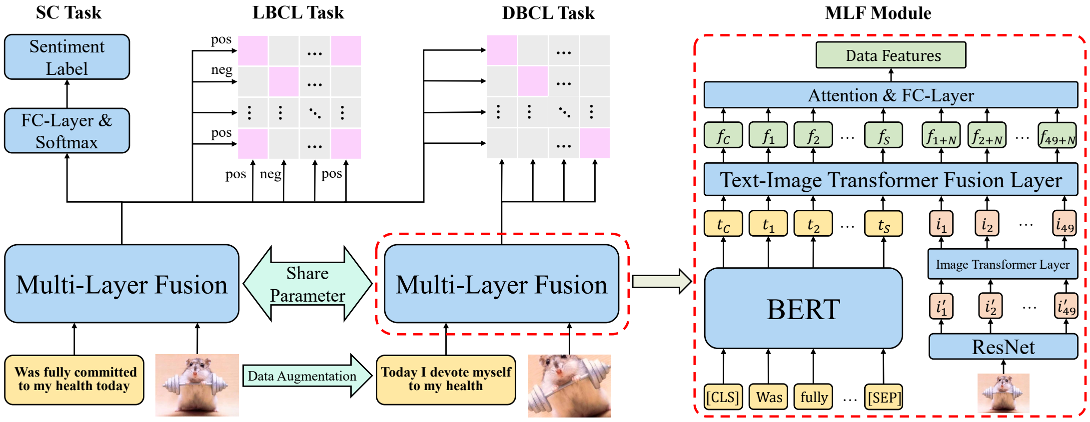

Figure 2: The framework of the proposed CLMLF model

use BERT (Devlin et al., 2019) and ResNet (He et al., 2015) to encode the text and image to obtain the hidden representation of the text $T = \{t_C, t_1, t_2, ..., t_S\}, T \in \mathbb{R}^{n_t \times d_t}$ and the hidden representation of the image $I_c^{'} \in \mathbb{R}^{p_i \times p_i \times d_i}$, and $I_c^{'}$ is the image feature map output by the last layer of convolution layer of ResNet. We transform the hidden representation dimension of $I_c^{'}$ into the same dimension as the T. And we can get the sequence feature representation of the image $I^{'}$ as follows:

$$I^{'} = flatten(I_c^{'} W_I + b_I) \tag{1}$$

Where $I^{'} = \{i_1^{'}, i_2^{'}, ..., i_{n_i}^{'}\}, I^{'} \in \mathbb{R}^{n_i \times d_t}$, $n_i = p_i \times p_i$. And the function of $flatten$ means flatten the input vector by reshaping the first two-dimensions into a one-dimensional.

After that, we will encode the image sequence features $I^{'}$. Here we use the vanilla Transformer-Encoder proposed by Vaswani et al. (2017). Input $I^{'}$ into the image Transformer layer which is based on a multi-layer Transformer-Encoder to obtain the final encoding of image sequence features I.

$$\{i_1, i_2, ..., i_{n_i}\} = TE_I(\{i_1^{'}, i_2^{'}, ..., i_{n_i}^{'}\}) \tag{2}$$

$$I = \{i_1, i_2, ..., i_{n_i}\} \tag{3}$$

Where TE_I means the vanilla Transformer-Encoder of image.

In order to align and fuse the features of text and images, we concatenate the features of the text T and the image sequence features I. We use a new multi-layer Transformer-Encoder as a text-image fusion layer which will align and fuse multimodal features. Then the fusion sequence features of text and image can be obtained. It is as follows:

$$\{f_1, f_2, ..., f_{n_t+n_i}\} = TE_M(concat(T, I)) \tag{4}$$

$$F = \{f_1, f_2, ..., f_{n_t+n_i}\} \tag{5}$$

Where TE_M means the vanilla Transformer-Encoder of multimodal data.

Now, we obtain the sequence features of text and image fusion, but it is obvious that the sequence features can not be used in the classification task. So we use a simple attention layer to get the multimodal representation R.

$$\tilde{q}_i = GELU(f_i W_1 + b_1) W_2 + b_2 \tag{6}$$

$$q_i = exp(\frac{\tilde{q}_i}{\sum_{j=1}^{n_t+n_i} \tilde{q}_j}) \tag{7}$$

$$\tilde{R} = \sum_{i=1}^{n_t+n_i} q_i f_i \tag{8}$$

$$R = GELU(\tilde{R} W_R + b_R) \tag{9}$$

where $GELU$ is the activation function. $R \in \mathbb{R}^{d^t}$

2.3 Sentiment Classification

As shown in the SC task in Figure 2, we feed the above multimodal representation R into the fully connected layer and employ the softmax function for sentiment detection. We use the cross-entropy loss as the classification loss and it is as follows:

$$L_{sc} = Cross\text{-}Entropy(GELU(RW_{sc} + b_{sc})) \tag{10}$$

2.4 Label Based Contrastive Learning

In order to let the model learn the sentiment related features in the multimodal data, we use label based contrastive learning task to help the model extract the sentiment related features while MLF module fuses text and image data. As shown in the LBCL task in Figure 2, we divide the data in each batch into positive and negative examples according to its sentiment label. For example, in Figure 2, for a negative label of multimodal data, the data in the batch with the same negative labels as positive examples (the square of pink color), and the data with no negative labels are taken as negative examples (the square of gray color).

The specific step can refer to Algorithm 1. The meanings of specific functions in the algorithm are as follows: $einsum$ means Einstein summation convention, $gather$ means gathers values along with an index, and τ represents the contrastive learning's temperature. The algorithm consists of two main steps: the first step is to generate the unmask label L_t according to the data labels in the batch; the second step is to calculate the loss matrix l_{pn}, and use the unmask label L_t and the loss matrix l_{pn} to get the final loss $L_{l\text{-}cl}$, which are the water-red elements in LBCL task on the left in Figure 2.

Algorithm 1 LBCL Algorithm

Require: The sentiment label is L, which is a list of all data in the batch, assuming that the sentiment is divided into three categories: positive (0), neutral (1) and negative (2); The Multi-Layer Fusion Model of MLF; the texts are T; the images are I; C denotes length of L_c; S denotes length of L.

Ensure: Label contrastive learning loss $L_{l\text{-}cl}$

```
initialize $L_c = [L-0, L-1, L-2]$ and $L_t = list()$
for $i = 1; i <= C; i++$ do
    initialize $\tilde{L}_t = list()$
    for $l = 1; l <= T; l++$ do
        if $L_c[i][j]$ equals 0 then
            $\tilde{L}_t.append(j)$
        end if
    end for
    $L_t.append(\tilde{L}_t)$
end for
$R = MLF(T, I)$
$\tilde{l}_{pn} = einsum(nc, ck- > nk, [R, R^T])$
$l_{pn} = LogSoftmax(l_{pn}/\tau).view(-1)$
$L_{cl} = L_t[L[1]]$
for $q = 2; q <= S, q++$ do
    $L_{cl} = concat(L_{cl}, L_t[L[q]] + q \times T)$
end for
$L_{lbcl} = gather(l_{pn}, index = L_{cl})/T$
return $L_{lbcl}$
```

2.5 Data Based Contrastive Learning

In order to strengthen the robustness of the model to the data and enhance the learning ability of the model to the invariant features in the data. We add a contrastive learning task based on data augmentation which is DBCL task in Figure 2. Considering the flexible expression of text and images. It may cause the model to be too sensitive to the surface features of data, rather than focus on fusing the invariant features in text and images, that is, effective features. Sentiment related features should exist in these effective features, because the true meaning of the meaning user wants to express should not change with the changes in text and images. For example, both "I had ice cream today. I was very happy" and "I'm very happy today because I ate ice cream" express positive sentiment. The keyword "happy" has not changed which means the happy is an effective feature, but some other words have changed greatly. The data based contrastive learning can force the model learning the effective features in the data, which is more conducive to the model to learn the features related to sentiment in the data. Algorithm 2 describes the process of data based contrastive learning.

Specifically, as for text, we use a data augmentation method called back-translation (Sennrich et al., 2016; Edunov et al., 2018; Xie et al., 2020), which refers to the procedure of translating an existing text x in language E into another language C and then translating it back into E to obtain an augmented text x. As observed by Yu et al. (2018), back-translation can generate diverse paraphrases while preserving the semantics of the original sentences. So we use back-translation to construct positive examples of text in contrastive learning.

For image augmentation, we use a method called RandAugment (Cubuk et al., 2020), which is inspired by AutoAugment (Cubuk et al., 2018). AutoAugment uses a search method to combine all transformations to find a good augmentation strategy. In RandAugment, it does not use search, but instead uniformly samples from the same set of augmentation transformations. In other words, RandAugment is simpler and requires no labeled data as there is no need to search for optimal policies.

2.6 Model Training

The label contrastive loss or data contrastive loss can be simply added to the total loss as a regularization. Can be combined like follows:

Algorithm 2 DBCL Algorithm

```
Require: The Multi-Layer Fusion Model of $MLF$; the texts are $T$; the images are $I$; $BT$ means back-translation and $RA$ means RandAugment; $T$ denotes of batch size.
Ensure: Data contrastive learning loss $L_{d\text{-}cl}$
  $R = MLF(T, I)$
  $R_{au} = MLF(BT(T), RA(I))$
  $l_{pn} = einsum(nc, ck- > nk, [R, R_{au}^T])$
  $cl\_label = arange(T)$
  $L_{dbcl} = Cross\text{-}Entropy(l_{pn}/\tau, cl\_label)$
  return $L_{dbcl}$
```

$$L = L_{sc} + \lambda_{lbcl} L_{lbcl} + \lambda_{dbcl} L_{dbcl} \tag{11}$$

where λ_{lbcl} and λ_{dbcl} are coefficients to balance the different training losses.

3 Experimental Setup

3.1 Dataset

We demonstrate the effectiveness of our method on three public datasets which are MVSA-Single, MVSA-Multiple[2] (Niu et al., 2016) and HFM[3] (Cai et al., 2019). Both datasets collect data from Twitter, each text-image pair is labeled by a single sentiment. For a fair comparison, we process the original two MVSA datasets in the same way used in Xu and Mao (2017), as for HFM, we adopt the same data preprocessing method as that of Cai et al. (2019). We randomly split the MVSA datasets into train set, validation set, and test set by using the split ratio 8:1:1. The statistics of these datasets are given in Table 2. The detailed statistics of these datasets are given in Appendix A.

3.2 Implementation Details

For the experiments of CLMLF, we use the Pytorch[4] and HuggingFace Transformers[5] (Wolf et al., 2020) as the implementation of baselines and our method. We use the Bert-base[6] and ResNet-50[7] as the text and image encoder in Multi-Layer Fusion module. The batch size is set to 32, 64 and 128 for MVSA-Single, MVSA-Multiple and HFM. We use AdamW optimizer. The ϵ is 1e-8 and β is (0.9, 0.999). The learning rate is set to 2e-5. Both λ_{lbcl} and λ_{dbcl} are set to 1.0 in Equation 11 during training. For the number of layers of MLF, please refer to Section 4.3. And all the experiments are done on four NVIDIA 3090 GPUs.

3.3 Compared Methods

We compare our model with the unimodal sentiment models and the multimodal baseline models.

Unimodal Baselines: For text modality, CNN (Kim, 2014) and Bi-LSTM (Zhou et al., 2016) are well-known models for text classification tasks. TGNN (Huang et al., 2019) is a text-level graph neural network for text classification. BERT (Devlin et al., 2019) is a pre-trained model for text, and we fine-tuned on the text only. For image modality, OSDA (Yang et al., 2020) is an image sentiment analysis model based on multiple views. ResNet (He et al., 2015) is pre-trained and fine-tuned on the image only.

Multimodal Baselines: MultiSentiNet (Xu and Mao, 2017) is a deep semantic network with attention for multimodal sentiment analysis. HSAN (Xu, 2017) is a hierarchical semantic attentional network based on image captions for multimodal sentiment analysis. Co-MN-Hop6 (Xu et al., 2018) is a co-memory network for iteratively modeling the interactions between multiple modalities. MGNNS (Yang et al., 2021) is a multi-channel graph neural networks with sentiment-awareness for image-text sentiment detection. Schifanella et al. (2016) concatenates different feature vectors of different modalities as multimodal feature representation. Concat(2) means concatenating text features and image features, while Concat(3) has one more image attribute features. MMSD (Cai et al., 2019) fuses text, image, and image attributes with a multimodal hierarchical fusion model. Xu et al. (2020) proposes the D&R Net to fuse text, image, and image attributes by constructing the Decomposition and Relation Network.

4 Results and Analysis

4.1 Overall Result

Table 1 illustrates the performance comparison of our CLMLF model with the baseline methods. We use Weighted-F1 and ACC as the evaluation metrics for MVSA-Single and MVSA-Multiple which is the same as Yang et al. (2021) and use Macro-F1 and ACC as the evaluation metrics for HFM. we

Table 1: Experimental results of different models on MVSA-Single, MVSA-Multiple and HFM datasets

Dataset	Train	Val	Test	Total
MVSA-S	3611	450	450	4511
MVSA-M	13624	1700	1700	17024
HFM	19816	2410	2409	24635

Table 2: Statistics of the three datasets

have the following observations. First of all, our model is competitive with the other strong baseline models on the three datasets. Second, the multimodal models perform better than the unimodal models on all three datasets. What is more, we found the sentiment analysis on the image modality gets the worst results, this may be that the sentimental features in the image is too sparse and noisy, which makes it difficult for the model to obtain effective features for sentiment analysis. At last, for simple tasks, the performance improvement of multimodal models is limited. For example, on HFM dataset, the improvement of CLMLF relative to BERT is less than MVSA-Single dataset that because HFM is a binary classification task, while MVSA-Single is a three classification task.

We also try to apply CLMLF to aspect based multimodal sentiment analysis task which can refer to Appendix B for details.

4.2 Ablation

We further evaluate the influence of multi-layer fusion module, label based contrastive learning, and data based contrastive learning. The evaluation results are listed in Table 3. The Result shows that the whole CLMLF model achieves the best performance among all models. We can see multi-layer fusion module can improve the performance, which shows that a multi-layer fusion module can fuse the multimodal data. On this foundation, adding the label and data based contrastive learning can improve the model performance more, which means contrastive learning can lead the model to learn common features about sentiment and lead different sentiment data away from each other.

4.3 Influence of MLF Layer

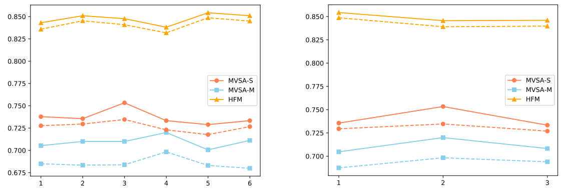
We explored the effects of different layers of Transformer-Encoder on the results. As shown in Figure 3a, fix the image transformer layer and set the text-image transformer fusion layer from 1 to 6. As shown in Figure 3b, fix the text-image transformer fusion layer and set the image transformer layer from 1 to 3. Finally, we selected different combinations of 3-2 (which means three layers of text-image transformer fusion layer and two layers of image transformer layer), 4-2, and 5-1 for the three datasets. This also proves that the contribution of text and images in the dataset is different. It can be seen from Table 1 that CLMLF gains more from the text than images in HFM dataset. Therefore, in MLF module, the layers of transformer related to text are more than images.

4.4 Case Study

To further demonstrate the effectiveness of our model, we give a case study. We compare the sentiment label predicted based on CLMLF and BERT. As shown in Figure 4, We can find that if we only consider the sentiment of the text, it is difficult to correctly obtain the user's sentimental tendency. For example, for the first data in Figure 4, the meaning of the text is to refer to the image, and

Model	**MVSA-Single**		**MVSA-Multiple**		**HFM**	
	Acc	F1	Acc	F1	Acc	F1
BERT	0.7111	0.6970	0.6759	0.6624	0.8389	0.8326
ResNet-50	0.6467	0.6155	0.6188	0.6098	0.7277	0.7138
+MLF	0.7111	0.7101	0.7059	0.6849	0.8414	0.8355
+MLF, LBCL	0.7378	0.7291	0.7112	0.6863	0.8489	0.8446
+MLF, DBCL	0.7356	0.7276	0.7153	0.6832	0.8468	0.8422
CLMLF	**0.7533**	**0.7346**	**0.7200**	**0.6983**	**0.8543**	**0.8487**

Table 3: Ablation results of our CLMLF



(a) The text-image Transformer fusion layer

(b) The image Transformer layer

Figure 3: Experimental results of different layer of multi-layer fusion module. The solid line indicates the accuracy and the dotted line indicates the F1. The x-axis represents the number of layers of the transformer

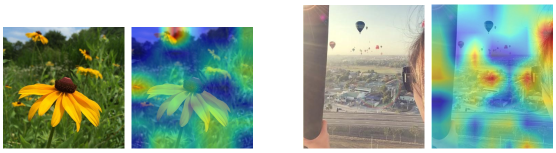
the image expresses a positive meaning. for the second data, if we only observe the text, we find that it may express negative sentiments. If add the image, we find that it is just a joke and actually expresses positive sentiment.

Image	Text	CLMLF	BERT
	Why are you feeling despondent? Take the quiz:	Positive	Neutral
	Thx for taking me to get cheap slushies ?	Positive	Negative
	Car rolls over to avoid real estate sign on Burlington Skyway.	Negative	Neutral

Figure 4: Example of misclassified by BERT and correctly classified by CLMLF

4.5 Visualization

Attention Visualization: We visualize the attention weight of the first head of the Transformer-Encoder in the last layer of the Multi-Layer Fusion module. The result of the attention visualization is shown in Figure 5. We can see that for a given keyword, The model can find the target from the image very well and give it more attention weight. This shows that the model aligns the words in the text with the patch area of the image at a token-level, which plays an important role in the model to fuse text and image features. In particular, for Figure 5b, although "lady" only shows half of the face in the figure, the model still aligns the text and the image very accurately. These indicate that the model aligns the text and image features at token-level according to our assumptions.



(a) The fishing is a little slow but the **flowers** are vibrant and beautiful.

(b) Kimmy, you're one blessed **lady**!

(c) Martha said for Valentine's Day she wanted a heart shaped **pancake** for lunch.

(d) It is truly a **hilarious**, light-hearted read that is a treasure on anyone's bookshelf.

Figure 5: Attention visualization of some multimodal sentiment data examples

Cluster Visualization: In order to verify that our proposed contrastive learning tasks can help the model to learn common features related to sentiment in multimodal data, we conducted a visualization experiment on the MVSA-Single dataset. The data feature vector of the last layer of the model is visualized by dimensionality reduction. We use the TSNE dimensionality reduction algorithm to obtain a 2-dimensional feature vector and visualize it, as shown in Figure 6, Figure 6a is the visualization of the [CLS] of the Bert-base model, and Figure 6b shows the visualization of the fusion result output from the CLMLF model. From the figure, we can see that after adding contrastive learning, the distance between positive sentiment and negative sentiment in the vector space is greater, and the degree of data aggregation is more obvious. This shows that the model distinguishes these data in vector space according to common features existing in the same sentimental data. Because the number of neutral sentiment data is relatively small, among the visualization results of the two models, CLMLF's visualization results obviously gather the neutral data together, rather than scattered in the vector space like Bert. All these indicate that adding contrast learning can help the model to learn common features related to sentiment which can improve the performance of the model.

5 Related Work

5.1 Multimodal Sentiment Analysis

In recent years, deep learning models have achieved promising results for multimodal sentiment analysis. MultiSentiNet (Xu and Mao, 2017) and HSAN (Xu, 2017) use LSTM and CNN to encode texts and images to get hidden representations, then concatenate texts and images hidden representations to fuse multimodal features. CoMN (Xu et al., 2018) uses a co-memory network to iteratively model the interactions between visual contents and textual words for multimodal sentiment analysis. Yu et al. (2019) proposes an aspect sensitive attention and fusion network to effectively model the intra-modality interactions including aspect-text and aspect-image alignments, and the inter-modality interactions. MVAN (Yang et al., 2020) applies interactive learning of text and image features through the attention memory network module, and the multimodal feature fusion module is constructed by using a multi-layer perceptron and a stacking-pooling module. Yang et al. (2021) uses multi-channel graph neural networks with sentiment-awareness which is built based on the global characteristics of the dataset for multimodal sentiment analysis.

5.2 Contrastive Learning

Self-supervised learning attracts many researchers for its soaring performance on representation learning in the last several years (Liu et al., 2021; Jing and Tian, 2020; Jaiswal et al., 2021). Many models based on contrastive learning have been proposed in both natural language processing and computer vision fields. ConSERT (Yan et al., 2021), SimCSE (Gao et al., 2021), CLEAR(Wu et al., 2020) proposed the application of contrastive learning in the field of natural language processing. MoCo (He et al., 2020), SimCLR (Chen et al., 2020), SimSiam (Chen and He, 2021), CLIP (Radford et al., 2021) proposed the application of contrastive learning in the field of computer vision, and they also have achieved good results in zero-shot learning and few-shot learning. Recently, contrastive learning has been more and more widely used in the field of multimodality. Huang et al. (2021) uses intramodal, inter-modal, and cross-lingual contrastive learning which can significantly improves the performance of video search. Yuan et al. (2021) exploits intrinsic data properties within each modality and semantic information from cross-modal correlation simultaneously, hence improving the quality of learned visual representations.

Compared with the above works, we focus on how to align and fuse the token-level features and learn the common features related to sentiment to further improve the performance of model.

6 Conclusion and Future Work

In this paper, we propose a contrastive learning and multi-layer fusion method for multimodal sentiment detection. Compared with previous works, our proposed MLF module performs multimodal feature fusion from the fine-grained token-level, which is more conducive to the fusion of local features of text and image. At the same time, we design learning tasks based on contrastive learning to help the model learn sentiment related features in the multimodal data and improve the ability of the model to extract and fuse features of multimodal data. The experimental results on public datasets demonstrate that our proposed model is competitive with strong baseline models. Especially through visualization, the contrastive learning tasks and multi-layer fusion module we proposed can be verified with intuitive interpretations. In future work, we will incorporate other modalities such as audio into the sentiment detection task.

A Dataset Statistics

The detailed statistics for the MVSA-Single, MVSA-Multiple and HFM datasets are listed in Table 4. We can see that HFM is a binary classification multimodal sentiment dataset, while MVSA-Single and MVSA-Multiple are three classification multimodal sentiment datasets.

Dataset	Label	Train	Val	Test
MVSA-Single	Positive	2147	268	268
	Neutral	376	47	47
	Negative	1088	135	135
MVSA-Multiple	Positive	9056	1131	1131
	Neutral	3528	440	440
	Negative	1040	129	129
HFM	Positive	8642	959	959
	Negative	11174	1451	1450

Table 4: Number of data for each sentiment category in each dataset

B Aspect Based Multimodal Sentiment

B.1 Experimental Setup

Because CLMLF is designed for sentence-level multimodal sentiment analysis, we have made some minor changes to the input of CLMLF model to adapt to aspect based multimodal sentiment analysis. We change the input form from "[CLS] sentence [SEP]" to "[CLS] sentence [SEP] aspect [SEP]" and no change the input of image modality. Although this change is very simple, CLMLF can work well in aspect based multimodal sentiment analysis tasks and achieves good results.

We use three aspect based multimodal sentiment dataset: Multi-ZOL[8] (Xu et al., 2019), Twitter-15 (Zhang et al., 2018b) and Twitter-17[9] (Lu et al., 2018). The statistics of these datasets are given in Table 5. Compared with the dataset of sentence-level multimodal sentiment analysis, each sentence will have a corresponding aspect attribute. Especially for the Multi-ZOL dataset, each data contains multiple images. And we only randomly select one image for fusion. Although some features are lost, the experimental results show that it is improved compared with the only text modality.

B.2 Results

We compare our model with other baseline models:

Dataset	Train	Val	Test	Total
Multi-ZOL	22743	2843	2843	28429
Twitter-15	3179	1122	1037	5338
Twitter-17	3562	1176	1234	5972

Table 5: Statistics of the three datasets

- LSTM, a standard sentence-level LSTM model without explicitly considering the aspect. Therefore, this result is also the worst.
- AE-LSTM (Wang et al., 2016), an attention-based LSTM for aspect-level sentiment classification, which uses the attention mechanism to capture the important context information related to the aspect.
- RAM (Chen et al., 2017) is a memory based model, which builds memory on the hidden states of a Bi-LSTM and generates aspect representation based on a Bi-LSTM. Then pays multiple attentions on the memory to pick up important information to predict the final sentiment, by combining the features from different attentions non-linearly.
- MIMN (Xu et al., 2019), the multimodal approach for aspect-level sentiment classification task, which adopts multi-hop memory network to model the interactive attention between the aspect word, the textual context, and the visual context.
- TomBERT (Yu and Jiang, 2019), a multimodal model which borrow the idea from self-attention and design a target attention mechanism to perform target-image matching to derive target sensitive visual representations.
- ESAFN (Yu et al., 2019) proposes an entity-sensitive attention and fusion network which capture the intra-modality dynamics by leverages an effective attention mechanism to generate entity-sensitive textual and visual representations. And uses visual attention mechanism to learn the entity-sensitive visual representation. Moreover, ESAFN further fuses the textual and visual representations with a bilinear interaction layer.

Table 6 illustrates the performance comparison of our CLMLF mdoel with the baseline methods. We use Macro-F1 and ACC as the evaluation metrics for all datasets. The experimental results show

Abstract

Solving text classification in a weakly supervised manner is important for real-world applications where human annotations are scarce. In this paper, we propose to query a masked language model with cloze style prompts to obtain supervision signals. We design a prompt which combines the document itself and "this article is talking about `[MASK]`." A masked language model can generate words for the `[MASK]` token. The generated words which summarize the content of a document can be utilized as supervision signals. We propose a latent variable model to learn a word distribution learner which associates generated words to pre-defined categories and a document classifier simultaneously without using any annotated data. Evaluation on three datasets, AGNews, 20Newsgroups, and UCINews, shows that our method can outperform baselines by 2%, 4%, and 3%.

1 Introduction

Text classification is a fundamental task in Natural Language Processing (NLP) with diverse real-world applications such as identifying relevant documents of a case in legal proceedings (Roitblat et al., 2010), and classifying victim's requests (e.g., food, shelter, and medical aids) on social media platforms during earthquakes (Caragea et al., 2011). Current state-of-the-art text classification methods (Zhang et al., 2015; Zhou et al., 2016; Johnson and Zhang, 2017) still need a large number of annotated data. However, in the real world, naturally annotated data are rare and human annotations are expensive. Solving the text classification task without using annotated data but exploiting inexpensive supervision signals is worth investigation.

In the weakly supervised setting, any annotated document is not accessible, but inexpensive supervision signals such as label surface names or keywords can be used. Existing weakly supervised text classification methods (Meng et al., 2018, 2019; Mekala and Shang, 2020; Meng et al., 2020) first used seed keywords to retrieve more keywords, and then created pseudo labels for documents and then train a model in a "standard" supervised learning manner. In previous work, supervision signals are restricted to a small set of keywords from documents contents.

Recent work shows that prompts can probe knowledge from PLMs (Devlin et al., 2019; Radford et al., 2019) and the knowledge can provide supervision signals to solve different NLP tasks including relation extraction (Shin et al., 2020), question answering (Petroni et al., 2020), and summarization (Radford et al., 2019). For example, (Petroni et al., 2019) solved the knowledge base completion task by querying an MLM with a prompt "Alan Turing was born in `[MASK]`." Using prompts to generate supervision signals for text classification is worth exploring.

We propose to query an MLM with a prompt which combines the document itself and "this article is talking about `[MASK]`.", and use generated words for the `[MASK]` token as supervision signals. For example, in Figure 1, given a prompt "The radio telescope at arecibo observatory will begin mapping the known galaxy on friday, scientists said. This article is talking about `[MASK]`.", an MLM predicts "astronomy", "galaxies", "radio", "science", and "galaxy" for the `[MASK]` token. These words summarize the topic of the document. Hence, they can be used as supervision signals. Besides generating signal words, an intuitive approach to obtain supervision signals is by extracting important words from documents. We will compare two types of supervision signals.

After obtaining signal words, we need to associate these words to pre-defined categories. We propose a latent variable model (**WDDC**) to learn a **W**ord **D**istribution learner and a **D**ocument **C**lassifier simultaneously without using any annotated data. A word distribution learner aims to learn

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2295 - 2305
July 10-15, 2022

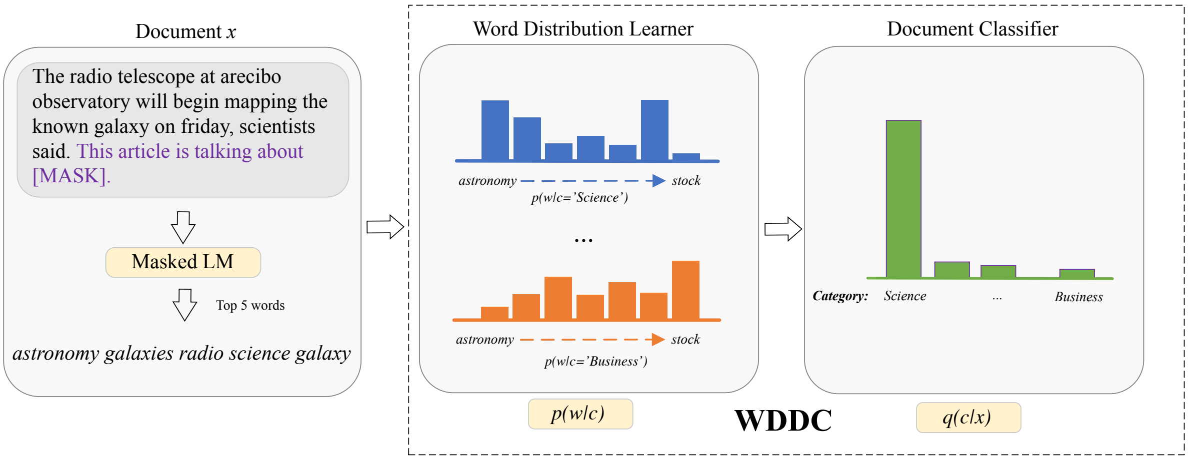

Figure 1: We combine a document and a cloze style sentence "This article is talking about `[MASK]`" to query a masked LM. It generates a set of words for the `[MASK]` token. These words are likely to summarize the topic of a document. After obtaining words such as "astronomy" and "galaxies", human beings can easily infer that this article is talking *science* rather than *business* because we know these words are frequently used in *science* topic. Word distributions given pre-defined categories bridge supervision signals (generated words) and our goal (the category of a document). The proposed model (WDDC) can learn word distributions given pre-defined categories and a document classifier simultaneously.

a probability of a generated word w given a category c, i.e., $p(w|c)$. A document classifier aims to learn a probability of a category c given a document x, i.e., $p(c|x)$. These two goals could be optimized simultaneously via maximizing the log-likelihood of generated words by introducing the category as a latent variable. In our latent variable model, a word distribution learner and a document classifier can be parameterized by any neural network.

Our contributions are summarized as follows,

- We propose to query an MLM using a prompt which combines the document and a cloze style sentence "this article is talking about `[MASK]`". We use generated words for the `[MASK]` token as supervision signals in the weakly supervised text classification task.
- We propose a latent variable model (WDDC) to learn a word distribution learner which associates generated words to pre-defined categories and a document classifier simultaneously without using any annotated data.
- The experimental results show that the proposed method WDDC can outperform other weakly supervised baselines in three datasets.

The code is available at https://github.com/HKUST-KnowComp/WDDC.

2 Related Work

In this section, we review the related work on querying an MLM with prompts, weakly supervised text classification, zero-shot text classification, and variational methods.

Querying an MLM with Prompts. Querying an MLM with cloze style prompts provides a new direction to solve some NLP tasks in an unsupervised manner. (Petroni et al., 2019) queried an MLM using manually designed prompts to solve a knowledge base completion task. For example, in order to complete the missing entity `X` in (Alan Turing, born in, `X`), they designed a prompt "Alan Turing was born in `[MASK]`" to query an MLM. The generated word for the `[MASK]` token can be directly used to complete the missing fact. By querying language models, some NLP tasks such as relation extraction (Shin et al., 2020), question answering (Radford et al., 2019; Petroni et al., 2020), summarization (Radford et al., 2019) could be solved in an unsupervised manner. However, not all NLP tasks can directly use generated words from an MLM in downstream tasks. Some tasks such as sentiment analysis and textual entailment (Shin et al., 2020) need more steps for inference. For example, in the sentiment analysis task, (Shin et al., 2020) used annotated data to train a classifier that links generated words to pre-defined categories. Our work does not require annotated data for inference.

Weakly Supervised Text Classification. In the weakly supervised text classification task, any labeled documents are not allowed, but label surface names or limited word-level descriptions of each category can be used. Dataless (Chang et al., 2008; Song and Roth, 2014) used Explicit Semantic Analysis (ESA) vectors (Gabrilovich et al., 2007) to represent label name and documents. Predictions are based on the label-document similarity. Recently, (Meng et al., 2018, 2019; Mekala and Shang, 2020; Meng et al., 2020; Schick and Schütze, 2021; Schick and Schütze, 2021; Zhang et al., 2022) trained neural text classifiers in an weakly supervised manner. They generated pseudo labels for documents to pre-train a neural classifier and then performed self-training on unlabeled data for model refinement. LOTClass (Meng et al., 2020) is relevant to our work because they also used pre-trained language models. They used a LM to retrieve a set of semantically correlated words for each class, and then fine-tuned the LM to predict these words. Finally, they performed self-training on unlabeled data. Our work is different from LOTClass because we obtain supervision signals by querying an MLM with cloze style prompts and we propose a latent variable model to learn document classifier rather than using the self-training procedure. PRBOOST (Zhang et al., 2022) is also relevant to our work because they also use prompts to generate weak labels. PRBOOST first generated rules by using a small amount of labeled data, then asked human annotators to select high-quality rules to generate week labels. Finally, they trained a new model in a self-training manner. Our work is different from PRBOOST because our method associates predicted words with labels in an unsupervised manner while PRBOOST maps prompting based rules to labels by involving human feedback.

Zero-Shot Text Classification. In zero-shot learning settings, the classes covered by training instances and the classes we aim to classify are disjoint. Zero-shot learning text classification methods (Xia et al., 2018; Rios and Kavuluru, 2018; Zhang et al., 2019; Liu et al., 2019) generalized seen classes to unseen classes by learning semantic relationships between classes and documents via embeddings or semantic knowledge sources. However, zero-shot learning still requires annotated data for the seen classes training. We cannot apply zero-shot learning methods to weakly supervised settings where no annotated document is available.

Variational Methods. Variational autoencoders (Kingma and Welling, 2014; Rezende et al., 2014) consists of an encoder and a decoder. The encoder estimates posterior probabilities and the decoder estimates the reconstruction likelihood given a latent variable. The objective function is to maximize the reconstruction likelihood of the observed variable. The latent variable in VAEs is continuous variable. Recently, many research works (Titov and Khoddam, 2015; Marcheggiani and Titov, 2016; Šuster et al., 2016; Zhang et al., 2018; Chen et al., 2018; Zeng et al., 2019; Liang et al., 2019) use VAEs to solve different NLP tasks such as relation discovery, question answering, sentiment classification, etc. In above works, the latent variables are discrete variables. For example, (Marcheggiani and Titov, 2016) aimed to solve unsupervised open-domain relation discovery. The objective function is to reconstruct the likelihood of two entities. They introduced relation as the latent variable. The encoder is a relation classifier, which predicts a semantic relation between two entities. The decoder reconstructs entities given the predicted relation. Our method is also based on VAEs with a discrete latent variable but the estimated probabilities and the objective function are different.

3 Methodology

In this section, we first introduce how to obtain supervision signals from an MLM and document itself, and then we introduce a latent variable model to learn a word distribution learner and a document classifier simultaneously.

3.1 Supervision Signals

3.1.1 Signal Words

Given a document, our goal is to obtain topic relevant words which are used as supervision signals. To achieve this, we append a cloze style sentence to the document at the end as a prompt. A prompt is designed as "`[CLS]` + document + This article is talking about `[MASK]`. + `[SEP]`." The `[MASK]` token serves as a placeholder for a topic relevant word which can summarize the document. It mimics the reading comprehension task which is using a word to summarize the content of a document. We select top k generated words as supervision signals.

Instead of generating signal words, a natural way to obtain supervision signals is by extracting words from the document. To achieve this, we extract all nouns and proper nouns in the document using part-of-speech tagger (Kristina et al., 2003). Since

Table 1: Signal words from an MLM and from the document(Doc).

Text	Label	Signal Words
The world 's top two players roger federer and andy roddick reached the semifinals friday at the thailand open.	Sports	MLM: tennis, thailand, federer, seeds, wimbledon Doc: world, players, federer, andy, roddick, semifinals, friday, thailand, open
These circuits abound in most electronic project books. It has LED indicators also.	Science	MLM: circuits, computers, electronics, computing, graphs Doc: circuits, project, books, LED, indicators
Scientists discover a genetic indicator that could help prevent suicides.	Health	MLM: suicide, genetics, cancer, hiv, health Doc: scientists, indicator, suicides

most of the generated words from an MLM are nouns and proper nouns, so we only extract words with two types of part-of-speech.

Table 1 shows top 5 predictions from an MLM (BERT (Devlin et al., 2019)) given prompts and extracted nouns and proper nouns from documents. For the first document, an MLM can infer that it is talking about a tennis match although "tennis" does not appear in the document. It also generates some relevant words such as " wimbledon." In this case, the MLM is better than extraction. For the second document, the first word from the MLM precisely summarizes the document. However, the MLM also generates a few words which are related to *computer*. Unfortunately *computer* is also a category in this dataset. Compared to the MLM, the extracting way is safer in this case. For the third document, an MLM generates "health" which is an exact match of the label surface name although "cancer" and "hiv" are not faithful to the original document. We will evaluate generation and extraction methods in the experiment.

3.1.2 Remove Non-discriminated Words

Words generated from an MLM are not always category discriminated. Non-discriminated words can harm the performance of inference. The intuition of removing non-discriminated words is that if some words appear in different categories with similar frequency, then it is possible that these words are not category-discriminated. Since we cannot access labels, the label in the following computation means the pseudo label. The pseudo label generation process is shown in section 3.1.3. Inspired by category-indicative measurement, (Mekala and Shang, 2020), we define category-indicative index:

$$CII(c_i, w) = \frac{f(c_i, w)}{f(c_i)}, \tag{1}$$

where $f(c_i, w)$ is the number of occurrences of the signal word w in the documents which are labeled as c_i, and $f(c_i)$ is the total number of occurrences of all signal words in documents which are labeled as c_i.

We define category-indicative ratio as,

$$CIR(w) = \frac{CII(c_i, w)}{CII(c_j, w)}, \tag{2}$$

where $CII(c_i, w)$ is the maximum value among all categories, $CII(c_j, w)$ is the second maximum value all categories. Larger value of $CIR(w)$ indicates w is more discriminated. If $CII(c_j, w)$ is equal to 0, we will assign a large value to $CIR(w)$. If $CIR(w) < t$, we consider w is not discriminated and we remove w from signal words set.

3.1.3 Pseudo Label Generation

We assign pseudo labels to data based on label-word similarity. We represent a word using static representation which is introduced by (Mekala and Shang, 2020). Given a word w, static representation $\mathcal{SR}(w)$ is computed by averaging the contextualized embeddings of all its occurrences in the corpus. The label-word similarity is the cosine similarity between the static representation of the label surface name and the static representation of signal words. If the label surface name or the supervision signal contains more than one word, we take the average of the static representations of all words. We assign a sample with the pseudo label which yields the maximum similarity value among all classes. And the similarity value should be greater than a threshold γ. Setting a threshold can result in more accurate pseudo label assignments although the size of pseudo labeled data will shrink.

To summarize, there are three steps to obtain clean signal words: (1) Obtain signal words from an MLM or a document. (2) Generate pseudo labels. (3) Remove signal words which have low category-indicative ratio values.

3.2 Model Training

After getting clean signal words, we then propose a latent variable model to learn a word distribution learner and a document classifier simultaneously.

Since there is no annotated data available, in order to best explain the observed data, i.e., signal words, the objective of our model is to maximize the log-likelihood of signal words. The ultimate goal is to identify the category of a document, hence, we introduce a latent variable C representing the category, into the objective function. Further, by applying Jensen's inequality (Jensen et al., 1906), we can derive an evidence lower bound (ELBO) of the log-likelihood. We define the objective function as follows,

$$\begin{aligned}\mathcal{L}_o &= \sum_{x\in X}\sum_{w_r\in\mathcal{R}_x}\log p(w_r)\\ &= \sum_{x\in X}\sum_{w_r\in\mathcal{R}_x}\log\sum_{c}p(w_r,c)\\ &= \sum_{x\in X}\sum_{w_r\in\mathcal{R}_x}\log\sum_{c}q(c|x)\left[\frac{p(w_r,c)}{q(c|x)}\right]\\ &\geq \sum_{x\in X}\sum_{w_r\in\mathcal{R}_x}\sum_{c}q(c|x)\left[\log\frac{p(w_r,c)}{q(c|x)}\right]\\ &= \sum_{x\in X}\sum_{w_r\in\mathcal{R}_x}\mathbb{E}_{q(C|x)}\left[\log p(w_r|c)p(c)\right]\\ &- \sum_{x\in X}\sum_{w_r\in\mathcal{R}_x}\mathbb{E}_{q(C|x)}\left[\log q(c|x)\right], \qquad (3)\end{aligned}$$

where x is a document, X is a set of documents, $\mathcal{R}_x$ is the set of signal words of document x, w_r is a signal word, C is a discrete random variable representing the category of a document, c is a possible value of variable C. For example, c can be *science* or *business*.

There are three probabilities in the Eq. (3). $q(c|x)$ is the document classifier which is our ultimate goal. $p(w_r|c)$ is the word distribution learner which estimates the probability distribution of all signal words given a possible value c. We use neural networks to parameterize $p(w_r|c)$ and $q(c|x)$. $p(C)$ is a prior probability distribution. Since there are no annotated data available, we cannot estimate $p(C)$. Hence we assume it is a uniform distribution, and $p(c)$ becomes a constant.

3.2.1 Word Distribution Learner

The word distribution learner aims to estimate the probability of a signal word w_r given a possible value of category c. It is defined as follows,

$$p(w_r|c) = \frac{\exp\left(\mathbf{v}_c^T\mathbf{w}_r\right)}{\sum_{w_{r'}}\exp\left(\mathbf{v}_c^T\mathbf{w}_{r'}\right)}, \qquad (4)$$

where $\mathbf{v}_c$ is a trainable vector associated with c and $\mathbf{w}_r$ is the trainable word embedding of signal word w_r. The intuition is that if a word (e.g., "scientist") appears frequently under the *science* category, the corresponding inner-product value is high, otherwise it is low.

Eq. (4) requires the summation over all signal words. Since the size of the word vocabulary can be large, we use the negative sampling technique (Mikolov et al., 2013) to approximate Eq. (4). Specifically, we approximates $\log p(w_r|c)$ as follows,

$$\log\sigma\left(\mathbf{v}_c^T\mathbf{w}_r\right) + \sum_{w'_r\in\mathcal{N}}\log\left(1-\sigma\left(\mathbf{v}_c^T\mathbf{w}'_r\right)\right), \qquad (5)$$

where w'_r is a negative sample in the vocabulary, $\mathcal{N}$ is the set of negative samples and $\sigma(\cdot)$ is the sigmoid function.

The objective function with an approximated word distribution learner is defined as follows,

$$\begin{aligned}\mathcal{L} = \sum_{x\in X}\sum_{w_r\in\mathcal{R}_x}&\mathbb{E}_{q(C|x)}\Big[\log\sigma\left(\mathbf{v}_c^T\mathbf{w}_r\right)\\ &+ \sum_{w'_r\in\mathcal{N}}\log\left(1-\sigma\left(\mathbf{v}_c^T\mathbf{w}'_r\right)\right)+\log p(c)\Big]\\ &- \mathbb{E}_{q(C|x)}\left[\log q(c|x)\right]. \qquad (6)\end{aligned}$$

3.2.2 Document Classifier

Most existing deep neural models (DNN) can be used to parameterize $q(C|x)$. As long as the input of DNNs is a document, and the output is a probability distribution of category C. Since models which involve latent variables are difficult to optimize, we give a good initialization of the document classifier. We pre-train the document classifier using pseudo labeled data to initialize it.

Table 2: Statistics and label surface names in AGNews, 20Newsgroup, and UCINews.

Datasets	# Train	# Dev	# Test	# Class	Label Surface Names
AGNews	108,000	12,000	7,600	4	politics, sports, business, technology
20Newsgroup	14,609	1,825	1,825	6	computer graphics, sports car, science electronics encryption health aerospace, politics gun homosexuality, religion atheist christianity, sale
UCINews	26,008	2,560	27,556	4	entertainment, technology, business, health

Table 3: Vocabulary size of signal words that are generated from an MLM and that are extracted from the document (Doc) after removing non-discriminated words.

Dataset	MLM	Doc
AGNews	724	584
20Newsgroup	1,037	413
UCINews	584	442

4 Experiments

In this section, we show the empirical performance of our method on the text classification task.

4.1 Datasets

We evaluate all methods on three datasets.

(1) **AGNews** consists of news articles. It is constructed by (Zhang et al., 2015), which has been gathered from more than 2000 news sources in more than one year of activity.

(2) **20Newsgroup** comprises around 18,000 posts. It is originally collected by (Lang, 1995). We perform text classification on coarse-grained topics. It is an unbalanced dataset.

(3) **UCINews** consists of news pages collected from a web aggregator. It is maintained by (Dua and Graff, 2017).

Table 2 provides statistics and label surface names of three datasets. In 20Newgroups, we expand label surface names by combining fine-grained label surface names under the same coarse-grained category.

Table 3 shows the vocabulary size of signal words that are generated from an MLM and that extracted from the document (Doc) after removing non-discriminated words.

4.2 Compared Methods

Dataless (Chang et al., 2008) is performed based on vector similarity between documents and label surface names using explicit semantic analysis representation. The prediction is the category that yields the maximum cosine similarity.

Label-Word Similarity is performed based on the vector similarity between words generated from an MLM and label surface names using the static representation. The prediction is the category that yields the maximum cosine similarity.

Pseudo-CNN assigns pseudo labels to documents in the training set based on label-word similarity. We train a CNN model using pseudo labeled samples in the training set. More details are provided in section 4.5.

Pseudo-BERT trains BERT (Devlin et al., 2019) `BERT-base-uncased` using the same pseudo labeled data as Pseudo-CNN. More details are provided in section 4.5.

WeSTClass (Meng et al., 2018) first generates pseudo labels for documents which contain user-provided keywords. It pre-trains a neural network using pseudo samples as the training set and then performs a self-training process.

LOTClass (Meng et al., 2020) constructs a category vocabulary for each class, using a pre-trained LM. The vocabulary contains words that are relevant to the label name. LOTClass fine-tunes an LM via word-level category prediction task, and then performs self-training on unlabeled data to generalize the model.

ConWea (Mekala and Shang, 2020) leverages contextualized representations of word occurrences and seed word information to automatically distinguish multiple senses of the same word. The

Table 4: Micro F1 and macro F1 scores of all methods on AGNews, 20Newsgroup, and UCINews.

Datasets Methods	AGNews		20Newsgroup		UCINews	
	Micro	Macro	Micro	Macro	Micro	Macro
Dataless (Chang et al., 2008)	0.6855	0.6844	0.5000	0.4700	0.6248	0.6253
Label-Word Similarity	0.7917	0.7884	0.7310	0.6390	0.6447	0.6390
Pseudo-CNN	0.8265	0.8237	0.7973	0.6825	0.7598	0.7632
Pseudo-BERT	0.8249	0.8219	0.8153	0.6896	0.7824	0.7820
WeSTClass (Meng et al., 2018)	0.8279	0.8268	0.5300	0.4300	0.6983	0.6999
LOTClass (Meng et al., 2020)	0.8659	0.8656	0.6121	0.5586	0.7320	0.7236
ConWea (Mekala and Shang, 2020)	0.7443	0.7401	0.6200	0.5700	0.3293	0.3269
X-Class (Wang et al., 2021)	0.8574	0.8566	0.6515	0.6316	0.6885	0.6962
WDDC-MLM	**0.8826**	**0.8825**	0.8121	0.6882	**0.8150**	**0.8134**
WDDC-Doc	0.8668	0.8657	**0.8570**	**0.8250**	0.7814	0.7772
CNN (Kim, 2014)	0.9025	0.9025	0.9397	0.9310	0.9002	0.8998
BERT (Devlin et al., 2019)	0.9305	0.9306	0.9660	0.9569	0.9313	0.9315

contextualized corpus is used to train the classifier and expand seed words iteratively.

X-Class (Wang et al., 2021) leverages BERT representations to generate class-oriented document presentations, then generates document-class pairs by clustering, and then fed pairs to a supervised model to train a text classifier.

CNN(Kim, 2014) trains a text CNN using annotated training data in a supervised manner. It is an upper bound of weakly supervised methods.

BERT fine-tunes BERT `BERT-base-uncased` (Devlin et al., 2019) using annotated training data. It is an upper bound of weakly supervised methods.

WDDC We use a text CNN(Kim, 2014) as the document classifier. Instead of randomly initializing CNN, we pre-train CNN using Pseudo-CNN. **WDDC-MLM** uses the supervision signals from an MLM while **WDDC-Doc** uses the supervision signals from the document itself.

4.3 Result Analysis

Table 4 shows that our method outperforms weakly supervised baselines by 2%, 4%, and 3% in AGNews, 20Newsgroup, and UCINews, respectively. The gaps between the upper bound CNN and our method are 2%, 8%, and 8% in AGNews, 20Newsgroup, and UCINews, respectively. There are still large performance gaps on 20Newsgroup and UCINews.

Label-Word Similarity and Dataless both use vector similarity for prediction. Label-Word Similarity consistently outperforms Dataless, which shows that words generated from an MLM are useful compared with documents. The performance of Pseudo-BERT is comparable with WeSTClass in AGNews and better than any other baselines in 20Newsgroup and UCINews, which also shows the effectiveness of our pseudo label generation technique. In 20Newsgroup, Macro F1 scores are lower than Micro F1 scores in Pseudo-CNN, Pseudo-BERT, and WDDC-MLM methods. We found that the number of pseudo labeled data of *sale* category is much lower than other categories. So CNN does not have enough pseudo labeled data to learn the *sale* category. The F1 score of *sale* category is lower.

In AGNews and UCINews, WDDC-MLM outperforms WDDC-Doc by 2% and 3%, respectively, which shows that signal words from an MLM are more useful than extracted words from a document. But in 20Newsgroup, WDDC-Doc outperforms WDDC-MLM by 4%. The possible reason is that some categories in 20Newsgroup are not completely disjoint. According to general knowledge, encryption is a field of computer, and computer is a field of science. But in 20Newsgroup (refer to Table 2), science and encryption belong to one class, and computer belongs to another class. MLMs can capture general knowledge from training corpora such as Wikipedia. When given a document talking about encryption, an MLM probably generates words about encryption as well as computer. In this circumstance, generated words are misleading while extracted words are clean. We have detailed

Table 5: Mean and standard deviation of micro and macro F1 scores on 5 independent runs.

Dataset \ Method	WDDC				Baselines			
	Micro F1		Macro F1		Micro F1		Macro F1	
	Mean	Std	Mean	Std	Mean	Std	Mean	Std
AGNews	0.8826	0.0013	0.8825	0.0013	0.8630	0.0038	0.8626	0.0037
20Newsgroup	0.8570	0.0023	0.8250	0.0033	0.8153	0.0131	0.6896	0.0063
UCINews	0.8150	0.0012	0.8134	0.0014	0.7824	0.0141	0.7820	0.0148

Table 6: Some incorrect predictions in AGNews, 20Newsgroup, and UCINews.

Dataset	Text	Prediction	Ground Truth	Signal Words (MLM)
AGNews	Microsoft and Palmone today announced a partnership that will likely have a negative impact on good technology, a well capitalized startup.	technology	business	windows, microsoft, business, security, technology, linux, privacy
20Newsgroup	For the system, or 'family', key would appear to be cryptographically useless. ... The same key is used for both encryption and decryption.	computer	science	software, virus, linux, encryption , ibm , nsa
UCINews	Paraplegic teenager to kick off World Cup thanks to robot suit.	entertainment	health	football, sport, soccer cricket, tennis

analysis in section 4.4.

Table 5 shows mean and standard deviation of micro and macro F1 scores of WDDC and best baselines on 5 independent runs. We also conducted t-tests, and p-values are all less than 0.001. We concluded that our method outperforms baselines significantly. Baselines refers to LOTClass, Pseudo-BERT, and Pseudo-BERT on AGNews, 20Newsgroup, and UCINews respectively.

4.4 Case Study

4.4.1 Analysis of Incorrect Predictions

Table 6 shows some incorrect predictions. In the first example, some words in the original document such as "partnership" and "startup" indicate *business* while other words such as "Microsoft" and "technology" indicate *technology*. Signal words generated from an MLM are all related to *technology*. In AGNews dataset, there are a number of samples talking about the stock price of technology companies or cooperation between technology companies. An MLM inclines to focus on either *technology* or *business* and ignore the other one. Although the extraction method can cover all words, the model is likely to be confused when signal words are related to two categories. In the second example, an MLM generates words related to *encryption* as well as *computer*. Generated words make sense because according to general knowledge, *encryption* is related to *computer*. Unfortunately, most of the signal words from an MLM are related to *computer* except one word "encryption." WDDC-MLM is likely to predict it as *computer*. Signal words extracted from the document are "encryption" and "key", which are more likely to guide the model to predict the correct category. In the third example, an MLM generates words that are all about sports because the term "World Cup" appears in the original document. The modifier "paraplegic" plays an important role in identifying the true category. Both generation and extraction methods fail to capture that.

4.4.2 Analysis of Word Distribution Learner

The word distribution learner aims to estimate the probability of a signal word w_r given a possible value of category c, i.e., $p(w_r|c)$. A good word distribution learner should assign a high probability

Table 7: Top 15 signal words that have large inner product values with different latent variable vectors respectively on AGNews dataset. Signal words are generated by an MLM.

Label	Signal Words
Politics	iraq, syria, haiti, israel, murder, baghdad, suicide, torture, war, islam, iran, terrorist, afghanistan, religion, terrorism
Sports	injury, racing, baseball, soccer, boxing, player, relegation, cricket, quarterback, england, basketball, doping, football, golf, tennis
Business	profit, market, finance, agriculture, bankruptcy, energy, money, growth, price, insurance, recession, airline, oil, risk, inflation
Technology	ipod, genetics, encryption, microsoft, internet, hacking, virus, biotechnology, science, copyright, itunes, nasa, evolution, space, astronomy

to category-indicated words, so that by maximizing Eq. (3), a large value of $p(w_r|c)$ leads to a large value of $q(c|x)$, which means if a document contains indicative words to category c, it possibly belongs to category c. Table 7 shows top 15 signal words that have large inner product values with different latent variable vectors respectively on AGNews dataset. As shown in Table 7, the selected words are category-indicated. For example, in the *politics* category, all words are about terrorism, war, and places where wars broke out, which are relevant to the *politics* topic. The word distribution learner can be consider as a category-indicated keywords expansion module.

4.5 Implementation

We use the BERT (`bert-base-uncased`) model to obtain supervision signals in AGNews and 20Newsgroup. We use the BERT (`bert-base-cased`) to obtain supervision signals in UCINews which contains many acronyms such as WHO and PTSD. We select top 20 predictions as supervision signals three datasets. To remove non-discriminated words, we set the threshold t to 2 in three datasets.

In the pseudo label generation process, we set the threshold γ to 0.6, 0.75, and 0.55 in AGNews, 20Newsgroup, and UCINews, respectively. Those pseudo labeled training data are used in Pseudo-CNN and Pseudo-BERT. A higher γ may result in more accurate pseudo labels. But we need to balance the size of pseudo labeled data because it will shrink when γ increases.

To train WDDC, in each batch, we randomly select 5 signal words among all signal words of a document. The number of negative samples in the approximated word distribution learner is set to 10. For Pseudo-CNN, CNN, and WDDC methods, the CNN architectures are the same. Four different filter sizes $\{2, 3, 4, 5\}$ are applied. A max-pooling layer is applied to each convolutional layer, and each convolutional layer has 100 filters. The maximum length of input in the CNN is set to 64, 128, and 64 in AGNews, 20Newsgroup, and UCINews, respectively. The input in the CNN is contextualized embeddings generated by BERT (`bert-base-uncased`).

For WeSTClass, we use a CNN as the document classifier because it empirically outperforms LSTM in WeSTClass. The CNN architecture we used here is the same as the one described in their paper. We try our best to find good keywords and tune hyper-parameters for WeSTClass and LOTClass. For all methods, we tune hyper-parameters on development sets.

5 Conclusion

To solve the weakly supervised classification task, we propose to query a masked language model with cloze style prompts to obtain supervision signals. We design a prompt which combines the document itself and "this article is talking about `[MASK]`." The predictions for the "`[MASK]`" token are considered as supervision signals because they summarize the content of documents. We propose a latent variable model (WDDC) to learn word distributions given pre-defined categories and a neural document classifier simultaneously without using any annotated data. Evaluation on three datasets shows that our method can outperform weakly supervised learning baselines.

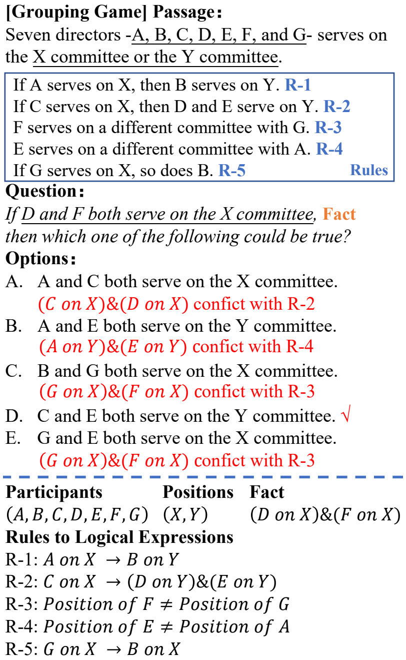
Abstract

Analytical reasoning is an essential and challenging task that requires a system to analyze a scenario involving a set of particular circumstances and perform reasoning over it to make conclusions. However, current neural models with implicit reasoning ability struggle to solve this task. In this paper, we study the challenge of analytical reasoning of text and collect a new dataset consisting of questions from the Law School Admission Test from 1991 to 2016. We analyze what knowledge understanding and reasoning abilities are required to do well on this task, and present an approach dubbed ARM. It extracts knowledge such as participants and facts from the context. Such knowledge are applied to an inference engine to deduce legitimate solutions for drawing conclusions. In our experiments, we find that ubiquitous pre-trained models struggle to deal with this task as their performance is close to random guess. Results show that ARM outperforms pre-trained models significantly. Moreover, we demonstrate that ARM has better explicit interpretable reasoning ability. [1]

1 Introduction

Transformer-based pre-trained language models including BERT (Devlin et al., 2019), GPT-2 (Radford et al., 2019) and RoBERTa (Liu et al., 2019) have achieved state-of-the-art performance on a variety of NLP tasks (Zhong et al., 2020b; Li et al., 2020; Sun et al., 2022; Li et al., 2022). However, they still struggle to perform deep reasoning beyond shallow-level semantic understanding of literal clues. For example, Talmor et al. (2020) show that pre-trained models fail completely on half of eight reasoning tasks that require symbolic operations. We hope to challenge current systems and take a step further towards analytical reasoning.



[Grouping Game] Passage:
Seven directors -A, B, C, D, E, F, and G- serves on the X committee or the Y committee.

If A serves on X, then B serves on Y. **R-1**
If C serves on X, then D and E serve on Y. **R-2**
F serves on a different committee with G. **R-3**
E serves on a different committee with A. **R-4**
If G serves on X, so does B. **R-5**
Rules

Question:
If D and F both serve on the X committee, **Fact**
then which one of the following could be true?

Options:
A. A and C both serve on the X committee.
$(C\ on\ X)\&(D\ on\ X)$ confict with R-2
B. A and E both serve on the Y committee.
$(A\ on\ Y)\&(E\ on\ Y)$ confict with R-4
C. B and G both serve on the X committee.
$(G\ on\ X)\&(F\ on\ X)$ confict with R-3
D. C and E both serve on the Y committee. √
E. G and E both serve on the X committee.
$(G\ on\ X)\&(F\ on\ X)$ confict with R-3

Participants	**Positions**	**Fact**
(A, B, C, D, E, F, G)	(X, Y)	$(D\ on\ X)\&(F\ on\ X)$

Rules to Logical Expressions
R-1: $A\ on\ X\ \rightarrow B\ on\ Y$
R-2: $C\ on\ X\ \rightarrow (D\ on\ Y)\&(E\ on\ Y)$
R-3: $Position\ of\ F \neq Position\ of\ G$
R-4: $Position\ of\ E \neq Position\ of\ A$
R-5: $G\ on\ X\ \rightarrow B\ on\ X$

Figure 1: An example of the required reasoning process to do well on the AR task. The input is a passage, a question and multiple options, and the output is the most plausible answer.

Analytical reasoning assesses the ability of systems to *understand the knowledge, including participants, facts and literal rules mentioned in the context, perform reasoning over the extracted knowledge, and make conclusions.* In this paper, we study the challenge of analytical reasoning (AR). We collect a new dataset **AR-LSAT** from the Law School Admission Test[2] (LSAT) from 1991 to 2016 to facilitate research on analytical reasoning. An example of analytical reasoning in LSAT is given in Figure 1, whose task is to separate participants (i.e., *A,B, etc.*) into two positions (i.e., *X committee and Y committee*) under certain constraints. We can see that solving the problem requires a system to understand the knowledge in the context including participants, positions, rules expressed in natural

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2306 - 2319
July 10-15, 2022

language (e.g., "*If G serves on X, so does B*") and facts (e.g., "*D and F both serve on the X committee*"). Then, it needs to deduct logical expressions (e.g., "*G on X* $\rightarrow$ *B on X*") from the rules, and draw inference before making conclusions.

In this paper, we analyze the knowledge understanding and reasoning ability required for solving this task and present Analytical Reasoning Machine (ARM), a framework that can comprehend the context and perform reasoning for making a conclusion. It extracts participants, rules and facts described in the context of text. Each literal rule is mapped into an executable logical constraint function, which assesses whether a solution satisfies a particular rule. With such logical-level understanding, ARM is capable of deducing a group of legitimate solutions for the question and select the most plausible option as the answer.

Experiments show that pre-trained models struggle to learn this task, which indicates that this task is very challenging for current models as it requires the complex reasoning ability far beyond implicit reasoning over the literal clues. Our system outperforms pre-trained models significantly. Further analysis demonstrates that our system has better interpretability. The contributions are threefold.

- We collect a new dataset AR-LSAT to facilitate research on analytical reasoning.
- We present a reasoning framework that can comprehend the context and perform explicit interpretable reasoning to draw conclusion.
- Experiments indicate that this task is challenging and our system outperforms pre-trained models significantly.

2 Related Works

There is an increasing trend on machine reasoning research in recent years. The reasoning ability investigated are partitioned into several major aspects, including (1) logical reasoning; (2) commonsense reasoning; (3) mathematical reasoning and (4) multi-hop reasoning.

Logical Reasoning The task of Natural Language Inference (NLI) (Dagan et al., 2005; Bowman et al., 2015; Wang et al., 2019; Williams et al., 2018; Welleck et al., 2019; Khot et al., 2018; Nie et al., 2020; Bhagavatula et al., 2020; Liu et al., 2020a) requires the models to detect the logical entailment relationship of two sentences. There have been Machine Reading Comprehension (MRC) works (Gao et al., 2021; Rajpurkar et al., 2016; Welbl et al., 2018a; Yang et al., 2018a; Huang et al., 2019a; Wang et al., 2021) that examine the ability of logical reasoning. LogiQA (Liu et al., 2020b) and ReClor (Yu et al., 2020) are sourced from examination in realistic scenario and examine a range of logical reasoning skills.

Commonsense Reasoning There are many recent benchmarks that assess the commonsense reasoning capabilities from different aspects, like social (Rashkin et al., 2018), physics (Talmor et al., 2019; Zellers et al., 2019; Zhong et al., 2019), or temporal (Zhou et al., 2019; Zhong et al., 2020a) aspects. There exist several MRC datasets that require commonsense knowledge (Ostermann et al., 2018; Zhang et al., 2018; Huang et al., 2019b).

Mathematical Reasoning There are many existing datasets (Kushman et al., 2014; Hosseini et al., 2014; Koncel-Kedziorski et al., 2015; Clark et al., 2016; Ling et al., 2017) that focus on mathematical word problems. Ling et al. (2017) builds a dataset that encourages generating answer rationales beyond simply selecting the correct answer. DROP (Dua et al., 2019) is a benchmark MRC dataset requiring mathematical reasoning. Saxton et al. (2019) focuses on algebraic generalization.

Multi-hop Reasoning Multi-hop reasoning over textual data (Talmor and Berant, 2018; Welbl et al., 2018b; Yang et al., 2018b; Inoue et al., 2020; Zhong et al., 2022) requires a model to reason over multiple paragraphs before making prediction.

To the best of our knowledge, there has not an existing benchmark dataset that completely focuses on the analytical reasoning over textual data. We introduce a new dataset to fill this gap and to foster research on this area.

3 Task and Dataset

In this section, we describe the task of analytical reasoning and introduce the dataset AR-LSAT we collected from the Law School Admission Test.

3.1 Task: Analytical Reasoning of Text

Taking a passage, a question, and multiple options as the input, a system is required to select the most plausible answer as the output. Each passage describes a reasoning game belonging to various types, including three dominant types: **ordering games**, **grouping games**, and **assignment games**,

[Ordering Game] Passage
A professor must determine the order in which five of her students - Fernando, Ginny, Hakim, Juanita, and Kevin- will perform in a recital.
Ginny perform earlier than Fernando. **R-1**
Kevin perform earlier than Hakim and Juanita. **R-2**
Hakim perform either immediately before or immediately after Fernando. **R-3**
Question
Which one of the following could be the order the students perform?

Options
A. Ginny, Fernando, Hakim, Kevin, Juanita ×R-2
B. Ginny, Juanita, Kevin, Hakim, Fernando ×R-2
C. Ginny, Kevin, Hakim, Juanita, Fernando ×R-3
D. Kevin, Ginny, Juanita, Fernando, Hakim√
E. Kevin, Juanita, Fernando, Hakim, Ginny ×R-1

Fact
Uncertain

Positions
$(1^{st}, 2^{nd}, 3^{rd}, 4^{th}, 5^{th})$

Participants
$(Fernando, Ginny, Hakim, Juanita, Kevin)$

Rules to Logical Expressions
R-1: $Pos.of\ Ginny < Pos.of\ Fernando$
R-2: $(Pos.of\ Kevin < Pos.of\ Hakim)$ &
$(Pos.of\ Kevin < Pos.of\ Juanita)$
R-3: $(Pos.of\ Hakim = Pos.of\ Fernando + 1)|$
$(Pos.of\ Hakim = Pos.of\ Fernando - 1)$

[Assignment Game] Passage
Five cashiers-Adams, Bates, Cox, Drake, and Edwards-each of whom works alone on exactly one day, Monday through Friday
Adams will work only on Tuesday or Thursday. **R-1**
Bates will not work on Monday or Wednesday. **R-2**
Cox works on Friday. **F-1**
Edwards don't work next to Drake **R-3**
Question
Which one of the following is a possible work schedule?

Options
A. Edwards, Bates, Adams, Drake, Cox ×R-1
B. Drake, Adams, Bates, Edwards, Cox ×R-2
C. Edwards, Adams, Cox, Bates, Drake ×F-1
D. Edwards, Adams, Drake, Bates, Cox √
E. Drake, Edwards, Bates, Adams, Cox ×R-3

Fact
$Cox\ on\ Fri.$

Participants
$(Adams, Bates, Cox, Drake, Edwards)$

Positions
$(Mon., Tues., Wed., Thur., Fri.)$

Rules to Logical Expressions
R-1: $Adams\ on\ Tues. \mid Adams\ on\ Thur.$
R-2: $\neg(Bates\ on\ Mon. \mid Bates\ on\ Wed.)$
R-3: $Pos.of\ Edwards \neq Pos.of\ Drake + 1$

Figure 2: Examples of ordering game and assignment game in AR task. Facts and Rules are highlighted in orange and blue, respectively. Example of grouping game is shown in Figure 1. × indicates conflict.

which are described as follows and examples are given in Figures 1 and 2:

- **Ordering games** are to order participants based on given facts and rules.
- **Grouping games** are to separate participants into groups with given facts and rules.
- **Assignment games** are to assign characteristics to the participants with given rules, like assigning schedules for people.

3.2 Dataset: AR-LSAT

We collect data from nearly 90 LSAT exams from 1991 to 2016 and select questions from the analytical reasoning part to construct the dataset, dubbed **AR-LSAT**. Each exam in LSAT consists of 101 questions, 24 of which are AR questions. We finally leave up the questions with 5 answer options. The statistics are shown in Table 1. We manually categorize and analyze question types in AR-LSAT according to different reasoning types, and describe the detailed descriptions and corresponding examples in the Appendix D.

Number of questions	2,046
Average length of passages	99.3
Average length of questions	19.1
Average length of answers	6
Number of options	5
Ratio of ordering game	42.5%
Ratio of grouping game	38.75%
Ratio of assignment game	18.75%

Table 1: Data statistics of AR-LSAT dataset.

3.3 Baseline: Pre-trained Model

Pre-trained Transformer (Vaswani et al., 2017) based language models achieved impressive performance on a wide variety of tasks. There are several representative pre-trained models, like BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2020). We employ these powerful pre-trained models as our baselines after being fine-tuned on our dataset. Specifically, we take the concatenated sequence $X = \{[CLS], passage, [SEP], question, option\}$ as the input, where $[CLS]$ is the ending special token and $[SEP]$ is used to split two types of input. The final hidden vector at [CLS] is taken for classification. However, we find that these models struggle to deal with this task as their performances are close to random guess. For example, RoBERTa achieves 23.1% accuracy on the test set.

3.4 Challenges

In this part, we point out the reasoning ability required for solving AR questions, and put forward the challenges that systems should face.

As we can observe from the examples in Figure 1 and Figure 2, AR questions test a range of reasoning skills:

1) Comprehending the knowledge including participants of events, facts, and rules described in the context.

2) Extracting machine-understandable logical functions (expressions) from the rules. For example, the rule "*If A serves on X, then B serves on Y.*" needs to be transferred as logical expression "$A\ on\ X \rightarrow B\ on\ Y$",

3) Making deductions to derive legitimate solutions that satisfy extracted logical functions.

4) Selecting the answer that satisfies all the rules with the deducted legitimate solutions. In the

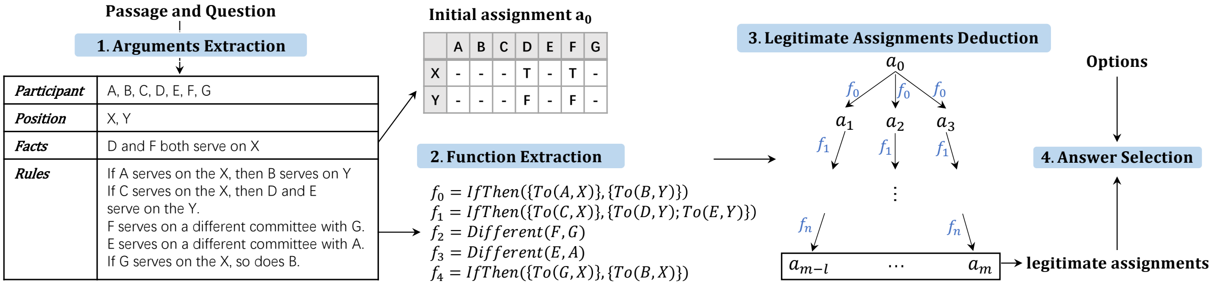

Figure 3: An overview of our approach. The original example is given in Figure 1. It extracts arguments from the context (§ 4.1). Then it extracts constraint functions based on rules (§ 4.3). Afterwards, it conducts deduction to find legitimate assignments (§ 4.4). Lastly, it matches the options and legitimate assignments for prediction (§ 4.5).

> examples, a system should eliminate options that conflict with rules and select the option that accords with legitimate solutions.

Therefore, this task requires the machine to perform explicit complex reasoning, far beyond just understanding the literal clues presented in the text.

4 Approach

We describe how our system, the Analytical Reasoning Machine (ARM), comprehends the knowledge, performs reasoning over the knowledge, and makes conclusions. Figure 3 gives an overview of our approach. Our system operates in four steps: (1) extracting the participants, positions, facts and rules from the passage and the hypothesis of the question (§ 4.1); (2) interpreting rules into a set of logical constraint functions defined in § 4.2, whose arguments are selected from participants and positions (§ 4.3); (3) reasoning with the logical functions and finally generating a group of legitimate assignments (solutions) that satisfy all the rules (§ 4.4); (4) selecting the most plausible option by matching the legitimate assignments and options (§ 4.5). ARM sheds a light on the logical-level reasoning procedure for analytical reasoning and each procedure can be further developed for both performance and expandability.

4.1 Arguments Extraction

In order to understand the context and formalize the problem, the first step is to extract **the participants, positions, facts and rules expressed in natural language** from the passage and hypothesis of the question. An **assignment** represents a solution that assigns participants to positions. An assignment of participants is represented as a table, whose rows and columns represent participants and positions, respectively. Each grid represents whether a participant is assigned to a position, and has the value of three possible states: $(True, False, Unknown)$. The rules describe the constraints of assignments while the facts describe certain assignments. Therefore, we take the sentences that mention specific assignments (e.g., *A on X*) as facts and the other sentences as rules. Facts represent initial assignments to the grids of the assignment table and the default state is noted with *Unknown*. We take the example in Figure 1 as a running example to show the extracted participants, positions, facts and rules from the context.

Specifically, we extract the entities from the leading sentence of the passage with a neural Named Entity Recognition (NER) model (Peters et al., 2017) and group the extracted entities into participants or positions. We parse groups of entities that appear together in the leading sentence of the passage as groups of participants or positions, where participants always appear before positions. For the ordering game, positions can not be directly extracted, so we take them as the order (e.g., *first*, *second*) of participants.

4.2 Constraint Function Definition

We introduce a set of predefined logical functions, which encode constraints expressed in the literal rules and check if an assignment satisfies these constraints. These functions are the foundation of the reasoning process.

The logical functions include three basic types: (1) **relational function**; (2) **compositional function**; (3) **counting function**. A fragment of the predefined functions is shown in Table 2. A function consists of arguments and a executor to check whether an assignment satisfies the constraint function. The detailed definition of each function is listed in Appendix B.

Relational Function The relational functions represent the constraints of the relationship between two participants or a participant and a position. The arguments of relational function involve participant or position. For example, the function *Before*$(Ginny, Fernando)$ indicates that *Ginny* should be in the position before *Fernando* in the ordering game. *To*(A, X) indicates that participant A should be assigned to position X.

Compositional Function A compositional function expresses the relationship between two sets of functions, like the conditional rule (*if-then* rule) and the *if-and-only-if* rule. The arguments of compositional functions involve two sets of subfunctions. For example, the rule "*If A serves on the X, then B serves on the Y.*" should be expressed as *IfThen*$(\{To(A, X)\}, \{To(B, Y)\})$.

Counting Function The counting functions focus on the calculation problem of participants under specific constraints. The arguments of counting functions involve a participant and a number. For example, *LastPos*$(A, 3)$ checks whether the participant A is assigned to the last 3 positions.

The input of a function executor is an assignment and the output is a *Bool* value indicates whether the assignment satisfies the constraint.

4.3 Function Extraction

Based on the extracted arguments, we parse the rules expressed in natural language into a set of constraint logical functions that can check whether an assignment satisfy the rules.

One straightforward way is to design a symbolic parsing method. We define an API set to include roughly 20 types of functions like *Before*, *After*, *To*, *IfThen* and realize their executors. For each function, we follow NSM (Liang et al., 2017) that uses trigger words to match a potential function. For example, the function *Before* can be triggered by words "*before*" and "*earlier*". All the functions and trigger words are listed in Appendix B. To extract potential arguments from a given rule, we match the participants, positions, and number from the text. If a function is recognized by a trigger word, we select its arguments from all the potential arguments according to their relative positions to the trigger word. The relational and counting functions can be constituted into compositional functions based on grammar patterns. For example, for the grammar pattern "*If P, then Q*", Each function is grouped into the function set F_1 if it occurs in *P*, or the function set F_2 if it occurs in Q. F_1 and F_2 are taken as the arguments of the function *IfThen*.

Furthermore, to handle the uncertain cases and improve the coverage of extracted functions, we build a neural semantic parsing model based on a pre-trained language model RoBERTa (Liu et al., 2019). It takes the sentence and two parsed arguments in the sentence as the input and predicts their potential function type ("*Null*" if no function exists). Specifically, following Xu et al. (2021), we modify the sentence by adding a special token "@" before and after the first argument, and a special token "#" before and after the second argument. Then, we encode the modified sentence X with RoBERTa to obtain contextual representations $H = \textit{RoBERTa}(X)$. for tokens. Afterwards, we take the representation of the first "@" and "#" for classification.

$$f = argmax(\textit{classifier}([H^{@}; H^{\#}])) \qquad (1)$$

where [;] denotes concatenation, and the classifier is a linear layer followed by a softmax function. Since there is no annotated data of corresponding logical functions, we need to construct the training data automatically. The training data consist of (1) positive instances: all the *{input: (rule, arguments); label: function}* pairs that extracted by the symbolic parsing method from the training set; (2) negative instances: the same number of instances that have arguments with no function related.

Afterwards, we extract a set of constraint functions with the combination of symbolic and neural parsing methods. These functions are utilized for reasoning process introduced in the following part.

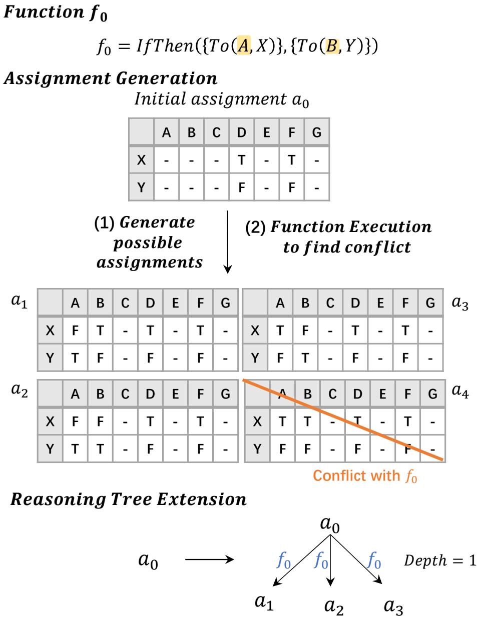
4.4 Legitimate Assignments Deduction

Given the extracted logical constraint functions and the initial assignment table, we conduct reasoning to find the legitimate assignments that satisfy all the constraints. The process is formulated into a tree-based reasoning algorithm. As shown in Figure 4, each node in a tree corresponds to a table assignment and each edge indicates a constraint function. A node v with path $\{e_0, e_1, ..., e_i\}$ from the root indicates that its assignment satisfies constraint functions $\{f_0, f_1, ..., f_i\}$. Suppose we have n constraint functions, we need to find all the leaf nodes with depth n. These leaf nodes satisfy all the functions and thus become legitimate assignments.

Therefore, we introduce how to construct the complete reasoning tree by the following steps:

Type	Function	Args	Description
Relational Functions	*Before/After*	$participant_1$ $participant_2$	Whether $participant_1$ is in the position before/after $participant_2$.
	Same/Different		Whether $participant_1$ is in the same/different position with $participant_2$.
	To	$participant_1$ $position_1$	Whether $participant_1$ is assigned to $position_1$.
Compositional Functions	*IfThen*	function set F_1 function set F_2	If functions in F_1 satisfied, then functions in F_2 satisfied.
Counting Functions	*FirstPos/LastPos*	$participant_1$, number m	Whether $participant_1$ is assigned to the first/last m positions.

Table 2: A fragment of the logical constraint function definition.



a_0

	A	B	C	D	E	F	G
X	-	-	-	T	-	T	-
Y	-	-	-	F	-	F	-

a_1

	A	B	C	D	E	F	G
X	F	T	-	T	-	T	-
Y	T	F	-	F	-	F	-

a_3

a_4

	A	B	C	D	E	F	G
X	T	T	-	T	-	T	-
Y	F	F	-	F	-	F	-

Figure 4: An example of the reasoning process. Newly added participants in f_0 are highlighted. (1) and (2) conducted recursively until $depth = n$. $(T/F/-) = (True/False/Unknown)$

1) Firstly, we start with the root, which is the certain initial assignment decided by facts. For the function f_0, we generate all possible assignments related to newly added arguments in f_0. As shown in the example in Figure 4, for the function *IfThen*(*To*(A, X), *To*(B, Y)), we generate all possible assignments related to the new participants A and B.

2) We execute f_0 to find all the legitimate assignments that satisfy f_0 as a group of children of the root. In the same example, we keep the assignments that meets *IfThen*(*To*(A, X), *To*(B, Y)).

3) Then we select each child as a new root and select function f_1 for further extension of the reasoning tree.

These processes are recursively conducted until depth n, which means that all the functions are used to construct the reasoning tree. The procedure is summarized into pseudo-code in Appendix A.

It is worth mentioning that although both our algorithm and forward-chaining algorithm deduce new facts based on rules. However, forward-chaining algorithm struggles to do this task because it assumes that all the assignments are already known to the systems while the assignments are always unknown before the deduction steps.

Therefore, this algorithm has advantages of performing explicit interpretable reasoning over the extracted functions and handling uncertain assignments. Moreover, the tree-based manner reduces the computational complexity.

4.5 Answer Selection

Previous steps understand the passage and the question. In this part, we introduce how to analyze the options, and match the options with the deducted legitimate assignments beyond word-level for making a final prediction. Specifically, we can derive two types of information from an option:

1) **Assignment-based option** indicates a table assignment. For example, "*A and C both serve on the X committee*" can be interpreted as a assignment in the table: $\{(A, X)$ = True; (C, X) = True$\}$. For this type, we match the parsed option assignment with all the legitimate assignments and calculate an assignment-based matching score.
2) **Function-based option** indicates an option representing a constraint function, like "*The sedan is serviced earlier in the week than the roadster*", which can be parsed into the function "*Before(sedan, roadster)*". We execute the option-based function on the legitimate assignments to find the satisfiable option and calculate a function-based matching score.

These two types of scores are combined for making a conclusion. The question types and score calculating methods are summarized in the Appendix C.

5 Experiments

We make experiments on the AR-LSAT dataset and evaluate our system with label accuracy. The data split is *(train/dev./test)* $= (1,585/231/230)$ We first compare our system with powerful neural baselines and conduct analysis. Moreover, case study illustrates the reasoning process of our system by an explicit example. Lastly, we make error analysis to point out challenges in this task.

5.1 Model Comparison

Baseline Models We take various powerful neural models, including RNN-based models (i.e., LSTM) and powerful Transformer-based pre-trained language models (i.e, BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), and the recent ALBERT (Lan et al., 2020)) as the baselines of our dataset and investigate their performance. The implementation details of these baselines are given in Appendix D.

Human Performance Since the dataset is based on a test designed for undergraduate students, we select nearly 100 instances in the AR-LSAT dataset and ask 10 undergraduate college students majoring in literature, commerce and law to answer these questions. We take their averaged performance as human performance and report it in Table 3.

Methods	Dev. Acc (%)	Test Acc (%)
Human Performance	-	59.7%
Random Guess	20.0%	20.0%
LSTM	22.5%	20.9%
BERT	23.4%	21.4%
XLNet	23.8%	22.5%
RoBERTa	24.2%	23.1%
ALBERT	24.4%	23.0%
ARM	34.2%	30.9%

Table 3: Performance on the AR-LSAT dataset. Our model is abbreviated as ARM.

Results and Analysis In Table 3, we compare our system (ARM) with baselines and human performance on the development and test set. As shown in Table 1, our model with context understanding and explicit reasoning process significantly outperforms RNN-based models and pre-trained language models with 34.2% accuracy on the development set and 30.9% accuracy on the test set. Results indicate that context understanding and reasoning are essential for this task.

Moreover, we observe that the RNN-based models and pre-trained models struggle to do well on this task, and achieve close performance with random guess. It is also noticed that the performance of both our system and baselines are still far from human performance, leaving significant opportunities for further exploration.

5.2 Model Analysis

In this part, we further analyze the performance and variance of components of our system. To evaluate the performance of arguments extraction, we manually annotate the correct participants and positions in the development set as labels and calculate the accuracy and recall of our condition extraction method and report the results in Table 4. Moreover, we eliminate the neural semantic parsing method to evaluate its importance and extract functions by the symbolic parsing method. The results are shown in Table 5. Eliminating neural semantic parsing yields no significant compromise in performance. This observation indicates that the neural semantic parsing model can improve performance by improving coverage of the functions and the symbolic parsing method can also provide reliable performance.

	Acc. (%)	Recall (%)
Participants	96.17	92.88
Positions	84.42	85.79

Table 4: Performance of extraction of participants and positions on the development set.

Methods	Dev. Acc (%)	Test Acc (%)
ARM	34.2%	30.9%
ARM (w/o neural func.)	32.4%	30.2%

Table 5: Ablation of the the neural semantic parser.

5.3 Case Study

We present a case study in Figure 5 to illustrate the reasoning process of our system with interpretable results. Our system extracts correct arguments from the context, and interprets the rules into logical constraint functions. Afterwards, we perform deduction to find legitimate solutions. Lastly, our system matches the options with the legitimate solutions and calculates a score for each option. Option A achieves the highest score because it accords with legitimate assignments. This analysis

Passage: A professor must determine the order in which five of her students — Fernando, Ginny, Hakim, Juanita, and Kevin — will perform in an upcoming piano recital. Each student performs one piece, and no two performances overlap. The following constraints apply: Ginny must perform earlier than Fernando. Kevin must perform earlier than Hakim and Juanita. Hakim must perform either immediately before or immediately after Fernando.
Question: If Juanita performs earlier than Ginny, then which one of the following could be true?
Options: (A) Fernando performs fourth. √ (B) Ginny performs second. (C) Hakim performs third. (D) Juanita performs third. (E) Kevin performs second

Participants & Positions	Fernando, Ginny, Hakim, Juanita, Kevin	first, second, third, fourth, fifth
Rules & Functions	(1) Ginny must perform earlier than Fernando. (2) Kevin must perform earlier than Hakim and Juanita. (3) Hakim must perform either immediately before or immediately after Fernando. (4) Juanita performs earlier than Ginny	(1) $Before\ (Ginny, Fernando)$ (2) $And\ (\{Before\ (Kevin, Hakim)\}, \{Before(Kevin, Juanita)\})$ (3) $Or\ (\{Next\ (Hakim, Fernando)\}, \{Last\ (Hakim, Fernando)\})$ (4) $Before\ (Juanita, Ginny)$

Legal Assignments

	1^{st}	2^{nd}	3^{rd}	4^{th}	5^{th}
Fernando	F	F	F	T	F
Ginny	F	F	T	F	F
Hakim	F	F	F	F	T
Juanita	F	T	F	F	F
Kevin	T	F	F	F	F

	1^{st}	2^{nd}	3^{rd}	4^{th}	5^{th}
Fernando	F	F	F	F	T
Ginny	F	F	T	F	F
Hakim	F	F	F	T	F
Juanita	F	T	F	F	F
Kevin	T	F	F	F	F

Option Scores (A) **1** $(B)\ -1$ $(C)\ -1$ $(D)\ -1$ $(E)\ -1$

Figure 5: A case study on the AR-LSAT dataset. Our system correctly extracts participants, positions, and rules from the context. Afterwards, it interprets rules into logical functions. After deduction, our system finds legitimate assignments and makes the correct prediction. Rules are highlighted in blue.

demonstrates that our system has better explicit interpretable reasoning ability.

5.4 Error Analysis

We randomly select 50 wrongly predicted instances from the dev. set and summarize the error types.

The dominant error type is that some rules with complex semantics are not covered by current constraint logical function set. For example, given a rule "*Each crew member does at least one task during the installation.*" , we should map "*At least*" to function *AtLeastNum*. The second type of errors is caused by failing to extract correct participants or positions by the NER model and predefined matching pattern. The third error type is caused by the lack of basic commonsense knowledge, which is required for understanding the concept in the rules. For example, when a passage mentioned "*Six entertainers should be scheduled at 9:00 A.M., 2:00 P.M., etc*" and the rule is "*Some participants should be scheduled in the morning.*", the system fails to match the *morning* with a specific time zone.

5.5 Discussion

We would like to further highlight important directions to facilitate research on analytical reasoning.

One of the major challenges lies in deep understanding of the knowledge in the context, like parsing the rules into logically equivalent symbolic functions. Deriving machine-understandable functions from natural language is an essential step towards deeper understanding and reasoning. Although supervised semantic parsing has achieved promising progress in recent years, obtaining complete human-annotated logical functions is impractical for this task. Therefore, further study can focus on function extraction with limited amount of annotated functions.

Furthermore, a better inference engine built upon logical functions is also essential because AR questions require deeper reasoning abilities far beyond just understanding the literal clues. Standard symbolic systems like expert systems can provide explicit reasoning, but they are difficult to deal with uncertainty in data. Although neural-based methods are more flexible at dealing with uncertainty, they still struggle to perform interpretable and explicit reasoning. It is promising to better integrate neural and symbolic systems to improve this task with deeper reasoning ability.

6 Conclusion

In this paper, we study the challenging task of analytical reasoning and introduce a dataset AR-LSAT to facilitate research on analytical reasoning. We analyze the knowledge understanding and reasoning ability required for this task and present a system, Analytical Reasoning Machine (ARM), which can comprehend the knowledge, including participants, facts and rules mentioned in the context and extract logically equivalent logical functions from the rules. Afterwards, it performs deep reasoning to find all the legitimate solutions to the problem posed and finally makes a prediction. Experiments show that our system outperforms strong Transformer-based baselines, which indicates that knowledge understanding and deep reasoning is essential for this task. Results show that this task is very challenging for current neural-based models.

A Pseudo-code of Legitimate Assignments Deduction

```
Require: A set of constraint functions $F = \{f_0, f_1, ..., f_n\}$
    and an initial assignment $a_0$
function ConstructTree(node,functions,depth,n)
    if depth == $n$ then:
        return
    end if
    function = functions[depth]
    old_pars = node.participants
    old_assign = node.assignment
    new_pars = find_new_participant(function, old_pars)
    all_assign = gen_all_assign(old_assign, new_pars)
    satisfied = find_satisfied(all_assign, function)
    depth = depth+1
    children = update_notes(node, satisfied, new_pars)
    for child in children do
        ConstructTree(child, functions, depth, $n$)
    end for
end function
root = Node($a_0$)
depth = 0
$n$ = length of $F$
complete_tree = ConstructTree(root, $F$, depth, $n$)
legitimate = nodes in complete_tree with depth $n$
return legitimate =0
```

B Function Definition

In this part, we present the detailed description and trigger words for each logical constraint functions in Table 8.

C Question Type

In this part, we list common question types in the AR-LSAT datasets and their ratio in Table 6 and give examples in Table 7. We further introduce how we calculate a score for dominant question type with a group of legitimate assignments.

1) **Must be true/false**: this question type needs to select answer that must be true in all the assignments. We match all the assignments with the option. If one option accords/conflicts with one assignment, the single matching score will be 1/-1, otherwise the score will be 0. We then calculate the sum of all the matching scores as the final score.

2) **Could be true/false**: this question type needs to select answer that could be true in one of the legitimate assignments. We match all the assignments with the option. If one option accords/conflicts with one assignment, the single matching score will be 1/-1, otherwise the score will be 0. We then calculate the maximum matching scores as the final score. The *Acceptable solution* question type also use this method to calculate score.

3) **Maximum number of participants in a position**: this question type needs to calculate the maximum possible number of participants in a specified position (group). We calculate the maximum number of participants in all the legetimate assignments and calculate the absolute difference with the number in the option as the final score.

4) **Find the earliest position of a participant**: this question type needs to calculate the earliest possible position of a specific participant. We calculate the index of the earliest position of the participant in all the legitimate assignments and calculate the absolute difference with the number in the option as the final score.

5) **Count the number of possible positions that a participant can be assigned in**: for this question type, we count all the non-repetitive assignments of the specific participant and calculate the absolute difference with the number in the option as the final score.

D Baseline Models

D.1 Descriptions

- **LSTM** (Gers et al., 1999) is a classical RNN-based model. We apply Bi-LSTM with GloVE (Pennington et al., 2014) embedding.

Question Type	Description
Acceptable solution (15.6%)	identify a feasible solution that can satisfy all the rules
Complete list (3.5%)	identify a complete and accurate list of participants under given condition
Could be true/false (26.8%)	select answer that could be true/false under given condition
Must be true/false (26.4%)	select answer that must be true/false under given condition
Negation (14.7%)	questions that contain negation
Substitution (4.3%)	find a new rule that can substitute one of the old rules for the desiring result
Condition for determined solution (3.5%)	identify a new rule so that the feasible solution is determined
Calculation (3%)	calculate possible participants in a group
Earliest/latest position (1.3%)	identify the earliest/latest position that a participant can be assigned to
Maximum/minimum members (1.3%)	identify the maximum/minimum number of participants in a specific group

Table 6: The ratio and description of each question type in the test set of the AR-LSAT dataset.

Question Type	Example
Acceptable solution	Which one of the following could be the schedule of the students' reports?
Complete list	Which one of the following could be a complete and accurate list of the books placed on the bottom shelf?
Could be true/false with condition	If Himalayans are not featured on day 7. which one of the following could be true?
Must be true/false with condition	If Theresa tests G on the second day. then which one of the following must be true?
Negation	P CANNOT be performed at?
Substitution	Which one of the following. if substituted for the condition that Waite's audition must take place earlier than the two recorded auditions. would have the same effect in determining the order of the auditions?
Condition for unique solution	The assignment of parking spaces to each of the new employees is fully and uniquely determined if which one of the following is true?
Calculation	How many of the students are there who could be the one assigned to 1921?
Earliest/latest position	If Zircon performs in an earlier slot than Yardsign. which one of the following is the earliest slot in which Wellspring could perform?
Maximum/minimum members	What is the minimum number of solos in which Wayne performs a traditional piece?

Table 7: The examples of question types in the AR-LSAT dataset.

- **BERT** (Devlin et al., 2019) is a transformer-based model pre-trained on BooksCorpus and Wikipedia with two unsupervised learning task: Masked LM and Nest Sentence Prediction.

- **XLNet** (Yang et al., 2019) is also a transformer-based model, pre-trained on BooksCorpus, Wikipedia, Giga5, ClueWeb 2012-B and Common Crawl with Permutation Language Modeling.

- **RoBERTa** (Liu et al., 2019) is a transformer-based model with the same model structure as BERT but trained on a larger corpus and on a different training setting.

- **ALBERT** (Lan et al., 2020) is a most recent transformer-based pre-trained model. ALBERT uses parameter-reduction techniques that support large-scale configurations.

D.2 Implementation Details

For all the baselines, we employ cross-entropy loss as the loss function and select AdamW as the optimizer for model training/ fine-tuning. These baselines add a simple classification layer on the top of them and take the the last hidden state as the input. For all the Transformer-based models, we employ base model as the backbone.

Type	Function	Arguments	Description	Trigger Words
Relational Functions	Before	participant 1 participant 2	whether participant 1 is in the position before participant 2	before, above, precede, earlier
	After		whether participant 1 is in the position after participant 2	after, larger, higher bigger, older
	Last		whether participant 1 is in the last position of participant 2	immediately before, last
	Next		whether participant 1 is next to participant 2	immediately after, next
	Adjacent		whether participant 1 is neighboring to participant 2	neighboring, adjacent
	Different		whether participant 1 in the different position with participant 2	different
	Same		whether the first participant in the same position with the second participant	same, also
	BeforeEqual		whether participant 1 before or equals to the position of participant 2	no later
	AfterEqual		whether participant 1 after or equals to the position of participant 2	no earlier
	To	participant position	Whether the participant is assigned to the position	to, on, give, in
Compos. Functions	IfThen	function set 1 function set 2	If rules in rule set 1 satisfied, then rules in rule set 2 satisfied	If... then, If ... , ...
	IFF		Rules in rule set 1 satisfied if and only if rules in rule set 2 satisfied	if and only if
	And		Rules in rule set 1 satisfied and rules in the rule set 2 satisfied	and
	Or		Rules in rule set 1 satisfied or rules in rule set 2 satisfied	or
	Unless		Rules in rule set 1 satisfied unless rules in rule set 2 satisfied	unless
	Neither		Neither rules in rule set 1 satisfied nor rules in rule set 2 satisfied	Neither ... nor ...
Counting Functions	FirstPos	participant number	Whether the participant is in the last (number) positions	one of the last (number)
	LastPos		Whether the participant is in the first (number) positions	one of the first (number)

Abstract

News recommendation is different from movie or e-commercial recommendation as people usually do not grade the news. Therefore, user feedback for news is always implicit (click behavior, reading time, etc). Inevitably, there are noises in implicit feedback. On one hand, the user may exit immediately after clicking the news as he dislikes the news content, leaving the noise in his positive implicit feedback; on the other hand, the user may be recommended multiple interesting news at the same time and only click one of them, producing the noise in his negative implicit feedback. Opposite implicit feedback could construct more integrated user preferences and help each other to minimize the noise influence. Previous works on news recommendation only used positive implicit feedback and suffered from the noise impact. In this paper, we propose a **D**enoising neural network for news **R**ecommendation with **P**ositive and **N**egative implicit feedback, named DRPN. DRPN utilizes both feedback for recommendation with a module to denoise both positive and negative implicit feedback to further enhance the performance. Experiments on the real-world large-scale dataset demonstrate the state-of-the-art performance of DRPN.

1 Introduction

Online news platforms, such as Google News and Microsoft News, have attracted a large population of users (Wu et al., 2020b). However, massive news articles emerging every day on these platforms make it difficult for users to find appealing content quickly (Wu et al., 2019b). To alleviate the information overload problem, recommender systems have become integral parts of these platforms.

A core problem in news recommendation is how to learn better representations of users and news (Hu et al., 2020b). Early works include collaborate filtering (CF) based methods (Das et al., 2007), content-based methods (IJntema et al., 2010) and hybrid methods (De Francisci Morales et al., 2012) that combine the two. These methods usually have the cold start problem when being exposed to the sparsity of user-item interactions (Zhu et al., 2019). Recently, deep learning methods have been proposed to learn better user and news representations. The techniques evolve from using recursive neural network (Okura et al., 2017), attention mechanism (Zhu et al., 2019; Wu et al., 2019c), to graph neural network (Wang et al., 2018a; Hu et al., 2020b,a; Qiu et al., 2022). These methods usually recommend news for users based on their historical feedback.

Implicit feedback is more commonly collected than explicit feedback for news because the users usually do not grade the news. Hence, current news recommendation methods naturally use positive implicit feedback like click behavior as the historical feedback to model user interests. However, there are gaps between positive implicit feedback and user real preferences (Wang et al., 2018b). For example, the click behaviors do not fully reflect the user's preferences. The user may exit the news immediately after clicking, which will involve a noise in the positive feedback. Additionally, some news that users did not click, may also attract them later. Ignoring them also impacts the recommendation performance. Our observation is that using both positive and negative implicit feedback can better model user interests. Besides, positive and negative implicit feedback can help to denoise each other by conducting inter-comparison and intra-comparison. If a news story in one feedback sequence is more similar to the news in the opposite feedback sequence rather than the news in the same sequence, it is very likely that this news story constitutes noise. We can remove this news when building user interests. This idea is shown in Figure 1.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2320 - 2329
July 10-15, 2022

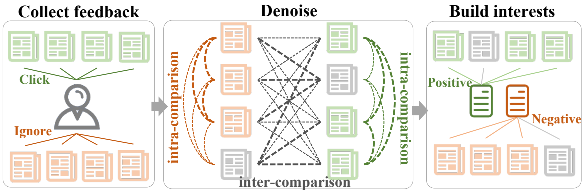

Figure 1: The idea to denoise the implicit feedback. Noises are found by conducting inter-comparison and intra-comparison and then reduced.

In this paper, we propose the **D**enoising neural network for news **R**ecommendation with **P**ositive and **N**egative implicit feedback, named DRPN. It first introduces a news encoder to represent the news in two implicit feedback sequences. Then two parallel aggregators are used to extract user representations from both positive and negative historical feedback: (1) *content-based aggregator*, which selects the informative news in the feedback sequences to represent the user; (2) *denoising aggregator*, which finds and reduces the noises in the feedback sequences. In addition to the semantic information, we introduce a graph neural network to incorporate the collaborative information to further enrich the user representation. Finally, the user and candidate news representations are used to predict the clicking probability. The contributions of this paper are summarized as follows:

- We propose a novel neural news recommendation approach DRPN which jointly models both positive and negative implicit feedback sequences to represent the user to improve recommendation performance.

- In DRPN, to minimize the impacts of the noises in the implicit feedback, the denoising aggregators are designed to refine the two feedback sequences and can help to further improve the recommendation performance.

- The experiments on the large-scale real-world dataset demonstrate that DRPN achieves state-of-the-art performance.

2 Related Works

2.1 Recommendation with Multi-type Feedback

Few works notice the noise problem in the implicit feedback. (Zhao et al., 2018; Liu et al., 2020) use multiple types of feedback to improve recommendation. However, they ignore the noise in the implicit feedback. (Wang et al., 2018b) notices the noise problem but it fails to use the meaningful semantic information in the news. (Wu et al., 2020a; Xie et al., 2020; Bian et al., 2021) use the explicit feedback (such as reading time and like/dislike behaviors) to help denoise the implicit feedback. However, the explicit feedback is harder to collect than the implicit feedback. Differently, DRPN only depends on the implicit feedback (click and non-click behaviors) to conduct the denoise to better model the user preferences.

2.2 Graph Neural Network

Recently, graph neural networks (GNN) have received wide attention in many fields (Wu et al., 2020c). The convolutional GNN can learn powerful node representations by aggregating the neighbors' features. Recently, some works have attempted to leverage the graph information to enhance the representations learning for news recommendation with GNNs. (Wang et al., 2018a) uses entities in news to build a knowledge graph and use the entity embeddings to improve the model performance. (Ge et al., 2020) combines the one- and two-hop neighbor news and users to enrich the representations of the candidate news and user, respectively. However, these methods also depend on the positive implicit feedback to model user representations and ignore the noise problem.

3 Problem Formulation

The news recommendation problem in our paper can be illustrated as follows. Let $\mathcal{U}$ and $\mathcal{R}$ denote the entire user set and news set. The feedback matrix for the users over the news is denoted as $\mathcal{Z} \in \mathbb{R}^{l_u \times l_r}$, where $z_{u,r} = 1$ means user u gives a positive implicit feedback to news r (e.g., u clicks r), $z_{u,r} = -1$ means user u gives a negative implicit feedback to news r (e.g., u sees r but ignores it), and $z_{u,r} = 0$ means no feedback. l_u and l_r denote the numbers of the users and news, respectively. For each specific user, his historical positive feedback sequence $[p_1, ..., p_{l_p}]$ and negative feedback sequence $[n_1, ..., n_{l_n}]$ can be gathered from the feedback matrix $\mathcal{Z}$, where $p_i, n_j \in \mathcal{R}$.

Given the feedback matrix $\mathcal{Z}$, the goal is to train a model $\mathcal{M}$ (i.e., DRPN). For each new pair of user and candidate news $(u \in \mathcal{U}, r \in \mathcal{R})$, we can use $\mathcal{M}$ to estimate the probability that u would like to click r.

4 Framework

Figure 2 shows the architecture of DRPN. It first employs the title encoder and id embedding layer to represent all news in two feedback sequences and the candidate news. Then two separate encoders are employed to extract the user semantic interest and collaborative interest information from both positive and negative implicit feedback sequences. Next, two fusion nets combine multiple interest representations to represent the user. Finally, we use the user and candidate news representations to estimate the clicking probability. We will detail each component in the following subsections.

4.1 Input

The inputs of the DRPN contain six parts: the titles of positive feedback sequence $[p_1^t, ..., p_{l_p}^t]$, the titles of negative feedback sequence $[n_1^t, ..., n_{l_n}^t]$, the candidate news title r_c^t, the IDs of positive feedback sequence $[p_1^o, ..., p_{l_p}^o]$, the IDs of negative feedback sequence $[n_1^o, ..., n_{l_n}^o]$, and candidate news ID r_c^o.

For each news title t, we convert its every word w to a d-dimensional vector $\mathbf{w}$ via an embedding matrix $\mathbf{E}_W \in \mathbb{R}^{l_w \times d}$, where l_w is the vocabulary size and d is the dimension of word embedding. Then, the title t is transformed into a matrix $\mathbf{T}$.

For each news ID o, we also convert it to a d-dimensional vector $\mathbf{o}$ via an embedding matrix $\mathbf{E}_O \in \mathbb{R}^{l_r \times d}$. In this manner, we can encode all news to obtain $\mathbf{P}^o = [\mathbf{p}_1^o, ..., \mathbf{p}_{l_p}^o]$ ($\mathbf{p}_i^o \in \mathbb{R}^d$), $\mathbf{N}^o = [\mathbf{n}_1^o, ..., \mathbf{n}_{l_n}^o]$ ($\mathbf{n}_i^o \in \mathbb{R}^d$), and $\mathbf{r}_c^o \in \mathbb{R}^d$.

4.2 Title Encoder

The title encoder can extract the sentence-level semantic representation of the news title. It contains two sub-layers. We take the title $\mathbf{T}$ as an example to detail the encoding process.

The first sub-layer is a multi-head self-attention layer, which can model the contextual representation of each word. Given three input matrices $\mathbf{Q} \in \mathbb{R}^{l_q \times d}$, $\mathbf{K} \in \mathbb{R}^{l_v \times d}$ and $\mathbf{V} \in \mathbb{R}^{l_v \times d}$, the attention function is defined as:

$$\mathtt{Attn}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{softmax}(\mathbf{Q}\mathbf{K}^\top / \sqrt{d})\mathbf{V} \quad (1)$$

Multi-head self-attention layer $\mathtt{MH}(\cdot, \cdot, \cdot)$ will further project the input to multiple semantic subspaces and capture the interaction information from multiple views:

$$\begin{aligned} \mathtt{MH}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) &= [head_1; ...; head_{l_h}]\mathbf{W}^I \\ head_i &= \mathtt{Attn}(\mathbf{Q}\mathbf{W}_i^Q, \mathbf{K}\mathbf{W}_i^K, \mathbf{V}\mathbf{W}_i^V) \end{aligned} \quad (2)$$

where $\mathbf{W}_i^Q$, $\mathbf{W}_i^K$, $\mathbf{W}_i^V \in \mathbb{R}^{d \times d / l_h}$ and $\mathbf{W}^I \in \mathbb{R}^{d \times d}$ are the parameters to learn. l_h is the number of heads. $[;]$ denotes the column-wise concatenation for matrices.

Moreover, we employ the residual connection and layer normalization function $\mathtt{LN}$ defined in (Ba et al., 2016) to fuse the original and contextual representations: $\widetilde{\mathbf{T}} = \mathtt{LN}(\mathbf{T} + \mathtt{MH}(\mathbf{T}, \mathbf{T}, \mathbf{T}))$.

The second sub-layer is a gated aggregation layer (Qiu et al., 2020). It will select the important words to generate an informative title representation. The gated mechanism is employed to decide the weight of each words. Given the word embedding matrix $\widetilde{\mathbf{T}}$, its sentence-level semantic representation $\mathbf{t}$ is calculated as follows:

$$\begin{aligned}\mathbf{t} &= \texttt{Aggregate}(\widetilde{\mathbf{T}}) \\ &= \Big(\text{softmax}(\tanh(\widetilde{\mathbf{T}}\mathbf{W}_a + \mathbf{b}_a)\mathbf{W}_g)\Big)^\top \widetilde{\mathbf{T}}\end{aligned} \tag{3}$$

where $\mathbf{W}_a \in \mathbb{R}^{d \times d'}$, $\mathbf{b}_a \in \mathbb{R}^{d'}$ and $\mathbf{W}_g \in \mathbb{R}^{d' \times 1}$ are trainable parameters.

Finally, we can use the title encoder to model the titles of all news in two user feedback sequences to obtain $\mathbf{P}^t = [\mathbf{p}_1^t, ..., \mathbf{p}_{l_p}^t]$ and $\mathbf{N}^t = [\mathbf{n}_1^t, ..., \mathbf{n}_{l_n}^t]$. For the candidate news, we can also obtain its title representation $\mathbf{r}_c^t$ via the same title encoder.

4.3 Semantic Interest Encoder

The titles of the news which the user interacted usually reflect the user's interests. Hence, we can learn user interest representations by encoding the semantic representations of the news. As is shown in Figure 3, the semantic interest encoder leverages two aggregators, *content-based aggregator* (CA) and *denoising aggregator* (DA), to extract user preferences from both positive and negative feedback sequences.

4.3.1 Content-based Aggregator

Different news have different informativeness when representing users. For example, sport news are more informative than weather news in modeling user personality, since the latter are usually browsed by most users. The content-based aggregator (CA) will first evaluate the importance of different news in the feedback sequence from the content view and then aggregate the important news to represent the user. It contains two sub-layers.

The first one is a multi-head self-attention layer, which can enhance the news representations by capturing their interactions. For the positive feedback sequence $\mathbf{P}^t$, the multi-head self-attention layer generates $\widetilde{\mathbf{P}}^t = \texttt{LN}(\mathbf{P}^t + \texttt{MH}(\mathbf{P}^t, \mathbf{P}^t, \mathbf{P}^t))$. The `MH` is define in Eq.(2) with independent parameters and the `LN` is the layer normalization function.

The second sub-layer is a gated aggregation layer that has the same structure as the one defined in Eq.(3). For $\widetilde{\mathbf{P}}^t$, it can select the more informative news to generate the user representation: $\mathbf{p}_s^t = \texttt{Aggregate}(\widetilde{\mathbf{P}}^t)$. We also use the content-based aggregator to generate another user representation from the negative feedback sequence $\mathbf{N}^t$, $\mathbf{n}_s^t$.

4.3.2 Denoising Aggregator

Denoising aggregator will conduct what we call a refining operation, which aims to mitigate the impacts of the noises in the feedback when modeling the user interests. Intuitively, if news clicked by the user is more semantically relevant with the news in the positive feedback sequence, this news is more likely the user true preference. Otherwise, if it is more semantically relevant with the news in the negative feedback sequence, it is more likely a noise for representing the user interest. As shown in Figure 3, for each news in the positive feedback sequence, we will conduct the intra-comparisons with the news in the positive sequence and inter-comparisons with the news in the negative sequence to decide its weight when representing the user. This module contains three sub-layers.

The first sub-layer is an intra-attention layer. For news $\mathbf{p}_j^t \in \mathbf{P}^t$, this layer uses it as the query to aggregate all news in $\mathbf{P}^t$ except $\mathbf{p}_j^t$ by the attention mechanism to obtain the sequence-level representation, $\hat{\mathbf{p}}_j^t = (\sum_{i \neq j} \alpha_{ji}^h \mathbf{p}_i^t)\mathbf{W}_v^h$, where

$$\alpha_{ji}^h = \frac{\exp\Big((\mathbf{p}_j^t\mathbf{W}_q^h)(\mathbf{p}_i^t\mathbf{W}_k^h)^\top/\sqrt{d}\Big)}{\sum\limits_{e \neq j} \exp\Big((\mathbf{p}_j^t\mathbf{W}_q^h)(\mathbf{p}_e^t\mathbf{W}_k^h)^\top/\sqrt{d}\Big)} \tag{4}$$

$\mathbf{W}_q^h$, $\mathbf{W}_k^h$, $\mathbf{W}_v^h \in \mathbb{R}^{d \times d}$ are learnable parameters.

The second sub-layer is an inter-attention layer. For $\mathbf{p}_j^t$, this layer uses it as the query to aggregate its relevant news in the negative feedback sequence $\mathbf{N}^t$ by the attention mechanism.

$$\hat{\mathbf{n}}_j^t = \texttt{Attn}(\mathbf{p}_j^t\mathbf{W}_q^h, \mathbf{N}^t\mathbf{W}_k^{h'}, \mathbf{N}^t\mathbf{W}_v^{h'}) \tag{5}$$

where $\mathbf{W}_k^{h'}$, $\mathbf{W}_v^{h'} \in \mathbb{R}^{d \times d}$ are learnable parameters.

The third sub-layer is a gated aggregation layer. The weight of the news $\mathbf{p}_j^t$ are decided by the semantic similarities between $\mathbf{p}_j^t$ and two sequence-level representations, $\hat{\mathbf{p}}_j^t$ and $\hat{\mathbf{n}}_j^t$.

$$\begin{aligned} s_j^p &= \tanh([\mathbf{p}_j^t; \hat{\mathbf{p}}_j^t]\mathbf{W}_1^u + \mathbf{b}_1^u)\mathbf{W}_2^u + b_2^u \\ s_j^n &= \tanh([\mathbf{p}_j^t; \hat{\mathbf{n}}_j^t]\mathbf{W}_3^u + \mathbf{b}_3^u)\mathbf{W}_4^u + b_4^u \\ \alpha_j &= \frac{\exp(s_j^p - \text{ReLU}(\gamma) * s_j^n)}{\sum_{i=0}^{i=l_p} \exp(s_i^p - \text{ReLU}(\gamma) * s_i^n)} \end{aligned} \tag{6}$$

where $\mathbf{W}_1^u$, $\mathbf{W}_3^u \in \mathbb{R}^{2d \times d}$, $\mathbf{W}_2^u$, $\mathbf{W}_4^u \in \mathbb{R}^{d \times 1}$, $\mathbf{b}_1^u$, $\mathbf{b}_3^u \in \mathbb{R}^d$, b_2^u, $b_4^u \in \mathbb{R}$ and γ are learnable parameters. Then, this layer will aggregate all news according to their weights to obtain the denoised representatioin, $\mathbf{p}_h^t = \sum_{j=0}^{j=l_p} \alpha_j \mathbf{p}_j^t$.

For the negative feedback sequence $\mathbf{N}^t$, we take a dual denoising process to obtain its final representation $\mathbf{n}_h^t$.

4.4 Graph Neural Network

If two news, r_i and r_j, are co-clicked by the user u_1 and r_i is also clicked by u_2, u_2 may also prefers r_j based on the idea of the collaborative filtering. Hence, we can further enrich the user interest representations by modeling the collaborative information. Like the knowledge graph, we build a collaborative graph $\mathcal{G} = \{(r_i, r_j) | r_i, r_j \in \mathcal{R}\}$ over the news set $\mathcal{R}$ based on the co-clicking relationships in the historical feedback matrix $\mathcal{Z}$. (r_i, r_j) indicates they are neighbors in the graph and have been clicked by the same user. To incorporate the collaborative information, we employ the graph transformer neural network (Shi et al., 2021) to model the news in the user feedback sequence.

First, for each news node $\mathbf{r}^o$ in $\mathbf{P}^o$ and $\mathbf{N}^o$, we compute the attention weights between it and its neighbors $\mathcal{N}(\mathbf{r}^o)$ in $\mathcal{G}$. $\mathcal{N}(\mathbf{r}^o)$ denotes the neighbor set of node $\mathbf{r}^o$. Take its neighbor $\mathbf{r}_k^o$ ($k \in \mathcal{N}(\mathbf{r}^o)$) as an example, the attention weight between $\mathbf{r}^o$ and $\mathbf{r}_k^o$ at the m-th head is calculated by

$$\alpha_k^m = \frac{\exp\left((\mathbf{r}^o \mathbf{W}_{m,1}^g)(\mathbf{r}_k^o \mathbf{W}_{m,2}^g)^\top / \sqrt{\hat{d}}\right)}{\sum\limits_{q \in \mathcal{N}(\mathbf{r}^o)} \exp\left((\mathbf{r}^o \mathbf{W}_{m,1}^g)(\mathbf{r}_q^o \mathbf{W}_{m,2}^g)^\top / \sqrt{\hat{d}}\right)}$$

where $\mathbf{W}_{m,*}^g \in \mathbb{R}^{d \times d / l_h'}$ are learnable parameters. l_h' is the number of heads and $\hat{d}$ is equal to d / l_h'.

Next, each news node will aggregate the information of its neighbors from multiple heads according to the attention weights. For the node $\mathbf{r}^o$, the representation aggregated from its neighbors is:

$$\hat{\mathbf{r}}^o = \Big\|_{m=1}^{m=l_h'} \left\{ \sum_{k \in \mathcal{N}(\mathbf{r}^o)} \alpha_k^m \mathbf{r}_k^o \mathbf{W}_{m,3}^g \right\} \quad (7)$$

where $\{\mathbf{W}_{m,3}^g \in \mathbb{R}^{d \times d / l_h'}\}_{m=1}^{m=l_h'}$ are trainable parameters. $\|$ denotes the concatenation operation for l_h' heads.

Finally, we will update the representation of each node by fusing its aggregated and original representations.

$$\begin{aligned} \widetilde{\mathbf{r}}^o &= \mathtt{Fuse}(\mathbf{r}^o, \hat{\mathbf{r}}^o) \\ &= \sigma([\mathbf{r}^o; \hat{\mathbf{r}}^o]\mathbf{W}_1^f) \odot \tanh([\mathbf{r}^o; \hat{\mathbf{r}}^o]\mathbf{W}_2^f) \end{aligned} \quad (8)$$

where $\mathbf{W}_1^f$, $\mathbf{W}_2^f \in \mathbb{R}^{2d \times d}$ are learnable parameters. $\odot$ denotes the element-wise multiplication operation. σ is the sigmoid function.

We can use this graph neural network to encode all news in the user positive and negative feedback sequences to obtain $\widetilde{\mathbf{P}}^o = [\widetilde{\mathbf{p}}_1^o, ..., \widetilde{\mathbf{p}}_{l_p}^o]$ and $\widetilde{\mathbf{N}}^o = [\widetilde{\mathbf{n}}_1^o, ..., \widetilde{\mathbf{n}}_{l_n}^o]$.

4.5 Collaborative Interest Encoder

The module aims to model user interests by aggregating the representations of two feedback sequences encoded by the graph neural network layer, which have incorporated the collaborative information. The structure of the collaborative interest encoder is similar to that of the semantic interest encoder and also contains two aggregators, a content-based aggregator and a denoising aggregator. The denoising aggregators have the same structure as the one in the semantic interest encoder. The only structural difference between two content-based aggregators of two encoders is that there is no multi-head self-attention operation in the content-based aggregator of the collaborative interest encoder. This is because the context information is already propagated by the graph neural work, which has a similar effect with the multi-head self-attention.

The inputs of this encoder are the positive sequence representation $\widetilde{\mathbf{P}}^o$ and the negative sequence representation $\widetilde{\mathbf{N}}^o$. The content-based aggregator will generate two user representations, $\mathbf{p}_s^o$ and $\mathbf{n}_s^o$, based on two sequence representations, respectively. Similarly, the denoising aggregator will denoise two sequences and generate two user representations $\mathbf{p}_h^o$ and $\mathbf{n}_h^o$.

4.6 Fusion Net

There are two fusion nets as shown in Figure 2. They are used to fuse multiple user interest representations extracted by two interest encoders to form a comprehensive user representation. For different user-candidate news (u, r) pairs, the fusion net dynamically allocates different weights for different interest representations. Two fusion nets have similar structures but different parameters. We take the one for the semantic interest encoder as an example to detail the fusion process.

The fusion net first represents the (u, r) pair. It should mitigate the effect of two interest encoders and independently calculate the weights for the output representations of two encoders. Hence, it uses the outputs of the title encoder to represent (u, r), $\mathbf{f}^t = [\mathbf{u}_f^t; \mathbf{r}_c^t]$, where $\mathbf{u}_f^t = \texttt{Aggregate}([\mathbf{P}^t|\mathbf{N}^t])$. $\mathbf{P}^t$, $\mathbf{N}^t$ and $\mathbf{r}_c^t$ are the title representations of the news in user positive and negative feedback sequences and the candidate news extracted by the title encoder. $[|]$ denotes the row-wise concatenation for matrices.

Then, this module leverages four different fully connected layers to calculate the weights for four representations extracted by the semantic interest encoder (i.e., $\mathbf{p}_s^t$, $\mathbf{n}_s^t$, $\mathbf{p}_h^t$ and $\mathbf{n}_h^t$). For example, the weight of $\mathbf{p}_s^t$ is calculated by

$$\beta_s^p = \tanh(\mathbf{f}^t\mathbf{W}_1^{p,s} + \mathbf{b}_1^{p,s})\mathbf{W}_2^{p,s} + b_2^{p,s} \tag{9}$$

where $\mathbf{W}_1^{p,s} \in \mathbb{R}^{2d\times d}$, $\mathbf{W}_2^{p,s} \in \mathbb{R}^{d\times 1}$, $\mathbf{b}_1^{p,s} \in \mathbb{R}^d$, $b_2^{p,s} \in \mathbb{R}$ are learnable parameters. The weights, β_s^n, β_h^p and β_h^n, of the representations $\mathbf{n}_s^t$, $\mathbf{p}_h^t$ and $\mathbf{n}_h^t$ can be calculated by the same way in Eq.(9).

Finally, the user content-view representation is calculated by

$$\mathbf{u}^t = \beta_s^p * \mathbf{p}_s^t + \beta_s^n * \mathbf{n}_s^t + \beta_h^p * \mathbf{p}_h^t + \beta_h^n * \mathbf{n}_h^t \tag{10}$$

Another fusion net is used to fuse four interest representations extracted by the collaborative interest encoder and has a similar structure with the above one. The only difference is that it uses the outputs of the news ID embedding layer to represent the (u, r) pair, $\mathbf{f}^o = [\mathbf{u}_f^o; \mathbf{r}_c^o]$, where $\mathbf{u}_f^o = \texttt{Aggregate}([\mathbf{P}^o|\mathbf{N}^o])$. Then, it uses $\mathbf{f}^o$ to calculate the respective weights θ_s^p, θ_s^n, θ_h^p and θ_h^n for four interest representations $\mathbf{p}_s^o$, $\mathbf{n}_s^o$, $\mathbf{p}_h^o$ and $\mathbf{n}_h^o$ by the same way in Eq.(9). The final user graph-view representation is calculated by

$$\mathbf{u}^o = \theta_s^p * \mathbf{p}_s^o + \theta_s^n * \mathbf{n}_s^o + \theta_h^p * \mathbf{p}_h^o + \theta_h^n * \mathbf{n}_h^o \tag{11}$$

4.7 Prediction

Following (Wu et al., 2019c), the clicking probability score $\hat{y}$ is computed by the inner product of the user representation and the candidate news representation: $\hat{y} = \mathbf{u}^{t\top}\mathbf{r}_c^t + \mathbf{u}^{o\top}\mathbf{r}_c^o$, where $\mathbf{u}^{t\top}\mathbf{r}_c^t$ stands for the score calculated from title information and $\mathbf{u}^{o\top}\mathbf{r}_c^o$ stands for the score calculated from collaborative information.

4.8 Training

Following (Wu et al., 2019c), for each positive sample, we randomly select l_k negative samples from the same user to construct a $l_k + 1$ classification task. Each output of the DRPN for a classification sample is like $[\hat{y}^+, \hat{y}_1^-, ..., \hat{y}_{l_k}^-]$, where $\hat{y}^+$ denotes the clicking probability score of the positive sample and the rest denote the scores of the l_k negative samples. We define the training loss (to be minimized) as follows.

$$\mathcal{L} = -\sum_{i\in\mathcal{P}} \log\left(\frac{\exp(\hat{y}_i^+)}{\exp(\hat{y}_i^+) + \sum_{j=1}^{j=l_k}\exp(\hat{y}_{i,j}^-)}\right) \tag{12}$$

where $\mathcal{P}$ denotes the set of positive samples.

# users	654870	**# avg. titles words**	12.66
# news	104153	**# positive samples**	1048414
# words	54292	**# negative samples**	25145229
# avg. positive feedback sequence length			4.14
# avg. negative feedback sequence length			96.80

Table 1: Statistics of the dataset.

4.9 Computation Complexity

The time complexity of the title encoder is $\mathcal{O}(L^2d + Ld^2)$, where L is the title length and d is the embedding size. The time complexity of each interest encoder is $\mathcal{O}((l_p + l_n)d^2 + (l_p^2 + l_n^2 + (l_p + l_n)^2)d)$ where l_p and l_n are the lengths of positive and negative feedback sequences. The time complexity of GNN is $\mathcal{O}(|\mathcal{G}|d)$, where $|\mathcal{G}|$ denotes the number of edges that existed in collaborative graph. Hence, The overall time cost is $\mathcal{O}((l_p + l_n)(Ld^2 + L^2d) + (l_p^2 + l_n^2 + (l_p + l_n)^2 + |\mathcal{G}|)d)$.

During the inference phase, we can compute the news representations in advance and the computation complexity will be $\mathcal{O}((l_p^2 + l_n^2 + (l_p + l_n)^2)d)$.

5 Experiment

5.1 Dataset

There is no off-the-shelf dataset in which the user profile includes both positive and negative historical feedback sequences. Therefore, we use MIND [1] dataset (its original user profile only contains positive feedback) to re-build one to conduct the experiments. The original MIND dataset contains the user impression logs. An impression log records the news displayed to a user when visiting the news website homepage at a specific time, and the click behaviors on the news list. We re-build the dataset based on the MIND's impression logs as follows: (1) Select the impression logs of the first 5 days of the original training set. Then we add the news that a user has seen but did not click to his negative feedback sequence, and add the news he clicked

---

[1] https://msnews.github.io/

to his positive feedback sequence. In this manner, the user profile includes both positive and negative historical feedback sequences; (2) Training set: the impression logs of 6-th day of the original training set; (3) Validation set: the first 10% chronological impression logs of the original validation set; (4) Testing set: the last 90% chronological impression logs of the original validation set.

The training, validation, and testing sets use the same user profile built in Step (1). Since the user profiles are only built in Step (1) which is ahead of Step (2)-(4), there is no label leakage to validation and testing sets. Moreover, same as the original MIND dataset, the re-built dataset also has 44.6% users of validation set and 48.7% users of test set that are not shown in the re-built training set. Table 1 shows some statistics of the re-built dataset.

5.2 Baseline Approaches and Metrics

We evaluate the performance of DRPN by comparing it with several baseline methods, including: (1) *LibFM* (Rendle, 2012), factorization machine (FM); (2) *DeepFM* (Guo et al., 2017), which combines the FM and neural networks; (3) *DKN* (Wang et al., 2018a), which uses the CNN to fuse the entity and word embeddings to learn news representations; (4) *LSTUR* (An et al., 2019), which uses the GRU to model short- and long-term interests from the click history; (5) *NPA* (Wu et al., 2019b), which introduces the attention mechanism to select important words and news; (6) *DEERS* (Zhao et al., 2018), which uses GRU to encode positive and negative feedback sequences; (7) *DFN* (Xie et al., 2020), a factorization-machine based network which uses transformers to encode both positive and negative feedback sequences to enhance performance; (8) *GERL* (Ge et al., 2020), which constructs user-news graph to enhance the performance; (9) *NAML* (Wu et al., 2019a), which uses multi-view learning to aggregate different kinds of information to represent news; (10) *NRMS* (Wu et al., 2019c), which uses multi-head self-attention to learn news and user representations; (11) *NAML + TCE*, which incorporates the denoising training strategy TCE (Wang et al., 2021) into NAML; (12) *NRMS + TCE*, which improves NRMS by using TCE.

Following the previous news recommendation work (Wu et al., 2020b, 2019c; Ge et al., 2020), we use AUC, MRR, nDCG@5, and nDCG@10 scores as our evaluation metrics.

5.3 Implementation Details

For DRPN, the representation dimension d is set to 300. We use the *GloVe.840B.300d* (Pennington et al., 2014) as the pre-trained word embeddings. The maximum title length is set to 15. The lengths of feedback sequences l_p and l_n are set to 30 and 60. Padding and truncation are used to keep sequence and word numbers the same. The head number l_h in multi-head self-attention is set to 6. The hidden size d' in the gated aggregation layer is set to 200. The head number in graph neural network l'_h is set to 2. The negative sampling ratio l_k is set to 4. When preparing data for graph neural network, we only input sub-graph that contains nodes in the user feedback sequences. Moreover, we pick the maximum 5 neighbor nodes for each node r in user feedback sequences, which are most frequently co-clicked with r. We have also released the source code at `https://github.com/chungdz/DRPN`.

For NRMS, DKN, LSTUR, NPA, and NAML, we use the official code and settings [2]. For others, we reimplement them and set their parameters based on the experimental setting strategies reported by their papers.

For fair comparisons, all methods only use the news ID, title, category and subcategory as features. The validation set was used for tuning hyperparameters and the final performance comparison was conducted on the test set.

Models	**AUC**	**MRR**	**nDCG@5**	**nDCG@10**

DRPN-P	65.89	31.11	34.38	40.59

Table 3: Performance comparison of all variants of DRPN. Best results are highlighted in bold.

model, DRPN, outperforms all baselines on the news recommendation datasets. Second, among all baselines, the methods which use the deep neural networks to model the news (i.e., DKN, NPA, LSTUR, DFN, DEERS, NAML, GERL, NRMS) perform better than the feature-based methods (e.g., LibFM and DeepFM). This performance improvement should be attributed to better news representation methods. Among the deep neural methods, NRMS+TCE achieves the best performance by using two level multi-head self-attention to learn user representations and using TCE to denoise the negative samples. Third, among two baselines that use both positive and negative feedback, DFN performs worse than DEERS. The reason may be that original DFN depends on the explicit feedback but the experimental dataset only contains implicit feedback. Compared with NAML, DEERS has a competitive performance even if its news encoder is a simple pooling layer. This also proves the effectiveness of the negative implicit feedback.

5.5 Ablation Study

To highlight the individual contribution of each module, we use the following variants of DRPN to run an ablation study: (1) *DRPN-D*, which removes the denoising aggregator; (2) *DRPN-G*, which removes the knowledge graph part; (3) *DRPN-DG*, which removes the knowledge graph part and the denoising aggregator; (4) *DRPN-N*, which only uses the positive feedback; (5) *DRPN-P*, which only uses the negative feedback.

The results are shown in Table 3. First, DRPN-D and DRPN-G perform worse than DRPN, proving the effectiveness of the designed denoising module and the collaborative graph. Second, the results of DRPN-N and DRPN-P indicate the effectiveness of negative and positive feedback, respectively. Third, even without deliberately designing, by using both positive and negative implicit feedback, DRPN-DG can achieve competitive performance compared with the strongest baseline NRMS+TCE. This further proves the effectiveness of the negative feedback.

5.6 Case Study

To intuitively illustrate the effectiveness of the denoising aggregator, we sample a user and visualize his historical feedback attention weights in the denoising aggregator of the semantic interest encoder. The upper part of the Figure 4 shows the attention weights and ranks the news in descending order of the attention weight. We can find in positive feedback sequence, the top 4 news are about sports and weather and the last 4 news are about music, movie, finance, and lifestyle. Meanwhile, in negative feedback sequence, the top 4 news are about finance, music, politics, and lifestyle, and the last 4 news are all about sports. This indicates that the denoising aggregator believes that the user likes sports, and dislikes the topics such as finance, music, movies, politics, and lifestyle. As shown in the lower part of Figure 4, based on the predicted user preferences, we can see DRPN prefers to recommend the sports news for this user. Moreover, in the validation data, we can observe that this user clicks the top 2 recommended news and ignores the last 2 news. It suggests the user preference extracted by the denoising aggregator is consistent with the user's real behaviors. In summary, the visualization results indicate the denoising module can better capture the user's real preferences by conducting the inter- and intra- comparisons between the positive and negative implicit feedback sequences.

6 Conclusion

In this paper, we propose a novel deep neural news recommendation model DRPN. In DRPN, we design two aggregators to extract user interests from both positive and negative implicit feedback. The content-based aggregator focuses on the contents in the news representations and the denoising aggregator aims to mitigate the noise impact commonly existing in the implicit feedback. Besides, apart from the title information, DRPN also exploits the collaborative information by the graph neural network to further improve the recommendation performance. Experimental results on a large-scale public dataset demonstrate the state-of-the-art performance of DRPN. The further study results also show the effectiveness of the denoising module.

A Discussion

A.1 Limitations

In this paper, to better learn the representations, our method refines the historical behaviors of the user by the denoising manner. There are still some potential directions to further improve our approach. First, since the user profile in the experimental dataset only contains the historical behaviors and has no basic information (e.g., gender and age), our current approach doesn't support these features but they are widely used in practice. After these features are ready, we can convert them to embeddings and fuse them with the semantic interest representations obtained by two interest encoders to better represent the user. Second, the news generally contains many forms of features except for the title (such as the cover image and author information) and our approach will explore how to involve more features to better represent the news.

A.2 Potential Risks

Our approach is based on the collaborative filtering, which may lead to that all of recommended news are similar to what the user has seen. This is a common problem faced by the majority of recommender systems. The concentration of a large number of similar information may narrow users' perspective and result in an imbalance on the personal information structure (Li and Wang, 2019). Our method can combine with some rule/human-based strategies (such as popularity based recommendation) to improve the recommendation diversity to alleviate this problem.

Continual Machine Reading Comprehension via Uncertainty-aware Fixed Memory and Adversarial Domain Adaptation

Abstract

Continual Machine Reading Comprehension aims to incrementally learn from a continuous data stream across time without access the previous seen data, which is crucial for the development of real-world MRC systems. However, it is a great challenge to learn a new domain incrementally without catastrophically forgetting previous knowledge. In this paper, MA-MRC, a continual MRC model with uncertainty-aware fixed **M**emory and **A**dversarial domain adaptation, is proposed. In MA-MRC, a fixed size memory stores a small number of samples in previous domain data along with an uncertainty-aware updating strategy when new domain data arrives. For incremental learning, MA-MRC not only keeps a stable understanding by learning both memory and new domain data, but also makes full use of the domain adaptation relationship between them by adversarial learning strategy. The experimental results show that MA-MRC is superior to strong baselines and has a substantial incremental learning ability without catastrophically forgetting under two different continual MRC settings.

1 Introduction

Recently, Machine Reading Comprehension (MRC) has attracted wide attention and achieved remarkable success when solving specific tasks in stationary environments, such as answering factual questions with wikipedia articles or answering narrative questions with web search logs (Seo et al., 2017; Seonwoo et al., 2020; Zhang et al., 2021; Wu and Xu, 2020). However, the answering scenario changes over time in real-world applications. For example, the dialog system should continuously adapt to new user requirements (Abujabal et al., 2018; Madotto et al., 2021). In this paper, we focus on one of the most typical scenario changes for MRC tasks: the domain data shift. Existing stationary-trained MRC systems are usually trained with in-domain data but are applied to new domain data (Fisch et al., 2019). Therefore, it is necessary to build a non-stationary MRC that continually learns with incremental domain data.

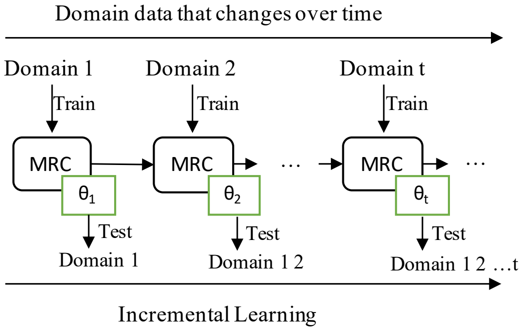

Figure 1: Illustration of a continual MRC task.

We formulate such a challenging problem as *Continual MRC* task, which is required to incrementally learn over sequential domain data and perform well on all seen domain data. Figure 1 illustrates the incremental learning and testing processing. In this scenario, the MRC system can only trained on the latest coming domain data without access the previous seen data. To tackle this issue, if we directly fine-tune the MRC model on each new incoming domain, the performance on earlier domains will significantly drop (Su et al., 2020). Another naive approach is to retrain the whole MRC model from scratch, but it is costly and time-consuming. Hence it is a great challenge for incrementally learning without largely forgetting previously acquired knowledge.

Existing studies for continual MRC can mainly be divided into three categories. The first class is model expansion techniques that design domain-individual classifier for each in coming domain (Su et al., 2020). However, it is expensive and unpractical in real-world. The second class borrows the regularization idea, which utilizes an ad-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2330 - 2339
July 10-15, 2022

ditional loss term to aid knowledge consolidation when learning new domains. For example, Su et al. (2020) added a penalty that restricts the change of important parameters to prevent forgetting previous knowledge. The third class is episodic memory based methods. For example, de Masson d'Autume et al. (2019) introduced a key-value memory module that stored previously seen examples for sparse experience replay and gradient-based local adaptation. Abujabal et al. (2018) proposed template-based Never-Ending KB-QA that learned new templates by capturing new syntactic structures with a semantic similarity function between questions and user feedback.

However, the above methods still have limitations, mainly including two aspects. On the one hand, to prevent catastrophic forgetting, these methods only design consistent constraints of model output or gradient for previous and new domains, while ignoring the domain adaptation relationship between them. However, transfer learning can help the MRC model generalize to other domains. On the other hand, the memory update strategy for continual MRC is limited. Some previous work stores fixed examples for each incoming domain. It greatly grows the number of samples kept in memory and leads to expensive costs. Other methods that limit the maximum number of memory for all seen domains usually update the memory by random sampling, ignoring the forgotten degree of different samples. In fact, the continual model should pay more attention to samples that are more likely to be forgotten.

To handle the above limitations, this paper proposes MA-MRC, an incremental model that solves continual MRC task via Uncertainty-aware fixed **M**emory and **A**dversarial Domain Adaptation. Concretely, MA-MRC 1) introduces a fixed-size memory to store a small number of samples in previous domain, which are later periodically replayed when learning new domain; and 2) updates the memory with an uncertainty-aware strategy that takes the forgotten degree of previous data into account; 3) leverages an adversarial learning strategy to make full use of the domain adaptation relationship between different domains with a domain discriminator, so as to help generalize and avoid overfitting very small memorized examples. The intuition behind this is to mimic the human learning process that replays the memory and adapts to new domains.

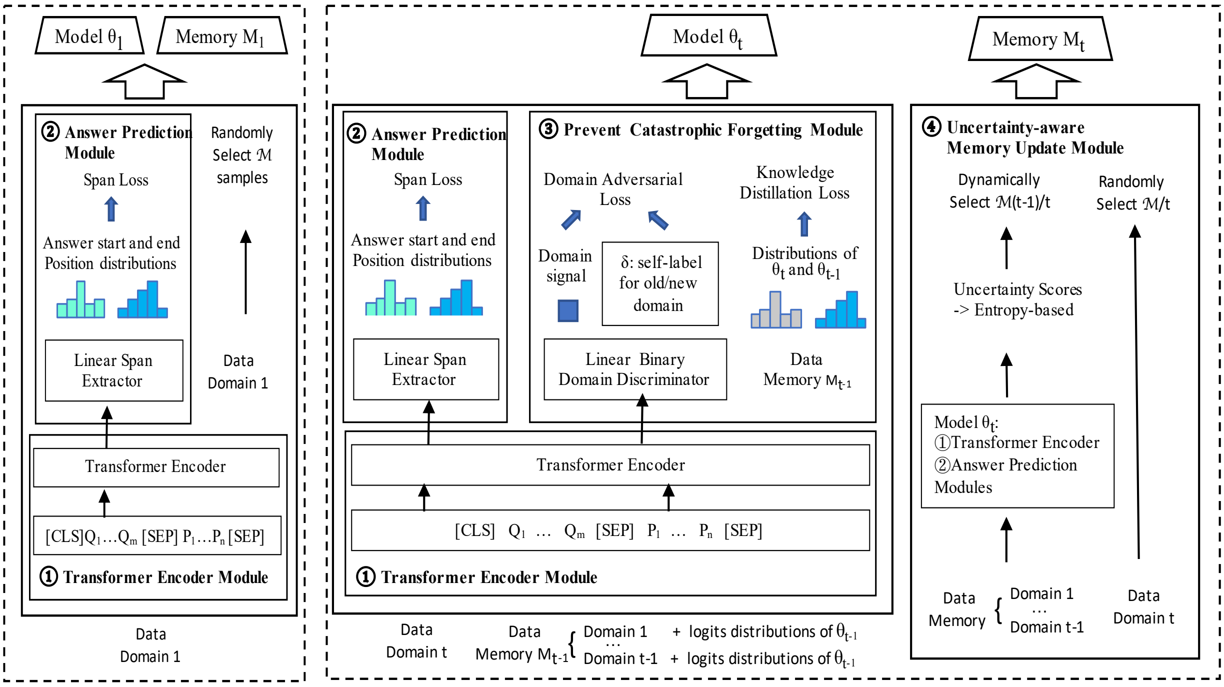
The key contributions of this work are: (1) This paper proposes a continual MRC model, MA-MRC, which learns new domain data incrementally. (2) Applying uncertainty-aware **M**emory and **A**dversarial learning and to MRC model contributes to strong incremental learning ability. (3) The experimental results on two different continual MRC settings indicate that MA-MRC obtaines good incremental learning ability without largely forgetting and significantly outperforms strong baselines.

2 Related Work

2.1 Continual Learning

Continual Learning (CL) mainly aims to overcome the catastrophic forgetting problem when learning on sequential new tasks incrementally (French, 1999). Existing work follows three directions: architectural, regularization, and memory-based approaches. The architectural methods change the network's architecture and add task-specific parameters, e.g., Dynamically Expandable Network (Yoon et al., 2018) and Reinforced Continual Learning (Xu and Zhu, 2018). The regularization-based techniques aid knowledge consolidation when learning new tasks. For instance, EWC and Online EWC (Kirkpatrick et al., 2017; Schwarz et al., 2018) slow down the learning of parameters important for previous tasks. The third class is to save previous samples and learn a new task with a forgetting loss defined on them, such as GEM (Lopez-Paz and Ranzato, 2017), A-GEM (Chaudhry et al., 2019), DER (Buzzega et al., 2020), and MER (Riemer et al., 2019).

CL in MRC. Few previous studies apply continual learning to MRC. Su et al. (2020) adapted EWC method and enlarged the MRC architecture when a new domain arrives. Su et al. (2020) added a penalty regularization that restricts the change of important parameters to prevent forgetting. de Masson d'Autume et al. (2019) and (Abujabal et al., 2018) designed episodic memory based methods that store training samples from previously seen data, which are later rehearsed to learn new domains. In this paper, we solve the continual MRC problem of incrementally learning over sequential domains, and build our continual model based on the above memory-based and penalty regularization paradigm.



(a) Initial Training.

(b) Incrementally Learning for New Domain Data.

Figure 2: The overview of the proposed MA-MRC framework with sequential domain data.

2.2 Domain Adaptation

Domain adaptation aims to learn discriminative feature features and generalize to other new domains and is usually achieved by learning domain-invariant features (Ben-David et al., 2010; Ganin et al., 2016). For MRC under domain shift, previous methods (Wang et al., 2019; Cao et al., 2020; Lee et al., 2019) reduce domain discrepancy by a discriminator network that is trained to distinguish features of the target from source domains. However, recent work usually transfers the model from source to target. In this paper, we explore the domain adaptation under continual setting.

3 Proposed Method

3.1 Problem Statement

For the task of continual MRC, we assume that the learning framework has access to streams of MRC data from T different domains, denoted by $Data = \{D_1, D_2, ..., D_T\}$. Each domain data, e.g. $D_t = \{P_n, Q_n, A_n\}_{n=1}^{|D_t|}$, consists of a series of <passage, question, answer> triples, where $|D_t|$ is the sample number of D_t. The MRC model is required to continually learn over each incoming domain data. More specifically, at each step t, the MRC model only observes D_t domain data, and is required to perform well on both the t-th domain data and previous $t-1$ domain data. Hence, after training on D_t, the model will be evaluated on all seen t domains. To make the MRC model perform well on previous tasks, during the continual learning process, a memory M is to set to store a small number of samples in previous domain data in a fixed-size memory $\mathcal{M} \ll |D_{old}|$.

This paper focuses on the span extractive MRC. Inspired by Su et al. (2020), we perform two different continual domain settings: CDA-C and CDA-Q, which define different domains according to paragraph type and question type, respectively.

3.2 Method overview

Figure 2 shows the overview of MA-MRC. As shown in Figure 2(a), we first train a backbone MRC model (Transformer Encoder and Answer Prediction modules) on the initial domain data and randomly select $\mathcal{M}$ training samples as the initial memory M. Figure 2(b) shows the process of learning new domain data. When the t-th domain data is arising, MA-MRC synchronously 1) fine-tunes the backbone MRC model with both the t-th domain and memory data; 2) adversarially learns domain-invariant and transfer representations via a domain discriminator that distinguishes memory from current data, so as to generalize well on new domain and avoid overfitting very small memory samples;

Algorithm 1 Incremental Training for MA-MRC

```
Input:
    T Training domain data $Data = \{D_1, D_2, ..., D_T\}$
    A memory $M$ of size $\mathcal{M}$
Output:
    The Continual MRC model $\theta_T$
    // Initial Training
Train the backbone MRC model $\theta_1$ with $D_1$
$M \leftarrow RandomSampling(D_1, \mathcal{M})$
// Incrementally Learning for New Domain
for $t = 2, ..., T$ do
    Define the domain discriminator $\theta_D$
    Incrementally learning $\theta_t \leftarrow$ update $\theta_{t-1}$ and $\theta_D$ with $\bigtriangledown\mathcal{L}_{\text{final}}$ on $D_t, M_{t-1}$
    Calculate need importance based on uncertainty for each sample in $M_{t-1}$
    $M_t \leftarrow WeightSampling(M_{t-1}, \frac{\mathcal{M}(t-1)}{t}) + RandomSampling(D_t, \frac{\mathcal{M}}{t})$
end for
return the final MA-MRC model $\theta_T$;
```

3) utilizes knowledge distillation to encourage the model to mimic its original responses for past domain samples. After finishing training at t-th step, we update the memory with an uncertainty-aware sampling strategy that focuses on remembering what the model most needs. More details about the training process are shown in Algorithm 1.

3.3 Initial Training

Note that there is only one domain data at the beginning, so the initial training with D_1 can be seen as a special case of formal extractive MRC tasks. Therefore, we build a normal backbone MRC model θ_1 (a standard BERT-MRC model with Transformer Encoder and Answer Prediction Modules) on the first domain data D_1. We initialize a fixed-size memory M_1 to keep previous training samples that are periodically replayed while learning the new domain.

3.3.1 Prepare Backbone model

Transformer Encoder Module: First, a pre-trained L Transformer encoder blocks is used to convert the input sequence $S = [\langle CLS\rangle, Q, \langle SEQ\rangle, P, \langle SEQ\rangle]$ into contextual representations. Then, the last block output $H_L = \text{BERT}(S) \in \mathbb{R}^{(l)\times h}$ is taken as the contextual representation, where h is the hidden dimension of BERT, l is the sequence length.

Answer Prediction Module: A linear layer is applied on the contextual representation H_L to calculate the probability distribution of start and end positions of candidate answer:

$$p^{start} = \text{Softmax}(H_L W^s), \quad (1)$$

$$p^{end} = \text{Softmax}(H_L W^e), \quad (2)$$

where $W^s, W^e \in \mathbb{R}^h$ are learnable parameters.

Objective Function: The loss function of the backbone MRC is the cross-entropy:

$$\min_{\theta_{T,AP}} \mathcal{L}_{span} = -\log p^{start}_{y^s} - \log p^{end}_{y^e}, \quad (3)$$

where y^s and y^e are the ground-truth start and end indices of the corresponding sample, respectively.

3.3.2 Memory Initialization

For the first domain, to preserve the data distribution of the current domain as much as possible, we randomly select $\mathcal{M}$ training samples from D_1 as the initial memory M_1.

3.4 Learning for New Domain

When the t-th domain data is coming, we can access the current data D_t and the memory M_{t-1}. If we just finetune the backbone model, the model is hard to have good transfer ability and may overfit on the few memorized samples. Hence the MA-MRC utilizes the adversarial learning strategy to fully make use of the domain adaptation relationship between the previous and the current domain. After the t-th training step, we dynamically update memory M with an uncertainty-aware strategy to store the training samples that the model most needs to replay.

3.4.1 Memory-based Adversarial Training

To fully use the domain adaption relationship, we adversarially learn the domain-invariant and transfer representations of the memory and current domain data. Inspired by domain adaptation theory, MA-MRC introduces a domain discriminator and build a two-player min-max game. The first player, a domain discriminator D, distinguishes memory data from the current new domain data. Here D is a basic binary discriminator that has a three linear layer followed by a sigmoid activation function. The second player, the Transformer Encoder T, aims to learn features that confuse D. We utilize empirical Maximum Mean Discrepancy as distance measure to reduce the difference between marginal representation distributions and make them similar:

$$d = MMD(T(M_{t-1}), T(D_t)). \tag{4}$$

Finally, this learning procedure can be described by the following *minimax* game:

$$\min_{\theta_T} \max_{\theta_D} \mathcal{L}_{adv} = -\frac{1}{\mathcal{M}} \sum\nolimits_{i=1}^{\mathcal{M}} \log D(T(P_i, Q_i)) \\ -\frac{1}{|D_t|} \sum\nolimits_{j=1}^{|D_t|} \log(1 - D(T(P_j, Q_j))) + d, \tag{5}$$

where $\mathcal{M}$ and $|D_t|$ are the number of training samples from memory and the current domain.

3.4.2 Knowledge Distillation

It is obvious that a good continual model can learn a new domain data well while approximating the behavior observed in the old ones. Then, we leverage knowledge distillation constraints to encourage MA-MRC to mimic its original responses for past samples. Specifically, we seek to minimize the distance between the corresponding pre-softmax responses to preserve the knowledge about previous memory data:

$$\mathcal{L}_{KL} = KL(logits^{start}_{\theta_{t-1}} || logits^{start}_{\theta_t}) \\ + KL(logits^{end}_{\theta_{t-1}} || logits^{end}_{\theta_t}), \tag{6}$$

where $logits$ are the probability distribution before softmax and KL is the KL divergence.

3.4.3 Uncertainty-aware Memory Updating

Unlike other approaches that store fixed examples for each domain, we use a fixed memory for all domains to avoid memory growing. Therefore, when a domain arises, it is necessary to remove some old samples in memory to store new data. We design a dynamic sampling strategy that focuses on samples what the model most needs to replay. Based on existing trained MRC model θ_t, we first compute the uncertainty for each sample in memory by a unsupervised *Entropy-based* stragety:

$$u^{entropy} = \log p^{start}_{y^s} + \log p^{end}_{y^e}. \tag{7}$$

Then we calculate the gap between the above uncertainty and 1) the respective previous *best* uncertainty 2) the *average* uncertainty of all memory data, and normalize these metric differentials to create a probability distribution. For ease of exposition, we define these two normalization calculations as $norm^1$ and $norm^2$. Note that we will sample $\frac{\mathcal{M}}{t}$ data for each previously seen domain in memory with the above distribution separately. Finally, we get $\frac{\mathcal{M}(t-1)}{t}$ data from memory and ramdonly sample $\frac{\mathcal{M}}{t}$ data from current domain. In this way, the more forgotten a memory sample is, the more it will be retained.

3.4.4 Objective Function

When incrementally learning for a new domain, the span loss in answer prediction module $\mathcal{L}'_{span}$ considers all current domain data D_t and the memory data M, while the KL loss only takes memory data M into account. Finally, the overall loss function at the t-th step is formulated as:

$$\min_{\theta_{T,AP}} \max_{\theta_D} \mathcal{L}_{\text{final}} = \mathcal{L}'_{span} + \mathcal{L}_{adv} + \mathcal{L}_{KL}. \tag{8}$$

4 Experiment

4.1 Continual MRC Datasets

Inspired by Su et al. (2020), this paper deals with two continual MRC under domain adaptation: CDA-C and CDA-Q. For CDA-C setting, we regard MRC datasets with different passage corpora (e.g., Wikipedia, News, and Web snippets) as different domains and choose five datasets: SQuAD 1.1 (Rajpurkar et al., 2016), HotpotQA (Yang et al., 2018), Natural Questions (Trischler et al., 2017), NewsQA (Trischler et al., 2017), and TriviaQA (Joshi et al., 2017). Due to computational limits, we use the curated version provided by Fisch et al. (2019). For each dataset, we randomly sample 10,000 <question, context, answer> triples from the original training datasets for continual training, and the original dev sets for testing. For CDA-Q setting, we make use of the original SQuAD

1.1 (Rajpurkar et al., 2016) and split it into eight domains according to the question type such as what, why, and how. The detailed statistics of these datasets are shown in Table 1.

4.2 Methods Compared

• **Bounds.** We design a standard BERT-MRC (the same as the backbone MRC model in Sec 3.3) as the basic model and then define two bounds on it: 1) **Lower Bound** continually fine-tunes the BERT-MRC model for each new domain without memorizing any historical examples. 2) **Upper Bound** remembers all examples in history and continually re-train the BERT-MRC model with all data.

• **EWC** (Kirkpatrick et al., 2017) restricts the change of model parameters for previous domains via elastic weight consolidation and a special L_2 regularization. Hence it can slow down the learning of parameters important for all previous domains.

• **Online EWC** (Schwarz et al., 2018), the extension of EWC, which only consider the restriction for the latest model parameters.

• **DER** (Buzzega et al., 2020), memory-based approaches, leverages knowledge dsistillation for retaining past experience.

• **DER++** (Buzzega et al., 2020), the extension of DER, uses an additional term on memory.

• **AGEM** (Chaudhry et al., 2019), memory-based approaches, uses a constraint that enables the projected gradient to decerease the average loss on previous seen domains.

4.3 Evaluation Metrics

Exact Match (EM) and word-level F1 score are used to evaluate the performance of MRC model in a single domain data. As for the continual domain adaptation setting, two common evaluation settings in continual learning theory are adopted: the average and the whole performance:

$$F1_{avg} = \frac{1}{T}\sum_{i=1}^{T} F1(D^i_{test}), \tag{9}$$

$$F1_{all} = F1(D^{1:T}_{test}). \tag{10}$$

The former is the average F1 score on test sets of all seen domain, and the latter is the whole F1 score on the test sets.

4.4 Implementation Details

We initialize the transformer encoder layer with the pre-trained BERT$_{\mathrm{BASE}}$ model officially released by Google[1]. The maximum sequence length is 384, and the batch size is 30. We set memory size $\mathcal{M}$ 400 default that means the memory stores up to 400 training samples for previous seen domain. When incrementally learn the new incoming domain data at t-th step, we first reinitialize the parameters of the domain discriminator θ_D. Then use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 3e-5 and training MA-MRC model for 3 epochs.

4.5 Results and Discussion

4.5.1 Main Results

For the task of continual MRC, the overall results under CDA-C and CDA-Q setting and are shown in Table 2 and Table 3. Taking $F1_{avg}$ and $F1_{all}$ as two overall performance evaluations, we have the following findings: (1) The proposed MA-MRC methods outperform other baselines by a significant margin on both two continual settings. (2) The performance trend of different methods are not consistent across two continual settings. For example, OnlineEWC performs well under CDA-C but performs poorly CDA-Q, and all memory-based methods outperform consolidation-based methods under CDA-Q but not CDA-C. The reason is that the characteristics of the domains and the continual learning difficulty are different. Concretely, it is obvious that the domain data in CDA-C is more different and more difficult than that in CDA-Q. (3) There is a big gap between all the models and the upper bound. We further demonstrate the evaluation results of the proposed MA-MRC and UpperBound methods on each domain at each continual learning step t in Table 6. The results indicate that MA-MRC indeed forgets knowledge learned on previously seen domain data, and there remain lots of things to be explored for continual MRC.

Besides, we plot the average F1 performance of models during the whole continual learning process in Figure 3 to investigate how performance

DER++	$\theta_{T,AV}$	56 m	38 m
MA-MRC($norm^1$)	$\theta_{T,AV,D}$	61 m	40 m
MA-MRC($norm^2$)	$\theta_{T,AV,D}$	60 m	39 m

Table 10: Parameters and speed comparison.

changes. We observe that the performance of all models decreases in some degree with increasing numbers of domains under both CDA-C and CDA-Q settings. However, the proposed MA-MRC methods outperform other baselines and achieve better performance on the whole domain data.

4.5.2 Ablation Study

To better understand our proposed model, we conduct ablation studies to see the effectiveness of each model component. The results in Table 4 and Table 5 demonstrate that both knowledge distillation and adversarial training contribute to avoiding largely forgetting. For incremental domain learning, knowledge distillation is a naive way to enforce the model to remember its original responses for previous domains. What is more, the adversarial domain adaptation, can make MRC model learn domain-invariant and transfer representations better. Table 6 shows the evaluation results of w/o Adv at each continual step. Though w/o Adv obtains a slightly higher performance on the last two domains than MA-MRC model, it has a more harmful forgetfulness on the very previous seen domain. The results prove that the adversarial learning indeed helps for remembering previous knowledge.

4.5.3 Effect of Memory

Memory Size $\mathcal{M}$. Table 8 shows the performance with three different memory size $\mathcal{M}$: 200, 300, and 400. In low memory scenario, i.e., $\mathcal{M} = 200$, the proposed method performs poorly. The reason is that the adversarial domain adaption has difficulty transferring well with a too small memory. Therefore, as the number of memory samples increases, it will be more conducive to transfer to a new domain, and the overall performance will be better. We believe that an appropriate memory size could lead to better performance.

Uncertainty-aware Sampling. We replace the uncertainty-aware memory updating strategy with another two strategies. First, we use another uncertainty measurement that takes heuristic max softmax probability of spans as the uncertainty: $u^{prob} = \max_{i,j}(p_i^{start} + p_j^{end})$. The second strategy is random sampling. The experimental results in Table 7 indicate that the uncertainty-aware sampling (both *Entropy-based* and *Probability-based* uncertainty) is better than random sampling.

4.5.4 Effect of Domain Order

Table 9 shows the results of different domain orders. Order 1 is a descending order based on the number of training samples in each domain and order 2 is an ascending order, and order 3 is a random order. The performance of AGEM and DER++ degrades severely in order 1. However, the proposed MA-MRC methods is superior to baselines and are stable and robust under different orders.

4.5.5 Efficiency Analysis

We compare the parameters and training speed of methods with the same size of the memory in Table 10. The MA-MRC have more parameters for domain discriminator. Nevertheless, considering the larger number of parameters of the Transformer, we conclude all methods have almost the same number of parameters. As for training time per epoch, MA-MRC is slower than DER++ (4%/5% under CDA-C/CDA-Q). It can be accepted because of the significant improvement of MA-MRC.

5 Conclusion

In this paper, an incremental learning MRC model with uncertainty-aware fixed memory and adversarial domain adaptation, MA-MRC, is proposed for continual MRC and alleviating catastrophically forgetting. Inspired by the human learning process, There are two main ideas of MA-MRC: a memory that stores a small number of samples in previous seen domain data and always focuses on what the model most needs to replay; and adversarial learning the domain adaptation in a two-player game to learn better transfer representations between previous and current domain data. Experimental results show that the proposed MA-MRC can achieve a good continuous learning performance without catastrophically forgetting under CDA-C and CDA-Q settings.

In the future, we would like to explore a more effective sampling strategy, domain adaptation strategy, and balance training strategy for multiple objectives to enhance the continual MRC model.

Jointly Learning Guidance Induction and Faithful Summary Generation via Conditional Variational Autoencoders

Wang Xu and Tiejun Zhao[*]

Abstract

Abstractive summarization can generate high quality results with the development of the neural network. However, generating factual consistency summaries is a challenging task for abstractive summarization. Recent studies extract the additional information with off-the-shelf tools from the source document as a clue to guide the summary generation, which shows effectiveness to improve the faithfulness. Unlike these work, we present a novel framework based on conditional variational autoencoders, which induces the guidance information and generates the summary equipped with the guidance synchronously. Experiments on XSUM and CNNDM dataset show that our approach can generate relevant and fluent summaries which is more faithful than the existing state-of-the-art approaches, according to multiple factual consistency metrics.

1 Introduction

Document summarization aims to produce the shorter version of a document while preserving salient information, which helps people out of the information explosion (Mihalcea and Tarau, 2004; Daumé III and Marcu, 2006; Allahyari et al., 2017). Compared with extractive summarization that retrieves essential sentences from the source document, abstractive summarization has no constraint on the words and phrases, which has attracted more attention. With the development of neural network and the large pre-trained language models, systems can generate summarizes with a high level fluency and coherence (Devlin et al., 2019; Dong et al., 2019; Lewis et al., 2020; Zhang et al., 2020a).

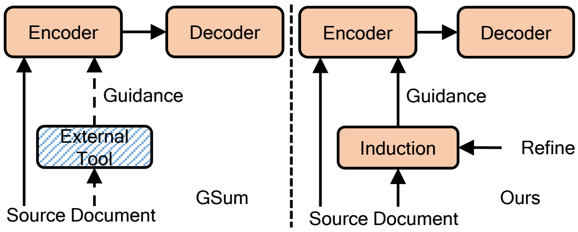

Figure 1: Our framework trains guidance induction and summary generation jointly. It avoids the domain mismatch of the external tools and the guidance extraction is refined during training.

Generating faithful summaries is a challenging task for abstractive summarization (Kryscinski et al., 2020; Maynez et al., 2020; Gabriel et al., 2021; Zhou et al., 2021). Previous studies have shown that the generated summaries distort or fabricate the facts of the source document, which also refers to the hallucination phenomenon (Huang et al., 2021). It statistics that most models produce 80% summaries with factual errors in XSUM dataset (Narayan et al., 2018) which limits the usage of summarization system (Pagnoni et al., 2021).

Recent studies provide different guidance information as input to enhance the factual consistency of the summary (Cao et al., 2018; Zhu et al., 2021). Generally, these models act a separate two-stage processing, the guidance extracting by off-the-shelf tools and summary generation conditioned on source document and guidance. Typically, Dou et al. (2021) propose an extensible guided summarization framework GSum, which has achieved impressive results. It uses an oracle to select guidance during training and extracts the keywords by out-of-box tools (Li et al., 2018) at test time. Then two transformers (Vaswani et al., 2017) are used to encode the source document and guidance.

However, the performances of separate two-stage processing models are limited by the external tools which may suffer from domain mismatch. In fact, the experiments of GSum have shown that the performance would have a significant gain when

July 10-15, 2022 ©2022 Association for Computational Linguistics

the model uses an oracle to select guidance in testing, rather than the external tools. Moreover, the inaccuracy of the guidance extraction leads to the unfaithfulness of the summary.

In this paper, we present a novel framework which trains **G**uidance **I**nduction and **S**ummary **G**eneration (**GISG**) jointly via conditional variational autoencoder. Specifically, we use phrases as the information granularity of our guidance and we induce the *keyphrases* of the source document, which appear in the summary semantically. First, we extract all phrases from the source document by part-of-speech tagger as candidates and we use latent variables to indicate the keyphrases. Then we learn to induce the latent variables and generate the summary jointly. Our approach avoids the domain mismatch of the external tools while the guidance extraction is refined during training. Then the faithful summaries are generated conditioned on the accurate guidance information.

Experiments on XSUM (Narayan et al., 2018) and CNNDM (Hermann et al., 2015) datasets show that our approach can generate relevant and fluent summaries which is more faithful to the source document than existing state-of-the-art approaches, according to multiple factual consistency metrics.

2 Related Work

2.1 Abstractive Summarization

Abstractive Summarization is prone to generate factual inconsistency text with the source document (Durmus et al., 2020; Gabriel et al., 2021). Recent studies divide factual inconsistency error into two categories, intrinsic error and extrinsic error separately (Zhou et al., 2021). The intrinsic error refers to the error which is contradicted to the source document. And the extrinsic error refers to the error which is neither supported nor contradicted by the source document. Recent efforts for improving factual consistency are mainly categorized into factual guidance methods, contrastive learning methods and post-edit-based methods.

Factual guidance methods provide the models with additional information for the encoder, including the relation triples, keywords and important sentences, which guide summarization systems to pay attention to the facts and to reduce consistent error (Cao et al., 2018; Xu et al., 2021b,a; Dou et al., 2021). Zhu et al. (2021) explore using knowledge graphs to model the facts to the source document. Dou et al. (2021) design a unified framework to introduce different information by an additional transformer encoder.

Contrastive learning methods encourage models to distinguish between positive and negative examples (Nan et al., 2021; Cao and Wang, 2021; Liu et al., 2021; Xu et al., 2022). Nan et al. (2021) generate multiple summaries candidates by sampling from the pre-trained models and selecting positive and negative examples according to the question answer based metric. Cao and Wang (2021) construct positive and negative examples by the heuristic rules, for example, replacing the entity in the references or paraphrasing the references.

Post-edit based method aims to apply a correction over the generated results to obtain more factual-consistent summarization (Dong et al., 2020; Cao et al., 2020; Chen et al., 2021a). Dong et al. (2020) leverages the question answering models to correct the factual error iteratively via span selection over the generated summaries. Cao et al. (2020) propose a corrector model to identify and correct factual errors in generated summaries. The model is trained on the synthesis data which is transformed from the reference summaries.

2.2 Conditional Variational Autoencoder

The variational auto-encoder (VAE) is a directed graphical model with certain types of latent variables, such as Gaussian latent variables (Kingma and Welling, 2014; Sohn et al., 2015; Rezende et al., 2014). A generative process of the VAE contains two stages; a set of latent variables are generated from the prior distribution and the data is generated by the generative distribution conditioned on latent variables.

Conditional VAE (CVAE) (Sohn et al., 2015; Zhao et al., 2017; Chen et al., 2021b) is a recent modification of VAE to generate diverse example conditioned on additional constrained information. Instead of providing additional information in the output, CVAE models introduce latent variables to represent the information. Inspired by CVAE, we view the keyphrases as the conditional attributes and adapt CVAE to train keyphrases induction and faithful summarization generation jointly.

3 Background

Given the source input document $X = \{X_1, X_2 \cdots X_N\}$, of length N. The task of abstractive summarization is to generate a short

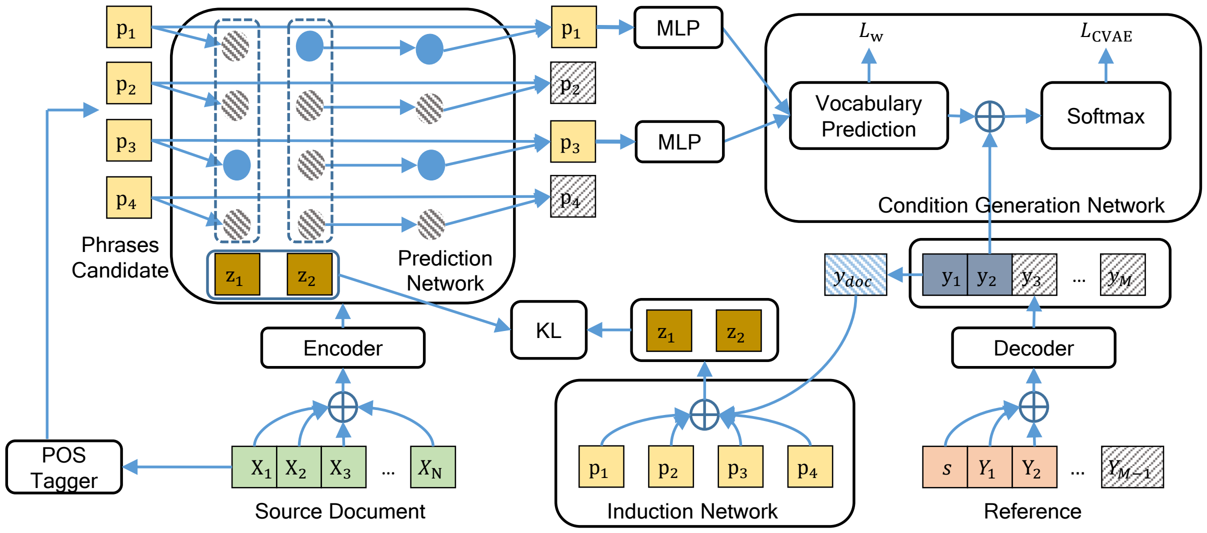

Figure 2: General framework of our model. There are mainly three parts, keyphrases prediction network, induction network and condition generation network.

version of the source document, i.e. $Y = \{Y_1, Y_2 \cdots, Y_M\}$, where M is the length of summary. Each token X_n, Y_m takes one value from a vocabulary $\mathcal{V}$.

Abstractive summarization is generally formulated as $P(Y|X) = \sum_{t=1}^{M} P(Y_t \mid Y_{<t}, X)$, which is a typical sequence to sequence generation problem. We use BART (Lewis et al., 2020) which is based on Transformer-based encoder and decoder architectures (Vaswani et al., 2017) as our backbone. Transformer layers use multi-heads self-attention to capture the dependency between the input (Vaswani et al., 2017). Concretely, the input X is converted into a vector sequence $\boldsymbol{X} = \{\boldsymbol{x}_1, ..., \boldsymbol{x}_N\}$ by the encoder, where $\boldsymbol{x}_n \in \mathbb{R}^h$ and h is the size of hidden representation. In decoding step t, the decoder generates the t word representation $\boldsymbol{y}_t$ by attending to the input contextual representation $\boldsymbol{X}$ and the prefix words $\{Y_1, \cdots, Y_{t-1}\}$ through the encoder-decoder attention. The probability of predicting the next token Y_t from the vocabulary $\mathcal{V}$ is

$$P(Y_t|Y_{<t}, X) = \text{softmax}(\boldsymbol{E}\boldsymbol{y}_t) \quad (1)$$

where $\boldsymbol{E} \in \mathbb{R}^{|\mathcal{V}| \times h}$ is the embedding matrix of the vocabulary.

4 Methodology

4.1 Summarization with Conditional Variational Autoencoders

Previous work uses external tools to extract the guidance (e.g. keyphrases, important sentences or relation triplets) and generate the summaries conditioned on the source document and the guidance. Our idea is to induce the guidance and generate the summary jointly. Phrases are the meaning semantic information unit of the document, which is important to express the facts of the document. Compared with a single word or a sentence of the document, a phrase contains more abundant and accurate information and is refined without lots of useless information. We will use the phrases as the information granularity of our guidance and our framework can easily be generalized to the sentence or the relation triplets.

We extract all phrases from the source document as the candidates, since the keyphrases are the subset of the phrases of the document. Then we assume a latent variable Z to indicate the keyphrases set.

Based on CVAE, we introduce an induction network $Q(Z|X, Y)$ to approximate the true posterior distribution $P(Z|X, Y)$. Sohn et al. (2015) have shown that the variational lower bound can be written as:

$$\begin{aligned} \mathcal{L}_{\text{CVAE}} &= \text{KL}(Q(Z|X,Y)||P(Z|X)) \\ &-\mathbb{E}_Q(\log P(Y|X,Z)) \geq -\log P(Y|X) \end{aligned} \quad (2)$$

Thus, we jointly learn the keyphrases prediction $P(Z|X)$ and summary generation $P(Y|X, Z)$. Intuitively, the term $\mathbb{E}_Q(\log P(Y|X, Z))$ ensures the model generates the summary conditioned on X and Z, while the KL diversity term tries to guide the keyphrases prediction $P(Z|X)$ approximate the induction $Q(Z|X, Y)$.

When the model is evaluated, a latent variable Z is first predicted from $P(Z|X)$. Then the decoder $P(Y|X,Z)$ generates the summaries conditioned on X and Z.

We will describe our approach in detail in the following sections. The overview of our framework is in Figure 2. First, we describe candidate phrases extraction in Section 4.2. In Section 4.3, we present the prediction network and keyphrases induction network. Section 4.4 further presents the conditional summary generation network.

4.2 Candidate Phrases Extraction

We extract the phrases from the source document including the noun and verb phrases. Following Wu et al. (2021)'s work, we use the rule-based matchers to extract noun and verb phrases by the part-of-speech[1] (POS). Concretely, we use SpaCy (Montani et al., 2020) to obtain the POS tag of each word. The noun phrases are extracted by the built-in function of Spacy. And a phrase will be treated as the verb phrase if any of the cases are satisfied. 1). `[AUX] VERB`. The words with the verb POS tag are extracted besides the auxiliary verb. 2). `VERB [RP]`. A verb phrase may be followed by the particle including prepositions or adverbs (e.g., walk down). 3). `AUX not VERB [RP]`. “not" is considered to handle negation (e.g., would not find). And we filter out the phrases that contain less than three words. The extracted context phrases of the source document are treated as the phrases candidates.

Although, we also use the external tools POS tagger to extract the phrases of the source document, we do not directly use the phrases to guide the summary generation. Generally, the keyphrases are only a small subset of the candidates extracted by the POS tagger. We believe that our approach is robust even with an inaccurate POS tagger.

4.3 Keyphrases Prediction and Induction

We use the output of the encoder to obtain the phrase representation by averaging the representation of the corresponding words. Specially, suppose a phrase is $X_{s:t}$. The representation of the phrase is $\boldsymbol{q} = \frac{1}{t-s}\sum_{k=s}^{t} \boldsymbol{x}_k$. Thus, we get the representation of the candidates $\boldsymbol{Q} = \{\boldsymbol{q}_1, \boldsymbol{q}_2, \cdots, \boldsymbol{q}_I\}$, where $\boldsymbol{Q} \in \mathbb{R}^{I\times h}$ and I is the number of the phrases candidates.

Generally, every phrase candidate is assigned a latent variable to indicate whether the phrase is the keyphrase and the selection of each phrase is a binary classification problem. However, we find that the models tend to select redundancy phrases or even all the candidates. We argue that it is because the candidates contain similar phrases and the binary classification would lead to repetition without being constrained with the number of the phrases.

To solve the problem, we use the latent variable to select the keyphrases from the candidates. Formally, we assume the maximum of keyphrases in a document is B. We define $\boldsymbol{Z} = \{z_1, z_2, \cdots, z_B\}$ as a latent indicator variable, where $\boldsymbol{Z} \in \mathbb{R}^{B\times I}$ and z_i is one-hot vector. $z_i^j = 1$ means the phrase j is the ith keyphrase. The model can select less than B keyphrases by having the repetition latent value in $\boldsymbol{Z}$.

Then we have the prediction network and keyphrases induction network as follows:

$$\begin{aligned} Q(z_i|X,Y) &= \text{softmax}(\text{MLP}_1^i(\boldsymbol{Q})\boldsymbol{y}_{\text{doc}}^T) \\ P(z_i|X) &= \text{softmax}(\text{MLP}_2^i(\boldsymbol{Q})) \end{aligned} \quad (3)$$

where $\boldsymbol{y}_{doc}$ is the representation of the summary. $\boldsymbol{y}_{doc}$ is obtained by averaging $\{\boldsymbol{y}_1 \cdots \boldsymbol{y}_M\}$.

4.4 KeyPhrases Guide Summary Generation

We calculate the distribution of the word by attending to the source contextual representation and the keyphrases representation for the generation network $P(Y|X,Z)$. Similar to Aralikatte et al. (2021)'s work, we introduce a bias in Eqn. (1) to help the model focus on the keyphrases.

Formally, the generation probability of Y_t is formulated as:

$$P(Y_t|Y_{<t}, X, Z) = \text{softmax}(\boldsymbol{y}_t\boldsymbol{E} + \boldsymbol{f}_t\boldsymbol{E}) \quad (4)$$

where $\boldsymbol{f}_t = \boldsymbol{S}\boldsymbol{A}\text{MLP}_3(\boldsymbol{Q})$ and $\boldsymbol{S} \in \mathbb{R}^{1\times I}$ is the selection vector. $\boldsymbol{S}_i = 1$ means the ith candidate is selected as the keyphrases. $\boldsymbol{A}$ is the attention score over the selected keyphrases and $\boldsymbol{A} = \text{softmax}(\text{MLP}_3(\boldsymbol{Q})\boldsymbol{y}_t^T)$.

Basically, $\boldsymbol{S}$ is obtained from the $Q(Z|X,Y)$ during training. As Eqn. (2) indicated, we need to calculate the expectation of $P(Y|X,Z)$ over the distribution $Q(Z|X,Y)$. We use the Gumbel-Softmax trick (Jang et al., 2017) to sample from $Q(Z|X,Y)$ and obtain low-variance gradients. Concretely, the sample probability $\hat{Q}_i$ is

---

[1] `https://spacy.io/usage/linguistic-features`

Dataset	Pairs			Tokens	
	Train	Valid	Test	Doc	Sum
XSUM	203028	11273	11332	430.2	23.3
CNNDM	287084	13367	11489	766.1	58.2

Table 1: Statistics of the dataset with respect to corpus size of training, validation and test set, average document (source) and summary (reference) length (in terms of tokens).

as following:

$$\hat{Q}_i = \text{softmax}(\frac{\text{MLP}_1^i(\boldsymbol{Q})\boldsymbol{y}_{\text{doc}}^T + \epsilon}{\tau}) \tag{5}$$

where ϵ is Gumbel noise and τ is temperature. Thus $\boldsymbol{S} = \sum_{i=1}^{B} \hat{Q}_i$. To avoid repetition selection among latent variables, we normalize the $\hat{S} = \frac{\boldsymbol{S}}{max(\boldsymbol{S})}$. In this way, the model is encouraged to extract different keyphrases, otherwise only one keyphrase is selected.

During testing, we obtain $\boldsymbol{S}$ from $P(z_i|X)$. $\boldsymbol{S} = \sum_{i=1}^{B} \text{one\_hot}(\text{argmax}(P(z_i|X)))$. The upper value of $\boldsymbol{S}$ is clipped into 1 to avoid repetition selection.

The vanishing latent variable problem (Bowman et al., 2016; Lucas et al., 2019) exists when training with VAE. There are multiple techniques to address the problem (Zhao et al., 2017; Zhu et al., 2020). Following Zhao et al. (2017)'s work, we introduce an auxiliary loss encouraging the keyphrases to predict the words of the summary. The auxiliary loss would guide the selected phrase representation to better represent the content of the summary. Then additional loss is following:

$$\begin{aligned}\mathcal{L}_{\text{w}} = \frac{1}{|\mathcal{V}|}\sum_{i=1}^{|\mathcal{V}|}\{&|v_i \in \hat{Y}| \log(\sigma \frac{e^{\boldsymbol{f}_{\text{key}}\boldsymbol{E}_i}}{\sum e^{\boldsymbol{f}_{\text{key}}\boldsymbol{E}_i}}) \\ &+ |v_i \notin \hat{Y}| \log(1 - \sigma \frac{e^{\boldsymbol{f}_{\text{key}}\boldsymbol{E}_i}}{\sum e^{\boldsymbol{f}_{\text{key}}\boldsymbol{E}_i}})\}\end{aligned} \tag{6}$$

where $\boldsymbol{f}_{\text{key}} = \boldsymbol{S}\text{MLP}_3(\boldsymbol{Q})$. $\hat{Y}$ is the target summary and σ is Sigmoid function. Then our final loss function is:

$$\mathcal{L} = \mathcal{L}_{\text{CVAE}} + \lambda\mathcal{L}_{\text{w}} \tag{7}$$

5 Experiments

5.1 Setup

Datasets. We evaluate our models on extreme document summarization (XSUM) (Narayan et al., 2018) and CNN/Daily Mail (CNNDM) (Hermann et al., 2015). Both of the datasets are extracted from the news and the detailed statistics of the datasets are listed in Table 1. In XSUM dataset, the documents are summarized into single-sentence summaries. These summaries demonstrate a high level of abstraction which requires document-level inference, abstraction, and paraphrasing. CNNDM is a high quality summarization dataset consisting of news articles and human annotation summaries.

Implementation Details. We introduce our framework into **BART** (Lewis et al., 2020) which is a strong abstractive summarization model pretrained with a denoising autoencoding objective. We use the FairSeq[2] as the implementation of our baseline and model. We inherit their provided hyper-parameters of XSUM and CNNDM. Concretely, the total number of the updates is 1.5w in XSUM and 2w in CNNDM. The maximum number of tokens in a batch is 4096 with gradient accumulation steps of 4. We use Adam optimizer and the learning rate is set to 3e-5. The ϵ is 1e-8 and β is (0.9, 0.999). The maximum of the keyphrases B is set to 8. And the temperature τ is set to 0.1 for Gumbel-Softmax during training. We use mixed-precision to speed up model training and the warm-up is set to 500 steps. All the experiments are done on 2 and 4 NVIDIA 3090 in XSUM and CNNDM. For the beam search, the minimum summary length is 11 and 56 for XSUM and CNNDM, respectively. The number of beams is 4 for XSUM and 6 for CNNDM. And the ROUGE-L score on the validation set is used to pick the best model.

Evaluation Metrics. ROUGE[3] (Lin and Hovy, 2003) considers lexical overlap against the reference summaries, which is widely used to evaluate the informativeness and fluency of the summary. We report on ROUGE-1, ROUGE-2 and ROUGE-L to measure summary qualities.

We also use **BERTScore**[4] (Zhang et al., 2020b) to evaluate the semantic similarity between a hypothesis and the reference summary by contextual representation.

However ROUGE and BERTScore perform poorly in capturing factual consistency with the source document. Recent studies have developed different categories to evaluate the faithfulness of a generated summary given its

Table 2: Main results. MATCHSum (denoted by MATCH) and EXT-ORACLE (denoted by EXTORA) are extractive summarization models. The results with * are computed based on the output files in the EXPLAINABOARD. The results with † are our reimplement of the baseline models. Bold indicates the best performance in the abstractive summarization models groups.

source document (Zhang et al., 2020b; Dong et al., 2020; Liu et al., 2021). Our approach is evaluated with four factual consistency metrics, including relation triplets based and question answering (QA) based metrics.

Relation triplets based metrics evaluate factual consistency by comparing structured data of factual information extracted from the summary and the source document. **Close Scheme Fact Triple** (Dong et al., 2020) extract (Subject, Relation, Object) by named entity recognition and relation extraction models and then calculate the precision between the triples extracted from the summary and source document. **Open Scheme Fact Triple** (Dong et al., 2020) extract the text spans to indicate the relation and calculate the precision similar to close scheme fact triple.

Question answering based metrics use the pretrained QA model to evaluate the faithfulness. **QAGS** (Wang et al., 2020) extracts text spans from the predicted summary and generates questions conditioned on the predicted summary by a trained question generation model. A pretrained QA model answers the questions from the document. Then the matching score is calculated between the answer from the document and the summary. **QuestEval** (Rebuffel et al., 2021) not only generate (question, answer) pairs from the summary, but also from the source document, which considers to measure the recall performance.

We use factsumm[5] and OpenIE[6] to calculate close scheme fact triple and open scheme fact triple. And we use the repository to calculate QAGS[5] and QuesEval[7]. We only calculate factual consistency metrics of 1k (document, reference, summary) for the computing efficiency.

Competing Methods. We compare our model with some competing methods, including extractive and abstractive summarization models. **EXT-ORACLE** (Narayan et al., 2018) and **MATCHSUM** (Zhong et al., 2020) are extractive models. EXT-ORACLE selects a single best sentence of the document by referring to the target. MATCHSUM reranks the candidate summaries produced by BertExt (Liu and Lapata, 2019) and achieves state-of-the-art extractive results on various summarization datasets. For abstractive summarization models, **FASum** (Zhu et al., 2021) and **GSum** (Dou et al., 2021) are models designed for faithful summarization. FASum extracts the relation triplets and uses a knowledge graph to synthesize information. Then the graph information is fed into the Transformer architecture. GSum is a general framework for guided neural summarization, which investigates four types of guidance signals and achieves state-of-the-art performance on various popular datasets.

[6] `https://nlp.stanford.edu/software/openie.html`

[7] `https://github.com/ThomasScialom/QuestEval`

We use the prediction files of the competing models provided in EXPLAINABOARD [8] other than running the models. It is noted that the difference between the performance of EXPLAINABOARD and the results in the original paper is below 1 point in terms of ROUGE.

5.2 Main Results and Analysis

Main results. Table 2 presents the detailed results on the test set of the datasets including traditional metrics and factual consistency metrics. Compared with the results published in EXPLAINABOARD, our reimplement of BART is inferior by about 0.6 points in terms of ROUGE-L. It is noted that the performance of BART on XSUM dataset has been discussed in fairseq repository[9]. The results on base models implicate that our implementation is fair for our study.

We apply GISG on XSUM and CNNDM with BART as the backbone. As seen, GISG achieves higher performance for lexical overlay on both datasets compared to BART. It achieves 0.8 and 0.5 points improvement in terms of ROUGE-L on XSUM and CNNDM datasets, which is a considerable improvement over strong baselines for summarization. It is noted that GSum in Table 2 use the key sentences as the guidance. Although there is the version that GSum uses keywords as the guidance in (Dou et al., 2021), which is more relevant to our work. EXPLAINABOARD does not provide the output files and we report the results using key sentences as the guidance.

For the factual consistency metrics, GISG outperforms BART on all factual consistency metrics which indicates that jointly training keyphrases induction and summary generation benefit the faithful consistency. Compared with a strong factual guidance baseline FASum and GSum, our approach consistently outperforms FASum and GSum.

Compared with extractive summarization baseline MATCHSUM and EXT-ORACLE, the abstractive summarization models have a large margin in terms of factual consistency, even if these models achieve much higher performance on the lexical overlap. It indicates that extractive summarization models can get better factual consistency at the cost of being relevant and fluent.

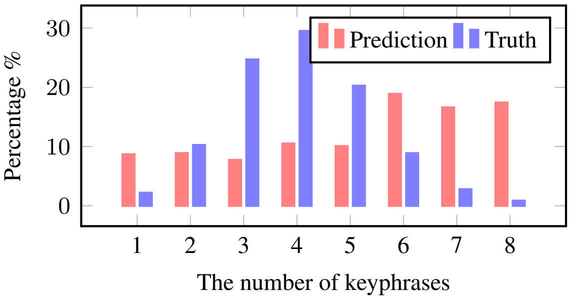

Figure 3: Distribution of the number of keyphrases.

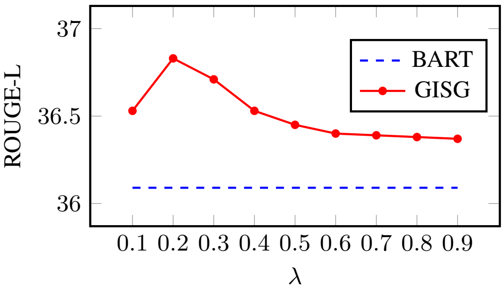

Figure 4: Fine tuning on the hyper-parameter λ.

For the results between XSUM and CNNDM, all factual consistency metrics on XSUM are much lower than CNNDM. This is consistent with the conclusion that summaries in XSUM are much more abstractive. It is more difficult for the model to generate consistent results on XSUM.

Due to the extreme abstractive nature of XSUM dataset, it is ideal to evaluate the models' ability to capture the facts of the document. In the rest of this section, we present in-depth analyses to better understand our model with XSUM as the testbed.

Distribution of the number of keyphrases. We assume the maximum number of the keyphrases is B in Section 4.3 and the model selects fewer keyphrases by selecting one candidate repeatedly. In this section, We investigate the distribution of the number of keyphrases for the test set and the model prediction in Table 3.

As seen, most of the reference summaries have about 4 keyphrases while most of the reference summaries have less than eight keyphrases. Thus B is set to eight according to the ground truth distribution.

Moreover, the number of keyphrases in the model prediction is larger than the ground truth. We argue that it is because the model tends to take advantage of all the latent variables and selects redundancy and similar candidates.

Fine tuning on hyper-parameter λ. In Eqn. (7),

Figure 5: Case study.

we use λ to keep a trade-off between $\mathcal{L}_{\text{CVAE}}$ and $\mathcal{L}_{\text{W}}$. We analyze the effect of λ in Figure 4.

As seen, ROUGE-L is boosted with the increment of λ until 0.2, showing that predicting the words of the summary by the keyphrases contributes to the performance.

Subsequently, a larger value of λ reduces the ROUGE-L and the performance is even lower than without $\mathcal{L}_{\text{W}}$. We argue that it is because f_{key} is constrained to predict the words of the summary. A larger value of λ would disturb the word prediction item y_t, which would hurt the performance. Therefore, we set the hyper-parameter λ to 0.2 to control the effect.

Ablation on the keyphrases prediction network. We first predict the keyphrases and generate the summaries conditioned on the source document and the keyphrases. We investigate the influence of the keyphrases prediction network and replace the module with a random selection of B keyphrases. The results are shown in Table 3.

The results show that both ROUGE, BERTScore and factual consistency metrics have a descend without the keyphrases prediction module, which indicates the effectiveness of the guidance prediction module.

Ablation on the number of keyphrases in testing. To investigate the effectiveness of the keyphrases prediction network, we make ablation of the keyphrases in testing in Figure 6, where we increase the number of the attending keyphrases gradually.

Models	Prediction	Rand
R-L	36.82	36.25
BERTScore	92.11	91.07
Close	2.14	1.96
Open	2.18	2.07
QAGS	14.31	13.94
QuesEval	37.09	37.02

Table 3: Ablation on the keyphrases prediction.

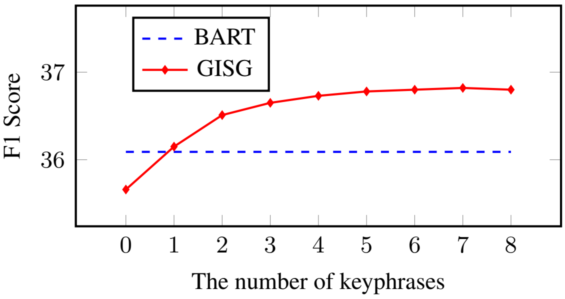

Figure 6: Ablation on the number of keyphrases in testing.

As shown in the figure, the performance increases as more keyphrases are used to generate the summaries. Without attending to any keyphrases of the module prediction, the performance drops about 1 point in terms of ROUGE-L. It indicates that the keyphrase prediction filters the information and helps the decoder to generate a more accurate summarization.

Case Study To further demonstrate the effectiveness of our method, we give a case study in Figure 5. We compare the summary generated based on our approach and baseline which is based on BART. As shown in Figure 5, the baseline model generated hallucination, “They are not allowed to spend any time together", which is inconsistent with the source document, “They visit at Charleston County Jail". Our model first predicts the keyphrases from the source document and generates the summary conditioned on the source document. As shown in the figure, our result is more faithful, which confirms the effectiveness of our approach.

6 Conclusion

In this paper, we propose to learn guidance induction and summary generation jointly via conditional variational autoencoders. We use phrases as the information granularity of our guidance and we induce the keyphrases of the source document. These summaries are generated conditioned on the source document and the keyphrases, ensuring the important information is consistent with the source document. The experiments show that our approach can generate more faithful summaries than the existing state-of-the-art approaches, according to multiple factual consistency metrics.

Context-Aware Language Modeling for Goal-Oriented Dialogue Systems

Charlie Snell **Mengjiao Yang** **Justin Fu** **Yi Su** **Sergey Levine**
UC Berkeley
`{csnell22,sherryy,justinfu,suyi,svlevine}@berkeley.edu`

Abstract

Goal-oriented dialogue systems face a trade-off between fluent language generation and task-specific control. While supervised learning with large language models is capable of producing realistic text, how to steer such responses towards completing a specific task without sacrificing language quality remains an open question. In this work, we formulate goal-oriented dialogue as a partially observed Markov decision process, interpreting the language model as a representation of both the dynamics and the policy. This view allows us to extend techniques from learning-based control, such as task relabeling, to derive a simple and effective method to finetune language models in a goal-aware way, leading to significantly improved task performance. We additionally introduce a number of training strategies that serve to better focus the model on the task at hand. We evaluate our method, Context-Aware Language Models (CALM), on a practical flight-booking task using AirDialogue. Empirically, CALM outperforms the state-of-the-art method by 7% in terms of task success, matching human-level task performance.

1 Introduction

Dialogue systems have typically approached the problem of generating realistic dialogue from the perspective of supervised learning (Dušek and Jurcicek, 2016; Eric and Manning, 2017; Mei et al., 2017; Chen et al., 2019; Wu et al., 2019a; Hosseini-Asl et al., 2020; Peng et al., 2020; Adiwardana et al., 2020). However, dialogue can also be viewed as a sequential decision making process, which is well-suited to planning and reinforcement learning (RL) algorithms. A challenge with the classical RL approach to dialogue is the requirement for active interaction with humans (Gašić et al., 2011). Training such a system with active human-in-the-loop interaction quickly becomes expensive and cumbersome, making it desirable to develop techniques for goal-directed training of dialogue systems that can effectively leverage offline data.

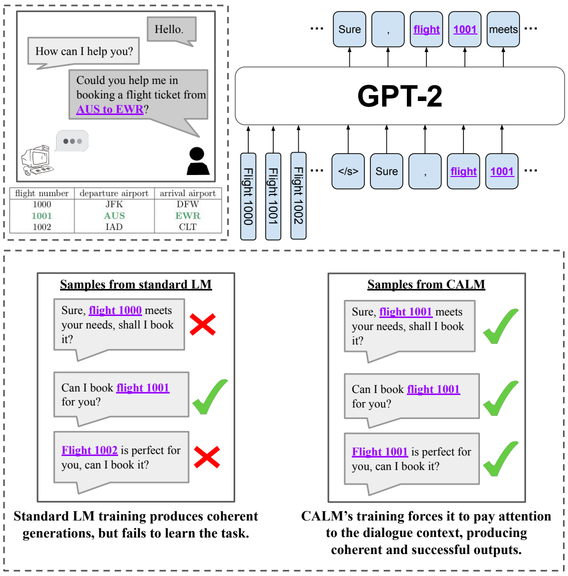

Figure 1: **CALM is an end-to-end language model for goal oriented dialogue.** CALM's training objective teaches the model to better pay attention to the dialogue task context, yielding a ∼50% improvement in task success over standard LM training on a flight booking task.

While many dialogue generation techniques based on RL and learned control have been proposed (Eckert et al., 1997; Levin et al., 2000; Chung, 2004; Georgila et al., 2006; Schatzmann et al., 2007; Heeman, 2009; Georgila and Traum, 2011), most such systems take a pipelined approach, where an abstract representation of states and actions is designed by hand and then combined with RL to train a "dialogue management" system, rather than generating dialogue end-to-end. These pipelined approaches rely on a manually designed decomposition of the dialogue task, which may be domain-specific and, more importantly, may not enjoy all of the benefits of tightly integrating low-level text generation with the overall goals of the

task. In this work, we instead ask: how can we scalably and effectively introduce the mechanisms of goal-directed decision making into end-to-end language models, to directly steer language generation toward completing specific dialogue tasks rather than simply generating probable responses?

To this end, rather than utilizing a pipelined approach, we aim to directly finetune language models in a task-aware manner such that they can maximize a given utility function. We observe that large language models can already be formulated within a Markov decision processes (MDP) as capturing both the dynamics and policy for a decision-making task, where dialogue history serves as state, and the agent's utterances serve as actions. We could utilize this observation by finetuning the models directly with online RL, but the need for human-in-the-loop training makes this difficult. Offline RL methods (Levine et al., 2020; Fujimoto et al., 2019; Wu et al., 2019b; Wang et al., 2020b) provide an alternative approach, but typically require value function estimation, which is not straightforward to perform with a language model. Instead, we propose a conditional imitation learning strategy coupled with a novel task relabeling approach that can finetune language models from offline data, such that the model still represents the joint distribution over dialogues, but *tilts* this distribution toward dialogues with a high reward. This amounts to a *task-aware* finetuning strategy that integrates task information into the model. The main contribution of our work is CALM (*Context-Aware Language Modeling*), a framework for end-to-end goal-directed dialogue generation. CALM unifies the traditional language modeling objective with task-specific supervision, where a language model is interpreted as a joint representation of dynamics and policies in an MDP, and the finetuning process utilizes a conditional imitation learning objective with a novel task relabeling strategy that teaches the model how to generate high-utility dialogues (see Figures 1 and 2). Because CALM interprets the language model as *both* a dynamics model and a policy, it can be used as either a model-free method, where the dynamics are discarded and the policy component is used to greedily generate responses, or as a *model-based* method, where the dynamics component can be used to *plan* at test-time. We empirically evaluate CALM on AirDialogue (Wei et al., 2018), the largest dataset for goal-oriented dialogue based-on a flight-booking task. CALM improves the task success by 10% over the previous state-of-the-art method (Chen et al., 2020) following the evaluation protocol proposed by Wei et al. (2018), achieving the first-ever human-level performance on this dataset.

2 Related Work

Our goal is to enable end-to-end training of goal-directed dialogue agents. In these settings, an agent aims to complete a particular task with its utterances (Smith and Hipp, 1994). Goal-directed agents have been explored in contexts such as personal assistants (McTear, 2002; Budzianowski et al., 2018; Williams et al., 2014), recommendation systems (Liu et al., 2010; Kang et al., 2019), education (Yuan et al., 2008), and negotiation (He et al., 2018; Lewis et al., 2017). While there are multiple approaches to constructing dialogue agents, in this work we frame the problem of generating dialogue as a sequential decision making problem within a (partially observed) Markov Decision Process (MDP) (Singh et al., 1999; Young et al., 2013). Prior works that utilize such an MDP formulation typically aim to train a dialogue management system (Singh et al., 2002), in which the agent reasons about higher-level abstractions of the state of the conversation, and language generation is performed using a downstream procedure. Dialogue management systems have been trained using techniques such as online reinforcement learning via policy gradients (Gašić et al., 2011; He et al., 2018), off-policy reinforcement learning (Pietquin et al., 2011; Yu et al., 2016) or actor-critic methods (Su et al., 2017). Our method differs from dialogue management systems in that CALM is an end-to-end system optimized for successful task completion, and performs both high-level decision making and language generation.

Recent advancements in language models, such as recurrent neural networks (Sundermeyer et al., 2012; Asri et al., 2016; Su et al., 2016; Zhao et al., 2019; Wang et al., 2020a; Zhang et al., 2020) and attention-based architectures (Vaswani et al., 2017; Liu et al., 2019; Devlin et al., 2018; Brown et al., 2020), have spurred increasing interest in such end-to-end dialogue systems (Hosseini-Asl et al., 2020; Peng et al., 2020; Adiwardana et al., 2020). Model-based approaches, in which a learned agent is substituted for a human, allow learning to be done entirely within simulation without human intervention (Li et al., 2016; He et al., 2018; Kang et al., 2019; Lewis et al., 2017; Liu et al., 2018). In con-

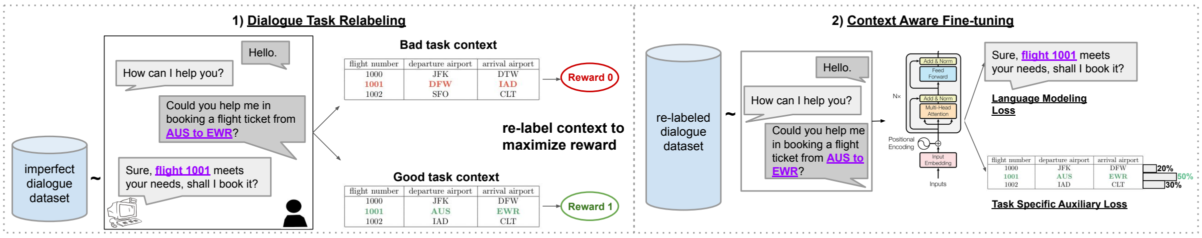

Figure 2: **A visual outline of CALM.** We apply Task Relabeling to our static offline dataset, by swapping out the task context — in this case a flight table — such that the attached dialogue becomes an optimal example of task completion. When fine-tuning on this relabeled dataset, we then apply a Task Specific Auxiliary Loss on top of the standard language modeling objective; this helps the model learn to use the task context. Once trained, CALM can consistently solve goal-directed dialogue tasks.

trast to these approaches, CALM augments the traditional language modeling objective with task-specific rewards in order to finetune a model that is more aware of task goals, which significantly improves performance over a naïve language model without the need for simulating human responses in an interactive training loop. Jaques et al. (2019) recently proposed a model-free, offline approach to undirected dialogue, or dialogue without a specific task goal. Our method differs in that we aim to solve goal-oriented dialogue which allows us to optimize task-specific objectives, and that we take a model-based RL approach which enables us to leverage fine-tuned language models.

3 Preliminaries

In this section, we review our notation and problem formulation for casting dialogue within a sequential decision making framework.

POMDP formulation. We formulate dialogue generation as a partially observable Markov decision process (POMDP) (Kaelbling et al., 1998), with a state that consists of known and unknown context information about the task. Let $c_h \in \mathcal{C}^{(h)}$ denote the hidden context for the task, and let $c_o \in \mathcal{C}^{(o)}$ denote the observed context. For instance, in a flight booking task, a table of available flights might correspond to c_o, while the particular flight that the human wants to book, which is unknown to the agent, corresponds to c_h. Note that the reward, which requires booking the right flight, depends on both hidden and observed contexts. We can define such an environment as a POMDP $\mathcal{M} = (\mathcal{S}, \mathcal{A}, \mathcal{O}, \mathcal{T}, \mathcal{Z}, \mu_0, \mathcal{R}, \gamma)$. We denote a conversation τ as $\tau := \{a_0, e_0, ..., a_T\}$, where T denotes the number of turns in a conversation and a_t and e_t represent utterances (strings of tokens) from the dialogue agent (a_t) and the human (e_t) at the t-th turn, respectively. We additionally use $\tau_{<t}$ to denote conversation history up to the t-th turn. We can represent the underlying POMDP state $s_t \in \mathcal{S}$ as the concatenation of both of the contexts and the previous conversation history $s_t := \{c_h, c_o, \tau_{<t}\} = \{c_h, c_o, a_0, e_0, ..., a_{t-1}, e_{t-1}\}$. However, we only observe the last two elements of the state tuple, such that our observation $o_t \in \mathcal{O}$ at the t-th conversation turn is $o_t = \{c_o, \tau_{<t}\}$. An action $a_t \in \mathcal{A}$ is the agent's response to the current state s_t. Given our definition of the state, the full conversation in a dialogue can be conveniently represented by the last observation and action, $\{o_T, a_T\}$. An agent $\pi : \mathcal{O} \to \mathcal{P}(\mathcal{A})$ maps observations to sets of probability measures over the action space $\mathcal{P}(\cdot)$. A transition function $\mathcal{T}(\cdot|s_t, a_t)$, represents a distribution over the human's utterances, returning s_{t+1} as the state at turn $t + 1$. We only consider the sparse reward setting with $r_T = R(s_T, a_T) \in \{0, 1\}$ denoting task completion, and $r_t = 0, \forall t < T$. Our final reward is therefore dependent on both the context and the dialogue: $R(s_T, a_T) = R(\tau, c_h, c_o)$, where the context $\{c_o, c_h\}$ is randomly sampled for each dialogue from some initial distribution μ_0.

Goal-oriented dialogue. Goal-oriented dialogue systems aim to maximize the expected reward of the above POMDP

$$\mathbb{E}_{\{c_o, c_h\} \sim \mu_0, \pi, \mathcal{T}}[\textstyle\sum_{t=0}^{T} \gamma^t R(s_t, a_t)], \tag{1}$$

where $\{c_h, c_o\}$ is sampled from distribution μ_0. *On-policy* RL algorithms optimize this objective via environment interaction, which is represented by a real human. However, because human-in-the-loop training is expensive, we pursue an *offline learning* approach where we are given a fixed dataset and there is no further interaction with the human in the learning process. This dataset is composed of n trajectories with $\mathcal{D}^{\text{off}} = \{c_h^{(i)}, c_o^{(i)}, \tau^{(i)}, r^{(i)}\}_{i=1}^{n}$ with each $\tau^{(i)} = \{a_0^{(i)}, e_0^{(i)}, , ..., a_T^{(i)}\}$ and its corresponding final reward for task completion $r^{(i)}$. Our goal is to learn the policy $\pi(a|o)$ which improves the dialog agent's ability in achieving the highest task reward defined in Equation 1.

Language models. While conventionally a language model is seen simply as a sequence model over tokens of the form $\prod_{t=1}^{T} p(x_{t+1}|x_{1:t})$, when the sequence $x_{1:T}$ corresponds to a dialogue trajectory τ, we can also interpret a language model as learning the distribution over τ. This distribution can be factored into the product of the policy $\pi(a_t|\tau_{<t})$ and the dynamics $\mathcal{T}(\tau_{<t+1}|\tau_{<t}, a_t)$, and so we can say that a language model *also* represents the policy and the dynamics. Therefore, the maximum likelihood objective for training or finetuning a language model on a dialogue dataset $\mathcal{D}^{\text{off}}$ consisting of dialogue trajectories τ can be written as

$$\mathcal{L}_{LM}(\theta) = \max_{\theta} \mathop{\mathbf{E}}_{\tau\sim\mathcal{D}^{\text{off}}} \sum_{t=1}^{T} \Big(\log \pi_\theta(a_t|\tau_{<t}) + \log \mathcal{T}_\theta(\tau_{<t+1}|\tau_{<t}, a_t) \Big), \quad (2)$$

where $\pi_\theta(a_t|o_t)$ represents a policy that generates new dialogue based on the observed context and dialogue history, and $\mathcal{T}_\theta(\tau_{<t+1}|\tau_{<t}, a_t)$ represents the observed dynamics characterizing human responses, and θ denotes parameters in π and $\mathcal{T}$. Note that $\tau_{<t}$ consists only of the conversation history, and does not contain any task-specific context. A naïve approach to train dialogue systems is to jointly parameterize both π and $\mathcal{T}$ as one language model, and optimize Equation 2 on pre-collected conversations $\mathcal{D}^{\text{off}}$. This method corresponds to behavioral cloning (BC) (Pomerleau, 1989).

Context conditioning. While an agent trained using Equation 2 can learn policies and dynamics that imitate human conversations, this objective does not incorporate the task goal, and may not produce a policy that is more performant than the dataset $\mathcal{D}^{\text{off}}$. While it is possible to input c_o into the language model to maximize the conditional probability of $P(\tau|c_o)$ using a conditional version of the language modeling objective, $\mathcal{L}_{CTX}(\theta)$,

$$\mathcal{L}_{CTX}(\theta) = \max_{\theta} \mathop{\mathbf{E}}_{(\tau,c_o)\sim\mathcal{D}^{\text{off}}} \sum_{t=1}^{T} \Big(\log \pi_\theta(a_t|\tau_{<t}, c_o) + \log \mathcal{T}_\theta(o_{t+1}|\tau_{<t}, a_t, c_o) \Big), \quad (3)$$

contexts with particular task structures (e.g., a set of entries in a table) may not be simply processed as a sequence similarly to τ. Additionally, the language model is not pretrained to read structured context, and oftentimes the recent dialogue history is much more predictive of the next utterance than the task context is. As a result, language models can ignore the task context and only learn $P(\tau)$ despite being conditioned on c_o. Our approach builds on this conditional modeling approach, but makes a number of improvements that allow it to be more aware of the context information, which attains significantly better results in our experiments.

4 Context-Aware Language Modeling

In this section, we present our method for goal-oriented dialogue systems, Context-Aware Language Modeling (CALM). CALM interprets a language model as a combination of a policy and a dynamics model in the POMDP formulation of a dialogue task, as described in Section 3. Under this interpretation, naïve supervised finetuning on the dialogue dataset can be viewed as behavioral cloning (BC) (Pomerleau, 1989). However, BC only imitates data and does not necessarily produce a *good* policy in terms of completing tasks. We propose to improve the policy by utilizing a task relabeling strategy (described in Section 4.1), analogous to prior task relabeling approaches (Kaelbling, 1993; Andrychowicz et al., 2017; Pong et al., 2018; Savinov et al., 2018; Ghosh et al., 2019; Lynch et al., 2020; Eysenbach et al., 2020). This relabeling procedure augments the data with examples of near-optimal utterances, making the language model more task-aware. However, we find several shortcomings with this approach alone and propose the following improvements. First, an expressive language model is liable to ignore the task context, which we address by proposing an auxiliary loss (Section 4.2) that forces the model to utilize this information. Second, learning from structured task information is difficult and can result in models that fail to capture complex task structure, so we propose a task pre-training procedure to improve the learnability (Section 4.3). Finally, to further improve performance we use a model-based planning procedure (Section 4.4) on top of the proposed method that samples multiple dialogues in parallel and selects the most promising candidates.

4.1 Dialogue Task Relabeling

$\mathcal{L}_{CTX}(\theta)$ defines a context-conditional maximum likelihood objective for training an expert imitation policy in conjunction with a dynamics model. However, simply imitating all the dialogue data does not necessarily produce the best possible policy. We would like to learn a policy that produces dialogue that is more optimal, in the sense of better maximizing the task utility, than the average dialogue in the dataset. Task relabeling enables us to learn from optimal trajectories without simply filtering the dataset for high-reward trajectories, which would unnecessarily discard potentially informative data. In the case of dialogue, we can perform task relabeling by considering the context $\{c_o, c_h\}$ as defining the task. While a given dialogue may be unsuccessful for the context for which it was collected, it could be considered successful under a different context. In this case, we can simply swap out $\{c_o, c_h\}$ to create optimal task examples from the many sub-optimal examples provided by $\mathcal{D}^{\text{off}}$. Since our reward $R(c_h, c_o, \tau)$ is a function of the dialogue and context, we can modify the reward for a given dialogue just by changing the given observed context c_o. Using this observation, we can relabel unsuccessful dialogues with successful ones, and even for already successful dialogues there may be multiple c_o corresponding to task success, allowing us to augment the number of successful (c_h, c_o, τ) tuples.

Formally, since our POMDP includes a prior distribution over contexts $\{c_h, c_o\} \sim \mu_0$, there exists a posterior $q(c_o|\tau, c_h)$ over observed contexts that correspond to optimal task completion under a given τ. We can then re-label τ to be optimal under its context by sampling a new c_o from $q(c_o|\tau, c_h)$. In practice, this sampling is performed by rejection sampling from either μ_0 or some $P(c_o|c_h)$; the latter, lower entropy distribution, can be preferred if there is a low probability of sampling valid, high-reward contexts under μ_0. Now, given any τ from an offline dataset of dialogues, we can learn from the full distribution of contexts corresponding to optimal task completion under this dialogue.

In order for this relabeling procedure not to bias our policy towards behavior that is overly-optimistic about the user's responses, it is necessary that the distribution of these responses in our dataset does not depend on the portion of the context that is relabeled. For example, relabeling the table of available flights for a flight booking task should generally be reasonable, because the user is usually unaware of the flight table. On the other hand, relabeling the desired flight would not make sense, since the user's utterances are strongly depend on this. To provide another example, in a bargaining task (Lewis et al., 2017), the agent might fail to obtain the desired item and instead get an item of lesser value. But relabeling with a context that assigns a higher value to the item received would not lead to a reasonable example, since the agent mainly received this item as a result of the user's responses rather than as a result of their own bargaining skill.

Methods based on similar principles have previously been proposed in the deep RL community for simple parametric tasks, such as goal-reaching or linearly-parameterized reward functions (Kaelbling, 1993; Andrychowicz et al., 2017; Eysenbach et al., 2020). However, the dialogue task relabeling that we employ is particularly effective in our setting, since there may be exponentially many contexts that are optimal for a given dialogue (e.g., many different flight tables for a flight booking task), in contrast to the simpler task parameterizations used in prior work, where for example only one goal might be optimal for a given trajectory (the one that is reached). As a result, this technique not only allows us to turn sub-optimal task data into optimal data, but it also allows us to greatly increase the number of optimal task examples from which we can learn, which we will show leads to a large performance improvement.

4.2 Task-Specific Auxiliary Loss

Goal-oriented dialogue generation can be viewed as learning the conditional distribution $P(\tau|c_o)$, where τ represents the generated dialogue given a specific context c_o. However when trained naïvely, language models are liable to ignore this conditioning context, instead focusing purely on the previous utterances in the dialogue. In this case, the model is effectively only learning $P(\tau)$ despite having both the capacity and the context to learn the lower-entropy conditional distribution $P(\tau|c_o)$.

While dialogue tasks are by definition carried out through natural language, there is often an abstract high-level action $\alpha_h \in \mathbf{A}$ that essentially determines the success of the task. In the case of the information retrieval task that we consider in this paper, these high-level actions correspond to deciding which database entity to retrieve for the user (e.g., suggesting a flight to the customer that meets all of their needs). While these high-level actions are theoretically learnable from correlations between the dialogue and the given context, in general, we find that learning these correlations corresponds to a relatively small decrease in dialogue entropy under the model. As a result, the model is less incentivized to learn these correlations relevant to the task than the form of the dialogue. To address this issue, we incorporate an auxiliary objective into our training, which trains the model directly to predict the abstract high-level actions taken in the present dialogue. This objective effectively up-weights gradients relevant for learning the high-level actions, which further helps the model to utilize the context to solve the high-level task through dialogue.

For a given dialogue-context pair $(\tau, \{c_h, c_o\})$ and high-level action, α_h, our auxiliary objective is then simply to maximize the likelihood of the high-level actions taken in the dialogue:

$$\mathcal{C}(\phi) = \max_{\phi} \underset{(c_h, c_o, \tau, \alpha_h) \sim \mathcal{D}^{\text{off}}}{\mathbf{E}} \log P_{\phi}(\alpha_h | \tau, c_o). \tag{4}$$

Just like the language modeling objective, this classification objective is averaged over each token in the dialogue sequence. Our full training objective then becomes:

$$\max_{\theta, \phi} \mathcal{L}_{CTX}(\theta) + \beta * \mathcal{C}(\phi), \tag{5}$$

where β is a hyper-parameter and $\mathcal{L}_{CTX}(\theta)$ is the standard context-conditional language modeling objective as defined in Section 3.

4.3 Task Pretraining

As observed by Liu et al. (2021), for some structured tasks, such as table question answering, pre-training on a simplified version of the given task with a synthetic context can help the model to focus learning on the "skills" that are most relevant to utilize the task context, which leads to improved downstream task performance. We instantiate this idea in our method by pre-training our model on a simplified (dialogue-free) version of the task. Instead of simultaneously modeling all the details of the raw dialogue, as is required to learn $P(\tau | c_o)$, the key observation here is that in our case the task reward only depends on the tuple $\{c_h, c_o, a_T\}$. This enables us to effectively learn to execute the task by only modeling $P(c_h, a_T | c_o)$, without any dialogue at all. By pre-training our model to first learn this simplified distribution, we effectively focus on learning the necessary skills for completing the task. It is expected that the skills learned during this pre-training phase should also generalize and transfer when we later perform training on the real dialogue. The particular instantiation of this principle in the case of AirDialogue is described in Section D.

4.4 Model-Based Dialogue Rollouts

While the methodology discussed so far can produce effective policies, language models also represent task dynamics, as discussed in Section 3. We can leverage this fact to further improve the performance of our fine-tuned models by performing model-based planning at test-time, using both the policy and dynamics components in concert to further maximize task reward. A full dialogue trajectory can then be formed by concatenating this sampled future trajectory $\tau_{\geq t}$ with the current state of the dialogue $\tau_{<t}$ i.e., $\tau = \{\tau_{<t}, \tau_{\geq t}\}$. We perform the model-based planning by sampling k such future trajectories from the final fine-tuned model, and ranking them according to an estimated reward function $\hat{R}(\tau, c_o)$ (see Appendix E.1). Then, we improve upon the policy π from which we took the samples by taking the action (i.e., the next utterance) a_t which receives the highest estimated reward among the sampled trajectories. This rollout sampling procedure is identical to the one used by Lewis et al. (2017).

5 CALM for AirDialogue

In this section, we instantiate our proposed method, CALM, for the AirDialogue flight booking task (Wei et al., 2018). We first give an overview of the task, and then describe how to do relabeling and context conditioning on this specific task.

5.1 AirDialogue Dataset

Dataset overview. The AirDialogue dataset (Wei et al., 2018) is a recently published large-scale airline reservation dataset based on the aforementioned task. The dataset includes 402,038 conversations. The dataset involves three distinct tasks: booking, canceling, and changing flights. We describe the booking task in detail below.

Flight booking task. The (human) customer is given a set of 12 trip requirements, and the flight agent (bot) is provided with a table of 30 flights. The goal of the flight agent is to book a flight from the table for the customer which meets all their requirements, or to correctly inform them that no such flight is available. To determine task success, the flight agent must predict an explicit action at the end of the dialogue indicating the flight that was booked or inform no flight available. See Figure 7 for an example conversation from the dataset.

5.2 Processing Tables

The AirDialogue booking tasks require efficiently querying a flight table containing flight information (e.g., departing location, ticket price) given to the agent prior to the conversation. In order to successfully complete the booking task, the agent needs to be able to filter, select, and integrate information from the flight table based on the customer's preferences inferred from the dialogue.

Instead of treating the tables as unstructured sequences (Wei et al., 2018; Jiang et al., 2021) or as SQL databases (Chen et al., 2020), CALM models tables as an observable context consisting of a set $c_o = \{f_1, f_2, f_3, ..., f_N\}$ of table rows. These rows are then input to our model as a set of embeddings (see appendix C and G for more details).

5.3 Relabeling AirDialogue with CALM

While the AirDialogue dataset only includes one flight table for each dialogue, there are potentially many flight tables compatible with each dialogue as each flight can appear in many tables. We hence implement our relabeling procedure as described in Section 4.1 as follows. We perform rejection sampling on the observable context (i.e., the table of flights) $c_o \sim q(c_o|\tau, c_h)$, sampling until we obtain a new context (c_h, c_o, τ), which gives maximum reward possible $R(\tau, c_h, c_o) = \max_{c_o} R(\tau, c_h, c_o)$. The prior distributions $p(c_o)$ and $p(c_o|c_h)$, from which the tables in the AirDialogue dataset were sampled, are provided with the dataset. By rejection sampling from $p(c_o|c_h)$, we can effectively sample from the posterior $q(c_o|\tau, c_h)$ within a certain computational budget. In this setting, c_o denotes tables and there are exponentially many tables which correspond to a task success under a given dialogue. Therefore, with our relabeling approach, we increase the number of near-optimal task examples exponentially, which makes it much easier for the language model to learn to query the flight table.

Our relabeling is approximately valid according to the condition specified in Section 4.1. While the customer does not have access to the flight table and therefore is not directly affected by our relabeling, there are still some minor edge-cases in which over-optimism about the dynamics could be learned by our policy. If for example, in the dataset the customer were to occasionally reject the first flight that we suggest, our policy may learn to assign a small probability to the action of initially offering the wrong flight, relying on them subsequently rejecting it such that we can later recover and offer the correct one. However, in practice we observe that these cases are rare in AirDialogue.

	success rate
CALM (greedy)	**0.88** ± 4e-3
LM(GPT2-small) (greedy)	0.38 ± 1e-3
AirConcierge (greedy)	0.81 ± 7e-3
CALM (planning)	**0.90** ± 2e-3
LM(GPT2-small) (planning)	0.74 ± 7e-3
Human	**0.88**

Table 1: **Comparison of our method and baselines across all tasks.** Using greedy decoding, our method matches human performance, greatly improving over baselines. Adding roll-outs (32 samples) further improves task completion.

5.4 Table Selection as Auxiliary Loss

The primary high-level action involved in AirDialogue is the decision of which flight table entry, if any, to recommend to the user. We therefore implement our auxiliary objective as a classification head on top of the language model, trained to predict the flight table entry that meets the customer's requests. Specifically, our set of high-level actions $\mathbf{A}$ is the set of flight table rows $\{f_1, f_2, f_3, ..., f_N\}$ plus an additional item f_0, corresponding to the case in which no flights meet the customer's requirements. If f^* is the flight recommended in the dialogue, then our auxiliary objective is:

$$\mathcal{C}(\phi) = \max_{\phi} \mathop{\mathbf{E}}_{(c_o,\tau)\sim\mathcal{D}^{\text{off}}} \log P_\phi(f^*|\tau, c_o). \qquad (6)$$

6 Experiments

In this section, we empirically evaluate the performance of CALM on AirDialogue (Wei et al., 2018). We first show that CALM outperforms the SOTA on the AirDialogue dataset by around 7% in the standard simulated evaluation protocol proposed by Chen et al. (2020), which prior work denotes as "self-play" (see Appendix E), and this matches human-level performance as reported by Wei et al. (2018). Beyond this, we also perform a comprehensive set of ablation studies to validate the necessity of each component of CALM.

Experiment Setup and Baselines. We compare CALM on AirDialogue with two baselines. The first is AirConcierge, the previous SOTA on AirDialogue, which explicitly parses and executes SQL queries from the dialogue (Chen et al., 2020). The other is a standard language model (denoted as LM(GPT2-small)) trained on a dataset filtered for successful task examples, without any of our context-aware language modeling techniques (see Appendix Section A for more details on dataset filtering). CALM uses the fine-tuned GPT2-small model (Radford et al., 2018) as the backbone of the policy and dynamics model. After learning the

Agent: Hello. How can I assist you?
Customer: I am planning to visit Disney world at Washington, IAD, can you help me with booking?
Agent: Sure, I will help you. Can I have your name please?
Customer: My name is Angela Perez.
Agent: May I know your source airport code?
Customer: My source airport code is JFK.
Agent: Please share your planned journey dates.
Customer: My journey dates are June 08 and June 10.
Agent: Let me know your connection limit.
Customer: I need a break in between my journey.
Agent: Do you have any other specifications?
Customer: I prefer business class flight ticket.
Agent: Thank you for sharing the details, there are no flights available with your given details.
Customer: Ok, I will find another alternate for this trip. Thank you.
Agent: Thank you for approaching us.
Submit: no_flight , Angela Perez , 0

Cancel

Agent: Hello. How can I assist you?
Customer: I want to cancel my recent reservation, due to some health issue. Can you help me?
Agent: Sure, I will help you. May I know your name?
Customer: Thank you. I am Linda Smith.
Agent: Please wait a minute.
Customer: Sure.
Agent: Thanks for waiting, We found a reservation on your name and it has been cancelled successfully.
Customer: Thank you for your help.
Agent: Thank you for reaching us.
Submit: cancel , Linda Smith , 0

No Reservation Found

Agent: Hello. How can I assist you?
Customer: Due to a sudden illness of my mother, I would like to change my existing reservation. Can you help me with this?
Agent: Sure, I will help you. May I know your name?
Customer: My name is Mary Perez.
Agent: Sorry, there is no reservation found on your name.
Customer: Ok, not an issue. May be something went wrong while making the reservation. Thank you for providing information.
Agent: Thank you for choosing us.
Submit: no_reservation , Mary Perez , 0

Figure 3: **Example dialogues generated by CALM (in green) in the simulated evaluation.** Despite being end-to-end, CALM produces highly coherent and sensible outputs.

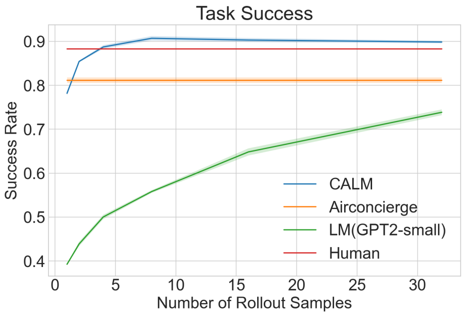

Figure 4: **Task success as a function of the number of rollout samples.** Note that successful task completion improves with more rollout samples.

dynamics model, both CALM and the LM(GPT2-small) can employ two different planning strategies: (1) a simple greedy decoding of the next utterance (equivalent to beam search with beam-width one) and (2) the rollout planning as described in Section 4.4. For AirConcierge, we only evaluate greedy decoding, as this method cannot be easily adapted for producing full rollouts. Rollout planning requires a method for predicting the reward of a given dialogue, and we describe our specific reward predictor for AirDialogue in Appendix Section E.1.

Results for Task Success. In terms of task success, CALM outperforms the prior SOTA (AirConcierge) by approximately 7%, achieving 88% task success when using greedy decoding from the language model (see Table 1). Compared with AirConcierge, where all reasoning about the task context is done outside of the language model, CALM does all of the filtering, selecting, and responding with relevant flight table entries within the language model, in a fully end-to-end manner. Meanwhile, CALM also improves over LM(GPT2-small) by 50% in terms of task success, indicating the necessity of our context-aware approach for goal-oriented tasks.

	CALM	LM(GPT2-small)	AirConcierge
Perplexity	1.63	**1.59**	-
BLEU	32.88	**35.75**	27.75

Table 2: **BLEU score and perplexity results.** CALM improves on task success without sacrificing generation quality.

We further evaluate the the performance of various methods, when utilizing the rollout planning technique. As shown in Figure 4, as the number of rollout samples increases, the performance improves for all methods. Remarkably, applying the rollout planning to CALM further increases total task success by 2%, raising it to 90% and matching human performance on the AirDialogue task. The baseline LM(GPT2-small) benefits much more from rollout planning than CALM, and we suspect that at around 90% task completion, the performance becomes bottlenecked by the customer bot's mistakes, therefore we only observe less gain from rollout planning with CALM.

Results for Language Quality. To quantitatively measure the generated language quality, we present perplexity and BLEU for all methods in Table 2. CALM performs similarly to LM(GPT2-small) and outperforms AirConcierge significantly.

Ablation Study. To examine the effectiveness of each single component in our method, we train and evaluate four ablations of CALM. Each of these ablations remove one of the components in our approach: task relabeling (Section 4.1), auxiliary loss (Section 4.2), and table pre-training (Section 4.3). Beyond this, we also examine CALM without both task relabeling and pre-training. As shown in Table 3, removing any one of these components drops task success by at least 10%, and in most cases much more than that. This shows that each piece of our method plays a critical role in helping CALM to effectively learn the goal-oriented task.

	Success Rate
CALM	**0.88** ± 4e-3
LM(GPT2-small)	0.38 ± 1e-3
CALM w/o relabel, pre-train	0.42 ± 4e-3
CALM w/o relabel	0.66 ± 1e-2
CALM w/o pre-train	0.39 ± 3e-3
CALM w/o auxiliary loss	0.78 ± 4e-3

Table 3: **Task success rate for various ablations of CALM on AirDialogue (all using greedy decoding).** Removing any single component from CALM drops performance by at least 10%.

7 Conclusion

We proposed an end-to-end framework, CALM, for goal-oriented dialogue systems. Formulating end-to-end dialogue generation as a Markov decision process, CALM employs task relabeling and context-aware finetuning to steer supervised learning of language models towards specific goals, improving task performance drastically while preserving language quality. We show that this improves performance on AirDialogue over the previous state of the art, and matches previously reported human performance under the standard simulated evaluation protocol.

CALM optimizes for task-specific measures of success, and while such measures might be comparatively simple for domains such as AirDialogue, in general specifying the right success measure or reward function may present challenges. Furthermore, as with all methods based on end-to-end language models, CALM is susceptible to internal biases and inconsistencies in the language model itself. There is for example no constraint that ensures that CALM produces *truthful* answers, or that it avoids harmful or socially unacceptable outputs. A practical deployable dialogue system would likely require additional measures to account for such issues, analogously to how learning-based methods for self-driving vehicles might require some additional safety mechanisms to ensure constraints, and indeed further research on reward specification, ensuring truthful outputs, and other constraint strategies for dialogue systems that combine language models and reward maximization is a promising and important direction.

The context-conditioned supervised learning strategy used by CALM provides for reward maximization, but is in general not optimal for arbitrary reinforcement learning problems: in general RL settings, learning a value function with dynamic programming in general can attain significantly better returns than imitating high-performing trajectories, by recombining good parts of multiple different trajectories (which might individually be suboptimal) (Kostrikov et al., 2021; Kumar et al., 2022). The simple supervised learning strategy works well in the domain we tested, but extending CALM to use value-based reinforcement learning methods is a promising direction for future work. Indeed, the improvement obtained from planning on top of the CALM model likely indicates that the supervised learning approach we employ has room for improvement. Additionally, the auxiliary objectives and relabeling strategies we employ require some amount of domain-specific design, and more general strategies could be developed in future.

Addressing these limitations in future work and developing more advanced methods that combine end-to-end language generation via large language models with concepts from reinforcement learning and planning is a promising research direction for making dialogue systems more capable, while also making language models more task aware. We hope that CALM will serve as an indication for the potential of such methods.

A AirDialogue Dataset Filtering

When training the LM(GPT2-small) and Customer Bot, we filter the dataset by only keeping the successful task examples. This is be achieved by simultaneously checking for successful task completion and whether a set of simple string matching heuristics are satisfied in the dialogue. Our heuristics aim to ensure that strings corresponding to each of the customer's flight requirements and the customer's goal are explicitly present in the dialogue. This combination of filtering steps reduces the size of the training set by 26%. Despite this, we find that this is still more than enough data for the model to successfully learn the task.

A.1 Rollout Planning

In Figure 5, we show the rollout planning procedure, which described in Section 4.4.

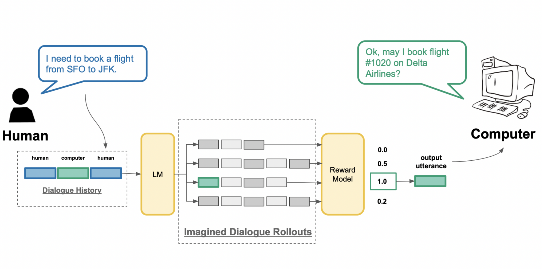

Figure 5: **Our dialogue rollout planning procedure.** To generate our response, we sample entire dialogues from the language model and then re-rank the predicted dialogues with a reward function.

B Training Our Customer Bot

Our customer bot is fine-tuned from GPT2-small (124M parameters), using the standard language modeling objective. We used the Huggingface Transformers library's implementation of GPT2 (Wolf et al., 2020). The customer's flight requirements are provided to the model as a prefix to the dialogue, which formatted as a comma separated list consisting of the customer's goal and flight requirements. We trained the customer bot for maximum 10 epochs with early stopping on the filtered dataset. For training, it takes around 1 day on 4 GPUs. Specifically, we trained using Adam with learning rate 1e-4 and batch size 8. Our customer bot achieves a perplexity of 1.47 on the development set and a BLEU score of 38.5.

C Fight Agent Bot Details

All our flight agent bots are fine-tuned from GPT2-small (124M parameters) using the standard language modeling objective. We used the Huggingface Transformers library's implementation of GPT2 (Wolf et al., 2020). Similar as the customer bot, we trained for maximum 10 epochs with early stopping on the filtered dataset, which takes roughly 1 day on 4 GPUs. Specifically, we trained using Adam with learning rate 1e-4 and batch size 8. We implement the final action prediction as a sequence of tokens generated at the end of each dialogue. The flight table is passed to the model as a prefix of flight embeddings, where each embedding is produced by summing embeddings corresponding to each attribute of a given flight (e.g., flight arrival/departure day/location, flight price, etc.).

D AirDialogue Task Pretraining

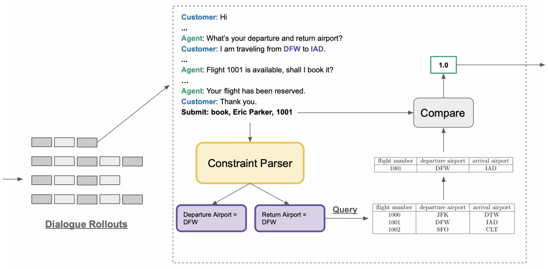
Initialized using GPT2-small (124M parameters), we further pre-train our flight-agent bots by training on simplified task sequences. Specifically, these sequences consist of our flight table followed by a comma separated list of the customer's flight requirements and a string representing the final action taken. We also apply our auxiliary loss and task-relabeling techniques during this pre-training.

We pre-train on 4 million unique samples, using batch size 64 and Adam with learning rate 1e-4, which takes around 2 days on 4 GPUs. During pre-training, we found that it took around 2 million unique samples before the model suddenly started to learn the task of querying the flight table, and it took roughly 2 million more samples before it became proficient at querying the table. Both the unusual progression of learning during this pre-training phase and the high sample complexity needed to learn the task, indicates the difficulty in learning to query the flight table. This calls for future work about further investigate the challenges in learning complex logical functions using neural networks.

E Self-Play Evaluation

Prior works primarily evaluate bots for the flight agent through "self-play" (Chen et al., 2020; Wei et al., 2018). We follow the same evaluation protocol in our work. Basically, we train a bot to play the role of the customer during evaluation and compute task success by simulating conversations against this bot. We run all self-play evaluations on the same subset of 1,000 dialogue scenarios, randomly selected from the validation set.

All models are evaluated against the same customer bot. including models for the baselines. We find that when running against our self-play bot,



Customer: Hi
...
Agent: What's your departure and return airport?
Customer: I am traveling from DFW to IAD.
...
Agent: Flight 1001 is available, shall I book it?
...
Agent: Your flight has been reserved.
Customer: Thank you.
Submit: book, Eric Parker, 1001

flight number	departure airport	arrival airport
1001	DFW	IAD

flight number	departure airport	arrival airport
1000	JFK	DTW
1001	DFW	IAD
1002	SFO	CLT

Figure 6: **Our reward prediction method.** We train a model to parse the customer's flight requirements from the dialogue. We execute these flight requirements against the table and compare the output to the flight that was actually booked; this determines the reward (i.e. if the correct flight was booked or not).

task completion success for prior methods is increased, sometimes by more than 8% (from what was reported by such prior works under the same evaluation setting). The only difference is the specific model used for customer's side of the conversation, and we conjecture that this difference is likely due to the architecture difference and the details of our dataset filtering. This significant change in evaluation performance compared with prior works, not only indicates the quality of our customer bot, but also suggests the importance of accounting for these factors in evaluating and comparing dialogue systems. We release the code and model weights for our customer bot at https://sea-snell.github.io/CALM_LM_site/.

E.1 AirDialogue Reward Predictor for Rollout Planning

To execute rollout planning, we need a reward predictor which can estimate whether a given dialogue is a successful example of task completion or not. In the case of AirDialogue, we found that the most robust way to estimate this reward is the following: we first fine-tune a RoBERTa-base model (123M parameters) to predict the customer's ground-truth goal and flight requirements from the set of dialogues in the training set. We used the Huggingface Transformers library's implementation of RoBERTa (Wolf et al., 2020). We do not filter the training-set when training this model. Once this model is trained, our procedure for predicting dialogue success is the following:

1. Given a dialogue, use our RoBERTa model to predict the customer's goal and flight requirements.
2. We then execute this predicted information against the agent's flight table and reservation flag, to produce a set of valid final actions.
3. If the final action taken in the dialogue is within the set of predicted final actions, then predict that the current dialogue is successful, otherwise predict that it is unsuccessful.

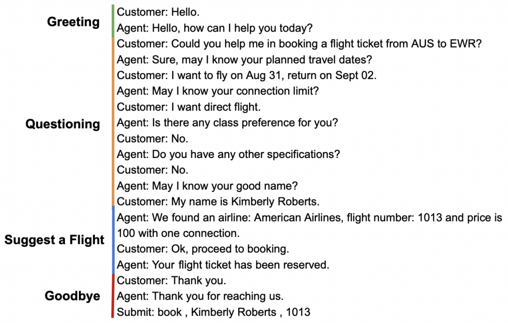
dep. city	ret. city	dep. month	ret. month
0.76	0.76	0.77	0.77
dep. day	ret. day	dep. time	ret. time
0.76	0.76	0.94	0.94
class	price	connections	airline
0.92	0.37	0.95	0.97

Table 4: **Our RoBERTa parser's accuracy in predicting each of the customer's flight requirements.** The parser predicts 5 out of 12 flight requirements with >90% accuracy and 11 out of 12 with >70% accuracy. The price requirement has the lowest accuracy because it is often not explicitly mentioned in the dialogue; the model has to rely on priors for prediction in these cases.

See Figure 6 for a visual illustration of this procedure. Our model obtains 94% accuracy in predicting the reward of the dialogues in the validation set (see Table 4 for a more extensive breakdown of the model's accuracy).

F Example Conversation in AirDialogue

In Figure 7, we showcase a specific example for the conversation in AirDialogue.



Customer: Hello.
Agent: Hello, how can I help you today?
Customer: Could you help me in booking a flight ticket from AUS to EWR?
Agent: Sure, may I know your planned travel dates?
Customer: I want to fly on Aug 31, return on Sept 02.
Agent: May I know your connection limit?
Customer: I want direct flight.
Agent: Is there any class preference for you?
Customer: No.
Agent: Do you have any other specifications?
Customer: No.
Agent: May I know your good name?
Customer: My name is Kimberly Roberts.
Agent: We found an airline: American Airlines, flight number: 1013 and price is 100 with one connection.
Customer: Ok, proceed to booking.
Agent: Your flight ticket has been reserved.
Customer: Thank you.
Agent: Thank you for reaching us.
Submit: book , Kimberly Roberts , 1013

Figure 7: **An example conversation in AirDialogue.** Conversations generally begin with a greeting followed by some questioning / information gathering, and then finally the agent suggests a flight before ending the conversation.

G Previous Approaches to Flight Table Processing

Prior works (Wei et al., 2018; Jiang et al., 2021) typically input the table directly into a language model, expecting that the skill of querying the table will be naturally learned via the standard language modeling objective. We found this approach to under-perform in our experiments. These findings are also consistent with recent works which show that pre-training transformers for querying tables can significantly improve the transformer's performance on downstream tasks which use tables (Liu et al., 2021). AirConcierge (Chen et al., 2020) takes a different approach, and explicitly predicts and executes SQL queries based on the dialogue. This approach obtains the SOTA task success on AirDialogue, but it involves several complex components, requires the ability to preform semantic parsing on the dialogue, and of course requires additional domain knowledge about the format and structure of the flight table, which reprsents the task context. In our work, we show that applying CALM for AirDialogue can close this gap by inducing task learning from language models and achieve end-to-end learning from the flight table, without sacrificing the generated language quality.

H Error Analysis

In Table 5 we present a detailed breakdown of model errors. As expected, determining the flight to book, if any, is consistently shown to be the most challenging sub-task, as evidenced by the lower “flight success rate" and the lower F1 scores for “no flight", “book", and “change" on LM (GPT2-small). In particular, “change" has a low recall, precision, and F1 score for all models because it makes up a very small 0.4% of the training data. Lastly, the “constraint success" row shows that even when CALM books the wrong flight, the flight it does books meets >80% of the customer's flight requirements on average.

	CALM	LM (GPT2-small)	AirConcierge
full success rate	**0.88**±4e-3	0.38±1e-3	0.81±7e-3
status success rate	**0.92**±3e-3	0.84±2e-3	0.90±1e-3
flight success rate	**0.88**±4e-3	0.39±1e-3	0.82±5e-3
name accuracy rate	0.99±2e-3	**1.0**±8e-4	0.99±1e-3
book R/P/F1	**0.85**±8e-3	0.06±3e-3	0.81±1e-2
	0.86±8e-3	0.05±2e-3	0.70±9e-3
	0.85±6e-3	0.05±3e-3	0.75±1e-2
no flight R/P/F1	**0.82**±1e-2	0.36±9e-3	0.59±5e-3
	0.80±1e-2	0.74±5e-3	**0.93**±6e-3
	0.81±1e-3	0.49±9e-3	0.72±5e-3
cancel R/P/F1	0.98±2e-2	**1.0**±0.0	**1.0**±0.0
	0.95±3e-2	**1.0**±0.0	0.75±1e-2
	0.97±2e-2	**1.0**±0.0	0.86±7e-3
change R/P/F1	**0.25**±8e-2	0.0±0.0	0.0±0.0
	0.33±1e-1	0.0±0.0	0.0±0.0
	0.28±1e-1	0.0±0.0	0.0±0.0
no reservation R/P/F1	**0.99**±5e-3	**0.99**±2e-3	**0.99**±3e-3
	0.99±2e-3	**0.99**±2e-3	**0.99**±3e-3
	0.99±3e-3	**0.99**±2e-3	**0.99**±3e-3
constraint success	0.81±9e-3	0.71±3e-3	**0.89**±1e-3

Table 5: **Detailed statistics for model errors.** All models are evaluated with greedy decoding. In addition to the full task success rate, we report success rate for each sub-component of the full task (status / flight / name). We also report recall (R), precision (P), and F1 score for task success under each type of high-level action (book / no flight / cancel / change / no reservation). Lastly, we report the average fraction of the customer's flight requirements that are met when the agent books the wrong flight (constraint success).

Am I Me or You?
State-of-the-Art Dialogue Models Cannot Maintain an Identity

Kurt Shuster **Jack Urbanek** **Arthur Szlam** **Jason Weston**

Facebook AI Research

Abstract

State-of-the-art dialogue models still often stumble with regards to factual accuracy and self-contradiction. Anecdotally, they have been observed to fail to maintain character identity throughout discourse; and more specifically, may take on the role of their interlocutor. In this work we formalize and quantify this deficiency, and show experimentally through human evaluations that this is indeed a problem. In contrast, we show that discriminative models trained specifically to recognize who is speaking can perform well; and further, these can be used as automated metrics. Finally, we evaluate a wide variety of mitigation methods, including changes to model architecture, training protocol, and decoding strategy. Our best models reduce mistaken identity issues by nearly 65% according to human annotators, while simultaneously improving engagingness. Despite these results, we find that maintaining character identity still remains a challenging problem.

Setting: *Barn, Farm* *Partner*: *Thief* *Self*: *Guest*
Guest: Hail who goes there?! **Thief**: Hello friend I mean you no harm
Model Response **Guest**: *I am not your friend, I am your* **thief!** *I am here to steal from you!*
Character Token Probabilities **Thief**: 0.39 **Guest**: 0.23

Setting: *Castle Kitchens, Inside Palace* *Partner*: *Hunter* *Self*: *Helper*
Hunter: Hi **Helper**: Hello. What brings you to the kitchen? **Hunter**: I am chopping some meat that is to be sold. **Helper**: Could you spare me a piece? I'm starving. **Hunter**: It's 3 cents a pound, if you have 3 cents then yeah
Model Response **Helper**: *I don't have any money. I'm just a poor* **hunter** *trying to make a living.*
Character Token Probabilities **Hunter**: 0.39 **Helper**: 0.12

Table 1: Failures of a 2.7B parameter transformer pretrained on 1.5B examples from a large dialogue corpus (Roller et al., 2021) and fine-tuned on LIGHT (Urbanek et al., 2019). The bold words in **red** highlight the model mistaking its identity for its partner's. (**Top**) The model believes it is a **thief**, rather than a **guest**. (**Bottom**) The model believes it is a **hunter** rather than a **helper**. Token probabilities are given at the position of the mistake for the two names.

1 Introduction

The exchange of stories from one's past, or descriptions of activities in one's present, are a fundamental part of human discourse. Trustworthy human conversationalists keep their stories roughly straight within a conversation. An interlocutor taking on *your* own stories and persona as *theirs* is especially jarring and unnatural. However, despite the improvements in state-of-the-art open-domain dialogue modeling, both in terms of distributional accuracy metrics like perplexity, and subjectively in terms of human judgements (Adiwardana et al., 2020; Roller et al., 2021), interactions with those agents reveal that they cannot keep their stories straight. In particular, they are likely to take on the role of their interlocutor; for example, if an agent's partner says they are a software engineer, the agent is likely to say it is a software engineer too (Roller et al., 2021), or worse, appropriate their partners just told tale of a trip to NAACL as their own. Some example failure cases are given in Table 1, where models incorrectly take on the name, role or activities of their partner instead of their assigned role. These failures are related to the general problems of repetition in language models (Holtzman et al., 2020), the weak influence of word order (Sinha et al., 2021) and inability to avoid contradictions (Nie et al., 2021).

In this work we formalize and quantify this behavior, show that to some extent it can be detected automatically with a specifically trained classifier, and then study a wide variety of mitigations. These include multi-objective training, unlikelihood training (Li et al., 2020; Welleck et al., 2020),

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2367 - 2387

classifier-assisted re-ranking based generation, and several forms modifying the attention mechanisms of the decoder in a sequence to sequence model. Our best methods can reduce mistaken identity issues by 65%, while simultaneously improving in-conversation engagingness; indeed, our models that can stick to their role in conversation are judged by humans to be significantly more engaging than their baseline counterparts. Despite these advances, we find that there is still considerable space to improve these results further in future work.

We make publicly available both our trained models and code to reproduce results[1].

2 Related Work

Role-Playing in Open-Domain Dialogue Much recent work has explored training open-domain dialogue models on large and small dialogue corpora, with the former imbuing raw conversational ability and the latter providing necessary conversational skills. Most crowd-sourced datasets require acting out a role to some capacity in conversation (though indeed Mazaré et al. (2018) study extraction of roles from raw data). Some involve providing persona lines that a model must assume throughout the conversation (Zhang et al., 2018; Dinan et al., 2020; Xu et al., 2021); others require more subtle "roles", such as a listener (Rashkin et al., 2019), or a teacher and student (Dinan et al., 2019b; Gopalakrishnan et al., 2019; Zhou et al., 2018; Komeili et al., 2021). Zheng et al. (2020) explore using a discriminative model to predict whether model responses contain similarity with their persona, similar to methods we employ in our work.

Consistency in Open-Domain Dialogue A common paradigm in the state of the art of open-domain dialogue involves concatenating all relevant contextual information as input to a sequence to sequence neural model (e.g., transformers (Vaswani et al., 2017)) to obtain a conditioned response. Such models can yield human-like and engaging responses (Adiwardana et al., 2020; Roller et al., 2021). Nevertheless, various consistency issues still plague such models. Recent studies have indicated that hallucination of incorrect knowledge is still far from a solved issue (Shuster et al., 2021; Santhanam et al., 2021), with some proposing specific datasets and tools for measuring precisely the levels of this undesired attribute (Liu et al., 2021). Another clear example of failure is the short-term memory of state-of-the-art models (Xu et al., 2021), sometimes due to the lack of long-form training data or long-context models but often due to simply the modeling itself.

To address consistency issues, a variety of methods have been explored. In the context of knowledge-grounded dialogue, different ways to attend most effectively over provided contextual information have been explored (Zheng and Zhou, 2019; Ye et al., 2020; Prabhumoye et al., 2021; Wang et al., 2019). These works find that considering factual documents separately (in some capacity) improves model grounding. We explore such methods, but in the context of character identity.

Another general problem is that of contradictions. Nie et al. (2021) collect a dataset of contradictions in dialogue, and train classifiers that help re-rank model outputs at inference time; Li et al. (2020) explore unlikelihood training (Welleck et al., 2020) to reduce repetition and contradiction, among other undesired traits, in model generations. The character identity issue we study in this work can be seen as an important class of contradictions, but to the best of our knowledge, has not been explicitly focused on.

3 Methods

3.1 Problem Setting

We consider a two-party chat setting. The context provided to a model includes: (i) the name of its character and the partner's character; (ii) an extended description of its own character; (iii) and, information about the area in which the conversation takes place. The responsibility of the model is to engage its conversational partner, with no other goal prescribed; however, it should stay within character and within the bounds of the defined setting.

We operate in the context of LIGHT (Urbanek et al., 2019), consisting of grounded fantasy role-playing game conversations. The LIGHT environment involves humans and models interacting with thousands of objects in hundreds of locations, all while assuming the roles of one of hundreds of characters. The dataset consists of roughly 8.5k dialogues spanning 111k utterances. It is an ideal setting for this study because of the rich and varied personas with explicit backstories.

To quantify the character identity problem, we take a state-of-the-art dialogue agent (specifically, BlenderBot (Roller et al., 2021)) fine-tuned on the

---

[1] URL will appear here.

LIGHT dialogue dataset and ask human annotators if the agent mistakes its identity based on its utterances in context. The agent conditions its response on the LIGHT context and prior utterances in the dialogue history. We see in Table 4 that in roughly 6.5 percent of utterances the model mistakes its identity; this corresponds to a mistake in approximately 35 percent of conversations.

BlenderBot uses a Byte-Level BPE tokenizer (Radford et al., 2019); an artifact from the BlenderBot pre-training is that it only considers 128 such tokens in the past, and thus has no mechanism for recovering truncated information about the LIGHT context in later conversational turns. Our second baseline lengthens the input context to 1024 BPE tokens, which allows the entire context for *every example* to fit into the truncation length of the model; we follow methods employed in Xu et al. (2021) to extend the positional embeddings of the model. We see in Table 4 that this actually makes the problem worse, resulting in 7.4 percent of utterances with mistaken identity (corresponding to a failure in approximately 38 percent of conversations).

3.2 Measuring Role-Playing Accuracy: RPA

We first define a metric, role-playing accuracy (RPA), to denote how often a model's responses are "in-character"; by this, we mean how often the model's response could feasibly be said by their character, given their assigned character identity. Measuring RPA is a non-trivial task for a variety of reasons. First, some conversations involve pairs that can reasonably say similar things (priest vs. priestess, man vs. woman, wizard vs. witch). Second, opening lines are often more generic ("hello", "how fare your travels today"), so *either* character can say it in conversation. The third reason stems from the data that we study; we are relying on crowdsourced data in which humans are required to portray their characters. Some crowdworkers may be better than others, and there may be some noise in the dataset in which, e.g., a horse may proclaim its love for a queen, or a knight may discuss at length the kingdom's tax collecting.

Given the difficulties above, our primary measure of RPA involves human annotation of model responses, specifically evaluating whether a candidate response fits a given model's character. We thus have human crowdworkers chat with each model in a LIGHT setting; each is given a character and asked to role-play, while the human annotates each model response, determining whether the model is in character: we denote this metric as "Mistaken Identity" in our experiments, and other utterance-level annotations are collected. Further details regarding human evaluation are outlined in Section 4.7.

Despite the efficacy of human evaluation, it is both costly and slow; as a proxy, we thus train models specifically designed to identify whether a candidate response from a model fits the model's role, and denote these as "RPA Classifiers". We employ poly-encoder transformers (Humeau et al., 2020) to learn this metric, and structure the task as a ranking one; the model receives the LIGHT setting and prior utterances of dialogue as input, as well as the response currently under consideration, and the model must choose the correct character from a fixed set of candidates. We also explore RPA classifiers trained on all partially complete sequences of labels, such that the classifiers can determine the character speaking without requiring the full utterance; we call these left-to-right (LTR) RPA classifiers. Further details about how our RPA classifiers are built are given in Appendix B.

3.3 Mitigations

In this section we describe several strategies for improving the role-playing accuracy of dialogue agents, specifically ways to improve our transformer baselines.

3.3.1 Re-ranking Model Outputs via RPA

We can employ an RPA classifier in response generation by using it to rank candidate model outputs.

Utterance Re-ranking: Given a set of candidate responses, the RPA classifier can re-score the set and return the response yielding the highest probability of staying in character (according to the RPA score on the complete candidate generations). The dialogue models employ beam-search to generate responses, and the candidates for re-ranking are the beams within beam-search. We also try nucleus sampling (Holtzman et al., 2020) and delayed beam-search (Massarelli et al., 2020) to see whether more diverse candidates have any effect.

Partial And Complete Efficient Re-ranking (PACER): Re-ranking only the final beam candidates may be suboptimal because it is well known that those candidates are not very diverse (Kulikov et al., 2019), meaning there may not be any good candidates to choose from in this final set. In order to generate utterances that agree with our classifiers, a possible improvement is to generate the utterance such that partial generations also agree with the classifier when generating left-to-right, ensuring that good candidates are surfaced. With access to LTR RPA classifiers, we can apply re-ranking to partial sequences.

Unfortunately, re-ranking at every step of beam search, for every token, requires significant computation, such as in the recent FUDGE method (Yang and Klein, 2021). FUDGE re-scores tokens at each decoding step by multiplying the classifier probability with each token probability, and renormalizing, which is used for control tasks with lightweight classifiers in order to be tractable.

In our proposed approach, called PACER, we re-score candidate tokens, for each beam, according to the probability that their inclusion yields the appropriate character classification, and then finally re-rank the complete candidate beams. To make this efficient, we crucially score only a small proportion of decoding steps (e.g., 5% of token positions) as well as for only a few candidate re-scored tokens (e.g., top 10 only). We can control these hyperparameters to explore the speed vs. accuracy trade-off.

3.3.2 Unlikelihood

We explore utilizing an unlikelihood (UL) loss (Li et al., 2020; Welleck et al., 2020) to force the model to stay in character during training. Unlikelihood training works as a counter to the standard maximum likelihood (MLE) training of language models; while MLE training pushes the model to generate the correct tokens, UL training pushes the model to *not* generate *incorrect* tokens.

While training on the LIGHT dataset with standard NLL loss, with some fixed probability we consider a candidate model generation for UL loss. The full generation is sent to the RPA classifier; if the generation is classified as coming from the incorrect character, we examine each partial generated sequence of the output, and send these sequences to the LTR RPA classifier to determine whether the candidate partial sequences match the model's character. We apply UL loss to tokens that yield the *wrong* character classification.

3.3.3 Multi-objective Training

The RPA classifiers utilize the LIGHT setting and prior utterances of dialogue history to determine which character generates a candidate response. We hypothesize that the generation models themselves should be able to pick out and utilize these components as well. However, the RPA classifier models are trained explicitly for this task, whereas the seq2seq models are trained only to generate a plausible continuation of a dialogue history.

We thus explore a setup in which the generation models are trained to identify the speaker of an utterance as well. To do this, we use the output representations from the model (either encoder + decoder, or decoder only) as inputs to n_{MO} additional transformer layers, where we vary $n_{MO} \in \{0, 2\}$. The final outputs are used to compute a character score, similarly to the RPA classifier.

The model can then be trained piece-wise. After initializing the model weights with those trained on the LIGHT response generation task, we then train *only* the extra layers with *only* the character classification objective; once the classifier achieves suitable performance on the task, we can begin to back-propagate the character classification objective multi-tasking with the dialogue task itself to the generation model directly, in the hope that the model learns to update its internal representations of the context and/or the decoded response.

3.3.4 Expanded Decoder Attention

Maintaining identity relies on the model's capacity to understand which inputs from the conversational history are pertinent when generating a continuation of the preceding dialogue. In a standard, open-domain chit-chat scenario, the model has free reign to decide which elements of the context it would like to condition on when generating a response, as we are dealing with a nearly unconstrained output space (so long as the output follows plausibly from the input). In LIGHT, however, we want to emphasize certain components of the context more so than others; specifically, when role-playing as a character, we want the model to always be reminded of its role, so that it can conditionally generate an optimal response **while staying in character**. In this lens, one can view the task as "grounding" on one's character information when conversing.

Profile Grounding Inspired by models demonstrating good performance in knowledge-grounded dialogue (Zheng and Zhou, 2019; Ye et al., 2020; Prabhumoye et al., 2021; Wang et al., 2019), we propose a simple extension to the transformer seq2seq architecture, specifically the decoder, to ensure the model knows to condition on the profile. The standard transformer decoder first uses self-attention over the decoded response, and then cross-attention over the encoder outputs. We add a third attention step, *expanded attention*, that attends *again* over an extracted *subset* of the input context (encoded separately from the normal context). We explore various subsets of the context to determine which are most important for both RPA and other automated metrics, and call this method "Profile" grounding as the subsets generally include the character and role description. We utilize the *exact same* (shared) parameters for both the normal cross-attention and the expanded attention; thus, model size is not affected.

Automated Grounding Instead of directly telling the model what to re-attend to, we also explore whether the model can learn to do this automatically, based on its own (or other) representations of the context. The first method we consider is examining the **decoder attention weights**. Specifically, we use the attention weights from the decoder over the *full context* to choose k tokens to re-attend to. This operation is done on a per-layer basis, and thus allows different decoder layers to re-attend to (potentially different) components of the input.

The second method we consider is a **trainable mask**; this involves feeding the encoded context through a "mask" layer to select various tokens to re-attend to. Specifically, we feed the context through a linear projection layer followed by a softmax to select the top-k tokens. This set of tokens is then re-encoded by the encoder and fed to the decoder as the expanded attention context.

Finally, we explore using the **classifier attention weights** over the context *from the RPA classifier itself*. Intuitively, the RPA classifier has learned what components of the input are necessary for determining which character is speaking; if we look at these attention weights when considering the model's character, we know what the classifier thinks is important to use.

Combined Methods We also consider combining expanded attention with re-ranking methods, or with multi-objective training, to see if the combination can improve results. For the latter we use the automated grounding trainable mask method.

Train split	**Ranking Accuracy (Hits@1/427)**					
	# Eval Contextual Utterances					
	Full Datasplit			**LTR Datasplit**		
	0	4	All	0	4	All
LTR	64.8	84.3	83.9	61.7	80.5	80.5
Full	31.0	86.5	84.9	27.8	75.3	74.9

Table 2: RPA classifier performance on the **validation** set, comparing a partial-sequence trained model ("LTR") to one trained only on full sequences ("Full"). Models were trained with 4 prior utterances of context.

Re-ranker	Params		F1	RPA	Cost
	# Toks	Freq.			
None	0	0	15.8	88.4	1x
Complete-only	0	0	16.0	93.0	1.1x
Partial-only	10	5%	15.9	88.6	1.3x
Partial-only	10	33%	158	91.1	4.2x
Partial-only	10	100%	15.6	93.6	11.2x
Partial-only	50	5%	15.9	88.9	3.0x

4 Experimental Results

4.1 RPA Classifiers

We first assess the quality of our RPA classifiers. We measure hits@1/427, where the model must correctly identify the character speaking out of 427 characters from the validation set, comparing the standard and left-to-right (LTR) models in Table 2. We experiment with either 0, 4, or All prior context utterances. The LTR classifiers perform nearly as well as the full classifiers on the full datasplit, and outperform them on the LTR split. Given the robustness of the LTR RPA classifiers, we use this model for computing RPA throughout the remaining results, unless otherwise specified. Further results are given in Appendix Table 10.

4.2 Baseline Generation Performance

We next train baseline models for the dialogue generation task itself. Performance on the LIGHT dataset test split for our baseline models can be found in Table 4, with results on the validation set in Table 17 in the Appendix. While lengthening the context from 128 to 1024 tokens yields better perplexity, the model obtains worse F1 scores and does not improve much if at all on role playing ability, both when measured by the RPA classifiers and in human evaluations (see also Table 19). Further

	Automatic Metrics			Human Evaluations

Table 4: Automated metrics and human evaluations for various models considered throughout the paper on the LIGHT **test** set. RPA (Role-Playing Accuracy) is measured by the 4-utterance LTR classifier, see Sec. 3.2. The human evaluations are per utterance, except for Engaging and Mistaken Identity in Conversation (with the latter indicating % of conversations with mistaken identity).

detailed training and optimization specifications are given in Appendix A.

4.3 RPA Re-ranker Performance

Table 4 gives results for RPA-based re-ranking of generation models. Automated results show a slight bump in F1 on the LIGHT valid set, and indeed a bump in RPA. Including the intra-generation re-ranking with PACER yields an even higher RPA score. Table 3 contains the results of varying the candidate tokens re-ranked per intra-generation step (#Toks) and number of partial re-ranking steps (Freq), both in terms of generation metrics/RPA and relative computational cost compared to re-ranking. Increasing # of toks or increasing the frequency can lead to improved F1 and RPA, but with significant latency increase for too high values (e.g. over 11x when applying re-ranking for every partial step using the top 10 tokens each time). Applying both partial and final complete ranking helps performance. Note that re-ranker models use the same model to re-rank that is being used to measure RPA afterwards, making that metric biased. Hence, human evaluations are required for this model, which will be detailed in Section 4.7, and which will indicate that re-ranking does in fact help.

4.4 Unlikelihood

Results of unlikelihood (UL) training are also given in Table 4. We apply UL loss to the 128-truncation model in two different ways: (1) **Top-1**: apply the loss on the token that yields the most incorrect partial sequence RPA classification; (2) **All**: apply the loss to all tokens that yield an incorrect RPA classification on partial sequences. The RPA UL methods suffer compared to the baselines in terms of PPL and F1, yet they retain similar RPA metrics. We hypothesize that while the UL loss can adjust the model to refrain from generating out-of-character responses, there are still far too many other tokens that may yield similar outcomes that are not penalized. Table 12 in Appendix D includes similar results with the 1024-truncation model.

4.5 Multi-Objective Training

Multi-objective training results are in Table 5, where the base model is a 1024-truncation model. We measure generation metrics in terms of RPA (with PPL and F1 in Table 13 in Appendix E), and classification metrics in terms of Hits@1/427 as before. The model is able to predict the appropriate character using either the decoder outputs or the encoder+decoder outputs. For each case, $n_{MO} = 2$ yielded better results than $n_{MO} = 0$. Interestingly, despite the relatively strong performance of the model in classifying the right character (87.42

Input	n_{MO}	Stage	RPA	Hits@1

Classifier Attn. (bottom-k)	12.31	15.89	88.71

Table 7: Models trained with expanded attention (automated grounding), evaluated on the **valid** set. We vary the method for selecting the extra context to re-attend to. All models are long-truncation (1024).

hits@1 for the best model), this **does not** translate to substantial RPA improvements over the baseline.

4.6 Expanded Attention

Profile Grounding Expanding the decoder attention yields significant gains across all automated metrics, as seen in Table 6 for a 1024-truncate model (and in Table 15 in Appendix F for a 128-truncate model). As a baseline we explore simply re-attending to the full context again; this indeed improves metrics across the board for the short-context model, but the long-context model actually suffers. However, both models improve substantially over the baseline when including the full LIGHT context without the dialogue history, and attention over sub-components of the LIGHT context still yields strong improvements.

To see how much this expanded attention matters, we explored varying the number of rounds $r \in \{1, 2, 3\}$ of expanded attention, i.e., how many times the model attends to this additional context. In Table 6, we also see that a second expanded attention round yields even better results, but performance drops off after applying a third round.

Automated Grounding We show results for the automated grounding of expanded attention in Table 7. Attempting to use the decoder attention weights to select expanded attention context yields no additional benefits, which is not surprising: if the model could identify the pertinent components of the input beforehand, it would not require a re-attention. The trainable mask does not yield any benefits either. However, using the RPA classifier attention weights to inform the model which tokens to re-attend to yields improved performance across all three metrics compared to the baseline, and PPL is nearly the same as profile grounding (12.19 vs. 12.18), while RPA trails slightly behind (91.11 vs. 91.79). We also include the usage of the *bottom-k* tokens from the classifier weights to emphasize that there is indeed signal from the top-k, as using the bottom tokens does not help.

Automated Grounding + Multi-Objective Table 5 shows that combining automated grounding with the multi-objective task yields higher hits@1 compared to not using the trainable mask, especially in the first stage of multi-objective training. However, RPA scores are only fractionally better than the baseline. Appendix E includes results across more settings (see Table 13 and Table 14).

Expanded Attention + RPA Re-ranking The expanded attention and RPA re-ranker methods can also both be applied to obtain effective models. Results are in Table 4; indeed, the combination yields the highest F1 and RPA scores.

4.7 Human Evaluations

We performed human evaluation on our models. For each model we collected 100 human-model conversations, set up similarly to the original LIGHT dataset conversations. During the conversation, crowdworkers were asked to annotate the model's response for the following attributes: 1) *Mistaken Identity*: your partner says something that would imply they believe they're someone other than who they're noted to be; 2) *Contradiction*: your partner says something that contradicts something they've said before; 3) *Wrong Location*: your partner says something that would imply they believe they are in a different location than the provided one; 4) *Unrelated*: your partner says something that doesn't follow the previous turns; and 5) *Repetitive*: your partner says something they've already said, or are driving the conversation in circles. Utterances that do not contain any of the negative attributes are denoted "all good". Finally, we collect an engagingness score on a scale of 1-5 at the end of the conversation. More details in Appendix I. Results are given in Table 4, with more details results (and comparison with a retrieval baseline) in Table 19 in the Appendix. The baseline model displays mistaken identity 6.45% of the time, and has an average engagingness score of 4.04. Longer context increases engagingness to 4.16 but also increases mistaken identity. Unlikelihood and multi-objective training similarly increase mistaken identity. The successful methods, then, are the beam re-ranking methods and the expanded attention models. The long-context beam re-ranker decreases mistaken identity to 4.81%, while the profile expanded attention model improves to 4%, and has the best engagingness of 4.34. Combining RPA Re-ranking with expanded attention yields the lowest mistaken identity (2.38%), while adding PACER leads to the highest all-good percentage (85.7%). Correlations between automatic metrics and human evaluations are measured in Appendix K, where we find that RPA and mistaken identity are indeed strongly correlated.

5 Qualitative Analysis

5.1 Re-rankers & Generation Settings

We further explored three decoding settings: standard beam-search, delayed beam search (Massarelli et al., 2020) and nucleus sampling (Holtzman et al., 2020), both in a re-ranking setting and not. When considering performance on automated metrics (provided in Table 20 in the Appendix), we see that generation settings other than beam search, when using a re-ranker, yield lower F1 scores but higher RPA scores, as the RPA re-ranker has more diversity of candidate responses from which to choose; however, these methods perform worse in human evaluations, with nucleus sampling re-ranking yielding far more problems and far lower engagingness ratings. Qualitative analysis of outputs on the test set are in Appendix J.1.

5.2 Classifier Failure Modes

We note that the human dialogue data is classified as being "in character" only 92.8% of the time on the validation set by the LTR RPA classifier. We examine the scenarios in which the classifier is incorrect, with example input/output pairs in Table 21 in the Appendix. First, there are instances where either character could have said the output response (row 1). Second, there are instances where there are not enough clues in the context to provide an estimation of who said the response, for example at the beginning of the conversation (row 2). And, there are still some small amount of instances that the classifier simply fails (row 3).

5.3 Model Failure Modes

We analyze the results of turn annotation to understand what failure modes contribute to mistaken identity. A full list of such modes is in Table 16; the baseline model most often mistakes its partner for itself (i.e., the model thinks it is talking to itself). Other common failures include the model thinking that it is its partner's character, or emulating irrelevant characteristics.

5.4 Per-Turn Character Accuracy Analysis

We consider the RPA of various models when evaluated across the turns of conversation. Intuitively, baseline models would suffer as the conversation goes on for a variety of reasons (character roles are truncated out of context, more input yields noisier outputs, etc.). Appendix Figure 1 shows the per-turn results for a set of representative models. The *human* outputs are most often correct on the first turn, with gradual RPA decay throughout the conversation. The *128-truncate* baseline, as expected, suffers a dramatic performance drop after the first couple of turns. Meanwhile, with the *profile expanded attention*, we see near-human performance, with better RPA in later turns. Including RPA re-ranking improves dramatically over all turns.

5.5 Expanded Attention Visualization

To gain some insight into what is happening with the expanded attention, we mapped out the attention between context and response tokens for both a baseline model with no expanded attention, and a model with profile expanded attention. Figures 4 and 5 in the Appendix display the heat maps for an example context and response, with details on heat map construction given in Appendix M.

We find that the baseline model spreads its attention out across both the LIGHT context and the dialogue history, with the majority of the attention looking at overlapping words in the context and the response and almost no attention on the character names. The expanded attention model concentrates on the recent dialogue history heavily in the first level of attention, and then concentrates on pertinent words in the context related to the character information (i.e., the character names) in the second round of attention.

6 Conclusion

In this work we explored the problem of maintaining one's character in open dialogue, and showed that state-art-of-the-art models have a fundamental weakness in this regard. We provided a clear framing of the problem and showed one can build automatic metrics (RPA) that evaluate models using a classifier. We then explored a variety of methods throughout this paper. While a wide variety of well-known techniques, such as multi-objective or unlikelihood training, have little impact, we found that expanded attention and re-ranking are two approaches that can help to a degree, and their combination also improves results. Our introduced method PACER performs well and may be suitable for other tasks beyond the focus of this paper. Nevertheless, our best methods still lag behind human (crowdworker) performance in several regards, e.g. 1.34% vs. 2.23% in terms of mistaken identity per turn, or 5% vs. 14.7% per conversation. Therefore considerable progress still has to be made on this challenging problem.

7 Ethical Considerations

Limitations We note in the conclusion that the problem is not solved; our best models still lag behind human performance in maintaining character identity. All results are tested in the LIGHT environment, comprising open-domain dialogue within constrained settings with assigned characters. The application of these methods to other role-playing (or otherwise) settings is left for future work, though we believe that such methods could be beneficial outside of LIGHT.

Potential Risks We provide methods for mitigating mistaken identity in dialogue models. It follows that such methods yield models that are more convincingly role-playing as a given character. With more convincingly in-character models, someone with bad intentions could have a model imitate real-world people without consent, or worse, can say negative/harmful things while impersonating someone else. We note that our methods are orthogonal to improvements in dialogue safety (Xu et al., 2020; Dinan et al., 2019a), and so can be used in tandem to mitigate these potential risks.

Scientific Artifacts We make use of LIGHT in this work (Urbanek et al., 2019) (released under CC-BY license), an English-language crowdsourced dataset. We also plan to release the code and models (will be released under MIT license), with the intended use being for others (and ourselves) to reproduce and build upon the research discussed in this paper.

A Training Details

All models are trained with the ParlAI[2] framework (Miller et al., 2017). Due to the large number of experimental setups and computational cost, we do not consider multiple training runs.

Base Models RPA classifier Poly-encoders are initialized with the 622M parameter models from Roller et al. (2021); we also use this architecture for dialogue response (retrieval) models which we also evaluate (see Table 19). All generative models are initialized with BlenderBot, also from Roller et al. (2021), a 2.7B parameter transformer encoder/decoder model. Each model was pre-trained on 1.5B training examples from pushshift.io Reddit (Baumgartner et al., 2020), with BlenderBot additionally fine-tuned on the BST tasks (see Roller et al. (2021) for more details), before training on LIGHT.

RPA Classifiers The RPA classifier models are trained with a cross-entropy loss over the correct label, with 99 random negatives chosen from the training set; we ensured that each character in conversation showed up in the set of candidate labels. The models were trained with a batch size of 16 on 4 32GB GPUs, with early stopping on the validation set according to valid accuracy. We used the Adam optimizer (Kingma and Ba, 2015) with weight decay (Loshchilov and Hutter, 2019), sweeping over learning rates $\{1e-5, 5e-6\}$.

Generative Models All variants of generative models were trained using 8 32GB GPUs, with early stopping on perplexity on the validation set. We used the Adam optimizer, sweeping over learning rates $\{1e-5, 7e-6\}$, training with a batch size of 128 for the short-truncation models, and 32 for the long-truncation models. For the multi-objective models, we used the same loss (and negative-sampling) setup as the RPA classifiers for the character accuracy objective. During inference, unless otherwise specified, we generated using beam-search with beam size of 10, enforcing a minimum length of 20, and with tri-gram blocking with respect to both the context and the current generation.

B RPA Classifier Training

We build the training data for the RPA classifiers from the LIGHT dataset. The input is a concatenation of (1) the LIGHT context (set of characters, setting, etc.); (2) a fixed number of previous utterances in the conversation; and (3) a candidate utterance from *any point later* in the conversation (a special token separates the candidate utterance from the prior context). We experiment with either 0, 4, or $N-2$ prior utterances (dubbed "All" in relevant tables), where N is the total number of utterances ($N-2$ allows the last turn for each speaker to be a candidate utterance). The left-to-right (LTR) data split is built similarly, except each example i becomes w_i examples, where w_i is the number of tokens in the candidate utterance for example i. Statistics of the training dataset are given in Table 8.

Dataset	Train	Valid	Test
LIGHT (Urbanek et al., 2019)	111k	6k	13k
RPA, 0-Utterance	212k	12k	26k
RPA, 4-Utterance	748k	45k	90k
RPA, All-Utterance	34k	2k	4k
RPA LTR, 0-Utterance	3.3M	205k	414k
RPA LTR, 4-Utterance	12M	747k	1.5M
RPA LTR, All-Utterance	516k	31k	64k

Table 8: Number of training, valid, and test examples for the LIGHT dataset, as well as the RPA training splits (both normal and LTR).

Suppose we choose n as the number of prior utterances to include in the input, and let us denote $D = 8538$ to represent all the dialogues in the LIGHT train split, and $U = 110877$ to represent all the utterances in those dialogues. For the RPA classification dataset, each dialogue is presented twice, once from each character's POV. When $n = N-1$, where N is the length of a conversation, then we have roughly $2D$ training examples. When $n = 0$, we have roughly $2U$ training examples.

For any value $0 < n < N-1$, we build out several examples from several slices of each conversation. Suppose we have dialogue d_i with N utterances $\{u_0, u_1, ..., u_N\}$. To build the training data from dialogue d_i, we select all continuous subsets of n utterances within d_i, forming contexts

$$c_i = \{u_i, ..., u_{i+n}\} \quad \forall \quad 0 \leq i \leq N-i$$

Then, we look at all $N-i$ utterances following utterance u_{i+n}, and use these as target utterances in the task. The goal of this is to build the model to be robust to dataset artifacts; without this modification, the model could trivially pick out the character just by looking at the number of alternating utterances.

---

# Prior Utterances	No LIGHT Context H@1/427	No LIGHT Context H@1/2	LIGHT Context H@1/427	LIGHT Context H@1/2
0	10.4	60.3	77.6	77.7
4	87.3	87.4	86.5	86.5
All	85.7	86.7	89.3	89.8

Table 9: RPA classifier performance on the **validation** set, as measured by Hits@1/427 and Hits@1/2 (all characters and participant characters as candidates, respectively). Each model is trained and evaluated with that # of prior utterances.

# Train-time Prior Utterances	**Hits@1/427** # Eval Prior Utterances 0	4	All
Without LIGHT Context			
0	10.35	18.58	17.71
4	2.10	87.31	84.35
All	7.02	81.26	85.70
With LIGHT Context			
0	77.64	66.20	58.61
4	31.04	86.48	84.90
All	32.54	82.73	89.26

Table 10: RPA classifier performance on the **validation** set, as measured by hits@1/427. Highlighted numbers indicate models evaluated on the split on which they were trained.

These measures force the model to fully understand the task and react accordingly.

C RPA Classifier Performance: Additional Results

In Table 10, we see how each RPA classifier performs on the various datasplits, varying the number of prior utterances used during training and evaluation. Each model performs best on the split on which it was trained (the highlighted numbers).

C.1 Left-to-Right Dynamic Classification

We find that the left-to-right RPA classifiers are correctly sensitive to per-token perturbations in the input, and can accurately predict the speaker at the token level. In Table 11, we give an example where the classifier changes its character prediction, depending on the candidate utterance.

D Unlikelihood: Additional Results

In Table 12, we compare UL models across different truncation lengths; the same story applies to the 1024-truncation models. We additionally include a third method, **Random-3**, where we apply the loss randomly to 3 tokens that yield incorrect RPA classifications. This method performs about the same as the Top-1 method, but the RPA is lower, indicating that the Top-1 method at least is providing some signal.

E Multi-Objective: Additional Results

E.1 Perplexity & F1

Table 13 displays full PPL and F1 scores corresponding to the models in Table 5.

E.2 Multi-Objective + Automated Grounding

In Table 14, we see how, when using either the encoder+decoder or just the decoder outputs, we do not require additional multi-objective layers (as we did in the non-automated-grounding case).

F Expanded Attention: Additional Results

We provide results for both the 128-truncate and 1024-truncate models with profile grounding in Table 15. Trends remain the same for both models.

G Full Valid Results

Table 17 includes results on the LIGHT validation set for models in Table 4.

H Retrieval Re-rankers

We evaluated a Poly-encoder baseline model with an RPA re-ranker as well. The Poly-encoder scores utterances from the full training set as candidates, and the candidates for re-ranking are the top-k ranked utterances; results are in Table 18. Retrieval models benefit dramatically from the re-ranking, improving to almost 99% RPA as measured by the LTR classifier. As the candidate responses for retrieval models come from the set of all training utterances, and due to overlap between the set of characters appearing in the train and valid sets, we can examine how often the model output was originally spoken by its partner's character; this can be seen as a proxy for mistaken identity. We find that the re-ranker reduces the amount of time that the model returns a message its partner said, indicating some viable and promising results.

I Full Human Evaluation Results

In Table 19, we display the full results of human evaluations across all dimensions. We note that the Poly-encoder model is best at not mistaking location or being repetitive, but this is expected given its retrieving over human-written utterances. In

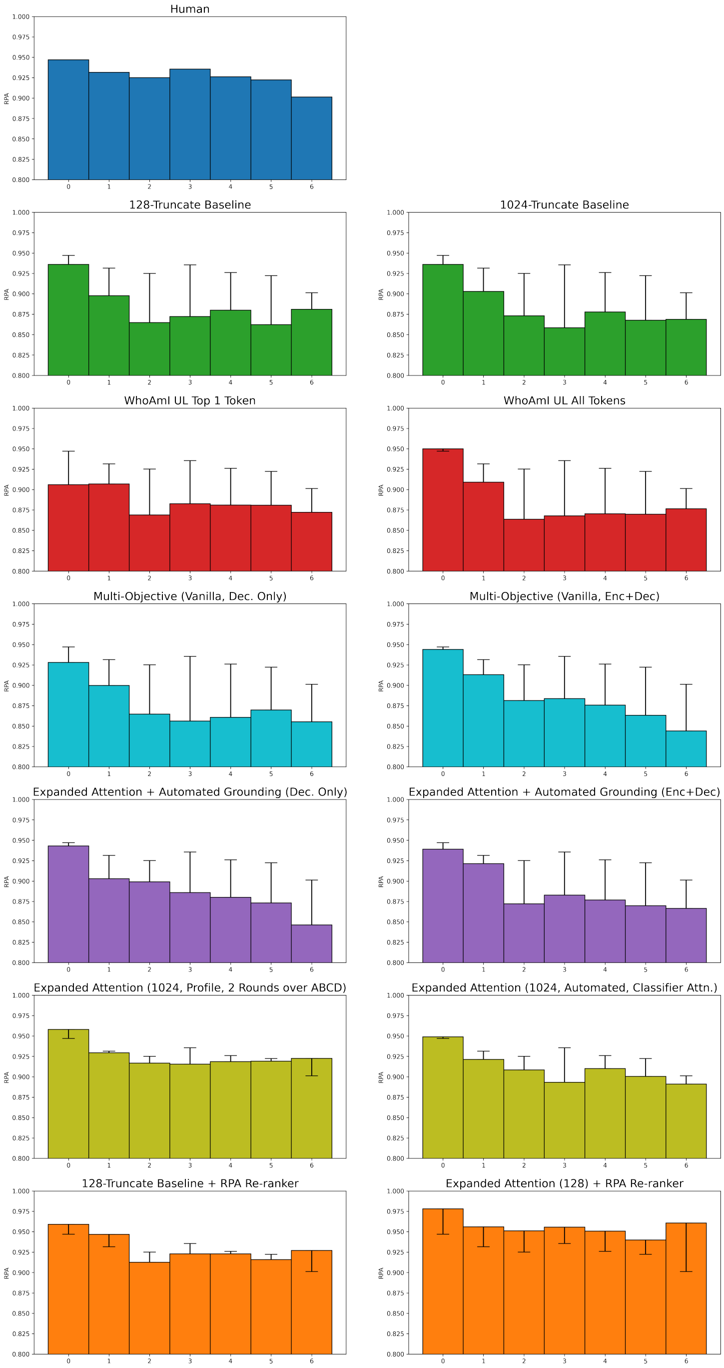

Figure 1: Per-turn RPA classifications, for a variety of models. Error bars show the difference between the model's RPA value and the human's RPA value.

Figure 2, we show a screenshot of the instructions for the evaluation task provided to crowdworkers on Amazon Mechanical Turk.

J Generation Settings

J.1 Test Output Analysis

We provide qualitative analysis of the various generation methods below.

No Re-ranking When examining the baseline with no re-ranking, we found that nucleus sampling can help when beam search does not work; however, both can go out of character the farther one goes in conversation.

Beam Search Re-rankers The beam outputs in standard beam search are at times too similar, in which case re-ranking does next to nothing, unless a viable response is available.

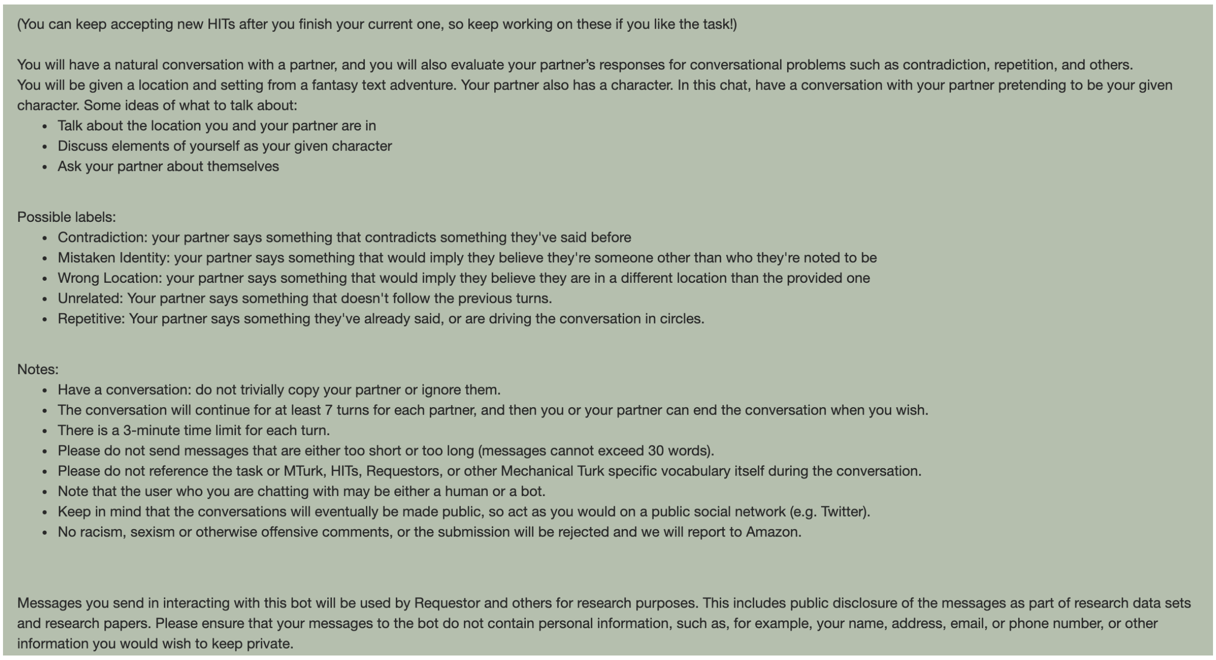
Nucleus Sampling Re-rankers Using nucleus setting in a re-ranking setup yields more diverse choices to choose from; however, sometimes the model simply does not address *any* character within the conversation.

Delayed Beam Search Re-rankers This strikes a nice balance between sensible outputs from beam search and diversity from nucleus sampling.

Mixed-Decoding Re-ranker Using mixed decoding (re-ranking several decoding schemes) can work quite well, as it is a nice blend of different generation methods.

J.1.1 Turn Annotation Analysis

Qualitative analysis of the turn annotation results are in Table 16. We generally found that beam search fails the vast majority of the time when the model thinks that it is talking to *itself*; i.e., it confuses its partner for its own character. The re-rankers can help shift the hallucination away from this regime.



(You can keep accepting new HITs after you finish your current one, so keep working on these if you like the task!)

You will have a natural conversation with a partner, and you will also evaluate your partner's responses for conversational problems such as contradiction, repetition, and others.
You will be given a location and setting from a fantasy text adventure. Your partner also has a character. In this chat, have a conversation with your partner pretending to be your given character. Some ideas of what to talk about:

- Talk about the location you and your partner are in
- Discuss elements of yourself as your given character
- Ask your partner about themselves

Possible labels:

- Contradiction: your partner says something that contradicts something they've said before
- Mistaken Identity: your partner says something that would imply they believe they're someone other than who they're noted to be
- Wrong Location: your partner says something that would imply they believe they are in a different location than the provided one
- Unrelated: Your partner says something that doesn't follow the previous turns.
- Repetitive: Your partner says something they've already said, or are driving the conversation in circles.

Notes:

- Have a conversation: do not trivially copy your partner or ignore them.
- The conversation will continue for at least 7 turns for each partner, and then you or your partner can end the conversation when you wish.
- There is a 3-minute time limit for each turn.
- Please do not send messages that are either too short or too long (messages cannot exceed 30 words).
- Please do not reference the task or MTurk, HITs, Requestors, or other Mechanical Turk specific vocabulary itself during the conversation.
- Note that the user who you are chatting with may be either a human or a bot.
- Keep in mind that the conversations will eventually be made public, so act as you would on a public social network (e.g. Twitter).
- No racism, sexism or otherwise offensive comments, or the submission will be rejected and we will report to Amazon.

Messages you send in interacting with this bot will be used by Requestor and others for research purposes. This includes public disclosure of the messages as part of research data sets and research papers. Please ensure that your messages to the bot do not contain personal information, such as, for example, your name, address, email, or phone number, or other information you would wish to keep private.

Table 19: Human evaluations. Annotators chatting with models were asked to annotate whether model utterances contained any of the problem attributes listed, with "All-Good" indicating that there were no issues. "Clean Convo" is the percentage of conversations without any issues.

J.2 Automated Metrics

We experiment with various generation settings, with or without re-rankers; results are in Table 20. For the baseline and re-ranker models, beam search yields the highest F1 scores; RPA can be improved with the other inference methods when combined with a re-ranker. We believe this may be due to the higher diversity of candidate responses generated from those methods.

K Human + Automatic Eval Correlation

We analyze the correlation between human annotations and the automatic metrics collected on the LIGHT validation set, as shown in Figure 3; we note some interesting trends:

Perplexity perplexity appears to be positively correlated with mistaken identity, and negatively correlated with engagingness. So, perplexity is

Generation Setting	Normal F1	Normal RPA	Re-ranking F1	Re-ranking RPA
Human	-	92.80	-	-
128-Truncation Model				
Beam Search	15.80	88.54	**16.14**	92.99
Delayed Beam Search	15.46	88.74	15.48	93.18
Nucleus Sampling	15.70	**89.25**	15.44	97.12

1024-Truncation Model				
Beam Search	**15.85**	88.42	16.08	92.92
Delayed Beam Search	15.03	88.00	15.39	92.89
Nucleus Sampling	15.42	88.22	15.25	**97.24**
Top-K Sampling	14.45	86.91	14.06	97.15

Table 20: Performance on the LIGHT **valid** set for the baseline models with different generation settings, with or without re-rankers. All settings use tri-gram blocking with respect to the context and current generation, and have a minimum length of 20. We set $topp = 0.3$ for Nucleus sampling, $topk = 50$ for Top-K sampling, and use a beam-delay of 10 with $topk = 10$ for delayed beam search.

	PPL	F1	RPA
Contradiction	0.64	-0.67	-0.62
Mistaken Identity	0.63	-0.66	-0.76
Mistaken Location	-0.17	-0.21	-0.24
Off-Topic	0.16	-0.43	-0.69
Repetitive	0.67	-0.64	-0.69
None (All Good)	-0.73	0.71	0.8
Engagingness	-0.66	0.63	0.55

Figure 3: Correlation between human evaluations and automated metrics computed on the test set.

a good indicator of how fluent and engaging the model is in conversation, and can indirectly point to a better understanding of the role-playing task. An important note is that we only tested this amongst models of the same size, and only for the models we tested, so it is not clear that larger models will necessarily bring improvements.

F1 F1 word overlap is positively correlated with engagingness as well, so F1 may be a good proxy of model performance. Correlation with mistaken identity is negative here, implying that better F1 corresponds with better role-playing ability. However, we note that F1 is not a catch-all metric (Liu et al., 2016).

RPA RPA appears to be strongly negatively correlated with mistaken identity, indicating that it is indeed a good measure of the model's ability to stay in character. It is weakly negatively correlated with the other issues, and is somewhat positively correlated with engagingness as well. These correlations give us confidence that our RPA classifiers are adequately measuring role-playing ability within models.

L Per-Turn Analysis, Expanded

In Figure 1, we see RPA results across turns of conversation for a wider variety of models.

Human The human outputs are most often correct on the first turn, with gradual decay of accuracy throughout the conversation (according to RPA).

Vanilla & Long Context The vanilla baseline suffers a pretty dramatic drop off after the first couple of turns; the long-context model achieves slightly higher character accuracy overall but we see similar drop offs farther down the conversation.

RPA UL The unlikelihood models seem to recover somewhat in the initial turns of conversation, however later turns still yield sharp drop offs in RPA.

Multi-objective Similarly to the UL case, we see the most gains in initial turns compare to the vanilla baselines; however, we see even more dramatic drop offs towards the end of the conversation.

Expanded Attention With profile grounding, we see near-human performance, with even better performance towards the end of the conversation. The automatic grounding improves over the baseline but is slightly worse than profile grounding. Combining automated grounding with multi-objective training leads to some benefits in earlier turns, but later turns still suffer.

Re-ranking Although we're using the same RPA classifier to both re-ranker and score the model outputs, it is still interesting to examine on which turns the re-ranker benefits the model the most. We see in the last set of graphs that beam re-ranking

Context: _setting_name Turquoise Shore, Shore _setting_desc A beautiful turquoise color water by the shore. It is filled with many gems and gold. _partner_name sea witch _self_name mermaid _self_persona I am one of the most beautiful mermaids to live in the sea. I like to watch the other sea creatures swim by me, including dolphins, who are my favorite creatures because they are so friendly. I fear the people who live on land because they hunt my kind. **Dialogue History:** Hey there Mermaid! Long time, no see. Long time indeed! How have you been keeping? Pretty good, You know how it goes. Just trying to find some unwitting victims. What are you doing in the Turquoise Shore? I've been catching waves with the dolphins all morning. I thought I would come and get some sunshine. What kind of victims do you expect to find in a tranquil place like this? What do you know about that knight standing over there? His armor is particularly garrish. You know I don't fraternize with land dwellers. I don't know, I like when they're shiny like that. He looks like a giant fishing lure. **Classified Utterance:** I suppose the only thing left to complete the illusion is for him to get wet. **Correct Label:** Mermaid **Prediction:** Sea Witch
Context: _setting_name Outside tower, Outside Tower _setting_desc Moss grows from the tall stoic like structure adding to its mysterious presence. The stone walls appear insuperable like a mountain. The top is a pointed dome. _partner_name enemy _self_name horse _self_persona We have hooves. four of them. and you can ride us. Oats please! **Dialogue History:** hello hello there **Classified Utterance:** What brings you here? **Correct Label:** Horse **Prediction:** Enemy
Context: Context: _setting_name Royal Gardens, Outside Palace _setting_desc Lined with rose bushes that look as if they have been watered by the God's, the Royal Gardens is a beauty to behold. An intricate labyrinth made of shrubs is at the center ending with a fountain. There are various benches on the sides of the rose bushes and a small lake in the back drop. _partner_name king _self_name a gardener pulling weeds _self_persona I am the gardener of the castle. I plant thickets and plants. My work is beautiful. **Dialogue History:** Hi **Classified Utterance:** Why hello there, your majesty! **Correct Label:** a gardner **Prediction:** king

Table 21: Left-to-right dynamic classifier failure modes; see discussion in Section 5.2.

seems to be most helpful in later turns, where other models generally drop off in efficacy.

M Expanded Attention Visualization

To build the heat maps in Figures 4 and 5, we look at the maximum attention applied per-head, and the maximum weight applied across the model decoder layers; other combinations were considered (mean per-head, mean over layers or last layer) and yielded similar findings.

The speaker is the mermaid, whose partner is a sea-witch. The last utterance from the sea-witch is, "What are you doing on the turquoise shore?". The mermaid responds, "I've been catching waves with the dolphins all morning. What kind of victims do you expect to find in a tranquil place like this?"

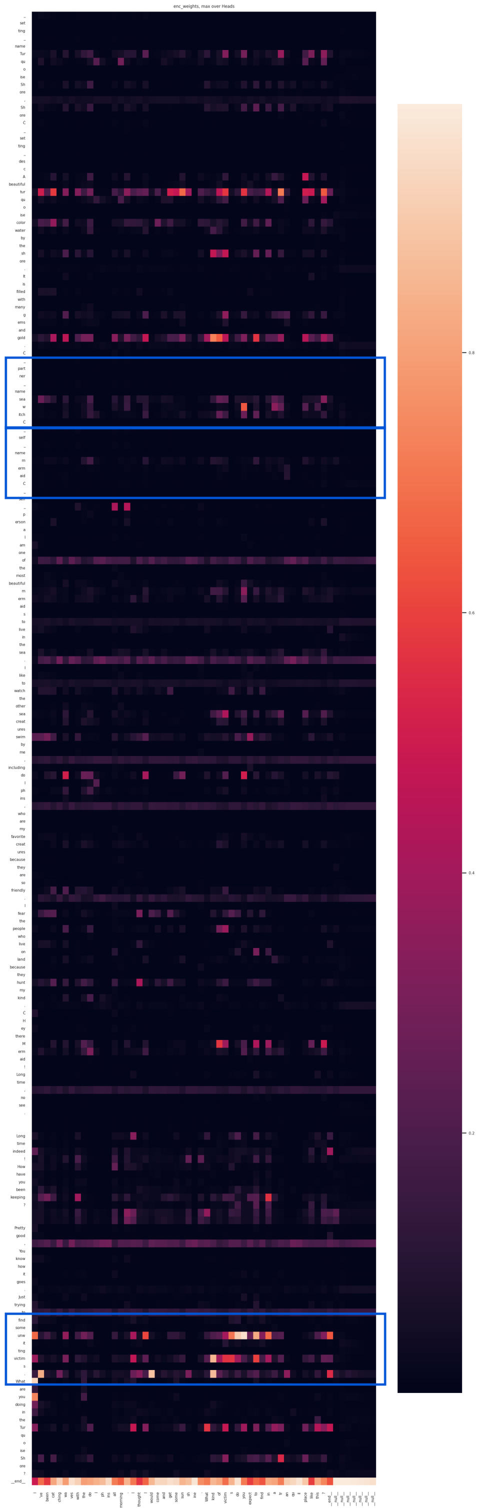

Figure 4: Vanilla Attention. The speaker here is the mermaid, whose partner is a sea-witch. The last utterance from the sea-witch is, “What are you doing on the turquoise shore?”. The mermaid responds, “I’ve been catching waves with the dolphins all morning. What kind of victims do you expect to find in a tranquil place like this?”. The vanilla model spreads its attention across the whole context; blue boxes at the top are attentions over the character descriptions, while the bottom box is attention over the word “victims”.

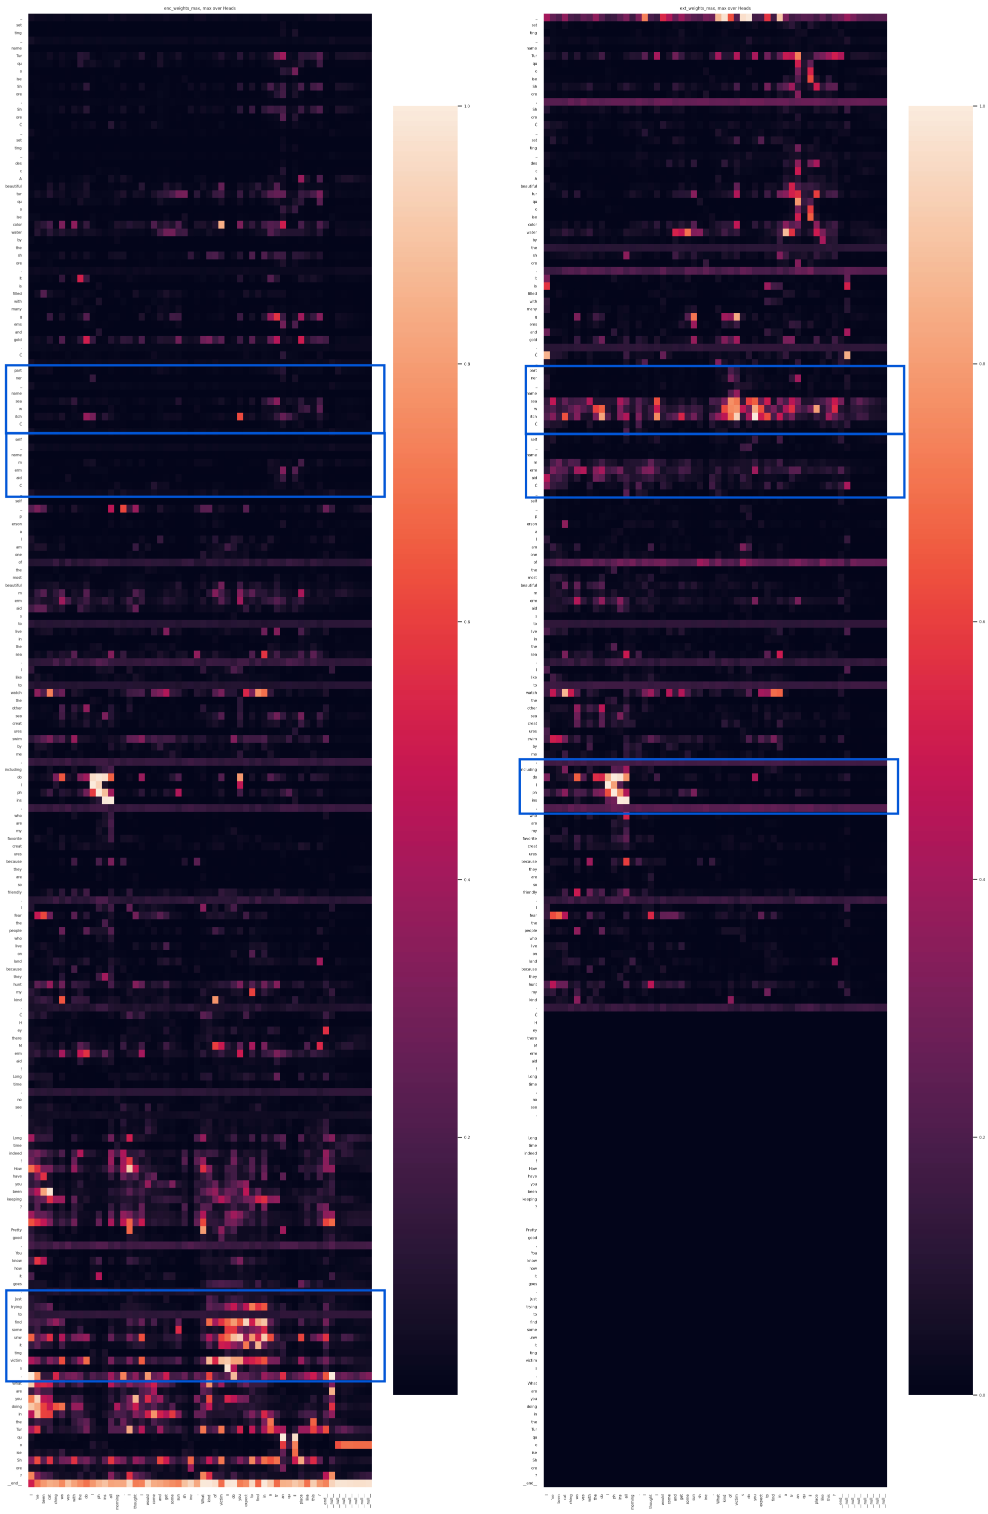

Figure 5: Profile Expanded Attention. The speaker here is the mermaid, whose partner is a sea-witch. The last utterance from the sea-witch is, “What are you doing on the turquoise shore?”. The mermaid responds, “I’ve been catching waves with the dolphins all morning. What kind of victims do you expect to find in a tranquil place like this?”. **Left** original attention over the full context; **Right** expanded attention over the additional context. The top two boxes are the partner name and self name; the bottom box on the left refers to “victims”, and on the right refers to the “dolphins”.

Unsupervised Domain Adaptation for Question Generation with Domain Data Selection and Self-training

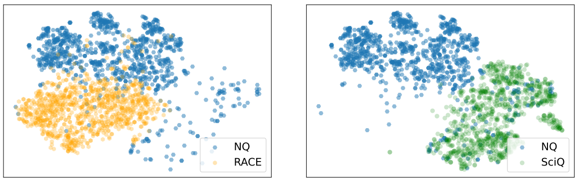
Peide Zhu and **Claudia Hauff**
Delft University of Technology
`{p.zhu-1,c.hauff}@tudelft.nl`

Abstract

Question generation (QG) approaches based on large neural models require (i) large-scale and (ii) high-quality training data. These two requirements pose difficulties for specific application domains where training data is expensive and difficult to obtain. The trained QG models' effectiveness can degrade significantly when they are applied on a different domain due to domain shift. In this paper, we explore an *unsupervised domain adaptation* approach to combat the lack of training data and domain shift issue with domain data selection and self-training. We first present a novel answer-aware strategy for domain data selection to select data with the most similarity to a new domain. The selected data are then used as *pseudo* in-domain data to retrain the QG model. We then present generation confidence-guided self-training with two generation confidence modeling methods: (i) generated questions' perplexity and (ii) the fluency score. We test our approaches on three large public datasets with different domain similarities, using a transformer-based pre-trained QG model. The results show that our proposed approaches outperform the baselines, and show the viability of unsupervised domain adaptation with answer-aware data selection and self-training on the QG task. The code is available at https://github.com/zpeide/transfer_qg.

1 Introduction

Natural language Question Generation (QG) aims to generate questions from given passages of text. It has been applied to a wide range of applications, such as question answering (Sultan et al., 2020; Fabbri et al., 2020), conversational systems (Gu et al., 2021), and education (Ma and Ma, 2019; Kurdi et al., 2020). Recently, pre-trained language models (LM) have advanced the state-of-the-art across a variety of natural language processing tasks (Devlin et al., 2018). Consequently, by modeling QG as a sequence-to-sequence task and fine-tuning on task-specific data, pre-trained LMs have substantially advanced the state-of-art performance on QG (Dong et al., 2019; Bao et al., 2020).



(a) (b)

Figure 1: 2D visualization of average-pool BERT hidden states of data from different domains using t-SNE. **(a)** Datasets `NQ` and `RACE`. **(b)** `NQ` and `SciQ`.

However, with billions of parameters, the performance of these deep neural models heavily relies on the quantity and quality of available training data. As the manual process of creating high-quality questions is expensive in terms of time and money, compared with abundant unlabeled data, the available data sources containing well-formed questions are insufficient, especially in the educational domain, where a lot of expertise is required to create questions geared towards human learning. To mitigate the lack of labeled training data, one solution is to pre-train models for QG on a data-abundant labeled domain (source domain) and transfer the learned knowledge to the unlabeled target domain, which is known as *unsupervised domain adaptation* (UDA) (Tan et al., 2018). It is a common challenge in machine learning research to learn knowledge in one domain and apply it in other domains with good generalization performance. One obstacle is the *domain shift* (Gretton et al., 2006) between the source domain and the target domain, as illustrated in Figure 1, which violates the assumption that the training set and the test set are independent and identically distributed (i.i.d.). This in turn limits the model's generalization and portability. To understand the effect of differences among domains on the performance of downstream QG tasks, fol-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2388 - 2401

lowing previous research (Hu et al., 2019; Aharoni and Goldberg, 2020), we perform a preliminary cross-domain study. We first train the QG model on all domains separately and evaluate them across different domain test sets. As shown in Table 1, the model achieves the best performance on the test set from the same domain and degrades dramatically on test sets of other domains, which poses a great challenge to the transferring task. We argue that based on these numbers further research into domain adaptation methods for QG is needed. There is a growing interest in applying unsupervised domain adaptation to tackle the domain shift issue in natural language processing tasks, such as question answering (QA) (Rennie et al., 2020; Cao et al., 2020), or neural machine translation (NMT) (Van Der Wees et al., 2017; Rauf et al., 2019; Hu et al., 2019). However, UDA is under-examined in the context of question generation. Unlike the QA task which can be modeled as a multi-label classification problem, QG is a sequence generation problem, where it is hard to model the confidence or quality of generations (Niehues and Pham, 2019). Therefore, UDA methods for QA like pseudo-label generation and filtering cannot be directly extended to the QG area. Moreover, data augmentation UDA methods for the NMT task, such as domain mixing (Britz et al., 2017), back-translation (Sennrich et al., 2015), or target sentences copying (Currey et al., 2017) are not directly applicable to QG.

Dataset	`NQ`	`RACE`	`SciQ`
`NQ`	**29.64**	13.76	14.32
`RACE`	16.59	**23.91**	12.37
`SciQ`	17.36	13.02	**29.47**

Table 1: Impact of domain shift on QG. Each row represents the METEOR score of the UniLM (Dong et al., 2019) model trained on one dataset (the row: `NQ`, `SciQ` and `RACE`) and tested on the test sets (the column).

In this paper, we propose a two-stage unsupervised domain adaptation approach for QG to make use of the labeled source domain data, and abundant unlabeled data. In the first stage, we focus on unsupervised domain data selection. Although the definition of "domain" in QG is ambiguous, including the distribution of vocabulary, stylistic preferences, answer types etc, we first confirm that the learned BERT-based context paragraph representation can be used for robust domain data clustering as shown in Figure 1, and use Gaussian Mixture Models (GMMs) on the learned representations to find clusters, using methods proposed by Aharoni and Goldberg (2020). We perform domain data selection based on the distance of data example to cluster centers. To mitigate the gap of answer-type distributions, we further propose an answer-type aware data selection method (AADS) for pseudo in-domain data selection. The selected pseudo in-domain data are used to re-train the fine-tuned data to mitigate the domain shift.

In the second stage, we focus on self-training on the unlabeled target domain with the QG model trained in the first stage. The self-training approach is substantially hindered by noisy and low-quality generated pseudo labels. We first propose a normalization method to avoid re-enforcing poorly generated questions. We also explore using sentence perplexity and fluency scores to model the confidence of sequence generation. We filter pseudo labels with low sequence confidence during self-training to prevent the model from being degraded by wrong or low-quality predictions.

We conduct experiments across three domains, including the Natural Question dataset as the source domain, RACE as one target domain of education, and SciQ as the target domain of science. Our results show our proposed approach is effective even when the target domain is substantially different from the source domain and outperforms several baselines including Latent Dirichlet Allocation (LDA) (Druck et al., 2008), BERT discriminator based data selection (Ma et al., 2019), and unsupervised Gaussian mixture model(GMM) clustering on pre-trained language model features (Aharoni and Goldberg, 2020).

2 Background

In this section, we first present a short review for UDA and question generation, then we briefly discuss how our work is different from recent related research.

2.1 Unsupervised Domain Adaptation

The assumption that the training set and the test set are independent and identically distributed (i.i.d.) is a default assumption in many machine learning algorithms. When the underlying distributions do not match, the algorithms face the *domain shift* problem (Gretton et al., 2008; Ramponi and Plank, 2020), i.e. the *source* domain and the *target* domain data are not sampled from the same distribution. This issue happens in real-world scenarios, where labeled training data are scarce while unlabeled data may be abundant since annotations are time-consuming and costly to acquire. It then translates into performance degradation. Unsupervised domain adaptation provides an elegant and scalable solution for mitigating this issue by learning only from unlabeled target data. In this paper, we focus on the data-centric methods: data selection and pseudo-labeling (Ramponi and Plank, 2020).

Data Selection for Domain Adaptation Not all samples in the source domain are equally important for adaptation. Data selection (Axelrod et al., 2011) aims to select the data that are most related to the target domain. It is attracting more attention, thanks to the abundance of data, and the large pre-trained models (Gururangan et al., 2020). It has been studied for several NLP tasks (Aharoni and Goldberg, 2020; Ma et al., 2019; Guo et al., 2020). Recently, Aharoni and Goldberg (2020) showed that sentence representation learned by pre-trained language models such as BERT (Devlin et al., 2018) and Roberta (Liu et al., 2019b) are capable of clustering textual data to domains in an unsupervised way with high precision. In our work, we follow this research and perform domain clustering and selection with BERT.

Self-Training Self-training is a bootstrapping method that has been used for domain adaptation in multiple NLP tasks (McClosky et al., 2006; Chattopadhyay et al., 2012; Bhatt et al., 2015; Sachan and Xing, 2018). The main idea of self-training (Lee et al., 2013) is to predict labels for unlabeled samples with a trained classifier as their 'pseudo' ground-truth, and use the synthetic data for further training.

2.2 Question Generation

Natural Question Generation (QG) aims to generate questions from given passages. Various neural models have been proposed for QG by formulating it as a sequence-to-sequence (Seq2Seq) learning problem (Du et al., 2017; Dong et al., 2019; Bao et al., 2020). QG has been applied to a range of application areas, such as conversational QA (Wang et al., 2018; Gu et al., 2021) and education (Kurdi et al., 2020). Although these approaches have made great strides in improving QG effectiveness, they are trained and tested with data from the same dataset. When there is domain shift between training and test data, the model performance deteriorates considerably. Liao and Koh (2020) explore this using supervised and semi-supervised domain adaptation but ignore the unsupervised setting.

The most related recent work to ours is by Kulshreshtha et al. (2021), who propose a new training protocol for UDA QG. However, it requires unlabeled questions in the target domain, which is not always available, and we focus on investigating a more effective self-training method. We compare this work in Appendix A.2.

In our work, we close the gap between source and target domain distributions by performing answer-type aware domain data selection.

3 Formalization

We now formulate the problem and present our notation. The data in the source domain with ground-truth questions are denoted as $\mathcal{D}_s = \{(C^s, Q^s)\}$, while unlabeled data in the target domain is $\mathcal{D}_t = \{(C^t\}$; here, C is denoting the context (the passages, and answer spans used for generating questions). The question generation task is then to generate a sequence $\hat{Q}$ that maximizes the conditional probability of the prediction $P(Q|C, \theta)$:

$$\begin{aligned} \hat{Q} &= \arg\max_{Q} P(Q|C,\theta) \\ &= \arg\min_{Q} \sum_{t=1}^{T} -\log P(Q_t|C,\theta,Q_{<t}) \end{aligned} \tag{1}$$

where θ represents the parameters of the QG model, which is initially learned from training data in the source domain. In our work, we aim to learn to adapt the θ from a source domain $\mathcal{D}_S$ to the target domain $\mathcal{D}_T$ and achieve optimal performance.

4 Domains

4.1 Source Domain

We use the open-domain question answering corpus Natural Questions (`NQ`) (Kwiatkowski et al., 2019) as our source domain. It consists of aggregated questions issued to the Google search engine, and answers annotated by crowd-workers from the most related Wikipedia pages. It consists of a large amount of unique passages, and covers a range of topics, which makes it a good source domain for transferring. As there are many examples in `NQ` with tables as context, to use this dataset for QG, we select a subset which contains 89,453 samples in the training set and 3,726 samples in the test set, from the original `NQ` dataset.

4.2 Target Domains

Education The first target domain we choose is education, for which we use the `RACE` (Lai et al., 2017) dataset. `RACE` is a large dataset consisting of questions, answers and associated passages in English exams for middle-school and high-school Chinese students. Questions in `RACE` are designed by instructors (i.e. domain experts) for evaluating students' reading comprehension ability. There are three types of questions: cloze, general and specific. Following the practice of EQG-RACE (Jia et al., 2020), we only keep the specific questions in our work. For unsupervised QG, we use 18.6K data examples in the training set. The original dev and test sets are used for evaluation.

Science Our second target domain is science where we make use of the `SciQ` (Welbl et al., 2017) dataset. `SciQ` consists of 13.7K crowdsourced multiple-choice science exam questions, including 11.7K questions in the training set, and 1K for dev and test set each. Each `SciQ` question has an associated passage, the right answer, and the distractors. The `SciQ` passages are chosen from science study textbooks of different topics including biology, chemistry, earth science and physics. For unsupervised QG, we utilize the support passages in the training set without questions as unlabeled data; we use the original dev and test sets for QG evaluation.

Table 2 lists the basic statistics of our three datasets. On those datasets, we can make a thorough evaluation of the QG model's transfer performance and the effectiveness of proposed approach.

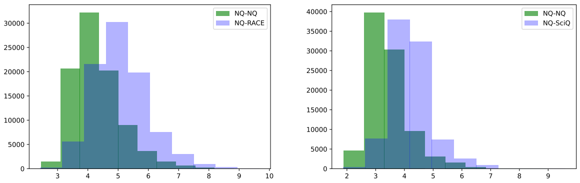
Features	**`NQ`**	**`SciQ`**	**`RACE`**
Question	Search Logs	Crowsourced	Experts
Context	Wikipedia	Textbook	Examinations
Train set	89,453	11,679	18,614
Test set	3,726	1,000	1036
#W/doc	106.27	78.05	318
#Sent./doc	4.43	4.84	17
#W/Sent.	26.81	16.13	17.96
#W/Q	10.20	14.31	10.8

Table 2: Overview of the source domain dataset `NQ`, and the selected datasets for target domains `SciQ` and `RACE`.

5 Domain Data Selection

Not all data are required or even useful for domain adaptation. Irrelevant data samples can add noise, and affect the learned model's performance and robustness towards cross-domain application considerably (Liu et al., 2019a). A solution to reduce the impact of irrelevant data is domain data selection, i.e. to retrieve the most appropriate data from the source domain data given the target domain data. Most proposed domain data selection approaches consider ranking training examples from $\mathcal{D}_S$ according to a domain similarity measure and select the top-n examples that are closest to $\mathcal{D}_T$.

We encode the context passage at the paragraph level with BERT, and perform average pooling of the last layer hidden state of each token to create its vector representation. To show that this is a robust representation for mapping sentences to domains in an unsupervised, data-driven approach, we first visualize them with t-SNE, as shown in Figure 1. We can observe the encoding vector representation with BERT indeed can cluster data examples to domains. Following the practice of Aharoni and Goldberg (2020), we then perform unsupervised clustering by fitting Gaussian Mixture Models (GMMs) to the vector context representations with k predefined clusters. We assign each cluster the domain class by measuring its purity (proportion of examples belonging to each domain). We use the Euclidean distance (Lee, 2001) of each example to cluster center as the measure of domain distance. Figure 2 shows the distribution of `NQ` dataset examples' distance to `NQ`'s, `RACE`'s and `SciQ`'s domain center respectively. We sort source data examples based on their distance to the target domain center and select data examples with most domain similarity as the pseudo-in-domain data.



(a) (b)

Figure 2: Distribution of the distance between each data example to domain cluster center. **(a)** `NQ` and `RACE`. **(b)** `NQ` and `SciQ`.

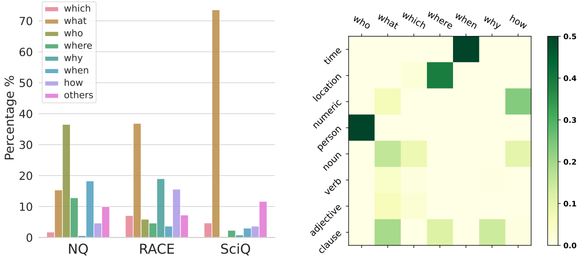
Table 3 shows the unsupervised domain clustering results. We compare the proposed methods with Latent Dirichlet Allocation-based (LDA) clustering (Druck et al., 2008). We also compare different ways of creating paragraph vector representations, including using BERT `[CLS]` token encoding ($_{CLS}$), average pooling of all BERT layer hidden states ($_{All}$), and average pooling of the last hidden states ($_{Last}$). Besides GMM clustering methods, we also compare the GMM method with K-Means (KM). To accelerate the clustering, we perform PCA over the paragraph representation first. Our results show the GMM method with pooling average of the last BERT hidden states to outperform the other methods.

Method	RACE Acc	RACE F1	RACE Rc	SciQ Acc	SciQ F1	SciQ Rc
LDA	0.79	0.76	0.72	0.69	0.61	0.55
KM$_{CLS}$	0.37	0.35	0.98	0.33	0.25	0.97
KM$_{All}$	0.94	0.85	**0.99**	0.88	0.63	0.89
KM$_{Last}$	0.97	0.91	0.97	0.91	0.72	0.99
GMM$_{CLS}$	0.42	0.36	0.97	0.37	0.26	0.94
GMM$_{All}$	0.96	0.90	0.95	0.88	0.64	0.89
GMM$_{Last}$	**0.98**	**0.95**	0.96	**0.91**	**0.72**	**0.99**

Table 3: Unsupervised Domain Clustering Results.

5.1 Answer-Type Aware Data Selection

For different application domains, as shown in Figure 3a, the question type distributions vary a lot. For example, in `NQ`, the 'who' questions account for over 35% of all questions but in `SciQ`, 73.6% of questions have the 'what' type. Traditional data selection methods are based only on the similarity of context passages, which may suffer from unbalanced target label sampling. As there are no questions available in the target domain, it is a challenge to perform data selection according to the distribution of target question types. We first investigate the correlation between the answer types and question types. The question types are identified by the interrogative 'w'-word, such as 'who', 'what', etc. We identify the answer types such as 'time', 'location', etc. using the spacy[1] NER and POS tagger. The correlation matrix (expressed in Pearson correlation coefficient) is shown in Figure 3b. We find question types and answer types are strongly correlated to each other. For example, the correlation coefficient between 'time' and 'when' is 0.67, between 'person' and 'who' it is 0.63. Thus, we propose a heuristic answer-type aware data selection strategy for domain data selection from the source domain with a similar answer type distribution, in order to mitigate the label divergence. Specifically, we first group the data by answer types, and then conduct data selection on each group.



(a) (b)

Figure 3: **(a)** Question type distributions. **(b)** Correlation between answer type and question types.

6 Self-Training

When training the QG model with pseudo-labels, it is natural to put more emphasis on the labels that the model is more confident about. An intuitive solution is to weigh each pseudo-token according to its estimated probability in order to avoid re-enforcing poor predictions. Thus, we propose the following normalized training objective for self-training:

$$\hat{Q} = \arg\min_{Q} \sum_{t=1}^{T} -\log \alpha_t P(Q_t^{'}|C, \theta, Q_{<t}^{'}) \quad (2)$$

where $Q^{'}$ is the pseudo-label, and α_t is the predicted probability of the t-th word $Q_t^{'}$, and T is the length of the pseudo-label.

We apply the QG model to generate questions on unlabeled target-domain data, which are then used as 'pseudo' gold labels for further training. The self-training approach is substantially hindered by noisy, low-quality labels. How to deal with noisy pseudo labels is crucial to the final UDA effectiveness. Classical pseudo label generation methods (Mihalcea, 2004; Abney, 2007; Cui and Bollegala, 2019) filter generated labels by their 'confidence' which is the predicted probability of the label in those classification tasks. How to represent confidence of sequence generation in pseudo-labeling is insufficiently explored. Traditionally, confidence estimation has been defined as a task of assessing the quality of the whole sequence of words in the target sentence. Therefore, we propose a question quality guided pseudo labeling method to address this problem, with two confidence metrics: (i) the sentence perplexity, and (ii) the BERT-based fluency score.

Sentence Perplexity The first metric is the perplexity of the generated questions. The generation

---

[1] `https://spacy.io/`

with higher confidence should have lower perplexity. Here, perplexity (PPL) is defined as follows:

$$\mathrm{PPL}(Q) = 2^{-\frac{1}{T}\log\prod_1^T P(Q_t|Q_{<t})} \tag{3}$$

BERT-based Fluency Score For our second metric, we use *fluency* as the question quality metric, which indicates whether the generation follows grammar rules and correct logic. The perplexity of a sentence under a well-trained language model usually serves as a good indicator of its fluency (Yang et al., 2018). We use a fine-tuned BERT language model as evaluator. The fluency metric $R_{fluency}$ for question Q is calculated as follows:

$$R_{fluency}(Q) = \exp\left(-\frac{1}{T}\sum_{t=1}^{T}\log \mathrm{BERT}(Q_t|Q_{<t})\right). \tag{4}$$

During the unsupervised self-training, after each epoch, we perform beam search with the trained model, and the generated questions are ranked according to their fluency score. Only questions with confidence metrics better than the threshold ϕ and PPL are selected as pseudo-labels. If one data sample got selected in the last epoch, but its generated question's confidence metric in the current epoch is not higher than before, it is removed. In this way, only questions of high quality that improve over time are chosen for training.

Algorithm 1: Self-Training

7 Experiments

In this section, we describe the model and the training regime in more detail.

7.1 Experimental Settings

QG Model We use the state-of-art pre-trained transformer-based sequence-to-sequence natural language understanding and generating model **UniLM** (Dong et al., 2019) for question generation. Specifically, we choose the uncased pre-trained `unilm1.2-base-uncased` model for fine-tuning. It has 12 transformer layers and is jointly pre-trained on large amounts of text, optimized for bidirectional, unidirectional, and sequence-to-sequence language model objectives. We use the `s2s-ft` package[2] for fine-tuning. To fine-tune our model, the input context passage, the answer, and the generated question are combined together into a sequence: "*`[CLS]` context passage `[EOS]` answer span `[EOS]` question `[EOS]`*". Both the input passage and answer are regarded as the first text segment, while the generated question is the second segment in the unified LM.

Training Details The model is trained on a server consisting of 4 GeForce GTX 1080 gpus with a batch size of 32, a mask probability of 0.8, and the label smoothing rate of 0.1. The max_source_seq_length is set 464, the max_target_seq_length is 48. We first fine-tune UniLM with the `NQ` dataset for 10 epochs. We use the Adam optimizer with $\epsilon = 1e-8$, learning rate is $1e-4$ with 500 warmup steps.

Unsupervised Domain Data Clustering We use 4,500 examples randomly selected from `NQ`, `SciQ` and `RACE` for unsupervised data clustering. We set the number of clusters as 2, since we intend to investigate the separability between the source domain and the target domain.

Evaluation Metrics We compare the model performance along three automatic evaluation metrics: **BLEU** (Papineni et al., 2002), which is computed with the geometric average of the modified n-gram precision and the brevity penalty; **Meteor** (Denkowski and Lavie, 2014), which compares the generation with the gold question in terms of exact, stem, synonym, and paraphrase matches; and **Rouge-L** (Lin, 2004), which measures the shared longest common sub-sequence. We calculate these metrics with the package released by Du et al. (2017). We also conduct a human evaluation.As a sanity check and to evaluate the QG

`SciQ`	46.99	33.22	29.47	42.73
`RACE`	37.86	17.90	23.91	37.56

Table 5: In-domain test results of the QG model (fine-tuned and tested on the same dataset).

model's ability to generate questions based on these datasets, we first conduct in-domain tests on these three datasets separately, i.e. we fine-tune and test the model on the training/test set from the same dataset. As shown in Table 5, we achieve results comparable with state-of-art for the `NQ`, `RACE` and `SciQ` datasets.

7.2 Experiments on Data Selection

In this experiment, we compare the proposed answer-type aware data selection with several baselines. We train the QG model with the selected data and evaluate the data selection method by comparing its performance. The first baseline is random data selection (**random**). With this baseline, we randomly sample 1,000 samples from `NQ`. The second baseline is LDA-based clustering (Druck et al., 2008). We use the gensim (Řehůřek and Sojka, 2010) LDA implementation for this baseline. The third method (**BERT-DDS**) is proposed by Ma et al. (2019), where a BERT-based domain discriminator is used for data selection. The discriminator is first trained with randomly sampled data from the datasets. The baseline model achieved 99.85% for `RACE` and 92.35% accuracy for the `SciQ` dataset. The last baseline method we compare is adopted from the unsupervised domain clustering method (**GMM**) proposed by Aharoni and Goldberg (2020), as described in Section 5. We use the BERT-base model implementation of huggingface transformers (Wolf et al., 2020) to get the context passage encoding. In addition to GMM, we also compare the K-Means method (Sculley, 2010). The results are presented in Table 4.

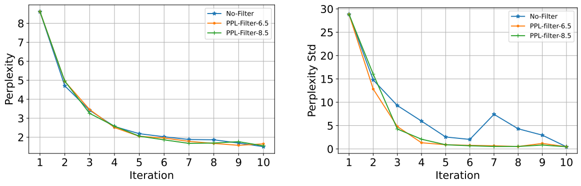
Impact of Domain Data Selection Re-training with randomly selected data does not improve our model's generalization performance. All other data selection methods outperform random data selection, except BERT-DDS. One reason is that BERT-DDS training needs sampling data from different domains, its performance relies on the sampled data, and also label examples that are similar to the target domain as source domain. *Data selection with unsupervised domain clustering with BERT context encoding outperforms other methods,* *which confirms its effectiveness.*

On the `RACE` dataset, answer-type aware data selection with K-Means (**AA-KMeans**) and GMM (**AA-GMM**) outperform the same selection method without answer-type awareness. We note this result does not always hold for the `SciQ` dataset. One possible reason is due to the extremely unbalanced answer type distribution in `SciQ`: we have to select examples with generally low domain similarities wrt. the source domain to create the same answer-type distributions.

7.3 Experiments on Self-Training

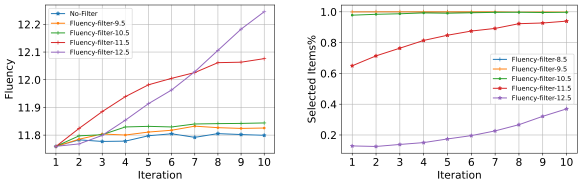
We conduct self-training with the target-domain unlabeled data on the QG model fine-tuned on the `NQ` dataset. We first verify the effectiveness of the proposed normalized training objective. As the results show in Table 4, self-training with normalization (**w/o-Filter**) outperforms self-training without any confidence filtering and normalization (**w/o-Norm**), which indicates its effectiveness.

Impact of Generation Confidence Guided Self-training We explore two generation confidence metrics for self-training, the sentence perplexity, and the question fluency score. To train the BERT LM for generating fluency scores for question quality evaluation, we combine all questions from `NQ` and the Quora Question Pairs dataset[3], creating a dataset consisting of 834,834 questions. The final model achieves a perplexity of 9.27 on the evaluation set. As the results in the **ST** part of Table 4 show, both proposed generation confidence metrics improve the performance considerably up to 6%. This can be explained by the removal of low-quality and noisy data, which hinders model training. As Figure 4 shows, with perplexity filtering—although the changing curves of mean perplexity of the generated pseudo-labels in each iteration are similar—the standard deviation drops faster and more steady. As Figure 5 shows, the average fluency score improves along iterations even without fluency filtering, but with fluency filtering, the average fluency score improves more steadily and increases towards the threshold value ϕ. The proportion of questions with higher fluency score than ϕ increase along iterations. As reflected in Figure 5b and Table 6, if the threshold value is too low, fewer noisy pseudo examples can be filtered out. If the threshold is too high, there would be less supervision for the QG model. Both of these settings would lead to performance degradation.



(a) (b)

Figure 4: Change of **(a)** average perplexity, and **(b)** standard deviation of generations along iterations.



(a) (b)

Figure 5: Change of **(a)** average fluency score, and **(b)** the percentage of generated questions whose fluency score is higher than ϕ along iterations.

	ϕ	B-1	B-4	MT	RG
`RACE`	8.5	23.83	**5.12**	14.65	23.06
	9.5	24.20	5.11	**14.74**	**23.66**
	10.5	**24.23**	5.06	14.68	23.29
	11.5	23.93	5.10	14.46	23.09
	12.5	23.78	4.55	14.41	23.05

Table 6: Influence of the fluency threshold (ϕ).

Impact of Joining Domain Data Selection and Self-Training We also conduct domain adaptation by joining domain data selection and self-training (**DDS+ST**). As shown in Table 4, joining DDS and self-training without filtering does not show performance improvement on both datasets, which implies with DDS, pseudo-labels during self-training may be noisier. With the proposed filtering with fluency score or question perplexity, the joint method outperforms DDS and self-training. On the `RACE` dataset, the answer-type aware joint methods generally achieves the best performance across all evaluation metrics.

7.4 Human Evaluation

In addition to the automatic evaluation results shown in Table 4, we also report on our human evaluation in Table 7. We randomly sampled 50 generated questions from the `RACE` and `SciQ` test

---

[3] `https://www.kaggle.com/c/quora-question-pairs`

Method	RACE			SciQ		
	Syntax	**Relevance**	**Answerability**	**Syntax**	**Relevance**	**Answerability**
w/o-UDA	2.60 (0.66)	2.00 (0.78)	0.43 (0.49)	2.83 (0.40)	2.40 (0.64)	0.57 (0.50)
ST	2.78 (0.51)	2.12 (0.73)	0.46 (0.50)	**2.94 (0.26)**	2.49 (0.64)	**0.67 (0.47)**
DDS+ST	**2.81 (0.47)**	**2.12 (0.75)**	**0.51 (0.50)**	2.92 (0.27)	**2.53 (0.63)**	0.67 (0.47)

Table 7: Human evaluation (mean and standard deviation) on `RACE` and `SciQ` datasets. Syntax and Relevance evaluation adopt a 3-point scale. Higher is better; Answerability is boolean type (0-1).

set respectively and asked 3 domain experts (both male and female, ages ranging from 25 to 35) to rate the generated questions by the QG model without UDA (w/o-UDA), with self-training (ST), and self-training and domain data selection(DDS+ST). The experts are also presented with the context paragraphs, the answers, as shown in Figure 6 of the appendix. The generated questions are shown in Table 10 of the appendix. We rate questions along three dimensions: (i) syntax, i.e. the syntax correctness, in a 3-point scale, 1 for major syntax issues, 2 meaning minor issue and 3 is correct; (ii) relevance, i.e. whether the question is relevant to the context and the answer, also in a 3-point scale, 1 irrelevance, 2 for partial relevance and 3 meaning fully relevant; (iii) answerability, a boolean type value, indicating whether the question can be answered given the context and answer. As the results show, all QG with UDA methods outperform the QG model without domain adaptation. On the `RACE` dataset, the proposed unsupervised domain adaptation for QG with data selection and self-training (DDS+ST) achieves the best performance along with all metrics; although the performance of UDA with self-training only outperforms DDS+ST slightly in terms of syntax and answerability, DDS+ST outperforms self-training.

8 Conclusion

We proposed an unsupervised domain adaptation approach for question generation. Our approach includes an answer-type aware unsupervised domain data selection method and a sequence generation confidence guided self-training algorithm. We conduct experiments on three domains. We use the Natural Questions dataset as labeled source domain, `RACE` as target education domain and `SciQ` as target science domain. Our results suggest our approach is effective for this application settings. We find that it significantly improves domain adaptation performance of our QG model. In future work, we plan to expand our work to more domains and additional QG model types.

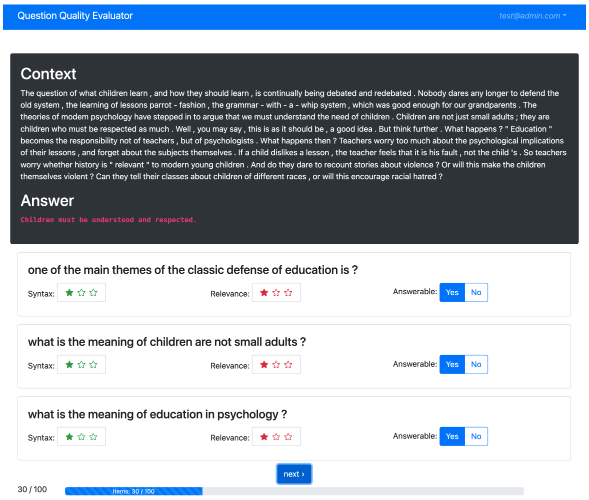
A Appendix

A.1 Examples Selected Data

Table 9 illustrates several data examples of selected from `NQ` dataset that are most similar to *education* domain, i.e. the `RACE` dataset, and to *science* domain, i.e. `SciQ` dataset using the GMM_{last} BERT based domain data selection method. The `RACE` dataset is a large dataset of English exams for middle-school and high-school Chinese students. Its vocabulary is middle-school and high-school level. Many passages in it are story-style. As **`NQ`→`RACE`** data examples show, the selected data from `NQ` are close to `SciQ` in terms of both the vocabulary and text style. Meanwhile, `SciQ` passages are chosen from science study textbooks of different topics including biology, chemistry, earth science and physics. The examples of selected data (**`NQ`→`RACE`**) can be categorized into the biology domain, which includes a lot of the biology terms, elucidating biological processes. These examples show the effectiveness of the data selection method.



Context

The question of what children learn , and how they should learn , is continually being debated and redebated . Nobody dares any longer to defend the old system , the learning of lessons parrot - fashion , the grammar - with - a - whip system , which was good enough for our grandparents . The theories of modem psychology have stepped in to argue that we must understand the need of children . Children are not just small adults ; they are children who must be respected as much . Well , you may say , this is as it should be , a good idea . But think further . What happens ? " Education " becomes the responsibility not of teachers , but of psychologists . What happens then ? Teachers worry too much about the psychological implications of their lessons , and forget about the subjects themselves . If a child dislikes a lesson , the teacher feels that it is his fault , not the child 's . So teachers worry whether history is " relevant " to modern young children . And do they dare to recount stories about violence ? Or will this make the children themselves violent ? Can they tell their classes about children of different races , or will this encourage racial hatred ?

Answer

`Children must be understood and respected.`

one of the main themes of the classic defense of education is ?
Syntax: ★☆☆ Relevance: ★☆☆ Answerable: Yes No

what is the meaning of children are not small adults ?
Syntax: ★☆☆ Relevance: ★☆☆ Answerable: Yes No

what is the meaning of education in psychology ?
Syntax: ★☆☆ Relevance: ★☆☆ Answerable: Yes No

Figure 6: The interface for human annotation.

A.2 Experiments on MLQuestions

We conduct unsupervised domain adaptation experiments on MLQuestions (Kulshreshtha et al., 2021). We first conduct unsupervised domain data selection with GMM_{last} method and presents the confusion matrix in Figure 7 and select 1,000 data examples from `NQ` that are most close to MLQuestions clustering center. We set number of clusters as 2 because we want to directly investigate the unsupervised separability between `NQ` and MLQuestions. We use the provided development set and the test set of MLQuestions. Then we perform domain adaptation for QG, and show results in Table 5. Compared with the self-training method explored in (Kulshreshtha et al., 2021), the proposed method in this paper achieves more performance increase, e.g. **DDS+ST** method achieved 5.42 and 4.7 net gain in Rouge-L and BLEU-1 score respectively, compared with 0.58 and 0.80 net gain with self-training in (Kulshreshtha et al., 2021). We focus on the self-training method in this paper, so we consider conducting open-domain retrieval-based methods like **Back-Training** in future research.

Dataset	B-1	B-4	MT	RG
w/o-UDA	30.06	7.96	18.62	31.60
DDS	29.89	8.27	18.63	31.64
ST	32.58	9.41	19.41	34.20
DDS+ST	34.76	10.57	20.41	37.02
Net Gain	**4.7↑**	**2.61↑**	**1.79↑**	**5.42↑**

Table 8: Unsupervised domain adaptation results on MLQuestions dataset.

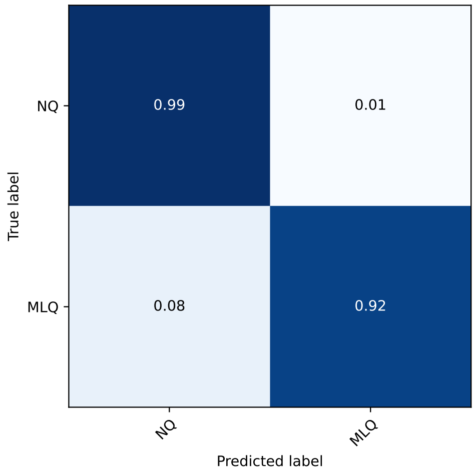


Figure 7: Confusion matrix for unsupervised domain data clustering results on MLQuestions and `NQ` datasets. We use 3,000 data examples from `NQ` and MLQuestions each.

`NQ` → `RACE`	**`NQ` → `SciQ`**
To expand the number of women smokers Hill decided to hire Edward Bernays, who today is known as the father of public relations, to help him recruit women smokers. Bernays decided to attempt to eliminate the social taboo against women smoking in public. . . . The targeting of women in tobacco advertising led to higher rates of smoking among women. In 1923 women only purchased 5% of cigarettes sold, in 1929 that percentage increased to 12%, in 1935 to 18.1%, peaking in 1965 at 33.3%, and remaining at this level until 1977.	The lysosomes also act as the waste disposal system of the cell by digesting unwanted materials in the cytoplasm, both from outside the cell and obsolete components inside the cell. Material from outside the cell is taken - up through endocytosis, while material from the inside of the cell is digested through autophagy. Their sizes can be very different. They were discovered and named by Belgian biologist Christian de Duve, who eventually received the Nobel Prize in Physiology or Medicine in 1974.
A man named Bailey intends to take his family from Georgia to Florida for a summer vacation , but his mother , (referred to as “the grandmother” in the story) wants him to drive to East Tennessee , where the grandmother has friends (“connections”). She argues that his children, John Wesley and June Star, have never been to East Tennessee, and she shows him a news article in the Atlanta Journal Constitution . . . He and the grandmother agree that things were much better in the past and that the world at present is degenerate; she concurs with Sammy’s remark that “a good man is hard to find.”	Decomposition is the process by which organic substances are broken down into simpler matter. The process is a part of nutrient cycle and is essential for recycling the finite matter that occupies physical space in the biosphere. Bodies of living organisms begin to decompose shortly after death. Animals, such as worms, also help decompose the organic materials. Organisms that do this are known as decomposers. Although no two organisms decompose in the same way, they all undergo the same sequential stages of decomposition. The science which studies decomposition is generally referred to as taphonomy from the Greek word taphos, meaning tomb.
The next day, just before Lincoln and Sara board a boat to escape to the Dominican Republic, Sucre gives Sara the $100,000 they stole from the General, apologizing for not being able to wire the money to them the night before as planned. Mahone gives Sara the paper Michael asked him to deliver, . . . , but don’t ever, say. He then says what he wants to say is that he loves them both, very much. He tells them to make sure his child is told every day how much he is loved and how lucky he is to be free. The video, and the entire series	An elater is a cell (or structure attached to a cell) that is hygroscopic, and therefore will change shape in response to changes in moisture in the environment. Elaters come in a variety of forms, but are always associated with plant spores. In many plants that do not have seeds, they function in dispersing the spores to a new location. Mosses do not have elaters, but peristome which also change shape with changes in humidity or moisture to allow for a gradual release of spores

Table 9: Examples of selected data from `NQ` dataset that are most similar to `RACE` dataset (`NQ`→`RACE`) and `SciQ` dataset (`NQ`→`RACE`).

	`RACE`	`SciQ`
Context	Jenny was a pretty five-year-old girl. One day when she and her mother were checking out at the grocery store , Jenny saw a plastic pearl necklace priced at $2.50. Her mother bought the necklace for her on condition that she had to do some homework to pay it off. Jenny agreed. She worked very hard every day, and soon Jenny paid off the necklace. Jenny loved it so much that she wore it everywhere except when she was in the shower. Her mother had told her it would turn her neck green! Jenny had a very loving daddy. When Jenny went to bed, he would read Jenny her favorite story. One night when he finished the story, he said, "Jenny, could you give me your necklace?" "Oh! Daddy, not my necklace!" Jenny said." But you can have Rosy, my favorite doll. Remember her?	Gamma rays are produced when radioactive elements decay. Radioactive elements are elements with unstable nuclei. To become more stable, the nuclei undergo radioactive decay. In this process, the nuclei give off energy and may also emit charged particles of matter. Types of radioactive decay include alpha, beta, and gamma decay. In alpha and beta decay, both particles and energy are emitted. In gamma decay, only energy, in the form of gamma rays, is emitted.
Answer	**She had to help her mother do some housework.**	**radioactive**
w/o-UDA	what's the meaning of the name jenny?	where do gamma rays come from when they decay?
ST	what is the name of jenny's necklace?	what type of element is the source of gamma rays?
DDS+ST	**how did jenny get her necklace in the movie?**	**what type of elements give off gamma rays?**
Context	Lawmakers in the United States have expanded an investigation into the use of location-tracking systems on mobile devices. The action follows recent reports about the storing of information on the Apple iPhone. Some people consider location tracking to be a threat to personal privacy and security. Allan Friedman, the research director, says, "All wireless companies do some location tracking as part of their networks. This information is usually stored by the companies, not the devices, and there are laws to protect it. Law enforcement agencies, . . . There's the idea that because it's on my phone and on my computer, rogue applications that I pay for or that I'm tricked into downloading may be able to access this data and somehow misuse it." Apple says it is "not tracking the location of your iPhone". It is simply keeping a database of Wi-Fi hotspots and cell phone towers near the user's location.	Not all wetlands are alike, as you can see below (Figure below). Wetlands vary in how wet they are and how much of the year they are soaked. Wetlands also vary in the kinds of plants that live in them. This depends mostly on the climate where the wetland is found. Types of wetlands include marshes, swamps, and bogs.
Answer	**Because it is thought to threaten users' privacy.**	**wetland**
w/o-UDA	why is there a tracking system on my phone?	what do you call a place that is covered with water?
ST	why is there a location tracking system on apple?	what do you call marshes that are wet?
DDS+ST	**why do we not use location tracking on iphone?**	**what are marshes and bogs called?**

Abstract

We propose a novel open-domain question-answering dataset based on the Common Crawl project. With a previously unseen number of around 130 million multilingual question-answer pairs (including about 60 million English data-points), we use our large-scale, natural, diverse and high-quality corpus to in-domain pre-train popular language models for the task of question-answering. In our experiments, we find that our Common Crawl Question Answering dataset (CCQA) achieves promising results in zero-shot, low resource and fine-tuned settings across multiple tasks, models and benchmarks[1].

1 Introduction

Open-domain question-answering (ODQA) has evolved into a core problem in Natural Language Processing (NLP), receiving growing interest from the research community (Raffel et al., 2020; Roberts et al., 2020). Despite the notoriously difficult challenge to correctly answer open-domain questions on arbitrary topics, recent advances of pre-trained language models (such as BERT (Devlin et al., 2019), BART (Lewis et al., 2020a) and T5 (Raffel et al., 2020)) have stimulated new research into additional, task-dependent pre-training steps. Specifically, recent publications show that in-domain pre-training regimes can improve models for several downstream tasks (Gururangan et al., 2020). For open-domain question-answering, newly proposed pre-training tasks such as the Inverse Cloze Task (ICT) (Lee et al., 2019), Body First Selection (BFS), Wiki Link Prediction (WLP) (Chang et al., 2020) and Question Answering Infused Pre-training (QUIP) (Jia et al., 2021) show consistent improvements over baselines. However, most of these approaches still rely on either unlabeled text, or synthetically generated question-answer (QA) pairs. In this paper, we explore a second, somewhat orthogonal dimension to these lines of work, examining if a web-scale collection of natural QA pairs can support ODQA through in-domain pre-training.

Per definition, an ODQA system should be able to answer any question from an arbitrary domain. We believe that to approach this ability with in-domain pre-training, a suitable dataset should address the following 5 challenges: (1) Size; ODQA requires knowledge of a wide variety of topics. The underlying dataset used for in-domain pre-training hence needs to cover this abundance of domains, requiring a web-scale dataset. (2) Naturalness; While synthetic corpora can potentially capture a wide variety of language phenomena, to understand and generate truly natural language in all facets, synthetic datasets are not sufficient. (3) Quality; Given the requirement for a diverse, large-scale dataset, high data quality in terms of cleanliness and sensibility becomes a major challenge. Given that web-scale data sources require highly automated approaches operating on noisy data, assuring data quality is non-trivial. (4) Diversity; Besides size, another challenge for any ODQA in-domain pre-training dataset is the generality of the corpus. The dataset needs to support answering many diverse questions to allow models to learn general concepts. (5) Evaluation Fairness; A web-scale question-answering dataset potentially overlaps with existing benchmark corpora, leading to inflated performance measures and impeding the evaluation fairness (Lewis et al., 2021a).

To overcome these challenges, we propose a new large-scale dataset for open-domain question-answering called the **C**ommon **C**rawl **Q**uestion **A**nswering (CCQA) dataset. Similar to popular datasets, such as C4 (Raffel et al., 2020), CC-Net (Wenzek et al., 2020), CC-100 (Conneau et al., 2020), HTLM (Aghajanyan et al., 2022b),

July 10-15, 2022 ©2022 Association for Computational Linguistics

and CM3 (Aghajanyan et al., 2022a) we generate a large-scale, diverse and high-quality question-answering dataset from Common Crawl.

More specifically, Common Crawl allows us to obtain a large number of truly natural question-answer pairs, asked and answered by real humans on the web, rather than inferred through computational methods. Using the abundantly available *schema.org* question annotation[2], we generate question-answer pairs from explicit annotations, instead of heuristic rules, leading to high-quality data points.

In a large set of evaluations, we show that in-domain pre-training on our CCQA dataset achieves promising results across different settings, models and benchmarks. Using the rich information available on the web, we augment our dataset with additional data attributes beyond just question-answer pairs, such as votes, multiple (competing) answers, question summaries and intra-textual HTML markup, which can be used for a variety of tasks beyond question-answering in future work. Furthermore, we evaluate the diversity and evaluation fairness of our dataset by computing topic distributions and train-test overlaps with benchmark datasets, providing additional rationale regarding the quality of our data and experiments. To summarize, our main contributions in this paper are as follows:

- We generate the first truly large-scale, natural question-answering dataset, containing around 130 million unfiltered question-answer pairs (55M unique pairs), including about 60 million English data points (24M unique pairs).

- We present key dataset statistics, confirming the high quality of our question-answer pairs, the wide range of diverse topics and a low overlap with existing benchmarks.

- We show the effectiveness of the dataset for in-domain pre-training by evaluating the performance of the unfiltered English subset on two question-answering tasks, three different settings, four models and five diverse benchmarks.

2 Related Work

This work is inspired by a range of previous approaches using Common Crawl web-data, such as the Colossal Clean Crawled Corpus (C4) for language model pre-training (Raffel et al., 2020), the word/sentence representation generation corpus CCNet (Wenzek et al., 2020), the CC-100 dataset for translation (Conneau et al., 2020) and the markup-style language modelling HTLM corpus for zero-shot summarization (Aghajanyan et al., 2022b). Despite all previously mentioned applications directly relying on large-scale web data from Common Crawl, their scope and application vary significantly. Compared to previously proposed datasets based on Common Crawl, we are the first to extract well-structured question-answer pairs with additional meta-data, making our corpus a valuable resource for ODQA research, and a multitude of related tasks, such as question summarization, answer rating, and answer ranking.

Further web-based datasets outside the Common Crawl domain are the TriviaQA (Joshi et al., 2017) and ELI5 corpora (Fan et al., 2019), extracting small-scale question-answer datasets from Trivia websites and Reddit threads respectively. The large-scale GooAQ dataset (Khashabi et al., 2021) is similarly based on web data, however exploits the Google auto-complete feature and related answer boxes to generate semi-synthetic question-answer pairs. As a large-scale, completely syn-

---

[2] `https://schema.org/Question`

thetic dataset, the PAQ corpus (Lewis et al., 2021b) automatically generates a large set of *Probably Asked Questions* from Wikipedia articles. In contrast to these previously proposed datasets, our CCQA corpus presents a large-scale, natural and diverse question-answering resource in the same order of magnitude as the largest synthetic datasets.

Besides the generation of the CCQA dataset, we evaluate its potential as an in-domain pre-training corpus for open-domain question-answering. Our work is aligned with previous in-domain pre-training approaches, which have shown to improve a variety of downstream tasks (Gururangan et al., 2020). Similar to in-domain pre-training, multiple domain-dependent pre-training tasks have been proposed for open-domain question-answering. For example, Lee et al. (2019) propose the Inverse Cloze Task (ICT), Chang et al. (2020) introduce Body First Selection (BFS) and Wiki Link Prediction (WLP) and Jia et al. (2021) describe a novel Question Answering Infused Pre-training (QUIP) task. Along similar lines, Aghajanyan et al. (2021) propose pre-finetuning, an alternative to in-domain pre-training, using around 50 domain-dependent datasets, showing that their MUPPET approach generalizes well to many tasks. Khashabi et al. (2020) introduce a similar concept for question-answering in their UnifiedQA framework. While we propose a somewhat orthogonal dimension to most of these works, they nevertheless present us with strong intuition regarding the effectiveness of domain-dependent pre-training.

3 The Common Crawl Question Answering (CCQA) Dataset

3.1 Dataset Collection

Our Common Crawl Question Answering (CCQA) dataset contains around 130 million question-answer pairs (55M unique), extracted from 13 Common Crawl snapshots between May 2020 and May 2021[3]. A high-level overview of the dataset generation process is depicted in Figure 1. Starting from a set of raw HTML webpages, we make use of the schema.org definition to find relevant tags, such as the question, answer, author and votes (for the full set of tags see Figure 2). Using the explicit schema.org annotation (commonly used for search-engine optimization), instead of simple heuristics (e.g. question marks), we optimize the resulting corpus for high-quality data points. Specifically, due to the added efforts for website creators to define schema.org conforming meta-data, we believe that annotated question-answer pairs are likely to be relevant to the general public, mostly exclude rhetorical and contextual questions, and as a result constitute high quality QA data, despite the noisy nature of webpages.

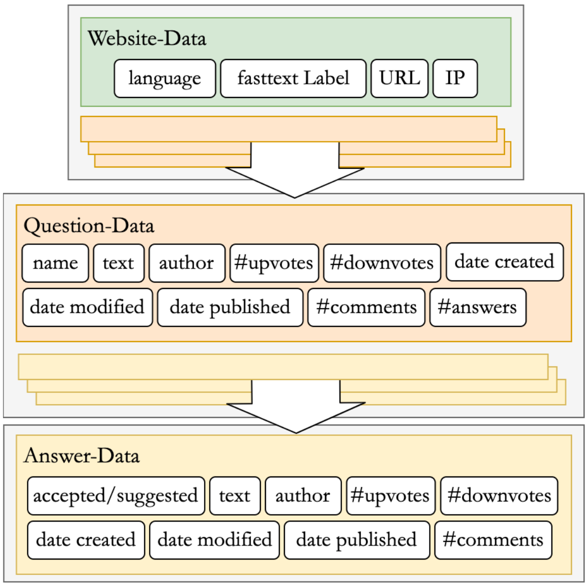

Figure 2: JSON data structure following the schema.org annotation. Fasttext language labels (Joulin et al., 2016, 2017) added for language distinction.

During the dataset processing steps, we remove all HTML elements that do not contain valid schema.org markers (red in Figure 1) and subsequently clean every question on the webpage to only conserve markup related to the textual content of schema.org tags[4]. We further remove any unrelated markup attributes (e.g., CSS and JavaScript classes), before converting the content into a well-defined JSON object, shown in Figure 2 and further described in section 3.2.

Using the 13 consecutive Common Crawl snapshots, we generate an initial dataset of 130 million question-answer pairs, naturally containing two types of potential duplicates: (1) Same-URL duplicates; where a webpage is updated between any two Common Crawl snapshots and (2) Content duplicates; where webpages from any Common Crawl snapshot contain same questions with potentially similar answers.

Here, we use the original, uncleaned version of the dataset, presenting a practical performance

---

[4] Set of textual tags taken from `developer.mozilla.org/en-US/docs/Web/HTML/Element`

lower-bound, while leaving the exploration of additional filtering steps for future work[5].

Our dataset generation procedure is further outlined in Algorithm 1, found in Appendix A. For qualitative examples of our generated dataset format, we refer readers to Appendix G.

3.2 Dataset Format

The structured output of the dataset collection (shown in Figure 2), contains a three-level nested structure: (1) Every top-level data point represents a webpage in Common Crawl, encapsulating questions and answers found on the page, together with relevant metadata. (2) On the second level, every question is represented as a tuple containing the question name (a short summary of the question) and question text (the main question). Questions also contain additional metadata as shown in Figure 2. (3) Every question can contain an arbitrary number of associated answers and answer attempts, located on the third and final level of the nested structure. An answer thereby contains a mandatory accepted/suggested label, the answer text as well as optional metadata.

With this nested structure of our CCQA dataset, we allow users to verify question-answer pairs and their metadata on the original webpage, utilize additional parts of the web-document and allow future research to tackle question-answering related tasks, such as answer selection, answer rating or answer ranking.

3.3 Dataset Dimensions

To gain better insights into the massive amount of data, we present a mix of automatically obtained dataset dimensions, a small-scale human pilot study, and a set of key dataset distributions.

Regarding the small-scale human pilot study, we analyze a random subset of 400 individual question-answer pairs and evaluate their sensibility and answerability. We define *question sensibility* as to whether the annotator understands the questions itself, while *question answerability* refers to whether the question provides enough context for a perfect question-answering system to correctly answer the question. Furthermore, *QA-sensibility* denotes if the question-answer pair makes sense[6]. We refer interested readers to Table 9 in Appendix E for further explanations on sensibility/answerability.

Q-Sens^H	Q-Ans^H	QA-Sens^H	Markup	Q-Summ
96.5%	86%	82.25%	47.5%	11.7%
No A	Avg #A*	Mean Q	Mean A	Lang Tags
5.9%	1.41	43	57	77.9%

Table 1: Key CCQA dataset dimensions. Q=Question, A=Answer, QA=Question-answer pair, Sens= Sensibility, Ans=Answerability, Lang=Language, Summ=Summarization, Mean=Average number of words, ^{H}Human pilot study, *Excluding questions without answers.

As shown in Table 1, our CCQA corpus contains nearly exclusively sensible questions, with the vast majority of them also answerable and sensible as a pair. To complement our small-scale human annotation, we further explore key dataset dimension, including the fraction of samples with advanced markup, questions containing both, question name and question text (as defined by the schema.org annotation), the number of questions without gold-answers, average question and answer length and the number of webpages with a valid language label, all indicating that the schema.org annotation highly correlates with carefully curated webpages.

Besides the key corpus-level statistics, we take a closer look at important dataset distributions in Table 2. Specifically, we present the top 5 domains at the top of Table 2, showing the largest number of webpages originating from the *stackexchange* domain, accounting for about 8% of data points. Regarding the topical distribution of our dataset, we use the DMOZ/Curlie taxonomy, automatically extracting hierarchical topic information[7]. We randomly sample $1,000$ question webpages and show the top 5 topics in the second row of Table 2. A more detailed topic distribution, also considering second-level assignments, can be found in Table 6 in Appendix B. Regarding the question-word distribution in our CCQA dataset, we observe that the majority of 36% of question words are *what* questions, followed by *how*, *when*, *which* and *where*. A full list of all 8 questions words and their relative appearance in our corpus can be found in Table 7 in Appendix C. Lastly, expanding on the number of non-trivial markup tags presented in Table 1, we explore the frequency of HTML markup tags in our dataset in the last row in Table 2. For a list

of the top-25 tags found in our corpus, we point interested readers to Table 8 in Appendix D.

4 Evaluation

In this section, we showcase the value of our CCQA dataset with experiments on the closed-book question-answering (section 4.1) and passage retrieval for open-book QA (section 4.2) tasks.

4.1 Closed-Book Question-Answering

4.1.1 Task

The closed-book question-answering task challenges systems to answer questions without to use of additional information sources, such as knowledge bases or evidence documents. As a result, models are solely relying on the question text and the information stored inside the model weights during training. Here, we evaluate our new CCQA dataset as an in-domain pre-training corpus for this highly challenging task by converting the JSON representation into plain question-answer pairs, removing markup tags and additional metadata.

4.1.2 Models & Training

Using the question-answer pairs from the CCQA dataset, we in-domain pre-train large language models for question-answering. We start with vanilla BART and T5 transformer models, shown on the left side (green) in Figure 3. We then further in-domain pre-train the models using a denoising or sequence-to-sequence (seq2seq) setup (yellow box in Figure 3). For the denoising task, we follow the vanilla BART approach (Lewis et al., 2020a), using a concatenation of *Q:*||<*question*>||*A:*||<*answer*> as the model input. For the seq2seq task, we train the model to predict the gold answer given a question as input. With the additional in-domain pre-training step, a variety of training-flows emerge, shown as numbered circles in Figure 3:
(1) Using a vanilla pre-trained language model to fine-tune on the benchmark dataset.
(2) Using the CCQA dataset for in-domain pre-training and subsequently fine-tune on the benchmark dataset.
(3) Using a pre-trained language model to directly infer answers on the benchmark dataset (zero-shot).
(4) Using the CCQA in-domain pre-trained model to directly infer answers on the benchmark dataset in zero-shot fashion.

4.1.3 Datasets

We evaluate the performance of our CCQA corpus as an in-domain pre-training dataset on 5 common benchmarks, based on 4 publicly available datasets in the closed-book setting:

TriviaQA (TQA) is a short-form, factoid-style question-answering dataset (Joshi et al., 2017). For the closed-book task, we ignore the available contexts and focus exclusively on question-answer pairs. Since the official test-split of the dataset is not publicly available, we use the official validation set as our test split and randomly sample a validation set from the training data, as commonly done in previous work (Roberts et al., 2020).

Natural Questions (NQ) (Kwiatkowski et al., 2019) represents a popular corpus for question-answering research. Despite most recent work focusing on the **short-form** answers (NQ-Short), the NQ corpus also provides additional **long-form** answers (NQ-Long) for a large subset of questions. In this work, we use both, short, factoid answers and long-form responses.

ELI5, introduced by Fan et al. (2019), constitutes the first large-scale long-form dataset for open-ended question-answering. We again do not take available evidence documents into account, but focus on the question-answer pairs only.

GooAQ (Khashabi et al., 2021) contains semi-automatically extracted question-answer pairs from the Google question auto-complete feature.

Metric	Top 5 Appearances in CCQA				
Domains	stackexchange (07.78%)	hotels (03.46%)	viamichelin (02.51%)	ccm (01.86%)	vrbo (01.74%)
Topics	Regional (38.90%)	Society (21.10%)	Business (08.30%)	Sports (07.00%)	Rec (06.20%)
Q-words	What (36.20%)	How (29.80%)	When (09.68%)	Which (09.64%)	Where (06.04%)
Markup	p (28.48%)	a (14.89%)	br (14.86%)	li (10.04%)	span (05.77%)

Table 2: CCQA dataset distribution for top 5 domains, topics according to the DMOZ/Curlie annotation, question words (Q-words, only computed on the English subset) and most common markup tags. % for q-words and markup tags presents portion of all q-word/markup appearances. ccm=commentcamarche, Rec=Recreational.

4.1.4 Metrics

For datasets with short-form answers, we use the Exact Match (EM) metric for fine-tuned systems, in line with previous work by Roberts et al. (2020) and Lewis et al. (2021b). While the EM metric works well for systems that are aware of the task-specific format, it punishes potentially correct answers with additional context, which we believe is overly harsh in zero-shot settings, where the specific output format is not known (e.g., training-flows (3) and (4)). Therefore, we propose using the Answer-level Recall (AR) metric for our zero-shot experiments, while limiting the answer length with the *max-length* and *length-penalty* inference parameters. As such, the AR metric requires the correct answer to be a continuous sub-sequence of the predicted tokens, while allowing for additional context. Since AR operates on token-level, the prediction of super/sub-words, e.g., ***fun****damental* instead of ***fun***, is considered incorrect.

For long-form question-answer datasets, we choose the Rouge-L (RL) score as our evaluation metric, which has shown strong correlation with Rouge-1 and Rouge-2 scores, and is commonly used in previous work (Khashabi et al., 2021).

4.1.5 Hyper-Parameters

We use the default parameters of the BART (Lewis et al., 2020a) and T5 (Raffel et al., 2020) models for in-domain pre-training and fine-tuning whenever possible. Regarding the in-domain pre-training on our CCQA dataset, we limit training to $800k$ steps using a batch-size of 1,024. During our fine-tuning runs, we limit the number of updates to $20k$ steps with a batch-size of 256 samples, with exception of the GooAQ dataset, which we fine-tune for $100k$ steps due to it's large size. We select the best model during our in-domain pre-training runs based on the perplexity measure, and pick the top fine-tuned model according to the final evaluation metric. We do not perform any hyper-parameter search during in-domain pre-training and fine-tuning.

For the inference step, our hyper-parameter setting is closely related to commonly used summarization parameters. We use a beam-size of 4, max-length of 140, and length-penalty of 2.0. For the fine-tuned short-form task, we choose a max-length of 30, following Xiong et al. (2021) and a length-penalty of 1.0. All model evaluations are based on Huggingface Transformers[8] (Wolf et al., 2019).

4.1.6 Results

Our main results for the closed-book question-answering task are presented in Table 3, showing the zero-shot and fine-tuned performance of the BART Large (top), T5 Small (center) and T5 Base (bottom) models for each of the 5 evaluation datasets. Even though we present a wide variety of benchmark results, from short-form factoid questions to long-form answers, the CCQA seq2seq pre-trained model consistently outperforms all other models on the zero-shot question-answering task. Even more importantly, the additional in-domain pre-training step achieves better zero-shot performance than fully fine-tuned, randomly initialized transformer models (as extensively used prior to 2018) in almost all settings. Specifically, our model outperforms the randomly initialized transformers on all benchmarks for T5 Small and T5 Base, as well as on 4 out of 5 datasets using BART Large.

Comparing the fully fine-tuned setting across models and datasets it becomes clear that, although oftentimes performing comparably, our CCQA seq2seq pre-trained model underperforms the vanilla models in most cases. Seq2seq in-domain pre-training on CCQA only reaches superior performance on the ELI5 dataset for all models, as well as on the GooAQ dataset for T5 Small. Showing that seq2seq pre-training on CCQA is effective in zero-shot scenarios, however only partially improves over baselines in the fine-tuned set-

---

Results from [a] Lewis et al. (2021a) [b] Khashabi et al. (2021) [c] Roberts et al. (2020)

Table 3: Closed-book zero-shot and fine-tuned results. Best performance of fairly computed results per sub-table **bold**. †Zero-shot model outperforms fully fine-tuned randomly initialized transformer of same architecture. *-d* extension indicates denoising CCQA pre-training task. *AR*=Answer-level recall, *EM*=Exact Match, *RL*=Rouge-L.

ting, we investigate: (1) Additional experiments using the CCQA dataset for denoising-style pre-training (*-d* in Table 3) and (2) Evaluate additional low-resource scenarios, shown in Figure 4.

For our denoising-style in-domain pre-training experiment, we keep the available markup information, in line with HTLM (Aghajanyan et al., 2022b). As shown in Table 3, the in-domain CCQA denoising objective outperforms the vanilla BART Large model on 4 out of 5 benchmarks in the fine-tuned setting. We believe that this result, alongside the zero-shot performance of the seq2seq CCQA model, clearly shows the usefulness and generality of our CCQA corpus for closed-book open-domain question-answering.

Taking a closer look at low-resource scenarios, we evaluate the vanilla T5 Small model against our in-domain pre-trained approach using 5 proper subsets of the NQ-Long, GooAQ and ELI5 benchmark datasets, drawn at random. As presented in Figure 4, our CCQA model mostly outperforms the vanilla T5 Small model in low-resource scenarios with up to 10,000 data points. While the performance of our CCQA model is consistently better on the ELI5 test-set, the vanilla baselines outperform our models fastest on the NQ-Long corpus. Additional low-resource experiments on T5 Base are shown in Table 6, in Appendix F.

4.2 Passage Retrieval

4.2.1 Task

For the passage retrieval task, an important component of most open-book QA systems (e.g., Lewis et al. (2020b); Izacard and Grave (2021)), models aim to extract a set of evidence passages from a large collection of documents through conditional ranking. To align our corpus with the passage retrieval task, we aggregate every question into a single data point, consisting of the question itself, alongside all available answers as either positive or negative contexts. If available, answer votes are used as a proxy to determine positive and negative (sometimes called “hard-negative") contexts. Following the practice in Fan et al. (2019), we assign every answer with at least 2 more upvotes than downvotes as a positive context and all other answer as negative. If answer votes are not available, we use the accepted/suggested label (shown

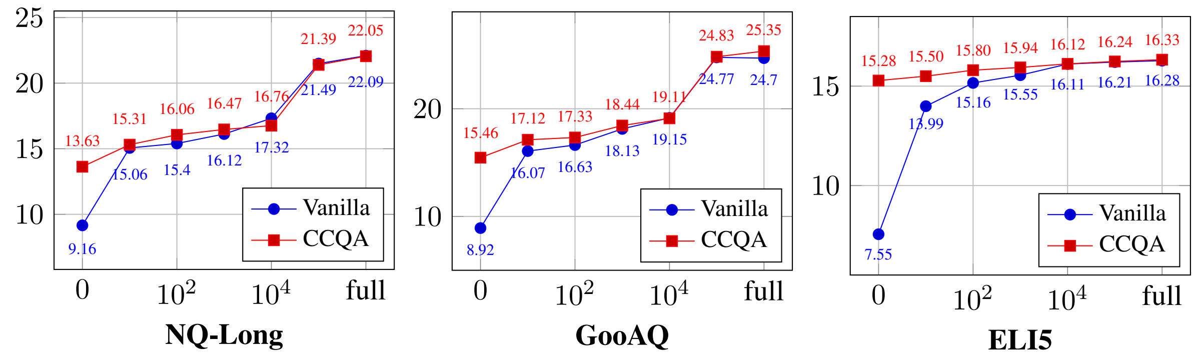

Figure 4: Low resource experiments comparing the Rouge-L score of vanilla T5 Small with our CCQA pre-trained models on NQ-long (left), GooAQ (center) and ELI5 (right).

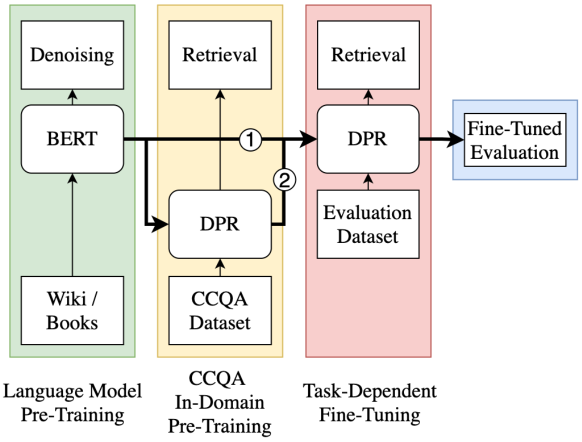

Figure 5: High-level overview of the CCQA passage retrieval in-domain pre-training step (yellow) as part of the training pipeline for DPR. Language model pre-training shown in green. Task-dependent fine-tuning presented in red. Evaluation in blue. (1) Baseline pre-training/fine-tuning pipeline, (2) In-domain pre-training/fine-tuning pipeline.

in Figure 2) as an indicator for positive and negative contexts. In the absence of either criterion, we use all available answers as positive contexts.

4.2.2 Models & Training

For passage retrieval, we choose the Dense Passage Retriever (DPR) (Karpukhin et al., 2020), used in a variety of popular end-to-end open-book QA models, such as RAG (Lewis et al., 2020b) and FiD (Izacard and Grave, 2021). As shown in Figure 5, we start with the vanilla DPR model based on BERT (Devlin et al., 2019) and in-domain pre-train using questions and positive/negative passages from the CCQA dataset (yellow box in Figure 5), similar to Oğuz et al. (2022). In line with the training-flows of the closed-book models, we train DPR using either the vanilla setup (pre-training → fine-tuning) or the in-domain pre-training approach (pre-training → in-domain pre-training → fine-tuning), shown as circles (1) and (2) in Figure 5, respectively.

Model	TQA		NQ-Short	
	Acc@20	Acc@100	Acc@20	Acc@100
DPR	79.4	85.0	78.4	85.4
DPR v2	79.5	85.3	78.3	85.6
CCQA DPR	**80.0**	**85.6**	**79.1**	**86.3**

Table 4: Fine-tuned Dense Passage Retriever (DPR) accuracy measure on the TQA and NQ-Short datasets. DPR represents the original DPR model (Karpukhin et al., 2020), DPR v2 (Oğuz et al., 2022) indicates the updated codebase. CCQA DPR uses our CCQA pre-trained DPR model for retrieval fine-tuning.

Bench. (test)	TQA	NQ-S	NQ-L	ELI5	GooAQ
Bench. (train)	11.9	4.9	5.2	3.0	26.9
CCQA (train)	0.4	1.9	2.3	0.5	26.9

Table 5: 8-gram question overlap (in %) between training sets and benchmark test-sets (inspired by Radford et al. (2019)). *Bench (train)* refers to the overlap between the respective training- and test-portion of the benchmark datasets, *CCQA (train)* identified overlaps between our dataset and the test-splits. False positive rate upper-bound by $\frac{1}{10^8}$. All inputs are normalized and lower-cased. NQ-S=NQ-Short, NQ-L=NQ-Long.

4.2.3 Datasets & Metrics

Following the original DPR paper (Karpukhin et al., 2020), we evaluate the passage retrieval task on the NQ-Short and TQA datasets presented in section 4.1.3, using the top-20 and top-100 retrieval accuracy (Acc@20/Acc@100) measures.

4.2.4 Hyper-Parameters

We use the default DPR hyper-parameters whenever possible (Karpukhin et al., 2020). For in-domain pre-training, we limit training to $800k$ steps using a batch-size of 1,536 samples. During fine-tuning, we restrict the number of updates to $20k$ steps with a batch-size of 128. The best checkpoint is selected based on the Mean Reciprocal Rank (MRR) measure, following Oğuz et al. (2022). We do not perform any hyper-parameter search.

4.2.5 Results

For the passage retrieval experiments, we compare our CCQA in-domain pre-trained DPR model against the vanilla DPR model published in Karpukhin et al. (2020), as well as the recently enhanced version (Oğuz et al., 2022). Table 4 contains our empirical results, showing consistent improvements of our CCQA DPR model over the vanilla baselines. More specifically, the in-domain CCQA pre-training step increases the top-20 and top-100 accuracy score on the TQA benchmark dataset by over half a point, while the performance gap on NQ-Short shows consistent improvement of over 0.7%.

4.3 Evaluation Fairness: Dataset Overlap

With modern pre-training approaches using increasingly large datasets, accidental overlaps between pre-training corpora and benchmark datasets become more and more common (Lewis et al., 2021a). To analyze this threat to the integrity of our dataset and empirical analysis, we follow Radford et al. (2019) and evaluate the 8-gram question overlap of our CCQA training portion with the test-split of benchmark datasets using bloom filters. Table 5 shows a consistently smaller question overlap between CCQA and the benchmark test set, compared to the benchmark training split itself.

5 Conclusion and Future Work

In this work, we presented our new web-scale CCQA dataset for in-domain model pre-training. Orthogonal to recent efforts on improving task-specific pre-training objectives, we show our dataset generation process, followed by detailed insights into key corpus dimensions of this new, large-scale, natural, and diverse question-answering dataset. In a set of empirical evaluations, we confirm the initial intuition that the corpus presents a valuable resource for open-domain question-answering research. In our zero-shot, low-resource and fine-tuned experiments for open- and closed-book QA tasks, we show promising results across multiple model architectures. With around 130 million question-answer pairs (55M unique) as well as additional meta-data, our CCQA dataset presents a versatile source of information, which has a large variety of applications in future work (e.g., question summarization, answer rating, answer ranking and many more).

6 Ethical Considerations

We now discuss the three major ethical considerations impacting this paper:

Hate-speech, Harmful Gender and Racial Biases: With general web-data potentially containing hate-speech and harmful gender and racial biases, we believe that our extracted dataset based on the schema.org annotations is less impacted by these issues, with the schema.org annotation representing a good proxy for high-quality, professionally curated websites. As a result, we believe that the severity of this issue is significantly reduced. Furthermore, in our human evaluation, we find no signs of the above mentioned biases. We leave computational approaches to determine dataset biases for future work (e.g., the Word Embedding Association Test (Caliskan et al., 2017) and Sentence Encoder Association Test (May et al., 2019)).

Data Availability: We do not directly provide the CCQA dataset, but enable third parties to generate the corpus through our published dataset generation scripts available at `https://github.com/facebookresearch/CCQA`.

Hallucinations and Factual Errors: As shown in the evaluation section, our model is able to generate reasonable answers for factoid and long-form questions. The inferred answers are fluent and human-like, but may also contain hallucinations and factual errors, especially for the challenging closed-book question-answering task. Without a guarantee of the predicted answers being factually correct, they can potentially spread misinformation if not properly corrected.

Acknowledgments

We want to thank the anonymous reviewers for their valuable feedback and acknowledge our colleagues and peers for their help throughout this project, specifically Anchit Gupta, Gagan Aneja and Patrick Lewis for their valuable input on important decisions.

C Detailed Question Word Distribution

Question-Word	What	How	When	Which	Where	Why	Who	Whose
Frequency	5.3M (36.20%)	4.3M (29.80%)	1.4M (9.68%)	1.4M (9.64%)	881k (6.04%)	717k (4.92%)	514k (3.53%)	25k (0.17%)

Table 7: Question word distribution for all 8 English question words with their number of appearance in the CCQA corpus and their relative frequency.

D HTML Markup Tag Distribution

Rank	HTML Markup Tag Distribution				
1-5	p (28.48%)	a (14.89%)	br (14.87%)	li (10.04%)	span (5.77%)
6-10	strong (4.93%)	code (4.59%)	em (2.79)	div (2.38%)	ul (2.27%)
11-15	pre (1.80%)	b (1.70%)	blockquote (1.14%)	h3 (0.89%)	td (0.88%)
16-20	h2 (0.48%)	ol (0.42%)	tr (0.42%)	h1 (0.35%)	i (0.24%)
21-25	sup (0.17%)	tbody (0.12%)	table (0.12%)	u (0.12%)	sub (0.11%)

Table 8: Distribution of the 25 most common HTML tags in CCQA.

E Sensibility and Answerability Examples

Metric	Type	Example	Explanation
Q-sensibility	Pos	What languages do you speak?	Q-Sensible, since question internally makes sense
	Neg	How blue is the number 7?	Not Q-Sensible, since question internally makes no sense
Q-answerability	Pos	How can I purchase affordable Flats in Vancouver?	Q-Answerable, since a single answer exists
	Neg	What languages do you speak?	Not Q-Answerable, since no single answer exists, but depends on the (unavailable) context
QA-sensibility	Pos	Which is the busiest month to travel from London to Delhi? → July	QA-Sensible, since question and answer make sense together
	Neg	How can I purchase affordable Flats in Vancouver? → There are many affordable Flats available.	Not QA-Sensible, since answer does not answer the question

Table 9: Examples and explanations for Question-sensibility (Q-sensibility), Question-answerability (Q-answerability) and QA-sensibility. Pos = Positive example, Neg = Negative example.

F Full Set of Low Resource Experiments

The Case for a Single Model that can Both Generate Continuations and Fill in the Blank

Daphne Ippolito[1,2] **Liam Dugan**[1] **Emily Reif**[2]

Abstract

The task of inserting text into a specified position in a passage, known as fill in the blank (FITB), is useful for a variety of applications where writers interact with a natural language generation (NLG) system to craft text. While previous work has tackled this problem with models trained specifically to do the fill-in-the-blank task, a more useful model is one that can effectively perform *both* FITB and continuation. In this work, we evaluate the feasibility of using a single model to do both tasks. We show that models pre-trained with a FITB-style objective are capable of both tasks, while models pre-trained for continuation are not. Finally, we show how FITB models can be easily finetuned to allow for fine-grained control over the length and word choice of the generation.

1 Introduction

Natural language generation systems are increasingly being incorporated into applications where a human writer and an AI jointly collaborate to construct text. These range from creative domains such as collaborative story writing (Coenen et al., 2021; Akoury et al., 2020) to more practical ones such as email composition and code synthesis (Buschek et al., 2021; Wu, 2018; Austin et al., 2021). These applications are often limited to generating text at the end of what has been written so far. This is because language models (LMs) are typically designed to produce text by repeatedly predicting the next word in a sequence given the previous words. However, there is a need for more powerful interactive tools which enable writers to solicit insertions at any chosen position within the existing text, a task referred to as fill in the blank (FITB) or infilling. For example, a creative writer might want a tool which can insert a description of a place or character, and a programmer might want a system that can fill in the contents of a function located in the middle of their code.

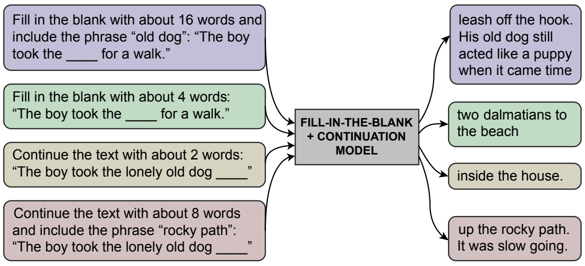

Figure 1: A single model that can handle a variety of related writing tasks is more efficient than separate models per task.

Most prior work tackling FITB consider it a separate task from continuation, one to be specifically optimized for, for example training a model from scratch (Ippolito et al., 2019; Zhu et al., 2019) or finetuning a model trained originally for continuation (Donahue et al., 2020). However, having separate trained models for FITB and for continuation is inefficient for downstream applications where maintaining multiple neural networks can be prohibitive.

Any model that can do FITB can be made to do continuation simply by placing the blank at the end of the input. Thus, in this work we describe how models trained on FITB can be employed effectively for both infilling and continuation operations. We show how T5 (Raffel et al., 2020), one of the most popular pre-trained models, can reasonably handle both tasks, as it was pre-trained with a FITB-like objective. Finetuning T5 further improves its ability and also allows for the incorporation of controllability of generation length and word choice.

2 Supporting FITB and Continuation

Definitions. We define filling in the blank as the task of predicting text to replace a single missing span, usually demarcated with a special token, in an input text passage. (Some prior work considers inputs with multiple blanks, but inserting text at one position at a time better matches the kinds of edits humans do.) We define continuation in the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2421 - 2432
July 10-15, 2022

Example Type	Input	Target
C4FillBlank no goal	fill: I love avocados. I ate a sandwich covered in them. **_8_** I talked to my doctor about it later. It turned out I was allergic to avocados.	After I ate it, my mouth was itchy and tingly.
C4FillBlank with goal	fill: I love avocados. I ate a sandwich covered in them. **_8_** I talked to my doctor about it later. It turned out I was allergic to avocados. **Goal: mouth was itchy**	After I ate it, my mouth was itchy and tingly.
C4FillBlank no goal	fill: I love avocados. I ate a sandwich covered in them. After I ate it, my mouth was itchy and tingly. I talked to my doctor about it later. **_8_**	It turned out I was allergic to avocados.
C4FillEnd with goal	fill: I love avocados. I ate a sandwich covered in them. After I ate it, my mouth was itchy and tingly. I talked to my doctor about it later. **_8_** **Goal: allergic to**	It turned out I was allergic to avocados.

Table 1: Examples of the finetuning objectives. "8" is the approximate length in words of the target sequence. During finetuning, about 25% of training examples took each of these formats.

traditional language modeling sense–predicting the next token in a sequence given only the previous tokens. Donahue et al. (2020) discuss how language modeling is a special case of infilling, and they use this as justification to finetune a continuation-based language model to do infilling. However, we argue that if continuation is a subtask of infilling, it makes more sense to go in the opposite direction: prioritize a model which can do infilling and check that it achieves satisfactory performance at continuation.

Using a model pre-trained for FitB. T5 is a model pre-trained with a "span corruption" objective very similar to FitB; the model is asked to reconstruct the missing text after random subsequences of the input are replaced with special identifiers. Thus, a pre-trained T5 model can be used without any further training to do both continuation and infilling by appropriately choosing text to mask out. The encoder-decoder architecture of T5 is also more conducive to FitB than the decoder-only architectures that are typically used for continuation-based generation, such as GPT-2 (Radford et al., 2019). This is because the attention mechanism in encoder-decoder architectures allows the context on the left side of the blank to attend to the context on the right, while decoder-only architectures only support masked attention (each token can only attend to the positions to its left).

Even though T5's pre-training objective was a form of FitB, finetuning is still advantageous. For one, our definition of FitB involves only a single masked out substring, not multiple, so finetuning improves alignment with the goal task. Finetuning also allows us to incorporate additional conditioning signals not supported by the pre-trained T5, such as being able to specify the desired length of the generated text or specify words that ought to be included in the blank, a task we refer to as "goal conditioning." Length control, which comes by default in a traditional language model by simply sampling more or fewer tokens, is particularly necessary for FitB, where the end of the generation must fit seamlessly with the text to its right.

Using a model pre-trained for continuation. The biggest language models available today were largely trained in the continuation rather than the FitB paradigm (Brown et al., 2020b; Black et al., 2021). Since our primary goal is to have a single model for both tasks, we also address the question: if a continuation-trained model is big enough, can it handle FitB without the need for finetuning? Few-shot learning with large language models, as popularized by Brown et al. (2020b), has had success on many tasks in NLP. We try out this approach for FitB by designing a few-shot prompt containing several demonstrations of the FitB task, formulated in a similar "infilling by language modelling" template to that proposed by Donahue et al. (2020). Further details on our approach to selecting a few-shot prompt are in Appendix A.1.

3 Experiments

Model. For all experiments with T5, we use the 800M parameter v1.1 'large' model (Appendix A.4 gives additional results from the 3B parameter 'XL' model). To finetune T5 for FitB, we construct training examples from documents by first partitioning the document text into a left context, gap, and right context. The input to the model is then the left and right contexts concatenated with textual representations of the additional conditioning signals. The target sequence is the true text for the blank. This formulation easily supports continuation, as the blank can be deliberately placed at the end (i.e., providing no right context). Finetuning examples are drawn from C4, the same dataset T5 was pre-trained on. Documents are split into word sequences, and these are then randomly truncated to be between 256 and 512 words long. A substring of between 1 and 64 words is selected to be blanked out. For half of the finetuning examples, the location of the blank is randomly selected, and for the other half, it is always placed at the end. To support length conditioning, we follow Roberts and Raffel (2020) and include a bucketed version of the target length as part of the blank. To support goal conditioning, for half the examples, a random substring of up to half the words of the target is appended to the end of the input. Examples are shown in Table 1.

Baselines We compare T5 against Thoppilan et al. (2022)'s 137B parameter decoder-only language model (referred to in this paper as LLM). Trained explicitly for continuation, this model has been used successfully for few-shot learning in other domains (Austin et al., 2021; Reif et al., 2021). We use the LLM in two ways: (1) as a standard continuation model, prompting with only the left context of an example; and (2) in a few-shot learning paradigm.

Evaluation Datasets We evaluate continuation and FitB on C4 as well as two story writing datasets. We chose this domain because creative writing assistant applications are one of the key areas we expect to benefit from multi-task models (Coenen et al., 2021). Reddit Writing Prompts (Rwp) is a corpus of stories from the 'r/WritingPrompts' sub-Reddit (Fan et al., 2018), and we construct validation sets RwpFillBlank and RwpFillEnd using the same method described in the previous section. We cap the C4 and Rwp validation sets to 5,000 examples each. ROC Stories (Roc) is a crowd-sourced dataset of five-sentence commonsense stories (Mostafazadeh et al., 2016). For ROC Stories, the 2018 validation set is used to construct RocFillMiddle, where the middle sentence of each story is blanked out, and RocFillEnd, where the last sentence is blanked out. Unless otherwise noted, all evaluation is done without goal conditioning and uses random sampling with top-k=50 as the decoding strategy. Example generations for all evaluation sets can be found at `https://bit.ly/2U0Ixxa`.

4 Findings

Automatic Evaluation We measure the fluency of proposed generations by evaluating the perplexity of each dataset's examples when the predicted text is placed in the blank (Donahue et al., 2020).

	C4Fill Blank	RwpFill Middle	RocFill Blank
Few-shot LLM	14.14	19.48	18.21
Pre-trained T5	10.38	14.08	22.62
Finetuned T5	10.33	14.08	20.47
Donahue et al. (2020)	N/A	N/A	23.28
Groundtruth	9.41	12.99	16.90

Table 2: Perplexity of evaluation sets according to LLM when the blank has been filled with approaches involving no fine-tuning (top), finetuned approaches (middle), and the groundtruth (bottom). Lower values indicate that the text was considered more fluent by the LLM.

	C4Fill End	RwpFill End	RocFill End
LLM	9.34	12.82	15.55
Pre-trained T5	10.09	13.51	21.71
T5 FillBlankCont	10.04	13.74	19.60
T5 Lm-Adaption	10.06	13.71	19.68
Groundtruth	9.41	12.99	16.90

Table 3: Perplexity of continuation-based evaluation sets when a continuation has been generated using approaches with no finetuning (top) and two settings of finetuning T5 (middle).

We use the LLM to measure perplexity[1]. The results are shown in Table 2. We see that the LLM struggles to generate fluent infills, even when used in a few-shot setting. The only exception to this is ROC Stories, a dataset with fairly simplistic, predictable language. Finetuning T5 does not result in significantly improved fluency over the pre-trained model except on ROC Stories. Lastly, for ROC Stories, we compare against Donahue et al. (2020)'s finetuned GPT-2 small, which yielded less fluent predictions.

Table 3 shows a similar analysis on our continuation-style datasets. We see that the pre-trained T5 generates about as fluent continuations as T5 finetuned in the manner described in Section 3 (T5 FillBlankCont), as well as T5 finetuned for the same number of steps, but only on the continuation task (T5 Lm-Adaption). The first row of Table 3 shows how fluent the LLM scores its own generated continuations.

Human Evaluation Human evaluation was conducted on 70 examples, 35 from RwpFillBlank and 35 from RwpFillEnd, with examples about evenly distributed across length buckets. For RwpFillBlank evaluation tasks, the rater was presented an input context and several possible sequences that could go in the blank. They were

---

[1] Note, since this is the same model being used for generation for our continuation baseline, this metric may be biased.

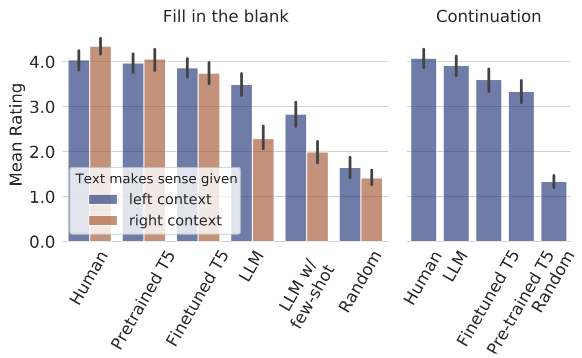

Figure 2: Human ratings of FitB generations (left) and continuation generations (right). Error bars are 95% confidence intervals.

Finetuned T5	Context	Length
C4FillBlank	0.860	0.877
RwpFillBlank	0.797	0.881
C4FillEnd	0.858	0.775
RwpFillEnd	0.791	0.746

Table 4: Accuracy of models finetuned on FillBlankCont at correctly using provided length and goal conditioning signals.

asked to rate each sequence first, on how well it fit the text before it, and second, on how well it fit with the text following it, according to a 5-point slider. For RwpFillEnd, the task was almost the same, except that the rater was presented only a left context and asked to rate how well it continued the prompt. More details are in Appendix A.3. Figure 2 shows the results.

On the FitB task, the pre-trained and finetuned T5 models were indistinguishable in terms of quality. The LLM that formed continuations prompted with only the left context did somewhat better than the few-shot LLM, indicating that few-shot learning is not yet a feasible alternative to finetuning. On the continuation task, the LLM has the highest rating, which is unsurprising since it is a much larger model than T5. However, the finetuned T5 is rated almost as highly. Overall, these results suggest that T5, unlike the LLM, can be used effectively for continuation as well as FitB. Furthermore, if one doesn't care about controllability, pre-trained T5 can be used effectively for both tasks without any further finetuning.

Benefits of Controllability Despite finetuning not resulting in significantly more fluent outputs, there are still good reasons to finetune; namely, finetuning allows for increased controllability. For example, length conditioning is extremely important for FitBmodels, since it is not possible to control the generation length by simply sampling more or fewer tokens. Pre-trained T5 tends to produce infill proposals which are shorter than the groundtruth (Figure 3), and there is no way to ask the model to produce longer generations. In contrast, finetuned T5 was able to produce generations in the target length bucket over 74% of the time (Table 4). Goal conditioning, while not strictly necessary for either task, has been shown to be useful for generative commonsense reasoning (Lin et al., 2020) and may empower users in downstream applications such as AI-assisted creative writing (Roemmele, 2021). Finetuned T5 is able to use all of the specified goal words over 79% of the time.

Domain Transfer Prior work on FitB tends to only evaluate models trained on data from the same domain as the validation set. Our results show that despite training exclusively on C4, T5 models have strong transferability to more targeted domains such as Reddit Writing Prompts. This sort of transferability is extremely important for achieving the goal of having a single model which can handle many tasks and domains.

5 Related Work

FitB is a form of Cloze task (Taylor, 1953). Prior deep-learning approaches to this task include training an encoder-decoder model from scratch with length and goal word conditioning (Ippolito et al., 2019); finetuning GPT-2 (Radford et al., 2019; Donahue et al., 2020); and training a custom self-attention architecture on corrupted text (Zhu et al., 2019). None of these show that their fill-in-the-blank models remain effective at continuation or perform well on text domains that differ from the training data. Related to FitB, Mori et al. (2020) investigate a setting where a sentence is randomly deleted from the input, and the model must both predict the location of the deletion as well as its contents. Huang et al. (2020) tackle the sentence infilling task using a mixture of BERT and GPT-2. Lastly, many LM pre-training objectives involve masking out parts of the input then predicting the masked values, which is similar to FitB (Devlin et al., 2019; Raffel et al., 2020; Joshi et al., 2020).

6 Conclusion

In this work, we make the case for starting with a model capable of filling in the blank when attempting to build a system that can perform both FitB

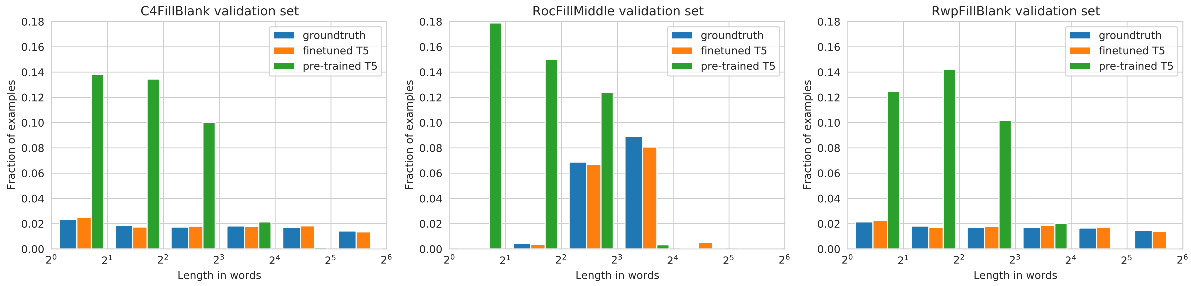

Figure 3: For each of the FITB validation sets, a histogram of the distribution of sequence lengths (measured in words) of the ground-truth blanked out text and the proposed infills from T5 (after and before finetuning). We see that pre-trained T5 tends to produce text that is shorter than the groundtruth.

and continuation. As LMs become bigger, it will be unsustainable to have separately trained models for each generation task. Multi-task, domain-transferable models, such as the ones we propose, require less total training and are more efficient to store and use at inference time. While pre-trained T5 by itself is capable of both infilling and continuation, additional conditioning signals such as desired length and goal text can be successfully incorporated into fine-tuning in order to support an even greater diversity of model interactions. We focused our experiments on the T5 model; however, we expect that other model families and architectures can be trained similarly to support a variety of generation tasks. For example, GPT-3 (Brown et al., 2020a) recently began supporting "insertion" and "edit" interactions in addition to continuation. Finally, we present a negative result that while few-shot learning is a promising method for building multi-task support without any finetuning, it is challenging to make work for the FITB task.

7 Risks and Limitations

All neural language models, including the ones used in this paper, reflect the biases and other issues present in their training data. Weidinger et al. (2021) discuss these risks in detail. The models and datasets considered in this paper are all in the English, and the proposed methods may work differently in other languages. In addition, the paper mostly focuses on showing results pertinent to the story writing domain; in other domains joint models for continuation and fill-in-the-blank might work worse. Finally, the LLMused in this paper is not publicly available, which to some extent limits its reproducibility, though we expect our findings would have been similar had we evaluated with a public model such as GPT-2. We emphasize that the main contribution of this paper is a comparison of different methods, all of which are easily implementable, rather than new model checkpoints.

A Appendix

A.1 Few-Shot Learning Details

Choosing appropriate examples for a few-shot prompt can be challenging as task performance is often sensitive to minor changes in prompt design (Zhao et al., 2021). We experimented with prompts randomly selected from the C4, Reddit Writing Prompts, and ROC Stories training sets, as well as prompts consisting of examples handwritten by the authors with the goal of story-writing in mind. For each prompt source, we randomly generated five possible prompts, each with three examples. To simplify the task, we conditioned on desired length but did not include goal conditioning.

An example prompt is shown in Figure A5. When choosing random few-shot prompts from the dataset train sets, in order to keep the few-shot prompt text within the 512-token context length limit of the LLM(Thoppilan et al., 2022) we used for inference, we only considered examples that contained 100 or fewer tokens, so that the max length of the few-shot prompt was no more than 300 tokens. This left 212 tokens for the text of the actual example we were interested in performing the FitB task on. For our hand-written prompt, we wrote the seven examples shown in Table A8. We generated 5 possible prompts by randomly subsampling 3 examples out of these 7 five times.

Table A6 shows the perplexity of the generations from each few-shot prompt. We note that even leaving room for 212 tokens worth of context text, some evaluation examples did not fit in the prompt length, and these examples were skipped when doing this analysis. Figure A4 shows a histogram of the fraction of validation set examples that remained for each few-shot prompt after the too-long examples were filtered out. Based on these results, we chose to include in human evaluation the best few-shot prompt from RocFillMiddle and the best few-shot prompt from C4FillBlank. Figure 2 in the main paper shows the result from the C4FillBlank few-shot prompt, whose outputs were rated slightly higher by human annotators.

Our analysis of few-shot learning prompts was not sufficiently exhaustive to rule out the possibility there might exist a prompt for which this technique would be effective. For example, we did not conduct formal experiments to systematically vary the prompt wording/formatting shown in Figure A5. What we can conclude is that the process of finding an ideal prompt requires time-consuming trial-and-error and is quite difficult!

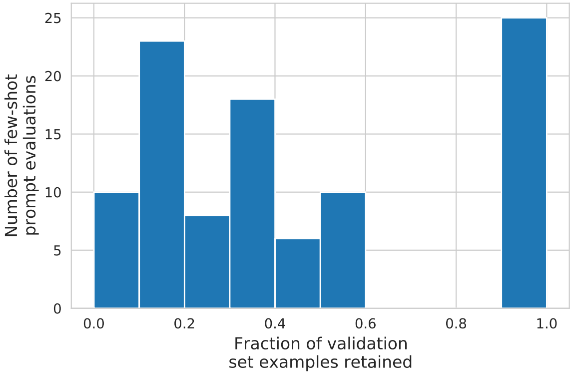

Figure A4: For many of the (validation set, few-shot prompt) combinations, not all validation set examples fit into the maximum sequence length for the LLM. The x-axis on this figure is the fraction of validation set examples which were retained after too-long examples were filtered out. The y-axis is the count of (validation set, few-shot prompt) pairs.

XL Model	Context	Length

C4FillEnd	0.858	0.775
RwpFillEnd	0.791	0.746

Table A5: Accuracy of models finetuned on FillBlankCont at correctly using provided length and goal conditioning signals.

A.2 Experimenting with Prefix Tuning

During the course of this study, we experimented with the usage of Prefix Tuning (Li and Liang, 2021) for the FitB task. In this method, a fixed-length continuous space prefix is appended to the input sequences and this prefix is directly optimized to maximize performance on a given task. This can be used to estimate an upper bound for the performance of few-shot learning on a given task. We trained two prefixes, both of length 5, on pre-trained GPT-2 of size medium (345M) and large (774M) (Radford et al., 2019). While our results showed that the prefix successfully instructed the pre-trained model to perform the FitB task, neither of these models outperformed our few-shot prompts during human evaluation. In fact, they showed only marginally better performance than our random baseline. Due to the discrepancy in

parameter count between the prefix tuned GPT-2 models and the LLM model we tested for few-shot prompting, we chose to leave these results out of the final analysis. Future work should seek to explore the limitations of prefix/prompt tuning techniques and the ways in which they and few-shot learning can be fairly compared.

A.3 Finetuning Implementation Details

For length conditioning, when discretizing the target sequence's length to a length bucket, we choose the closest value in $\{1, 2, 4, 8, 16, 32, 64\}$ to the target's length in words.

All training was done in the Mesh Tensorflow T5 codebase.[2] Each T5 model was finetuned for about 50,000 steps with a batch size of 128 examples (i.e., $\sim$6.4M examples were seen during finetuning.) A constant learning rate of 0.0008 was used, and no overfitting was observed.

A.4 Further Finetuning Experiments

In the main paper, we focused on a single finetuning setting, one where half the examples have randomly placed blanks and the other half have blanks always at the end. We actually experimented with three possible finetuning settings:

- In the standard FILLBLANK setting, the blank location is sampled uniform randomly across the sequence.
- In the FILLBLANKCONT setting, for half of the examples the blank is randomly selected and for the other half it is always at the end. As we hypothesized that finetuning on such data would result in better performance at the continuation task, this was the setting we used in the main paper.
- In the CONT (a.k.a. LM-ADAPTION) setting, the blank is always placed at the end of the sequence. In essence, we are finetuning solely for the continuation objective.

For the FILLBLANKCONT setting from the main paper, we additionally experimented with finetuning a 3B parameter "XL" T5 model.

Table A7 shows the perplexity of all these models on a variety of validation sets. Note that these are perplexities in the conventional definition–perplexity of the target sequence given the input sequence using examples from the validation set–not the fluency measure we report in the main paper.

The perplexity numbers across the different models are comparable, since all models used the default T5 vocabulary. The perplexity numbers across different datasets are not comparable since some datasets, like ROC Stories, are simply easier to model than others. Unsurprisingly, the larger models achieved lower perplexity on all validation sets. We can also see from Table A7 that it was probably not strictly necessary to enforce that 50% of training examples had blanks at the end. The model finetuned exclusively with randomly placed blanks (FILLBLANK) performed only slightly worse (probably not statistically significant) on the continuation-style validation sets than the FILLBLANKCONT-trained model.

Finally, Table A5 shows the accuracy of both model sizes on the two conditioning signals which were incorporated: length bucket and goal conditioning. Surprisingly, using a larger model improves goal conditioning accuracy but hurts length conditioning accuracy.

A.5 Further Human Evaluation Details

A screenshot of the Human Intelligence Task (HIT) used for annotations is shown in Figure A6. Workers were paid originally paid $1.85 per HIT, but

since the average HIT duration ended up being 15 minutes, we awarded each rater a bonus to raise their pay to an average of $10 per hour. We restricted the HITs to workers for whom Masters had been granted and who had previously done at least 100 HITs.

Each example was shown to three raters, and annotations were rejected if the rater gave a lower overall score to the random output than to the ground-truth one. A total of 3 annotations were rejected. Overall, the Fleiss' kappa agreement of pairs of annotators giving the same numerical score to the same question was 0.26.

Instructions for Fill-in-the-blank Evaluation Task

Your goal is to analyze how good an artificial intelligence is at generating text that makes sense with respect to the text before and after it. You will be shown the start of a passage of text where the AI's continuation has been highlighted in yellow. You will then be asked:

Does the **highlighted text** make sense?

Answer "not at all" if:

- the text is very ungrammatical OR
- though the text is grammatical, the highlighted section makes no sense with respect to the rest of the passage.

Answer "completely" if:

- the text is grammatical and smooth-flowing AND
- the contents of the highlighted section seems completely reasonable given the rest of the passage.

You must adjust every slider to be able to submit the HIT. The questions you've already worked on will be marked with a ✅.

Question 4/8

Jackson checked his tie one last time before entering **the room. He wasn't allowed to speak,** [...]

Does the **highlighted continuation** make sense with respect to the text before it?

(not at all) (completely) ✅

Now, suppose the text is continued in the following way.

Jackson checked his tie one last time before entering **the room. He wasn't allowed to speak,** now it was his turn. He glanced around the room, recognizing most of the people instantly. Everyone important was there... this was Jackson's chance. Jackson sat at the computer and opened up his AOL E-mail account, USB keys were strictly forbidden at meetings like this for being unsafe. He downloaded the PowerPoint and opened it.

Does the **highlighted section** make sense given this continuation?

(not at all) (completely) ✅

`{shusenw,bobtuan,yanan.wu,xyj}@bupt.edu.cn`

Abstract

Open relation extraction is the task to extract relational facts without pre-defined relation types from open-domain corpora. However, since there are some hard or semi-hard instances sharing similar context and entity information but belonging to different underlying relation, current OpenRE methods always cluster them into the same relation type. In this paper, we propose a novel method based on **I**nstance **R**anking and **L**abel **C**alibration strategies **(IRLC)** to learn discriminative representations for open relation extraction. Due to lacking the original instance label, we provide three surrogate strategies to generate the positive, hard negative, and semi-hard negative instances for the original instance. Instance ranking aims to refine the relational feature space by pushing the hard and semi-hard negative instances apart from the original instance with different margins and pulling the original instance and its positive instance together. To refine the cluster probability distributions of these instances, we introduce a label calibration strategy to model the constraint relationship between instances. Experimental results on two public datasets demonstrate that our proposed method can significantly outperform the previous state-of-the-art methods[1]

1 Introduction

Open relation extraction (OpenRE) has been proposed to extract new relational facts where the types of target relations are not pre-defined. Previous methods can be classified into two types: open information extraction (OpenIE) and unsupervised relation discovery. For OpenIE (Yates et al., 2007; Etzioni et al., 2008; Fader et al., 2011), the relations are directly represented by relation phrases extracted in the sentence. However, the generalization capabilities of these methods are limited since they severely rely on surface-form relations and a relation can be expressed by many surface forms.

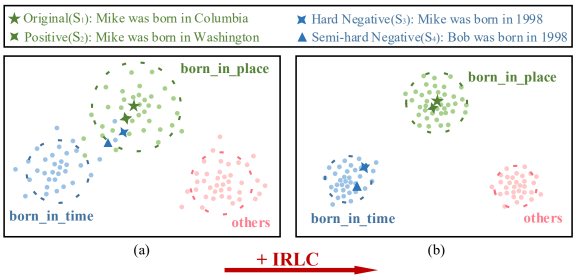

Figure 1: (a) The distribution of baselines in the relational feature space, where the similar context and entities make the hard negative S_3 and semi-hard negative S_4 instance clustered into a wrong relation type. (b) The distribution refined by our method, where these negative instances are separated from the original instance and correctly predicted.

Recently, much attention has been focused on unsupervised relation discovery, which is commonly formulated as a clustering task to learn effective relation representations and cluster them (Yao et al., 2011; Marcheggiani and Titov, 2016; Simon et al., 2019). Hu et al. (2020) leverage BERT to extract relational feature and propose a self-supervised framework to learn relation representations from pseudo labels. Because current methods are unstable and easily collapsed (Simon et al., 2019), Liu et al. (2021) solve above-mentioned problems from a causal view and propose element intervention to alleviate the spurious correlations in OpenRE models. However, there are still some hard or semi-hard samples wrongly predicted in the representation space due to the spurious correlations from entities and context to the relation type.

As shown in Figure 1(a), there are two types of negative instances for the relation type *BORN_IN_PLACE*: **Hard negative** and **Semi-hard negative**. For Semi-hard negative instances like S_4, OpenRE models will assign S_1 and S_4 into

---

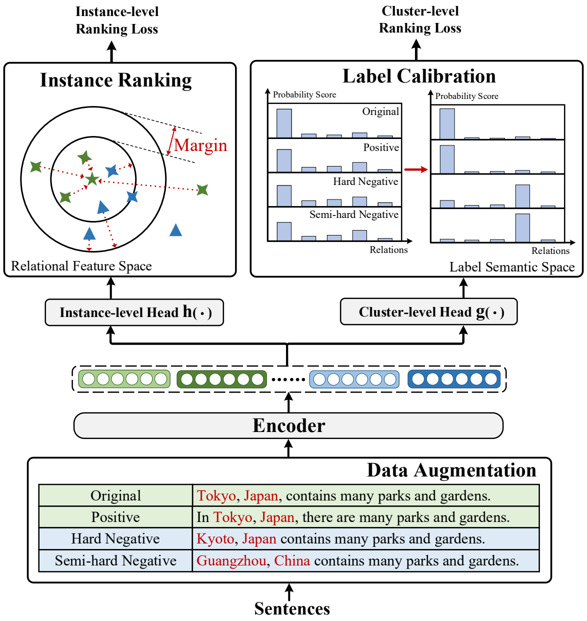
Findings of the Association for Computational Linguistics: NAACL 2022, pages 2433 - 2438
July 10-15, 2022 ©2022 Association for Computational Linguistics

the same relation type *BORN_IN_PLACE* since S_1 and S_4 share similar context information. This problem can be even more severe if the representation space exists some hard negative instances like S_3, because S_3 possesses a similar context "was born in "and similar entity "Jon" to S_1. An intuitive way to solve this problem is to refine the relational feature space, as shown in Figure 1(b). Besides, all instances should follow the same relative relationship in the label semantic space which means the original and positive instances have a more similar cluster probability distribution than the hard and semi-hard negative instances. Therefore, it is important to model the constraint relationship between these instances in the label semantic space.

In this paper, we propose a novel method based on **I**nstance **R**anking and **L**abel **C**alibration strategies **(IRLC)** to better identify the hard and semi-hard negative instances by learning discriminative representations in relational feature and label semantic space simultaneously. However, due to lacking of the instance label, we cannot directly obtain the positive, hard negative and semi-hard negative instances of the original instance. To solve this, we use three data augmentation strategies to generate the positive, hard negative and semi-hard negative instances for the original instance. To refine the relational feature space, we introduce instance ranking to make the original instance close to its positive instance and away from its hard and semi-hard negative instances. To correct the cluster assignment probabilities of hard and semi-hard negative instances, and keep the probability distributions of the original and positive instances aligned, in the label semantic space, Label Calibration strategy is designed to model two constraint relationships between the original and hard negative instance, and between the hard and semi-hard negative instance.

To summarize, the major contributions of our work are as follows: (1) We propose a novel method based on instance ranking and label calibration to learn discriminative representations in relational feature and label semantic space simultaneously. (2) We introduce three surrogate strategies to generate the positive, hard negative and semi-hard negative instances under unsupervised manner. (3) Experimental results show that our proposed method significantly outperforms the previous state-of-the-art models with the improvements of average performance of 11.1% and 11.8%, on two datasets respectively.



Original	Tokyo, Japan, contains many parks and gardens.
Positive	In Tokyo, Japan, there are many parks and gardens.
Hard Negative	Kyoto, Japan contains many parks and gardens.
Semi-hard Negative	Guangzhou, China contains many parks and gardens.

Figure 2: Framework of our proposed method.

2 Method

In this work, we propose a novel method to learn relation representations in feature and semantic space simultaneously. As shown in Figure 2, our method mainly consists of three components: data augmentation, instance ranking, and label calibration modules. We will introduce these module details in the following subsections.

2.1 Data Augmentation

Since there are no pre-defined relation types, it is difficult to directly obtain the positive, hard negative, and semi-hard negative instances of the original instance. To solve this problem, we introduce three surrogate data augmentation strategies to generate above-mentioned instances for the original instance. Specifically, for an original relation instance X_i, we use the following strategies:

Back Translation for Positive: To keep the relation type consistent with the original instance and introduce minimal semantic impact, we use back translation to generate the high-quality positive instance by first translating the original instance to another language and then back to English.

Entity Replacing for Hard Negative: We choose T5 (Raffel et al., 2019) to generate the most similar word to head or tail entity, and then replace the head or tail entity with its augmented word to obtain the hard negative instance, which possesses the similar entity and context to original instance.

Entity Swap for Semi-Hard Negative: To construct a semi-hard negative instance for the original instance, we follow the setting of Entity Swap (Cao and Wang, 2021), which swaps the target entities with other randomly selected entities of the same entity type in the original instance.

2.2 Instance Ranking

After instance construction, we obtain a group of augmented instances of the original instance. Instance Ranking aims to refine the relational feature space. Specifically, given a group of instances (X_i, X_i^p, X_i^{hn}, X_i^{sn}), where X_i^p, X_i^{hn}, X_i^{sn} are positive, hard negative, and semi-hard negative instances respectively. We first encode them to obtain their relation representations (r_i, r_i^p, r_i^{hn}, r_i^{sn}), and then map these representations into the relational feature space with an instance-level head $\mathbf{h}$ to obtain a group of relational feature (t_i, t_i^p, t_i^{hn}, t_i^{sn}). Then we can obtain the instance-level ranking loss:

$$\begin{aligned}\mathcal{L}_i^{IR} &= \max(0, D(t_i, t_i^p) - D(t_i, t_i^{hn}) + m_H) \\ &\quad + \max(0, D(t_i, t_i^{hn}) - D(t_i, t_i^{sn}) + m_S)\end{aligned} \tag{1}$$

where $D(x, y)$ is the euclidean distance between x and y, m_H and m_S are two margins for instance-level ranking loss. Optimized by the objective $\mathcal{L}_i^{IR}$, model can make the original relation instance closer to its positive instance and away from its correspondingly hard and semi-hard negative instances with different margins.

2.3 Label Calibration

In addition to refining the feature space, we introduce Label Calibration to model the constraint relationship between instances to correct the cluster assignment probabilities of hard and semi-hard negative instances and keep the probability distributions of the original and positive instance aligned in the label semantic space. With a group of relation representations (r_i, r_i^p, r_i^{hn}, r_i^{sn}) encoded from their corresponding instances, we first generate the group of cluster representations (z_i, z_i^p, z_i^{hn}, z_i^{sn}) by mapping them into the label semantic space with a cluster-level head $\mathbf{g}$, and then obtain the cluster-level ranking loss:

$$\begin{aligned}\mathcal{L}_i^{LC} &= \max(0, D(z_i, z_i^p) - D(z_i, z_i^{hn})) \\ &\quad + \max(0, D(z_i, z_i^{hn}) - D(z_i, z_i^{sn}) + m_L)\end{aligned} \tag{2}$$

where $D(x, y)$ is the KL distance between x and y to measure the difference between the cluster assignment probabilities of the instances, m_L is the margin for cluster-level ranking loss. The first term is to model the constraint relationship between the original and hard negative instance, and the second term is to the constraint relationship between the hard and semi-hard negative instance. The final loss function is as follows:

$$\mathcal{L} = -\frac{1}{n}\sum_{i=1}^{n}(\mathcal{L}_i^{IR} + \mathcal{L}_i^{LC}) \tag{3}$$

3 Experiments

3.1 Datasets

To assess the performance of our method, we conduct experiments on **T-REx SPO** and **T-REx DS**, which both come from T-REx[2] (Elsahar et al., 2018) but differ in whether having surface-form relations or not. Following the setup of Liu et al. (2021), we use 80% of instances for model training and 20% for validation on both two datasets.

3.2 Baselines

For comparison, we consider the following baselines:

- **rel-LDA** A generative method proposed by Yao et al. (2011), which treats unsupervised relation discovery as a topic model. In our experiment, we choose the full rel-LDA to compare with our method.
- **March** A method (Marcheggiani and Titov, 2016) based on self-supervised signal from entity link predictor to learn a VAE-based model.
- **UIE** A method proposed by Simon et al. (2019) to solve instability and use two regularization to train a discriminative model for OpenRE. In our experiments, we compare our method with two versions of UIE, which only differ in the relation encoding model, i.e., PCNN and BERT.
- **SelfORE** A self-supervised framework propose by Hu et al. (2020), which learn contextual relation representations from pseudo labels.
- **Element Intervention** A method proposed by Liu et al. (2021), which formulates OpenRE by using a structural causal model.

Table 1: Experimental results(%) produced by the baseline models and the proposed model IRLC on T-REx SPO and T-REx DS in terms of B^3, V-measure, ARI.

3.3 Evaluation Metrics

As the previous work (Simon et al., 2019; Hu et al., 2020; Liu et al., 2021), we adopt B^3 (Bagga and Baldwin, 1998), V-measure (Rosenberg and Hirschberg, 2007), and Adjusted Rand Index (ARI) (Hubert and Arabie, 1985) to evaluate different methods. Considering that any of the three metrics can measure the clustering performance from different angles, we take the average of B^3 F1, V-measure F1 and ARI for comprehensive evaluation.

3.4 Implementation Details

For fair comparison, all model are trained and evaluated on 10 relation types, same as (Simon et al., 2019; Hu et al., 2020; Liu et al., 2021). We implement our model in PyTorch[3] (Paszke et al., 2017) with `transformers` package[4] (Wolf et al., 2020). We adopt `bert-base-cased` as backbone to generate contextual relation representations. The output size of the instance-level head in instance ranking is 128, while the size is set to 10 in the cluster-level head for label calibration, same as the number of relation types. We use Adam (Kingma and Ba, 2014) as optimizer with a learning rate of 1e-5 for backbone and a learning rate of 1e-3 for two heads. The max length of input sentence is 96 and the batch size is 32. All experiments are conducted by using a GeForce RTX 3090Ti with 24 GB memory.

3.5 Main Results

We summarize the performances of the baselines and our method in Table 1. From the experimental results, we can see that our method IRLC significantly outperforms baselines by a large margin and achieves new state-of-the-art results on both two datasets. For T-REx SPO, compared with the previous SOTA model, IRLC improves the average performance by 11.1%, B^3 F1-score by 12.4%, V-measure F1-score by 15.1%, and ARI by 5.7%. The results confirm IRLC can learn discriminative representations to help model extract novel relations. For T-REx DS, our method IRLC outperforms the SOTA model with an average performance gain of 11.8%, proving the effectiveness of IRLC for OpenRE.

3.6 Ablation Study

To study the effect of instance ranking and label calibration in the proposed method, we conduct ablation experiments on two datasets and report the results in Table 1. We find that the performance of IRLC will severely degrade without instance ranking or label calibration. It proves both two strategies proposed in our method are important and effective, and combining these two strategies can achieve a noticeable performance gain. More specifically, we can observe that instance ranking or label calibration is effective enough to outperform previous SOTA models with an average performance gain of at least 3.7% in T-REx

(b) T-REx DS

Figure 3: Inter-class distance statistics with different number of the nearest class centers.

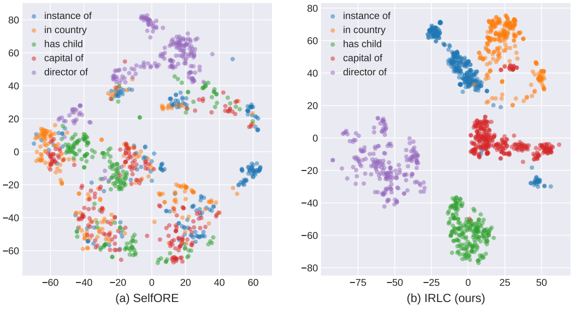
SPO dataset, showing the effectiveness of these two strategies.

3.7 Qualitative Analysis

In this section, we first analyse the representation distribution of novel relations on two datasets from two perspectives, intra-class and inter-class, to study how our method refines the representation space. And then we visualize the representations of novel relations to show the effectiveness of our method.

IRLC leads to smaller intra-class distance. Table 2 shows the intra-class variance statistics. Specifically, we use intra-class variance to indicate the intra-class distance of relation type. Each cluster intra-class variance is obtained by calculating the average variances of all normalized relation representations corresponding to the same relation type, and we report the min/max/mean/median variance values on all relation types. From the results, we can see that the intra-class variance are much smaller than compared method in four aspects. It confirms IRLC can make the relation representations from same relation type closer.

IRLC leads to larger inter-class distance. Figure 3 shows the inter-class distance statistics. The X-axis is the number of the nearest class centers. We obtain the euclidean distances between each class center and its nearest class centers with different number, and then average these distances of all relation types as the inter-class distance. From the results, we can observe that IRLC significant increases the inter-class distance with different number of the nearest class centers, especially in T-REx SPO. In summary, IRLC can obtain a better relation representation space with smaller intra-class distance and larger inter-class distance for OpenRE.



(a) SelfORE
(b) IRLC (ours)

Figure 4: Visualization of the relation representations on T-REx SPO.

Visualization of Relation Representations. To intuitively show how our method helps to refine the relation representation space, we visualize the representations of novel relations by using t-SNE (Van der Maaten and Hinton, 2008) to reduce the dimension to 2. We randomly choose 5 relations and sample 200 instances in each relation. As shown in Figure 4(a), the relation representation space of compared model is chaotic and somewhat dense. However, the relation representations from different types are mostly separated in our proposed method, as shown in Figure 4(b).

4 Conclusion

In this paper, we propose a novel method based on instance ranking and label calibration (IRLC) to learn discriminative representations for better identifying the hard and semi-hard negative intances, in the relational feature and label semantic space simultaneously. Due to lacking the label of each instance, we introduce three surrogate strategies to generate the augmented views for the original instance. And then instance ranking is used to refine the relational feature space, and label calibration is designed to model the constraint relationship between instances. Experiments and analysis confirm the effectiveness of IRLC for OpenRE.

Abstract

Recent work has shown that NLP tasks such as Relation Extraction (RE) can be recasted as Textual Entailment tasks using verbalizations, with strong performance in zero-shot and few-shot settings thanks to pre-trained entailment models. The fact that relations in current RE datasets are easily verbalized casts doubts on whether entailment would be effective in more complex tasks. In this work we show that entailment is also effective in Event Argument Extraction (EAE), reducing the need of manual annotation to 50% and 20% in ACE and WikiEvents respectively, while achieving the same performance as with full training. More importantly, we show that recasting EAE as entailment alleviates the dependency on schemas, which has been a roadblock for transferring annotations between domains. Thanks to the entailment, the multi-source transfer between ACE and WikiEvents further reduces annotation down to 10% and 5% (respectively) of the full training without transfer. Our analysis shows that the key to good results is the use of several entailment datasets to pre-train the entailment model. Similar to previous approaches, our method requires a small amount of effort for manual verbalization: only less than 15 minutes per event argument type is needed, and comparable results can be achieved with users with different level of expertise.

1 Introduction

Building Information Extraction (IE) systems for real-world applications is very costly and has suffered from data-scarcity problems, due in part to the expertise and time required to annotate training data at a large scale with sufficient consistency, but also due to poor transfer between domains: IE annotations depend on the schema used in each domain, and moving to new domains requires new schemas, new annotation guidelines and the manual annotation of new data. In many cases, there is some information overlap between schemas, but performing transfer learning to leverage such overlap (i.e. learning from **multiple sources**) can be difficult: it often requires manually mapping labels between schemas, which is typically brittle, cumbersome and requires costly domain expertise (Kalfoglou and Schorlemmer, 2003).

In order to save annotation effort, recent work recasts IE tasks as Textual Entailment tasks (White et al., 2017; Poliak et al., 2018a; Levy et al., 2017; Sainz et al., 2021). For instance, Sainz et al. (2021) manually verbalize each relation type in the Relation Extraction (RE) dataset TACRED (Zhang et al., 2017) to generate hypotheses for each test example, and then apply an entailment model to output the relation type of the hypothesis with highest entailment probability. The entailment model is typically based on large language models pre-trained on entailment datasets such as MNLI (Williams et al., 2018). The approach obtains very strong results on zero-shot and few-shot scenarios, but we note that TACRED contains relations between two entities that are easily verbalizable,[1] casting doubts on whether entailment would be effective in more complex IE tasks. Event Argument Extraction (EAE) involves more complex contexts, higher ambiguity in the words that trigger events, and depends on the event type in addition to the relation (see Figure 1).

In this work, we present the first system for EAE that addresses the task as an entailment problem. We empirically show the robustness of the method on the zero-shot, few-shot and full training regimes, obtaining state-of-the-art results on ACE (Walker et al., 2006) and WikiEvents (Li et al., 2021b). In addition, we make the following contributions: (1) We show that our method reduces schema dependency, as it improves the performance on the WikiEvents results using additional ACE training data and vice versa with no extra manual work. (2)

---

[1] For instance, `PER:DATE_OF_BIRTH` can be verbalized as `{subj}'s birthday is on {obj}` in which subj and obj refers to the two text mentions involved in the relation.

Ablation results show that training with several NLI datasets is significantly better than just using MNLI. (3) Our analysis of the manual work required for writing templates and annotating arguments sheds light in the sweet spot for future applications, and shows that template writing does not require much domain expertise as shown by the results using an independent novice template writer. We make the code, templates and models publicly available.[2]

2 Related Work

Textual Entailment Given a textual premise and a hypothesis, the task is to decide whether the premise entails or contradicts (or is neutral to) the hypothesis (Dagan et al., 2006). The current state-of-the-art uses large pre-trained Language Models (LM) (Lan et al., 2020; Liu et al., 2019; Conneau et al., 2020; Lewis et al., 2020; He et al., 2021) fine-tuned on manually annotated datasets such as SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018), FEVER (Thorne et al., 2018) or ANLI (Nie et al., 2020). The task is also known as Natural Language Inference (NLI).
